The algorithm will treat bundles of M-items like any other item (except for the occasional merging of bundles to maintain the property that each bin (auxiliary storage) can have at most one open bundle). Note that a bin can contain at most 10 bundles; hence, we say that no bin can contain more than 10 items. Bundling is one of the tools used to accomplish *M-thoroughness*. It is natural to ask whether or not the technique of bundling is essential for *MMP*; the answer is in the affirmative, since it can be shown that moving only a constant number of very small items per *Insert/Delete* operation disallows competitive ratios below $\frac{4}{3}$, regardless of the running time (see [8]).

3. The data structure and the details of *MMP*.

3.1. The data structure of *MMP*. In this section we describe the data structure utilized by *MMP*. The data structure is rather complex, and it consists of several components.

1. *The regular packing*. The regular packing consists of the bins of the allowed types and some of the information required for the maintenance of an *MMP* packing (LLS-maximal and M-thorough). As mentioned before, the regular packing is maintained via a 2-3 tree. The leaves represent the bins, while the internal nodes store some of the information required for the proper maintenance of the packing (LLS-maximal and M-thorough).

Each leaf contains a record with the following information that provides for a full description of a bin B:

- *content*(B)—Five doubly linked circular lists are utilized to record the set of items currently packed in B, one list for the B-items, one for the L-items, one for the S-items, one for the T-items, and one for the M-bundles packed in B. The entries of these lists are the individual records associated with the B-items, L-items, S-items, T-items, and M-bundles that are currently packed in B. Recall that each bin can contain at most one B-item, two L-items, three S-items, four T-items, and ten M-bundles (at most nine closed bundles and at most one open bundle). Thus these lists are very short.
- Each leaf contains a pointer to the open bundle in B, if any.
- Five numbers that record the myopic levels of B include the following: $level_{\mathrm{B}}(B) = \sum_{a \in content(B) \wedge a \in \mathrm{B}} size(a)$, $level_{\mathrm{L}}(B) = \sum_{a \in content(B) \wedge a \in \mathrm{B} \cup \mathrm{L}} size(a)$, $level_{\mathrm{S}}(B) = \sum_{a \in content(B) \wedge a \in \mathrm{B} \cup \mathrm{L} \cup \mathrm{S}} size(a)$, $level_{\mathrm{T}}(B) = \sum_{a \in content(B) \wedge a \in \mathrm{B} \cup \mathrm{L} \cup \mathrm{S} \cup \mathrm{T}} size(a)$, and $level_{\mathrm{M}}(B) = level(B)$.
- Each leaf contains the type of B.

Each internal node contains the following information about its left, middle, and right (if present) subtree: (1) the largest gaps in the subtree ($gap_{\mathrm{B}} = 1 - level_{\mathrm{B}}$, $gap_{\mathrm{L}} = 1 - level_{\mathrm{L}}$, $gap_{\mathrm{S}} = 1 - level_{\mathrm{S}}$, $gap_{\mathrm{T}} = 1 - level_{\mathrm{T}}$, and $gap_{\mathrm{M}} = 1 - level_{\mathrm{M}}$) and (2) the most inferior type of bin in the subtree.

2. *Inferior trees*. One of the consequences of executing an *Insert* or *Delete* operation is that, in order to maintain a packing that is LLS-maximal, the packing of a bin B may require that some items be removed from bins inferior to B and packed into B. In order to efficiently search for such items in bins inferior to B, *MMP* maintains for each allowed bin type i a set of items of each type of item that appears in a bin of type i. These sets are each represented by a heap (implemented as a 2-3 tree), and we call them the *inferior trees*. To accomplish this efficient search, *MMP* utilizes 15 min-heaps implemented as 2-3 trees: (1) L-items in bins of type BL, (2) L-items in bins of type LLS, (3) L-items in bins of type LLT, (4) L-items in bins of type LL,

(5) S-items in bins of type BST, (6) S-items in bins of type BS, (7) S-items in bins of type LLS, (8) S-items in bins of type SSST, (9) S-items in bins of type SSS, (10) T-items in bins of type BST, (11) T-items in bins of type BTT, (12) T-items in bins of type BT, (13) T-items in bins of type LLT, (14) T-items in bins of type SSST, and (15) T-items in bins of type TTTT.

For example, if the algorithm attempts to pack a B-item into a bin of type BST, it needs to search for an S-item and a T-item from bins whose type is inferior to BST. Thus, an S-item will be searched for in *Aux* (see below) and in the following inferior trees: the tree of S-items in bins of type BS, the tree of S-items in bins of type LLS, the tree of S-items in bins of type SSST, and the tree of S-items in bins of type SSS. Similarly, a T-item will be searched for in *Aux* and in the following inferior trees: the tree of T-items in bins of type BTT, the tree of T-items in bins of type BT, the tree of T-items in bins of type LLT, the tree of T-items in bins of type SSST, and the tree of T-items in bins of type TTTT.

In an inferior tree, each leaf contains an item, or more precisely the record associated with that item, and the internal nodes contain, for left, middle, and (if present) right subtree, the size of the smallest item in the subtree. This enables an easy search for the smallest item in that inferior tree.

3. *Aux*. Admitting only allowed types of bins to the regular packing possibly results in a few excess items that cannot be packed into the regular packing: at most one L-item, two S-items, and three T-items. These items are stored in *Aux*. In addition, in the course of maintaining an *MMP* packing, all of the bins that lose an item(s) a (so that a could be packed into a superior bin), or simply had an item deleted, need to be deleted from the regular packing, and their content, except for the lost/deleted item(s), temporarily stored into *Aux*. The items that are temporarily stored into *Aux* within an operation must all, except for at most one L-item, two S-items, and three T-items, be reinserted into the packing as an integral part of an *Insert/Delete* operation. Later in this section we show that the number of items stored in *Aux* at any time during the execution of *MMP* is bounded by a rather small constant.

Aux is implemented using five min-heaps (again, each heap is implemented as a 2-3 tree), one for each type of item: Aux_{B} for B-items, Aux_{L} for L-items, Aux_{S} for S-items, Aux_{T} for T-items, and Aux_{M} for M-bundles. Each leaf contains an item (bundle), or more precisely the record associated with that item (bundle), and the internal nodes contain, for left, middle, and (if present) right subtree, the size of the smallest item in the subtree. This enables an easy search for the smallest B-item, L-item, S-item, T-item, or M-bundle in *Aux*.

As it turns out, only closed M-bundles will be stored in the 2-3 tree of M-bundles. *Aux* will contain at any time at most one open M-bundle that will be stored separately from the 2-3 tree of (closed) M-bundles.

4. *M-items/bundles*. As mentioned earlier, M-items will be collected in bundles. These bundles may undergo a number of changes in the course of execution of *MMP*: M-items may be inserted to/deleted from bundles; two bundles could be merged into one bundle of M-items; further, there is a need to allow at most one open bundle per bin (at most one open bundle in *Aux*) and to ensure that all of the other bundles in a bin (in *Aux*) are closed. Each M-bundle b will be represented by a 2-3 tree of M-items that are collected into b. With each M-bundle b there will be an associated record that stores detailed information about b.

2-3 trees are particularly suitable for the maintenance and manipulation of bun-

dles. Insertions and deletions of individual M-items into/from a bundle correspond to the operations *Insert* and *Delete*, which are supported by 2-3 trees in logarithmic time. Furthermore, if there is a need to pack a bundle b into a bin B (or store it into *Aux*), b can be easily added onto the list of M-bundles in B (inserted into the 2-3 tree of M-bundles in *Aux* by means of an *Insert* operation on that tree in case b is closed or designated as open and stored into *Aux* in case b is open). If there is a need to merge two bundles, this can be easily accomplished by executing the operation *Union*, also supported by 2-3 trees in logarithmic time, on the two 2-3 trees representing the two bundles.

5. *The list of items in L.* Each item a will have, for the duration of its presence in L (i.e., from operation *Insert(a)* to operation *Delete*(a)), an associated record that maintains detailed information about a ($size(a)$ and a few pointers for manipulation of a in the data structures utilized by *MMP*). In addition, *MMP* will maintain L by storing its items at the leaves of a 2-3 tree of the current items of L. The leaves of that tree are each associated with an item currently in L. Each leaf stores, next to the pointers required for the manipulation of the 2-3 tree of the current items, a unique identifier associated with the item and the pointer to the corresponding record associated with that item.

When an operation *Insert(a)* is initiated, the new item a is inserted into the 2-3 tree of items, and its associated record is created. This is followed by other actions described in subsequent sections. Conversely, the operation *Delete(a)* involves certain actions (described in subsequent sections) and, finally, removes a from the 2-3 tree of the current items and destroys a's associated record. The processing of an *Insert/Delete* operation will typically cause changes to the packing and will affect several items in the packing. None of those changes will, however, have any impact on the 2-3 tree of the current items.

Finally, we note that, in the course of executing an *Insert/Delete* of an item a, the 2-3 tree of current items is used to locate the bin in which a is packed (or to realize that a is in *Aux*) and, furthermore, if a is an M-item, to locate the bundle b that a belongs to. Given an identifier associated with a, $\Theta(\log n)$ running time is required to locate the leaf in the 2-3 tree of current items that is associated with a. Then the pointer to the corresponding record associated with a is followed to gain access to that record within $\mathcal{O}(\log n)$ uniform running time.

3.2. Details of *MMP*. In this section we furnish the details of *MMP*. In the following subsections we will first provide a top level description of *MMP* and then furnish the details of *clear_Aux*, a key function from that description. In the following, b denotes a B-item, l denotes an L-item, s denotes an S-item, t denotes a T-item, and m denotes a M-bundle.

3.2.1. Top level description of *MMP*. We now describe *MMP*. Simply put, both *Insert*(x) and *Delete*(x) rely heavily on the function *clear_Aux*. The idea behind *Insert* is to insert the item x into *Aux* and then let *clear_Aux* complete the insertion of x in a manner that will maintain LLS-maximality and M-thoroughness. The idea behind *Delete* is similar, except that before invoking *clear_Aux*, the *Delete* operation needs to remove x from all of the data structures utilized by *MMP*.

In the description below, we utilize the following functions:

- *store_Aux*(x)—store the item x into *Aux*.
- *store_Aux*(X)—store the items and M-bundles from the set X into *Aux*. Then, for each L-item, S-item, and T-item from X, delete that item from the inferior tree

to which it belonged (if any). The set X will be either all of the content of some bin B or a part of it. In the latter case, adjust the myopic levels of B.

• *locate_structure*(x)—return a pointer to the structure to which x belongs (either a bin B or Aux).

• *terminate*(x,p)—delete x from all of the data structures. A pointer p points to the structure containing x (either a bin B or Aux). If x is an M-item, then delete x from the M-bundle m to which x belongs; m is contained in the structure pointed to by p (either a bin B or Aux). If x is a non-M-item, then (1) delete x from the structure to which p points (either a bin B or Aux), and then (2) if p points to a bin B, then delete x from the inferior tree to which x belongs (if any). At the conclusion of *terminate*, adjust the myopic levels of B, delete x from L, and delete the record associated with x.

• *remove*(B)—delete a bin B from the 2-3 tree representing the regular packing. Then destroy the record associated with B.

• *add*(B)—insert a bin B into the 2-3 tree representing the regular packing. Let TYPE be the type of B. *add* will insert B immediately after the highest numbered bin of type superior or equal to TYPE. This is accomplished via the information stored at the internal nodes (the most inferior type of bin in the left, middle, and right (if present) subtree). *add* starts at the root and walks down the tree, always to the subtree that stores the largest type that is still inferior to TYPE, until a leaf q is reached, or no subtree with a type that is inferior to TYPE could be found. In the latter case, B is the most inferior bin in the packing, and it will be inserted as the rightmost leaf of the 2-3 tree of bins. In the former case, B is inserted immediately to the left of q.

Both *remove* and *add* will update the information in the interior nodes on the path from B to the root of the 2-3 tree representing the regular packing.

• *open_new_bin*(B)—create a record associated with a new, unpacked bin; call it B. Initialize *content*(B) as empty, and B's myopic levels to 0. Leave the type of B unspecified.

• *pack*(B, $x_1, \ldots, x_k$, TYPE)—pack items/bundles $x_1, \ldots, x_k$ into B. Set the type of B to TYPE, if the value of TYPE is one of the allowed bin types (including M-bins). If TYPE is 0, then *pack* does not set the type of B. The latter option will be convenient when packing M-bundles into non-M, nonempty bins. Note that B need not be empty prior to the execution of the *pack* operation.

• *search_myopic*_K(x) (K $\in$ {L, S, T, M}, x is a K-item)—perform a search for the leftmost bin into which x can fit, with a myopic "K or larger" view of the packing. The search utilizes the information on the largest gap_{K} in the left, middle, and right (if present) subtree stored at the internal nodes of the 2-3 tree representing the regular packing and searches that tree in an *FF* fashion. *search_myopic*_K(x) returns a pointer p to the bin that can accommodate x (in the myopic sense). In this case we let B_p refer to that bin. If the value of the pointer p is *null*, then x could not fit into any of the bins in the (current) regular packing.

• *unload_Aux*$_{\mathrm{M}}$(B)—pack the following M-bundles into a bin B for as long as they fit or until Aux_{M} is empty: (1) the open M-bundle from Aux_{M}, (2) one by one, the smallest remaining closed M-bundle from Aux_{M}. *unload_Aux*$_{\mathrm{M}}$ terminates when either an M-bundle from Aux that cannot fit into B is found or Aux_{M} is empty.

• *top_with*_M(B)—fill up a bin B with M-bundles from Aux_{M}. If Aux_{M} is emptied in the process, the rightmost M-bin B_r of the regular packing (if any) is removed from the regular packing, and all of the M-bundles from B_r are inserted into Aux_{M}, at which point filling B with M-bundles from Aux_{M} is resumed.

```
    Insert(x):
1       store_Aux(x);
2       clear_Aux;

    Delete(x):
3       p =locate_structure(x);
4       terminate(x,p);
5       if (x ∈ M) then
6           begin
7               top_with_M(B_p); /* B_p is a bin pointed to by p */
8               reload_M;
9           end;
10      else /* x is a non-M-item */
11          if p points to a bin B_p then
12              begin
13                  store_Aux(content(B_p)); /* x is already deleted from B_p */
14                  remove(B_p);
15                  clear_Aux;
16              end;
```

FIG. 4. *A top level description of MMP's Insert and Delete.*

```
    top_with_M(B):
        unload_Aux_M(B);
        while Aux_M = ∅ and B_r is a M-bin do /* B_r—rightmost bin in packing */
            begin
                store_Aux(content(B_r));
                remove(B_r);
                unload_Aux_M(B);
            end;
```

• *discharge*($x_1, \ldots, x_k$,TYPE)—creates a new bin B, packs the items/bundles $x_1, \ldots, x_k$ into B, sets the type of B to TYPE, and then inserts B into the regular packing:

```
    discharge(x_1, ..., x_k, TYPE):
        open_new_bin(B);
        pack(B,x_1, ..., x_k,TYPE);
        add(B);
```

• *reload*_M—empty Aux_M by packing each of its bundles into the regular packing via *FF*:

```
    reload_M:
        while Aux_M ≠ ∅ do
            begin
                b=delete_min(Aux_M); /* Extract the smallest M-bundle m from Aux_M */
                p =search_myopic_M;
                if p = null then /* pack m into a new bin */
                    discharge(m,M-bin);
                else pack(B_p,0); /* pack m into B_p, the leftmost possible bin */
            end;
```

We complete this subsection with an observation that it is easy to see that all of the functions outlined above run in logarithmic uniform running time (using the data structures outlined in section 3.1).

We now summarize the top level description of *Insert* and *Delete* in Figure 4.

clear_Aux:
17 phase 1: clear all of the B-items from Aux_B;
18 phase 2: pack L-items, S-items, and T-items from *Aux* into B-bins of the regular packing;
19 phase 3: form LLS-coalitions;
20 phase 4: pack the remaining L-items, S-items, and T-items from *Aux* into non-B-bins;
21 phase 5: *reload*_M;

FIG. 5. *The five phases of clear_Aux.*

3.2.2. Details of *clear_Aux*. In this subsection we provide a description of *clear_Aux*, the most involved function invoked by *Insert* and *Delete* operations. *clear_Aux* proceeds in five phases. The first four phases (Figures 6 through 9) are aimed at the maintenance of LLS-maximality, while the last phase is a simple invocation of *reload*_M aimed at the maintenance of M-thoroughness. The five phases are listed in Figure 5.

We proceed with a detailed description of the first four phases. We utilize the functions defined in the previous subsection, as well as the function *seek* defined below.

• *seek*$(x_1, \ldots, x_k, y_1[s_1^1, \ldots, s_{y1}^1], \ldots, y_j[s_1^j, \ldots, s_{yj}^j])$—given items $x_1, \ldots, x_k$, *seek* searches for an item y_1 in the sources from the list $[s_1^1, \ldots, s_{y1}^1]$, ... , and for an item y_j in the sources from the list $[s_1^j, \ldots, s_{yj}^j]$ such that all of the x's and y's fit together; i.e., their cumulative size does not exceed 1. The first source on each list is always Aux_{K_y} (the type of K_y is the same as the type of the corresponding y item), while the remaining sources are the appropriate inferior trees (see code). The length of each list is always bounded by a small constant. This search gives preference to the "recruitment" of as many y's from *Aux* as possible. When an item currently packed into a bin must be utilized, it is preferred to search for items from the second source, and if that fails from the third source, etc. The search in any source is nothing more than checking the minimum size item in that source, which is easily accomplished in logarithmic time, since each source is maintained as a min-heap.

If the search is successful and the desired y's are found, *seek* proceeds by deleting all of the entries associated with the y's that are currently packed into bins from their respective inferior trees. Further, *seek* deletes such y's from their bins, stores the remaining content of these bins into *Aux*, and finally deletes these bins from the regular packing and destroys the records associated with these bins.

Note that *seek* runs in logarithmic uniform running time, since the number of searches of various balanced trees in the data structure from section 3.1 is bounded by a small constant (depending on the lengths of the lists of sources).

3.2.3. Implementation of queries. In this subsection we briefly comment on the implementation of queries *size* and *packing*. The query *size* asks for the number of bins in the (current) *MMP* packing. It is easy to implement it in $\mathcal{O}(1)$ uniform running time by maintaining a global integer variable *number* that reflects the number of bins in the regular packing. When a query *size* is processed, the algorithm will first look into *Aux*, which will at that time contain at most one L-item, two S-items, and three T-items. *MMP* will then compute (in constant time) z, the number of bins needed to pack these items from *Aux* ($z \leq 2$), and return *number* $+ z$ as the response to query *size*.

Recall that the query *packing* requests a description of the packing in the form of

```
    phase 1:
22      while Aux_B ≠ ∅ do
23          begin
24              b = delete_min(Aux_B);
25              if seek(b, l[Aux_L,4,3,2]) then
26                  discharge(b, l,BL);
27              else if seek(b, s[Aux_S,9,8,7,6]) then
28                  if seek(b, s, t[Aux_T,15,14,13,12,11]) then
29                      discharge(b, s, t,BST);
30                  else discharge(b, s,BS);
31              else if seek(b, t[Aux_T,15,14,13,12]) then
32                  if seek(b, t, t'[Aux_T,15,14,13,12]) then
33                      discharge(b, t, t',BTT);
34                  else discharge(b, t,BT);
35              else discharge(b,B);
36          end;
```

FIG. 6. *Phase* 1 *of clear_Aux: clear all of the B-items from* Aux_B.

a list of pairs $(x, \mathrm{Bin}(x))$, where $\mathrm{Bin}(x)$ denotes the bin into which an item x is packed, in time linear in the number of items in the current instance. Such a description of the regular packing can be obtained by a preorder traversal of the 2-3 tree representing the regular packing, and a computation of the packing of the items from *Aux* (without actually packing the items from *Aux* into bins, thereby removing these items from *Aux*). It is easy to see that this processing requires a uniform running time that is linear in n, the size of the (current) list L.

4. Competitive ratio and running time of *MMP*.

4.1. *MMP* is $\frac{5}{4}$-competitive. In this section the proof of the upper bound on the competitive ratio of *MMP* is presented. Lower bound examples with a $\frac{5}{4}$ ratio can be given; hence, this bound is tight. See Figure 10 for details.

4.1.1. Overview of the proof of the upper bound on the competitive ratio of *MMP*. The proof of the upper bound on the competitive ratio of *MMP* consists of several parts. First, we establish that *MMP* maintains regular packings that are LLS-maximal. Second, we show that *MMP* maintains M-thoroughness. Once these two important facts about *MMP* are proved (see subsections 4.1.2 and 4.1.3 below), we consider only lists of non-M-items and prove that the upper bound on the competitive ratio of *MMP* for such lists is $\frac{5}{4}$. This is the most difficult part of the proof. We then prove that *MMP* is $\frac{5}{4}$-competitive for arbitrary lists by an easy application of M-thoroughness.

4.1.2. *MMP* maintains LLS-maximality. In this subsection we prove the LLS-maximality of packings produced by *MMP*. In the proof, we will appeal to the code presented in the previous section.

LEMMA 1. *MMP maintains LLS-maximality of packings of lists of non-M-items.*

Proof. The proof proceeds by induction on the number of *Insert* and *Delete* operations processed by *MMP*. Suppose that the packing P produced by *MMP* is LLS-maximal immediately before an *Insert* or *Delete* operation is requested from *MMP*. We proceed to show that *MMP* will process that operation in a manner that maintains LLS-maximality.

```
    phase 2:
37      do
39          l = min(Aux_L);
40          p = search_myopic_L(l);
41          if p points to a B-bin, call it B_p then
38              begin
42                  success = true;
43                  l = delete_min(Aux_L);
44                  store_Aux({y ∈ content(B_p)| y of type ≺ L});
45                  pack(B_p, l,BL);
46                  top_with_M(B_p);
47              end
48      while Aux_L ≠ ∅ and success;
49      do
50          s = min(Aux_S);
51          p = search_myopic_S(s);
52          if p points to a B-bin, call it B_p then
53              begin
54                  success = true;
55                  s = delete_min(Aux_S);
56                  store_Aux({y ∈ content(B_p)| y of type ≺ S});
57                  if seek(b, s, t[Aux_T,15,14,13,12,11]) then /* b ∈ content(B_p) */
58                      pack(B_p, s, t,BST);
59                  else pack(B_p, s,BS);
60                  top_with_M(B_p);
61              end
62      while Aux_S ≠ ∅ and success;
63      do
64          t = min(Aux_T);
65          p = search_myopic_T(t);
66          if p points to a B-bin, call it B_p then
67              begin
68                  success = true;
69                  t = delete_min(Aux_T);
70                  store_Aux({y ∈ content(B_p)| y of type ≺ T});
71                  if seek(b, t, t'[Aux_T,15,14,13,12]) then /* b ∈ content(B_p) */
72                      pack(B_p, t, t',BTT);
73                  else pack(B_p, t,BT);
74                  top_with_M(B_p);
75              end
76      while Aux_T ≠ ∅ and success;
```

FIG. 7. *Phase* 2 *of clear_Aux: pack L-items, S-items, and T-items from Aux into B-bins of the regular packing.*

LLS-maximality concerns only non-M-items. Thus, operations of interest here are *Inserts* and *Deletes* of non-M-items. To complete the proof, it suffices to examine the first four phases of *clear_Aux* and to verify that their execution maintains LLS-maximality. This is in turn easy to verify by inspection of the definitions of thoroughness and LLS-maximality (Definitions 2 and 3, respectively) and the code of *clear_Aux*. □

```

106             t_3 = delete_min(Aux_T);
107             t_4 = delete_min(Aux_T);
108             discharge(t_1, t_2, t_3, t_4,TTTT);
109         end;
```

FIG. 9. *Phase* 4 *of clear_Aux: pack the remaining L-items, S-items, and T-items from Aux into non-B-bins.*

4.1.3. *MMP* maintains M-thoroughness. In this subsection we prove that *MMP* maintains M-thorough packings. This proof also proceeds by induction on the number of *Insert* and *Delete* operations processed by *MMP*. Suppose that the packing P produced by *MMP* is M-thorough immediately before an *Insert* or *Delete* operation is requested from *MMP*. We proceed to show that *MMP* will process that operation in a manner that maintains M-thoroughness.

We first consider the operation *Insert*(x): the item x is simply stored into *Aux*, and then *clear_Aux* is invoked. Within *clear_Aux*, each bin B whose content is changed (B can be a new bin or a bin whose content partially changes in the course of execution

$$L = \Big(\frac{1}{2}+\epsilon, \frac{1}{2}+2\epsilon, \ldots, \frac{1}{2}+\frac{\mathrm{N}}{2}\epsilon, \ldots, \frac{1}{2}+\mathrm{N}\epsilon,$$
$$\frac{1}{2}-\mathrm{N}\epsilon, \frac{1}{2}-(\mathrm{N}-1)\epsilon, \ldots, \frac{1}{2}-\frac{\mathrm{N}}{2}\epsilon, \ldots, \frac{1}{2}-\epsilon \Big)$$

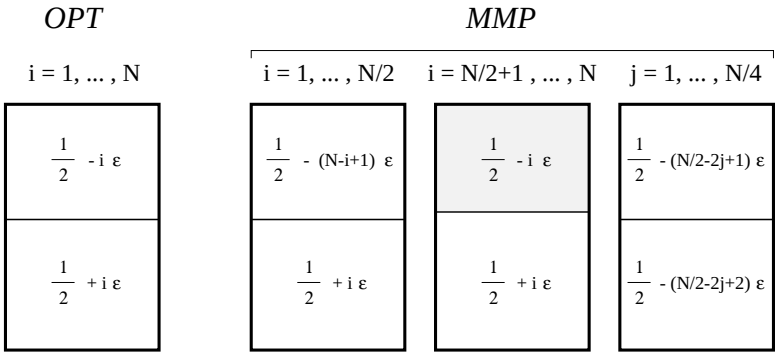

FIG. 10. *A lower bound example for MMP. Here the items are inserted precisely in the order in which they are listed in L above. This example proves that there are arbitrarily large lists L (N is an arbitrarily large integer divisible by 4) for which OPT(L) = N, and MMP(L) = $\frac{5}{4}N$, thus establishing a lower bound of $\frac{5}{4}$ on the competitive ratio of MMP, i.e., R(MMP) $\geq \frac{5}{4}$.*

of *clear_Aux*) is filled with M-bundles via the *top_with_*M function. This function continues filling B until an M-bundle that cannot fit into B is found, in which case *level*$(B) > \frac{4}{5}$ or until there are no more M-bins and Aux_{M} is empty. Finally, phase 5 of *clear_Aux* is an execution of the function *reload_*M. This function will, in case Aux_{M} is *not* empty at the conclusion of maintaining LLS-maximality (phases 1 through 4), accomplish M-thoroughness by packing the M-bundles from Aux_{M} into the regular packing in an *FF* fashion. This will guarantee that (1) there could only be M-bins if each non-M-bin has a level $> \frac{4}{5}$ and (2) any M-bin, except, perhaps, for the rightmost bin in the packing, has a level $> \frac{4}{5}$.

Next, we consider the operation *Delete*(x), where x is a non-M-item. If x is packed into a bin B_p, x is deleted from B_p, the remaining content of B_p is inserted into *Aux*, B_p is deleted from the regular packing, and *clear_Aux* is invoked. (As argued above *clear_Aux* maintains the M-thoroughness of the packing.) Note that deletion of non-M-items from *Aux* has no effect on M-thoroughness of *MMP*. Finally, deletion of M-items (see code: lines 3–9 in *Delete*) also preserves M-thoroughness via functions *top_with_*M and *reload_*M.

Thus we proved the following lemma.

LEMMA 2. *MMP maintains M-thoroughness of packings of arbitrary lists.*

4.1.4. Consideration of lists with no M-items. We fix an arbitrary list L that contains no M-items. Recall that L may be obtained by an arbitrary sequence of *Inserts* and *Deletes* of items. This arbitrariness may lead to various *MMP* packings of L. We thus fix an arbitrary *MMP* packing P_L of L. P_L consists of the regular packing P_0 and the auxiliary storage *Aux*.

We then fix an arbitrary optimal packing OPT_0 of L and derive from it another optimal packing *OPT* of L. *OPT* is a reordering of the bins from OPT_0 such that the bins of type BL are the leftmost bins of *OPT*, the bins of type BST are the next

leftmost bins of OPT, ... , and the bins of type T are the rightmost bins of OPT.

We note that it will be convenient to fix P, a reordering of the bins from P_0. P is defined as follows: the kth leftmost B-bin in OPT and the kth leftmost B-bin in P must contain the same B-item; the order of non-B-bins of P_0 and P is identical.

For both OPT and P, let the *index* of a B-bin B in the packing $OPT(P)$ be the number assigned to B in the "left to right" numbering of the bins from $OPT(P)$. Clearly, for an arbitrary B-item b from L, the indices of B-bins into which b is packed in OPT and P are equal.

Intuitively, the above construction will enable us to view OPT and P in a special way: we may imagine that the B-items of L are "static"—they "remain in the same bin" in an imaginary transformation between OPT and P, and the L-items, S-item, and T-items "migrate," since they may be packed into the k_1th leftmost bin in OPT and into the k_2th leftmost bin in P, where $k_1 \neq k_2$.

The underlying idea. The underlying idea of the proof is to develop an elegant way of capturing the following imaginary series of events. At the outset, someone "glued" the B-items from L into $\mathcal{B}$ bins, one B-item per bin. That person is then required to take the non-B-items from L and pack them into those $\mathcal{B}$ bins and as many additional bins as necessary (these will be non-B-bins), so as to create OPT. Next, that person is required to remove all of the non-B-items from bins and retain the bins containing the glued B-items in the "left to right" order produced by OPT. Finally, that person is again required to take the non-B-items from L and pack them into those $\mathcal{B}$ bins and as many additional bins as necessary (again, these will be non-B-bins), so as to create P. As indicated in the course of defining P, we are interested in "migrations" of non-B-items *from* bins of all types in OPT *to* B-bins in P. The notion of glued B-items motivated the definitions of OPT and P: B-items may be viewed as "static"; they do not move from bin to bin when the packing is changed from OPT to P. L-items, S-items, and T-items, on the other hand, may "migrate"; i.e., the indices of the bins they are packed into in OPT and P may differ. The remainder of the proof explores this "itemographic process."

We perform an extensive analysis of the structure of P in terms of different types of bins in P and OPT and their respective multiplicity f_i, $1 \leq i \leq 30$, where f_i denotes the number of bins of type i in OPT (i is the canonical index of bin types with respect to the superiority relation. See Figure 1.) The proof will *not at all* depend on the particular sequence of *Inserts* and *Deletes* that led to L and its *MMP* packing P_L. The proof will depend *only* on the fact, proved in subsection 4.1.2, that *MMP* produces packings that are LLS-maximal. Based on that property, we derive lower bounds on the quantities L_B, S_B, and T_B, and N_{LLS} defined thus.

DEFINITION 5. *Let L_B (S_B, T_B) denote the number of L-items (S-items, T-items) in B-bins in P. Let N_{LLS} denote the number of bins of type LLS in P.*

A preliminary result. We begin with a preliminary lemma. We establish an upper bound on the number of bins *MMP* would require to pack a given number of L-items, S-items, and T-items.

LEMMA 3. *Suppose L contains only L-items, S-items, and T-items.* MMP *will pack L into at most $\frac{\mathcal{L}}{2} + \frac{\mathcal{S}}{3} + \frac{\mathcal{T}}{4} + 2$ bins.*

Proof. Recall that *MMP* maintains LLS-maximality (see Lemma 1). P_0 will require precisely $\lfloor \frac{\mathcal{L}}{2} \rfloor$ bins with two L-items (these bins may each contain an additional S-item or an additional T-item), followed by at most $\lfloor \frac{\mathcal{S}}{3} \rfloor$ bins with three S-items (analogously, these bins may each contain an additional T-item), followed by at most

$\lfloor \frac{\mathcal{T}}{4} \rfloor$ bins with four T-items. In addition, *Aux* might contain at most one L-item, two S-items, and three T-items. All of these items can fit into at most two bins (one bin of type LTT and one bin of type SST). Hence the number of bins required by *MMP* to pack all of the items of L is at most

$$\left\lfloor \frac{\mathcal{L}}{2} \right\rfloor + \left\lfloor \frac{\mathcal{S}}{3} \right\rfloor + \left\lfloor \frac{\mathcal{T}}{4} \right\rfloor + 2 \leq \frac{\mathcal{L}}{2} + \frac{\mathcal{S}}{3} + \frac{\mathcal{T}}{4} + 2. \qquad \square$$

Several technical results. We now proceed with several technical results that are important in estimating the quantities L_B, S_B, T_B, and N_{LLS}. A precise estimate of these quantities is the key ingredient in the proof. Each of the following lemmas contains three statements that are quite analogous and are moreover proved analogously. We adopt this particular style of presentation to avoid unnecessary repetition.

LEMMA 4. *Consider an optimal packing P_{opt} consisting only of k bins of type BL (BS; LLS). Consider a list L whose optimal packing could be P_{opt} and is constructed in stages:*[5]

stage 0: $X =$ *the set of items in* P_{opt}*;*
$L = \emptyset$*;*
go to stage 1;

stage i: ($1 \leq i \leq k$)
$Y =$ (*the smallest B-item in* X (*B-item; two L-items*),
the smallest L-item in X (*S-item; S-item*));
$L = L \cdot Y$*;*
$X = X -$ *set of items in* Y*;*
go to stage $i + 1$*;*

stage $k + 1$: *return* L*;*

Then the B-item and the L-item (the B-item and the S-item; the two L-items and the S-item) assigned to Y in stages 1 *through* $\alpha = \lceil \frac{k}{2} \rceil$ ($\lceil \frac{k}{2} \rceil$; $\lceil \frac{k}{3} \rceil$), *respectively, must fit together into a bin of type BL (BS, LLS).*

Proof. Suppose by way of contradiction that it is *not* the case that the B-item and the L-item (the B-item and the S-item; the two L-items and the S-item) assigned to Y in all of the stages 1 through $\alpha = \lceil \frac{k}{2} \rceil$ ($\lceil \frac{k}{2} \rceil$; $\lceil \frac{k}{3} \rceil$), respectively, fit together into a bin of type BL (BS, LLS).

Then there exists a positive integer $1 \leq \beta < \alpha$ such that only the B-items and the L-items (the B-items and the S-items; the L-items and the S-items) assigned to Y in stages 1 through β, respectively, fit into a bin of type BL (BS; LLS).

Consider L arranged in a table with 2 (2;3) rows and k columns as follows: ith column contains exactly the items added to L in the ith stage of the construction of L, where within a column the items are arranged in successive rows according to the order in which they were added to L. Refer to Figure 11 for details.

Note that only the items from the first β columns of this table can, according to the supposition, fit together into bins: one bin per column of type BL (BS; LLS).

Let $\mathcal{C}_1$ be the set of all of the items that lie in the first row (first row; first two rows) and are also in the first β columns. Let $n_1 = card(\mathcal{C}_1)$. Clearly $n_1 = \beta$ (β; 2β). Let $\mathcal{C}_2$ be the set of all of the items in the last row that belong to the columns $\beta + 1, \beta + 2, ..., k$. Let $n_2 = card(\mathcal{C}_2)$. Clearly $n_2 = k - \beta$.

Any item $a \in \mathcal{C}_2$ could only be packed into a bin of type BL (BS; LLS) if b, the B-item (the B-item; at least one of the two L-items) with which a would be packed,

[5] In the construction below, the operator $\cdot$ denotes concatenation; i.e., $\cdot$ is a binary operator that appends its second operand to its first operand.

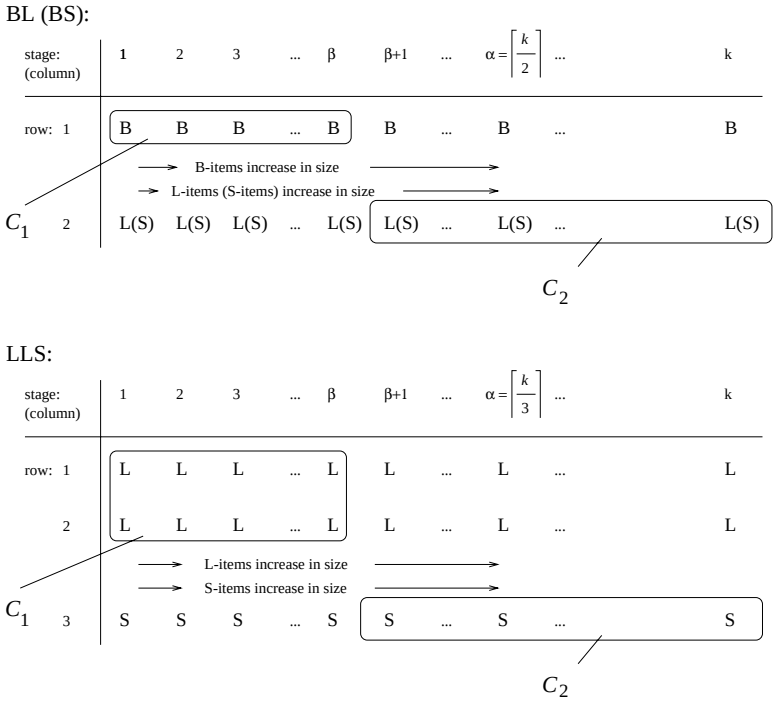

FIG. 11. *A tabular arrangement of L. Letters B, L, and S denote B-items, L-items, and S-items of L, respectively.*

would be from $\mathcal{C}_1$; otherwise the level of such a bin would exceed 1. Thus, since the optimal packing of L contains only bins of type BL (BS; LLS), there should be sufficiently many items in $\mathcal{C}_1$ to ensure the packing of each $a \in \mathcal{C}_2$; i.e., it should be the case that $n_1 \geq n_2$, i.e., $n_1 - n_2 \geq 0$. However,

$$\begin{aligned} n_1 - n_2 = (c-1)\beta - (k-\beta) \;&=\; c\beta - k \;\leq c\left(\left\lceil \frac{k}{c} \right\rceil - 1\right) - k \\ &\leq \left(\frac{k+c-1}{c}\right) - c - k \;=\; -1, \end{aligned}$$

where c=2 (2;3) bins of type BL (BS; LLS). This is a contradiction. □

Clearly, if *MMP* packs this particular list L in a series of *Inserts* of items in the order in which the items appear in L, *MMP* will pack at least α bins of type BL (BS; LLS).

COROLLARY 1. *The MMP packing of the list L defined in the statement of Lemma* 4*, carried out as a series of Inserts of items in the order in which the items appear in L, must contain at least* $\alpha = \lceil \frac{k}{2} \rceil$ ($\lceil \frac{k}{2} \rceil$; $\lceil \frac{k}{3} \rceil$) *bins of type BL (BS, LLS).*

Thus we have shown that a very particular sequence of *Inserts* will pack an L with a very specific optimal packing in the manner that will, informally, "salvage" about one half (one half; one third) of the bins of type BL (BS; LLS). The following lemma shows that this particular order of packing the items of L, inserted one by one in the order in which they appear in L, is not at all essential. Furthermore, it is not essential that an optimal packing of L consists only of bins of type BL (BS; LLS). In other words, to determine the lower bound on the number of bins of type BL (BS; LLS) in

an *MMP* packing of a list L containing only B-items, L-items, S-items, and T-items (B-items, S-items, and T-items [note a careful avoidance of L-items); L-items, S-items, and T-items (note a careful avoidance of B-items)), the only relevant information is the maximum number of bins of type BL (BS; LLS) that can be constructed from items in L. *MMP* will, informally, "salvage" about one half (one half; one third) of that maximum number of bins of type BL (BS; LLS). We again choose this particular style of presentation to avoid the unnecessary repetition.

LEMMA 5. *Let L' be a list containing B-items, L-items, S-items, and T-items (B-items, S-items, and T-items; L-items, S-items, and T-items). Let k be the maximum number of bins of type BL (BS; LLS) that could be packed from the items of L'. Then any MMP packing of L', obtained by an arbitrary sequence of Inserts and Deletes leading to L', contains at least $\alpha = \lceil \frac{k}{2} \rceil$ ($\lceil \frac{k}{2} \rceil$; $\lceil \frac{k}{3} \rceil$) bins of type BL (BS; LLS).*

Proof. Suppose by way of contradiction that there is an *MMP* packing P_{bad} of L' that contains only $\gamma < \alpha$ bins of type BL (BS; LLS). Let $P_{desired}$ be a maximum cardinality packing of B-items and L-items (B-items and S-items; L-items and S-items) from L' into bins of type BL (BS; LLS) (note the correspondence of $P_{desired}$ with P_{opt} from Lemma 11). By a hypothesis, the maximum number of bins of type BL (BS; LLS) in the $P_{desired}$ packing is precisely k. Let L be the list of items derived from $P_{desired}$ in the manner of Lemma 11. Let P' be the *MMP* packing of L obtained by a sequence of *Inserts* of items from L in the order in which the items appear in L (note the correspondence with the situation from Corollary 1). Since there are only $\gamma < \alpha$ bins of type BL (BS; LLS) in P_{bad}, there must be at least one B-item b (one B-item b; two L-items l_1, l_2) and one L-item l (one S-item s; one S-item s) that are packed in one of the first α bins of type BL (BS; LLS) in P', and are not packed in a bin of type BL (BS; LLS) in P_{bad}. Note that the size of each of b and l (b and s; l_1, l_2, and s) is no greater than the size of the B-item and the L-item (the B-item and the S-item; the two L-items and the S-item) from the αth bin in P_{bad}. Thus b and l (b and s; l_1, l_2, and s) can fit into a bin. This is a contradiction, since *MMP* produces packings that are thorough (thorough; LLS-maximal) (Lemma 1) for bins of type BL (BS; LLS), and would therefore have packed at least one more bin of type BL (BS; LLS) in P_{bad}. □

Toward a lower bound on N_{LLS}. We proceed by stating several properties that will be used to obtain a lower bound on the value of N_{LLS}. We begin by considering bins of type LSTT. We show that two L-items and one S-item, each from any, and not necessarily the same, bin of type LSTT must fit into a bin.

LEMMA 6. *Let l_1, l_2, and s be two L-items and an S-item, each from any, and not necessarily the same, bin of type LSTT. Then l_1, l_2, and s can fit into a bin.*

Proof. It suffices to show that $2L_{max} + S_{max} \leq 1$, where L_{max} (S_{max}) denotes the maximum size of L-items (S-items) in any bin of type LSTT;

$$L_{max} = 1 - S_{min} - 2T_{min} < 1 - \frac{1}{4} - 2 \cdot \frac{1}{5} = \frac{7}{20},$$
$$S_{max} = 1 - L_{min} - 2T_{min} < 1 - \frac{1}{3} - 2 \cdot \frac{1}{5} = \frac{4}{15},$$
$$2L_{max} + S_{max} < 2 \cdot \frac{7}{20} + \frac{4}{15} = \frac{29}{30} < 1,$$

where S_{min} and T_{min} denote the minimum size of an S-item and an T-item, respectively. □

Establishing a good lower bound on the number of bins of type LLS that would be

produced by *MMP* is very important later in the proof, since that bound is a measure of the success of the technique of LLS-coalitions utilized by *MMP*. To that end, we state and prove the following lemma.

LEMMA 7. *Suppose that L is a list of non-B-items. Let P_{opt} be an arbitrary optimal packing of L satisfying the following three conditions:*

1. *P_{opt} contains at least n_1 bins of type LLS;*
2. *at least n_2 L-items from L are not packed into bins of type LLS in P_{opt}, and each of these L-items can fit into a bin of type LSTT;*
3. *at least n_2 S-items from L are not packed into bins of type LLS in P_{opt}, and each of these S-items can fit into a bin of type LSTT.*

Then the number of bins of type LLS in any MMP *packing of L is at least $\lceil \frac{n_1+n_2}{4} \rceil - 1$.*

Proof. First, the following fact follows immediately from Lemma 6.

FACT 1. *The maximum number of bins of type LLS that can be packed from the items of L is at least $n_0 = n_1 + \lfloor \frac{n_2}{2} \rfloor$.*

Now to prove this lemma, we consider two cases.

Case 1. $n_1 \geq n_2$.

By Lemma 5, *MMP* will pack at least $\lceil \frac{n_0}{3} \rceil$ bins of type LLS:

$$\left\lceil \frac{n_0}{3} \right\rceil = \left\lceil \frac{n_1 + \lfloor \frac{n_2}{2} \rfloor}{3} \right\rceil \geq \left\lceil \frac{n_1 + \frac{n_2-1}{2}}{3} \right\rceil = \left\lceil \frac{\frac{3}{4}n_1 + \frac{1}{4}n_1 + \frac{1}{2}n_2 - \frac{1}{2}}{3} \right\rceil$$
$$= \left\lceil \frac{n_1+n_2}{4} - \frac{1}{6} \right\rceil \geq \left\lceil \frac{n_1+n_2}{4} \right\rceil - 1.$$

Case 2. $n_1 < n_2$.

By Lemma 6 and the fact that *MMP* maintains LLS-maximality of bins of type LLS (Lemma 1), *MMP* will pack at least $\lfloor \frac{n_2}{2} \rfloor$ bins of type LLS. Further, note that $n_1 + n_2 < 2n_2$:

$$\left\lfloor \frac{n_2}{2} \right\rfloor \geq \left\lfloor \frac{\frac{n_1+n_2}{2}}{2} \right\rfloor = \left\lfloor \frac{n_1+n_2}{4} \right\rfloor \geq \left\lceil \frac{n_1+n_2}{4} \right\rceil - 1. \qquad \square$$

Toward lower bounds on L_B, S_B, and T_B. The next several lemmas establish important properties that will be used later to bound L_B, S_B, and T_B.

LEMMA 8. *A B-item from a bin of type BL can be packed together with any S-item.*

Proof. It suffices to show that $B_{max} + S_{max} < 1$, where B_{max} denotes the maximum size of B-items in any bin of type BL, and S_{max} denotes the maximum size of S-items:

$$B_{max} = 1 - L_{min} < 1 - \frac{1}{3} = \frac{2}{3}, \quad S_{max} = \frac{1}{3}, \quad B_{max} + S_{max} < \frac{2}{3} + \frac{1}{3} = 1,$$

where L_{min} denotes the minimum size of L-items. $\square$

The next nine lemmas are proved quite analogously.

LEMMA 9. *A B-item from a bin of type BL can be packed together with any T-item.*

LEMMA 10. *A B-item from a bin of type BST can be packed together with an L-item from a bin of type LLS.*

LEMMA 11. *A B-item from a bin of type BST can be packed together with an L-item from a bin of type LSTT.*

LEMMA 12. *A B-item from a bin of type BST can be packed together with any S-item.*

LEMMA 13. *A B-item from a bin of type BST can be packed together with any T-item.*

LEMMA 14. *A B-item from a bin of type BS can be packed together with any T-item.*

LEMMA 15. *A B-item from a bin of type BTT can be packed together with an L-item from a bin of type LSTT.*

LEMMA 16. *A B-item from a bin of type BTT can be packed together with any S-item.*

LEMMA 17. *A B-item from a bin of type BTT can be packed together with any T-item.*

***MMP* is $\frac{5}{4}$-competitive for lists with no M-items.** Recall that there are 30 possible types of bins involving B-items, L-items, S-items, and T-items: BL, BST, ... , T (see Figure 1). We will find it convenient to refer to these types of bins according to their canonical index in the lexicographical ordering based on the relation of superiority. For example, a bin of type 1 is a bin of type BL, a bin of type 2 is a bin of type BST, ... , a bin of type 30 is a bin of type T, as depicted in Figure 1.

Next, recall that only a subset of the above types of bins is *allowed* in *MMP* packings. The allowed bin types are BL, BST, BS, BTT, BT, B, LLS, LLT, LL, SSST, SSS, and TTTT. Alternatively, using the canonical indices, the allowed bin types are 1, 2, 3, 4, 5, 6, 7, 8, 9, 18, 19, and 27.

Intuitively, certain types of bins will be more important for the proof of the upper bound on the competitive ratio than the others. We therefore classify the bin types into the *front* (more important) types of bins and the *back* (less important) types of bins.

DEFINITION 6. *The* front *types of bins are BL, BST, BS, BTT, BT, B, LLS, and LSTT* (*types* $1, 2, \ldots, 7, 11$). *All of the other types are* back *types of bins. Let* $\mathcal{L}_{back}$ ($\mathcal{S}_{back}$, $\mathcal{T}_{back}$) *denote the number of L-items (S-items, T-items) in the bins of back types in OPT.*

Recall that f_i, $1 \le i \le 30$, denotes the number of bins of type i in *OPT*. The following equations hold (see Figure 1):

$$\mathcal{L}_{back} = 2(f_8 + f_9) + f_{10} + \sum_{i=12}^{17} f_i,$$

$$\mathcal{S}_{back} = 3(f_{18} + f_{19}) + 2(f_{10} + f_{20} + f_{21} + f_{22}) + f_{12} + f_{13} + \sum_{i=23}^{26} f_i,$$

$$\begin{aligned}\mathcal{T}_{back} = {} & 4f_{27} + 3(f_{14} + f_{23} + f_{28}) + 2(f_{15} + f_{20} + f_{24} + f_{29}) \\ & + f_8 + f_{12} + f_{16} + f_{18} + f_{21} + f_{25} + f_{30},\end{aligned}$$

$$\mathcal{L} = f_1 + 2f_7 + f_{11} + \mathcal{L}_{back},$$

$$\mathcal{S} = f_2 + f_3 + f_7 + f_{11} + \mathcal{S}_{back},$$

$$\mathcal{T} = f_2 + 2f_4 + f_5 + 2f_{11} + \mathcal{T}_{back}.$$

We next furnish a technical definition of the *list of indices*.

DEFINITION 7. *A list of indices* $l = i_1, i_2, \ldots, i_k$ *is a list of positive integers.* $*$ *will be used as an abbreviation for the list* 8, 9, 10, 12, 13, ..., 30.[6]

[6]Note that this list corresponds to the back types of bins.

We would like to use this notation to count the number of bins in OPT whose type is an element of the list of indices l. To that end, we furnish the following definition.

DEFINITION 8. *Let l denote a list of indices. Let f_l denote the number of bins in OPT whose type is an element of l. Then $f_l = \sum_{i \in l} f_i$.*

For example, the number of bins in OPT that contains a B-item and an S-item (bins of type BST (2) or BS (3)) is $f_{2,3} = f_2 + f_3$.

Let us define another technical definition of *ranges of bins*. Each range of bins r_i captures precisely the indices of B-bins of type i in OPT.

DEFINITION 9. *Ranges of bins r_i, $1 \leq i \leq 6$, are segments of positive integers defined as follows: $r_1 = [1, \ldots, f_1]$, $r_2 = [f_1 + 1, \ldots, f_{1,2}]$, $r_3 = [f_{1,2} + 1, \ldots, f_{1,2,3}]$, $r_4 = [f_{1,2,3} + 1, \ldots, f_{1,2,3,4}]$, $r_5 = [f_{1,\ldots,4} + 1, \ldots, f_{1,\ldots,5}]$, and $r_6 = [f_{1,\ldots,5} + 1, \ldots, f_{1,\ldots,6}]$.*

We would like to count the number of items of a certain type (L-items, S-items, or T-items) that are packed into a bin of type i in OPT and into a B-bin with an index from the range r_j in P. Intuitively, we would like to count how many items of a certain type "migrated" from bins of type i in OPT (intuitively, the source bins) to B-bins in P that "used to be" bins of type j in OPT; i.e., the index of such bins in both OPT and P is from the range r_j (intuitively, the destination bins).

We would also like to count the number of items of a certain type (L-items, S-items, or T-items) that are packed into a bin in OPT whose type is an element of the list of indices l_s (intuitively, the types of source bins), and into a B-bin in P whose index is from a range of bins indexed by an element of the list of indices l_d (intuitively, the ranges of destination bins).

DEFINITION 10. *Let L_d^s (S_d^s, T_d^s), $s \in \{1, 2, \ldots, 5, 7, 8, \ldots, 30\}$ and $d \in \{1, 2, \ldots, 6\}$, denote the number of L-items (S-items, T-items) that are packed into bins of type s (source) in OPT, and into B-bins with an index from r_d (destination) in P.*

Let l_s and l_d denote lists of indices. Let $L_{l_d}^{l_s}$ ($S_{l_d}^{l_s}$, $T_{l_d}^{l_s}$) denote the number of L-items (S-items, T-items) that are packed into a bin in OPT whose type is an element of the list of indices l_s, and into a B-bin in P whose index is from a range of bins indexed by an element of the list of indices l_d. Then

$$L_{l_d}^{l_s} = \sum_{i \in l_s} \sum_{j \in l_d} L_j^i \quad \left(S_{l_d}^{l_s} = \sum_{i \in l_s} \sum_{j \in l_d} S_j^i \,, \quad T_{l_d}^{l_s} = \sum_{i \in l_s} \sum_{j \in l_d} T_j^i \right).$$

We illustrate this notation with two examples.

First, L_1^7 denotes the number of L-items that are packed into bins of type 7 (LLS) in OPT, and into bins with an index from r_1 in P, that is, into one of the f_1 leftmost bins, bins that contain a B-item that is packed into a bin of type 1 (BL) in OPT.

Second, the number of T-items that are packed into a bin of one of the types BST (2), BT (4), or LLT (8) in OPT, and into a B-bin whose index is from one of the ranges r_2 or r_3 (that is, into one of the bins that contains a B-item that is packed into a bin of type 2 (BST) or a bin of type 3 (BS) in OPT) is written as follows:

$$T_{2,3}^{2,4,8} = \sum_{i \in 2,4,8} \sum_{j \in 2,3} T_j^i = T_2^2 + T_2^4 + T_2^8 + T_3^2 + T_3^4 + T_3^8.$$

We now state and prove the main result of this subsection.

LEMMA 18. *$MMP(L) \leq \frac{5}{4} OPT(L) + 3$.*

Proof. We begin with a series of four claims that establish lower bounds on the values of L_B, S_B, T_B, and N_{LLS}, respectively.

CLAIM 1. $L_B \geq L^{1,7,11,*}_{1,3,\ldots,6} + L^{1,*}_2 + \min(2f_7 + f_{11} - L^{7,11}_{1,3,\ldots,6}, f_2 - L^{1,*}_2)$.

Proof. The key to the proof of this lemma is an observation that any B-item from a bin of type 2 (BST) can be packed together with any L-item from a bin of type 7 or 11 (LLS or LSTT) (Lemmas 10 and 11).

The right-hand side of the above inequality consists of the follwing three additive terms.

1. The first term accounts for all of the L-items that are packed into one of the bins of type 1, 7, 11, or into one of the bins of back type in *OPT*, and into one of the B-bins in P that contains a B-item that is packed into a bin of type 1, 3, 4, 5, or 6 in *OPT* (note a careful avoidance of bins of type 2 (BST)).

2. The second term accounts for all of the L-items that are packed into one of the bins of type 1, or into one of the bins of back type in *OPT*, and into one of the B-bins in P that contains a B-item that is packed into a bin of type 2 (again, note a careful avoidance of bins of type 2 (BST)).

3. The third term, the min term, is somewhat more involved.

The first operand of the min term is $2f_7 + f_{11} - L^{7,11}_{1,3,\ldots,6}$. This number denotes the number of L-items from bins of type 7 (LLS) and 11 (LSTT) in *OPT* that are *not* packed into a bin in P together with a B-item that is packed into a bin of type 1, 3, 4, 5, or 6 in *OPT* (note a careful avoidance of B-items from bins of type 2 (BST) in *OPT*).

The second operand of the min term is $f_2 - L^{1,*}_2$. This number denotes the number of B-items that are (1) packed into a bin of type 2 (BST) in *OPT* and (2) are *not* packed into a bin in P together with an L-item that is packed into a bin of type 1 (BL) or one of the back-type bins in *OPT* (note a careful avoidance of L-items from bins of type 7 (LLS) and 11 (LSTT) in *OPT*).

Thus, by Lemmas 10 and 11, any B-item accounted for by the second operand can be packed together with any L-item accounted for by the first operand of the min expression. By the LLS-maximality of *MMP* (see Lemma 1), P will feature $\min(2f_7 + f_{11} - L^{7,11}_{1,3,\ldots,6}, f_2 - L^{1,*}_2)$ bins of type 1 (BL) containing the above B-items and L-items. □

The following two lemmas are proved quite analogously.

CLAIM 2. $S_B \geq S^{2,3,7,11,*}_{3,5,6} + \min(f_2 + f_3 + f_7 + f_{11} - S^{2,3,7,11}_{3,5,6}, f_1 + f_2 + f_4 - (L_B - L^{1,7,11,*}_{3,5,6}))$.

CLAIM 3. $T_B \geq T^{2,4,5,11,*}_{5,6} + \min(f_2 + 2f_4 + f_5 + 2f_{11} - T^{2,4,5,11}_{5,6},\ f_{1,\ldots,4} - (L_B - L^{1,7,11,*}_{5,6}) - (S_B - S^{2,3,7,11,*}_{5,6}))$.

CLAIM 4. $N_{LLS} \geq \frac{1}{4}(\max(0, f_7 - (L^7_{1,\ldots,6} + S^7_{1,\ldots,6})) + f_{11} - \max(L^{11}_{1,\ldots,6}, S^{11}_{1,\ldots,6})) - 1$.

Proof. The key to the proof of this lemma is the statement of Lemma 7. Let the set of items packed into non-B-bins in *OPT* play the role of L in Lemma 7. Let the non-B-bins of *OPT* play the role of P_{opt} in Lemma 7. Further, note the following conditions.

1. $\max(0, f_7 - (L^7_{1,\ldots,6} + S^7_{1,\ldots,6}))$ is a (conservative) lower bound on the number of bins of type LLS in *OPT* that do *not* contain an item that is packed into a B-bin in P. These $\max(0, f_7 - (L^7_{1,\ldots,6} + S^7_{1,\ldots,6}))$ bins of type LLS play the role of n_1 bins of type LLS in Lemma 7.

2. $f_{11} - \max(L^{11}_{1,\ldots,6}, S^{11}_{1,\ldots,6})$ is a (conservative) lower bound on the number of L-items and the number of S-items from bins of type LSTT in *OPT* that are *not* packed into B-bins in P. These $f_{11} - \max(L^{11}_{1,\ldots,6}, S^{11}_{1,\ldots,6})$ L-items and $f_{11} - \max(L^{11}_{1,\ldots,6}, S^{11}_{1,\ldots,6})$ S-items play the role of n_2 L-items and S-items in Lemma 7.

This claim, then, follows directly from Lemma 7. Note that, unlike in Lemma 7, we did not choose to apply the ceiling operator, as this will have no substantive effect on the analysis of the competitive ratio of *MMP*. □

Next, we apply Lemma 5 to establish lower bounds on the values of L_1^1 and S_3^3. Note that we do not provide a lower bound for T_5^5. Again, while a lower bound on T_5^5 could be established in an analogous manner, accounting for T_5^5 will have no substantive effect on the analysis of the competitive ratio of *MMP*.

CLAIM 5. $L_1^1 \geq \frac{1}{2}(f_1 - \min(f_1, L_1^{7,11,*} + L_{2,\ldots,6}^1))$.

Proof. The proof is immediate from Lemma 5. Let Γ be the set of B-items from L that are packed into bins of type BL in *OPT* and at the same time satisfy the following two properties.

1. They are packed into a bin in *OPT* together with L-items which satisfy the property that they are *not* packed into a bin of type BL in P together with a B-bin with an index from $r_2 \cup r_3 \ldots \cup r_6$. Informally, the B-items from Γ cannot be packed in *OPT* together with L-items that "migrate" from bins with indices from r_1 in *OPT* to other B-bins in P.

2. They are *not* packed into a bin in P together with L-items that are packed into non-B-bins in *OPT*.

A conservative estimate of the lower bound on the cardinality of Γ is $f_1 - \min(f_1, L_1^{7,11,*} + L_{2,\ldots,6}^1)$. We say that the estimate is conservative, since there may be B-items that violate both properties, whereas this bound assumes that each B-item violates at most one property; i.e., it is assumed that there are no "overlaps."

The list consisting of B-items of Γ and L-items that are packed together with a B-item from Γ in *OPT* now plays the role of L' from Lemma 5. Further, the above conservative estimate of the cardinality of Γ plays the role of k from Lemma 5.

The claim follows directly from Lemma 5. Note that, unlike in Lemma 5, we did not apply the ceiling operator, as this will have no substantive effect on the analysis of the competitive ratio of *MMP*. □

The following claim is proved quite analogously.

CLAIM 6. $S_3^3 \geq \frac{1}{2}(f_3 - \min(f_3, L_3^{1,7,11,*} + S_3^{2,7,11,*} + S_{1,2,4,5,6}^3))$.

Next, we note that the number of bins in *OPT* is precisely $OPT(L) = \sum_{i=1}^{30} f_i$. Let us now bound the value of $MMP(L)$ in terms of f_i's, L_B, S_B, T_B, and N_{LLS}. The number of B-bins, $\mathcal{B} = \sum_{i=1}^{6} f_i = f_{1,2,3,4,5,6}$, is identical for *OPT* and P. Further, *MMP* packs L_B (S_B, T_B) L-items (S-items, T-items) into B-bins, and N_{LLS} bins of type LLS. Finally, we assume that the L-items, S-items, and T-items that are not explicitly accounted for via L_B, S_B, T_B, and N_{LLS} are packed in the "worst possible way." Hence, we bound the value of $MMP(L)$ as follows:

$$\begin{aligned} MMP(L) &\leq f_{1,\ldots,6} + N_{LLS} + \frac{1}{2}(\mathcal{L} - L_B - 2N_{LLS}) \\ &\quad + \frac{1}{3}(\mathcal{S} - S_B - N_{LLS}) + \frac{1}{4}(\mathcal{T} - T_B) + 2 \\ &= f_{1,\ldots,6} + \frac{1}{2}(f_1 + 2f_7 + f_{11} + \mathcal{L}_{back} - L_B) \\ &\quad + \frac{1}{3}(f_2 + f_3 + f_7 + f_{11} + \mathcal{S}_{back} - S_B - N_{LLS}) \\ &\quad + \frac{1}{4}(f_2 + 2f_4 + f_5 + 2f_{11} + \mathcal{T}_{back} - T_B) + 2. \end{aligned}$$

Note that

$$\frac{\mathcal{L}_{back}}{2} + \frac{\mathcal{S}_{back}}{3} + \frac{\mathcal{T}_{back}}{4} \leq \frac{5}{4} f_*,$$

which can be verified by a straightforward substitution. Hence, to complete the proof it suffices to show that

$$\mathcal{K} \leq \frac{5}{4} f_{1,\ldots,7,11} + 1,$$

where $\mathcal{K}$ is defined as follows:

$$\begin{aligned}\mathcal{K} = f_{1,\ldots,6} &+ \frac{1}{2}(f_1 + 2f_7 + f_{11} - L_B) \\ &+ \frac{1}{3}(f_2 + f_3 + f_7 + f_{11} - S_B - N_{LLS}) \\ &+ \frac{1}{4}(f_2 + 2f_4 + f_5 + 2f_{11} - T_B).\end{aligned}$$

We outline four conditions, (I),...,(IV), by observing Claims 1 through 4. Our case analysis will be guided by these conditions:

$$\begin{aligned}&\text{(I) holds} \iff 2f_7 + f_{11} - L^{7,11}_{1,3,\ldots,6} \leq f_2 - L^{1,*}_2, \\ &\text{(II) holds} \iff f_2 + f_3 + f_7 + f_{11} - S^{2,3,7,11}_{3,5,6} \leq f_1 + f_2 + f_4 - (L_B - L^{1,7,11,*}_{3,5,6}), \\ &\text{(III) holds} \iff f_2 + 2f_4 + f_5 + 2f_{11} - T^{2,4,5,11}_{5,6} \\ &\qquad\qquad \leq f_{1,\ldots,4} - (L_B - L^{1,7,11,*}_{5,6}) - (S_B - S^{2,3,7,11,*}_{5,6}), \\ &\text{(IV) holds} \iff L^7_{1,\ldots,6} + S^7_{1,\ldots,6} \leq f_7.\end{aligned}$$

Before proceeding with the analysis, we note several useful facts:

1. $L_B \geq \frac{1}{2} f_1$ (immediate from Lemma 5).
2. If (I) holds,

$$\begin{aligned}L_B &\geq L^{1,7,11,*}_{1,3,\ldots,6} + L^{1,*}_2 + 2f_7 + f_{11} - L^{7,11}_{1,3,\ldots,6} \\ &= L^{1,*}_{1,3,\ldots,6} + L^{1,*}_2 + 2f_7 + f_{11} \\ &\geq 2f_7 + f_{11}.\end{aligned}$$

3. If (I) does not hold (¬(I) holds),

$$\begin{aligned}L_B &\geq L^{1,7,11,*}_{1,3,\ldots,6} + L^{1,*}_2 + f_2 - L^{1,*}_2 \\ &= f_2 + L^{1,7,11,*}_{1,3,\ldots,6} \\ &= f_2 + L^1_1 + L^{1,7,11,*}_{3,\ldots,6} + L^{7,11,*}_1 \\ &\geq f_2 + \frac{1}{2}(f_1 - \min(f_1, L^{7,11,*}_1 + L^1_{2,\ldots,6})) + L^{1,7,11,*}_{3,\ldots,6} + L^{7,11,*}_1 \\ &= f_2 + \frac{1}{2}(f_1 - \min(f_1, L^{7,11,*}_1 + L^1_{2,\ldots,6})) + \left(\frac{1}{2} + \frac{1}{2}\right) L^1_{3,\ldots,6} \\ &\quad + L^{7,11,*}_{3,\ldots,6} + \left(\frac{1}{2} + \frac{1}{2}\right) L^{7,11,*}_1 + \left(\frac{1}{2} - \frac{1}{2}\right) L^1_2 \\ &= f_2 + \frac{1}{2} f_1 + \frac{1}{2}(L^{7,11,*}_1 + L^1_{2,\ldots,6}) - \frac{1}{2}\min(f_1, L^{7,11,*}_1 + L^1_{2,\ldots,6})\end{aligned}$$

$$
\begin{aligned}
&+\frac{1}{2}L^1_{3,\dots,6}+L^{7,11,*}_{3,\dots,6}+\frac{1}{2}L^{7,11,*}_1-\frac{1}{2}L^1_2\\
&\geq \frac{1}{2}f_1+f_2-\frac{1}{2}L^1_2+\frac{1}{2}L^1_{3,\dots,6}+L^{7,11,*}_{3,\dots,6}+\frac{1}{2}L^{7,11,*}_1\\
&\geq \frac{1}{2}f_1+f_2-\frac{1}{2}L^1_2+\frac{1}{2}L^{7,11}_{1,3,\dots,6}.
\end{aligned}
$$

4. If (II) holds,

$$
\begin{aligned}
S_B &\geq S^{2,3,7,11,*}_{3,5,6}+f_2+f_3+f_7+f_{11}-S^{2,3,7,11,*}_{3,5,6}\\
&= f_2+f_3+f_7+f_{11}.
\end{aligned}
$$

5. If ¬(II) holds,

$$
\begin{aligned}
S_B &\geq S^{2,3,7,11,*}_{3,5,6}+f_1+f_2+f_4-L_B+L^{1,7,11,*}_{3,5,6}\\
&= f_1+f_2+f_4-L_B+S^{2,7,11,*}_{5,6}+L^{1,7,11,*}_{5,6}+S^3_3+S^{2,7,11,*}_3+S^3_{5,6}+L^{1,7,11,*}_3\\
&\geq f_1+f_2+f_4-L_B+S^{2,7,11,*}_{5,6}+L^{1,7,11,*}_{5,6}+\frac{1}{2}f_3\\
&\quad-\frac{1}{2}\min(f_3,L^{1,7,11,*}_3+S^{2,7,11,*}_3+S^3_{1,2,4,5,6})+S^{2,7,11,*}_3+S^3_{5,6}+L^{1,7,11,*}_3\\
&= f_1+f_2+f_4-L_B+S^{2,7,11,*}_{5,6}+L^{1,7,11,*}_{5,6}+\frac{1}{2}f_3\\
&\quad-\frac{1}{2}\min(f_3,L^{1,7,11,*}_3+S^{2,7,11,*}_3+S^3_{1,2,4,5,6})+\left(\frac{1}{2}+\frac{1}{2}\right)S^{2,7,11,*}_3\\
&\quad+\left(\frac{1}{2}+\frac{1}{2}\right)S^3_{5,6}+\left(\frac{1}{2}+\frac{1}{2}\right)L^{1,7,11,*}_3+\left(\frac{1}{2}-\frac{1}{2}\right)S^3_{1,2,4}\\
&= f_1+f_2+f_4-L_B+S^{2,7,11,*}_{5,6}+L^{1,7,11,*}_{5,6}+\frac{1}{2}f_3\\
&\quad+\frac{1}{2}(L^{1,7,11,*}_3+S^{2,7,11,*}_3+S^3_{1,2,4,5,6})\\
&\quad-\frac{1}{2}\min(f_3,L^{1,7,11,*}_3+S^{2,7,11,*}_3+S^3_{1,2,4,5,6})\\
&\quad+\frac{1}{2}S^{2,7,11,*}_3+\frac{1}{2}S^3_{5,6}+\frac{1}{2}L^{1,7,11,*}_3-\frac{1}{2}S^3_{1,2,4}\\
&\geq f_1+f_2+\frac{1}{2}f_3+f_4-L_B+\frac{1}{2}L^{1,7,11,*}_3+L^{1,7,11,*}_{5,6}+\frac{1}{2}S^{2,7,11,*}_3\\
&\quad+S^{2,7,11,*}_{5,6}+\frac{1}{2}S^3_{5,6}-\frac{1}{2}S^3_{1,2,4}\\
&\geq f_1+f_2+\frac{1}{2}f_3+f_4-L_B-\frac{1}{2}S^3_{1,2,4}.
\end{aligned}
$$

6. If (III) holds,

$$
\begin{aligned}
T_B &\geq T^{2,4,5,11,*}_{5,6}+f_2+2f_4+f_5+2f_{11}-T^{2,4,5,11}_{5,6}\\
&= f_2+2f_4+f_5+2f_{11}.
\end{aligned}
$$

7. If ¬ (III) holds,

$$
\begin{aligned}
T_B &\geq T^{2,4,5,11,*}_{5,6}+f_{1,\dots,4}-(L_B-L^{1,7,11,*}_{5,6})-(S_B-S^{2,3,7,11,*}_{5,6})\\
&\geq f_{1,\dots,4}-(L_B-L^{1,7,11,*}_{5,6})-(S_B-S^{2,3,7,11,*}_{5,6})\\
&\geq f_{1,\dots,4}-L_B-S_B.
\end{aligned}
$$

Based on the bounds on L_B, S_B, T_B, and N_{LLS}, the proof of Lemma 18 is completed by an case analysis.

Case 1. (II) holds; (III) holds.

$$\begin{aligned}
\mathcal{K} &= f_{1,\ldots,6} + \frac{1}{2}(f_1 + 2f_7 + f_{11} - L_B) \\
&\quad + \frac{1}{3}(f_2 + f_3 + f_7 + f_{11} - S_B - N_{LLS}) \\
&\quad + \frac{1}{4}(f_2 + 2f_4 + f_5 + 2f_{11} - T_B) \\
&\le f_{1,\ldots,6} + \frac{1}{2}(f_1 + 2f_7 + f_{11} - L_B) \\
&\quad + \frac{1}{3}(f_2 + f_3 + f_7 + f_{11} - (f_2 + f_3 + f_7 + f_{11}) - N_{LLS}) \\
&\quad + \frac{1}{4}(f_2 + 2f_4 + f_5 + 2f_{11} - (f_2 + 2f_4 + f_5 + 2f_{11})) \\
&= f_{1,\ldots,6} + \frac{1}{2}(f_1 + 2f_7 + f_{11} - L_B) - \frac{1}{3}N_{LLS} \\
&\le f_{1,\ldots,6} + \frac{1}{2}\left(f_1 + 2f_7 + f_{11} - \frac{1}{2}f_1\right) \\
&= \frac{5}{4}f_1 + f_{2,\ldots,7} + \frac{1}{2}f_{11} \\
&\le \frac{5}{4}f_{1,\ldots,7,11} + 1.
\end{aligned}$$

Case 2. (II) holds; ¬(III) holds.

$$\begin{aligned}
\mathcal{K} &= f_{1,\ldots,6} + \frac{1}{2}(f_1 + 2f_7 + f_{11} - L_B) \\
&\quad + \frac{1}{3}(f_2 + f_3 + f_7 + f_{11} - S_B - N_{LLS}) \\
&\quad + \frac{1}{4}(f_2 + 2f_4 + f_5 + 2f_{11} - T_B) \\

Case 4.2.2. ¬(IV) holds. $\mathcal{K}' = f_7 - L_{1,\ldots,6}^7 - S_{1,\ldots,6}^7 < 0$. □

4.1.5. Consideration of arbitrary lists. We established that the competitive ratio of *MMP* packings of lists of non-M-items is $\frac{5}{4}$. We now use the M-thoroughness of *MMP*, established in Lemma 2, to establish $\frac{5}{4}$ as the competitive ratio of *MMP* for arbitrary lists.

THEOREM 1. *Let L be a list of items of arbitrary size from $(0, 1]$. Then*

$$MMP(L) \leq \frac{5}{4}OPT(L) + 3.$$

Proof. We consider the following two cases.

Case 1. There are no M-bins in any *MMP* packing of L.

We may disregard all of the M-items from L and directly apply Lemma 18.

Case 2. There exists at least one *MMP* packing of L that contains an M-bin.

Fix an arbitrary *MMP* packing P_L of L that contains an M-bin. Let P_0 and *Aux* be the regular packing and the auxiliary storage of P_L, respectively. By M-thoroughness of *MMP* (Lemma 2), all of the bins of the regular packing have a level of at least $\frac{4}{5}$, except for, possibly, the last bin. This immediately implies that the regular packing P_0 requires at most $\frac{5}{4}OPT(L)+1$ bins to pack all of the items of L, *except* for the excess items from *Aux*: at most one L-item, two S-items, and three T-items, all of which can be packed into two bins. Thus the overall number of bins required by P_L is at most $\frac{5}{4}OPT(L)+3$. □

4.2. The running time of *MMP* is $\Theta(\log n)$.

THEOREM 2. MMP *can be implemented to run in* $\Theta(\log n)$ *uniform running time per* Insert/Delete *operation.*

Proof. Recall from sections 3.2.1 and 3.2.2 that each of the functions utilized by *MMP* runs in logarithmic time. It is easy to see from the code that there is a small bounded number of calls to these functions preceding each packing of an item and in particular each insertion and deletion of a whole bin. Note that this in itself is not sufficient to prove the logarithmic running time of *MMP*. However, it does suffice to show that the number of bins that are inserted and deleted as a consequence of a single *Insert* or *Delete* operation is bounded by a constant.

The proof proceeds by a case analysis. The nontrivial cases are the following: *Insert* of a B-item, *Insert* of an L-item, *Insert* of an S-item, and *Insert* of a T-item; *Delete* of a B-item, *Delete* of an L-item, *Delete* of an S-item, and, finally, *Delete* of a T-item.

We only show the case of an *Insert* of an S-item and note that the proofs are quite analogous for each of the other cases.

To facilitate a simple exposition of the proof, we denote items by upper case letters corresponding to their type (e.g., a T-item will be denoted as T in this proof). Items that could form an LLS-coalition will be decorated with an apostrophe.

What is the longest possible sequence of bin insertions/deletions an *Insert* of an S-item S' could generate?

We consider two subcases. First, S' is inserted so as to form an LLS' bin. Second, S' is inserted into a B-bin. It can be shown that the more difficult case is the second case and with that case the subcase leading to a BS'T bin is more difficult than the subcase leading to a BS' bin.

We proceed with an analysis of the case of a BS'T bin. Before the *Insert* of S', the content of *Aux* was in the worst case: {L, 2S, 3T}.

To construct BS'T, S' may have in the worst case evicted two T-items from a BTT bin and "recruited" a T-item from another BTT bin. At this moment, one bin (BS'T) is inserted, one bin (BTT) is deleted, and the content of *Aux* is in the worst case: {B, L, 2S, 6T}.

The B-item from *Aux* could now, in the worst case, form a BTT bin with two T-items, each from a BT bin. At this moment, one bin (BTT) is inserted and two bins (BT, BT) are deleted. *Aux* is now {2B, L, 2S, 8T}.

The two B-items from *Aux* could now, in the worst case, each form a BT bin with a T-item from an LLT bin. At this moment, two bins (BT, BT) are inserted, and two bins (LLT, LLT) are deleted. *Aux* is now {5L, 2S, 8T}.

By LLS-maximality of *MMP*, none of the L-items from *Aux* can form LLS-coalitions. Thus, in the worst case, each of the five L-items from *Aux* can form

an LLT bin with a T-item from an SSST bin. At this moment, five LLT bins are inserted, and five SSST bins are deleted. *Aux* is now {L, 17S, 8T}.

Again, by LLS-maximality of *MMP*, none of the S-items from *Aux* can form LLS-coalitions. Thus, in the worst case, five SSST bins are formed out of 15 S-items from *Aux*, coupled with five T-items, each from a TTTT bin. At this moment, five SSST bins are inserted, and five TTTT bins are deleted. *Aux* is now {L, 2S, 23T}.

Finally, five TTTT bins are inserted, each containing four T-items from *Aux*. At the conclusion, the content of *Aux* is {L, 2S, 3T}.

Thus, the overall number of inserted bins is 18, and the overall number of deleted bins is 15. Note that we ignored the possibility that M-bins may be deleted to execute *top_with*_M, and at the end of the *Insert* of S' *reload*_M. Clearly, consideration of M-bins could contribute only very few inserted or deleted M-bins. For example, a (generous) upper bound on the number of deleted M-bins is 18. □

5. Conclusion. We have studied the problem of maintaining an approximate solution for *one-dimensional bin packing* when items may arrive and depart dynamically and when the packing may be rearranged to accommodate arriving and departing items. Our main result is a fully dynamic bin packing algorithm *MMP* that is $\frac{5}{4}$-competitive and requires $\Theta(\log n)$ uniform running time per *Insert/Delete* operation. Relative to the best practical off-line algorithms, our algorithm is the best possible with respect to its running time and is nearly approximation-competitive with those algorithms (losing but a factor of $\frac{1}{15}$ to the best of those [13]).

The major unresolved issue is whether there exist fully dynamic bin packing algorithms (accommodating both *Inserts* and *Deletes*) that attain better competitive ratios, i.e., are there algorithms that are α-competitive for some $\alpha < \frac{5}{4}$, and require $o(n)$ time per operation. Here, both uniform and amortized algorithms are of interest.

Other unresolved issues are (1) what is the nature of the trade-off between running times and competitive ratios of fully dynamic bin packing algorithms for bin packing (both uniform and amortized), and (2) is there a competitive ratio for which there are no fully dynamic approximation algorithms for bin packing featuring sublinear running times (uniform or amortized)?

DYNAMIC TREES AND DYNAMIC POINT LOCATION*

MICHAEL T. GOODRICH† AND ROBERTO TAMASSIA‡

Abstract. This paper describes new methods for maintaining a point-location data structure for a dynamically changing monotone subdivision $\mathcal{S}$. The main approach is based on the maintenance of two interlaced spanning trees, one for $\mathcal{S}$ and one for the graph-theoretic planar dual of $\mathcal{S}$. Queries are answered by using a centroid decomposition of the dual tree to drive searches in the primal tree. These trees are maintained via the link-cut trees structure of Sleator and Tarjan [*J. Comput. System Sci.*, 26 (1983), pp. 362–381], leading to a scheme that achieves vertex insertion/deletion in $O(\log n)$ time, insertion/deletion of k-edge monotone chains in $O(\log n + k)$ time, and answers queries in $O(\log^2 n)$ time, with $O(n)$ space, where n is the current size of subdivision $\mathcal{S}$. The techniques described also allow for the dual operations *expand* and *contract* to be implemented in $O(\log n)$ time, leading to an improved method for spatial point location in a 3-dimensional convex subdivision. In addition, the interlaced-tree approach is applied to on-line point location (where one builds $\mathcal{S}$ incrementally), improving the query bound to $O(\log n \log\log n)$ time and the update bounds to $O(1)$ amortized time in this case. This appears to be the first on-line method to achieve a polylogarithmic query time and constant update time.

1. Introduction.

An exciting direction in algorithmic research has been to show how one can efficiently maintain various properties of a combinatoric or geometric structure while updating that structure in a dynamic fashion (e.g., see [13]). A problem with tremendous potential for dynamization is planar point location, a classic problem in computational geometry (e.g., see [1, 17, 28, 33, 37]). Given a subdivision S of the plane into "cells," described by a total of n line segments, the problem is to preprocess S to allow for efficiently naming the cell containing a query point p. An important special case of the point-location problem occurs when each face in the planar subdivision is a monotone polygon with respect to the y-axis; that is, the boundary of each face is intersected at most twice by any horizontal line. Given such a subdivision, Kirkpatrick [26] shows that one can construct an $O(n)$-space structure in $O(n)$ time that allows $O(\log n)$-time point-location queries. Edelsbrunner, Guibas, and Stolfi [18] show that one can achieve these same bounds by applying the fractional cascading paradigm of Chazelle and Guibas [8, 9] to the chain method of Lee and Preparata [27]. Cole [15] and Sarnak and Tarjan [41] independently show that one can also achieve these bounds after $O(n \log n)$ preprocessing by applying a per-

sistence technique (e.g., see Driscoll et al. [16]) to a simple plane-sweeping procedure (as an example of a static→dynamic→static conversion). (See [17, 28, 37] for other references on this important problem.)

We are interested in maintaining a monotone subdivision dynamically, subject to edge insertion and deletion, vertex insertion and deletion, as well as the insertion or deletion of a monotone chain of k edges. In addition, we are also interested in operations that are duals to edge insertion and deletion, as in the framework of Guibas and Stolfi [25], where we allow for vertex expansion and contraction: an *expansion* splits a vertex v into two new vertices connected by an edge, and a *contraction* merges two adjacent vertices into a new vertex. These operations are useful in applying a dynamic point location to spatial point location in 3-dimensional subdivisions [40] via persistence [16].

1.1. Previous work. Before we describe our main results, let us briefly review previous work on dynamic point location, which we summarize in Table 1. Early work on dynamic point location includes a method by Overmars [35], which is based on a segment-tree [4] approach to planar-point location, and achieves an $O(\log^2 n)$ query and update time with $O(n \log n)$ space. Fries [20] and Fries, Mehlhorn, and Näher [21] present a data structure with $O(n)$ space, $O(\log^2 n)$ query time, and $O(\log^4 n)$ amortized update time (for edge insertion/deletion only), using an approach based on the static chain method of Lee and Preparata [27]. Neither of these methods seems to extend to the dual update operations of expand and contract, however.

TABLE 1

Previous results for dynamic point location. N denotes the number of possible y-coordinates for edge endpoints in the subdivision. Also, we use $\bar{O}(*)$ to denote an amortized bound.

Type	Queries	Insert	Delete
General [3]	$O(\log n \log\log n)$	$\bar{O}(\log n \log\log n)$	$\bar{O}(\log^2 n)$
Connected [11]	$O(\log^2 n)$	$O(\log n)$	$O(\log n)$
Connected [12]	$O(\log n)$	$\bar{O}(\log^3 n)$	$\bar{O}(\log^3 n)$
Monotone [14]	$O(\log n)$	$\bar{O}(\log^2 n)$	$\bar{O}(\log^2 n)$
Convex [39]	$O(\log n + \log N)$	$O(\log n \log N)$	$O(\log n \log N)$
Staircase [2]	$O(\log n)$	$\bar{O}(\log n)$	$\bar{O}(\log n)$

Preparata and Tamassia [38] have given techniques for maintaining monotone subdivisions that are also based on this chain method, but they improve the bounds of Fries, Melhorn, and Näher by representing the chains topologically rather than geometrically. In their scheme, inserting/deleting vertices on edges requires $O(\log n)$ time, and inserting/deleting monotone chains of edges requires $O(\log^2 n + k)$ time. Moreover, as shown in [40], their scheme can be extended to the dual update operations, which leads, via persistence [16], to a data structure for spatial point location that uses $O(N \log^2 N)$ space, requires $O(N \log^2 N)$ processing time, and allows for queries to be answered in $O(\log^2 N)$ time, where N is the size of the 3-dimensional subdivision.

Cheng and Janardan [11] present two methods for dynamic planar point location that improve the time of edge updates. In their Scheme I they achieve $O(\log^2 n)$ query time, $O(\log n)$ time for inserting/deleting a vertex, and $O(k \log n)$ time for inserting/deleting a chain of k edges, and in their Scheme II they achieve $O(\log n \log\log n + k)$ time for inserting/deleting monotone chains, at the expense of increasing vertex insertion/deletion time to $O(\log n \log\log n)$ and increasing the query time to $O(\log^2 n \log\log n)$. Both of their methods are based on a search strategy derived

from the priority search tree data structure of McCreight [30]. They dynamize this approach with the $BB(\alpha)$ tree data structure (e.g., see [32]) using the approach of Willard and Lueker [43] to spread local updates over future operations and the method of Overmars [34] to perform global rebuilding (at the same time) before the "current" data structure becomes too unbalanced. Their methods do not seem to extend to the dual update operations, however, nor does it seem possible to improve their bounds for the on-line case.

The dynamic data structure by Baumgarten, Jung, and Mehlhorn [3] combines interval trees, segment trees, fractional cascading, and the data structure of [11]. It achieves $O(n)$ space, $O(\log n \log\log n)$ query and insertion time, and $O(\log^2 n)$ deletion time, where the time bounds for updates are amortized.

Chiang and Tamassia [14] present a dynamic data structure for monotone subdivisions, which is based on the static trapezoid method of Preparata [36] and extends previous work by Preparata and Tamassia [39] on dynamic point location in convex subdivisions with vertices on a fixed set of lines. The operations supported are insertion and deletion of vertices and edges and horizontal translation of vertices. They show how to achieve queries in $O(\log n)$ time, while requiring $O(\log^2 n)$ time for updates. The space requirement for their method is $O(n \log n)$. Finally, Atallah, Goodrich, and Ramaiyer [2] show how to apply a new data structure, which they call *biased finger trees* to achieve an $O(\log n)$ query time and $O(\log n)$ amortized update time for a fairly restricted class of subdivisions known as staircase subdivisions, where each face is bounded above and below by "staircase" polygonal chains.

In related work, Chiang, Preparata, and Tamassia [12] have shown that one can achieve an $O(\log n)$ query time in a dynamic environment that allows for ray-shooting queries and subdivision updates in $O(\log^3 n)$ time, and Goodrich and Tamassia [23] show how to maintain a similar environment so as to achieve $O(\log^2 n)$ time for all updates and queries (using a method built upon the scheme of the present paper).

1.2. Our results. In this paper we show how to dynamically maintain a monotone subdivision so as to achieve $O(\log^2 n)$ query time, $O(\log n)$ time for vertex insertion/deletion, and $O(\log n + k)$ time for the insertion/deletion of a monotone chain of k edges. Our methods are based on the maintenance of two interlaced spanning trees, one for the subdivision and one for its graph-theoretic dual, to answer queries. Queries are performed by using a centroid decomposition of the dual tree to drive searches in the primal tree. We dynamize this approach using the edge-ordered dynamic tree data structure of Eppstein et al. [19], which is an extension of the link-cut trees data structure of Sleator and Tarjan [42]. We use the "built-in" operations of *link*, *cut*, *split*, and *merge* to implement both our updates and queries. Our methods improve the previous bounds for dynamically maintaining monotone subdivisions.

We also show how to extend our approach to implement the dual operations of *expand* and *contract*, which, in turn, leads to an improved data structure for spatial point location via the persistence paradigm of Driscoll et al. [16], where one dynamizes the problem to a 3-dimensional space sweep that uses our data structure to maintain the current "slice." This leads to an $O(N \log N)$ space data structure that requires only $O(N \log N)$ preprocessing time while achieving an $O(\log^2 N)$ query time, for a 3-dimensional convex subdivision with N facets, which improves the space and preprocessing of the previous method [40] by a $\log N$ factor.

Finally, we show how to apply our approach to on-line planar point location, where one builds a monotone subdivision incrementally. In this case we show how to maintain the centroid decomposition of the dual tree explicitly (in a $BB(\alpha)$ tree [32])

and apply a simple version of the fractional cascading paradigm of Chazelle and Guibas [8, 9] to improve the query time to $O(\log n \log\log n)$ while also improving the complexity of updates to $O(1)$ amortized time. We believe this is the first on-line point location method to achieve a polylogarithmic query time and constant update time.

2. Preliminaries.

2.1. Monotone subdivisions. A *(planar) subdivision* $\mathcal{S}$ is a partition of the plane into polygons, called the *regions* of $\mathcal{S}$. We assume that $\mathcal{S}$ has one unbounded region, called the external region. A subdivision $\mathcal{S}$ is generated by a planar graph embedded in the plane such that the edges are straight-line segments. We assume a standard representation for the subdivision $\mathcal{S}$ such as doubly connected edge lists [37].

A *monotone chain* is a polygonal chain such that each horizontal line intersects it in at most one point. A polygon is *monotone* if its boundary is partitionable into two monotone chains. A *monotone subdivision* is such that all its regions are monotone polygons (even the external region). A *triangulation* is a subdivision such that the boundary of each region has three edges.

Let us orient each edge of a monotone subdivision $\mathcal{S}$ by decreasing ordinate, i.e., so that it "points down." Because each face in $\mathcal{S}$ is a monotone polygon, in orienting the edges of $\mathcal{S}$ in this way we obtain a planar st-graph, i.e., a planar acyclic digraph with exactly one source (vertex without incoming edges) and one sink (vertex without outgoing edges). The source s and sink t of $\mathcal{S}$ are the highest and lowest vertices of $\mathcal{S}$, respectively. The *left chain* of a region r of $\mathcal{S}$ is the monotone chain on the boundary of r such that r is on the left side of it when traversed from top to bottom. The *right chain* is similarly defined. Note that according to this definition the left (resp., right) chain of the external region appears on the right (resp., left) boundary of the subdivision.

2.2. Centroid decomposition. Let T be free tree with n vertices of degree at most 3. A *centroid edge* of T is an edge e whose removal partitions T into two trees of size at most $1 + 2n/3$ each. It is well known that if $n > 1$, such an edge exists and can be found in time $O(n)$ (e.g., see [6, 31]).

A *centroid decomposition tree* for T is a rooted binary tree B recursively defined as follows: if T has a single vertex v, then B consists of a single leaf node that stores vertex v. Otherwise, let e be a centroid edge of T, and let T' and T'' be the trees that result when removing e from T. The root of B stores edge e, and the left and right subtrees of B are centroid trees for T' and T'', respectively. The centroid decomposition tree B has $O(\log n)$ height and can be constructed in $O(n)$ time (e.g., see [10, 24]).

2.3. Dynamic trees. Dynamic trees [42] are a versatile dynamic data structure for maintaining a forest of rooted trees. We shall use an extension of dynamic trees, called *edge-ordered dynamic trees* [19].

An edge-ordered tree is a rooted tree in which a cyclic order is imposed on the edges incident on each node (including the edge to the parent). The circular sequence of edges incident to node μ is called the *edge ring* of μ. For example, in our application the trees are drawn in the plane and we use the counterclockwise ordering of the edges around each vertex given by the embedding. Edge-ordered dynamic trees support the following repertory of update operations [19].

link(μ', μ'', e', e''). This operation assumes that μ' is the root of a tree T', μ'' is a node of another tree T'', and e'' is an edge incident on μ''. Add a new edge

e' from node μ' to node μ'', thus making T' a subtree of T''. The new edge e' is inserted after edge e'' in the edge ring of μ''.

cut(μ, e). This operation assumes that node μ is not the root of a tree and e is the edge from μ to its parent. Remove edge e, thus separating the subtree rooted at μ.

split$(\mu, \mu', \mu'', e, e_1, e_2)$. Split node μ into two nodes μ' and μ'' connected by a new edge e. If $(\alpha e_1 \beta e_2 \gamma)$ is the edge ring of μ, then $\alpha e \gamma$ and $e e_1 \beta e_2$ are the edge-rings of μ' and μ'', respectively.

merge(μ', μ'', e). Merge adjacent nodes μ' and μ'' connected by edge e into a single node μ. If αe is the edge ring of μ' and βe is the edge ring of μ'', then $\alpha\beta$ is the edge ring of μ.

Let T be a dynamic tree, subject to the above operations. Sleator and Tarjan [42] present two schemes for efficiently performing the link and cut operations on T, and these schemes carry over naturally to edge-ordered dynamic trees [19]. In this paper we assume the scheme that uses *partitioning by size*. In this scheme the edges of T are considered to be directed from the child to the parent, and an edge e from μ to ν is said to be *solid* if the subtree rooted at μ has more than half of the edges of the subtree rooted at ν. Otherwise, edge e is said to be *dashed*. There is at most one solid edge entering any node (from its children). Therefore, every node is in exactly one path of solid edges (of length 0 or more). We refer to these paths as *solid paths*. (See Fig. 1a.) A solid path π is represented as a balanced binary tree P_π, so that T is then stored as a collection of these *path trees*. For more details on partitioning by size and how it can be exploited to efficiently perform dynamic tree updates and queries, see [19, 42].

While link-cut trees support a variety of query operations, such as finding the least-common ancestor of two nodes, we shall use only the following operation that is part of the standard repertory of dynamic trees [19, 42].

expose(μ). Create a solid path π from node μ to the root by converting to solid all the dashed edges of π, and converting to dashed all the solid edges that enter a node of π but are not on π. (See Fig. 1b.) This operation may violate the definition of solid edges, so it is always followed by a procedure that undoes its effects.

Edge-ordered dynamic trees use linear space and support each of the above operations in $O(\log n)$ time, where n is the size of the tree(s) involved in the operation [19, 42].

3. Our approach. In this section we address the problem of performing point location in a triangulation $\mathcal{S}$ with n vertices. Without loss of generality, we assume that $\mathcal{S}$ does not have horizontal edges. General subdivisions can be handled via a preliminary triangulation step, which takes $O(n)$ time if the subdivision is connected [7], and $O(n \log n)$ time otherwise [22].

We describe here a static method that uses $O(n \log n)$ space and preprocessing time and supports point-location queries in $O(\log^2 n)$ time. We will show in the subsequent section how to dynamize this approach so as to achieve $O(n)$ space, the same query time, and an update time that is $O(\log n)$.

3.1. Building the structure. A *monotone spanning tree* T of $\mathcal{S}$ is a rooted spanning tree such that any root-to-leaf path of T is monotone with respect to the y-axis. The root T then is the vertex t in $\mathcal{S}$ with smallest y-coordinate. Such a monotone spanning tree T is obtained by choosing for each vertex v in $\mathcal{S}$ some edge emanating from v, assuming all edges are directed downward. Note that this simple choosing

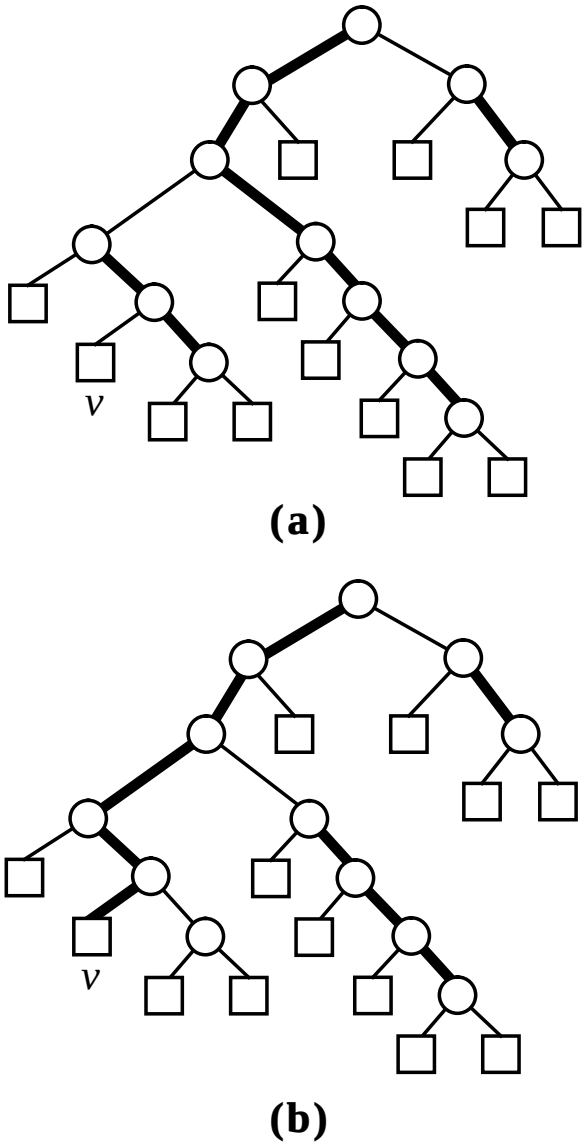

FIG. 1. (a) *A link-cut tree with edges partitioned into solid and dashed.* (b) *Effect of operation* expose(v) *on the tree of part* (a).

operation would not necessarily define a spanning tree if $\mathcal{S}$ were not monotone. (See Fig. 2.) As we show in the next lemma, such a spanning tree has a nice property that can be exploited for point location.

LEMMA 3.1. *For any nontree edge e of $\mathcal{S}$, the fundamental cycle $F(e)$ determined by e and T is a monotone polygon.*

Proof. Let $e = (v', v'')$. Since the spanning tree T is monotone, the paths π' and π'' of T from v' to t and v'' to t are monotone chains. Let v be the least-common ancestor of v' and v''. The cycle $F(e)$ that results when adding e to T is the polygon formed by the following monotone chains: (i) the subpath of π' from v to v' plus edge e and (ii) the subpath of π'' from v to v''. Therefore, we have that $F(e)$ is a monotone polygon. □

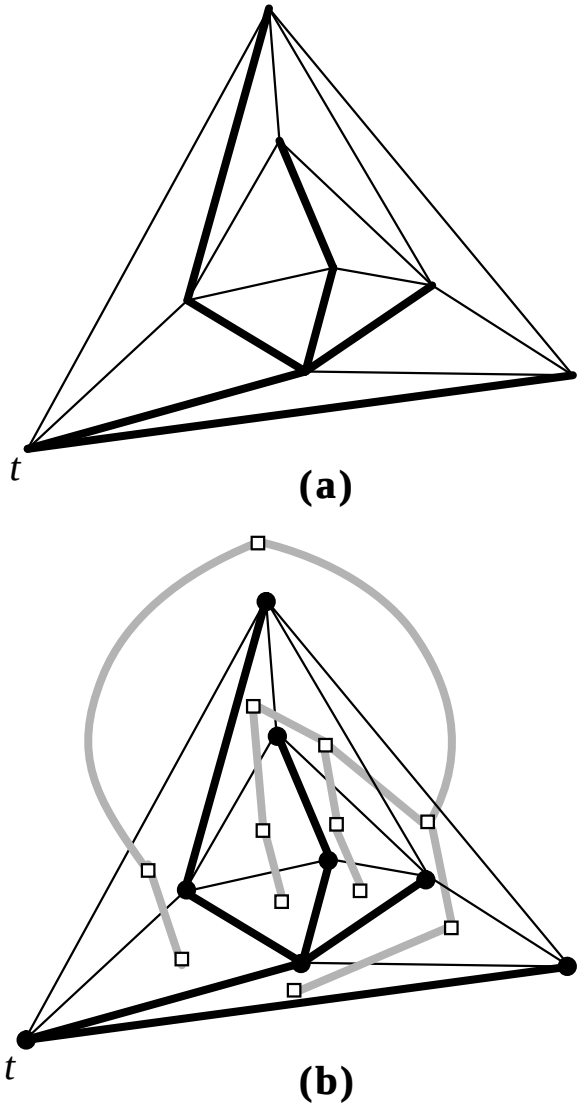

FIG. 2. (a) *A monotone spanning tree.* (b) *Its dual spanning tree.*

This motivates the construction of our point-location structure, which is performed in the following four steps.

Step 1. Construct a monotone spanning tree T for $\mathcal{S}$ and represent T as an edge-ordered tree rooted at the sink vertex t, where the ordering of the edges incident on a vertex is given by the planar embedding.

Step 2. Construct the graph-theoretic planar dual [5] of $\mathcal{S}$, but exclude any edges dual to edges in T. This defines a spanning tree D on the dual graph [19], called the *dual spanning tree* of T (see Fig. 2). Each node of D is a region r of $\mathcal{S}$, and each edge e^* of D corresponds to a nontree edge e in $\mathcal{S}$, which in turn determines a unique cycle $F(e)$ in $\mathcal{S}$ (when e is added to T). We represent D as an edge-ordered tree rooted at the external region, where the ordering of the edges incident on a node (region) is given by the planar embedding.

Step 3. Form a centroid decomposition of D [6, 10, 24]. Recall that a centroid edge in D divides D into two subtrees whose sizes are in the interval $[|D|/3, 2|D|/3]$; hence, a centroid decomposition defines a binary tree B, where each internal node μ in B corresponds to a centroid edge e^*_μ of D, with the left child of μ being the portion of D "below" e_μ (i.e., inside $F(e_\mu)$) and the right child being the portion "above" e_μ (i.e., outside $F(e_\mu)$). (See Fig. 3.)

Step 4. With each node μ in B we store the left and right chains of monotone polygon $F(e_\mu)$ in two sorted arrays $L(\mu)$ and $R(\mu)$, respectively. Note that to avoid confusion in the L and R lists we consider each edge to have two sides, a left side and a right side, which are distinct edges for the sake of this definition. (See Fig. 3.)

LEMMA 3.2. *The above method runs in $O(n \log n)$ time and uses $O(n \log n)$ space.*

Proof. Steps 1 and 2 can be easily implemented in $O(n)$ time. Step 3 takes $O(n)$ time using the method of [10, 24]. Step 4 is the bottleneck step, in that it requires $O(n \log n)$ time and space to copy and store all the L and R lists for the nodes in B (since B has depth $O(\log n)$). □

Having presented our structure, let us describe how it can be used to answer a point-location query.

3.2. Querying the structure. Suppose we are given a query point p, and we wish to locate the cell in $\mathcal{S}$ containing p. Our method for performing this point-location query is actually quite simple. We perform a search down B, where at each node μ we use the lists $L(\mu)$ and $R(\mu)$ to determine if p is inside or outside the polygon $F(e_\mu)$. Since $L(\mu)$ and $R(\mu)$ are stored as arrays, we can perform two binary searches to determine if p is inside $F(e_\mu)$ in $O(\log n)$ time. If p is inside $F(e_\mu)$, then we visit μ's left child next; otherwise, we visit μ's right child next. This procedure continues until we reach the leaf of B corresponding to a single region—the cell of $\mathcal{S}$ containing p. Therefore, we have the following lemma.

LEMMA 3.3. *Our point-location data structure supports point-location queries in $O(\log^2 n)$ time.*

Incidentally, one can improve the query time to $O(\log n)$, while increasing the preprocessing time and space by at most a constant factor, via the *fractional cascading* technique of Chazelle and Guibas [8, 9]. Thus one can modify the above approach to match the query bounds of previous point location methods [18, 26, 41]. Our motivation for designing this new method was not to simply match the performance of previous methods, however, but to design a scheme that leads to an efficient dynamic point-location method. So, let us leave the details of this static data structure to the interested reader and concentrate instead on how this approach can be dynamized.

4. Dynamic planar point location. In this section we show how to implement our point-location method dynamically using dynamic trees. Our dynamic environment supports the following repertory of update operations on a monotone subdivision $\mathcal{S}$ (i.e., we assume that each operation is performed only if it is known to preserve the monotonicity of $\mathcal{S}$).

InsertEdge$(e, r, v, w; r_1, r_2)$. Insert edge e between vertices v and w inside region r, which is then decomposed into regions r_1 and r_2 to the left and right of e, respectively.

DeleteEdge$(e, v, w, r_1, r_2; r)$. Remove edge e between vertices v and w and merge into region r the two regions r_1 and r_2 formerly to the left and right of e, respectively.

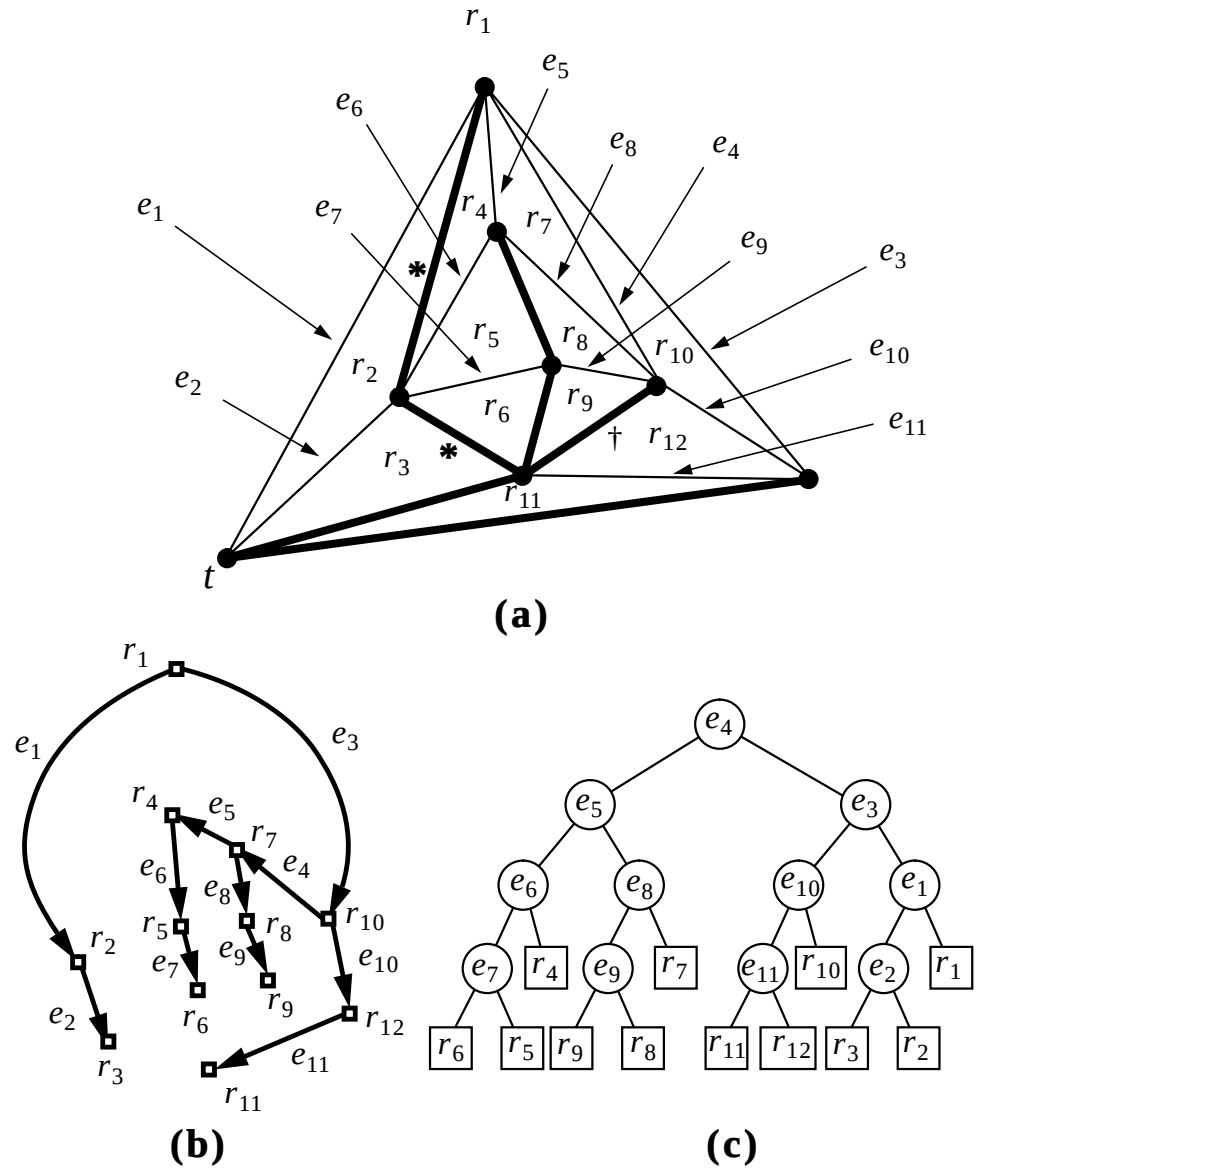

FIG. 3. *A centroid decomposition of the dual spanning tree of the previous figure.* (a) *The subdivision $\mathcal{S}$ and monotone spanning tree T. In this example the edges in $L(\mu)$ are marked with a "$*$" and the edge in $R(\mu)$ (other than e_4) is marked with a "†," where μ is the node in B associated with edge e_4.* (b) *The dual tree D.* (c) *The centroid decomposition tree B.*

Expand$(e, v, r_1, r_2; v_1, v_2)$. Expand vertex v into vertices v_1 and v_2 connected by edge e, which has regions r_1 and r_2 to its left and right, respectively.

Contract$(e, r_1, r_2, v_1, v_2; v)$. Contract edge e between vertices v_1 and v_2 into vertex v. Regions r_1 and r_2 are those formerly to the left and right of e, respectively.

InsertChain$(\gamma, r, v, w; r_1, r_2)$. Insert a monotone chain γ between vertices v and w inside region r, which is then decomposed into regions r_1 and r_2 to the left and right of e, respectively.

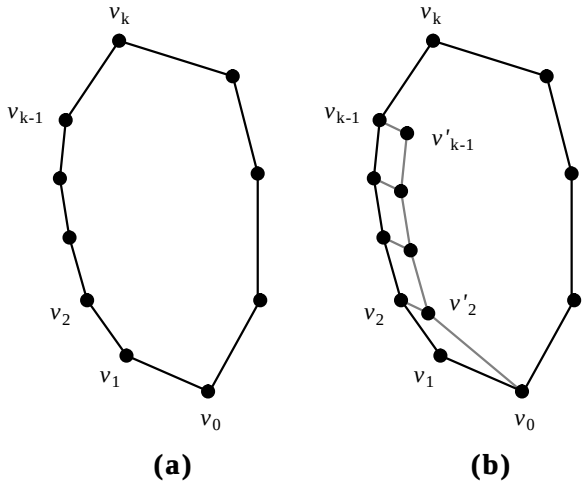

FIG. 4. *Example of refinement of a region.*

DeleteChain$(\gamma, v, w, r_1, r_2; r)$. Let γ be a monotone chain between vertices v and w, whose internal vertices have degree 2. Remove γ and merge into region r the two regions r_1 and r_2 formerly to the left and right of γ, respectively.

Several problems arise in the dynamization of the static structure of section 3. The first is that the static data structure assumes a preliminary triangulation step to ensure that the dual spanning tree has bounded degree and therefore admits a centroid decomposition. But it appears difficult to dynamically maintain a triangulation, since a newly inserted edge could intersect many triangulation edges. So we do not attempt to maintain a triangulation of our current subdivision; instead we refine it so as to maintain a crucial property that such a triangulation would give us.

4.1. A virtual triangulation of the regions in $\mathcal{S}$. Let $\mathcal{S}$ be a monotone subdivision. We refine $\mathcal{S}$ into a new subdivision $\mathcal{R}$ as follows. For each region r of $\mathcal{S}$, let $v_k, v_{k-1}, \ldots, v_0$ be the left chain of r as traversed from top to bottom. If $k \geq 3$, we add inside r a "comb" consisting of $k-2$ new vertices, $v'_2, v'_3, \ldots, v'_{k-1}$, and $2(k-2)$ edges, (v_2, v'_0), (v'_{i+1}, v'_i), $(i = 2, \ldots, k-2)$, and (v_i, v'_i) $(i = 2, \ldots, k-1)$. See an example in Fig. 4. We assume that each new vertex v'_i is placed below and to the right of v_i and infinitesimally close to it. Hence the above refinement affects only the topology of the subdivision, so that a point location query has the same answer in $\mathcal{S}$ and $\mathcal{R}$. Also, it is immediate to verify that the refined subdivision has $O(n)$ vertices.

The *leftist spanning tree* of a monotone subdivision is defined as the monotone spanning tree obtained by selecting the leftmost outgoing edge of every vertex, except the source (see Fig. 5a). In addition to the above refinement of $\mathcal{S}$ into $\mathcal{R}$, we also maintain T as a leftist spanning tree of $\mathcal{R}$, with D being its graph-theoretic planar dual. As we show in the following lemma, this is sufficient to achieve the desired result.

LEMMA 4.1. *The planar dual of the leftist spanning tree in $\mathcal{R}$ has degree at most* 3.

Proof. Let T be the leftist spanning tree, and D its dual (see Fig. 5b). We observe that tree D exactly consists of the dual edges of the topmost edges of the right chain of each region. Also, all the remaining edges of the right chain of each region are in tree T. Hence the degree of a node r of D is at most one plus the number of nontree edges on the left chain of region r.

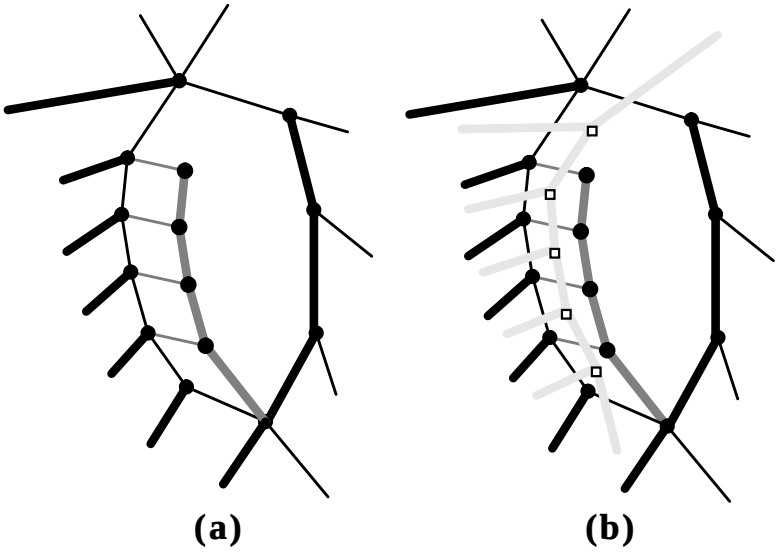

FIG. 5. (a) *Leftist spanning tree of a refined subdivision* $\mathcal{R}$. (b) *Dual of the leftist spanning tree of part* (a). *Tree edges are drawn thick, with the comb edges in this tree being dark gray. The edges of the dual tree are drawn as thick light gray lines, and their dual edges in the comb are drawn as dotted lines. (We use this same convention in all the figures that follow as well.)*

To prove the lemma, we show that every region r of the refined subdivision $\mathcal{R}$ has at most two nontree edges in its left chain. Namely, if region r is to the left of a comb, then it has exactly two edges and thus no more than two nontree edges in its left chain. Else (r is to the right of a comb), only the two topmost edges of the left chain of r may not be in T, since each of the remaining edges (which form the "spine" of the comb) is the only outgoing edge of its end vertex and hence is in T. □

Our dynamic data structure for point location in $\mathcal{S}$ simply consists of the leftist spanning tree T of $\mathcal{R}$, and of its dual spanning tree D, each represented as an edge-ordered dynamic tree [19, 42]. Tree T is rooted at the node associated with the (bottom-most) sink vertex t, and tree D is rooted at the node associated with the external region. In both trees, the ordering of the edges incident on each node is given by the planar embedding. The overall space requirement of the data structure is $O(n)$.

4.2. Finding fundamental cycles. In order to perform queries efficiently we must be able to construct searchable representations of fundamental cycles in T, the monotone spanning tree for $\mathcal{R}$. More significantly, like our triangulation, our representations must be virtual, since an update operation may cause substantial restructurings in the centroid tree and edge lists. Our approach for overcoming this difficulty consists of representing T as an edge-ordered dynamic tree [19] (see also [42]). As we show in the following lemma, this is sufficient for us to be able to quickly perform a point-cycle query in T.

LEMMA 4.2. *Let T be a monotone spanning tree of $\mathcal{S}$, with root t. By representing T as an edge-ordered link-cut tree, one can determine in time $O(\log n)$ whether a query point p is on, inside, or outside the fundamental cycle $F(e)$ induced by a nontree edge e of $\mathcal{S}$.*

Proof. In a link-cut tree [19, 42] representing T the operation *expose*(v) returns a balanced binary tree P_π that represents the path π of T between the root t and vertex v (i.e., the external and internal nodes of P_π store the vertices and edges of π, respectively, such that the in-order visit of P_π yields π). Hence we can determine if a query point p is inside $F(e)$ as follows. Let v' and v'' denote the left and right endpoints of edge e, respectively. We issue an *expose*(v') and perform a binary search on the balanced-tree representation of the left chain of $F(e)$, minus edge e, that is returned, to determine if p is to the left, to the right, or outside the scope of y-coordinates for this chain. After the structural changes in the link-cut representation of T from this expose are undone, we then issue an *expose*(v'') and perform a similar binary search on the balanced-tree representation of the right chain of $F(e)$, minus edge e, that is returned. Whether a point p is on, inside, or outside cycle $F(e)$ can then be easily determined from the results of these two searches and a simple comparison involving the edge e. All of the above steps take $O(\log n)$ time. □

Constructing fundamental cycles in $\mathcal{S}$ is important, but not sufficient, for, in order to achieve an $O(\log^2 n)$ query time, we must also be able to find a centroid edge in the dual tree, D.

4.3. Locating a centroid edge in the dual tree. We do not explicitly maintain a centroid decomposition tree for D, however. Instead, we show in the following lemma that the link-cut representation of D can itself be used to quickly find a centroid edge in D.

LEMMA 4.3. *Let D be a tree of degree 3 represented by a link-cut tree with partitioning by size. Then a centroid edge in D can be located in $O(\log n)$ time.*

Proof. As mentioned above, one of the main ideas of the link-cut tree data structure is to partition the tree D into "solid" paths and "dashed" edges [19, 42] and represent each solid path with a binary search tree. Let π be the solid path containing the root of D. We claim that the set of edges that are either in π or incident on the first node of π contains a centroid edge.

Proof of claim. Let $\pi = (\mu_1, \ldots, \mu_k)$. We denote with S_i the subset of nodes of D consisting of node μ_i and the nodes in the (at most three) subtrees connected to μ_i by dashed edges (see Fig. 6a). Let w_i be the size of S_i, called the *weight* of node μ_i. We have that $\sum_{i=1}^{k} w_i = n$, where n is the number of nodes of D. From the definition of dashed edges [19, 42], we have that $w_i < n/2$ for $i = 2, \ldots, k$. We distinguish two cases. If $w_1 \leq 1 + 2n/3$, then there exists some j such that $n/3 - 1 \leq \sum_{i=1}^{j} w_i \leq 1 + 2n/3$. In this case the solid edge from μ_j to μ_{j+1} is a centroid edge. Otherwise, the dashed edge connecting the largest subtree of μ_1 is a centroid edge, since the largest of the subtrees of μ_1 has at most $n/2$ nodes (because it is connected by a dashed edge) and at least $n/3 - 1$ nodes (because μ_1 has no more than three incident edges). The claim is proved.

Therefore, we can find a centroid edge of D in $O(\log n)$ time by traversing a root-to leaf path in the binary tree of the solid path containing the root of D. (See Fig. 6b.) □

Thus we have shown how to perform the two main components of our point-location procedure.

4.4. Point-location querying. The location of a query point p, therefore, is performed as follows.

1. If D consists of a single node, we return the corresponding region and stop.
2. We find a centroid edge e^* of D using the algorithm of Lemma 4.3.

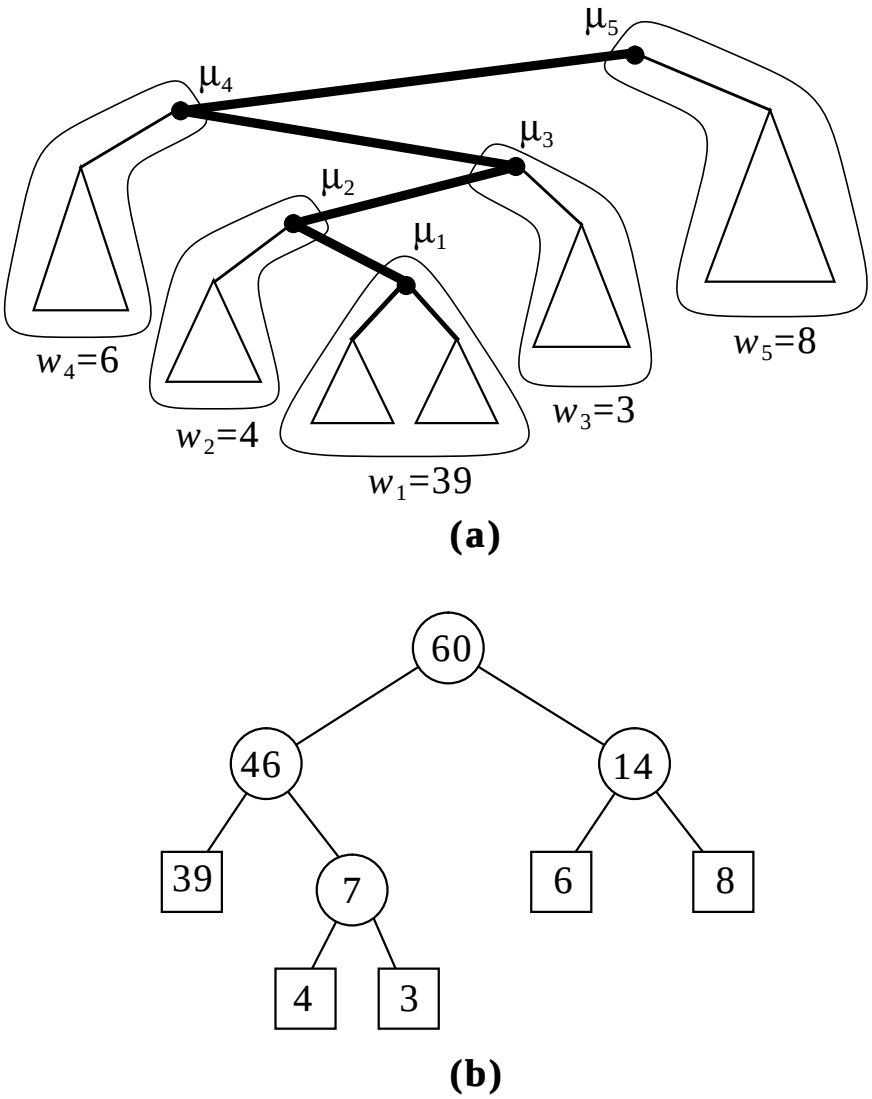

FIG. 6. (a) *Solid path containing the root of a dynamic tree.* (b) *Balanced tree associated with the solid path of part* (a).

3. We cut tree D at edge e^* and let D' and D'' be the resulting trees, where D'' contains the former root of D. Note that since this is a query step, not an update, we also store the edge e^* on a stack in this step, so that after the query is done we can reconstruct the original D via a series of link operations.
4. We determine if p is on, inside, or outside cycle $F(e)$ by applying the algorithm of Lemma 4.2 to tree T.
5. If p is on cycle $F(e)$, return the edge or vertex of $F(e)$ that contains e. Else, if p is inside the cycle, recursively apply the algorithm using D'. Otherwise (p is outside the cycle), recursively apply the algorithm using D''.

Our query operation is completed by reconstructing tree D by means of a sequence of $O(\log n)$ link operations that undo the cuts (by a series of pop operations on the stack used in step 3).

Thus we have the following theorem.

THEOREM 4.4. *The above dynamic point-location data structure supports point-location queries in time $O(\log^2 n)$ and uses $O(n)$ space.*

Proof. The query time bound should be immediately apparent given the above description. For the space bound note that the data structure is no more than $\mathcal{R}$, represented using any standard plane graph representation and T and D represented as link-cut trees (plus cross pointers, so, for example, each nontree edge in $\mathcal{R}$ has a pointer to its dual in D). □

Having given our method for performing queries, let us next address our methods for updating $\mathcal{R}$. We begin with the *Contract*and *Expand*operations.

4.5. Edge contraction and expansion. Recall that in the *Expand*(v, v_1, v_2, e) operation we expand vertex v into vertices v_1 and v_2 connected by edge e with regions r_1 and r_2 being to the left and right of e, respectively (see Fig. 7). There are two cases. In the first case the relative positions of v_1 and v_2 require that e become an edge in the leftist spanning tree T (as illustrated in Fig. 7a). In this case we perform the obvious *split* in T at v and update the corresponding pointer structures in $\mathcal{R}$ and D. We may also have to add an edge to the combs of pseudo edges in r_1 and r_2 so as to maintain our refinement invariant. If this occurs we also need to update the dual tree D (using $O(1)$ *split* and *link* operations) so that it remains a planar dual to $\mathcal{R}$. This can all be done in $O(\log n)$ time.

In the second case the positions of v_1 and v_2 require that e become a nontree edge (see Fig. 7b). In this case we perform the obvious *split* in T at v, forming v_1 and v_1, *cut* T along e, and then link v_2 to its leftmost adjacent node, w in $\mathcal{R}$. We also perform any edge additions to combs in r_1 and r_2, if necessary, as in the first case. Of course, our modifications of T require that we perform changes to D. Specifically, we must cut D at the edge dual to (v_2, w) and perform a link to create a node dual to e. Since this can all be done in $O(\log n)$ time, it implies that we can perform the *Contract*operation in $O(\log n)$ time.

We implement the *Expand*operation by "reversing" the above steps in the obvious manner. Thus we may also perform the *Expand*operation in $O(\log n)$ time.

4.6. Edge insertions and deletions. The next update operation we consider is edge insertion. Recall that in the operation *InsertEdge*$(e, r, v, w; r_1, r_2)$ we insert edge e between vertices v and w inside region r, which is then decomposed into regions r_1 and r_2 to the left and right of e, respectively. There are two cases.

In the first case v and w are on opposite sides of r; i.e., without loss of generality, v is on the left chain of r and w is on the right chain of r (see Fig. 8). We distinguish two subcases.

1.1. Suppose $e = (v, w)$ must become an edge in the leftist spanning tree T (see Fig. 8a). In this case we perform a *cut* in T along the edge going out of w and then link the resulting subtree rooted at w to v. This may also require that we cut the comb in r at the vertex associated with v, deleting its incident edges, and begin a new comb at v (which contains any previous comb edges above v). Likewise, each *cut* in T has a corresponding *link* in D, and each *link* in T has a corresponding *cut* in D. Since the number of needed *cut* and *link* operations is $O(1)$, the total time for this case is $O(\log n)$.

1.2. Suppose $e = (v, w)$ must become a nontree edge (see Fig. 8b). In this case we need only change the comb in r by cutting it at the vertex associated with v and beginning a new comb at w. This can be done with $O(1)$ *cut* and *link* operations in T, but it does not change the topology of D. Thus this case

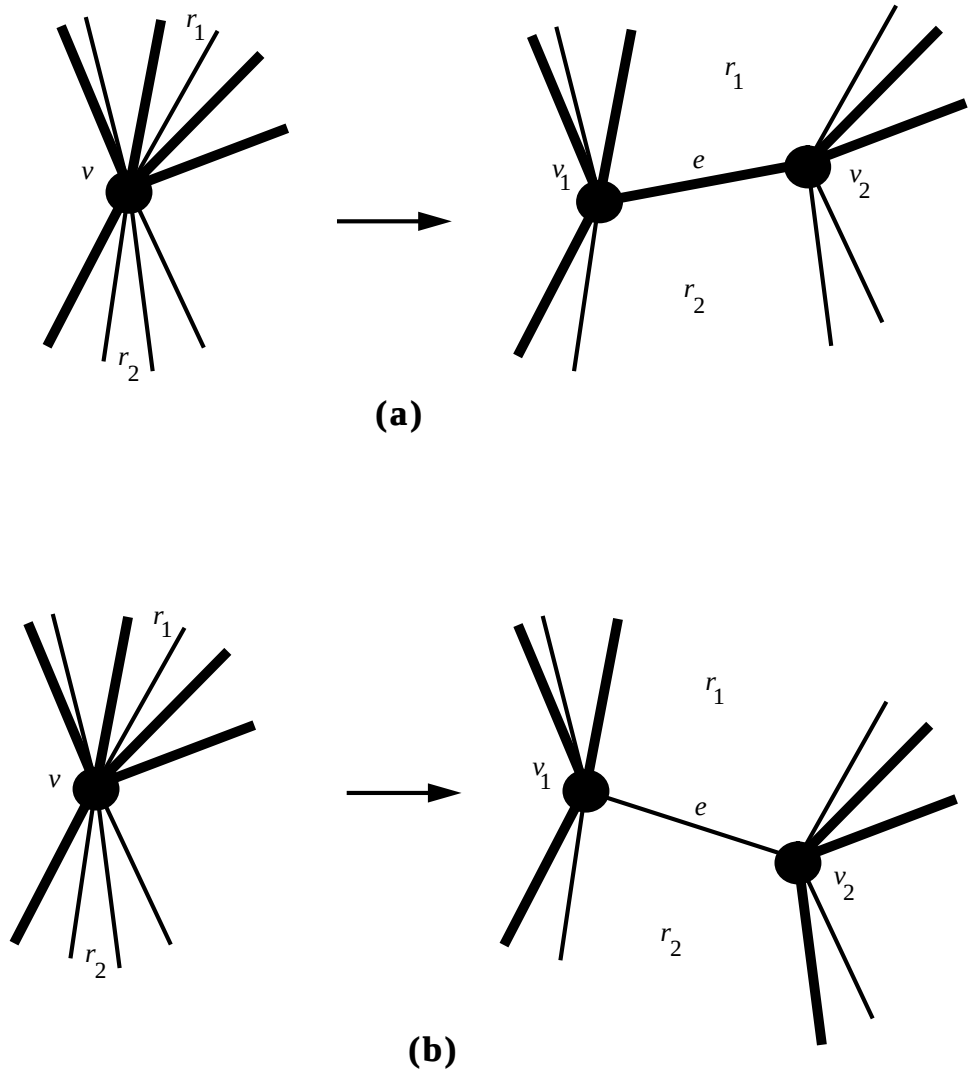

FIG. 7. (a) *An* Expand*operation in which* e *becomes an edge in the leftist spanning tree* T*, and* (b) *an* Expand*in which* e *becomes a nontree edge.*

also takes only $O(\log n)$ time.

In the second case for edge insertion vertices v and w are on the same side of r. There are two obvious subcases.

2.1. Suppose v and w are both in the left chain of r (see Fig. 9a), where, without loss of generality, v has larger y-coordinate than w. In this case we must cut the comb in r at the vertex associated with v and the vertex associated with w, and add the edge $e = (v, w)$ as a nontree edge in $\mathcal{R}$. We begin a new comb at w in r_1 that retains the edges of the old comb between the vertices associated with v and w, and we concatenate the portion of the old comb below the vertex associated with w with the portion of the old comb above the vertex associated with v, to form the new comb for r_2. This can all be done using $O(1)$ *link* and *cut* operations in T. Likewise, cutting the

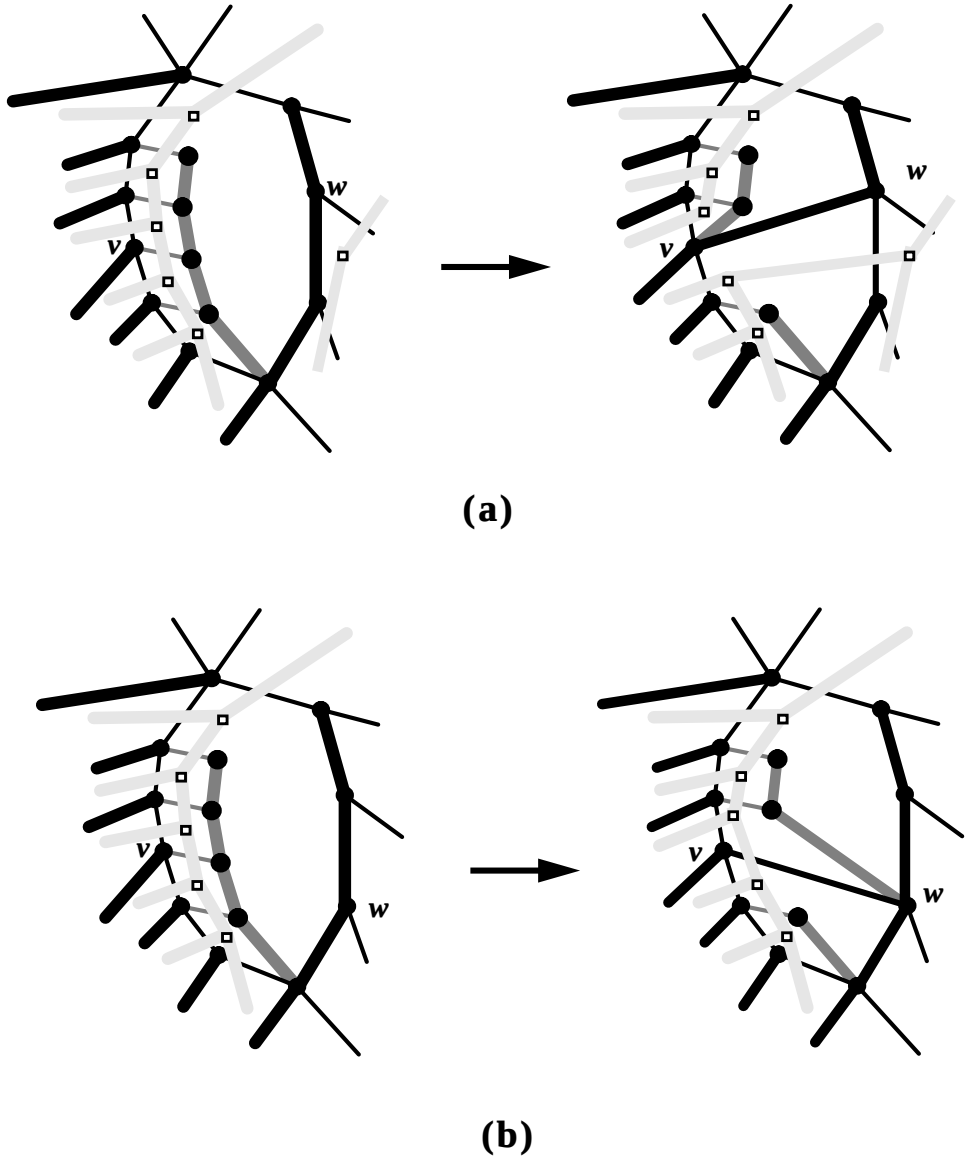

FIG. 8. *Insertions where v and w are on opposite sides of the region r. We illustrate in* (a) *an* InsertEdge*operation in which e becomes an edge in the leftist spanning tree T and in* (b) *an* InsertEdge*in which e becomes a nontree edge.*

comb in r also requires that we perform associated cuts in D, and the comb concatenations have associated links in D. Again, there are only $O(1)$ such operations, however, so this case can be implemented in $O(\log n)$ time.

2.2. Suppose v and w are both in the right chain of r (see Fig. 9b), where, without loss of generality, v has larger y-coordinate than w. In this case we simply cut T at the edge f going out of v and perform a link of the subtree rooted at v along the edge $e = (v, w)$. This also requires that we create a new (leaf) node in D and link it along the edge dual to f. We need not change the comb

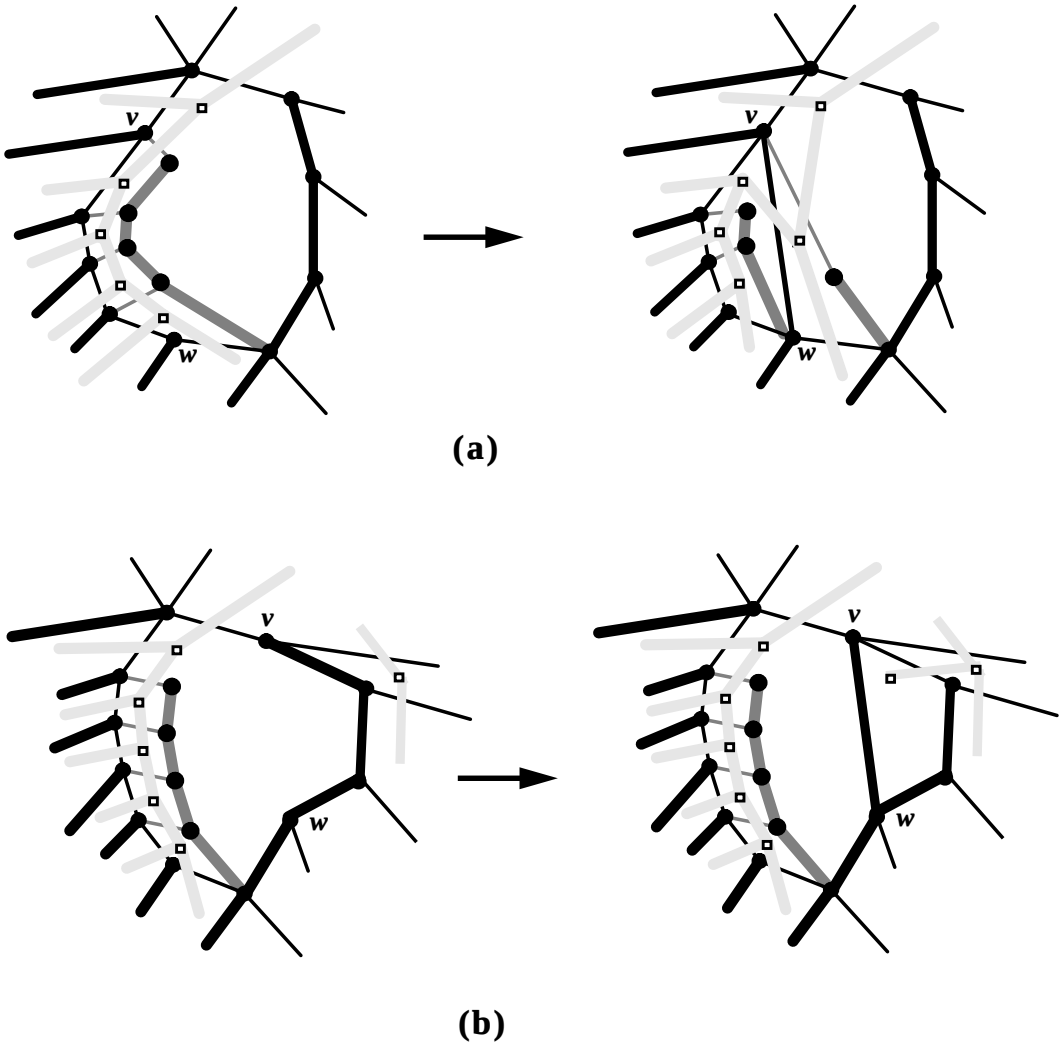

FIG. 9. *Insertions where v and w are on the same side of the region r. We illustrate in* (a) *the case when v and w are in the left chain and in* (b) *the case when v and w are in the right chain.*

in r (which is now the comb for r_1), and the comb in r_2 is the null comb, so this completes the construction. Clearly, this case requires $O(\log n)$ time.

Thus we can perform the *InsertEdge*operation in $O(\log n)$ time. Since the *DeleteEdge*operation is the "reverse" of an *InsertEdge*, this also implies that we can perform the *DeleteEdge*operation in $O(\log n)$ time.

4.7. Chain updates. The only update operations that remain to be described are the chain update operations. Recall that in the operation *InsertChain*$(\gamma, r, v, w; r_1, r_2)$ we insert a monotone chain γ between vertices v and w inside region r, which is then decomposed into regions r_1 and r_2 to the left and right of e, respectively. Note that this is essentially the same as in the case of the *InsertEdge*operation, except that instead of adding a single edge (v, w) we are now inserting a monotone chain. It should not be surprising, then, that our method for performing the *InsertChain*operation

is the same as that for the *InsertEdge*operation, except that where we previously performed a single link in T from v to w, and added a trivial chain in r_2 from v to w, we must now link in an entire chain in T, as well as its corresponding comb. If we perform these link operations in series, then we will require $O(k \log n)$ time, where k is the length of the chain. So, instead, we first build a link-cut tree representation of the chain and its corresponding comb, which takes $O(k)$ time [19, 42], and then we perform the $O(1)$ link operations required to link these chains into T. Likewise, we must build a chain of size $O(k)$ dual to the inserted chain and its comb and link this into D, but again a link-cut tree representation of the chain can be built in $O(k)$ time, and then this can be linked into D with $O(1)$ link operations. Thus the entire time needed for the *InsertChain*operation is $O(\log n + k)$. Since the *DeleteChain*operation amounts to the reversal of this procedure, this also implies that the *DeleteChain*operation can be implemented in $O(\log n + k)$ time (it is actually easier, since we replace the building of link-cut tree representations of $O(k)$-length chains with the garbage collection of the space used by such representations). Therefore, we have the following theorem.

THEOREM 4.5. *Let $\mathcal{S}$ be a monotone subdivision of current size n that is subject to a sequence of on-line updates. Point location in $\mathcal{S}$ can be done with a fully dynamic data structure that uses $O(n)$ space and supports queries in time $O(\log^2 n)$ and update operations* InsertEdge*,* DeleteEdge*,* Expand*, and* Contract*in time $O(\log n)$. Also, update operations* InsertChain*and* DeleteChain*take time $O(\log n + k)$, where k is the size of the monotone chain being inserted or deleted. All the time bounds are worst case.*

5. Spatial point location. We can extend our method further to derive an efficient algorithm for performing point location in 3-dimensional cell complexes whose cells are convex polytopes. Let $\mathcal{C}$ be such a convex cell complex with n vertices and N facets. Note that both n and the number of edges of $\mathcal{C}$ are $O(N)$. Following the same general approach of Preparata and Tamassia [40], we obtain a spatial point-location data structure by combining the persistence-addition technique of Driscoll et al. [16] and our dynamic structure for planar point location.

A conventional dynamic data structure is called *ephemeral* since its instantiation preceding an update is not recoverable after the execution of the update. A *fully persistent* structure supports both accesses and updates to any of its past versions; a *partially persistent* structure supports accesses to any of its past versions but updates only to its most current version. The general technique of Driscoll et al. [16] can be used to add persistence to an ephemeral linked data structure whose records are pointed to by a bounded number of pointers. The resulting persistent data structure uses additional $O(1)$ amortized space per update operation and has the same asymptotic query time (worst case for partial persistence and amortized for full persistence). Since each of our update operations requires a total time of $O(\log n)$ in the worst case, this implies that we make at most $O(\log n)$ pointer updates in any update. Therefore, each of our update operations can be implemented persistently in $O(\log n)$ amortized time, and each one adds $O(\log n)$ amortized additional space to be added to the persistent data structure. In order to implement this persistent strategy, however, we need the following lemma.

LEMMA 5.1. *The dynamic point-location data structure of Theorem* 4.5 *can be implemented with a linked representation such that each record is pointed to by a bounded number of pointers.*

Proof. As mentioned above, our data structure is essentially just a link-cut tree representation of a leftist monotone spanning tree T and its graph-theoretic planar dual D. Moreover, we maintain D as a degree-3 tree, which implies that the underlying link-cut tree representation satisfies the bounded number of pointers condition (see [19, 42] for details). The tree T need not have bounded degree, however. Nevertheless, by using the implementation of edge-ordered dynamic trees given by Eppstein et al. [19], we represent T so as to satisfy the bounded-degree condition (see [19] for details). □

Thus we can create a persistent version of our point location data structure. But being able to search in the "past" must also be meaningful. We find this meaning in the following lemma.

LEMMA 5.2. *Let $\mathcal{S}_1$ and $\mathcal{S}_2$ be monotone subdivisions whose associated planar st-graphs are isomorphic. A dynamic point location data structure for $\mathcal{S}_1$ (as discussed in Theorem* 4.5*) can be used for dynamic point location in $\mathcal{S}_2$ after changing only the values of the vertex coordinates.*

Proof. Since the planar *st*-graphs associated with $\mathcal{S}_1$ and $\mathcal{S}_2$ are isomorphic, the leftist spanning tree for (the refinement of) $\mathcal{S}_1$ and the leftist spanning tree for (the refinement of) $\mathcal{S}_2$ are isomorphic (as are their respective graph-theoretic planar duals). Thus applying our construction to $\mathcal{S}_1$ yields a data structure that is topologically identical to that for $\mathcal{S}_2$. Moreover, at no place in our point-location method do we ever explicitly need the coordinates of the subdivision endpoints. We only needed to be able to perform a comparison-based binary search for a y-coordinate in a monotone chain, and then we must be able to determine to which side of a line L a query point lies. That is, we can use the actual x- and y-coordinates of a query point *implicitly* to resolve y-coordinate comparisons in a binary search of a monotone chain or the "side-of" comparisons with an oriented line L (i.e., we "plug" them in at the last moment). Thus by replacing the comparison tests of $\mathcal{S}_1$ with the isomorphic tests in $\mathcal{S}_2$, we obtain a dynamic point-location structure for $\mathcal{S}_2$. □

We reduce the 3-dimensional point-location problem to an application of persistence to a dynamic 2-dimensional point location where we "sweep" space by a plane $\pi(z)$ parallel to the x- and y-axes and at height z for $z = -\infty$ to $z = +\infty$. Let $\mathcal{C}(z)$ be the intersection of $\mathcal{C}$ with the plane $\pi(z)$. It is easy to verify that $\mathcal{C}(z)$ is a convex (and hence monotone) subdivision. We view the z-axis as a measure of "time" and consider the process of making plane $\pi(z)$ sweep the cell complex $\mathcal{C}$. The location of a query point $q = (x, y, z)$ in the cell complex $\mathcal{C}$ can be reduced to the location of point (x, y) in the monotone subdivision $\mathcal{C}(z)$. Hence spatial point location can be performed using a partially persistent planar point location data structure.

While the geometry of $\mathcal{C}(z)$ continuously evolves in time, its topology changes only when plane $\pi(z)$ goes through a vertex v of $\mathcal{C}$; i.e., for z', z'' such that $z_i < z' < z'' < z_{i+1}$ the planar *st*-graphs associated with $\mathcal{C}(z')$ and $\mathcal{C}(z'')$ are isomorphic. Hence the space-sweep process goes through $2n+1$ topologically different subdivisions. Also, when the plane $\pi(z)$ goes through a vertex v_i, the resulting modification of the subdivision $\mathcal{C}(z)$ can be performed by a sequence of f_i update operations, each an *Expand*or a *Contract*, where f_i is the number of facets whose top or bottom vertex is v_i (see Preparata and Tamassia [40] for more details). Note that $\sum_{i=1}^{n} f_i = O(N)$.

By Lemma 5.2, the same planar point-location data structure can be used for all query points whose z-coordinate is in the range (z_i, z_{i+1}), provided the x and y coordinates of the vertices are expressed as (linear) functions of z. Thus our data structure for spatial point location consists of a partially persistent version of the dynamic

planar point-location data structure of Theorem 4.5. By Lemma 5.1, such structure satisfies the hypothesis for applying the persistence-addition technique of [16].

It is important to observe that although our query algorithm modifies the ephemeral data structure (see section 4.2), such changes are only temporary and need not be remembered by the persistent data structure. Hence at the expense of increasing the storage space by a constant factor we can use duplicate copies for the pointers and data fields that are modified by a query operation. The duplicate fields are disregarded during the updates.

We summarize the performance of our spatial point-location data structure in the following theorem.

THEOREM 5.3. *Let $\mathcal{C}$ be a convex 3-dimensional cell complex with N facets. There exists a data structure for point location in $\mathcal{C}$ that uses $O(N \log N)$ space and supports queries in $O(\log^2 N)$ time worst case.*

6. On-line point location. Many applications involve constructing an object incrementally while requiring that all the properties of the structure be maintained *on line*. In the context of this paper, we desire a scheme to incrementally construct a planar subdivision while maintaining an efficient point-location data structure for it. This can also be viewed as an instance of dynamic point location when only insertions are allowed. In this section we show how to implement our centroid-decomposition approach to planar point location on line using $BB(\alpha)$ trees and some dynamic data structuring techniques of Overmars [34] to achieve $O(1)$ amortized time per update and $O(\log n \log\log n)$ time (worst case) for answering queries.

We support the following operations.

InsertVertex$(v, e, r_1, r_2; e_1, e_2)$. Insert a vertex v on edge e, which has regions r_1 and r_2 to its left and right, respectively, expanding e into e_1 and e_2.

InsertEdge$(e, r, v_1, v_2; r_1, r_2)$. Insert edge e between vertices v_1 and v_2 inside region r, which is decomposed into regions r_1 and r_2 to the left and right of e, respectively. v_1 and v_2.

InsertChain$(\gamma, r, v_1, v_2; r_1, r_2)$. Insert a monotone chain γ between vertices v_1 and v_2 inside region r, which is decomposed into regions r_1 and r_2 to the left and right of e, respectively.

6.1. A simple on-line point location structure. We explicitly maintain the monotone tree T and the dual tree D for the refined subdivision $\mathcal{R}$. We also explicitly maintain B, the balanced decomposition tree of D, in a $BB(\alpha)$ tree. Each node μ in B corresponds to a subtree D_μ of D, which in turn corresponds to a subpolygon P_μ of P. Thus each leaf in B corresponds to a node of D, which in turn corresponds to a region in $\mathcal{R}$. For each node μ in B we explicitly store the chains $L(\mu)$ and $R(\mu)$. In addition, in the spirit of *fractional cascading*[1] [8, 9], for each node μ we maintain auxiliary lists $AL(\mu)$ and $AR(\mu)$, which are defined recursively as follows:

$$AL(\mu) = \begin{cases} L(\mu) & \mu \text{ is a leaf,} \\ L(\mu) \cup AL(\lambda) \cup AL(\nu) & \text{otherwise,} \end{cases}$$

$$AR(\mu) = \begin{cases} R(\mu) & \mu \text{ is a leaf,} \\ R(\mu) \cup AR(\lambda) \cup AR(\nu) & \text{otherwise,} \end{cases}$$

where λ and ν are the children of μ should μ be an internal node. By keeping pointers from each element x in $AL(\mu)$ to its predecessors in $L(\mu)$, $AL(\lambda)$, and $AL(\nu)$ (and

[1] Specifically, we create auxiliary search lists as in the fractional cascading paradigm; we do not, however, need to implement fractional list propagation.

similar pointers for each x in $AR(\mu)$) we can answer queries in $O(\log n)$ time. This is because after an $O(\log n)$ time binary search in the AL and AR lists for the root of B, the search at every other node in B requires only $O(1)$ time, and there are $O(\log n)$ such other nodes. The update operations are easily implemented as follows.

InsertVertex$(v, e, r_1, r_2; e_1, e_2)$. We first make the obvious update to the planar graph representation of $\mathcal{R}$, inserting v on e and splitting e into e_1 and e_2. We then use the pointer to e to locate the records in $L(\mu)$ and $R(\mu')$ for the endpoint w of e that is nearer to the root of T. We then add a record for v next to w's record in $L(\mu)$ and $R(\mu')$, respectively. This can all easily be done in $O(1)$ time. We must also update the auxiliary lists, however, by adding a record for v to the AL list for each node from μ to the root of B and a record for v to the AR list for each node from μ' to the root. This can be implemented in $O(\log n)$ time by performing a query for v from the root to μ and μ', respectively, and adding v to each list we search in along the way.

InsertEdge$(e, r, v_1, v_2; r_1, r_2)$. We first make the obvious update to the planar graph representation of $\mathcal{R}$, inserting e into r and splitting r into r_1 and r_2. This also necessitates that we modify the node λ in D corresponding to r. This modification will be in the form of the division of λ into two nodes λ_1 and λ_2, with some of λ's adjacencies becoming λ_1's adjacencies and the other adjacencies of λ becoming λ_2's adjacencies. Of course, in performing this modification of D we must also update B to reflect this modification. We do this by visiting the leaf μ in B associated with λ, creating two new nodes μ_1 and μ_2, which are associated with λ_1 and λ_2, respectively, and making these nodes be the children of μ. This addition, in turn, requires that we update the balance information stored in B, and in some cases this requires that we perform node rotations in B to maintain the weight-balance requirements of this $BB(\alpha)$ tree. Performing a rotation at a node μ in B requires more than just updating balance information and changing some pointers at the nodes around μ—it also requires that we change the L and R lists (and their associated auxiliary lists) for μ and ν, the child of μ that is now becoming the parent of ν. Note, however, that we must change the pointer fields of the records in the auxiliary lists at μ's old parent ρ, but we do not need to add or delete any records from these lists. This is because the set of descendants of ρ do not change. Thus the time required to perform such a rotation is proportional to the size of the L, R, AL, and AR lists at μ and ν, which is proportional to n_μ, the number of descendants of μ.

InsertChain(γ, v_1, v_2). This operation can be implemented by combining the methods for *InsertVertex* and *InsertEdge*. We leave the details to the interested reader.

From the above descriptions it should be clear that queries can be answered in $O(\log n)$ worst-case time, as can *InsertVertex* operations. Also, the worst-case time for an *InsertEdge* operation is $O(n)$. Nevertheless, since we are represented B as a $BB(\alpha)$ tree, we can derive an efficient amortized running time for the *InsertEdge* operation. In particular, we observe that performing a rotation at μ requires $O(n_\mu)$ time, where n_μ is the number of leaf descendants of μ. This is because the size of $AL(\mu)$ and $AR(\mu)$ is bounded by the number of vertices in $P(\mu)$, the subpolygon associated with μ, which is $O(n_\mu)$. We can, therefore, take advantage of the following lemma.

LEMMA 6.1 (see [32]). *Let $\alpha \in (1/4, 1 - \sqrt{2}/2)$ and let f be a nondecreasing function such that the cost of performing a rotation in a $BB(\alpha)$ tree at a node μ is $f(n_\mu)$. Then the total cost of the rebalancing operations in a sequence of m insertions*

and deletions into an initially empty tree is

$$O\left(m \sum_{i=1}^{c \log m} (1-\alpha)^i f((1-\alpha)^{-i-1})\right),$$

where $c = 1/\log(1-\alpha)$.

This immediately implies that the cost of performing a sequence of n *InsertEdge* operations starting with an initially empty subdivision is $O(n \log n)$; hence the amortized cost of each *InsertEdge* operation is $O(\log n)$. This gives us the following theorem.

THEOREM 6.2. *One can maintain a monotone subdivision on-line with* $O(\log n)$ *query time for point locations and* $O(\log n)$ *amortized time for vertex and edge insertions (inserting a chain of* k *vertices requires* $O(k \log n)$ *amortized time). The space for this data structure is* $O(n \log n)$.

One can improve the space of the above method to $O(n)$ at the expense of making the query time an amortized bound, using the methods of Fries [20], and Fries, Melhorn, and Näher [21]. As we mentioned earlier, however, our interest is in performing updates in $O(1)$ amortized time ($O(k)$ time for chain insertion). In the next section we show how to modify our approach to achieve this goal. Our modification reduces the space to $O(n)$ and increases the query time by only a $\log \log n$ factor.

6.2. Improving the implementation. The main idea of our improvement is to apply a "bucketing" technique [34] at two different places in our structure. The first application is for the L and R lists at the nodes of B. For simplicity of expression, let us concentrate our attention on the L lists; the modifications for the R lists are similar. For each node μ we add a list $L'(\mu)$, which we maintain to be a subsequence of $L(\mu)$ so that between any two consecutive elements (e, f) in $L'(\mu)$ there are at most $2N$ elements of $L(\mu)$, where N is $\Theta(\log n)$. Moreover, for each pair of consecutive elements (e, f) in $L'(\mu)$ we store the elements of $L(\mu)$ that fall between e and f in a data structure that allows $O(1)$ insertion time, given an element's position, and $O(\log n_e)$ query time, where $n_e = O(N)$ is the number of elements between e and f [29]. The elements of $L(\mu)$ between e and f can intuitively be viewed as belonging to a "bucket" for the pair (e, f).

We modify our definition of the AL and AR lists to take advantage of the sublists L' and R'. In particular we now define $AL(\mu)$ and $AR(\mu)$ as follows:

$$AL(\mu) = \begin{cases} L'(\mu) & \mu \text{ is a leaf,} \\ L'(\mu) \cup AL(\lambda) \cup AL(\nu) & \text{otherwise,} \end{cases}$$

$$AR(\mu) = \begin{cases} R'(\mu) & \mu \text{ is a leaf,} \\ R'(\mu) \cup AR(\lambda) \cup AR(\nu) & \text{otherwise,} \end{cases}$$

where λ and ν are the children of μ should μ be an internal node. This immediately implies that the query time increases to $O(\log n \log N) = O(\log n \log \log n)$, since, given a query value x, determining the predecessor of x in $L(\mu)$ requires $O(\log N) = O(\log \log n)$ time given the position of x in $AL(\mu)$. Nevertheless, this modification has a worthwhile consequence—it reduces the time for *InsertVertex* operations to $O(1)$ (amortized). This bound follows from the fact that an *InsertVertex* requires more than $O(1)$ time only if that *InsertVertex* operation causes a bucket size to grow larger than $2N$. In such a case we simply split this bucket into two buckets with sizes N and $N+1$, respectively. Of course, splitting a bucket in, say, $L(\mu)$ requires that we add a

new element to $L'(\mu)$ and, hence, to the AL list at each node from μ to the root of B. Since all of these updates can be implemented in $O(\log n + N) = O(N)$ time, we can charge this cost to the N operations that previously inserted elements to this bucket (to make it grow to size $2N$). Thus the amortized cost of an *InsertVertex* is $O(1)$.

We can also reduce the space of this method to $O(n + n \log n/N) = O(n)$, since N is $\Theta(\log n)$, by insuring that any time two consecutive buckets have size smaller than $\lfloor N/2 \rfloor$ we concatenate these buckets into a single bucket.

These modifications do not reduce the cost for *InsertEdge* operations, however. To reduce their cost we apply the bucketing idea a second time, this time to the tree B itself. In particular, we modify our maintenance of B so that, instead of associating a single node of D (corresponding to a single region of $\mathcal{R}$) with each leaf of B, we associate a subtree of D with at most $2N$ nodes. Any time an *InsertEdge* operation causes a leaf subtree D_μ to grow to more than $2N$ nodes, we locate the centroid edge in D_μ and split D_μ into two trees D_{μ_1} and D_{μ_2}, creating two new nodes μ_1 and μ_2, which become the children of μ. This of course necessitates that we build new lists (L, R, L', R', AL, and AR) for μ_1 and μ_2 and update the AL and AR lists from μ to the root to reflect the addition of any new values (needed to maintain the recursive definitions of the AL and AR lists). Nevertheless, this can all be done in $O(\log n + N) = O(N)$ time, which can be charged to the N previous *InsertEdge* operations at μ (each were implemented in $O(1)$ time). Thus each *InsertEdge* will run in $O(1)$ amortized time.

The method for implementing *InsertChain* operations is basically a combination of the methods for *InsertVertex* and *InsertEdge*, the details of which we leave to the interested reader. Thus we have the following theorem.

THEOREM 6.3. *One can maintain a monotone subdivision on-line with the query time $O(\log n \log\log n)$ for point locations and $O(1)$ amortized time for vertex and edge insertions (inserting a chain of k vertices requires $O(k)$ amortized time). The space needed for this data structure is $O(n)$.*

We believe this theorem provides the first on-line point-location data structure with an $O(1)$ amortized update time and polylogarithmic query time.

7. Conclusion. We have given a new approach to planar point location and showed how it can be used to derive new, improved bounds for dynamic point location, spatial point location, and on-line point location. We leave as an open problem the existence of a fully dynamic method for point location in subdivisions that are at least as combinatorially rich as the monotone subdivisions that runs in $O(\log n)$ time per query and $O(\log n)$ amortized time per update. As mentioned in the introduction, Atallah, Goodrich, and Ramaiyer [2] achieve this result for the fairly restrictive class of staircase subdivisions.

Acknowledgments. We would like to thank Bernard Chazelle for suggesting the pursuit of an on-line point-location method with $O(1)$ amortized update time. We would also like to thank Siu-Wing Cheng, Ravi Janardan, and S. Rao Kosaraju for several stimulating conversations related to topics addressed in this paper.

QUERY ORDER*

LANE A. HEMASPAANDRA†, HARALD HEMPEL‡, AND GERD WECHSUNG§

Abstract. We study the effect of query order on computational power and show that $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$—the languages computable via a polynomial-time machine given one query to the jth level of the boolean hierarchy followed by one query to the kth level of the boolean hierarchy—equals $\mathrm{R}^p_{j+2k-1\text{-tt}}(\mathrm{NP})$ if j is even and k is odd and equals $\mathrm{R}^p_{j+2k\text{-tt}}(\mathrm{NP})$ otherwise. Thus unless the polynomial hierarchy collapses it holds that, for each $1 \leq j \leq k$, $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]} = \mathrm{P}^{\mathrm{BH}_k[1]:\mathrm{BH}_j[1]} \iff (j = k) \vee (j \text{ is even} \wedge k = j+1)$. We extend our analysis to apply to more general query classes.

Key words. ordered computation, bounded queries, computational complexity theory

1. Introduction.

This paper studies the importance of query order. Everyone knows that it makes more sense to first look up in your on-line date book the date of the yearly computer science conference and then phone your travel agent to get tickets, as opposed to first phoning your travel agent (without knowing the date) and then consulting your on-line date book to find the date. In real life, order matters.

This paper seeks to determine—for the first time to the best of our knowledge—whether one's everyday-life intuition that order matters carries over to complexity theory.

In particular, for classes $\mathcal{C}_1$ and $\mathcal{C}_2$ from the boolean hierarchy [10, 11], we ask whether one question to $\mathcal{C}_1$ followed by one question to $\mathcal{C}_2$ is more powerful than one question to $\mathcal{C}_2$ followed by one question to $\mathcal{C}_1$. That is, we seek the relative powers of the classes $\mathrm{P}^{\mathcal{C}_1[1]:\mathcal{C}_2[1]}$ and $\mathrm{P}^{\mathcal{C}_2[1]:\mathcal{C}_1[1]}$.

As is standard [26], for any constant m we say A is m-truth-table reducible to B ($A \leq^p_{m\text{-tt}} B$) if there is a polynomial-time computable function that, on each input x, computes both (a) m strings $x_1, x_2, \ldots, x_m$ and (b) a boolean function, α, of m boolean variables, such that $x_1, x_2, \ldots, x_m$ and α satisfy

$$x \in A \iff \alpha(\chi_B(x_1), \chi_B(x_2), \ldots, \chi_B(x_m)) = 1,$$

where χ_B denotes the characteristic function of B. For any a and b for which $\leq^b_a$ is defined and for any class $\mathcal{C}$, let $\mathrm{R}^b_a(\mathcal{C}) = \{L \mid (\exists C \in \mathcal{C})[L \leq^b_a C]\}$.

We prove via the mind change technique that for $j, k \geq 1$,

$$\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]} = \begin{cases} \mathrm{R}^p_{j+2k-1\text{-tt}}(\mathrm{NP}) & \text{if } j \text{ is even and } k \text{ is odd,} \\ \mathrm{R}^p_{j+2k\text{-tt}}(\mathrm{NP}) & \text{otherwise.} \end{cases}$$

§Institut für Informatik, Friedrich-Schiller-Universität Jena, 07740 Jena, Germany (wechsung@informatik.uni-jena.de).

Informally, this says that the second query counts more toward the power of the class than the first query does. In particular, assuming that the polynomial hierarchy does not collapse, we have that if $1 \leq j \leq k$ then $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$ and $\mathrm{P}^{\mathrm{BH}_k[1]:\mathrm{BH}_j[1]}$ differ unless $(j = k) \vee (j \text{ is even } \wedge\, k = j + 1)$.

The interesting case is the strength of $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$ when j is even and k is odd. In some sense, $j + 2k$ NP questions underpin this class. However, by arguing that a certain underlying graph must contain an odd cycle, we show that one can always make do with $j + 2k - 1$ queries. We generalize our results to apply broadly to classes with tree-like query structure.

The work of this paper (especially Theorem 3.6), which first appeared in [21], should be compared with the independent work of Agrawal, Beigel, and Thierauf [1]. In particular, let $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]_+}$ denote the class of languages recognized by some polynomial-time machine making one query to a BH_j oracle followed by one query to a BH_k oracle and accepting if and only if the second query is answered "yes." Agrawal, Beigel, and Thierauf prove (using different notation)

$$\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]_+} = \begin{cases} \mathrm{BH}_{j+2k-1} & \text{if } j \not\equiv k \pmod 2, \\ \mathrm{BH}_{j+2k} & \text{otherwise.} \end{cases}$$

Note that this result is incomparable with the results of Theorem 3.6, as their result deals with a different and seemingly more restrictive acceptance mechanism. Some insight into the degree of restrictiveness of their acceptance mechanism, and its relationship to ours, is given by the following claim (Corollary 3.7), which follows immediately from Theorem 5.7 and Lemma 5.9 of [1] and Theorem 3.6 of the present paper:

$$\mathrm{R}^p_{1\text{-tt}}(\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]_+}) = \begin{cases} \mathrm{P}^{\mathrm{BH}_{j-1}[1]:\mathrm{BH}_k[1]} & \text{if } j \text{ is odd and } k \text{ is even,} \\ \mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]} & \text{otherwise.} \end{cases}$$

2. Preliminaries. For standard notions not defined here, we refer the reader to any computational complexity textbook, e.g., [6, 2, 27]. Let χ_A, m-truth-table reducibility ("$\leq^p_{m\text{-tt}}$"), $\mathrm{R}^b_a(\mathcal{C})$, and $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]_+}$ be as defined in section 1.

The boolean hierarchy [10, 11] is defined as follows, where $\mathcal{C}_1 \ominus \mathcal{C}_2 = \{L \mid (\exists A \in \mathcal{C}_1)(\exists B \in \mathcal{C}_2)[L = A - B]\}$:

$$\mathrm{BH}_1 = \mathrm{NP},$$

$$\mathrm{BH}_k = \mathrm{NP} \ominus \mathrm{BH}_{k-1}, \text{ for } k > 1,$$

$$\mathrm{coBH}_k = \{L \mid \overline{L} \in \mathrm{BH}_k\}, \text{ for } k > 0, \text{ and}$$

$$\mathrm{BH} = \bigcup_{i \geq 1} \mathrm{BH}_i.$$

The boolean hierarchy has been intensely investigated, and quite a bit has been learned about its structure (see, e.g., [10, 11, 9, 25, 24, 30, 14, 3, 5]). Recently, various results have also been developed regarding boolean hierarchies over classes other than NP [7, 13, 5, 22].

For any language classes $\mathcal{C}_1$ and $\mathcal{C}_2$, define $\mathrm{P}^{\mathcal{C}_1[1]:\mathcal{C}_2[1]}$ to be the class of languages accepted by polynomial-time machines making one query to a $\mathcal{C}_1$ oracle followed by one query to a $\mathcal{C}_2$ oracle. For any language classes $\mathcal{C}_1$, $\mathcal{C}_2$, and $\mathcal{C}_3$, define $\mathrm{P}^{\mathcal{C}_1[1]:\mathcal{C}_2[1],\mathcal{C}_3[1]}$ to be the class of languages accepted by polynomial-time machines making one query to a $\mathcal{C}_1$ oracle followed in the case of a "no" answer to this first query by one query to a $\mathcal{C}_2$ oracle, and in the case of a "yes" answer to the first query by one query to a $\mathcal{C}_3$ oracle.

3. The importance of query order. We ask whether the order of queries matters. We will study this in the setting of the boolean hierarchy. In particular, does $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$ equal $\mathrm{P}^{\mathrm{BH}_k[1]:\mathrm{BH}_j[1]}$, or are they incomparable, or does one strictly contain the other?

For clarity of presentation, in this section we will handle classes only of the form $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$. We show that for no j, k, j', and k' are $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$ and $\mathrm{P}^{\mathrm{BH}_{j'}[1]:\mathrm{BH}_{k'}[1]}$ incomparable. In section 4 we will handle the more general case of classes of the form $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1],\mathrm{BH}_l[1]}$, and even classes with a more complicated tree-like query structure.

Indeed, we show in this section that in almost all cases, $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$ is so powerful that it can do anything that can be done with $j+2k$ truth-table queries to NP. Since, based on the answer to the first BH_j query, there are two possible BH_k queries that might follow, $j+2k$ is exactly the number of queries asked in a brute force truth-table simulation of $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$. Thus, our result shows that (in almost all cases) the power of the class is not reduced by the nonlinear structure of the $j+2k$ queries underlying $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$—that is, the power is not reduced by the fact that in any given run only $j+k$ underlying NP queries will be even implicitly asked (via the BH_j query and the one asked BH_k query). We say "in almost all cases" as if j is even and k is odd, we prove there is a power reduction of exactly one level.

All the results of the previous paragraph follow from a general characterization that we prove. For $j, k \geq 1$,

$$\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]} = \begin{cases} \mathrm{R}^p_{j+2k-1\text{-tt}}(\mathrm{NP}) & \text{if } j \text{ is even and } k \text{ is odd,} \\ \mathrm{R}^p_{j+2k\text{-tt}}(\mathrm{NP}) & \text{otherwise.} \end{cases}$$

Our proof employs the mind change technique, which predates complexity theory. In particular we show that $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$ has at most $j+2k$ ($j+2k-1$ if j is even and k is odd) mind changes, and that BH_{j+2k} (BH_{j+2k-1} if j is even and k is odd) is contained in $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$.

The mind change technique or equivalent manipulation was applied to complexity theory in each of the early papers on the boolean hierarchy, including the work of Cai et al. ([10]; see also [32, 12]); Köbler, Schöning, and Wagner [25]; and Beigel [3]. These papers use mind changes for a number of purposes. Most crucially they use the maximum number of mind changes (what a mind change is will soon be made clear) of a class as an upper bound that can be used to prove that the class is contained in some other class. In the other direction, they also use the number of mind changes that certain classes—especially the classes of the boolean hierarchy due to their normal form as nested subtractions of telescoping sets [10]—possess to show that they can simulate other classes. Even for classes that have the same number of mind changes, relativized separations are obtained via showing that the mind changes are of different character (mind change sequences are of two types, depending on whether they start with acceptance or rejection). The technique has also proven useful in many other more recent papers, e.g., [14, 13, 5].

To make clear the basic nature of mind change arguments, in a simple form, we give an example. We informally argue that each set that is k-truth-table reducible to NP is in fact in $\mathrm{R}^p_{1\text{-tt}}(\mathrm{BH}_k)$.

LEMMA 3.1. *For every $k \geq 1$, $\mathrm{R}^p_{k\text{-}tt}(\mathrm{NP}) = \mathrm{R}^p_{1\text{-}tt}(\mathrm{BH}_k)$.*

Proof. This fact (stated slightly differently) is due to Köbler, Schöning, and Wagner [25], and the proof flavor presented here is most akin to the approach of Beigel [3]. Consider a k-truth-table reduction to an NP set F. Let L be the language accepted by the k-truth-table reduction to F. Consider some input x and without loss of generality assume k queries are generated. Let us suppose for the moment that the reduction rejects when all k queries receive the answer "no." Consider the k-dimensional hypercube such that one dimension is associated with each query (0 in that dimension means the query is answered no and 1 means it is answered yes). So the origin is associated with all queries getting the answer no, and the point (1,1,...,1) is associated with all queries getting the answer yes. Now, also label each vertex with either A (Accept) or R (Reject) based on what the truth-table would do given the answers represented by that vertex. So under our supposition the origin has the label R. Finally, label each vertex with an integer as follows. Label the origin with 0. Inductively label each remaining vertex with the *maximum* integer induced by the vertices that immediately precede it (i.e., those that are the same as it except one yes answer has been changed to a no answer). A preceding vertex v with integer label i induces in a successor v' the integer $i+1$ if v and v' have different A/R labels, and i if they have the same label. Note that vertices given even labels correspond to rejection and those given odd labels correspond to acceptance. Informally, a mind change is just changing one or more strings from no to yes in a way that moves us from a vertex labeled i to one labeled $i+1$. For $1 \leq i \leq k$, let B_i be the NP set that accepts x if (in the queries/labeling generated by the action of the truth-table on input x) for some vertex v labeled i all the queries v claims are yes are indeed in the NP set F. Note that $B_1 \supseteq B_2 \supseteq B_3 \supseteq \cdots$, as if a node labeled v is in B_j, $j \geq 2$, then certainly its predecessor node with label $j-1$ must be in B_{j-1}, as that predecessor represents a subset of the strings v represents. But now note that L is exactly $B_1 - (B_2 - (B_3 - (\cdots - (B_{k-1} - B_k)\cdots)))$. Why? Let the vertex w (say with integer label i_w) represent the true answers to the queries. Note that by construction $x \in B_q$ for all $q \leq i_w$ but $x \notin B_q$ for any $q > i_w$. As the B_i were alternating in terms of representing acceptance and rejection, and given the format $B_1-(B_2-(B_3-(\cdots-(B_{k-1}-B_k)\cdots)))$, the set $B_1-(B_2-(B_3-(\cdots-(B_{k-1}-B_k)\cdots)))$ will do exactly what B_{i_w} represents, namely, the action on the correct answers. Thus, we have just given a proof that a k-truth-table reduction that rejects whenever all answers are no can be simulated by a set in BH_k. Of course, one cannot validly assume that the reduction rejects whenever all answers are no. But it is not hard to see (analogously to the above) that the case of inputs where the reduction accepts when all answers are no can (analogously to the above) be handled via the complement of a BH_k set and that (since what the truth-table reduction does when all answers are no is itself polynomial-time computable) via a set in $\mathrm{R}^p_{1\text{-tt}}(\mathrm{BH}_k)$ we can accept an arbitrary set in $\mathrm{R}^p_{k\text{-tt}}(\mathrm{NP})$. Of course, it is clear by brute force simulation that $\mathrm{R}^p_{1\text{-tt}}(\mathrm{BH}_k) \subseteq \mathrm{R}^p_{k\text{-tt}}(\mathrm{NP})$, and so it holds that $\mathrm{R}^p_{1\text{-tt}}(\mathrm{BH}_k) = \mathrm{R}^p_{k\text{-tt}}(\mathrm{NP})$. □

What actually is being shown above is that $\mathrm{R}^p_{1\text{-tt}}(\mathrm{BH}_k)$ can handle k appropriately structured mind changes, starting either from reject or accept. In the following theorem, the crucial things we show are that (a) $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$ can simulate, starting at either accept or reject, $j+2k$ (respectively, $j+2k-1$) mind changes if j is odd

or k is even (respectively, if j is even and k is odd), and (b) for j even and k odd, $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$ can *never* have more than $j+2k-1$ mind changes. We achieve (b) by examining the possible mind change flow of a $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$ machine, j even and k odd, and showing that either a mind change is flagrantly wasted, or a certain underlying graph has an odd length directed cycle (which thus is not two-colorable, and from this will lose one mind change).

Since our arguments in the proofs of this section use paths in hypercubes, we will find useful the concept of an ascending path in a hypercube. Let $K = \{0,1\}^d$ be the d-dimensional hypercube. Then every path p in K can be described as a linear combination of unit vectors $u_1, \ldots, u_d$, where u_i is the ith unit vector. We call p an ascending path in K leading from $(0,0,\ldots,0)$ to v if and only if it can be identified with a sum

$$u_{i_1} + u_{i_2} + \cdots + u_{i_n}$$

of distinct unit vectors u_ν such that the vertices of this path p are

$$v_0 = (0,\ldots,0), v_1 = u_{i_1}, v_2 = u_{i_1} + u_{i_2}, \ldots, v = u_{i_1} + u_{i_2} + \cdots + u_{i_n}.$$

We will call this sum the description of p. Note that the order of the u's matters, as a permutation of the u's results in another path. We call p an ascending path (without specifying starting point and endpoint) if p is an ascending path leading from $(0,0,\ldots,0)$ to $(1,1,\ldots,1)$.

Before turning to results, first we will study the structure of ascending paths in labeled hypercubes and give some necessary definitions. Building upon them, we will then prove Lemma 3.5, which states that $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$ can handle exactly $j+2k$ ($j+2k-1$ if j is even and k is odd) mind changes.

Let M be a $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$ machine with oracles $A \in \mathrm{BH}_j$ and $B \in \mathrm{BH}_k$ and let $x \in \Sigma^*$. On input x, M first makes a query $q_1(x)$ to A and then if the answer to the first query was "no" asks query $q_2(x)$ to B and if the answer to the first query was "yes" asks query $q_3(x)$ to B. Without loss of generality assume that on every input x exactly two queries are asked.

Every set $C \in \mathrm{BH}_l$ can be written as the nested difference of sets $C_1, C_2, \ldots, C_l \in \mathrm{NP}$

$$C = C_1 - (C_2 - (\cdots - (C_{l-1} - C_l)\cdots))$$

and following Cai et al. [10] we even can assume that

$$C_l \subseteq C_{l-1} \subseteq \cdots \subseteq C_2 \subseteq C_1.$$

Hence a query "$q \in C$?" can certainly be solved via l queries "$q \in C_1$?," "$q \in C_2$?," $\ldots$, "$q \in C_l$?"

In light of this comment, we let

$$A = A_1 - (A_2 - (\cdots - (A_{j-1} - A_j)\cdots)) \quad \text{where} \quad A_i \in \mathrm{NP} \quad \text{for} \quad i = 1,2,\ldots,j \quad \text{and} \quad A_j \subseteq \cdots \subseteq A_1, \text{ and}$$

$$B = B_1 - (B_2 - (\cdots - (B_{k-1} - B_k)\cdots)) \quad \text{where} \quad B_i \in \mathrm{NP} \quad \text{for} \quad i = 1,2,\ldots,k \quad \text{and} \quad B_k \subseteq \cdots \subseteq B_1.$$

For the sake of definiteness let us assume that the queries

$$q_1(x) \in A_1, \ldots, q_1(x) \in A_j, q_2(x) \in B_1, \ldots, q_2(x) \in B_k, q_3(x) \in B_1, \ldots, q_3(x) \in B_k$$

correspond in this order to the $j+2k$ dimensions of the $(j+2k)$-dimensional hypercube $H = \{0,1\}^{j+2k}$. More precisely, a vector $(a_1, \ldots, a_{j+2k}) \in H$ is understood to consist of the answers to the above-mentioned queries, where 0 means "no" and 1 means "yes."

Since a query "$q \in C$?" for some $C \in \mathrm{BH}_l$ and $C = C_1 - (C_2 - (\cdots (C_{l-1} - C_l) \cdots))$ can be solved by evaluating the answers to "$q \in C_1$?," "$q \in C_2$?," $\ldots$, "$q \in C_l$?" every node $v \in H$ gives us answers to "$q_1(x) \in A$?" (by evaluating the first j components of v), to "$q_2(x) \in B$?" (by evaluating the k components of v that immediately follow the first j components of v), and to "$q_3(x) \in B$?" (by evaluating the last k of v's components). This gives us a labeling of all vertices of H. We simply assign label A (Accept) to vertex $v \in H$ if $M^{A[1]:B[1]}(x)$ accepts if the answers to the two asked questions are as determined by v. If $M^{A[1]:B[1]}(x)$ rejects in this case we assign label R (Reject) to v.

So let $H_M(x)$ be the $(j+2k)$-dimensional hypercube labeled according to $M^{A[1]:B[1]}(x)$. The number of mind changes on an ascending path p of $H_M(x)$ leading from $(0,0,\ldots,0)$ to a vertex t is by definition the number of label changes when moving from $(0,0,\ldots,0)$ to t along p. The number of mind changes of an internal node v of $H_M(x)$ is the maximum number of mind changes on an ascending path leading from $(0,0,\ldots,0)$ to v. And, finally, the number of mind changes of a $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$ machine M is by definition the maximum number (we take the maximum over all $x \in \Sigma^*$) of mind changes of the vertex $(1,1,\ldots,1)$ in $H_M(x)$; in other words, this number is the maximum number of label changes on an ascending path in $H_M(x)$ for some $x \in \Sigma^*$.

We say we lose a mind change (between two adjacent vertices v_i and v_{i+1}) along an ascending path if when moving from v_i to v_{i+1} the machine does not change its acceptance behavior.

One can easily verify the following fact.

FACT 3.2. *If M is a $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$ machine such that on input x the acceptance behavior is independent of the answer to one or more of the two possible second queries (that is, if for at least one of the second queries both a "yes" and a "no" answer yield the same acceptance or rejection behavior), then we lose at least one mind change on every path in $H_M(x)$.*

So from now on, in light of Fact 3.2, let $M^{A[1]:B[1]}(x)$ be a $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$ machine that has, on input x, one of the following four acceptance schemes (the scheme may depend on the input).

(1) M accepts if and only if exactly one of the two sequential queries is answered "yes."
(2) M accepts if and only if either both or neither of the two asked queries is answered "yes."
(3) M accepts if and only if the second query is answered "yes."
(4) M accepts if and only if the second query is answered "no."

FACT 3.3. *If p is an ascending path in $H_M(x)$ such that p contains adjacent vertices v and $v + u_d$ such that*

$$d \leq j \text{ and the } (d')\text{th component of } v \text{ is } 0 \text{ for some } d' < d,$$

then p loses a mind change.

Proof. Since $A \in \mathrm{BH}_j$ and thus $A = A_1 - (A_2 - (\cdots - (A_{j-1} - A_j) \cdots))$ and there is a 0 in the (d')th component of v and $v + u_d$, both vertices yield the same answer

to "$q_1(x) \in A$?" The 1 in the dth component of $v + u_d$ has no effect at all on the answer to "$q_1(x) \in A$?" and so on the outcome of $M^{A[1]:B[1]}(x)$. Hence both vertices have the same label and p loses a mind change. □

Similarly, one can prove that if p is an ascending path and p contains two adjacent vertices v and $v + u_d$ such that $j < d' < d \leq j + k$ and the (d')th component of v is 0 or $j + k < d' < d \leq j + 2k$ and the (d')th component of v is 0, then p also loses one mind change.

Furthermore, in light of Fact 3.3, let us focus only on paths p that change their first j, second k, and last k dimensions from the smallest to the highest dimension in each group. This allows us to simplify the description of paths as follows. Let e_1 be the following operator on H:

$$e_1((a_1, \ldots, a_{j+2k})) = \begin{cases} (a_1, \ldots, a_{i-1}, 1, \ldots, a_{j+2k}) & \text{if } i \leq j,\ a_i = 0 \wedge (\forall j : j < i)[a_j = 1], \\ (a_1, \ldots, a_{j+2k}) & \text{otherwise.} \end{cases}$$

The operators e_2 and e_3 act on the index groups $(j + 1, \ldots, j + k)$ and $(j + k + 1, \ldots, j + 2k)$, respectively, in the same manner: the zero component with smallest index among the zero components is incremented by 1. The only reasonable paths to consider are those emerging from repeated applications of e_1, e_2, and e_3 to $(0, \ldots, 0)$. We will use $(e_{i_1}, e_{i_2}, \ldots, e_{i_{j+2k}})$ to denote the path with vertices $v_0 = (0, \ldots, 0)$, $v_1 = e_{i_1}(v_0), v_2 = e_{i_2}(v_1), \ldots, v_{j+2k} = e_{i_{j+2k}}(v_{j+2k-1}) = (1, 1, \ldots, 1)$.

The next fact gives sufficient conditions for an ascending path to lose a mind change.

FACT 3.4. *On any ascending path p a mind change loss occurs if*

Case 1.1. *there is an e_2 after an odd number of e_1's in the description of p, or*

Case 1.2. *there is an e_3 after an even number of e_1's in the description of p, or*

Case 2. *the description of p contains a sequence of odd length at least 3 that starts and ends with e_1 and contains no other e_1's.*

Proof. We will call the occurrence of Case 1.1 (Case 1.2) in p an "e_2-loss" ("e_3-loss") and the occurrence of Case 2 an "odd episode." In general we call a subpath of p of length at least 3 that starts and ends with e_1 and contains no other e_1 an episode.

Intuitively p loses a mind change in the case of Case 1.1 (Case 1.2), since in the actual computation $M(x)$ does not really ask query $q_2(x)$ $(q_3(x))$ and so a change in the answers to the k underlying NP queries of $q_2(x)$ $(q_3(x))$ does not affect the outcome of the overall computation.

Intuitively in Case 2 the following argument holds. If the description of p contains an odd episode, say starting with $e_{i_l} = e_1$ and ending with $e_{i_{l'}} = e_1$, then $v_{l-1}, v_l, \ldots, v_{l'}$ form an even-length subpath p' of p. If the odd episode contains both e_2's and e_3's then note that Case 1 applies and we are done. In fact due to Case 1 we may henceforth assume the odd episode, between the starting and the ending e_1's, has only e_2's (respectively, e_3's) if we have an even (respectively, odd) number of e_1's up to and including the e_1 starting the odd episode. So in this case v_{l-1} and $v_{l'}$ have the same label Accept/Reject. The acceptance behavior of $M^{A[1]:B[1]}(x)$ due to v_{l-1} and $v_{l'}$ is the same, because after two e_1's the answer to "$q_1(x) \in A$?" is the same as it was before the two e_1's, and the e_2's (e_3's) have not influenced the answer to $q_3(x)$ $(q_2(x))$. Thus we have a subpath of even length, namely, $v_{l-1}, v_l, \ldots, v_{l'}$, whose starting point and endpoint have the same Accept/Reject label. To assign to each vertex of this path an Accept/Reject label in such a way that no mind changes are lost is equivalent to the impossible task of 2-coloring an odd cycle. Hence we lose at least one mind change for every occurrence of an odd episode. □

Before proving the main theorem of this section, we show Lemma 3.5, which tells how many mind changes $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$ can handle. We say a complexity class $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$ can handle exactly m mind changes if and only if (a) no $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$ machine has more than m mind changes and (b) there is a specific $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$ machine that has m mind changes. It is known (see, e.g., [10, 25, 3]) that $\mathrm{R}^p_{k\text{-tt}}(\mathrm{NP})$ can handle exactly k mind changes.

LEMMA 3.5. *The class* $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$ *can handle exactly* m *mind changes, where*

$$m = \begin{cases} j + 2k - 1 & \text{if } j \text{ is even and } k \text{ is odd,} \\ j + 2k & \text{otherwise.} \end{cases}$$

Proof. We first consider the case in which j is even and k is odd.

We want to argue that for every $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$ machine M and every $x \in \Sigma^*$, on every ascending path in the $j + 2k$-dimensional, appropriately labeled hypercube $H_M(x)$ there are at most $j+2k-1$ mind changes. Let $x \in \Sigma^*$ and M be a $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$ machine with the oracles A and B. Due to Facts 3.3 and 3.2, it suffices to consider a $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$ machine M with one of the four previously mentioned acceptance schemes on input x and to show that every path p having the introduced description loses at least one mind change. Let $M(x)$ be such a machine and p be such a path. There are two possibilities.

Case A. The description of p contains an e_2-loss or an e_3-loss.
According to Fact 3.4, p loses at least one mind change.

Case B. The description of p contains neither an e_2-loss nor an e_3-loss.
Hence the description of p consists of blocks of consecutive e_2's and e_3's separated by blocks of e_1's. Since the description of p contains k e_3's and k is odd, there is a block of e_3's of odd size in p. Since we have no e_3-loss and j is even, this block is surrounded by e_1's. Thus we have an odd episode in the description of p and, according to Fact 3.4, p loses a mind change.

So no $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$ machine can realize more than $j + 2k - 1$ mind changes.

It remains to show that there is a deterministic $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$ machine and an input $x \in \Sigma^*$ such that in the associated hypercube $H_M(x)$ there is a path having exactly $j + 2k - 1$ mind changes.

Let us consider the path p_0,

$$p_0 = (\underbrace{e_2, e_2, \ldots, e_2}_{k}, \underbrace{e_1, e_1, \ldots, e_1}_{j-1}, \underbrace{e_3, e_3, \ldots, e_3}_{k}, e_1).$$

Consider the deterministic oracle machine W that asks two sequential queries and accepts an input x if and only if the second query of $W(x)$ was answered "yes" (acceptance scheme (3)). We know as was just shown that all ascending paths of $H_W(x)$ have at most $j + 2k - 1$ mind changes. Note that for every $x \in \Sigma^*$ the path p_0 loses only one mind change and thus $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$ can handle exactly $j + 2k - 1$ mind changes.

This completes the proof of the case "j is even and k is odd." We now turn to the "j is odd or k is even" case of the lemma being proven.

Since our hypercube has (in all cases) $j + 2k$ dimensions, certainly $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$ can handle (in all cases) no more than $j + 2k$ mind changes.

If j is odd, we consider the path

$$p_1 = (\underbrace{e_2, e_2, \ldots, e_2}_{k}, \underbrace{e_1, e_1, \ldots, e_1}_{j}, \underbrace{e_3, e_3, \ldots, e_3}_{k})$$

and—using the acceptance scheme numbering introduced just after Fact 3.3—we consider the machine having for every input x acceptance scheme (3) or (1) for k odd or even, respectively. If j is even and k is even, we consider path p_0 and we consider the machine having acceptance scheme (1) for every input.

In each of these cases the considered machine changes its mind along the associated path exactly $j+2k$ times. Hence for j odd or k even the class $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$ can handle exactly $j+2k$ mind changes. □

Now we are ready to prove our main theorem of this section.

THEOREM 3.6. *For $j,k \geq 1$,*

$$\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]} = \begin{cases} \mathrm{R}^p_{j+2k-1\text{-}tt}(\mathrm{NP}) & \text{if } j \text{ is even and } k \text{ is odd,} \\ \mathrm{R}^p_{j+2k\text{-}tt}(\mathrm{NP}) & \text{otherwise.} \end{cases}$$

Proof. In order to avoid unnecessary case distinctions we prove the fact for arbitrary j and k and simply denote the appropriate number of mind changes by m, namely (see Lemma 3.5), $j+2k-1$ if j is even and k is odd and $j+2k$ otherwise. First we would like to show that $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]} \subseteq \mathrm{R}^p_{m\text{-}\mathrm{tt}}(\mathrm{NP})$. We show this by explicitly giving the appropriate truth-table reduction.

Let $A \in \mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$ and let m be the number of mind changes (according to Lemma 3.5) the class $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$ can handle. Let M be a deterministic oracle machine, witnessing $A \in \mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$, via the sets $S_1 \in \mathrm{BH}_j$ and $S_2 \in \mathrm{BH}_k$. As noted by Beigel [3], the set $Q = \{\langle x,k\rangle \mid M(x) \text{ has at least } k \text{ mind changes}\}$ is an NP set. Note that if $M^{S_1[1]:S_2[1]}(x)$ on a particular input x rejects (respectively, accepts) if both queries have the answer "no," then $M^{S_1[1]:S_2[1]}(x)$ accepts if and only if the node (of the implicit hypercube) associated with the actual answers has an odd (respectively, even) number of mind changes.

Define the variables $o, y_1, y_2, \ldots, y_m$ and the m-ary boolean function α:

$o = 0$ if $M^{S_1[1]:S_2[1]}(x)$ rejects if both queries are answered "no,"

$o = 1$ if $M^{S_1[1]:S_2[1]}(x)$ accepts if both queries are answered "no,"

$$\begin{aligned} y_1 &= \langle x,1\rangle, \\ y_2 &= \langle x,2\rangle, \\ y_3 &= \langle x,3\rangle, \\ &\vdots \\ y_m &= \langle x,m\rangle, \quad \text{and} \end{aligned}$$

$$\alpha(z_1,z_2,\ldots,z_m) = 1 \iff (\max\{l \mid z_l = 1\} + o) \equiv 1 \pmod 2.$$

Clearly we can compute the just defined variables for a given x and also evaluate the function α at $(\chi_Q(y_1),\chi_Q(y_2),\ldots,\chi_Q(y_m))$ in polynomial time. And, finally, we have $x \in A \iff \alpha(\chi_Q(y_1),\chi_Q(y_2),\ldots,\chi_Q(y_m)) = 1$. Thus $A \in \mathrm{R}^p_{m\text{-}\mathrm{tt}}(\mathrm{NP})$.

It remains to show that $\mathrm{R}^p_{m\text{-}\mathrm{tt}}(\mathrm{NP}) \subseteq \mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$. Recall $\mathrm{R}^p_{k\text{-}\mathrm{tt}}(\mathrm{NP}) = \mathrm{R}^p_{1\text{-}\mathrm{tt}}(\mathrm{BH}_k)$ from Lemma 3.1. Since the class $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$ is closed under $\leq^p_{1\text{-}\mathrm{tt}}$ reductions it suffices to prove $\mathrm{BH}_m \subseteq \mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$.

So let $B \in \mathrm{BH}_m$. Following Cai et al. [10] we may assume that the set B is of the form $B = B_1 - (B_2 - (B_3 - (\cdots - (B_{m-1} - B_m)\cdots)))$ with $B_1, B_2, \ldots, B_m \in \mathrm{NP}$ and $B_m \subseteq \cdots \subseteq B_2 \subseteq B_1$.

We show $B \in \mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$ by using ideas of the second part of the proof of Lemma 3.5, namely by implementing the specific good path p_0, respectively p_1. B is accepted by a $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$ machine M as follows:

Case 1. j is odd.

Define the two oracle sets O_1 and O_2:

$O_1 = B_{k+1} - (B_{k+2} - (\cdots - (B_{k+j-1} - B_{k+j})\cdots))$, and

$$O_2 = \{\langle y, 2\rangle \mid y \in B_1 - (B_2 - (\cdots - (B_{k-1} - B_k)\cdots))\}$$
$$\cup\{\langle y, 3\rangle \mid y \in B_{j+k+1} - (B_{j+k+2} - (\cdots - (B_{j+2k-1} - B_{j+2k})\cdots))\}.$$

Note that $O_1 \in \mathrm{BH}_j$ and $O_2 \in \mathrm{BH}_k$. On input x M first queries "$x \in O_1$." In case of a "no" answer $M(x)$ queries $\langle x, 2\rangle \in O_2$ and in case of a "yes"answer to the first query $M(x)$ asks $\langle x, 3\rangle \in O_2$.

Case 1.1. k is odd.

$M(x)$ accepts if and only if the second query is answered "yes."

Case 1.2. k is even.

$M(x)$ accepts if and only if exactly one of the two queries is answered "yes."

Case 2. j is even.

Define the two oracle sets O_1 and O_2:

$O_1 = B_{k+1} - (B_{k+2} - (\cdots - (B_{k+j-1} - B_m)\cdots))$, and

$$O_2 = \{\langle y, 2\rangle \mid y \in B_1 - (B_2 - (\cdots - (B_{k-1} - B_k)\cdots))\}$$
$$\cup\{\langle y, 3\rangle \mid y \in B_{j+k} - (B_{j+k+1} - (\cdots - (B_{m-2} - B_{m-1})\cdots))\}.$$

Note that $O_1 \in \mathrm{BH}_j$ and $O_2 \in \mathrm{BH}_k$. On input x M first queries "$x \in O_1$." In case of a "no" answer $M(x)$ queries $\langle x, 2\rangle \in O_2$ and in case of a "yes" answer to the first query $M(x)$ asks $\langle x, 3\rangle \in O_2$.

Case 2.1. k is odd.

$M(x)$ accepts if and only if the second query is answered "yes."

Case 2.2. k is even.

$M(x)$ accepts if and only if exactly one of the two queries is answered "yes." □

It is interesting to note which properties of NP are actually required in the above proof for the result to hold. The proof essentially rests on the fact that the key set Q (describing that, for given x and m, the $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$ machine M on input x has at least m mind changes) is an NP set. So considering an arbitrary underlying class $\mathcal{C}$, for proving $Q \in \mathcal{C}$ it suffices to note that Q is in the class $\exists^b \cdot \mathrm{R}^p_{\text{c-btt}}(\mathcal{C})$,[1] and to assume that $\mathcal{C}$ be closed under $\exists^b$ and conjunctive bounded truth-table reductions. Indeed, the $\exists^b$ quantifier describes that there is a path in the boolean hypercube $H_M(x)$, and via the $\leq^p_{\text{c-btt}}$-reduction it can be checked that this path is an ascending path and all the answers the vertices on that path claim to be "yes" answers indeed correspond to query strings that belong to the class $\mathcal{C}$. Similar observations have been stated in earlier papers [3, 5]. In terms of the present paper, note in particular that the assertion of Theorem 3.6 holds true for all classes $\mathcal{C}$ closed under union, intersection, and polynomial-time many-one reductions. $\mathrm{C}_=\mathrm{P}$, R, and FewP all have these closure properties, to name just a few examples. If the underlying class $\mathcal{C}$ is closed under polynomially bounded $\exists$ quantification and unbounded conjunctive truth-table reductions, it is not hard to see that this analysis can even be done safely up to the case of logarithmically bounded query classes, as the number of paths in the hypercube is polynomial and thus generates a polynomial-sized disjunction.

Theorem 3.6 allows us to derive a relationship between classes of the form $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$ and $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]_+}$. Classes of the latter form were studied in [1].

[1] Here, $\leq^p_{\text{c-btt}}$ denotes the conjunctive bounded truth-table reducibility, and for any class $\mathcal{K}$, $\exists^b \cdot \mathcal{K}$ is defined to be the class of languages A for which there exists a set $B \in \mathcal{K}$ and a constant bound m such that $x \in A$ if and only if there exists a string y of length at most m with $\langle x, y\rangle \in B$.

COROLLARY 3.7. *For every $j, k \geq 1$,*

$$\mathrm{R}^{p}_{1\text{-}tt}(\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]_+}) = \begin{cases} \mathrm{P}^{\mathrm{BH}_{j-1}[1]:\mathrm{BH}_k[1]} & \text{if } j \text{ is odd and } k \text{ is even,} \\ \mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]} & \text{otherwise.} \end{cases}$$

The proof is immediate by the results of Theorem 3.6 of this paper and Theorem 5.7 and Lemma 5.9 of [1].

From Theorem 3.6 we can immediately conclude that order matters for queries to the boolean hierarchy unless the boolean hierarchy itself collapses.

COROLLARY 3.8.

1. *If $(j = k) \vee (j$ is even and $k = j + 1)$, $1 \leq j \leq k$, then $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]} = \mathrm{P}^{\mathrm{BH}_k[1]:\mathrm{BH}_j[1]}$.*
2. *Unless the boolean hierarchy (and thus the polynomial hierarchy) collapses, for every $1 \leq j \leq k$, $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]} \neq \mathrm{P}^{\mathrm{BH}_k[1]:\mathrm{BH}_j[1]}$ unless $(j = k) \vee (j$ is even and $k = j + 1)$.*

The corollary holds, in light of the theorem, simply because the boolean hierarchy and the truth-table hierarchy are interleaved [25] in such a way that the boolean hierarchy levels are sandwiched between levels of the bounded-truth-table hierarchy, and thus if two different levels of the bounded-truth-table hierarchy are the same (say levels r and s, $r < s$), then some level (in particular, BH_{r+1}) of the boolean hierarchy is closed under complementation, and thus, by the downward separation property of the boolean hierarchy [10], the boolean hierarchy would collapse. Furthermore, Kadin [24] has shown that if the boolean hierarchy collapses then the polynomial hierarchy collapses, and Wagner [28, 29], Chang and Kadin [14], and Beigel, Chang, and Ogiwara [5] have improved the strength of this connection. The strongest known connection is: If $\mathrm{BH}_q = \mathrm{coBH}_q$, then $\mathrm{PH} = (\mathrm{P}^{\mathrm{NP}}_{(q-1)\text{-tt}})^{\mathrm{NP}}$ [5], where $(\mathrm{P}^{\mathrm{NP}}_{m\text{-tt}})^{\mathrm{NP}}$ denotes the class of languages accepted by P machines given m-truth-table access to an $\mathrm{NP}^{\mathrm{NP}}$ oracle and also given unlimited access to an NP oracle (note that $(\mathrm{P}^{\mathrm{NP}}_{1\text{-tt}})^{\mathrm{NP}}$ is equal to $\mathrm{P}^{\mathrm{NP}^{\mathrm{NP}}[1]:\mathrm{NP}}$ as leading NP queries can be absorbed into the $\mathrm{NP}^{\mathrm{NP}}$ query).

In light of this discussion, we can make more clear exactly what collapse is spoken of in the second part of the above corollary. In particular, the collapse of the polynomial hierarchy is (at least) to $(\mathrm{P}^{\mathrm{NP}}_{(k+2j)\text{-tt}})^{\mathrm{NP}}$.[2]

Note added in proof. A connection, stronger than that obtained in [5], between boolean and polynomial hierarchy collapses has very recently been obtained by Hemaspaandra, Hemaspaandra, and Hempel [33] and Reith and Wagner [34].

Of course, Theorem 3.6 applies far more generally. From it, for any j, k, j', and k', one can either immediately conclude equality, or can immediately conclude that the classes are not equal unless the polynomial hierarchy collapses to $(\mathrm{P}^{\mathrm{NP}}_{(\min(\alpha(j,k),\, \alpha(j',k')))\text{-tt}})^{\mathrm{NP}}$, where $\alpha(a, b)$ equals $a + 2b - 1$ if a is even and b is odd and $a + 2b$ otherwise.

The point of Theorem 3.6 is that from the even/odd structure of $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$ classes one can immediately tell their number of mind changes, and thus their strength, without having to do a separate, detailed, mind change analysis for each j and k pair. However, note that one can, via a time-consuming but mechanical procedure, analyze

[2] Although one level is gained by the $q - 1$ in the [5] connection between the boolean hierarchy and the polynomial hierarchy, one level is lost in the collapse of the boolean hierarchy that follows from a given collapse in the truth-table hierarchy. We speculate that it might be possible for the $k + 2j$ claim to be strengthened by one level by applying the [5] technique directly to the truth-table hierarchy.

almost any class with a query tree structure (namely, by looking at the full tree of possible queries and answers, and for each of the huge number of possible ways its leaves can each be labeled accept-reject compute the number of mind changes that labeling creates, and then look at the maximum over all these numbers). For example, one can quickly see that one query to DP followed by 4-tt access to NP yields exactly the languages in $\mathrm{R}^p_{10\text{-}\mathrm{tt}}(\mathrm{NP})$.

4. General case. In the previous section, we studied classes of the form $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$. We completely characterized them in terms of reducibility hulls of NP and noted that in this setting the order of access to different oracles matters quite a bit. What can be said about, for example, the class $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]:\mathrm{BH}_l[1]}$? Is it equal to $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1],\mathrm{BH}_l[1]}$? (We'll see that the answer is "no" in certain cases.) Even more generally, what can be said about the classes of languages that are accepted by deterministic oracle machines with tree-like query structures and with each query being made to a (potentially) different oracle from a (potentially) different level of the boolean hierarchy? Is it possible that with a more complicated query structure we might lose even more than the one mind change lost in the case of $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1]}$ with j even and k odd? (From the results of the section, it will be clear that the answer to this question is "yes"; mind changes can, in certain specific circumstances, accumulate.)

First , we can immediately derive a characterization of the class $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1],\mathrm{BH}_l[1]}$ from the results of the previous section, namely, we have Theorem 4.1.

THEOREM 4.1. *For $j,k,l \geq 1$,*

$$\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1],\mathrm{BH}_l[1]} = \begin{cases} \mathrm{R}^p_{j+k+l-1\text{-}tt}(\mathrm{NP}) & \text{if } j \text{ is even and } l \text{ is odd,} \\ \mathrm{R}^p_{j+k+l\text{-}tt}(\mathrm{NP}) & \text{otherwise.} \end{cases}$$

Proof. Note that in Lemma 3.5 we handle the special case of $k = l$. However, notice that the mind change loss for j even and k odd is due only to the fact that the query made after the first query is answered "yes" is made to an oracle from an odd level, namely, k, of the boolean hierarchy. In particular the mind change loss is not tied to the query we ask in case the first query is answered "no." Thus we have the following claim.

Claim. The class $\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1],\mathrm{BH}_l[1]}$ can handle exactly m mind changes where

$$m = \begin{cases} j+k+l-1 & \text{if } j \text{ is even and } l \text{ is odd,} \\ j+k+l & \text{otherwise.} \end{cases}$$

Similar to the proof of Theorem 3.6 one can now show the equality we claim. □

Note that for every $j,k,l \geq 1$, we obviously have

$$\mathrm{P}^{\mathrm{BH}_j[1]:\mathrm{BH}_k[1],\mathrm{BH}_l[1]} = \mathrm{P}^{\mathrm{R}^p_{1\text{-}\mathrm{tt}}(\mathrm{BH}_j)[1]:\mathrm{R}^p_{1\text{-}\mathrm{tt}}(\mathrm{BH}_k)[1],\mathrm{R}^p_{1\text{-}\mathrm{tt}}(\mathrm{BH}_l)[1]},$$

and thus the following corollary holds.

COROLLARY 4.2. *For $j,k,l \geq 1$,*

$$\mathrm{P}^{\mathrm{R}^p_{1\text{-}tt}(\mathrm{BH}_j)[1]:\mathrm{R}^p_{1\text{-}tt}(\mathrm{BH}_k)[1],\mathrm{R}^p_{1\text{-}tt}(\mathrm{BH}_l)[1]} = \begin{cases} \mathrm{R}^p_{j+k+l-1\text{-}tt}(\mathrm{NP}) & \text{if } j \text{ is even and } l \text{ is odd,} \\ \mathrm{R}^p_{j+k+l\text{-}tt}(\mathrm{NP}) & \text{otherwise.} \end{cases}$$

The last corollary is the key tool to use in evaluating any class of languages that is accepted by deterministic oracle machines with tree-like query structures and with

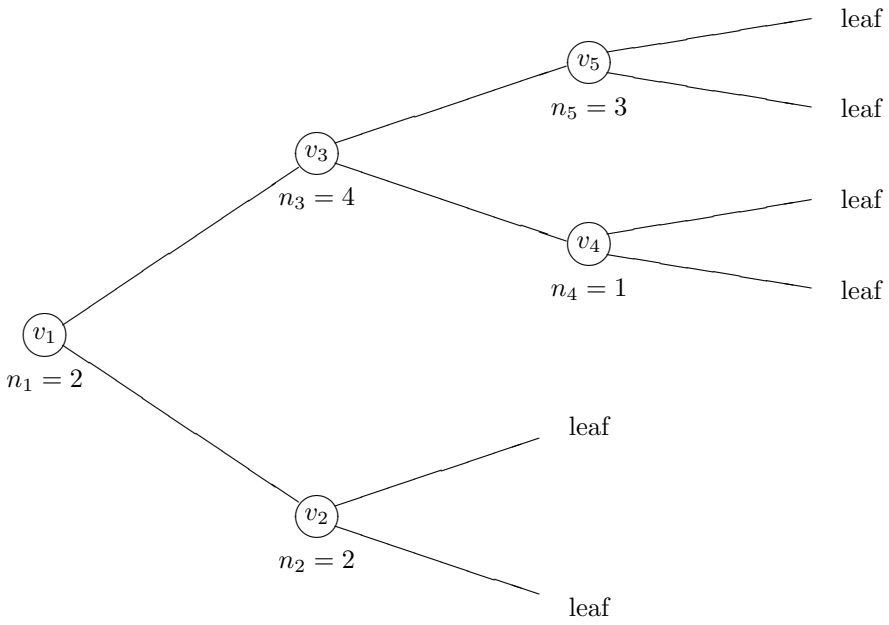

FIG. 1. *Tree* $\mathcal{T}$.

each query being made to a (potentially) different oracle from a (potentially) different level of the boolean hierarchy.

We formalize some notions to use in studying this. Let T be a binary tree, not necessarily complete, such that each internal node v_i (a) has exactly two children and (b) is labeled by a natural number n_i (whose purpose will be explained below). For such a tree T, define f_T by $f_T(v_i) = n_i$. Henceforward, we will write f for f_T in contexts in which T is clear. Let $root_T$ be the root of the tree (we will assign to this node the name v_1) and let LT_T and RT_T, respectively, be the left and right subtrees of the root. We will denote the class of sets that are accepted by a deterministic oracle machine with a T-like query structure by $\mathrm{P}^{(T)}$. Here the structure of the tree T gives the potential computation tree of every $\mathrm{P}^{(T)}$ machine in the sense that inductively if a query at node v is answered "no" ("yes") we keep on moving through the tree in the left (right) subtree of v. And at each internal node v_i of T the natural number n_i gives the level of the boolean hierarchy from which the oracle queried at that node is taken.

For example consider the tree $\mathcal{T}$ (see Figure 1), in which $f(v_1) = 2$, $f(v_2) = 2$, $f(v_3) = 4$, $f(v_4) = 1$, and $f(v_5) = 3$. A $\mathrm{P}^{(\mathcal{T})}$ machine works as follows. The first query is made to a DP oracle. If the answer to that first query is "no" a second query is made to the DP oracle associated with v_2, and if the answer to the first query is "yes" the second query is made to the BH_4 oracle associated with v_3. A third query is made only if the answer to the first query is "yes"; in this case, the oracle set of the third query is in NP if the answer to the second query is "no," and is in BH_3 if the answer to the second query is "yes." Note that for every input $x \in \Sigma^*$ every $\mathrm{P}^{(\mathcal{T})}$

machine $M(x)$ assigns a label A (Accept) or R (Reject) to each leaf of $\mathcal{T}$ with its own specific acceptance behavior (which, in particular, may depend on x).

If T is the complete tree of depth 1 (i.e., a root plus two leaves), then by definition $m(T) = f(root_T)$, and otherwise define

$$m(T) = \begin{cases} f(root_T) + m(LT_T) + m(RT_T) - 1 & \text{if } f(root_T) \equiv 0 \pmod 2 \text{ and} \\ & \quad m(RT_T) \equiv 1 \pmod 2, \\ f(root_T) + m(LT_T) + m(RT_T) & \text{otherwise.} \end{cases}$$

For our example tree $\mathcal{T}$ we have $m(\mathcal{T}) = 10$. The main theorem of this section will prove $m(T)$ determines the number of bounded truth-table accesses to NP that completely characterize the class $\mathrm{P}^{(T)}$. It follows from the main theorem that, for example, $\mathrm{P}^{(\mathcal{T})} = \mathrm{R}^p_{10\text{-tt}}(\mathrm{NP})$.

THEOREM 4.3. $\mathrm{P}^{(T)} = \mathrm{R}^p_{m(T)\text{-}tt}(\mathrm{NP})$.

Proof. The proof consists of an obvious induction over the depth d of the tree. Note that the correctness of the base case of the induction, $d = 2$, is given by Theorem 4.1. The proof of the inductive step follows immediately from the obvious fact that

$$\mathrm{P}^{(T)} = \mathrm{P}^{\mathrm{BH}_{f(root_T)}:\mathrm{P}^{(LT_T)},\mathrm{P}^{(RT_T)}},$$

combined with Lemma 3.1 ($\mathrm{R}^p_{k\text{-tt}}(\mathrm{NP}) = \mathrm{R}^p_{1\text{-tt}}(\mathrm{BH}_k)$) and Corollary 4.2. □

Finally, we mention that a study of query order in the polynomial hierarchy (as opposed to the boolean hierarchy) has very recently been initiated by E. Hemaspaandra, L. Hemaspaandra, and H. Hempel ([19]; see also [31, 4]) and this study has led to a somewhat surprising downward translation result: for $k > 2$, $\Sigma^p_k = \Pi^p_k \iff \mathrm{P}^{\Sigma^p_k[1]} = \mathrm{P}^{\Sigma^p_k[2]}$ ([16]; see also the extensions obtained in [8, 20]). Query order (see also the survey [17]) has also recently proven useful in studying the structure of complete sets [18] and in characterizing bottleneck-computation classes [23].

Acknowledgments. We thank Edith Hemaspaandra, Johannes Köbler, and Jörg Vogel for helpful conversations. We thank Johannes Köbler for providing an advance copy of [15]. We are extremely indebted to Jörg Rothe for his generous help. The insights of the paragraph after the proof of Theorem 3.6 are due to him and appear here with his kind permission. He also made countless invaluable suggestions throughout this project and proofread an earlier version of this paper. We also are deeply grateful to editor Ker-I Ko and two anonymous referees for their invaluable suggestions regarding the organization of the paper and a very nice proof simplification for section 4.

FINDING THE k SHORTEST PATHS*

DAVID EPPSTEIN†

Abstract. We give algorithms for finding the k shortest paths (not required to be simple) connecting a pair of vertices in a digraph. Our algorithms output an implicit representation of these paths in a digraph with n vertices and m edges, in time $O(m + n \log n + k)$. We can also find the k shortest paths from a given source s to each vertex in the graph, in total time $O(m+n \log n+kn)$. We describe applications to dynamic programming problems including the knapsack problem, sequence alignment, maximum inscribed polygons, and genealogical relationship discovery.

Key words. shortest paths, network programming, path enumeration, near-optimal solutions, dynamic programming, knapsack problem, sequence alignment, inscribed polygon, genealogy

1. Introduction.

We consider a long-studied generalization of the shortest path problem, in which not one but several short paths must be produced. The *k-shortest-paths problem* is to list the k paths connecting a given source-destination pair in the digraph with minimum total length. Our techniques also apply to the problem of listing all paths shorter than some given threshold length. In the version of these problems studied here, cycles of repeated vertices are allowed. We first present a basic version of our algorithm, which is simple enough to be suitable for practical implementation while losing only a logarithmic factor in time complexity. We then show how to achieve optimal time (constant time per path once a shortest path tree has been computed) by applying Frederickson's [26] algorithm for finding the minimum k elements in a *heap-ordered tree*.

1.1. Applications.

The applications of shortest path computations are too numerous to cite in detail. They include situations in which an actual path is the desired output, such as robot motion planning, highway and power line engineering, and network connection routing. They include problems of scheduling such as critical path computation in PERT charts. Many optimization problems solved by dynamic programming or more complicated matrix searching techniques, such as the knapsack problem, sequence alignment in molecular biology, construction of optimal inscribed polygons, and length-limited Huffman coding, can be expressed as shortest path problems.

Methods for finding k shortest paths have been applied to many of these applications, for several reasons.

- *Additional constraints.* One may wish to find a path that satisfies certain constraints beyond having a small length, but those other constraints may be ill defined or hard to optimize. For instance, in power transmission route selection [18], a power line should connect its endpoints reasonably directly, but there may be more or less community support for one option or another. A typical solution is to compute several short paths and then choose among

†Department of Information and Computer Science, University of California, Irvine, CA 92697-3425 (eppstein@ics.uci.edu, http://www.ics.uci.edu/~eppstein).

them by considering the other criteria. We recently implemented a similar technique as a heuristic for the NP-hard problem of, given a graph with colored edges, finding a shortest path using each color at most once [20]. This type of application is the main motivation cited by Dreyfus [17] and Lawler [39] for k-shortest-path computations.

- *Model evaluation.* Paths may be used to model problems that have known solutions, independent of the path formulation; for instance, in a k-shortest-path model of automatic translation between natural languages [30], a correct translation can be found by a human expert. By listing paths until this known solution appears, one can determine how well the model fits the problem, in terms of the number of incorrect paths seen before the correct path. This information can be used to tune the model as well as to determine the number of paths that need to be generated when applying additional constraints to search for the correct solution.
- *Sensitivity analysis.* By computing more than one shortest path, one can determine how sensitive the optimal solution is to variation of the problem's parameters. In biological sequence alignment, for example, one typically wishes to see several "good" alignments rather than one optimal alignment; by comparing these several alignments, biologists can determine which portions of an alignment are most essential [8, 64]. This problem can be reduced to finding several shortest paths in a grid graph.
- *Generation of alternatives.* It may be useful to examine not just the optimal solution to a problem but a larger class of solutions, to gain a better understanding of the problem. For example, the states of a complex system might be represented as a finite state machine, essentially just a graph, with different probabilities on each state transition edge. In such a model, one would likely want to know not just the chain of events most likely to lead to a failure state but rather all chains having a failure probability over some threshhold. Taking the logarithms of the transition probabilities transforms this problem into one of finding all paths shorter than a given length.

We later discuss in more detail some of the dynamic programming applications listed above and show how to find the k best solutions to these problems by using our shortest path algorithms. As well as improving previous solutions to the general k-shortest-paths problem, our results improve more specialized algorithms for finding length-bounded paths in the grid graphs arising in sequence alignment [8] and for finding the k best solutions to the knapsack problem [15].

1.2. New results. We prove the following results. In all cases we assume we are given a digraph in which each edge has a nonnegative length. We allow the digraph to contain self-loops and multiple edges. In each case the paths are output in an implicit representation from which simple properties such as the length are available in constant time per path. We may explicitly list the edges in any path in time proportional to the number of edges.

- We find the k shortest paths (allowing cycles) connecting a given pair of vertices in a digraph in time $O(m + n \log n + k)$.
- We find the k shortest paths from a given source in a digraph to each other vertex in time $O(m + n \log n + kn)$.

We can also solve the similar problem of finding all paths shorter than a given length, with the same time bounds. The same techniques apply to digraphs with negative edge lengths but no negative cycles, but the time bounds above should be

modified to include the time to compute a single source shortest path tree in such networks, $O(mn)$ [6, 23] or $O(mn^{1/2} \log N)$ where all edge lengths are integers and N is the absolute value of the most negative edge length [29]. For a directed acyclic graph (DAG), with or without negative edge lengths, shortest path trees can be constructed in linear time and the $O(n \log n)$ term above can be omitted. The related problem of finding the k longest paths in a DAG [4] can be transformed to a shortest path problem simply by negating all edge lengths; we can therefore also solve it in the same time bounds.

1.3. Related work. Many papers study algorithms for k shortest paths [3, 5, 7, 9, 13, 14, 17, 24, 31, 32, 34, 35, 37, 38, 39, 40, 41, 43, 44, 45, 47, 50, 51, 56, 57, 58, 59, 60, 63, 65, 66, 67, 68, 69]. Dreyfus [17] and Yen [69] cite several additional papers on the subject going back as far as 1957.

One must distinguish several common variations of the problem. In many of the papers cited above, the paths are restricted to be *simple*; i.e., no vertex can be repeated. This has advantages in some applications, but as our results show this restriction seems to make the problem significantly harder. Several papers [3, 13, 17, 24, 41, 42, 58, 59] consider the version of the k-shortest-paths problem in which repeated vertices are allowed, and it is this version that we also study. Of course, for the DAGs that arise in many of the applications described above, including scheduling and dynamic programming, no path can have a repeated vertex and the two versions of the problem become equivalent. Note also that in the application described earlier of listing the most likely failure paths of a system modelled by a finite state machine, it is the version studied here rather than the more common simple path version that one wants to solve.

One can also make a restriction that the paths found be edge disjoint or vertex disjoint [61] or include capacities on the edges [10, 11, 12, 49]; however, such changes turn the problem into one more closely related to network flow.

Fox [24] gives a method for the k-shortest-path problem based on Dijkstra's algorithm, which with more recent improvements in priority queue data structures [27] takes time $O(m + kn \log n)$; this seems to be the best previously known k-shortest-paths algorithm. Dreyfus [17] mentions the version of the problem in which we must find paths from one source to each other vertex in the graph, and describes a simple $O(kn^2)$ time dynamic programming solution to this problem. For the k-shortest-simple-paths problem, the best known bound is $O(k(m + n \log n))$ in undirected graphs [35] or $O(kn(m + n \log n))$ in directed graphs ([39], again including more recent improvements in Dijkstra's algorithm). Thus all previous algorithms took time $O(n \log n)$ or more per path. We improve this to constant time per path.

A similar problem to the one studied here is that of finding the k minimum weight spanning trees in a graph. Recent algorithms for this problem [22, 21, 25] reduce it to finding the k minimum weight nodes in a *heap-ordered tree*, defined using the *best swap* in a sequence of graphs. Heap-ordered tree selection has also been used to find the smallest interpoint distances or the nearest neighbors in geometric point sets [16]. We apply a similar tree selection technique to the k-shortest-path problem; however, the reduction of k shortest paths to heap-ordered trees is very different from the constructions in these other problems.

2. The basic algorithm. Finding the k shortest paths between two terminals s and t has been a difficult enough problem to warrant much research. In contrast, the similar problem of finding paths with only one terminal s, ending anywhere in the graph, is much easier: one can simply use breadth first search. Maintain a priority

queue of paths, initially containing the single zero-edge path from s to itself; then repeatedly remove the shortest path from the priority queue, add it to the list of output paths, and add all one-edge extensions of that path to the priority queue. If the graph has bounded degree d, a breadth first search from s until k paths are found takes time $O(dk + k \log k)$; note that this bound does not depend in any way on the overall size of the graph. If the paths need not be output in order by length, Frederickson's heap selection algorithm [26] can be used to speed this up to $O(dk)$.

The main idea of our k-shortest-paths algorithm, then, is to translate the problem from one with two terminals, s and t, to a problem with only one terminal. One can find paths from s to t simply by finding paths from s to any other vertex and concatenating a shortest path from that vertex to t. However, we cannot simply apply this idea directly, for several reasons: (1) There is no obvious relation between the ordering of the paths from s to other vertices and the ordering of the corresponding paths from s to t. (2) Each path from s to t may be represented in many ways as a path from s to some vertex followed by a shortest path from that vertex to t. (3) Our input graph may not have bounded degree.

In outline, we deal with problem (1) by using a potential function to modify the edge lengths in the graph so that the length of any shortest path to t is zero; therefore concatenating such paths to paths from s will preserve the ordering of the path lengths. We deal with problem (2) by considering only paths from s in which the last edge is not in a fixed shortest path tree to t; this leads to the implicit representation we use to represent each path in constant space. (Ideas similar to these appear also in [46].) However, this solution gives rise to a fourth problem: (4) We do not wish to spend much time searching edges of the shortest path tree, as this time can not be charged against newly found s-t paths.

The heart of our algorithm is the solution to problems (3) and (4). Our idea is to construct a binary heap for each vertex, listing the edges that are not part of the shortest path tree and that can be reached from that vertex by shortest-path-tree edges. In order to save time and space, we use persistence techniques to allow these heaps to share common structures with each other. In the basic version of the algorithm, this collection of heaps forms a bounded-degree graph having $O(m+n \log n)$ vertices. Later we show how to improve the time and space bounds of this part of the algorithm using tree decomposition techniques of Frederickson [25].

2.1. Preliminaries. We assume throughout that our input graph G has n vertices and m edges. We allow self-loops and multiple edges, so m may be larger than $\binom{n}{2}$. The *length* of an edge e is denoted $\ell(e)$. By extension we can define the length $\ell(p)$ for any path in G to be the sum of its edge lengths. The *distance* $d(s,t)$ for a given pair of vertices is the length of the shortest path starting at s and ending at t; with the assumption of no negative cycles, this is well defined. Note that $d(s,t)$ may be unequal to $d(t,s)$. The two endpoints of a directed edge e are denoted *tail*(e) and *head*(e); the edge is directed from *tail*(e) to *head*(e).

For our purposes, a *heap* is a binary tree in which vertices have weights, satisfying the restriction that the weight of any vertex is less than or equal to the minimum weight of its children. We will not always care whether the tree is balanced (and in some circumstances we will allow trees with infinite depth). More generally, a *D-heap* is a degree-D tree with the same weight-ordering property; thus the usual heaps above are 2-heaps. As is well known (e.g., see [62]), any set of values can be placed into a balanced heap by the *heapify* operation in linear time. In a balanced heap, any new element can be inserted in logarithmic time. We can list the elements of a heap in

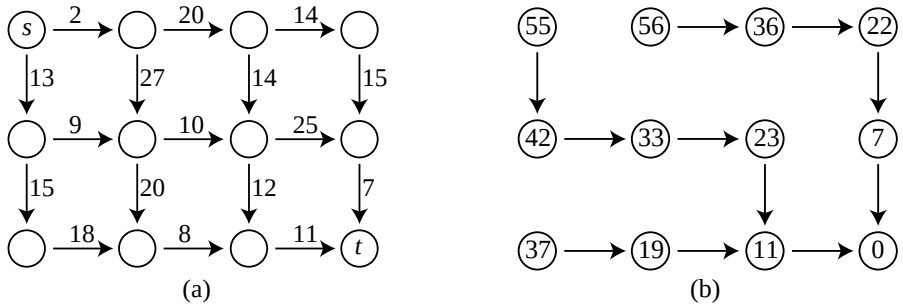

FIG. 1. (a) *Example digraph G with edge lengths and specified terminals;* (b) *shortest path tree T and distances to t in G.*

order by weight, taking logarithmic time to generate each element, simply by using breadth first search.

2.2. Implicit representation of paths. As discussed earlier, our algorithm does not output each path it finds explicitly as a sequence of edges; instead it uses an implicit representation, described in this section.

The ith shortest path in a digraph may have $\Omega(ni)$ edges, so the best time we could hope for in an explicit listing of shortest paths would be $O(k^2n)$. Our time bounds are faster than this, so we must use an implicit representation for the paths. However, our representation is not a serious obstacle to use of our algorithm: we can list the edges of any path we output in time proportional to the number of edges, and simple properties (such as the length) are available in constant time. Similar implicit representations have previously been used for related problems such as the k minimum weight spanning trees [22, 21, 25]. Further, previous papers on the k-shortest-path problem give time bounds omitting the $O(k^2n)$ term above, so these papers must tacitly or not be using an implicit representation.

Our representation is similar in spirit to those used for the k minimum weight spanning trees problem: for that problem, each successive tree differs from a previously listed tree by a *swap*, the insertion of one edge and removal of another edge. The implicit representation consists of a pointer to the previous tree and a description of the swap. For the shortest path problem, each successive path will turn out to differ from a previously listed path by the inclusion of a single edge not part of a shortest path tree and appropriate adjustments in the portion of the path that involves shortest path tree edges. Our implicit representation consists of a pointer to the previous path, and a description of the newly added edge.

Given s and t in a digraph G (Figure 1(a)), let T be a single-destination shortest path tree with t as destination (Figure 1(b); this is the same as a single source shortest path tree in the graph G^R formed by reversing each edge of G). We can compute T in time $O(m + n \log n)$ [27]. We denote by $next_T(v)$ the next vertex reached after v on the path from v to t in T.

Given an edge e in G, define

$$\delta(e) = \ell(e) + d(head(e), t) - d(tail(e), t).$$

Intuitively, $\delta(e)$ measures how much distance is lost by being "sidetracked" along e instead of taking a shortest path to t. The values of δ for our example graph are shown in Figure 2(a).

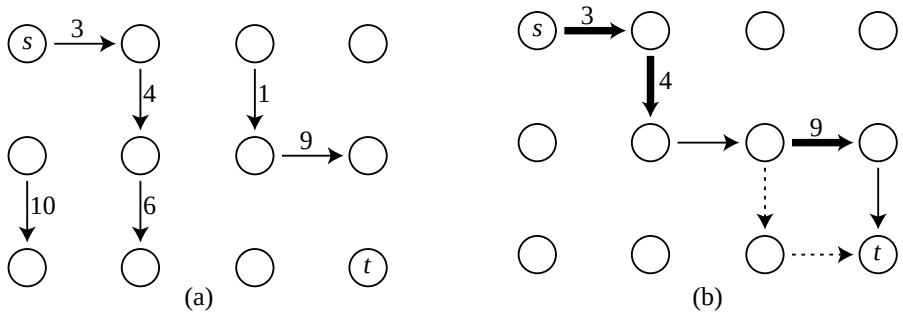

FIG. 2. (a) *Edges in $G-T$ labeled by $\delta(e)$ ($\delta(e)=0$ for edges in T);* (b) *path p, sidetracks(p) (the heavy edges, labeled* 3, 4, *and* 9*), and prefpath(p) (differing from p in the two dashed edges; sidetracks(prefpath(p)) consists of the two edges labeled* 3 *and* 4*).*

LEMMA 1. *For any $e \in G$, $\delta(e) \geq 0$. For any $e \in T$, $\delta(e) = 0$.*

For any path p in G, formed by a sequence of edges, some edges of p may be in T, and some others may be in $G-T$. Any path p from s to t is uniquely determined solely by the subsequence *sidetracks*(p) of its edges in $G-T$ (Figure 2(b)). For, given a pair of edges in the subsequence, there is a uniquely determined way of inserting edges from T so that the head of the first edge is connected to the tail of the second edge. As an example, the shortest path in T from s to t is represented by the empty sequence. A sequence of edges in $G-T$ may not correspond to any s-t path, if it includes a pair of edges that cannot be connected by a path in T. If $S = \mathit{sidetracks}(p)$, we define *path*($S$) to be the path p.

Our implicit representation will involve these sequences of edges in $G-T$. We next show how to recover $\ell(p)$ from information in *sidetracks*(p).

For any nonempty sequence S of edges in $G-T$, let *prefix*(S) be the sequence formed by the removal of the last edge in S. If $S = \mathit{sidetracks}(p)$, then we denote this last sidetrack edge by *lastsidetrack*(p); *prefix*(S) will define a path *prefpath*(p) = *path*(*prefix*(S)) (Figure 2(b)).

LEMMA 2. *For any path p from s to t,*

$$\ell(p) = d(s,t) + \sum_{e \in \mathit{sidetracks}(p)} \delta(e) = d(s,t) + \sum_{e \in p} \delta(e).$$

LEMMA 3. *For any path p from s to t in G, for which sidetracks(p) is nonempty, $\ell(p) \geq \ell(\mathit{prefpath}(p))$.*

Our representation of a path p in the list of paths produced by our algorithm will then consist of two components:

- the position in the list of *prefpath*(p).
- edge *lastsidetrack*(p).

Although the final version of our algorithm, which uses Frederickson's heap selection technique, does not necessarily output paths in sorted order, we will nevertheless be able to guarantee that *prefpath*(p) is output before p. One can easily recover p itself from our representation in time proportional to the number of edges in p. The length $\ell(p)$ for each path can easily be computed as $\delta(\mathit{lastsidetrack}(p)) + \ell(\mathit{prefpath}(p))$. We will see later that we can also compute many other simple properties of the paths in constant time per path.

2.3. Representing paths by a heap. The representation of s-t paths discussed in the previous section gives a natural tree of paths, in which the parent of any path p

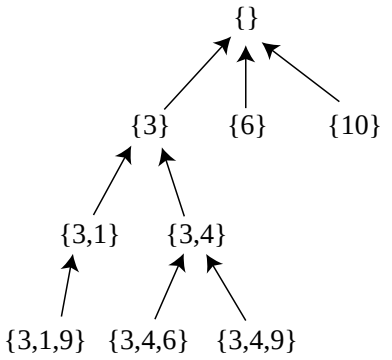

FIG. 3. *Tree of paths, labeled by sidetracks(p).*

is *prefpath*(*p*) (Figure 3). The degree of any node in this *path tree* is at most m, since there can be at most one child for each possible value of *lastsidetrack*(*p*). The possible values of *lastsidetrack*(*q*) for paths q that are children of p are exactly those edges in $G-T$ that have tails on the path from *head*(*lastsidetrack*(*p*)) to t in the shortest path tree T.

If G contains cycles, the path tree is infinite. By Lemma 3, the path tree is heap-ordered. However, since its degree is not necessarily constant, we cannot directly apply breadth first search (nor Frederickson's heap selection technique, described later in Lemma 8) to find its k minimum values. Instead we form a heap by replacing each node p of the path tree with an equivalent bounded-degree subtree (essentially, a heap of the edges with tails on the path from *head*(*lastsidetrack*(*p*)) to t, ordered by $\delta(e)$). We must also take care that we do this in such a way that the portion of the path tree explored by our algorithm can be easily constructed.

For each vertex v we wish to form a heap $H_G(v)$ for all edges with tails on the path from v to t, ordered by $\delta(e)$. We will later use this heap to modify the path tree by replacing each node p with a copy of $H_G(\mathit{head}(\mathit{lastsidetrack}(p)))$.

Let *out*(v) denote the edges in $G-T$ with tails at v (Figure 4(a)). We first build a heap $H_{out}(v)$ for each vertex v of the edges in *out*(v) (Figure 4(b)). The weights used for the heap are simply the values $\delta(e)$ defined earlier. $H_{out}(v)$ will be a 2-heap with the added restriction that the root of the heap only has one child. It can be built for each v in time $O(|\mathit{out}(v)|)$ by letting the root *outroot*(v) be the edge minimizing $\delta(e)$ in *out*(v) and letting its child be a heap formed by heapification of the rest of the edges in *out*(v). The total time for this process is $\sum O(|\mathit{out}(v)|) = O(m)$.

We next form the heap $H_G(v)$ by merging all heaps $H_{out}(w)$ for w on the path in T from v to t. More specifically, for each vertex v we merge $H_{out}(v)$ into $H_G(\mathit{next}_T(v))$ to form $H_G(v)$. We will continue to need $H_G(\mathit{next}_T(v))$, so this merger should be done in a persistent (nondestructive) fashion.

We guide this merger of heaps using a balanced heap $H_T(v)$ for each vertex v, containing only the roots *outroot*(w) of the heaps $H_{out}(w)$, for each w on the path from v to t. $H_T(v)$ is formed by inserting *outroot*(v) into $H_T(\mathit{next}_T(v))$ (Figure 5(a)). To perform this insertion persistently, we create new copies of the nodes on the path updated by the insertion (marked by asterisks in Figure 5(a)), with appropriate pointers to the other, unchanged members of $H_T(\mathit{next}_T(v))$. Thus we can store $H_T(v)$ without changing $H_T(\mathit{next}_T(v))$ by using an additional $O(\log n)$ words of memory to store only the nodes on that path.

We now form $H_G(v)$ by connecting each node *outroot*(w) in $H_T(v)$ to an additional

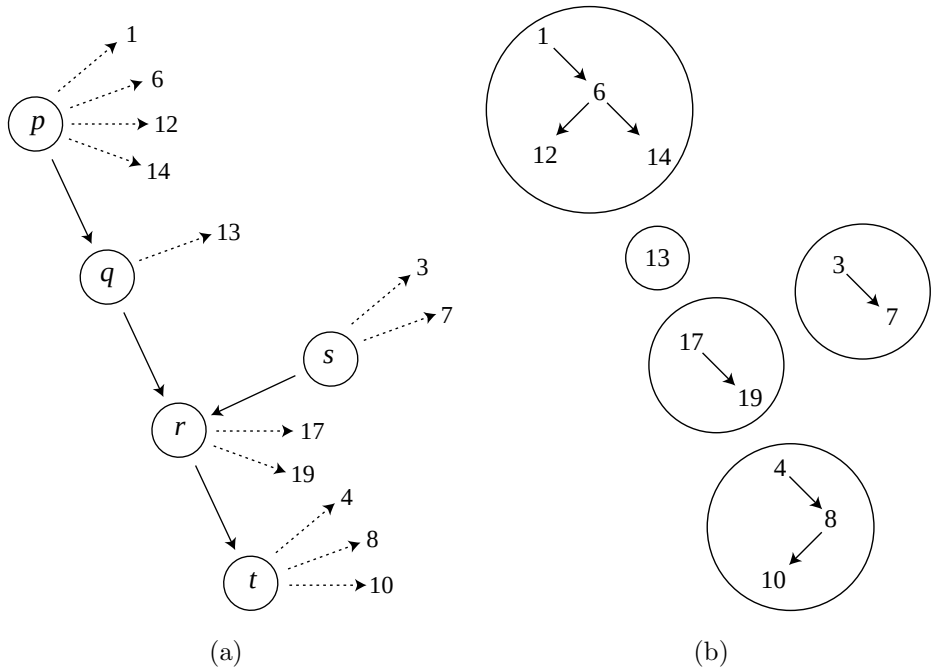

FIG. 4. (a) *Portion of a shortest path tree, showing out*(v) *and corresponding values of* δ*;* (b) $H_{out}(v)$.

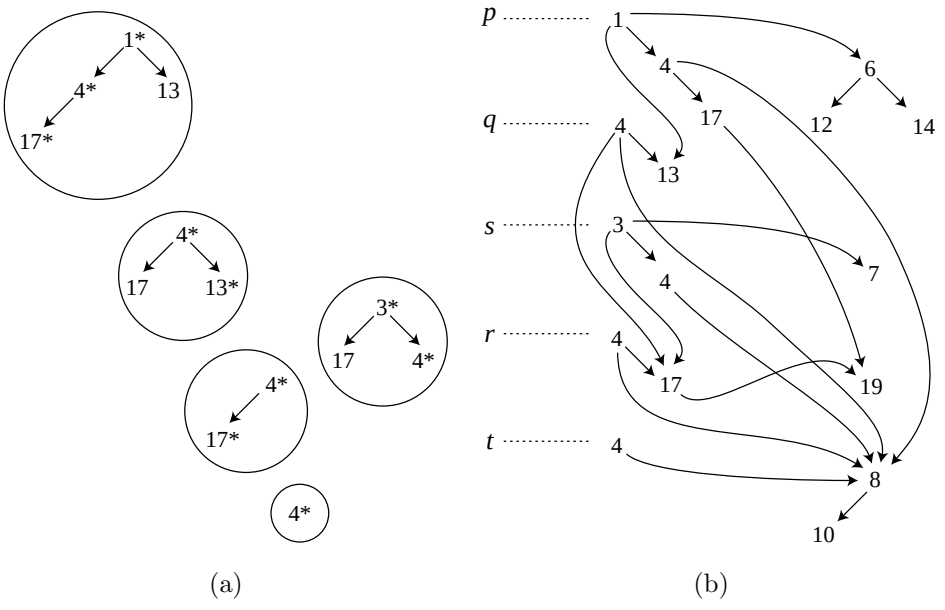

FIG. 5. (a) $H_T(v)$ *with asterisks marking path of nodes updated by insertion of outroot*(v) *into* $H_T(next_T(v))$*;* (b) $D(G)$ *has a node for each marked node in Figure* 5(a) *and each nonroot node in Figure* 4(b).

subtree beyond the two it points to in $H_T(v)$, namely, to the rest of heap $H_{out}(w)$.

$H_G(v)$ can be constructed at the same time as we construct $H_T(v)$, with a similar amount of work. $H_G(v)$ is thus a 3-heap, as each node includes at most three children, either two from $H_T(v)$ and one from $H_{out}(w)$ or none from $H_T(v)$ and two from $H_{out}(w)$.

We summarize the construction so far in a form that emphasizes the shared structure in the various heaps $H_G(v)$.

LEMMA 4. *In time $O(m + n \log n)$ we can construct a DAG $D(G)$ and a map from vertices $v \in G$ to $h(v) \in D(G)$, with the following properties:*

- *$D(G)$ has $O(m + n \log n)$ vertices.*
- *Each vertex in $D(G)$ corresponds to an edge in $G - T$.*
- *Each vertex in $D(G)$ has out-degree at most 3.*
- *The vertices reachable in $D(G)$ from $h(v)$ form a 3-heap $H_G(v)$ in which the vertices of the heap correspond to edges of $G - T$ with tails on the path in T from v to t, in heap order by the values of $\delta(e)$.*

Proof. The vertices in $D(G)$ come from two sources: heaps $H_{out}(v)$ and $H_T(v)$. Each node in $H_{out}(v)$ corresponds to a unique edge in $G - T$, so there are at most $m - n + 1$ nodes coming from heaps $H_{out}(v)$. Each vertex of G also contributes $\lfloor \log_2 i \rfloor$ nodes from heaps $H_T(v)$, where i is the length of the path from the vertex to t, $1 + \lfloor \log_2 i \rfloor$ measures the number of balanced binary heap nodes that need to be updated when inserting $outroot(v)$ into $H_T(next_T(v))$, and we subtract one because $outroot(v)$ itself was already included in our total for $H_{out}(v)$. In the worst case, T is a path and the total contribution is at most $\sum_i \lfloor \log_2 i \rfloor \le n \log_2 n - cn$, where c varies between roughly 1.91 and 2 depending on the ratio of n to the nearest power of two. Therefore the total number of nodes in $D(G)$ is at most $m + n \log_2 n - (c+1)n$. The degree bound follows from the construction, and it is straightforward to construct $D(G)$ as described above in constant time per node, after computing the shortest path tree T in time $O(m + n \log n)$ using Fibonacci heaps [27].

Map $h(v)$ simply takes v to the root of $H_G(v)$. For any vertex v in $D(G)$, let $\delta(v)$ be a shorthand for $\delta(e)$, where e is the edge in G corresponding to v. By construction, the nodes reachable from $h(v)$ are those in $H_T(v)$ together with, for each such node w, the rest of the nodes in $H_{out}(w)$; $H_T(v)$ was constructed to correspond exactly to the vertices on the path from v to t, and $H_{out}(w)$ represents the edges with tails at each vertex, so together these reachable nodes represent all edges with tails on the path. Each edge (u, v) in $D(G)$ corresponds to an edge either in some $H_T(w)$ or in some $H_{out}(w)$, and in either case the heap ordering for $D(G)$ is a consequence of the ordering in these smaller heaps. □

$D(G)$ is shown in Figure 5(b). The nodes reachable from s in $D(G)$ form a structure $H_G(s)$ representing the paths differing from the original shortest path by the addition of a single edge in $G - T$. We now describe how to augment $D(G)$ with additional edges to produce a graph which can represent all s-t paths, not just those paths with a single edge in $G - T$.

We define the *path graph* $P(G)$ as follows. The vertices of $P(G)$ are those of $D(G)$, with one additional vertex, the *root* $r = r(s)$. The vertices of $P(G)$ are unweighted, but the edges are given lengths. For each directed edge (u, v) in $D(G)$, we create the edge between the corresponding vertices in $P(G)$, with length $\delta(v) - \delta(u)$. We call such edges *heap edges*. For each vertex v in $P(G)$, corresponding to an edge in $G - T$ connecting some pair of vertices u and w, we create a new edge from v to $h(w)$ in $P(G)$, having as its length $\delta(h(w))$. We call such edges *cross edges*. We also create

an *initial edge* between r and $h(s)$, having as its length $\delta(h(s))$.

$P(G)$ has $O(m + n \log n)$ vertices, each with out-degree at most four. It can be constructed in time $O(m + n \log n)$.

LEMMA 5. *There is a one-to-one length-preserving correspondence between s-t paths in G, and paths starting from r in $P(G)$.*

Proof. Recall that an s-t path p in G is uniquely defined by *sidetracks*(p), the sequence of edges from p in $G - T$. We now show that for any such sequence, there corresponds a unique path from r in $P(G)$ ending at a node corresponding to *lastsidetrack*(p), and conversely any path from r in $P(G)$ corresponds to *sidetracks*(p) for some path p.

Given a path p in G, we construct a corresponding path p' in $P(G)$ as follows. If *sidetracks*(p) is empty (i.e., p is the shortest path), we let p' consist of the single node r. Otherwise, form a path q' in $P(G)$ corresponding to *prefpath*(p) by induction on the length of *sidetracks*(p). By induction, q' ends at a node of $P(G)$ corresponding to edge $(u, v) =$ *lastsidetrack*(*prefpath*(p)). When we formed $P(G)$ from $D(G)$, we added an edge from this node to $h(v)$. Since *lastsidetrack*(p) has its tail on the path in T from v to t, it corresponds to a unique node in $H_G(v)$, and we form p' by concatenating q' with the path from $h(v)$ to that node. The edge lengths on this concatenated path telescope to $\delta($*lastsidetrack*$(p))$, and $\ell(p) = \ell($*prefpath*$(p)) + \ell($*lastsidetrack*$(p))$ by Lemma 2, so by induction $\ell(p) = \ell(q') + \ell($*lastsidetrack*$(p)) = \ell(p')$.

Conversely, to construct an s-t path in G from a path p' in $P(G)$, we construct a sequence of edges in G, *pathseq*(p'). If p' is empty, *pathseq*(p') is also empty. Otherwise *pathseq*(p') is formed by taking in sequence the edges in G corresponding to tails of cross edges in p' and adding at the end of the sequence the edge in G corresponding to the final vertex of p'. Since the nodes of $P(G)$ reachable from the head of each cross edge (u, v) are exactly those in $H_G(v)$, each successive edge added to *pathseq*(p') is on the path in T from v to t, and *pathseq*(p') is of the form *sidetracks*(p) for some path p in G. □

LEMMA 6. *In $O(m + n \log n)$ time we can construct a graph $P(G)$ with a distinguished vertex r, having the following properties.*

- *$P(G)$ has $O(m + n \log n)$ vertices.*
- *Each vertex of $P(G)$ has out-degree at most four.*
- *Each edge of $P(G)$ has nonnegative weight.*
- *There is a one-to-one correspondence between s-t paths in G and paths starting from r in $P(G)$.*
- *The correspondence preserves lengths of paths in that length ℓ in $P(G)$ corresponds to length $d(s, t) + \ell$ in G.*

Proof. The bounds on size, time, and out-degree follow from Lemma 4, and the nonnegativity of edge weights follows from the heap ordering proven in that lemma. The correctness of the correspondence between paths in G and in $P(G)$ is shown above in Lemma 5. □

To complete our construction, we find from the path graph $P(G)$ a 4-heap $H(G)$, so that the nodes in $H(G)$ represent paths in G. $H(G)$ is constructed by forming a node for each path in $P(G)$ rooted at r. The parent of a node is the path with one fewer edge. Since $P(G)$ has out-degree four, each node has at most four children. Weights are heap-ordered, and the weight of a node is the length of the corresponding path.

LEMMA 7. *$H(G)$ is a 4-heap in which there is a one-to-one correspondence between nodes and s-t paths in G, and in which the length of a path in G is $d(s, t)$*

plus the weight of the corresponding node in $H(G)$.

We note that, if an algorithm explores a connected region of $O(k)$ nodes in $H(G)$, it can represent the nodes in constant space by assigning them numbers and indicating for each node its parent and the additional edge in the corresponding path of $P(G)$. The children of a node are easy to find simply by following appropriate out-edges in $P(G)$, and the weight of a node is easy to compute from the weight of its parent. It is also easy to maintain along with this representation the corresponding implicit representation of s-t paths in G.

2.4. Finding the k shortest paths.

THEOREM 1. *In time $O(m + n \log n)$ we can construct a data structure that will output the shortest paths from s to t in a graph in order by weight, taking time $O(\log i)$ to output the ith path.*

Proof. We apply breadth first search to $P(G)$, as described at the start of the section, and translate the search results to paths using the correspondence described above. □

We next describe how to compute paths from s to all n vertices of the graph. In fact our construction solves more easily the reverse problem of finding paths from each vertex to the destination t. The construction of $P(G)$ is as above, except that instead of adding a single root $r(s)$ connected to $h(s)$, we add a root $r(v)$ for each vertex $v \in G$. The modification to $P(G)$ takes $O(n)$ time. Using the modified $P(G)$, we can compute a heap $H_v(G)$ of paths from each v to t and compute the k smallest such paths in time $O(k)$.

THEOREM 2. *Given a source vertex s in a digraph G, we can find in time $O(m + n \log n + kn \log k)$ an implicit representation of the k shortest paths from s to each other vertex in G.*

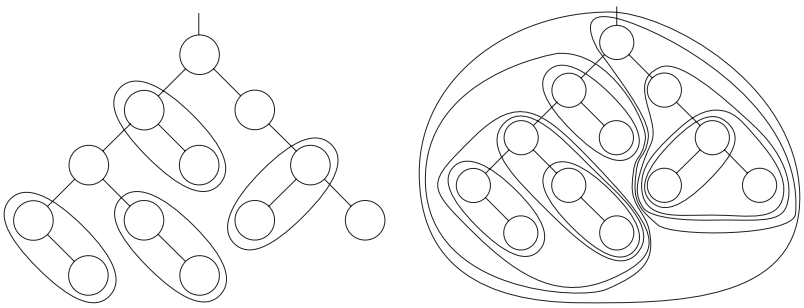
Proof. We apply the construction above to G^R, with s as destination. We form the modified path graph $P(G^R)$, find for each vertex v a heap $H_v(G^R)$ of paths in G^R from v to s, and apply breadth first search to this heap. Each resulting path corresponds to a path from s to v in G. □

3. Improved space and time. The basic algorithm described above takes time $O(m + n \log n + k \log k)$, even if a shortest path tree has been given. If the graph is sparse, the $n \log n$ term makes this bound nonlinear. This term comes from two parts of our method, Dijkstra's shortest path algorithm and the construction of $P(G)$ from the tree of shortest paths. But for certain graphs, or with certain assumptions about edge lengths, shortest paths can be computed more quickly than $O(m+n \log n)$ [2, 28, 33, 36], and in these cases we would like to speed up our construction of $P(G)$ to match these improvements. In other cases, k may be large and the $k \log k$ term may dominate the time bound; again we would like to improve this nonlinear term. In this section we show how to reduce the time for our algorithm to $O(m + n + k)$, assuming a shortest path tree is given in the input. As a consequence we can also improve the space used by our algorithm.

3.1. Faster heap selection. The following result is due to Frederickson [26].

LEMMA 8. *We can find the k smallest weight vertices in any heap in time $O(k)$.*

Frederickson's result applies directly to 2-heaps, but we can easily extend it to D-heaps for any constant D. One simple method of doing this involves forming a 2-heap from the given D-heap by making $D - 1$ copies of each vertex, connected in a binary tree with the D children as leaves, and breaking ties in such a way that the Dk smallest weight vertices in the 2-heap correspond exactly to the k smallest weights in



(a) (b)

FIG. 6. (a) *Restricted partition of order* 2*;* (b) *multilevel partition.*

the D-heap.

By using this algorithm in place of breadth first search, we can reduce the $O(k \log k)$ term in our time bounds to $O(k)$.

3.2. Faster path heap construction. Recall that the bottleneck of our algorithm is the construction of $H_T(v)$, a heap for each vertex v in G of those vertices on the path from v to t in the shortest path tree T. The vertices in $H_T(v)$ are in heap order by $\delta(\mathit{outroot}(u))$. In this section we consider the abstract problem, given a tree T with weighted nodes, of constructing a heap $H_T(v)$ for each vertex v of the other nodes on the path from v to the root of the tree. The construction of Lemma 4 solves this problem in time and space $O(n \log n)$; here we give a more efficient but also more complicated solution.

By introducing dummy nodes with large weights, we can assume without loss of generality that T is binary and that the root t of T has indegree one. We will also assume that all vertex weights in T are distinct; this can be achieved at no loss in asymptotic complexity by use of a suitable tie-breaking rule. We use the following technique of Frederickson [25].

DEFINITION 1. *A restricted partition of order z with respect to a rooted binary tree T is a partition of the vertices of V such that*

1. *each set in the partition contains at most z vertices;*
2. *each set in the partition induces a connected subtree of T;*
3. *for each set S in the partition, if S contains more than one vertex, then there are at most two tree edges having one endpoint in S;*
4. *no two sets can be combined and still satisfy the other conditions.*

In general such a partition can easily be found in linear time by merging sets until we get stuck. However for our application, z will always be 2 (Figure 6(a)), and by working from the bottom up we can find an optimal partition in linear time.

LEMMA 9 (Frederickson [25]). *In linear time we can find an order-*2 *partition of a binary tree T for which there are at most* $5n/6$ *sets in the partition.*

Contracting each set in a restricted partition gives again a binary tree. We form a *multilevel* partition [25] by recursively partitioning this contracted binary tree (Figure 6(b)). We define a sequence of trees T_i as follows. Let $T_0 = T$. For any $i > 0$, let T_i be formed from T_{i-1} by performing a restricted partition as above and contracting the resulting sets. Then $|T_i| = O((5/6)^i n)$.

For any set S of vertices in T_{i-1} contracted to form a vertex v in T_i, define $\mathit{nextlevel}(S)$ to be the set in the partition of T_i containing S. We say that S is an

interior set if it is contracted to a degree two vertex. Note that if t has indegree one, the same is true for the root of any T_i, so t is not part of any interior set, and each interior set has one incoming and one outgoing edge. Since T_i is a contraction of T, each edge in T_i corresponds to an edge in T. Let e be the outgoing edge from v in T_i; then we define *rootpath*(S) to be the path in T from *head*(e) to t. If S is an interior set, with a single incoming edge e', we let *inpath*(S) be the path in T from *head*(e') to *tail*(e).

Define an *m-partial heap* to be a pair (M, H), where H is a heap and M is a set of m elements each smaller than all nodes in H. If H is empty, M can have fewer than m elements and we will still call (M, H) an m-partial heap.

Let us outline the structures used in our algorithm, before describing the details of computing these structures. We first find a partial heap $(M_1(S), H_1(S))$ for the vertices of T in each path *inpath*(S). Although our algorithm performs an interleaved construction of all of these sets at once, it is easiest to define them from the top down by defining $M_1(S)$ for a set S in the partition of T_{i-1} in terms of similar sets in T_i and higher levels of the multilevel partition. Specifically, let $M_2(S)$ denote those elements in $M_1(S')$ for those S' containing S at higher levels of the multilevel partition, and let $k = \max(i+2, |M_2(S)|+1)$; then we define $M_1(S)$ to be the vertices in *inpath*(S) having the k smallest vertex weights. Our algorithm for computing $H_1(S)$ from the remaining vertices on *inpath*(S) involves an intermediate heap $H_2(S')$ formed by adding the vertices in $M_1(S') - M_1(S)$ to $H_1(S')$, where S' consists of one or both of the subsets of S contracted at the next lower level of the decomposition and containing vertices of *inpath*(S). After a bottom-up computation of M_1, H_1, and H_2, we then perform a top-down computation of a family of $(i+1)$-partial heaps, $(M_3(S), H_3(S))$; M_3 is formed by removing some elements from M_1 and H_3 is formed by adding those elements to H_1. Finally, the desired output $H_T(v)$ can be constructed from the 1-partial heap $(M_3(v), H_3(v))$ at level T_0 in the decomposition.

Before describing our algorithms, let us bound a quantity useful in their analysis. Let m_i denote the sum of $|M_1(S)|$ over sets S contracted in T_i.

LEMMA 10. *For each i, $m_i = O(i|T_i|)$.*

Proof. By the definition of $M_1(S)$ above,

$$m_i = \sum_S \max(i+2, |M_2(S)|+1) \le \sum_S |M_2(S)| + i + 2 \le (i+2)|T_i| + \sum_S |M_2(S)|.$$

All sets $M_2(S)$ appearing in this sum are disjoint, and all are included in m_{i+1}, so we can simplify this formula to

$$m_i \le (i+2)|T_i| + m_{i+1} \le \sum_{j \ge i} (j+2)|T_j| \le \sum_{j \ge i} (j+2) \left(\frac{5}{6}\right)^{j-i} |T_i| = O(i|T_i|). \qquad \square$$

We use the following data structure to compute the sets $M_1(S)$ (which, recall, are sets of low-weight vertices on *inpath*(S)). For each interior set S, we form a priority queue $Q(S)$, from which we can retrieve the smallest weight vertex on *inpath*(S) not yet in $M_1(S)$. This data structure is very simple: if only one of the two subsets forming S contains vertices on *inpath*(S), we simply copy the minimum-weight vertex on that subset's priority queue, and otherwise we compare the minimum-weight vertices in each subset's priority queue and select the smaller of the two weights. If one of the two subsets' priority queue values change, this structure can be updated simply by repeating this comparison.

We start by setting all the sets $M_1(S)$ to be empty, then progress from the top down through the multilevel decomposition, testing for each set S in each tree T_i (in decreasing order of i) whether we have already added enough members to $M_1(S)$. If not, we add elements one at a time until there are enough to satisfy the definition above of $|M_1(S)|$. Whenever we add an element to $M_1(S)$ we add the same element to $M_1(S')$ for each lower level subset S' to which it also belongs. An element is added by removing it from $Q(S)$ and from the priority queues of the sets at each lower level. We then update the queues bottom up, recomputing the head of each queue and inserting it in the queue at the next level.

LEMMA 11. *The amount of time to compute $M_1(S)$ for all sets S in the multilevel partition, as described above, is $O(n)$.*

Proof. By Lemma 10, the number of operations in priority queues for subsets of T_i is $O(i|T_i|)$. So the total time is $\sum O(i|T_i|) = O(n\sum i(5/6)^i) = O(n)$. □

We next describe how to compute the heaps $H_1(S)$ for the vertices on *inpath*(S) that have not been chosen as part of $M_1(S)$. For this stage we work from the bottom up. Recall that S corresponds to one or two vertices of T_i; each vertex corresponds to a set S' contracted at a previous level of the multilevel partition. For each such S' along the path in S we will have already formed the partial heap $(M_1(S'), H_1(S'))$. We let $H_2(S')$ be a heap formed by adding the vertices in $M_1(S') - M_1(S)$ to $H_1(S')$. Since $M_1(S') - M_1(S)$ consists of at least one vertex (because of the requirement that $|M_1(S')| \geq |M_1(S)|+1$), we can form $H_2(S')$ as a 2-heap in which the root has degree one.

If S consists of a single vertex we then let $H_1(S) = H_2(S')$; otherwise we form $H_1(S)$ by combining the two heaps $H_2(S')$ for its two children. The time is constant per set S or linear overall.

We next compute another collection of partial heaps $(M_3(S), H_3(S))$ of vertices in *rootpath*(S) for each set S contracted at some level of the tree. If S is a set contracted to a vertex in T_i, we let $(M_3(S), H_3(S))$ be an $(i+1)$-partial heap. In this phase of the algorithm, we work top down. For each set S, consisting of a collection of vertices in T_{i-1}, we use $(M_3(S), H_3(S))$ to compute for each vertex S' the partial heap $(M_3(S'), H_3(S'))$.

If S consists of a single set S', or if S' is the parent of the two vertices in S, we let $M_3(S')$ be formed by removing the minimum weight element from $M_3(S)$ and we let $H_3(S')$ be formed by adding that minimum weight element as a new root to $H_3(S)$.

In the remaining case, if S' and *parent*(S') are both in S, we form $M_3(S')$ by taking the $i+1$ minimum values in $M_1(\textit{parent}(S')) \cup M_3(\textit{parent}(S'))$. The remaining values in $M_1(\textit{parent}(S')) \cup M_3(\textit{parent}(S')) - M_3(S')$ must include at least one value v greater than everything in $H_1(\textit{parent}(S'))$. We form $H_3(S')$ by sorting those remaining values into a chain, together with the root of heap $H_3(\textit{parent}(S'))$, and connecting v to $H_1(\textit{parent}(S'))$.

To complete the process, we compute the heaps $H_T(v)$ for each vertex v. Each such vertex is in T_0, so the construction above has already produced a 1-partial heap $(M_3(v), H_3(v))$. We must add the value for v itself and produce a true heap, both of which are easy.

LEMMA 12. *Given a tree T with weighted nodes, we can construct for each vertex v a 2-heap $H_T(v)$ of all nodes on the path from v to the root of the tree, in total time and space $O(n)$.*

Proof. The time for constructing (M_1, H_1) has already been analyzed. The only

remaining part of the algorithm that does not take constant time per set is the time for sorting remaining values into a chain, in time $O(i \log i)$ for a set at level i of the construction. The total time at level i is thus $O(|T_i| i \log i)$ which, summed over all i, gives $O(n)$. □

Applying this technique in place of Lemma 4 gives the following result.

THEOREM 3. *Given a digraph G and a shortest path tree from a vertex s, we can find an implicit representation of the k shortest s-t paths in G, in time and space $O(m + n + k)$.*

4. Maintaining path properties. Our algorithm can maintain along with the other information in $H(G)$ various forms of simple information about the corresponding s-t paths in G.

We have already seen that $H(G)$ allows us to recover the lengths of paths. However, lengths are not as difficult as some other information might be to maintain, since they form an additive group. We used this group property in defining $\delta(e)$ to be a difference of path lengths, and in defining edges of $P(G)$ to have weights that were differences of quantities $\delta(e)$.

We now show that we can in fact keep track of any quantity formed by combining information from the edges of the path using any monoid. We assume that there is some given function taking each edge e to an element *value*(e) of a monoid, and that given two edges e and f we can compute the composite value *value*$(e) \cdot$ *value*(f) in constant time. By associativity of monoids, the value *value*(p) of a path p is well defined. Examples of such values include the path length and number of edges in a path (for which composition is real or integer addition) and the longest or shortest edge in a path (for which composition is minimization or maximization).

Recall that for each vertex we compute a heap $H_G(v)$ representing the sidetracks reachable along the shortest path from v to t. For each node x in $H_G(v)$ we maintain two values: *pathstart*(x) pointing to a vertex on the path from v to t, and *value*(x) representing the value of the path from *pathstart*(x) to the head of the sidetrack edge represented by x. We require that *pathstart* of the root of the tree is v itself, that *pathstart*(x) be a vertex between v and the head of the sidetrack edge representing x, and that all descendents of x have *pathstart* values on the path from *pathstart*(x) to t. For each edge in $H_G(v)$ connecting nodes x and y we store a further value, representing the value of the path from *pathstart*(x) to *pathstart*(y). We also store for each vertex in G the value of the shortest path from v to t.

Then as we compute paths from the root in the heap $H(G)$, representing s-t paths in G, we can keep track of the value of each path merely by composing the stored values of appropriate paths and nodes in the path in $H(G)$. Specifically, when we follow an edge in a heap $H_G(v)$ we include the value stored at that edge, and when we take a sidetrack edge e from a node x in $H_G(v)$ we include *value*(x) and *value*(e). Finally we include the value of the shortest path to t from the tail of the last sidetrack edge to t. The portion of the value except for the final shortest path can be updated in constant time from the same information for a shorter path in $H(G)$, and the remaining shortest path value can be included again in constant time, so this computation takes $O(1)$ time per path found.

The remaining difficulty is computing the values *value*(x), *pathstart*(x), and also the values of edges in $H_G(v)$.

In the construction of Lemma 4, we need only compute these values for the $O(\log n)$ nodes by which $H_G(v)$ differs from $H_G($*parent*$(v))$, and we can compute each such value as we update the heap in constant time per value. Thus the construction

here goes through with unchanged complexity.

In the construction of Lemma 12, each partial heap at each level of the construction corresponds to all sidetracks with heads taken from some path in the shortest path tree. As each partial heap is formed the corresponding path is formed by concatenating two shorter paths. We let *pathstart*(x) for each root of a heap be equal to the endpoint of this path farthest from t. We also store for each partial heap the near endpoint of the path, and the value of the path. Then these values can all be updated in constant time when we merge heaps.

THEOREM 4. *Given a digraph G and a shortest path tree from a vertex s, and given a monoid with values value(e) for each edge $e \in G$, we can compute value(p) for each of the k shortest s-t paths in G, in time and space $O(m+n+k)$.*

5. Dynamic programming applications. Many optimization problems solved by dynamic programming or more complicated matrix searching techniques can be expressed as shortest path problems. Since the graphs arising from dynamic programs are typically acyclic, we can use our algorithm to find longest as well as shortest paths. We demonstrate this approach by a few selected examples.

5.1. The knapsack problem. The *optimization* 0-1 *knapsack problem* (or *knapsack problem* for short) consists of placing "objects" into a "knapsack" that has room for only a subset of the objects, and maximizing the total value of the included objects. Formally, one is given integers L, c_i, and w_i ($0 \le i < n$), and one must find $x_i \in \{0,1\}$ satisfying $\sum x_i c_i \le L$ and maximizing $\sum x_i w_i$. Dynamic programming solves the problem in time $O(nL)$; Dai et al. [15] show how to find the k best solutions in time $O(knL)$. We now show how to improve this to $O(nL+k)$ using longest paths in a DAG.

Let directed acyclic graph G have $nL+L+2$ vertices: two terminals s and t and $(n+1)L$ other vertices with labels (i,j), $0 \le i \le n$ and $0 \le j \le L$. Draw an edge from s to each $(0,j)$ and from each (n,j) to t, each having length 0. From each (i,j) with $i < n$, draw two edges: one to $(i+1,j)$ with length 0, and one to $(i+1, j+c_i)$ with length w_i (omit this last edge if $j + c_i > L$).

There is a simple one-to-one correspondence between s-t paths and solutions to the knapsack problem: given a path, define x_i to be 1 if the path includes an edge from (i,j) to $(i+1, j+c_i)$; instead let x_i be 0 if the path includes an edge from (i,j) to $(i+1,j)$. The length of the path is equal to the corresponding value of $\sum x_i w_i$, so we can find the k best solutions simply by finding the k longest paths in the graph.

THEOREM 5. *We can find the k best solutions to the knapsack problem as defined above, in time $O(nL+k)$.*

5.2. Sequence alignment. The *sequence alignment* or *edit distance* problem is that of matching the characters in one sequence against those of another, obtaining a matching of minimum *cost* where the cost combines terms for mismatched and unmatched characters. This problem and many of its variations can be solved in time $O(xy)$ (where x and y denote the lengths of the two sequences) by a dynamic programming algorithm that takes the form of a shortest path computation in a grid graph.

Byers and Waterman [8, 64] describe a problem of finding all near-optimal solutions to sequence alignment and similar dynamic programming problems. Essentially their problem is that of finding all s-t paths with length less than a given bound L. They describe a simple depth first search algorithm for this problem, which is

especially suited for grid graphs although it will work in any graph and although the authors discuss it in terms of general DAGs. In a general digraph their algorithm would use time $O(k^2m)$ and space $O(km)$. In the acyclic case discussed in the paper, these bounds can be reduced to $O(km)$ and $O(m)$. In grid graphs its performance is even better: time $O(xy + k(x + y))$ and space $O(xy)$. Naor and Brutlag [46] discuss improvements to this technique that among other results include a similar time bound for k shortest paths in grid graphs.

We now discuss the performance of our algorithm for the same length-limited path problem. In general one could apply any k shortest paths algorithm together with a doubling search to find the value of k corresponding to the length limit, but in our case the problem can be solved more simply: simply replace the breadth first search in $H(G)$ with a length-limited depth first search.

THEOREM 6. *We can find the k s-t paths in a graph G that are shorter than a given length limit L, in time $O(m+n+k)$ once a shortest path tree in G is computed.*

Even for the grid graphs arising in sequence analysis, our $O(xy + k)$ bound improves by a factor of $O(x + y)$ the times of the algorithms of Byers and Waterman [8] and Naor and Brutlag [46].

5.3. Inscribed polygons. We next discuss the problem of, given an n-vertex convex polygon, finding the "best" approximation to it by an r-vertex polygon, $r < n$. This arises, e.g., in computer graphics, in which significant speedups are possible by simplifying the shapes of faraway objects. To our knowledge the "k best solution" version of the problem has not been studied before. We include it as an example in which the best-known algorithms for the single solution case do not appear to be of the form needed by our techniques; however, one can transform an inefficient algorithm for the original problem into a shortest path problem that with our techniques gives an efficient solution for large enough k.

We formalize the problem as that of finding the maximum area or perimeter convex r-gon inscribed in a convex n-gon. The best known solution takes time $O(n \log n + n\sqrt{r \log n})$ [1]. However, this algorithm does not appear to be in the form of a shortest path problem, as needed by our techniques.

Instead we describe a less efficient technique for solving the problem by using shortest paths. Number the n-gon vertices v_1, v_2, etc. Suppose we know that v_i is the lowest numbered vertex to be part of the optimal r-gon. We then form a DAG G_i with $O(rn)$ vertices and $O(rn^2)$ edges, in r levels. In each level we place a copy of each vertex v_j, connected to all vertices with lower numbers in the previous level. Each path from the copy of v_i in the first level of the graph to a vertex in the last level of the graph has r vertices with numbers in ascending order from v_i, and thus corresponds to an inscribed r-gon. We connect one such graph for each initial vertex v_i into one large graph, by adding two vertices s and t, edges from s to each copy of a vertex v_i at the first level of G_i, and edges from each vertex on level r of each G_i to t. Paths in the overall graph G thus correspond to inscribed r-gons with any starting vertex.

It remains to describe the edge lengths in this graph. Edges from s to each v_i will have length zero for either definition of the problem. Edges from a copy of v_i at one level to a copy of v_j at the next level will have length equal to the Euclidean distance from v_i to v_j, for the maximum perimeter version of the problem, and edges connecting a copy of v_j at the last level to t will have length equal to the distance between v_j and the initial vertex v_i. Thus the length of a path becomes exactly the perimeter of the corresponding polygon, and we can find the k best r-gons by finding the k longest paths.

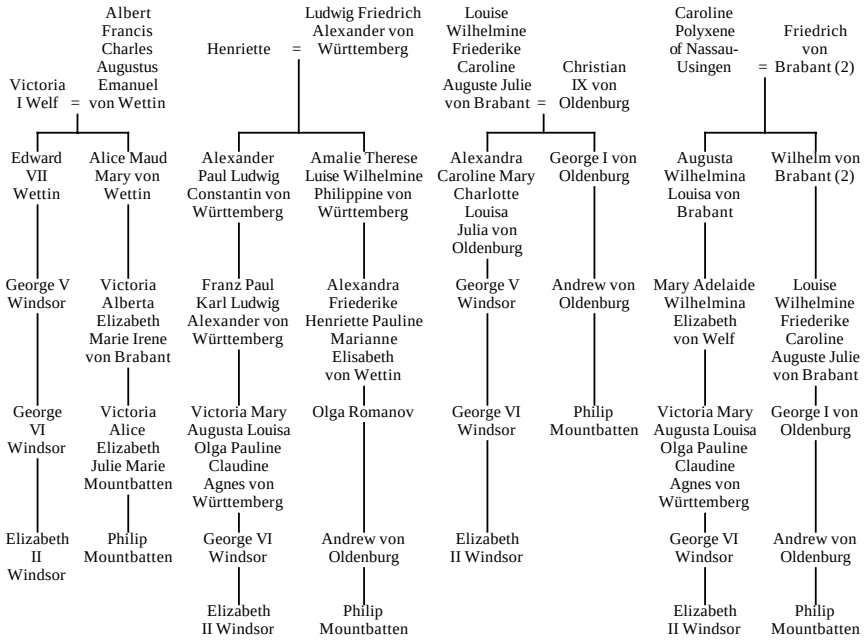


FIG. 7. *Some short relations in a complicated genealogical database.*

For the maximum area problem, we instead let the distance from v_i to v_j be measured by the area of the n-gon cut off by a line segment from v_i to v_j. Thus the total length of a path is equal to the total area outside the corresponding r-gon. Since we want to maximize the area inside the r-gon, we can find the k best r-gons by finding the k shortest paths.

THEOREM 7. *We can find the k maximum area or perimeter r-gons inscribed in an n-gon, in time $O(rn^3 + k)$.*

5.4. Genealogical relations. If one has a database of family relations, one may often wish to determine how some two individuals in the database are related to each other. Formalizing this, one may draw a DAG in which nodes represent people, and an arc connects a parent to each of his or her children. Then each different type of relationship (such as that of being a half-brother, great-aunt, or third cousin twice removed) can be represented as a pair of disjoint paths from a common ancestor (or couple forming a pair of common ancestors) to the two related individuals, with the specific type of relationship being a function of the numbers of edges in each path and of whether the paths begin at a couple or at a single common ancestor. In most families, the DAG one forms in this way has a tree-like structure, and relationships are easy to find. However, in more complicated families with large amounts of intermarriage, one can be quickly overwhelmed with many different relationships. For instance, in the British royal family, Queen Elizabeth and her husband Prince Philip are related in many ways, the closest few being second cousins once removed through King Christian IX of Denmark and his wife Louise, third cousins through Queen Victoria of England and her husband Albert, and fourth cousins through Duke Ludwig Friedrich Alexander of Württemberg and his wife Henriette (Figure 7). The single shortest relationship can be found as a shortest path in a graph formed by combining the DAG with its reversal, but longer paths in this graph

do not necessarily correspond to disjoint pairs of paths. A program my wife, Diana, and I wrote, Gene (`http://www.ics.uci.edu/~eppstein/gene/`), is capable of finding small numbers of relationships quickly using a backtracking search with heuristic pruning, but Gene starts to slow down when asked to produce larger numbers of relationships.

We now describe a technique for applying our k-shortest-path algorithm to this problem, based on a method of Perl and Shiloach [48] for finding shortest pairs of disjoint paths in DAGs. Given a DAG D, we construct a larger DAG D_1 as follows. We first find some topological ordering of D, and let $f(x)$ represent the position of vertex x in this ordering. We then construct one vertex of D_1 for each ordered pair of vertices (x, y) (not necessarily distinct) in D. We also add one additional vertex s in D_1. We connect (x, y) to (x, z) in D_1 if (y, z) is an arc of D and $f(z) > \max(f(x), f(y))$. Symmetrically, we connect (x, y) to (z, y) if (x, z) is an arc of D and $f(z) > \max(f(x), f(y))$. We connect s to all vertices in D_1 of the form (v, v).

LEMMA 13. *Let vertices u and v be given. Then the pairs of disjoint paths in D from a common ancestor a to u and v are in one-for-one correspondence with the paths in D_1 from s through (a, a) to (u, v).*

As a consequence, we can find shortest relationships between two vertices u and v by finding shortest paths in D_1 from s to (u, v).

THEOREM 8. *Given a DAG with n nodes and m edges, we can construct in $O(mn)$ time a data structure such that, given any two nodes u and v in a DAG, we can list (an implicit representation of) the k shortest pairs of vertex-disjoint paths from a common ancestor to u and v, in time $O(k)$. The same bound holds for listing all pairs with length less than a given bound (where k is the number of such paths). Alternately, the pairs of paths can be output in order by total length in time $O(\log i)$ to list the ith pair. As before, our representation allows constant-time computation of some simple functions of each path, and allows each path to be explicitly generated in time proportional to its length.*

For a proof of Lemma 13 and more details of this application, see [19].

6. Conclusions. We have described algorithms for the k-shortest-paths problem, improving by an order of magnitude previously known bounds. The asymptotic performance of the algorithm makes it an especially promising choice in situations when large numbers of paths are to be generated, and there already exist at least two implementations: one by Shibuya, Imai, and coworkers [52, 53, 54, 55] and one by Martins (`http://www.mat.uc.pt/~eqvm/eqvm.html`).

We list the following as open problems.

- The linear time construction when the shortest path tree is known is rather complicated. Is there a simpler method for achieving the same result? How quickly can we maintain heaps $H_T(v)$ if new leaves are added to the tree? (Lemma 4 solves this in $O(\log n)$ time per vertex, but it seems that at least $O(\log \log n)$ should be possible.)
- As described above, we can find the k best inscribed r-gons in an n-gon, in time $O(rn^3 + k)$. However, the best single-optimum solution has the much faster time bound $O(n \log n + n\sqrt{r \log n})$ [1]. Our algorithms for the k best r-gons are efficient (in the sense that we use constant time per r-gon) only when $k = \Omega(rn^3)$. The same phenomenon of overly large preprocessing times also occurs in our application to genealogical relationship finding: the shortest relationship can be found in linear time, but our k-shortest-relationship method takes time $O(mn + k)$. Can we improve these bounds?

- Are there properties of paths not described by monoids which we can nevertheless compute efficiently from our representation? In particular, how quickly can we test whether each path generated is simple?

Acknowledgments. I thank Greg Frederickson, Sandy Irani, and George Lueker for helpful comments on drafts of this paper.

EXACT LEARNING OF DISCRETIZED GEOMETRIC CONCEPTS*

NADER H. BSHOUTY†, PAUL W. GOLDBERG‡, SALLY A. GOLDMAN§, AND H. DAVID MATHIAS¶

Abstract. We first present an algorithm that uses membership and equivalence queries to exactly identify a discretized geometric concept defined by the union of m axis-parallel boxes in d-dimensional discretized Euclidean space where each coordinate can have n discrete values. This algorithm receives at most md counterexamples and uses time and membership queries polynomial in m and $\log n$ for any constant d. Furthermore, all equivalence queries can be formulated as the union of $O(md \log m)$ axis-parallel boxes.

Next, we show how to extend our algorithm to efficiently learn, from *only* equivalence queries, any discretized geometric concept generated from any number of halfspaces with any number of known (to the learner) slopes in a constant dimensional space. In particular, our algorithm exactly learns (from equivalence queries *only*) unions of discretized axis-parallel boxes in constant dimensional space in polynomial time. Furthermore, this equivalence query only algorithm can be modified to handle a polynomial number of lies in the counterexamples provided by the environment.

Finally, we introduce a new complexity measure that better captures the complexity of the union of m boxes than simply the number of boxes and the dimension. Our new measure, σ, is the number of segments in the target, where a segment is a maximum portion of one of the sides of the target that lies entirely inside or entirely outside each of the other halfspaces defining the target. We present a modification of our first algorithm that uses time and queries polynomial in σ and $\log n$. In fact, the time and queries (both membership and equivalence) used by this single algorithm are polynomial for *either* m or d constant.

1. Introduction.

Recently, learning geometric concepts in d-dimensional Euclidean space has been the subject of much research [6, 15, 17, 28, 30, 31, 32, 34]. We study the problem of learning geometric concepts under the model of learning with queries [1] in which the learner is required to output a final hypothesis that correctly classifies *every* point in the domain. To apply such a learning model to a geometric domain, it is necessary to look at a discretized (or digitalized) version of the domain. We use d to denote the number of dimensions and n to denote the number of discrete values that exist in each dimension. Thus a discretized geometric concept G is a set of

integer points $G \subseteq \mathcal{N}_n^d$, where $\mathcal{N}_n = \{1, \ldots, n\}$. In this paper we consider discretized geometric concepts whose boundaries are defined by hyperplanes of known slope.

We begin by studying a special case: the well-studied class of unions of axis-parallel boxes. (By a "box," we mean an axis-aligned hypercuboid.) The algorithm for this special case is easily extended to learn discretized geometric concepts defined by axis-parallel hyperplanes. We use BOX_n^d to denote the class of axis-parallel boxes[1] over $\mathcal{N}_n^d$, and $\bigcup_{\leq m} \text{BOX}_n^d$ to denote the class of the union of at most m concepts from BOX_n^d. Let c be a concept in $\bigcup_{\leq m} \text{BOX}_n^d$. We say that c is defined by $s \leq m$ boxes from BOX_n^d if s is the minimum number of boxes whose union is equivalent to c. We note that it is easy to show that this class is a generalization of disjunctive normal form (DNF) formulas and a special case of the class of unions of intersections of halfspaces over $\mathcal{N}_n^d$.

We first present a query algorithm that exactly learns $\bigcup_{\leq m} \text{BOX}_n^d$ with at most $md + 1$ equivalence queries[2] and $O((4m)^d + md(\log n + d))$ membership queries and computation time. Thus our algorithm exactly learns the union of m discretized axis-parallel boxes over $\mathcal{N}_n^d$ in polynomial time for any constant d.

The hypothesis class used by this algorithm can be evaluated in time $O(d \log m \log n)$. Furthermore, in $O((2m)^{2d})$ time we can transform our hypothesis to the union of at most $O(md \log m)$ boxes. Thus we obtain the stronger result that our algorithm can exactly learn the union of m axis-parallel boxes over $\mathcal{N}_n^d$ while making at most $md+1$ equivalence queries, where each equivalence query is simply the union of $O(md \log m)$ concepts from BOX_n^d; making $O((4m)^d+md(\log n+d))$ membership queries, and using $O((md)^2 \log m \cdot (2m)^{2d} + md \log n)$ computation time. Thus for any constant d, this algorithm still uses time and queries polynomial in m and $\log n$. We also describe a variation of this basic algorithm that uses *only* equivalence queries and still has complexity polynomial in m for time and queries and $\log n$ for d constant. Our algorithm uses $O((8d^2 m \log n)^d)$ equivalence queries and computation time.

Next we study the problem of learning with only equivalence queries the class of discretized geometric concepts in which the hyperplanes defining the boundaries of the concept need *not* be axis parallel but rather can have any known slopes. That is, the geometric discretized concepts we study here are those whose boundaries lie on hyperplanes $\{x = (x_1, \ldots, x_d) \mid \sum_{j=1}^d a_{ij} x_j = b\}$ for $i = 1, \ldots, |S|$, where S is the set of slopes of the hyperplanes. The possible slopes of those hyperplanes, i.e., $a_i = (a_{i1}, \ldots, a_{id})$, are known to the learner, but the same slope with different shifts b can be used for many hyperplanes in the target concept g. Note that if we choose the slopes $S = \{e_i\}$, the standard basis, then we get the special case in which all hyperplanes are axis parallel.

Let $S \subset \mathcal{Z}^d$ where $\mathcal{Z}$ is the set of integers, and let $\|S\|$ denote the representation size of S (the sum of the logarithms of the absolute values of the integers in S). Let g be a geometric concept whose boundaries lie on m hyperplanes in $\mathcal{N}_n^d$ with slopes from S. A key result of this paper is that for any constant d, any such geometric concept is exactly learnable in $poly(l, m, \|S\|, \log n)$ time and equivalence queries even if the equivalence oracle lies on l counterexamples. So for example, if the space is the plane $\mathcal{N}_n^2$ and $S = \{(0,1), (1,0), (1,1), (1,-1), (1,2), (2,1), (1,-2), (2,-1)\}$, then our algorithm can efficiently learn the geometric concepts generated from lines that make angles $0, 90, 135, 45, 120,\ 150, 30$, and 60, respectively, with the x-axis, in polynomial

[1] Note that we include in BOX_n^d boxes with zero size in any dimension.

[2] The final equivalence query is the correct hypothesis, and thus at most md counterexamples are received.

time. (As this example illustrates, the representation that we use for a slope is that derived from the formula, given above, defining a hyperplane.) In higher constant dimensional space our algorithm can efficiently learn any geometric concept whose boundary slopes are known. Another generalization of this result is an algorithm to exactly learn polynomially sized decision trees over the basis "Is $x_i \succ c$," where $\succ \in \{>, <, \geq, \leq\}$ in constant dimensional space.

Finally, we reexamine our first algorithm for learning the union of m discretized boxes. We introduce a new complexity measure that better captures the complexity of a union of boxes than simply the number of boxes and dimensions. More specifically, our new measure, σ, is the number of segments in the target concept, where a segment is a maximum portion of one of the defining hyperplanes of the target that lies entirely inside or entirely outside each of the other defining hyperplanes. We show that $\sigma \leq (2m)^d$. We present an improvement of our first algorithm that uses time and queries polynomial in σ and $\log n$. The hypothesis class used by this modified algorithm is that of decision trees of height at most $2md$. Thus, observe that the hypothesis output (and the intermediate hypotheses) can be evaluated in polynomial time without any restrictions on m or d. We then use an alternate analysis of this algorithm to show that the time and queries used are polynomial in d and $\log n$ for any constant m, thus generalizing the exact learnability of DNF formulas with a constant number of terms. Combining these two methods of analysis, we get the interesting result that this single algorithm is efficient for *either* m or d constant.

The paper is organized as follows. In section 2 we describe the learning model that we use. Next, in section 3 we summarize the previous work on learning geometric concepts. Then in section 4 we give some preliminary definitions. Section 5 describes our results for learning unions of boxes with membership and equivalence queries. We present this algorithm, in part, because it introduces the approach used to obtain our other results and also because it uses very few equivalence queries, which is of interest if one's goal is to minimize the number of prediction errors made by the learner [13]. Next, in section 6 we describe a modification of this algorithm that efficiently learns the union of boxes in constant dimensional space with only equivalence queries. In section 7 we present our extensions to learning the class of geometric concepts defined by any hyperplanes of known slopes using only equivalence queries. In section 8 we describe how to modify this algorithm to handle the situation in which there are lies in the answers to the equivalence queries. In section 9 we present our new complexity measure and describe a modification of our first algorithm that runs in polynomial time with respect to this complexity measure. Finally, in section 10 we conclude with some open problems. This paper subsumes the results presented by Goldberg, Goldman, and Mathias [22] and includes several results given by Bshouty [11].

2. Learning model. The learning model we use in this paper is that of learning with queries developed by Angluin [1]. When applied to our class of discretized geometric concepts, the learner's goal is to learn *exactly* how an unknown target concept, g, drawn from the *concept class* $\mathcal{G} \subseteq 2^{\mathcal{N}_n^d}$, classifies as positive or negative all instances from the *instance space* $\mathcal{N}_n^d$. Thus each concept is the set of instances from $\mathcal{N}_n^d$ that it classifies as positive. We say that $y \in \mathcal{N}_n^d$ is a positive instance for target concept g if $y \in g$ (also denoted $g(y) = 1$) and say that y is a negative instance otherwise (also denoted $g(y) = 0$). It is often convenient to view the target concept g as the Boolean function $g : \mathcal{N}_n^d \to \{0, 1\}$. A *hypothesis* h is a polynomial-time algorithm that, given any $y \in \mathcal{N}_n^d$, outputs a prediction for $g(y)$. Throughout we use y to denote an instance (i.e., a point in $\mathcal{N}_n^d$) and $x = (x_1, \ldots, x_d)$ to denote the

variables associated with the d axes. For example, for $d = 2$, $2x_1 + 3x_2 = 7$ defines a two-dimensional hyperplane. For the point $y = (2, 1)$, y is on this hyperplane.

As mentioned above, the learning criterion in this paper is that of *exact identification*. In order to achieve exact identification, the learner's final hypothesis, h, must be such that $h(y) = g(y)$ for all instances $y \in \mathcal{N}_n^d$. To achieve this goal the learner is provided with two types of queries with which to learn about g. A *membership query*, $\mathrm{MQ}(y)$, returns "yes" if $g(y) = 1$ and returns "no" if $g(y) = 0$. We note that learning using only membership queries is quite difficult for many concept classes. For example, to learn a single positive point in an n^d discrete grid requires $O(n^d)$ membership queries. An *equivalence query*, $\mathrm{EQ}(h)$, returns "yes" if h is logically equivalent to g or returns a counterexample otherwise. A *positive counterexample* y is an instance such that $g(y) = 1$ and $h(y) = 0$. Similarly, a *negative counterexample* is such that $g(y) = 0$ and $h(y) = 1$. Equivalence queries are answered by a computationally unbounded adversary with knowledge of the target concept and the learning algorithm. Several of the algorithms we present use only equivalence queries. The others use *both* membership and equivalence queries. In some domains, presenting the learner with a single positive instance (as a counterexample to an equivalence query) makes learning with membership queries feasible (see the discussion of *geometric probing* in section 3).

An exact learning algorithm is said to run in polynomial time if the computation time and the number of queries are polynomial in both the size[3] of an example (whether it is for a membership query or a counterexample from an equivalence query) and the size of the target concept. Here an example is one of the n^d points in $\mathcal{N}_n^d$ and thus it can be represented with $d\lceil \lg n \rceil$ bits. Each box in the target concept can be encoded with $2d\lceil \lg n \rceil$ bits, and thus encoding the entire target concept uses $2dm\lceil \lg n \rceil$ bits. Thus for the problems studied here, a polynomial-time algorithm must use time and queries polynomial in $d, \log n$, and m.

An *l-liar* equivalence oracle is an oracle that is allowed to lie at most l times during the learning session when providing counterexamples to equivalence queries. The teacher is allowed at most l lies *total* even if multiple lies are for the same instance. This definition seeks to capture a notion of erroneous data and robust, error-tolerant algorithms. We seek a more efficient approach than testing each counterexample we receive using a membership query, especially in view of the fact that we are interested in *algorithms that may use only equivalence queries*.

Another important learning model is the PAC model introduced by Valiant [38]. In this model the learner is presented with labeled examples chosen at random according to an unknown, arbitrary distribution $\mathcal{D}$ over the instance space. Given values for parameters ϵ and δ, the learner's goal is to output a hypothesis that with high probability, at least $(1 - \delta)$, correctly classifies most of the instance space. That is, the weight, under $\mathcal{D}$, of misclassified instances must be at most ϵ. This is in contrast to the query learning model in which the learner is required to classify correctly every instance in the instance space. The learner is permitted time polynomial in $1/\epsilon$, $1/\delta$, the size of an example, and the size of the target concept to formulate a hypothesis. The relationship between the PAC model and the query model is well understood. Angluin [1] showed that any class that is learnable using only equivalence queries is also PAC learnable. The relationship is unchanged by the addition of membership queries to each model. Blum [8] showed that PAC learnability does not imply query learnability. The concept class studied here has also been considered in the PAC

[3] By size we mean the number of bits to encode the example.

model, as summarized in the next section.

3. Previous work. The problem of learning geometric concepts over a discrete domain was extensively studied by Maass and Turán [31, 32]. One of the geometric concepts that they studied was the class BOX_n^d. They showed that if the learner is restricted to make only equivalence queries in which each hypothesis was drawn from BOX_n^d then $\Omega(d \log n)$ queries are needed to achieve exact identification [28, 31]. Auer [6] improves this lower bound to $\Omega(\frac{d^2}{\log d} \log n)$.

If one always makes an equivalence query using the simple hypothesis that produces the smallest box consistent with the previously seen examples, then the resulting algorithm makes $O(dn)$ equivalence queries. An algorithm making $O(2^d \log n)$ equivalence queries was given by Maass and Turán [30]. The best result known for learning the class BOX_n^d was provided by Chen and Maass [17]. They gave an algorithm making $O(d^2 \log n)$ equivalence queries. They also provide an algorithm to learn the union of two axis-parallel rectangles in the discretized space $\{1, \ldots, n\} \times \{1, \ldots, m\}$ in time polynomial in $\log n$ and $\log m$, where one rectangle has a corner at $(0, m)$ and the other has a corner at $(n, 0)$. More recently, Chen [15] gave an algorithm that used equivalence queries to learn general unions of two boxes in the (discretized) plane. The algorithm uses $O(\log^2 n)$ equivalence queries and involves a detailed case analysis of the shapes formed by the two rectangles.

Homer and Chen [25] presented an algorithm to learn the union of m rectangles *in the plane* using $O(m^3 \log n)$ queries (both membership and equivalence) and $O(m^5 \log n)$ time. The hypothesis class of their algorithm is the union of $8m^2 - 2$ rectangles. In work independent of ours, Chen and Homer [16] have improved upon their earlier result by giving an algorithm that learns any concept from $\bigcup_{\leq m} \text{BOX}_n^d$ using $O(m^{2(d+1)} d^2 \log^{2d+1} n)$ equivalence queries by efficiently applying the bounded injury method from recursive function theory. This algorithm appears in [11] along with the equivalence-query algorithms presented here in sections 6 and 7. While the Chen and Homer result is very similar to our result of section 6, they use a very different technique to obtain the result. Also, our algorithm uses only $O((8d^2 m \log n)^d)$ equivalence queries.

Finally, in other independent work, Maass and Warmuth [34] have developed, as part of a more general result, an algorithm to learn any concept from $\bigcup_{\leq m} \text{BOX}_n^d$ using $O(md \log n)$ equivalence queries and $O\left((md \log n)^{O(d)}\right)$ computation time. In addition their technique enables them to efficiently learn a single box in a constant dimensional space that is not axis parallel but uses slopes from a known set of slopes. Their algorithm improves upon our result of section 6, in that the number of equivalence queries has polynomial dependence on m, d, and $\log n$. However, their work does *not* give results comparable to the other results presented in this paper. Most notably, in section 7 we give an algorithm that can learn the union of non-axis-parallel boxes (using slopes from a known set of slopes) versus just learning a single box.

Closely related to the problem of learning the union of discretized boxes, is the problem of learning the union of nondiscretized boxes in the PAC model [38]. Blumer et al. [10] present an algorithm to PAC-learn an m-fold union of boxes in E^d by drawing a sufficiently large sample of size $m' = \mathit{poly}\left(\frac{1}{\epsilon}, \lg \frac{1}{\delta}, m, d\right)$ and then performing a greedy covering over the at most $(\frac{em'}{2d})^{2d}$ boxes defined by the sample. Thus for d constant this algorithm runs in polynomial time. Long and Warmuth [29] present an algorithm to PAC-learn this same class by again drawing a sufficiently large sample and constructing a hypothesis that consists of at most $m(2d)^m$ boxes consistent with

the sample. Thus both the time and the sample complexity of their algorithm depend polynomially on $m, d^m, \frac{1}{\epsilon}$, and $\lg \frac{1}{\delta}$. For m constant this yields an efficient PAC algorithm.

We note that either of these PAC algorithms can be applied to the class $\bigcup_{\leq m} \text{BOX}_n^d$ giving efficient PAC algorithms for this class for either d constant or m constant. As discussed by Maass and Turán [31], the task of a concept learning algorithm is to provide a "smart" hypothesis based on the data available. In other words, the hypothesis must be carefully chosen so that as much information as possible is obtained from each counterexample. To illustrate this point consider the task of learning a concept of a half interval over $\{1, \ldots n\}$ (so an example $x \in \{1, \ldots, n\}$ is positive iff $x \leq r$ where $0 \leq r \leq n$ is not known). Within the PAC model a satisfactory hypothesis would be $r = h$, where h is the maximum positive example (0 if no positive examples have been seen). However, in the exact learning model when using *only equivalence queries* this hypothesis performs very poorly in that each counterexample could just be one to the right of the last one. Thus n counterexamples may be needed. However, if one uses the "smarter" hypothesis of $r = (h+g)/2$, where h is the maximum positive example seen and g is the minimum negative example seen ($n+1$ if no negative examples have been seen), then at most $\lceil \log n \rceil$ counterexamples are needed. More generally, the results from Blumer et al. [10] show that under the PAC model any concise hypothesis that is consistent with the data is satisfactory. In other words, the PAC model provides no suitable basis for distinction among different consistent hypotheses. On the other hand, a criterion for defining a "smart" hypothesis is implicitly contained within the query learning model. One must select hypotheses for the equivalence queries so that sufficient progress is made with each counterexample. This requirement of selecting a "smart" hypothesis makes the problem of obtaining an efficient algorithm to learn *exactly* the class $\bigcup_{\leq m} \text{BOX}_n^d$ significantly harder than obtaining the corresponding PAC result. Also Blum [8] has shown that if one-way functions exist, then there exist functions that are PAC-learnable but not exactly learnable.

Finally, under a variation of the PAC model in which membership queries can be made, Frazier et al. [21] have given an algorithm to PAC-learn the m-fold union of boxes in E^d for which each box is entirely contained within the positive quadrant *and* contains the origin. Furthermore, their algorithm learns this subclass of general unions of boxes in time polynomial in both m and d. Recall that since $\bigcup_{\leq m} \text{BOX}_n^d$ generalizes DNF, a polynomial-time algorithm for arbitrary d and m would solve the problem of learning DNF. Observe that the class considered by Frazier et al. is a generalization of the class of DNF formulas in which all variables only appear negated.

While there has been some work addressing the general issue of mislabeled training examples in the PAC model [3, 27, 37, 26], there has been little research on learning geometric concepts with noise. Auer [6] investigates exact learning of boxes where some of the counterexamples, given in response to equivalence queries, are noisy. Auer shows that BOX_n^d is learnable using hypotheses from BOX_n^d if and only if the fraction of noisy examples is less than $1/(d+1)$ and presents an efficient algorithm that handles a noise rate of $1/(2d+1)$. In the query learning model, Angluin and Kriķis [2] examine the case in which membership queries can be answered incorrectly under adversarial control.

There has also been some work on learning discretized geometric concepts defined by non–axis-parallel hyperplanes. Maass and Turán [33] study the problem of learning a single discretized halfspace using only equivalence queries. They give an efficient algorithm using $O(d^2(\log d + \log n))$ queries and give an information theoretic lower

bound of $\binom{d}{2}$ on the number of queries when all hypotheses are discretized halfspaces. There has also been work on learning non–axis-parallel discretized rectangles with only equivalence queries. Maass and Turán [32] show an $\Omega(n)$ information theoretic lower bound on the number of equivalence queries when the hypotheses must be drawn from the concept class. Contrasting this lower bound, Bultman and Maass [14] give an efficient algorithm that uses membership and equivalence queries to learn this class using $O(\log n)$ equivalence queries. Their algorithm returns a hypothesis consisting of a description of the vertices and edges of the polygon.

Computational geometry researchers have looked at the slightly related problem of *geometric probing* (for example, see [36]). Geometric probing studies how to identify, verify, or determine some property of an unknown geometrical object using a measuring device known as a probe. In one special case of geometric probing the aim is to construct (or learn) an unknown convex polygon given a point inside the polygon along with the ability to make a probe in which the algorithm can "shoot" a ray in a specified direction to find out the location where the ray hits the polygon. Note that using a binary search technique, such a probe can be simulated for this problem with a polynomial number of membership queries (for discretized domains). Thus such work can be thought of as learning a convex polygon from only membership queries along with a single positive example. However, when working with nonconvex objects, the probe used in such work is more powerful than a membership query.

Geometric testing (for example, see [35, 4]) is a subarea of geometric probing involved with solving verification problems. The work that has been done on this problem [5, 7, 23, 24] involves determining which of a finite set of models is being probed, and seems to be the most closely related to this paper among the geometric probing literature. The restriction to a finite set of models effectively discretizes the domain of geometric points, as is done here by considering points with bounded integer coordinates.

4. Preliminaries. Let $\mathcal{N}, \mathcal{Z}$, and $\mathcal{R}$ be the set of nonnegative integers, integers, and reals, respectively. Recall, as discussed in section 2, that we use $x_1, \ldots, x_d$ to denote the variables associated with the d axes. Let $\mathcal{N}_n = \{1, \ldots, n\}$ and $S = \{a_1, \ldots, a_s\} \subset \mathcal{Z}^d$ be a set of slopes. A d-dimensional *hyperplane* is $\{x = (x_1, \ldots, x_d) \mid \sum_{j=1}^{d} a_{ij} x_j = b\}$ for some $a_{ij} \in \mathcal{Z}, b \in \mathcal{R}$. A *halfspace* is $\{x = (x_1, \ldots, x_d) \mid \sum_{j=1}^{d} a_{ij} x_j \succ b\}$, where $\succ \in \{>, \geq, <, \leq\}$. A *discretized hyperplane* (respectively, halfspace) is $H \cap \mathcal{N}_n^d$ for some hyperplane (respectively, halfspace) H. A *geometric concept generated from hyperplanes* with slopes from $S \subset \mathcal{Z}^d$ is a set $\hat{g} \subset \mathcal{R}^d$ whose boundaries are defined by hyperplanes with slopes from S. A *discretized geometric concept generated from hyperplanes* with slopes from $S \subset \mathcal{Z}^d$ is $g = \hat{g} \cap \mathcal{N}_n^d$.

The *complexity* $C_S(\hat{g})$ of a geometric concept $\hat{g}$ is the minimum number of hyperplanes with slopes from S such that their union contains the boundary of $\hat{g}$. The complexity $C_S(g)$ of a discretized geometric concept g is the minimum $C_S(\hat{g})$ over all geometric concepts $\hat{g}$ that satisfy $g = \hat{g} \cap \mathcal{N}_n^d$. By a simple information theoretic argument, it follows that any exact learning algorithm for a nontrivial discretized geometric concept g cannot run in time less than the complexity $C_S(g)$. Also, the complexity of learning one box in $\mathcal{N}_n^d$ is at least $\Omega(d \log n)$. The input for our algorithms is S, together with n and d. We use $\|S\|$ to denote the sum of the logarithms of the absolute values of the integers in S and call this the *size* of S. Thus, a learning algorithm, for the class of discretized geometric concepts with complexity measure $C_S(g)$, is a polynomial-time algorithm if the time and query complexities are $poly(\|S\|, C_S(g), \log n, d)$.

Observe that if we choose the slopes $S = \{e_i\}$, the standard basis, then for any discretized geometric concept g defined by the union of m boxes in d dimensional space, $C_S(g) \leq 2md$ since at most $2d$ halfspaces are needed to define the boundaries of each box.

5. Learning unions of boxes with membership and equivalence queries. In this section we present an algorithm that exactly identifies any concept from $\bigcup_{\leq m} \text{BOX}_n^d$ (so $S = \{e_i\}$, the standard basis) while receiving at most md counterexamples and using time and membership queries that are polynomial in m and $\log n$ for any constant d. This section serves two purposes: (1) the other algorithms presented build upon this basic algorithm, and thus for ease of exposition we present it here, and (2) it uses very few equivalence queries, which is of interest if one's goal is to minimize the number of prediction errors made by the learner [13].

The following definition is used throughout this section.

DEFINITION 1. *For a discretized geometric concept g, we define a $+/^i-$ pair to be a positive point $y_+ = (y_1, \ldots, y_i, \ldots, y_d)$ paired with a negative point y_- where $y_- = (y_1, \ldots, y_i+1, \ldots y_d)$ or $y_- = (y_1, \ldots, y_i-1, \ldots, y_d)$, where we implicitly assume that any point outside $\mathcal{N}_n^d$ is a negative point.*

We define the *halfspace* associated with a given $+/-$ pair to be the unique, axis-aligned halfspace H that contains the positive but not the negative point. So for a $+/^i-$ pair where the positive point's ith coordinate is c, if the negative point's ith coordinate is $c+1$, then H is given by $x_i \leq c$. Similarly, if the negative point's ith coordinate is $c-1$, then H is given by $x_i \geq c$. We define the associated *hyperplane* to be the set of all points satisfying $x_i = c$.

For each of the d dimensions, we maintain a set $\mathcal{H}_i$ of hyperplanes discovered for that dimension that define the boundaries of g. We let $\mathcal{H} = \bigcup_{i=1}^d \mathcal{H}_i$. Observe that in dimension i we have decomposed $\mathcal{N}_n^d$ into up to $2|\mathcal{H}_i|+1$ regions: $|\mathcal{H}_i|$ corresponding to the hyperplanes themselves and $|\mathcal{H}_i|+1$ corresponding to the "strips" obtained when $\mathcal{N}_n^d$ is cut by each of the $|\mathcal{H}_i|$ hyperplanes. Recall that $|\mathcal{H}_i| \leq 2m$, and thus our final hypothesis divides $\mathcal{N}_n^d$ into a *grid* $G_{\mathcal{H}}$ of

$$\prod_{i=1}^{d}(2|\mathcal{H}_i|+1) \leq \prod_{i=1}^{d}(4m+1) = (4m+1)^d \tag{5.1}$$

regions (or connected components). We say that $G_{\mathcal{H}}$ is *consistent* if for any two points, with known classification, in any region of $G_{\mathcal{H}}$, the points have the same classification. Given a consistent $G_{\mathcal{H}}$, a hypothesis is obtained by simply classifying all points according to the unique classification of all known points in that region (with negative used as a default).

We now demonstrate that we can represent such a hypothesis so that it is very efficient to evaluate. For each dimension i we maintain a balanced binary search tree T_i where each internal node corresponds to one of the hyperplanes in $\mathcal{H}_i$ and each leaf node corresponds to one of the strips created. The ith coordinate of the points in a hyperplane in $\mathcal{H}_i$ is used as the key for the associated node in T_i. For each leaf node v of T_i we keep a pair $(\min_v^i, \max_v^i)$, where $\min_v^i$ (respectively, $\max_v^i$) holds the minimum (respectively, maximum) x such that x is the ith coordinate of some point in the region corresponding to leaf v. (For the internal nodes, the key itself serves the role of both $\min_v^i$ and $\max_v^i$.)

We define $R_i = \{[\min_v^i, \max_v^i] \mid v$ is a node of T_i and $\min_v^i$ and $\max_v^i$ are the minimum and maximum values of the ith coordinates of points in $v\}$. Let $\mathcal{T} =$

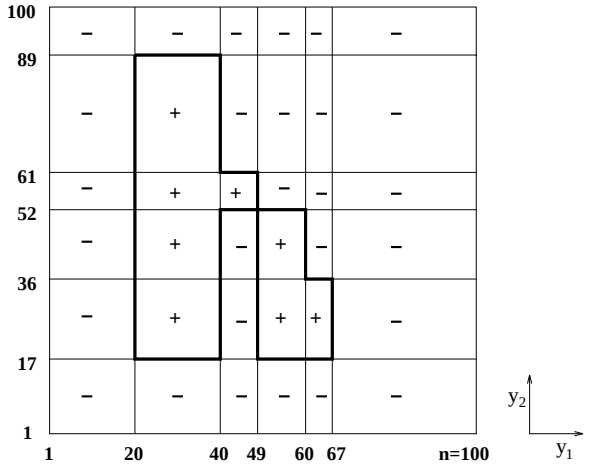

FIG. 1. *This shows the final set of regions corresponding to the target concept, formed by a union of $m = 4$ boxes, outlined in bold. The classification of each two-dimensional region is shown inside the region. (The classifications of the one-dimensional and zero-dimensional regions are not shown but are stored in the prediction matrix A.) The boundary of the target concept is segmented to illustrate a new complexity measure introduced in section 9.*

$\{T_1, \ldots, T_d\}$. Thus $G_{\mathcal{H}} = R_1 \times R_2 \times \cdots \times R_d$. For $r \in G_{\mathcal{H}}$, corresponding to nodes $v_i \in T_i$, we shall refer to the point $(\min^1_{v_1}, \ldots, \min^d_{v_d})$ as the *lower corner* of r and $(\max^1_{v_1}, \ldots, \max^d_{v_d})$ as the *upper corner* of r.

In addition to the trees $T_1, \ldots, T_d$, our hypothesis also maintains a prediction array A with $|G_{\mathcal{H}}|$ entries where, for $r \in G_{\mathcal{H}}$, $A[r]$ gives the classification for region r. For a consistent region (i.e., all known points have the same classification) A will contain either a 0 (for negative) or a 1 (for positive). However, for regions in which there is an inconsistency, there will be a pointer into a queue Q of inconsistent regions. In addition, for each region $r \in Q$ we store points y_+ and y_- giving a pair of inconsistent points in r. We use $h(G_{\mathcal{H}}, A)$ to denote the hypothesis defined by the regions in $G_{\mathcal{H}}$ with the classifications given in A. Note that the hypothesis is well-defined only if all regions are consistent. Figure 1 shows the set of regions defined by a target concept once all hyperplanes are discovered, and the classifications of all of the regions (as stored in A).

Given a hypothesis $h(G_{\mathcal{H}}, A)$ (we sometimes denote this simply as h) for which the queue Q of inconsistent regions is empty, and a point y, we can compute $h(y)$, the prediction made by hypothesis h on point y, as follows. For $1 \leq i \leq d$ we perform a search for y_i in tree T_i to find the node having y_i in its range. Combining the ranges of the d nodes found defines the region $r \in G_{\mathcal{H}}$ that contains y. Finally $h(y) = A[j_1, \ldots, j_d]$, where j_i is contained in the node found in T_i during the search for y and denotes the dimension i index for A corresponding to the region that contains y. Then combining the indices obtained from each of the trees provides an index into A. Since we know an upper bound on the number of nodes in each tree, we can initially allocate enough space for A.

5.1. The membership and equivalence query algorithm. Our algorithm works by repeatedly building a consistent hypothesis that incorporates all known halfspaces. The hypothesis is represented as a decision tree rather than as a union of boxes; subsequently we show how to express it as a union of (not too many) boxes.

Given an inconsistent hypothesis $h(G_{\mathcal{H}}, A)$ and the queue Q of inconsistent regions from $G_{\mathcal{H}}$, we refine $h(G_{\mathcal{H}}, A)$ so that it is consistent using the following procedure that uses membership queries to find *new* hyperplanes with which to modify the hypothesis. We never remove any hyperplane from $\mathcal{H}$ and search for a new hyperplane only in such a way that we are certain that an existing hyperplane will not be rediscovered in the process. We also maintain the invariant that Q always contains exactly one entry for each inconsistent region of $G_{\mathcal{H}}$. Note that we never make an equivalence query using an inconsistent hypothesis.

Our procedure to build a consistent hypothesis repeatedly does the following until Q is empty (and thus the hypothesis is consistent). Let r be the region at the front of the queue. Since r is not a consistent region, we know that there must be some unknown hyperplane of g that goes between y_+ (a known positive point in r) and y_- (a known negative point in r). Thus we can perform a binary search between y_+ and y_- (where the comparisons are replaced by membership queries) to find a $+/-$ pair contained within region r using only $d + \lceil \log n \rceil$ membership queries. We use $\lceil \log n \rceil$ queries to find a positive point and a negative point whose positions differ by at most one in each coordinate by performing a single binary search on all d dimensions. (Query points are chosen by bisecting the range in each dimension; noninteger coordinates may be rounded arbitrarily.) We then use d additional queries to determine the slope of the separating hyperplane. Furthermore, the hyperplane defined by this $+/-$ pair is guaranteed to be a hyperplane that has not yet been discovered (by the definition of a region).

The full details of procedure ADD-HYPERPLANE, which modifies $h(G_{\mathcal{H}}, A)$ to incorporate the new hyperplane found, is given in Figure 2. The learner begins by using a standard tree insertion procedure to insert the new hyperplane into the search tree for the appropriate dimension. Then the set of regions that have been split by the hyperplane are deleted from $\mathcal{H}$, and each is replaced by three new regions (one of them being a degenerate region corresponding to the hyperplane itself). For each new region of r we make a membership query on the lower and/or upper opposing corners if those queries have not already been made. As we shall discuss in section 6, this step can be replaced by just using 0 as the default value for $A[r]$. If the classifications of these two corners are the same, then the classification is entered in $A[r]$; otherwise the region is placed in Q with these corners used for y_+ and y_-.

Our algorithm LEARN-WITH-MQS works as follows. For ease of exposition we artificially extend the instance space from $\mathcal{N}_n^d$ to $\{0, 1, \ldots, n, n+1\}^d$, where it is known a priori that any example with a coordinate of 0 or $n+1$ in any dimension is a negative example. (The pseudocode does not explicitly make this check, but one could imagine replacing the calls to MQ with a procedure that first checks for such cases.) Initially, $G_{\mathcal{H}}$ just contains the single region corresponding to the entire instance space. Since the upper and lower corners of this region are negative, the initial hypothesis predicts 0 for all instances.

We then repeat the following process until a successful equivalence query is made. Let y be the counterexample received from an equivalence query made with a consistent hypothesis. Using membership queries (in the form of a binary search) we can find two new hyperplanes of the target concept. Without loss of generality, we assume that y is a positive counterexample in region r of $G_{\mathcal{H}}$. Since the hypothesis was consistent and y is a positive counterexample, we know that the upper and lower corners of r are classified as negative. Thus we can use these corners of r (with y) as the endpoints for binary searches to discover two new hyperplanes. We find a hyper-

```
ADD-HYPERPLANE(h(G_H, A), Q, i, c)
 Let v be the leaf of T_i for which min_v^i ≤ c ≤ max_v^i
 Using a standard balanced tree insertion procedure, update T_i so that
     v is an internal node with key c
     v has a left child with range [min_v^i, c − 1]
     v has a right child with range [c + 1, max_v^i]
 Let R_delete = R_1 × ··· × R_{i−1} × {[min_v^i, max_v^i]} × R_{i+1} × ··· × R_d
 Let R_add = R_1 × ··· × R_{i−1} × {[min_v^i, c − 1], [c, c], [c + 1, max_v^i]} × R_{i+1} × ··· × R_d

 For each r ∈ R_delete
     Let r_=, r_<, and r_> be the regions in R_add for which (r_= ∪ r_< ∪ r_>) = r
     If A[r] = b (for b = 0 or b = 1)
         Let A[r_=] = A[r_<] = A[r_>] = b
     Else (so A[r] is a pointer to element q of Q)
         Generate new queue nodes for r_=, r_<, and r_>
         Set the corresponding entries of A to point to these new nodes
         Copy y_− and y_+ in the appropriate queue entries for r_< and r_>
         Remove q from Q
     For each r' ∈ {r_=, r_<, r_>}
         Let y_u (respectively, y_ℓ) be the upper (respectively, lower) corner of r'
         Make a membership query to determine y_u and y_ℓ if not already known
         If g(y_u) = g(y_ℓ) then let A[r'] = g(y_u)
         Else (r' is inconsistent)
             Assign y_u and y_ℓ to y_− and y_+ as appropriate
             Q.ENQUEUE(r')
```

FIG. 2. *Our subroutine to update $h(G_{\mathcal{H}}, A)$ to incorporate the newly discovered hyperplane $x_i = c$. The new hyperplane is added to tree T_i. Then all regions in $G_{\mathcal{H}}$ that are split are removed from Q. Finally this procedure initializes the new entries of $G_{\mathcal{H}}$ in the prediction matrix A. Note that in the for loop that adds new regions, we could choose not to perform membership queries on the upper and lower corners of r, as is done in section 6. Instead, we could just use the known points in $r_=$, $r_<$, and $r_>$ to determine their labels (with 0 as a default if there are no points in the region). The advantage of doing this step is that the number of equivalence queries is reduced by a factor of 2 since two hyperplanes of the target are guaranteed to be found for each counterexample (Lemma 1). If we find that the opposing corners have different classifications then we place that newly created region on Q, which in turn will cause a binary search to be done to find a new hyperplane and split that region further.*

plane by doing a binary search until we find a $+/-$ pair (two points that are labeled differently and differ by at most one in each dimension). We know that a side of a target box must pass between these two points (or through one of the points). We then use d additional queries to discover the slope of this hyperplane. The hypothesis is updated using ADD-HYPERPLANE to incorporate these two hyperplanes. Finally, we call MAKE-CONSISTENT-HYPOTHESIS to refine any inconsistent regions. Figure 3 gives the complete algorithm.

5.2. Analysis. We now analyze the time and query complexity of LEARN-WITH-MQS. As part of this analysis we use the following lemma.

LEMMA 1. *Every counterexample can be used to discover at least two distinct new hyperplanes of the target concept.*

Proof. Let y be the counterexample and $r \in G_{\mathcal{H}}$ be the region containing y. Since $h(G_{\mathcal{H}}, A)$ is a consistent hypothesis, we know that the upper and lower corners of r

```
LEARN-WITH-MQS:
 Let Q ← ∅
 Let (0, ..., 0) and (n + 1, ..., n + 1) be negative corners of single region r
 For 1 ≤ i ≤ d
     Initialize T_i to be a single leaf covering the range 0 to n + 1
 For r the single region of G_H, let A[r] = 0

 While Equiv(h(G_H, A)) ≠ "yes"
     Let y be the counterexample where y is in region r of h(G_H, A)
     Let z_1 and z_2 be the lower and upper opposing corners of r
     For 1 ≤ ℓ ≤ 2
         Perform binary search between y and z_ℓ to find hyperplane x_i = c
         ADD-HYPERPLANE(h(G_H, A), Q, i, c)
     h(G_H, A) ←MAKE-CONSISTENT-HYPOTHESIS(h(G_H, A), Q)
 Return h(G_H, A)

MAKE-CONSISTENT-HYPOTHESIS(h(G_H, A), Q)
 While Q ≠ ∅
     r ← Q.DEQUEUE
     Perform binary search between y_− and y_+ from r
        to find the hyperplane x_i = c
     ADD-HYPERPLANE(h(G_H, A), Q, i, c)
```

FIG. 3. *Algorithm for learning unions of d-dimensional axis-parallel boxes using membership and equivalence queries. Note that i, in the calls to* ADD-HYPERPLANE*, is the dimension separated by the hyperplane found in the binary search.*

are classified opposite y and all points in r are classified opposite y by the hypothesis. Since a positive point and a negative point must be separated by some hyperplane of the target concept, searches between y and each of the upper and lower corners will find some $+/-$ pair. These will be distinct since the two searches move away from each other in all dimensions. □

We now prove that our first algorithm has the stated complexity.

THEOREM 1. *Given any* $g \in \bigcup_{\leq m} \text{BOX}_n^d$, LEARN-WITH-MQS *achieves exact identification of* g *making at most* $md + 1$ *equivalence queries, and using* $O((4m)^d + md(\log n + d))$ *time and membership queries.*

Proof. The correctness of LEARN-WITH-MQS is trivial. Since the algorithm only returns a hypothesis $h(G_{\mathcal{H}}, A)$ for which Equiv$(h(G_{\mathcal{H}}, A))$ returns "yes," the algorithm is correct upon returning a hypothesis.

We now analyze the query and time complexity of LEARN-WITH-MQS. Recall that since there are only m boxes in the target concept, there are at most $2md$ hyperplanes in the final hypothesis. Clearly, any box can be subdivided into a union of smaller boxes, unnecessarily increasing the complexity of the target. However, our algorithm adds hyperplanes only where there is evidence for the existence of a side of a target box (a $+/-$ pair) and, therefore, does not *unnecessarily* subdivide boxes (subdividing does occur due to extending hyperplanes through the entire domain, but this is already accounted for in our analysis). Furthermore, since no hyperplane is ever rediscovered and every binary search (which uses $O(\log n + d)$ membership queries) discovers a hyperplane, we know that $O(md(\log n + d))$ membership queries are used during all of the binary searches made by the algorithm. Also, as given in (5.1),

there are at most $(4m+1)^d$ regions in the final hypothesis, and thus the number of membership queries used for querying the upper and lower opposing corners is at most $2 \cdot (4m+1)^d = O((4m)^d)$. Since these are the only two places in which membership queries are performed, the total number of membership queries made by our algorithm is $O((4m)^d + md(\log n + d))$.

From Lemma 1 we know that each counterexample enables Learn-With-MQs to find at least two new, distinct hyperplanes of the target concept. Since there are at most $2md$ hyperplanes comprising the m boxes, at most md counterexamples can be received and thus at most $md+1$ equivalence queries are made.

The time needed to evaluate $h(G_{\mathcal{H}}, A)(x)$ for an unlabeled example y is $O(d \log m)$ since the key operation is performing d searches in balanced search trees of depth $O(\log m)$. Thus, the time complexity of this algorithm is found to be $O((4m)^d + md(\log n + d))$. □

Finally, it is easily seen that this algorithm extends to learning any discretized geometric concept generated by hyperplanes with slopes from $S = \{e_i\}$ (the standard basis) while receiving at most $C_S(g)/2$ counterexamples and using time and membership queries polynomial in $C_S(g)$ and $\log n$ for d any constant.

5.3. Using a hypothesis class of unions of boxes. We now describe how a consistent hypothesis can be converted to the union of $O(md \log m)$ boxes from BOX_n^d. Since all equivalence queries are made with consistent hypotheses, such a conversion enables our algorithm to learn the union of m boxes from BOX_n^d using as a hypothesis class the union of $O(md \log m)$ boxes from BOX_n^d. Note that it is NP-hard to find a minimum covering of a concept from $\bigcup_{\leq m} \text{BOX}_n^d$ by individual boxes [19].

Recall that a consistent hypothesis h essentially encodes the set of positive regions. Thus our goal is to find the union of as few boxes as possible that "cover" all of the positive regions. We now describe how to formulate this problem as a set covering problem for which we can then use the standard greedy set covering heuristic [18] to perform the conversion. The set X of objects to cover will simply contain all positive regions in h. Thus $|X| \leq (4m+1)^d$. Then the set $\mathcal{F}$ of subsets of X will be made as follows. Consider the set B of boxes where each box in B is formed by picking a minimum and maximum coordinate in each dimension from the hyperplanes represented in h for that dimension. For any $b \in B$, if b contains any negative region, then throw it out. Otherwise, place in $\mathcal{F}$ the set of regions contained within b. Thus $|\mathcal{F}| \leq (2m)^{2d}$ since there are at most $2m$ values in each dimension that can form the two sides of the box. Furthermore, $\mathcal{F}$ contains a subset of size m that covers all items in X. Finally, we can apply the greedy set covering heuristic to find a set of at most $m(\ln |X| + 1) = m(d \ln(4m+1) + 1) = O(md \log m)$ boxes that cover all positive regions. The time to perform the conversion is $O((2m)^{2d} md \log m)$. Thus, since at most $md+1$ equivalence queries are made, the total time spent in converting the internal hypotheses into hypotheses that are unions of boxes is at most $O((md)^2 \log m \cdot (2m)^{2d})$.

6. Learning unions of boxes using only equivalence queries. We now describe a simple method to remove the use of membership queries in Learn-With-MQs. First observe that the use of membership queries in this algorithm can easily be reduced to only their use within the binary searches. Instead of querying opposing corners of new regions created, we can instead use the classification of the single known point or otherwise a default of negative for the classification of the region. Then the counterexamples from the equivalence queries can be used to obtain a positive and negative point in the region that can be used for the binary search. (Of course, this

modification dramatically increases the number of equivalence queries used.)

Now to remove the use of membership queries in a binary search between y_+ and y_- we simply take the midpoint between y_+ and y_- (i.e., the first point on which a membership query would be made) and insert a hyperplane going through that point for each of the d dimensions. There are $2dm$ hyperplanes defining the target. We require at most $2\lceil \log n \rceil$ counterexamples (that cause $\mathcal{H}$ to be modified) to find each hyperplane. Thus, the total number of counterexamples required (that cause $\mathcal{H}$ to be modified) is at most $4dm\lceil \log n \rceil$. For each such counterexample (i.e., one that causes $\mathcal{H}$ to be modified) we insert d hyperplanes in the hypothesis. Thus the number of hyperplanes in the hypothesis is at most $4d^2m\lceil \log n \rceil$. By (5.1) there are at most $(8d^2m\lceil \log n \rceil + 1)^d$ regions in the final hypothesis. There is at most one equivalence query made for each of the hyperplanes found and at most one equivalence query made for each region. Thus we obtain the following result.

THEOREM 2. *Given any $g \in \bigcup_{\leq m} \text{BOX}_n^d$, there is an algorithm that achieves exact identification of g using $O((8d^2m \log n)^d)$ equivalence queries (and* no *membership queries). The time complexity is $O((8d^2m \log n)^d)$.*

It is easily seen that for d constant this algorithm exactly learns $\bigcup_{\leq m} \text{BOX}_n^d$ *using only equivalence queries* with both time and the number of equivalence queries polynomial in m and $\log n$.

7. Extending S to arbitrary known slopes. We now present a modification of the equivalence query algorithm described in section 6 that handles the situation in which S can be an arbitrary set of known slopes versus just being the standard basis. We let s denote the number of distinct slopes in S (i.e., $s = |S|$).

Let $S = \{a_1, \ldots, a_s\} \subset \mathcal{Z}^d$ be a set of slopes. Thus $a_i = (a_{i1}, a_{i2}, \ldots, a_{id})$ (for $1 \leq i \leq s$) defines a slope for a d-dimensional hyperplane, that is, a hyperplane of the form $\sum_{j=1}^{d} a_{ij}x_j = b$ (or equivalently $a_i x^T = b$) for any real constant b. Let $B = \{B_1, \ldots, B_s\}$, where $B_i \subset \mathcal{R}$ defines a set of $|B_i|$ possible values for the constant term "b" for those hyperplanes with slope given by a_i. Thus together S and B define a set of hyperplanes

$$\mathcal{H} = \{a_i x^T = b \mid x = (x_1, \ldots, x_d),\ i = 1, \ldots, s,\ b \in B_i\}.$$

The hypothesis $h = h(G_{\mathcal{H}}, A)$ is that which classifies each $x \in \mathcal{N}_n^d$ according to the unique classification of all known points (if any) in the region of $G_{\mathcal{H}}$ containing x. If there are no known points in the region containing x, then negative is used as the default.

As in our basic equivalence query algorithm, this algorithm begins with the entire region classified as negative. After the first two equivalence queries are made (the first with $h = \emptyset$ and the second with $h = \mathcal{N}_n^d$), the algorithm will have a positive counterexample y and a negative counterexample u. Thus the straight line between y and u must intersect one of the hyperplanes that define g. Let $v = (y + u)/2$ be the midpoint of the line between y and u. Without the ability to make membership queries it is not possible to find a $+/-$ pair. Furthermore, even if we could find a $+/-$ pair, we would not be able to determine the slope of the hyperplane that created that $+/-$ pair. As in the previous section, we address this problem by adding to our set of hyperplanes $\mathcal{H}$ a hyperplane passing through the midpoint v for *each* slope in S. We repeatedly use this process until an equivalence query made with $h(G_{\mathcal{H}}, A)$ is correct.

For ease of exposition, in this section we will not discuss the details of how to represent $\mathcal{H}$ so that $h(G_{\mathcal{H}}, A)$ can be efficiently evaluated (in terms of all parameters).

```
LEARN-GENERAL-SLOPES(S = {a_1, ..., a_s})
 H ← ∅
 Let r be the single region of G_H, let A[r] = 0
 While Equiv(h(G_H, A)) ≠ "yes"
     Let y be the counterexample where y is in region r of h(G_H, A)
     A[r] = 1 − h(G_H, A)(y)
     If there is a known point u in r classified opposite y
         v = (y + u)/2
         For i = 1 to s
             H ← H ⋃ (a_i x^T = b = (a_i v^T))
         Update A to incorporate the new regions created
 Return h(G_H, A)
```

FIG. 4. *Algorithm for exactly learning a discretized geometric concept defined by slopes in S using only equivalence queries.*

However, the technique of section 5 of using s balanced search trees, one for each element of S, generalizes in an obvious manner.

Our algorithm, at a high level, is shown in Figure 4. In this algorithm, LEARN-GENERAL-SLOPES, S is the set of the possible slopes of the hyperplanes. We initialize $\mathcal{H}$ to be the empty set and the classification of the single region to be 0. (And thus the initial hypothesis, $h(G_{\mathcal{H}}, A)$, is simply the always false hypothesis.) We ask the equivalence query $h(G_{\mathcal{H}}, A)$ and use the counterexample y to update A. If this counterexample is the first counterexample in its region then we just update A. Otherwise, if this counterexample is in some region for which we have already seen a point u, then y and u have different classifications in g and the line that passes through y and u must intersect a defining hyperplane of g. We then define $v = (y + u)/2$ and add all possible hyperplanes that pass through v to the set $\mathcal{H}$. We then repeat this process until $h(G_{\mathcal{H}}, A)$ is logically equivalent to g.

7.1. Analysis. We now prove the correctness of our algorithm and analyze its complexity. We use the following lemma to bound the maximum number of regions that will be contained in $G_{\mathcal{H}}$.

LEMMA 2. *Any t d-dimensional hyperplanes in a $(d+1)$-dimensional space divide the space into at most $t^{d+1} + 1$ regions.*

This result is well known. See Edelsbrunner [20] for a proof. We are now ready to analyze our algorithm LEARN-GENERAL-SLOPES.

THEOREM 3. *Let S be a set of slopes. Then* LEARN-GENERAL-SLOPES *exactly learns any target concept g from the class of discretized geometric concepts generated from hyperplanes with slopes from S using time and equivalence queries polynomial in $\|S\|, C_S(g)$, and $\log n$ for any constant d.*

Proof. The correctness follows trivially since the algorithm returns only a hypothesis $h(G_{\mathcal{H}}, A)$ for which Equiv$(h(G_{\mathcal{H}}, A))$ returns "yes," hence the algorithm is correct upon returning a hypothesis.

We now analyze the query and time complexity. Let $m = C_S(g)$. Recall that $\|S\|$ denotes the sum of the logarithms of the absolute values of the integers in S. Thus, by the definition of $\|S\|$, any $a_i \in S$ can be represented using at most $\|S\|$ bits. Thus there are at most $2^{\|S\|}$ possible values for a slope. Also, any example $x \in \mathcal{N}_n^d = \{1, \ldots, n\}^d$ and thus has n^d possible values. Let $H_1, \ldots, H_m$ be a minimum-size set of hyperplanes

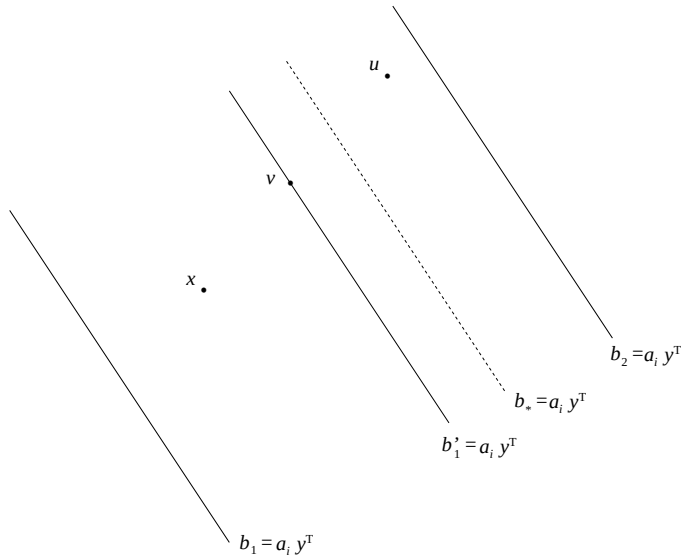

FIG. 5. *Here y is a counterexample to the current hypothesis and $b_1 = a_i x^T$ and $b_2 = a_i x^T$ are the nearest hyperplanes. The hyperplane $b'_1 = a_i x^T$ is added to $\mathcal{H}$ by* LEARN-GENERAL-SLOPES.

with slopes from S that generate the boundary of the geometric concept g. Since each hyperplane defining g is of the form $b = a_i x^T$, we have that the maximum number of values that any b can have is

$$\|b_i\| \leq \|a_i x^T\| \leq 2^{\|S\|} \cdot n^d = \gamma.$$

At any time during execution of our algorithm, for each of $H_1, \ldots, H_m$, there are two closest hyperplanes in $\mathcal{H}$ (one for each side) with the given slope. (At the beginning of execution, imagine two hyperplanes with each slope outside the domain and anchored at opposing corners of the domain.) We now show that for every counterexample that causes $\mathcal{H}$ to be modified there exists some H_i $(i = 1, \ldots, m)$ for which the distance between it and one of its closest hyperplanes is reduced by at least a factor of 2.

Suppose that y is a counterexample to the current hypothesis $h(G_{\mathcal{H}}, A)$ and that the region r of $G_{\mathcal{H}}$ that contains y already contains the point u (otherwise $\mathcal{H}$ is not modified). By the definition of $h(G_{\mathcal{H}}, A)$ it follows that $g(u) \neq g(y)$. Therefore the line segment between y and u must intersect some hyperplane—say, $H_* \equiv (a_i x^T = b_*)$—of g for $a_i \in S$ and $b_* \in \mathcal{Z}$. Let $b_1 = a_i x^T$ and $b_2 = a_i x^T$ be the two hyperplanes with slope a_i nearest H_* in $\mathcal{H}$. Let $v = (y + u)/2$ be the midpoint between y and u. Without loss of generality we assume that the hyperplane $b'_1 = a_i x^T$ that passes through v with slope a_i is between $b_1 = a_i x^T$ and $b_* = a_i x^T$ as illustrated in Figure 5. We denote the hyperplane that passes through y (respectively, u) with slope a_i by $b_y = a_i x^T$ (respectively, $b_u = a_i x^T$). Thus we have that $b_1 \leq b_y \leq b'_1 \leq b_* \leq b_u \leq b_2$.

Let $\Delta = b_* - b_1$. (Thus Δ is proportional to the distance between H_* and $b_1 = a_i x^T$.) Observe that LEARN-GENERAL-SLOPES will add the hyperplane $b'_1 = a_i x^T$ to $\mathcal{H}$, and this will now replace $b_1 = a_i x^T$ as a closest hyperplane of slope a_i to H_*. Let $\Delta' = b_* - b'_1$. (Thus Δ' is proportional to the new distance between H_* and its closest hyperplane in $\mathcal{H}$ in that direction.) We now show that $\Delta' \leq \Delta/2$. Observe that

$$\Delta' = b_* - b'_1$$

$$
\begin{aligned}
&= b_* - \left(\frac{(b_u + b_y)}{2}\right) \\
&\leq b_* - \left(\frac{(b_* + b_1)}{2}\right) \\
&= \frac{b_* - b_1}{2} = \frac{\Delta}{2}
\end{aligned}
$$

Thus the distance between H_* and one of its two nearest hyperplanes is reduced by a factor of two. Finally, when the distance between H_* and both of its two nearest hyperplanes is less than 1, the algorithm has determined the discretized hyperplane H_* and no other hyperplanes will be added for H_*.

Since the distance between each of $H_1, \ldots, H_m$ with both of its closest hyperplanes in $\mathcal{H}$ is at most γ it follows that the number of counterexamples needed to find one hyperplane is

$$2\lceil \log(\gamma) \rceil = 2\lceil \log(2^{\|S\|} \cdot n^d) \rceil = O(\|S\| + d \log n).$$

The number of hyperplanes is $m = C_S(g)$, and at each iteration we add $s = |S| \leq \|S\|$ hyperplanes to the hypothesis. Therefore the number of hyperplanes generated by our algorithm is $O(ms(\|S\| + d \log n))$. Thus by Lemma 2 the number of regions of the hypothesis is

$$O(ms(\|S\| + d \log n))^d.$$

The number of iterations that do not add any hyperplanes is bounded by the number of regions; thus the number of equivalence queries made by Learn-General-Slopes is

$$O(ms(\|S\| + d \log n))^d,$$

and clearly the time complexity is also polynomial in m, $\|S\|$, and $\log n$ for any constant d as desired. □

Finally, we note that since any slope in the discretized space $\mathcal{N}_n^d$ can be defined by two points from the domain, there are at most n^{2d} possible values for any one of the s slopes and thus $\|S\| \leq 2ds \log n$.

8. Handling lies in the counterexamples. In this section we consider the case in which the learner is provided with an l-liar teacher. Recall that an l-liar teacher is a teacher that can provide incorrect counterexamples as answers to at most l equivalence queries. This noise is not persistent. That is, if the teacher provides the same incorrect counterexample twice, then it counts as two lies (even if both were in response to the same query). Note that our learner in this model is not given access to a membership oracle. Thus, to learn the true classification of the points about which the environment has lied, it is necessary for the learner to isolate these instances. That is, the learner must create a region that consists of the single point that was the counterexample. This will force the teacher to give, eventually (after its l lies are exhausted), a correct classification for this instance if it is not already correctly classified by the hypothesis.

A degenerate region (a region consisting of fewer than d dimensions) is created whenever our algorithm adds to the hypothesis a hyperplane, passing through a given point, for each slope in S. We want to isolate the counterexample on which the lie occurred in a region of dimension 0. Notice, however, that given some set of

slopes, it is possible that the hyperplanes defined by the slopes, passing through the counterexample, do not create a 0-dimensional region.

Therefore, to ensure that the 0-dimensional region is created, we include in S the slopes of the elementary vectors $\{e_i\}$. Then the faulty points will be bounded by hyperplanes and at the end the oracle must give their real values. Thus, the main difference between our algorithm in this model and in the noise free model is the addition of hyperplanes through the counterexamples. Through the midpoints of $+/-$ pairs we still add only $|S|$ hyperplanes. It is only through the counterexamples that we add $|S| + d$ hyperplanes. This changes $C_S(g)$ to $C_S(g) + dl$, the number of slopes to $|S| + d$, and the complexity to

$$O((C_S(g) + dl)(|S| + d)(\|S\| + d + d \log n))^d.$$

9. A return to learning unions of boxes. Observe that by extending the hyperplane defined by a $+/-$ pair across the entire domain, our initial algorithm Learn-With-MQs may unnecessarily split a consistent region into a large number of smaller regions all of which make the same prediction. The algorithm we present here is motivated by the goal of reducing this unnecessary splitting by splitting only the region in which the counterexample is contained. We show that this algorithm runs in polynomial time for *either* m or d constant.

We begin by examining how one might measure the complexity of a concept from $\bigcup_{\leq m} \text{BOX}_n^d$. Observe that the minimum number m of boxes used to form the target concept is not a good measure of the complexity of the target concept. For example, consider the two examples shown in Figure 6. While both targets are composed of six boxes, the first is clearly more complex than the second. Thus the complexity of an algorithm should depend on some quantity other than just the number of boxes and dimension of the target concept. We now introduce such a new complexity measure, σ, to better capture the complexity of the target concept. We define a *segment* of the target concept g as a *maximal portion* of one of the sides of g that lies either entirely inside or entirely outside of each of the other halfspaces defining the target. (A halfspace defines the target if it labels some $+/-$ pair consistently with the labeling given by the target. See the definition of $+/-$ pair in Definition 1.) Note that two adjacent segments will intersect in a region of dimensionality less than the segments. We observe that there exist other possible measures of complexity besides σ that are potentially worthy of study. One example is the number of sides of a target polyhedron, where a side is a maximal connected set of coplanar boundary points of the polyhedron such that the interior of the polyhedron is on the same side of the set of boundary points. Sides (as opposed to segments) have the drawback of being of varying complexity (at least for polyhedra of more than two dimensions), as well as being apparently harder to work with. That is, we can have $0, 1, \ldots, d-1$ dimensional sides.

For example the target concept shown in Figure 1 has 14 sides. The same target concept has 22 segments. (The heavy black line defining the target concept is split into 20 clearly visible segments by the thin lines that correspond to the halfspaces that define the target concept. The final 2 segments come from the fact that the points $(20, 52)$ and $(49, 52)$ are segments due to the halfspaces $y_2 \geq 52$ and $y_2 \leq 52$.) The polygon in Figure 6(a) has 60 segments, since each of the long edges of the 6 boxes contributes 4 segments. By contrast the polygon in Figure 6(b) (defined by the same number of boxes) has 24 segments, since none of the sides of the individual boxes straddles any of the hyperplanes defining the boxes.

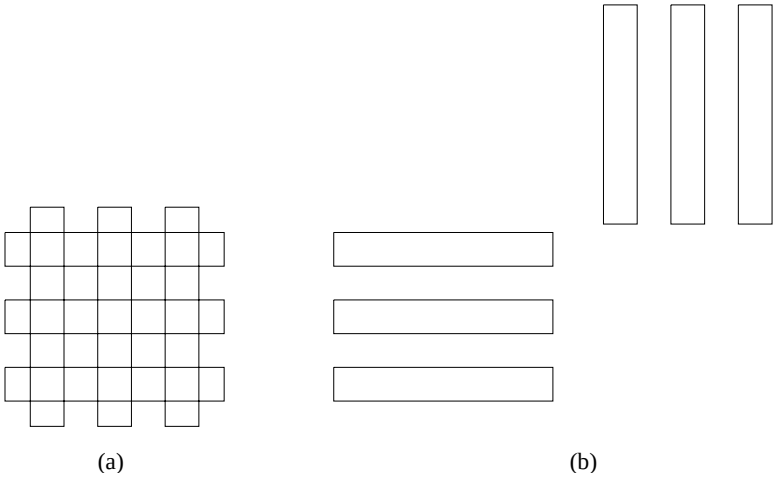

FIG. 6. *These concepts illustrate why "number of boxes" is an inadequate measure of complexity.* (a) *is more complex than* (b) *because of the large number of intersections of the sides of the boxes. For* (a) $\sigma = 60$. *For* (b) $\sigma = 24$.

For a concept $g \in \bigcup_{\leq m} \text{BOX}_n^d$ but not in $\bigcup_{\leq m-1} \text{BOX}_n^d$, we let σ denote the number of segments in the target concept corresponding to g. (In other words, suppose that m is the minimum number of boxes whose union is g.) First, observe that $m \leq \sigma$ since none of the boxes are contained within the union of the other $m-1$ boxes (which follows from the minimality of m). Furthermore, observe that $\sigma \leq (2m)^d$ since there are $2m$ halfspaces per dimension (one corresponding to each of the $2m$ sides per dimension) that can intersect to form at most $(2m)^d$ connected regions each of which would be part of at most one segment. Finally, it then follows that for any $g \in \bigcup_{\leq m} \text{BOX}_n^d$, the number of segments in $g \leq (2m)^d$ since the minimum number of boxes whose union is g is at most m.

The hypothesis class we use in this algorithm is a decision tree over the halfspaces defining the target concept. Namely, each hypothesis T is a rooted binary tree where each internal node is labeled with a halfspace and in which leaves are labeled from $\{0, 1\}$. We evaluate T recursively by starting at the root and evaluating the left subtree if the root's halfspace does not contain the point, and the right subtree otherwise. When a leaf is reached its label is output. Observe that each node of T corresponds to a subregion of the domain, with the root corresponding to the entire domain. The halfspace H associated with each internal node divides its region r into two subregions, with the left child being the subregion given by $\overline{H} \cap r$ and the right child being the subregion given by $H \cap r$. The leaves correspond to a set of nonoverlapping boxes that cover the entire region where the label for a given region is given by the label for the corresponding leaf. In Observation 1 we show that the height of the final decision tree will be at most $2md$. Thus the hypothesis can be evaluated in time polynomial in both m and d.

We now describe our algorithm. It has complexity polynomial in σ and $\log n$ as well as being an efficient algorithm for either m or d constant. We initialize T to be a single 0 leaf node. (Again we implicitly use the instance space $\{0, 1, \ldots, n, n+1\}^d$.) When a counterexample is received, we first search T to find the leaf v containing it. Let r be the subregion corresponding to v. Then as in LEARN-WITH-MQS we use a binary search to find a $+/-$ pair contained in r that defines a halfspace H. We

```
ALT-LEARN-WITH-MQS
 Initialize T to be the single 0-leaf
 While Equiv(T) ≠ "yes"
        Let y be the counterexample
        Search in T to find the leaf v corresponding to the region containing y
        T ←SPLIT-REGION(T, v, y)
 Return T

SPLIT-REGION(T, v, y)
▷T is the decision tree that defines the current hypothesis
▷y is a counterexample in a region r defined by T
▷v is the leaf of T that corresponds to r
 Perform binary search between y and a corner of region r
 Let H be the hyperplane found
 Let v_L and v_R correspond to the new regions created
 Make v an internal node labeled with H and having left child v_L and right child v_R
 Let r_L be the region H̄ ∩ r corresponding to v_L
 Let r_R be the region H ∩ r corresponding to v_R
 For each r' ∈ {r_L, r_R}
     Let v' be the leaf corresponding to region r'
     Perform a membership query on the upper and lower opposing corners of r'
     Call these corners upper and lower
     If both corners have classification b ∈ {0, 1} let v' be a b-leaf of T
         Let the predicted label of v' become b
     Else
         Let v' be a leaf of T with v' having the same classification as lower
         SPLIT-REGION(T, v', upper)
```

FIG. 7. *Alternate algorithm for learning unions of d-dimensional axis-parallel boxes that runs in polynomial time for* either *m or d constant. We note that the corner points of regions in the hypothesis, used throughout the algorithm, are easy to compute given the hypothesis.*

replace v with an internal node labeled with H, having left child leaf v_L corresponding to the region given by $\overline{H} \cap r$ and right child leaf v_R corresponding to the region given by $H \cap r$. At this point we call a procedure that recursively visits all newly created leaves in a depth-first manner and checks if the corresponding region is a consistent region. If the region r' associated with leaf v' is consistent (a region is consistent if its opposing corners have the same classification), then the classification field is filled; otherwise we use a binary search to obtain a halfspace H' for r' and replace v' with an internal node labeled with H'. We generate two new leaves: v'_L corresponding to the region $\overline{H'} \cap r'$ and v'_R corresponding to the region $H' \cap r'$. Then a recursive call is made to validate (if necessary) each of these new regions. The algorithm is shown in Figure 7. One possible final hypothesis that could be constructed by this algorithm, for the target concept shown in Figure 1, is shown in Figure 8. Figure 9 shows the decomposition of $\mathcal{N}_n^d$ that corresponds to the decision tree shown in Figure 8.

9.1. Analysis. We first show that the height of the final decision tree comprising our hypothesis is at most $2md$.

OBSERVATION 1. *The height of the final decision tree constructed by* ALT-LEARN-WITH-MQS (*shown in Figure* 7) *is at most* $2md$ *since each of the at most* $2md$ *halfspaces defining the target polyhedra can appear at most once on any path from*

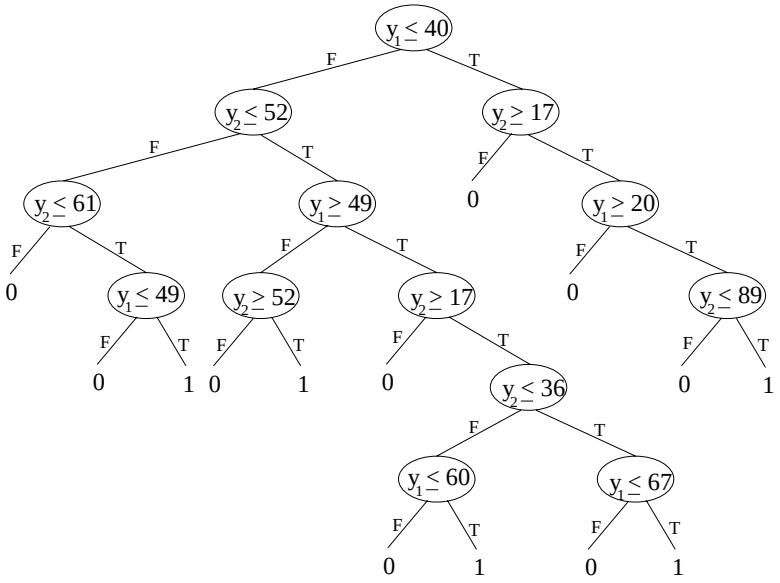

FIG. 8. *This shows the final decision tree that could be constructed by* ALT-LEARN-WITH-MQS *for the target geometric concept shown in Figure* 1.

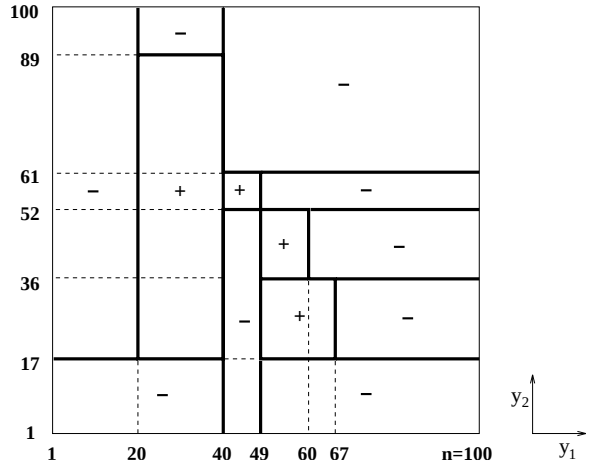

FIG. 9. *This shows the decomposition of* $\mathcal{N}_n^d$ *corresponding to the decision tree shown in Figure* 8.

the root to any leaf.

We now give two separate techniques for analyzing this algorithm. The first method of analysis gives that this algorithm uses queries and time polynomial in σ and $\log n$ (and thus polynomial in m and $\log n$ for d constant). The second method of analysis shows that our algorithm uses queries and time polynomial in d and $\log n$ for m any constant.

THEOREM 4. *Given any target concept* $g \in \bigcup_{\leq m} \text{BOX}_n^d$, *the algorithm* ALT-LEARN-WITH-MQS *achieves exact identification of* g *making at most* $(\sigma/2+1)$ *equivalence queries, and using* $O(\sigma(\sigma + \log n + d))$ *time and* $O(\sigma(\log n + d))$ *membership queries.*

Proof. Observe that each segment of g causes at most one region to be split. Thus the number of leaves in the decision tree created will be at most $\sigma + 1$.

By Lemma 1 we get that two segments are found as a result of the counterexample to each equivalence query (here the second halfspace is implicitly found by the call to SPLIT-REGION). Thus at most $\frac{\sigma}{2} + 1$ equivalence queries will be made.

Furthermore, since there are at most two membership queries made to query the upper and lower corners of each leaf, and $\lceil \log n \rceil + d$ membership queries used in the binary searches for the σ halfspaces, it follows that the number of membership queries made is at most $2\sigma + \sigma(\lceil \log n \rceil + d) = O(\sigma(\log n + d))$.

Observe that the depth of T is at most σ since any of the halfspaces defined by the σ segments in the target concept will appear at most once on any path from the root to a leaf. Thus the time to locate the region to split is $O(\sigma)$ and it immediately follows that the time complexity is $O(\sigma(\sigma + \log n + d))$. □

COROLLARY 5. *The algorithm* ALT-LEARN-WITH-MQS *achieves exact identification for any* $g \in \bigcup_{\leq m} \text{BOX}_n^d$ *using time and queries polynomial in* m *and* $\log n$ *for* d *constant.*

Proof. This follows immediately from Theorem 4 and the observation that $\sigma \leq (2m)^d$. □

Finally, observe that just as we described in section 5.3, our final hypothesis can be converted to the union of $O(md \log m)$ boxes from BOX_n^d. Recall that the time to perform the conversion is $O((2m)^{2d} md \log m)$ and thus, this will be efficient only if d is constant. Also, using the technique of section 6 we can refine this algorithm to use only equivalence queries.

We now use a different method of analysis to show that ALT-LEARN-WITH-MQS uses time and queries polynomial in d and $\log n$ for m constant.

We begin by examining the number of regions created by this algorithm. Each region is represented by a single leaf in the hypothesis decision tree. Thus, we can find the number of regions by finding the number of leaves in our hypothesis. We now derive a recurrence relation for the number of leaves in the final decision tree. Let $g \in \bigcup_{\leq m} \text{BOX}_n^d$ be the target concept and T be the final decision tree output by our algorithm. For each internal node of T there is an associated region of $\mathcal{N}_n^d$. For any node r in T, let h_r denote the height of the subtree of T rooted at r (we define the height of a leaf to be 0), and let m_r be the minimum number of boxes needed to cover the part of g contained in the region of $\mathcal{N}_n^d$ associated with r. Thus, for the region r corresponding to the root of T we have that $m_r \leq m$ and $h_r \leq 2md$ since, by Observation 1, the height of T is at most $2md$.

Let $L(m, h)$ denote the maximum number of leaves in a decision tree rooted at a node r with $m_r = m$ and $h_r = h$. Then we have that $L(m, h) = L(m, h-1) + L(m-1, h-1)$, where, for all $m \geq 0$, $L(m, 0) = 1$, and for all $h \geq 1$, $L(0, h) = 1$. To see this, observe that when we find, while building the hypothesis, a hyperplane that splits a node, the two subproblems that correspond to the left and right children both must have at most $h - 1$ hyperplanes left to find since in the worst case, all other hyperplanes are split by this one and thus appear on both sides. Finally, since the hyperplane just found must be the side of one of the m boxes, that box will not appear in one of the recursive calls. (In the worst case all other boxes will be split).

Consider the "largest possible" decision tree, according to the upper bound $L(m, h)$. (Note that a tree constructed from a problem instance will generally have fewer leaves.) Notice that in such a "largest" decision tree, there are no leaves in the decision tree on levels 0 (i.e., the root level) to $m - 1$. On each level from m to h there are leaves

caused by the base case $m = 0$ of the recurrence. The total number of these leaves is given by

$$\sum_{j=m}^{h} \binom{j-1}{m-1}$$

since the number of nodes, in the recursion tree, with $m = 0$ at level j is equal to the number of nodes with $m = 1$ at level $j - 1$. There are also leaf nodes caused by the other base case of the recurrence, $h = 0$. Note that this is the last level of the tree. The number of leaves here is given by

$$\sum_{j=0}^{m-1} \binom{h}{j}$$

since this gives the number of nodes for each nonzero value of m (the $m = 0$ nodes on this level were already counted in the previous expression). Thus, the total number of leaves is

$$\begin{aligned}
\sum_{j=m}^{h} \binom{j-1}{m-1} + \sum_{j=0}^{m-1} \binom{h}{j} &= \sum_{j=m-1}^{h-1} \binom{j}{m-1} + \sum_{j=0}^{m-1} \binom{h}{j} \\
&= \sum_{j=0}^{h-1} \binom{j}{m-1} + \sum_{j=0}^{m-1} \binom{h}{j} \\
&= \binom{h}{m} + \sum_{j=0}^{m-1} \binom{h}{j} \\
&= \sum_{j=0}^{m} \binom{h}{j}. \qquad (9.1)
\end{aligned}$$

Recall that $h \leq 2md$. In the following lemma we show that $(2md)^m$ is an upper bound on the summation in (9.1).

LEMMA 3. *The number of leaves in any hypothesis decision tree constructed by* ALT-LEARN-WITH-MQS *is bounded above by* $(2md)^m$ *for* $m > 1$ *and is* $2d + 1$ *for* $m = 1$.

Proof. Let $n = md$ and $k = m$ for $m > 1$. Then the expression we have derived for the number of leaves is $\sum_{j=0}^{k} \binom{2n}{j}$. It is easily shown by induction on k that $\sum_{j=0}^{k} \binom{2n}{j} \leq (2n)^k$ for $n \geq k > 1$, and thus the result follows for $m > 1$. Finally, for $m = 1$ the number of leaves in the hypothesis is $2d + 1$. □

We are now ready to prove the running time of our algorithm using this method of analysis. For ease of exposition we assume $m > 1$ in the remainder of this paper.

THEOREM 6. *Given any target concept* $g \in \bigcup_{\leq m} \text{BOX}_n^d$, *the algorithm* ALT-LEARN-WITH-MQS *achieves exact identification of* g, *making at most* $(2md)^m$ *equivalence queries, making* $O((2md)^m \cdot (\log n + d))$ *membership queries, and using* $O((2md)^{m+1} \cdot (\log n + d))$ *time.*

Proof. Observe that the number of counterexamples received by ALT-LEARN-WITH-MQS is at most the number of internal nodes in our final decision tree. Thus the number of equivalence queries made by ALT-LEARN-WITH-MQS is at most the number of leaves in the final decision tree.

Equation (9.1) shows that $L(m,h) = \sum_{j=0}^{m} \binom{h}{j}$, and Lemma 3 proves a bound for the number of leaves of T of at most $\sum_{j=0}^{m} \binom{2md}{j} \leq (2md)^m$. Thus it immediately follows that at most $(2md)^m$ equivalence queries are made. Since at most $\lceil \log n \rceil + d$ membership queries are used by the binary search procedure when splitting a node, it follows that the number of membership queries made by ALT-LEARN-WITH-MQS is $O((2md)^m \cdot (\log n + d))$. Finally, since it takes $O(md)$ time to find the node corresponding to the region containing the counterexample and at most $O(\log n + d)$ time for each binary search, it follows that the time complexity of ALT-LEARN-WITH-MQS is $O((2md)^{m+1} \cdot (\log n + d))$. □

Thus ALT-LEARN-WITH-MQS achieves exact identification for any $g \in \bigcup_{\leq m} \text{BOX}_n^d$ using time and queries polynomial in d and $\log n$ for m constant. We note that for $m \geq 6$ we can remove a factor of 2^m in the complexity by using the tighter upperbound that $\sum_{j=0}^{m} \binom{2md}{m} \leq (md)^m$.

10. Concluding remarks. We have given an efficient algorithm that uses membership and equivalence queries to exactly identify any concept from $\bigcup_{\leq m} \text{BOX}_n^d$ for d constant. Furthermore, this algorithm makes at most $md + 1$ equivalence queries, all of which can be formulated as the union of $O(md \log m)$ axis-parallel boxes.

We have also shown how to extend our basic algorithm to learn efficiently, using *only* equivalence queries, any discretized geometric concept generated from any number of halfspaces with any number of known (to the learner) slopes in a constant dimensional space. In particular, our algorithm exactly learns (from equivalence queries *only*) unions of discretized axis-parallel boxes in constant dimensional space in polynomial time. Further, this algorithm can be modified to handle a polynomial number of lies in the counterexamples provided by the environment.

Finally, we have introduced a new complexity measure, σ, that better captures the complexity of the union of m boxes than simply the number of boxes and the dimension. We presented an algorithm that uses time and queries polynomial in σ and $\log n$. In fact, the time and queries (both membership and equivalence) used by this single algorithm are polynomial for *either* m or d constant.

A number of important open questions that we have not answered concern the necessity of membership queries to exactly learn the class $\bigcup_{\leq m} \text{BOX}_n^d$ (or the more general class of a discretized geometric concept) in time polynomial in d and $\log n$ when the number of boxes (or defining hyperplanes) is constant.

While we have provided an algorithm to efficiently learn geometric concepts defined by hyperplanes that are *not* axis parallel, to achieve this goal it was necessary that the learner be given a priori knowledge as to the slopes of the hyperplanes. An interesting direction is to explore the learnability (even for fixed dimensions) of geometric concepts defined by hyperplanes whose exact slopes are not known to the learner.

Finally, it would be interesting to see if $\bigcup_{\leq m} \text{BOX}_n^d$ can be efficiently learned in time polynomial in m and $\log n$ for $d = O(\log m)$ or in time polynomial in d and $\log n$ for $m = O(\log d)$ (i.e., a generalization of the Blum and Rudich [9] result that $O(\log n)$-term DNF formulas are exactly learnable). Of course, since $\bigcup_{\leq m} \text{BOX}_n^d$ generalizes the class of DNF formulas, it seems very unlikely that one could develop an algorithm for the unrestricted case of $\bigcup_{\leq m} \text{BOX}_n^d$ that is polynomial in m, $\log n$, and d. It may be possible, however, to obtain a truly polynomial algorithm for some subclass of $\bigcup_{\leq m} \text{BOX}_n^d$.

Acknowledgments. We thank Peter Auer and the COLT committee for their comments. We thank Wolfgang Maass for suggesting we consider the material discussed in section 5.3. We also thank the anonymous referees whose comments improved this manuscript.

FAST EXPONENTIATION USING DATA COMPRESSION*

YACOV YACOBI†

Abstract. We present the first exponentiation algorithm that uses the entropy of the source of the exponent to improve on existing exponentiation algorithms when the entropy is smaller than $(1 + w(S)/l(S))^{-1}$, where $w(S)$ is the Hamming weight of the exponent, and $l(S)$ is its length. For entropy 1 it is comparable to the best-known general purpose exponentiation algorithms.

Key words. fast exponentiation, cryptography, discrete-log, compression

1. Introduction. Exponentiation with huge numbers is used heavily in modern cryptography, and the topic is the focus of attention of many researchers who try to achieve efficient exponentiation algorithms ([1], [2], [3], [4], [12], and many others). This paper is the first to make use of the entropy of the source of the exponent. In cases of entropy smaller than $(1 + w(S)/l(S))^{-1}$, where $w(S)$ is the Hamming weight of the exponent and $l(S)$ is its length, this method becomes asymptotically faster than all known general methods. For entropy 1 it is asymptotically comparable to the best-known general-purpose algorithms. The method is applicable to every repeated group operation. A preliminary version appeared in [13].

We now present an outline of the paper. Section 2 gives the required elements of the LZ theory, section 3 applies this theory to fast exponentiation, section 4 is a brief overview of other exponentiation methods, and the final section gives a cryptographic viewpoint.

2. The LZ theory. For the sake of completeness we present here the definitions and theorems of [8], which are needed for the complexity analysis. (The actual compression algorithm is in [9], [10]. The earlier paper, [8], is written more along the lines of decompression.)

Let A^* denote the set of all finite-length sequences over a finite alphabet A. Let $l(S)$ denote the length of $S \in A^*$ and let $A^n = \{S \in A^* | l(S) = n\}$, $n \geq 0$. The null sequence χ is in A^*. We use $S(i, j)$ to denote a substring of S that starts at location i and ends at location j. Let $S\pi^i$ denote $S(1, l(S) - i)$, $\quad i = 0, 1, \ldots, l(S)$. The *vocabulary*, $v(S)$, of S is the subset of A^* formed by all the substrings (words) of S. When a sequence S is extended by concatenation with one of its words, say $W = S(i, j)$, the resulting sequence $R = SW$ can be viewed as being obtained from S through a copying procedure. The same recursive copying procedure could be applied to generate an extension $R = SQ$ of S which is much longer than warranted by any word in $v(S)$. The only provision is that Q be an element of $v(SQ\pi)$.

We use the denotation $S \Rightarrow R$ if $R = SQ$ can be obtained from S by application of the above copying procedure, where at the end of the copying process we use "one-symbol innovation" (any symbol from A, not subject to the copying procedure). This process is called *reproduction*, while a single-step copying without innovation is called

†Microsoft, One Microsoft Way, Redmond, WA 98052 (yacov@microsoft.com).

production and is denoted $S \to R$. If R cannot be obtained from S by production we write $S \not\to R$.

Consider an m-step production process of a sequence S and let $S(1, h_i), \quad i = 1, 2, \ldots, m, \quad h_1 = 1, \quad h_m = l(S)$, be the m states of the process. The parsing of S into $H(S) = S(1, h_1)S(h_1+1, h_2) \cdots S(h_{m-1}+1, h_m)$ is called the *production history* of S, and the m words $H_i(S) = S(h_{i-1}+1, h_i), \quad i = 1, 2, \ldots, m$, where $h_0 = 0$, are called the components of $H(S)$. A component $H_i(S)$ and the corresponding reproduction step $S(1, h_{i-1}) \Rightarrow S(1, h_i)$ are called *exhaustive* if $S(1, h_{i-1}) \not\to S(1, h_i)$; a history is called exhaustive if each of its components, with the possible exception of the last one, is such. Every nonnull sequence S has a unique exhaustive history (denoted $E(S)$).

Let $c_H(S)$ denote the number of components in a history $H(S)$ of S. The production complexity of S is defined as $c(S) = \min\{c_H(S)\}$, where minimization is over all histories of S. Let $c_E(S)$ denote the production complexity of the exhaustive history of S.

$$\forall\ S, \quad c(S) = c_E(S). \tag{1}$$

Let $\alpha = |A|$. All logarithms are to base α. Let $\epsilon_n = 2(1 + \log\log(\alpha n))/\log(n)$. Then

$$\forall\ S \in A^n, \quad c(S) < n/((1 - \epsilon_n)\log(n)). \tag{2}$$

Consider an ergodic α-symbol source with normalized entropy $h, \quad 0 \le h \le 1$. For this source we have asymptotically:

$$c(S) \le hn/\log(n). \tag{3}$$

The previous three results were proved in [8].

While [8] is written along the lines of decompression, the two later papers, [9] and [10], give an efficient compression algorithm that creates the exhaustive history of any given sequence.

3. Using the LZ compression method for fast exponentiation. The binary case is presented for concreteness. The natural many-to-one mapping from sequences to integers is used, and it is assumed that $S(1, 1)$ is the least significant bit. S is used to denote both integer and sequence.

Given the exponent S, the computation of any exponentiation x^S proceeds as follows.

Build a binary tree where each path from the root to any node corresponds to some segment of the exponent $S(i, j)$, and the node contains the result of $x^{S(i,j)}$. The root contains $1 = x^0$ (0 corresponds to the string χ). Proceed inductively as follows. Suppose that the component $S(i, j)$ was already processed; i.e., the tree already contains a path from the root to some leaf which corresponds to this component, and the leaf contains the result of $x^{S(i,j)}$. Traverse the partial tree from the root according to the new (so far unscanned) bits of $S(j + 1, \ldots)$ until you reach a leaf. Proceed with S having one more symbol. The new component contains now exactly one new untraversed symbol. Extend the tree according to the new symbol, and mark the new branch with this symbol. Compute the value of the new leaf. This simple construction (without the exponentiation) is the heart of the LZ algorithm. Ziv and Lempel proved that this construction creates the exhaustive history of S, $H(S) = S(1, h_1)S(h_1 + 1, h_2) \cdots S(h_{m-1} + 1, h_m)$, where each path from the root to any node corresponds to one of the components of $H(S)$, and hence the number of nodes in the tree is $c(S)$.

For depth i we need to do one squaring (to compute $X^{2^i} = (X^{2^{i-1}})^2$), and whenever the new bit is 1 we need to multiply that value by the value of the father. For random exponents we can expect that to happen in half the cases for a total cost of $c(S)/2$, and in general, for exponent of length $l(S)$ and expected Hamming weight $w(S)$, the expected number of cases where the new symbol is 1, is $c(S) \cdot w(S)/l(S)$.

To evaluate the cost of squarings we need to know more about the shape of the LZ trees. In [7] an analysis is given, showing that the height of the tree has normal distribution with mean value $\log_\alpha(c(S))/h$, where h is the entropy of the source, and the deviation is rather big: $O(\log_\alpha(c(S)))$ (big "oh"); i.e., for almost all cases the squaring component is $o(c(S))$ (little "oh").

We combine the partial results (stored in the leaves) using $l(S)$ squarings and $c(S)$ multiplications in the natural way. The total expected complexity is $\mathcal{C}(S) = l(S) + (1 + w(S)/l(S))c(S) + o(c(S))$. Plugging in (3) and defining $\sigma(S) = 1 + w(S)/l(S)$, $1 \le \sigma(S) \le 2$, we get the asymptotical upper bound

$$\mathcal{C}(S) = l(S) + \sigma(S) \cdot h \cdot l(S)/\log(l(S)) + o(l(S)/\log(l(S))). \tag{4}$$

When $h < \sigma(S)^{-1}$ the above method wins asymptotically in expected complexity over all existing general purpose methods.

Applying the algorithm in practice. We improve somewhat on a straightforward LZ compression, by taking advantage of leading zeros. Leading zeros are not accounted for in the binary tree, thus reducing the tree size. When strings are taken from a uniform distribution the expected length of the run of zeros is $\sum_{j=1}^{\infty} j \cdot 2^{-(j+1)} = 1$, thus truncating the expected tree height by 1.

To raise an integer x to power S, the bits of S are parsed using an LZ parsing from least to most significant. Each time a new phrase is started, the leading zeros are skipped, a root-to-leaf path is traversed (skipping over the corresponding bits), and a new leaf is formed for the next bit. Stored at this new leaf are its depth, i, a back pointer to the previous parsed phrase, the number of leading zeros, and a value which is set to that of its parent if the next bit is zero, or that of its parent times x^{2^i}, if the next bit is 1. After S has been parsed into substrings in this manner we know the value of x raised to each of the parsed substrings, and the result can then be combined by following back pointers and successively multiplying by the next term and then raising to the power of 2 to {the number of leading zeros plus the length of the next term}. The powers of 2 needed in the above description can be computed once by successive squaring for all future uses.

4. Concluding remarks: Other methods. The addition-chain method runs in time $n+n/\log(n)+o(n/\log(n))$ ([5], [12], [4]), once an optimal addition chain for the exponent is found; however finding an optimal addition chain is NP-hard. Suboptimal heuristics exist. The m-ary method [11] (the most popular among practitioners) runs in time upper bounded by $n+n/m+2^{m-1}+1$, where m is an optimization parameter. For example, for $n = 1024$, $m = 6$ is optimal. In the practical range this is comparable to the complexity of the new method, with $h = 1$ and $w(S)/l(S) = 1/2$. Other heuristics exist [1].

In some applications the exponent is fixed for many bases, in which case it is natural to partition the operations into two stages: exponent processing and exponentiation. The new method is comparable to optimal addition chains in the exponentiation phase even for $h = 1$, and wins when $h < 1$.

In [2] a method is proposed that optimizes exponentiation complexity when the base is fixed for many exponents.

Cryptographic viewpoint. For discrete-log–based cryptosystems, when the modulus is "good," we can go down with $w(S)$ quite far before the complexity of the discrete-log problem deteriorates, per the best-known algorithm [6]. Specifically, the complexity is $A^{1/2}$, where

$$A = \left(\begin{array}{c} l(S) \\ w(S) \end{array} \right).$$

For example, for $l(S) = 512$ bits, $w(S) = 22$ gives $A^{1/2} = 2^{64}$.

When the Hamming weight is very low, the entropy is also low, thus we gain using the new method. Specifically we have $h \leq l^{-1} \cdot \log_2 A$ affecting the second term of $\mathcal{C}(\mathcal{S})$ (in the above example $h < 1/4$, while $\sigma(S) \approx 1$).

The above numbers are not a recommendation. The discrete-log problem for low-entropy exponents is not well studied yet (however the method of [6] *does not seem to apply directly to low entropy).*

Acknowledgments. I am indebted to Arjen Lenstra for many insightful discussions. I would also like to thank Shimon Even, Rich Graveman, and Stuart Haber for many helpful comments. Finally I would like to thank two anonymous referees for numerous helpful comments, and in particular for pointing me to the paper by P. Jacquet and W. Szpankowski [7].

A POLYNOMIAL TIME COMPLEXITY BOUND FOR COMPUTATIONS ON CURVES*

P. G. WALSH†

Abstract. In this paper, we use a recent quantitative version of Eisenstein's theorem on power series expansions of algebraic functions to compute a polynomial-time bit complexity bound for the computation of the genus of an algebraic curve over the rationals. The result is extendable to any field of characteristic zero which is finitely generated over the rationals.

Key words. algebraic curves, genus, Puiseux expansion, complexity

AMS subject classification. 14H05

PII. S0097539796300969

1. Introduction.

In [3] Duval describes a method based on computing Puiseux expansions for certain computations on curves. These include the computation of the ramification indices in the projection of a curve on any line, the genus of an algebraic curve, the construction of rational functions on a curve, and finding the irreducible components of a curve. An interesting aspect of this work is that it is shown that all of these computations can be done in polynomial time in the number of arithmetic operations. The shortcoming of this result is that there is no prior knowledge about the size of the integers on which these arithmetic operations are performed. In fact, due to a result of Coates (Lemma 3 of [2]) on the coefficients of algebraic power series, it is conceivable that Duval's algorithm would be completely impractical because of the exponential growth of the size of the integers involved. In this paper we use a recent result of Schmidt [11] on the coefficients of algebraic power series to prove that such exponential growth does not occur. As a result, the aforementioned computations on a curve can be computed in time which is polynomial in the size of the polynomial defining the curve.

Other work in this direction has been carried out by Chistov [1]. The main difference here is to compute explicit estimates on the number of bit operations required to complete the algorithms and show how this polynomial-time complexity depends entirely on the quantitative version of Eisenstein's theorem given in [11]. Kozen [6] has also described an algorithm for the resolution of plane curve singularities which has polynomial-time complexity in the number of bit operations. The method is based on passive factorization.

The main point of our paper is to show that the classical method, based on Puiseux expansion computation, does in fact have polynomial-time complexity in the number of bit operations, which is contrary to the wide belief that Coates' algorithm runs in exponential time. We make no claims as to the practicality of the classical method over the newer ones. In this regard, it is worth noting that Teitelbaum [12] also presents an efficient method for the resolution of singularities based on passive factorization.

2. Puiseux expansions of algebraic functions. In this section we describe Puiseux expansions and state a result on the computation of Puiseux expansions of algebraic functions. The proof can be found in [15].

We recall Puiseux's theorem (for example, see [4]), which states that at any point $\alpha \in \mathbf{C} \cup \{\infty\}$ there is a factorization

$$F(x,y) = A_n(x) \prod_{i=1}^{n} (y - y_{i,\alpha}(x)),$$

where for $i = 1, \ldots, n$

$$y_{i,\alpha} = \sum_{k=f_{i,\alpha}}^{\infty} a_{k,i,\alpha} (z_\alpha^{1/e_{i,\alpha}})^k, \tag{1}$$

with $f_{i,\alpha} \in \mathbf{Z}$, $e_{i,\alpha} \in \mathbf{Z}^+$, $a_{k,i,\alpha} \in \mathbf{C}$, $a_{f_{i,\alpha},i,\alpha} \neq 0$, and $z_\alpha = (x - \alpha)$ if $\alpha \in \mathbf{C}$, $z_\alpha = 1/x$ if $\alpha = \infty$. The *singular part* of $y_{i,\alpha}$ is the partial sum

$$y_{i,\alpha,T} = \sum_{k=f_{i,\alpha}}^{T} a_{k,i,\alpha} (z_\alpha^{1/e_{i,\alpha}})^k,$$

where T is minimal such that $y_{i,\alpha,T}$ distinguishes $y_{i,\alpha}$ from the other $n-1$ expansions at α of y. The number $e_{i,\alpha}$ is the *ramification index* of $y_{i,\alpha}$ and can be obtained by computing the singular part $y_{i,\alpha,T}$ of $y_{i,\alpha}$.

The n Puiseux expansions are partitioned into *cycles*, where the cycle corresponding to the expansion in (1) is the set of $e_{i,\alpha}$ series

$$y_{i,\alpha}^{(j)} = \sum_{k=f_{i,\alpha}}^{\infty} a_{k,i,\alpha} (\zeta_{e_{i,\alpha}}^{(j)} z_\alpha^{1/e_{i,\alpha}})^k, \qquad j = 0, \ldots, e_{i,\alpha} - 1,$$

where $\zeta_{e_{i,\alpha}}$ denotes a primitive $e_{i,\alpha}$th root of unity.

THEOREM 2.1. *Let $F(x,y) \in Z[x,y]$ be a square-free polynomial of degree n in y, m in x, and let h denote the maximum of the absolute values of the coefficients of F. Then, for any $\epsilon > 0$, the singular part of a Puiseux expansion at $x = 0$ of the algebraic function y defined by $F(x,y) = 0$ can be computed in*

$$O(n^{32+\epsilon} m^{3+\epsilon} \log^{2+\epsilon}(h))$$

bit operations.

The proof of this result is based on Schmidt's recent quantitative version of Eisenstein's theorem on power series expansions of algebraic functions [11]. Schmidt exploits the fact that the algebraic function satisfies a linear differential equation and is able to use this to prove a result which is roughly an order of magnitude smaller than the corresponding result proved by Coates in Lemma 3 of [2].

3. Computations on curves. In this section we state the main results of the paper. Throughout this section we let $F(x,y)$ denote a polynomial with integer coefficients of degree n in y, m in x, and h denotes the maximum of the absolute values of the coefficients of F, referred to as the *height* of F and denoted $ht(F)$.

THEOREM 3.1. *If F is square-free in $\mathbf{Q}[x,y]$, then, for any $\epsilon > 0$, the ramification indices at all critical places of F and the genus of the algebraic curve defined by $F(x,y) = 0$ can be computed in*

$$O(n^{70} m^{40} \left(n^{2+\epsilon} + m^{2+\epsilon} \log^{2+\epsilon}(h)\right))$$

bit operations.

In this section we describe an algorithm to compute the genus of the curve $F(x, y) = 0$. This is accomplished by computing the Puiseux expansions at all places which correspond to singularities of the algebraic function y defined by $F(x, y) = 0$ and then applying the Hurwitz genus formula.

The Hurwitz genus formula is

$$g = 1 - n + (1/2)\sum(e - 1), \tag{2}$$

where the sum is the sum of all ramification indices over all places and all cycles at each place. It is well known (see [4]) that if α is a regular point, then $e_{i,\alpha} = 1$. As a result, for computing the genus of the curve, we need only compute the ramification index for each cycle at each critical place α. Finite critical places α are characterized by the property that they are zeros of the resultant polynomial $R(x) = res_t(F, F_y)$, where F_y is the derivative of F with respect to y. Note that since F is square-free, $R(x)$ is a nonzero polynomial.

4. Algorithm to compute the genus of the curve $F(x, y) = 0$.

1. Compute $R(x) = res_y(F, F_y)$.
2. Compute $S(x) = R(x)/gcd(R(x), R'(x))$.
3. Factor $S(x)$ into irreducibles $P_1, \ldots, P_k$ in $\mathbf{Q}(x)$.
4. For each $i = 1, \ldots, k$, compute $G_i(x, y) = res_t(P_i(t), F(x + t, y))$.
5. For each $i = 1, \ldots, k$, compute $H_i(x, y) = G_i(x, y)/gcd(G_i, (G_i)_y)$.
6. For each $i = 1, \ldots, k$, compute the singular part at $x = 0$ of the Puiseux expansions of the algebraic function y defined by $H_i(x, y) = 0$.
7. Let $F_\infty(x, y) = x^m F(1/x, y)$, and compute the singular part at $x = 0$ of the Puiseux expansions of the algebraic function y defined by $F_\infty(x, y) = 0$.
8. Use the ramification indices computed in steps 6 and 7 in (1) to compute the genus.

Before proceeding to the complexity of the algorithm, we first give a justification for its correctness. The purpose of the algorithm is to compute the singular part of all of the Puiseux expansions at each place α, where α is a critical place, that is, a root of $R(x)$ or the infinite place. For a fixed irreducible factor $P(x)$ of $R(x)$ we can simultaneously compute all of the Puiseux expansions of y at all places corresponding to the roots of $P(x)$ by computing the Puiseux expansions at $x = 0$ of the algebraic function defined by $G(x, y) = 0$, where $G(x, y) = \prod_i F(x + \alpha_i, y)$, and the product is over all roots α_i of $P(x)$. Moreover, this product is the norm of $F(x + \alpha, y)$ from $\mathbf{Q}(\alpha)$ to $\mathbf{Q}$, and hence has rational coefficients. By Theorem 1 of [10], this norm can be computed as described in step 4 above. By doing this for each of the irreducible factors of $R(x)$, we obtain the ramification indices corresponding to all cycles of every finite critical place of the algebraic function y defined by $F(x, y) = 0$. In step 7 we obtain the ramification indices of the cycles corresponding to the infinite place, and thus all of the required data are obtained to use (2).

4.1. Complexity analysis. Computationally, the dominant step in the algorithm is the computation of the singular parts, as described in step 6. To apply Theorem 2.1 we need to estimate the degree of $H_i(x, y)$ in x and in y and a bound for the size of its coefficients. We remind the reader that $n = deg_y F$, $m = deg_x F$, and h is the height of F.

$R(x)$ is the determinant of a $2n - 1 \times 2n - 1$ matrix whose coefficients are the coefficients of F and F_y, regarded as polynomials in y. Thus the determinant has $(2n - 1)!$ summands, where each summand is the product of n coefficients of F_y and

$n-1$ coefficients of F. Since the height of the polynomial $(1+\cdots+x^m)^{2n}$ is no larger than $(m+1)^{2n}$, we deduce that

$$ht(R) < (2n)^{2n}(nh)^n h^n (m+1)^{2n},$$

and $deg_x R(x) < (2n-1)m$. Fix i with $1 \le i \le k$. Since P_i is a factor of $R(x)$, it follows from Lemma 2 on p. 135 of [5] that $ht(P_i) < e^{(2n-1)m} ht(R)$; therefore,

$$ht(P_i) < 2^{2nm} n^n (2nh(m+1))^{2n}.$$

Now $G_i(x,y)$ is the determinant of the matrix with coefficients of $P_i(t)$ and $F(x+t,y)$, the latter regarded as a polynomial in t. Note that $deg_t P_i(t) < (2n-1)m$. It is easy to see that the height of $F(x+t,y)$, regarded as a polynomial in t, is no larger than $h(m+1)(n+1)2^m$, and so a similar argument as above shows that

$$ht(G_i) < (2n!m)^{2nm} (ht(P_i))^m (h(m+1)(n+1)2^m)^{2nm} ((n+1)(m+1))^{2nm}.$$

From the definition of G_i, we have that

$$deg_x G_i < 2nm^2, deg_y G_i < 2n^2 m.$$

By the aforementioned result of [5], $ht(H_i) < e^{2nm^2+2n^2m} ht(G_i)$, so we deduce finally that

$$\log(ht(H_i)) < c(nm^2 + n^2 m + nm^2 \log(nmh))$$

for some positive constant c. Moreover,

$$deg_x H_i < 2nm^2, \;\; deg_y H_i < 2n^2 m,$$

and so by Theorem 2.1, together with the fact that there are at most $2nm$ polynomials H_i, we deduce the result in Theorem 3.1.

STOCHASTIC CONTENTION RESOLUTION WITH SHORT DELAYS*

PRABHAKAR RAGHAVAN† AND ELI UPFAL‡

Abstract. We study contention resolution protocols under a stochastic model of continuous request generation from a set of contenders. The performance of such a protocol is characterized by two parameters: the maximum arrival rate for which the protocol is stable and the expected delay of a request from arrival to service.

Known solutions are either unstable for any constant injection rate or have at least polynomial (in the number of contenders) expected delay. Our main contribution is a protocol that is stable for a constant injection rate, while achieving logarithmic expected delay. We extend our results to the case of multiple servers, with each request being targeted for a specific server. This is related to the *optically connected parallel computer* (or *OCPC*) model. Finally, we prove a lower bound showing that long delays are inevitable in a class of protocols including backoff-style protocols, if the arrival rate is large enough (but still smaller than 1).

1. Introduction.

The subject of this paper is the stochastic analysis of protocols for contention resolution. The most concrete setting of this problem is that of multiple access channels, and so the remainder of the paper will use the terminology of this application. Naturally, our analyses are not specific to this setting and apply whenever we have several contenders requesting service from shared resources.

There are n *senders* and m *receivers*. At each of a series of time steps, one or more senders may generate a *packet*. A packet when generated has a *destination*: a unique receiver to which it must be delivered. Any sender may attempt to send a packet to any receiver at any step, but a receiver may only receive one packet in a step. If a receiver is sent more than one packet in a step (a *collision*), all packets sent to that receiver are lost and the senders are notified of the loss. The senders must then try to send these packets again at a future step. There is no explicit communication between the senders for coordinating the transmissions the only information that senders have is the packet(s) they have waiting for transmission and the history of losses. A packet can only be transmitted directly from its sender to its receiver; intermediate hops are disallowed.

The case $m = 1$ is a classical instance of sharing a common resource such as a bus or an Ethernet channel (the shared bus is modeled by the single "receiver"). The binary exponential backoff Ethernet protocol [9] is the solution used most commonly in practice here. The case $m = n$ has received much attention recently under the name *optically connected parallel computer*, or OCPC [8]. However, work on the OCPC model has been restricted to studies in which each sender begins with at most h

packets for some positive integer h, with h or fewer packets bound for each receiver. In our work, we are interested in the more realistic setting in which packets are generated continuously. To this end, we adopt a stochastic model of packet generation.

1.1. The model. We assume that time is partitioned into intervals of equal length called *steps*. The injection distribution is characterized by an $n \times m$ matrix $\Lambda = (\lambda_{ij})$, in which $\sum_j \lambda_{ij} \leq \lambda$ for all i and $\sum_i \lambda_{ij} \leq \lambda$ for all j. At each step sender i generates a packet bound for receiver j with probability λ_{ij} independently of other senders and time steps. Since a sender can send no more than one packet per step, and a receiver can receive no more than one packet per step, we require $\lambda \leq 1$. For the special case $m = 1$, we use simplified notation: we assume that at each step sender i generates a packet with probability λ_i, independently of other steps and senders. Note that a sender generates at most one packet at a step, but several senders may generate a packet for a receiver. The reader is referred to the paper by Håstad, Leighton, and Rogoff [6] for a detailed account of the relation between these assumptions and reality.

Each sender uses a *protocol* to decide when to send a packet and what to do in the event of a collision. Informally, a protocol is an automaton that uses its state to remember the past. At each step, based on its state, the packets pending transmission, and any new packet it generates, it must decide which (if any) packet to transmit. For example, the binary exponential backoff protocol used in the Ethernet is the following: store arriving packets in a queue. When a packet reaches the head of the queue for the first time, transmit it. If there is a collision, retransmit the packet after T steps where T is selected randomly from $\{1, 2, 3, \ldots, 2^{\min\{10,b\}}\}$, where b is the number of times the packet has been involved in a collision.

Of primary interest is whether a protocol can sustain packet arrivals at some rate without *instability:* a protocol is unstable for a given arrival rate if the number of packets pending transmission grows unboundedly with time.[1] For stable protocols, two quantities are of interest: (1) the *maximum arrival rate* λ that can be sustained stably, and (2) the *delay*, defined to be the maximum over all senders of the expected number of steps from the generation of a packet to its delivery, in the steady state. Delay is of particular importance in high-speed communications applications such as video and ATM networks. (We actually prove a stronger result, a bound on the expected delay of any packet arriving after a polynomial number of steps from the start of the process.)

In our upper bounds, we do not assume that the sender knows the injection rates of other senders (i.e., the matrix Λ); we only assume that senders have some upper bound on the total number of active senders in the system. This bound does not need to be very accurate, as only the logarithm of this bound figures in the delay of our protocols. Since the total number of senders in the system is dictated by the hardware, it is reasonable to assume that this number cannot change very fast and that each sender has a good estimate of it. Our analysis holds even if the matrix Λ changes at every time step, subject to the constraints on row and column sums.

Throughout this paper, $\mathbf{Pr}[\mathcal{E}]$ denotes the probability of an event $\mathcal{E}$.

1.2. Related work. Most previous analysis focused on backoff protocols. The binary exponential backoff protocol used in the Ethernet was proposed by Metcalfe

[1] Formally let B_t denote the number of packets generated before time t that were not delivered until time t. Let F_t denote the distribution of B_t. A protocol is stable if the sequence $\{F_t \mid t \geq 1\}$ converges in distribution to a limit distribution F that is independent of t.

and Boggs [9]. Aldous [1] showed that for any positive constant λ, binary exponential backoff is unstable if the number of senders is infinite. Kelly [7] showed that any polynomial backoff protocol is unstable for infinitely many senders. Håstad, Leighton, and Rogoff [6] studied systems with a finite number of senders. They showed that binary exponential backoff is unstable for λ slightly larger than 0.567 even for a system with a finite number of senders, and that polynomial backoff protocol is stable for any $\lambda < 1$ and for any finite number of senders. Goldberg and MacKenzie [5] analyzed the backoff protocol for the multiple servers setting, showing that any superlinear polynomial backoff protocol is stable for any $\lambda < 1$. Our current work is motivated by the lower bound in Håstad, Leighton, and Rogoff [6] showing that long delays are inevitable in backoff-style protocols: they showed that the delay of any stable exponential or polynomial backoff protocol is at least polynomial in the total number of contenders. Following our work, Paterson and Srinivasan [11] recently gave a protocol with $O(1)$ expected delay assuming that the initial clock times of the senders are within a known bound of each other.

1.3. Our results. We follow the lead of [1, 6] here and make no unproven assumptions about the independence of the state of the system from one time step to the next, or between senders (many analyses in the queuing-theory literature do make such assumptions). We assume only that the generation of packets is independent between time steps and senders. Even for this case, complex dependencies arise between the transmissions at different senders and time steps. We focus on protocols with short packet delay. We first consider the case $m = 1$. Our main result (Theorem 1) is a protocol that ensures delay logarithmic in n, provided the arrival rate is no more than a fixed constant λ'. To our knowledge, this is the first protocol with sublinear delay (under an exact analysis) that is stable for a constant injection rate. Turning to the case $m > 1$, we present a protocol that achieves logarithmic delay provided that arrival rate at each sender and for each receiver is at most a fixed constant λ' (Theorem 2). Finally, we show (Theorem 3) that if every sender uses a class of protocols including backoff protocols, there is a fixed constant $\lambda_0 < 1$ such that if $\lambda > \lambda_0$, the delay must be $\Omega(n)$. Thus, in this class of protocols one cannot achieve full throughput and small delay simultaneously (whereas full throughput alone can be achieved by the polynomial backoff protocol that belongs to that class [6]).

2. Multiple access to one channel. In this section we consider the case $m = 1$. We show that there exists a positive constant λ_0 and a contention resolution protocol that is stable for any $0 < \lambda \leq \lambda_0$, with delay $O(\log n)$.

2.1. The protocol. Each sender in our protocol (Fig. 1) has a *transmission buffer* of size $O(\log n)$ and a *queue*. Packets awaiting transmission are stored either in the buffer or in the queue. Throughout the execution of the protocol a sender is in one of two states: a *normal state* or a *reset state*. Note that in the protocol, a transmission attempt may fail due to collision. The constants α and μ used in the protocol are fixed in the proof of Theorem 1 below.

Relation to practical protocols. The use of the queue and especially the reset state may appear to be somewhat artificial. We use these devices to cater to catastrophic events (e.g., every sender generates a packet in every one of n^{10} consecutive steps) that occur with extremely low but positive probabilities. In practice, such catastrophic events are handled by *dropping packets*: some packets are permanently erased from the system during such rare events. Rather than drop packets we invoke the emergency mechanism involving the queues and the reset state, while proving that the chance of resorting to these measures is extremely small.

$Count\_attempts(s)$ keeps a count of the number of times s tried to transmit a packet from its buffer in the $4\mu n \log n$ most recent steps.

$Failure\_counts(s)$ stores the failure rates in transmission attempts of packets from the buffer of s in the most recent $\mu \log n$ attempts.

$Random\_number()$ is a function that returns a random number uniformly chosen in the range $[0, 1]$, independent of the outcomes of previous calls to the function.

While in the normal state repeat:

1. Place new packets in the buffer.
2. Let X denote the number of packets in the buffer.
   If $Random\_number() \leq X/8\alpha \log n$ **then**
   (a) Try to transmit a random packet from the buffer.
   (b) Update $Count\_attempts(s)$ and $Failure\_counts(s)$.
   Else
   If $Random\_number() \geq 1 - 1/n^2$ **then** transmit the packet at the head of the queue.
3. **If** ($Count\_attempts(s) \geq \mu \log n$ **and** $Failure\_counts(s) > 5/8$), **or If** ($X > 2\alpha \log n$) **then**
   (a) Move all packets in the buffer to the end of the queue.
   (b) Switch to the reset state for $4\mu n^2 \log n + \gamma \log n$ steps.

While in the reset state repeat:

1. Append any new packets to the queue.
2. **If** $Random\_number() \leq 1/n^2$ **then** transmit the packet at the head of the queue.

FIG. 1. *Communication protocol for sender s.*

2.2. Analysis of the protocol. The performance of the protocol is summarized in the following theorem.

THEOREM 1. *There is a fixed constant $\lambda_0 > 0$, such that for any $\lambda \leq \lambda_0$ the above protocol is stable and the expected delay of each packet is $O(\log n)$.*

Proof. To simplify the analysis we assume, without loss of generality, that at each step each sender tries to transmit a packet from the queue with probability $1/n^2$ even if its queue is empty (in which case it tries to transmit an empty message). This assumption makes the process of transmitting from the buffers completely independent of the sizes of the queues at the beginning of that step.

Consider the n-vector of nonnegative integer whose ith component is the number of packets in the buffer of the ith sender. This vector defines a finite positive recurrent aperiodic Markov chain, which thus has a stationary distribution. Let X_t be a random variable counting the total number of packets at time t in all the buffers. By the condition tested in step 3 of the protocol, $X_t \leq 2\alpha n \log n + n$ for all t. The crux of the proof is to show that most of the time $X_t \leq 2\alpha \log n$, which guarantees short delays.

Throughout the analysis we use the following versions of the Chernoff bound [10]: let Z be the number of successes in k independent Bernoulli trials with probability p for success in each trial, then for $0 \leq \delta \leq 1$ $\mathbf{Pr}\{Z \leq (1-\delta)pk\} \leq e^{-\delta^2 pk/2}$, and $\mathbf{Pr}\{Z \geq (1+\delta)pk\} \leq e^{-\delta^2 pk/3}$. For $\delta > 1$ $\mathbf{Pr}\{Z \geq (1+\delta)pk\} \leq e^{-\delta \ln(1+\delta)pk}$. ∎

LEMMA 1. *Let $T = 4\mu n^2 \log n + \gamma \log n$ (the constant γ is determined in the proof of Claim 3). For any $x \le 2\alpha n \log n + n$ assumed by X_{t-T},*

$$\mathbf{Pr}[X_t > 2\alpha \log n \mid X_{t-T} = x] \le 1/n^{10}.$$

Proof. To prove the lemma, we begin with the following claim.

CLAIM 1. *If $X_{t-T} > 6\alpha \log n$, then with probability $1 - n^{-11}$ there is a step $\tau_1 \in [t - T, t - \gamma \log n]$ such that $X_{\tau_1} \le 6\alpha \log n$.*

Proof. We show that as long as the total number of packets in buffers exceeds $6\alpha \log n$, then in each interval of $4\mu n \log n$ steps at least one sender is very likely to switch to the reset state with high probability (and stays in that state for $4\mu n^2 \log n$ steps).

Consider the interval $[\tau_0, \tau_0 + 4\mu n \log n - 1]$ consisting of $4\mu n \log n$ steps. Let z_τ, $\tau \in [\tau_0, \tau_0 + 4\mu n \log n - 1]$ be a random variable defined as follows. If $X_\tau > 6\alpha \log n$, then z_τ equals the number of transmission attempts at this step; else $z_\tau = n$. Clearly $[z_\tau \mid z_{\tau_0}, z_{\tau_0+1}, \ldots, z_{\tau-1}]$ is stochastically lower-bounded[2] by a binomial distribution with expectation $(6\alpha \log n)/(8\alpha \log n)$, and $\sum_{\tau=\tau_0}^{\tau_0+4\mu n \log n-1} z_\tau$ is stochastically (lower-) bounded by a binomial distribution with expectation

$$\frac{(4\mu n \log n)(6\alpha \log n)}{8\alpha \log n} = 3\mu n \log n. \tag{1}$$

Thus, by the Chernoff bound, with probability at least

$$1 - e^{-\frac{2}{3}\mu n \log n}, \tag{2}$$

either $X_\tau \le 6\alpha \log n$ for some τ in this interval or there were at least $\mu n \log n$ attempts to transmit packets from buffers and at least one sender was involved in $\mu \log n$ or more attempts.

If there were at least $6\alpha \log n$ packets in buffers in a given step, then the success probability of an attempt at that step is at most

$$\left(1 - \frac{2\alpha \log n}{8\alpha \log n}\right)^2 \le 9/16. \tag{3}$$

(Since no sender has more than $2\alpha \log n$ packets in buffers, the "best" probability is when $6\alpha \log n$ packets are distributed equally among three senders.)

For a given sender s and given steps τ and τ' such that $\tau \ge \tau' \ge \tau_0$, let $y_\tau^{\tau',s}$ be a random variable defined as follows: $y_\tau^{\tau',s} = 1$ if sender s successfully transmitted a packet at time τ, $X_\tau > 6\alpha \log n$, and s had less than $\mu \log n$ transition attempts in the interval $[\tau', \tau]$; else $y_\tau^{\tau',s} = 0$. Let $\mathcal{H}_\tau$ describe the state of the system at all times before step τ. Clearly

$$\mathbf{Pr}[Y_\tau^{\tau',s} \mid \mathcal{H}_\tau] \le \frac{9}{16},$$

and $\mathbf{Pr}[\sum_{\tau=\tau'}^{\tau_0+4\mu n \log n-1} y_\tau^{\tau',s} \ge \frac{5}{8}\mu \log n]$ is upper-bounded by the probability that a binomial random variable with parameters $B(\mu \log n, \frac{9}{16})$ is at least $\frac{5}{8}\mu \log n$. Thus, using the Chernoff bound, with probability

$$1 - n(4\mu n \log n)e^{-\frac{1}{3}\frac{9}{16}(\frac{1}{9})^2 \mu \log n}, \tag{4}$$

[2]We say that distribution F is stochastically lower- (upper-) bounded by distribution G if for any x, $F(x) \ge G(x)$ (respectively, $F(x) \le G(x)$).

either $X_\tau \le 6\alpha \log n$ for some τ in that interval or no sender had a success rate of at least $\frac{5}{8}$ in a sequence of $\mu \log n$ attempts in that interval.

Combining the bounds in (2) and (4) we get that for each interval of $4\mu n \log n$ steps, with probability at least

$$1 - e^{-\mu \log n} - n(4\mu n \log n) e^{-\frac{1}{3}\frac{9}{16}(\frac{1}{9})^2 \mu \log n} \ge 1 - n^{-12}$$

(for sufficiently large constant μ), either $X_\tau \le 6\alpha \log n$ at some step of the interval or at least one sender switches to the reset state and moves all its packets from its buffer to its queue. Thus, with probability $1 - n^{-11}$, at some step $\tau_1 < t + 4\mu n^2 \log n$, $X_{\tau_1} \le 6\alpha \log n$. □

CLAIM 2. *Suppose that there is a positive integer L such that if $X_\tau \in [L, L + 2\alpha \log n]$ then the probability that a packet is delivered from a buffer at step τ is at least p for a constant $p > \lambda$. If $X_{\tau_1} \le L$, then*

$$\mathbf{Pr}[X_\tau \ge L + \alpha \log n \text{ for some step } \tau \in [\tau_1, \tau_1 + W]] \le W n^{-13}$$

for a sufficiently large constant α.

Proof. Since at most one message can be delivered from all buffers in each step, X_τ can decrease by at most one in each step. Thus, it is sufficient to prove that there is no time interval of length $\alpha \log n$ during which X_τ remains above L.

Consider an interval of $\alpha \log n$ steps, starting at step $\tau_2 \in [\tau_1, \tau_1 + W]$. Assume that $X_{\tau_2 - 1} \le L$. Let $\epsilon = (p - \lambda)/3\lambda$. The probability that more than $(1+\epsilon)\lambda\alpha \log n < 2\alpha \log n$ packets are placed in buffers in the interval is at most $n^{-13}/2$.

Let z_τ be a 0–1 random variable defined as follows: $z_\tau = 1$ if $X_\tau \le L$ or a packet is delivered from a buffer in step τ; else $z_\tau = 0$. Clearly, as long as $X_\tau \le L + 2\alpha \log n$, $\mathbf{Pr}[z_\tau = 1 \mid z_1, \ldots, z_{\tau-1}] \ge p$. Let $\delta = (p - \lambda)/3p$.

$$\mathbf{Pr}\left[\sum_{k=\tau_2}^{\tau_2 + \alpha \log n} z_k < (1 - \delta) p \alpha \log n\right] \le e^{-\frac{1}{3}\delta^2 p \alpha \log n} \le n^{-13}/2.$$

Since $(1 + \epsilon)\lambda\alpha \log n < (1 - \delta)p\alpha \log n$, the probability that $X_\tau > L$ for a given $\tau \in [\tau_2, \tau_2 + \alpha \log n]$ is at most n^{-13}, for any $p > \lambda$ and a sufficiently large constant α. □

CLAIM 3. *If $X_{\tau_1} \le 6\alpha \log n$ for some $\tau_1 \in [t - T, t - \gamma \log n]$, then with probability at least $1 - n^{-11}$, there is a step $\tau_2 \in [\tau_1, t]$ such that $X_{\tau_2} \le \alpha \log n$.*

Proof. As long as $X_\tau \in [\alpha \log n, 7\alpha \log n]$ the probability of a successful transmission from some buffer at time τ is at least p, where

$$p = \binom{X_\tau}{1} \frac{1}{8\alpha \log n} \left(1 - \frac{1}{8\alpha \log n}\right)^{X_\tau - 1} - \frac{n}{n^2} \ge \frac{X_\tau}{8\alpha \log n} - (\frac{X_\tau}{8\alpha \log n})^2 - \frac{n}{n^2} \ge \frac{1}{10}.$$

Let $\mathcal{E}_1$ denote the event: "$X_{\tau_1} \le 6\alpha \log n$, and there is a $\tau \in [\tau_1, \tau_1 + \gamma \log n]$ such that $X_\tau > 7\alpha \log n$."

By Claim 2, $\mathbf{Pr}[\mathcal{E}_1] \le n^{-13}\gamma \log n$ for any $\lambda < p$ and a sufficiently large constant α.

The expected number of new packets arriving in the time interval $[\tau_1, \tau_1 + \gamma \log n]$ is $\lambda\gamma \log n$. Let $\delta = (p - \lambda)/3\lambda$ and let $\mathcal{E}_2$ denote the event "More than $\lambda\gamma(1 + \delta) \log n$ packets arrived in the interval $[\tau_1, \tau_1 + \gamma \log n]$." Then $\mathbf{Pr}[\mathcal{E}_2] \le e^{-\delta^2 \lambda\gamma \log n/3} \le n^{-11}$ for a sufficiently large γ.

Let $\epsilon = (p-\lambda)/3p$ and define the event $\mathcal{E}_3$: "either $X_\tau \le \alpha \log n$ for some $\tau \in [t-\gamma\log n, t]$ or at least $(1-\epsilon)p\gamma\log n$ packets were delivered from the buffer at that interval." Then $\mathbf{Pr}[\mathcal{E}_3 \mid \bar{\mathcal{E}}_1] \ge 1 - e^{-\epsilon^2 p\gamma\log n/3}$.

Fix γ such that $\gamma(p-\lambda)/3 > 6\alpha$. Then the probability that there is no $\tau_2 \in [\tau_1, \tau_1+\gamma\log n]$ such that $X_{\tau_2} < \alpha\log n$ is at most

$$n^{-13}\gamma\log n + e^{-\lambda\gamma\delta^2\log n/3} + e^{-p\gamma\epsilon^2\log n/3} \le n^{-11}$$

for $\lambda < p$ and $\gamma \ge \max[\frac{18\alpha}{p-\lambda}, \frac{39}{\lambda\delta^2}, \frac{39}{p\epsilon^2}]$. □

CLAIM 4. *If $X_{\tau_1} \le \alpha\log n$ then the probability that there exists $\tau \in [\tau_1, \tau_1+T]$ such that $X_\tau > 2\alpha\log n$ is at most n^{-11}.*

Proof. If $X_\tau \in [\alpha\log n, 4\alpha\log n]$ then the probability of a successful transmission from a buffer at time τ is at least

$$p = \binom{X_t}{1}\frac{1}{8\alpha\log n}\left(1-\frac{1}{8\alpha\log n}\right)^{X_t-1} - \frac{n}{n^2}$$

$$\ge \frac{X_t}{8\alpha\log n} - \left(\frac{X_t}{8\alpha\log n}\right)^2 - \frac{n}{n^2} \ge \frac{1}{10}.$$

Using Claim 2, the probability of having $2\alpha\log n$ packets in buffers in the interval is at most Tn^{-13} for any $\lambda < p$ and a sufficiently large constant α. □

To conclude the proof of Lemma 1 we combine the error probabilities of the three lemmas above to show that for any value x,

$$\mathbf{Pr}[X_t > 2\alpha\log n \mid X_{t-T} = x] \le 3n^{-11} \le n^{-10}.$$ □

Comment. The statement of Lemma 1 implies that in the steady state, almost always $X_t \le 2\alpha\log n$. This observation is not used directly in the proof but gives a good intuition for the long-term behavior of the protocol.

We turn to the analysis of the queues. We focus on the performance of the protocol after the first $T_0 = 4\mu n^2\log n + \gamma\log n + 4\mu n\log n$ steps. We assume that at time 0 all queues are empty (this assumption affects only the length of the initial segment T_0).

CLAIM 5. *Let $t \ge T_0$. The probability that any sender switches to the reset state at step t is at most n^{-8}.*

Proof. If $X_\tau \le 2\alpha\log n$, then the probability of a success in a transmission attempt at step τ is at least $p = 1 - (2\alpha\log n)/(8\alpha\log n) - (n/n^2) \ge 3/4 - 1/n$.

For a given sender s and given steps $\tau \ge \tau' \ge t - 4\mu n\log n$, let $y_\tau^{\tau',s}$ be a random variable defined as follows: $y_\tau^{\tau',s} = 1$ if sender s successfully transmitted a packet at time τ, $X_\tau \le 2\alpha\log n$, and s had less than $\mu\log n$ transition attempts in the interval $[\tau', \tau]$; else $y_\tau^{\tau',s} = 1$. Let $\mathcal{H}_\tau$ describe the state of the system at all times before step τ. Clearly

$$\mathbf{Pr}[Y_\tau^{\tau',s} \mid \mathcal{H}_\tau] \le \frac{1}{4} + \frac{1}{n},$$

and $\sum_{\tau=\tau'}^{\tau_0+4\mu n\log n-1} y_\tau^{\tau',s}$ is stochastically upper-bounded by a binomial distribution with expectation $(\frac{1}{4}+\frac{1}{n})\mu\log n$. Thus, by the Chernoff bound with probability

$$1 - n(4\mu n\log n)e^{-\frac{1}{3}(\frac{1}{4}+\frac{1}{n})(\frac{1}{2})^2\mu\log n}, \tag{5}$$

either $X_\tau > 2\alpha \log n$ for some τ in that interval or no sender had a success rate less than $\frac{5}{8}$ in a sequence of $\mu \log n$ attempts in that interval. By Lemma 1, $\mathbf{Pr}[X_\tau > 2\alpha \log n]$ at any time $\tau \in [t-4\mu n \log n, t]$ is at most $4\mu n^{-9}(\log n+2)$, which together with the above bound proves the lemma. □

LEMMA 2. *Consider a packet that was generated at time $t \geq T_0$.*

1. *The expected number of steps a given packet spends in a buffer is $O(\log n)$.*

2. *The probability that a given packet is delivered from the buffer is at least $1 - n^{-5}$.*

Proof. Assume that the packet was generated at sender s.

Consider an interval of n steps throughout which (1) s is never in the reset state, and (2) $X_\tau \leq 2\alpha \log n$. Let $p = 1 - (2\alpha \log n)/(8\alpha \log n) - n/n^2$ as in the proof of Claim 5. If the packet was in the buffer of sender s at the start of the interval, the probability that it is not delivered until the end of the interval is at most $(1 - p/8\alpha \log n)^n$. During the interval the expected number of steps between two attempts to transmit the packet is $8\alpha \log n$, and the expected number of attempts until the packet is delivered is $1/p$. Thus, if the packet is delivered during the interval, by Wald's identity [2] the expected delay of the packet from the start of that interval is at most $(8\alpha \log n)/p$.

The probability that the interval $[t, t+n]$ satisfies conditions (1) and (2) is (by Lemma 1 and Claim 5) at least $1-(4\mu n^2 \log n+n)n^{-8}-n^{-9}$, and with this probability, any subsequent interval of $4\mu n^2 \log +n$ steps has a segment of n steps that satisfies the above conditions. Thus, the expected number of steps a packet spends in the buffer is at most

$$\frac{8\alpha \log n}{p} + \sum_{k \geq 1} k(n + 4\mu n^2 \log n) \left((4\mu n^2 \log n + n)n^{-8} + n^{-9} + \left(1 - \frac{p}{8\alpha \log n}\right)^n \right)^k$$

$$= \frac{8\alpha \log n}{p} + o(1).$$

(The above estimate ignores the possibility that a packet is moved to the queue before it is delivered from the buffer. This can only decrease the expected number of steps a packet spends in the buffer.)

The probability that the packet is delivered from the buffer is bounded from below by the probability that the first n steps following the creation of the packet satisfy conditions (1) and (2) and the packet is delivered in that time. This probability is at least

$$1 - (4\mu n^2 \log n + n)n^{-8} - n^{-9} - \left(1 - \frac{p}{8\alpha \log n}\right)^n \geq 1 - n^{-5}. \qquad \square$$

LEMMA 3. *Consider a packet that was generated at time $t > T_0$. Given that the packet enters the queue, the expected length of time it spends in the queue is $O(n^4 \log n)$.*

Proof. Assume that the packet was generated at sender s. When a sender switches to the reset state it moves all the (up to $2\alpha \log n + 1$) packets in its buffer to its queue. In addition, all the (up to $4\mu n^2 \log n + \gamma \log n$) packets it receives in the next $4\mu n^2 \log n + \gamma \log n$ steps are placed in the queue. Let $D = 4\mu n^2 \log n + \gamma \log n + 2\alpha \log n + 1$.

When a queue is not empty and the total number of packets in all buffers in the system is at most $2\alpha \log n$, a sender succeeds in transmitting a packet from its queue in each step with probability at least

$$p = \frac{1}{n^2}\left(1 - \frac{1}{8\alpha \log n}\right)^{2\alpha \log n}\left(1 - \frac{1}{n^2}\right)^{n} \geq \frac{1}{2n^2}.$$

Let τ_1 be the first step that X_t exceeds $2\alpha \log n$ (i.e., $X_{\tau_1 - 1} \leq 2\alpha \log n$ and $X_{\tau_1} > 2\alpha \log n$). Let τ_i, $i > 1$, be the first step that X_t exceeds $2\alpha \log n$ after step $\tau_{i-1} + T$ ($T = 4\mu n^2 \log n + \gamma \log n$ as defined in Lemma 1). We say that an interval $[\tau_i, \tau_{i+1}]$ is *good* (with respect to sender s) if either the queue of s was empty at some step in that interval or at least $2D$ packets were delivered from the queue. Note that no more than D packets can enter the queue in each interval, since a sender cannot switch twice to a reset state in the same interval.

By Lemma 1 the probability that an interval does not have a segment of $L = 4n^2 D$ steps in which $X_t \leq 2\alpha \log n$, conditioning on all events before that segment is bounded by Ln^{-10}. The probability that in L steps in which $X_t \leq 2\alpha \log n$, fewer than $2D$ packets are transmitted, is bounded by $e^{-\frac{1}{3}\frac{1}{2n^2}L} \leq e^{-\frac{2D}{3}}$. Thus, in a given interval the probability that either $Z_t = 0$ at some point in the interval or at least $2D$ packets are delivered from the queue is at least $1 - Ln^{-10} - e^{-\frac{2D}{3}} \geq 1 - \frac{1}{n^5}$, and for subsequent intervals these events are independent.

The probability that there are iD packets in the queue at time t is bounded by the probability that there are fewer than $(k-i)/2$ *good* intervals in the k most recent intervals, for some $k \geq i$. This probability is bounded by $\sum_{k \geq i} \binom{k}{(k+i)/2}(\frac{1}{n^5})^{(k+i)/2} \leq 2(\frac{e}{n^5})^i$, and the expected number of packets in the queue at time t is bounded by $\sum_{i \geq 0} iD(\frac{e}{n^5})^i = O(1)$. Our packet, however, arrives with another $D = O(n^2 \log n)$ packets, and the expected number of steps to send a packet from the head of the queue is $O(n^2)$. Thus, the expected time until all these packets are transmitted is $O(n^4 \log n)$. □

By Claim 2 the expected time a packet spends in the buffer in $O(\log n)$. With probability $O(n^{-5})$ the packet is transferred to the queue, where its expected delay is $O(n^4 \log n)$. Thus, the expected delay of a given packet is $O(\log n)$. □

3. The protocol for n senders and m receivers. In our protocol each sender runs m "one-channel protocols" simultaneously. Each sender keeps a counter of transmission failures for each of the receivers. When this count is too large the sender switches to the reset state only with respect to packets bound for that receiver.

The "one-channel protocol" requires that if there are X packets in the buffer of sender s, the sender tries to transmit a packet from the buffer with probability $X/8\alpha \log n$. To accommodate the m protocols simultaneously in one sender we modify step 2 in the "one-channel protocol" as follows:

2. Let $Y^i(s)$ denote the number of packets with destination i in the buffer of sender s. Let $Y(s) = \sum_{i=1}^{m} Y^i(s)$.
If $Y(s) > 2\alpha \log n$ **then** move all packets to the queue,
else with probability $Y(s)/8\alpha \log n$ transmit a random packet from the buffer.

It remains to show that the probability that a sender has more than $2\alpha \log n$ packets in the buffer is small. Thus, moving them to the queue does not significantly change the performance of the protocol.

LEMMA 4. *Let $Y_t(s)$ denote the total number of packets in the buffer of sender s at time t. In the stationary distribution,*

$$\mathbf{Pr}[\exists s \text{ such that } Y_t(s) > 2\alpha \log n] \leq n^{-7}.$$

Proof. As in the proof of Lemma 1 we show that there exists a constant γ such that if $T = 4\mu n^2 \log n + \gamma \log n$, then for any value y of $Y_{t-T}(s)$,

$$\mathbf{Pr}[Y_t(s) > 2\alpha \log n \mid Y_{t-T}(s)] = y \leq n^{-8}.$$

Let X_τ^i denote the total number of packets with destination i in the buffers of all senders. Let $\mathcal{E}$ denote the event: "For any $1 \leq i \leq m$ and $t - \beta \log n \leq \tau \leq t$, $X_\tau^i \leq 2\alpha \log n$."

By Lemma 1, regardless of the state of the system at time $t-T$, $\mathbf{Pr}[\mathcal{E}] \geq 1 - n^{-9}$ (since there are no more than n protocols).

The total injection rate of sender s is at most λ. Conditioning on the event $\mathcal{E}$, the probability that s successfully delivers a message at time τ, $\tau \in [t - \beta \log n, t]$ when $Y_\tau(s) > \alpha \log n$ is at least $p = \frac{\alpha \log n}{8\alpha \log n}(1 - 1/8\alpha \log n)^{2\alpha \log n}(1 - 1/n^2)^n \geq 1/20$. As in the proof of Claim 3 we show that with probability $1 - n^{-9}$ there is a step $\tau \in [t - \beta \log n, t]$, such that $Y_t(s) < \alpha \log n$, and using Claim 2 we show that once the number of packets is below $\alpha \log n$ the probability that this number reaches $2\alpha \log n$ before time T is at most n^{-8}. □

When a sender has $2\alpha \log n$ packets in its buffer it transfers them to its queue. Thus, the expected additional contribution to the queue from the modified protocol is $O(n^{-8} \log n)$ per step. This contribution does not change the delivery time of packets in the queue or the overall performance of the protocol significantly.

THEOREM 2. *There is a constant $\lambda_0 > 0$ such that the above protocol is stable for any $0 \leq \lambda \leq \lambda_0$ and the delay is $O(\log n)$.*

4. The lower bound. We state and prove the lower bound for the case $m = 1$; a similar bound holds for the general case. We consider n senders all running the same protocol. The protocol running at a sender does not change state unless (1) it attempts a transmission or (2) it generates a packet. We further assume that a sender is in a unique idle state when its queue is empty. (Thus, a sender does not keep information on the state of the channel when it does not have packets to transmit.) For any such protocol governed by a (probabilistic) automaton we show that there is a $\lambda_0 < 1$ such that for any injection rate $\lambda > \lambda_0$ the delay is $\Omega(n)$. Note that the class of protocols includes all variants of backoff protocols.

THEOREM 3. *If all senders follow protocols from the above class, there is a fixed constant $\lambda_0 < 1$ such that if $\lambda > \lambda_0$, the expected delay is $\Omega(n)$.*

Proof. Let $\lambda_i = \lambda/n$ for all i. Given a system of senders, we say that $X_t = j$ if the total number of packets pending transmission at all senders at step t is j. If the expected delay is bounded then the system has a steady state distribution. Consider the steady state distribution of X_t. We distinguish between two cases.

Case 1. In the steady state distribution, $\mathbf{Pr}[X_t] \geq n/2 \geq 1/2$. Since the system can transmit no more than one packet per step the expected delay in this case in clearly $\Omega(n)$.

Case 2. In the steady state distribution $\mathbf{Pr}[X_t] < n/2 > 1/2$. □

LEMMA 5. *If $X_t < n/2$, the probability of a collision at step $t + n/3$ is at least a constant q.*

Proof. If $X_t < n/2$, we have at least $n/2$ senders having no packets pending transmission at time t (call these *empty senders*). A protocol in our class defines a probability distribution p_i on the nonnegative integers i such that when an empty sender generates a packet at step t, it transmits it at step $t+i$ with probability p_i unless it changes its behavior (due to the generation of a packet) in the interval $[t, t+i]$.

An empty sender that generates a packet at time τ does not change the probabilities p_i in the interval $(\tau, \tau + n/3]$ unless it generates another packet in the interval. The probability that it generates such a packet in the interval $(\tau, \tau + n/3]$ is at most $(1-\lambda/n)^{n/3}$, which is at most a constant α. Thus the empty sender does transmit the packet at time $\tau + i$ with probability at least $(1-\alpha)p_i$. Clearly, $\sum_{i=0}^{n/3} p_i$ must be at least a constant β (for otherwise the delay is already at least $\alpha(1-\beta)n/3$). If at least $n/2$ senders are empty at time t, the probability that any one of them transmits at time $t + n/3$ is thus at least

$$(1-\alpha)\sum_{k=0}^{n/3} \frac{\lambda}{n} p_k \geq (1-\alpha)\beta\lambda/n.$$

Then, the probability of a collision at time $t + n/3$ is at least a constant q. ∎

Thus, if in the steady state distribution, $\mathbf{Pr}[X_t] < n/2 > 1/2$, then the probability of a collision in a given step in the steady state is at least a constant $q/2$. Since the expected number of new packets arriving in each step is λ and the system can transmit no more than one packet per step, the system cannot be stable if $\lambda > 1 - q/2$.

Acknowledgment. We thank Aravind Srinivasan for helpful comments.

ASYMPTOTICALLY OPTIMAL ELECTION ON WEIGHTED RINGS*

LISA HIGHAM† AND TERESA PRZYTYCKA‡

Abstract. In a network of asynchronous processors, the cost to send a message can differ significantly from one communication link to another. In such a setting, it is desirable to factor the cost of links into the cost of distributed computation. Assume that associated with each link is a positive *weight* representing the cost of sending one message along the link, and the cost of an algorithm executed on a *weighted* network is the sum of the costs of all messages sent during its execution. We determine the asymptotic complexity of distributed leader election on a weighted unidirectional asynchronous ring assuming this notion of cost, by exhibiting a simple algorithm and a matching lower bound for the problem for any collection of edge weights. As a consequence, we see that algorithms designed for unweighted rings are not in general efficient for the weighted case.

Key words. distributed election, weighted ring, message complexity, asynchronous network

1. Introduction.

Consider a network of asynchronous processors that communicate via message passing. The typical measure of the cost of a distributed algorithm on such a network is the number of messages sent. This measure assumes that the cost of sending a message along any link is equal to 1. In practice, the cost of sending a message may depend upon the link that the message traverses. This motivates the study of distributed algorithms where the cost of transmitting a message over a link is factored into the communication complexity of the algorithm. Awerbuch, Baratz, and Peleg [1] called this notion of communication complexity "cost-sensitive analysis." A *weighted network* is a network of processors where each link e of the network has associated with it a positive weight $w(e)$, which is the *cost* of sending a message along link e. The cost of a distributed algorithm for a given weighted network and input is the maximum, over all message delay patterns, of the sum of the costs of all message traffic that occurs while executing the algorithm on that input. When designing a distributed algorithm for a weighted network we try to limit the message traffic over heavy edges.

In this paper, we study the weighted cost of leader election when the network topology is an asynchronous unidirectional weighted ring with distinct identifiers. The leader election problem is to design a distributed algorithm that distinguishes exactly one processor from among all the processors of the network as a unique processor called the *leader*. Leader election on asynchronous unweighted rings has been very well studied. Early papers by LeLann [8], Chang and Roberts [2], and Hirschberg and Sinclair [7] solved the unidirectional and bidirectional version for rings with identifiers

using at most $O(n^2)$ and $O(n \log n)$ messages, respectively. Then, in 1982, Peterson [10] and Dolev, Klawe, and Rodeh [3] independently solved the unidirectional version of the problem using $O(n \log n)$ messages. By the results of Pachl, Korach, and Rotem [9] these algorithms are asymptotically optimal. Some effort has been made to reduce the constant [10, 3, 6] leading to the constant 1.271 [6]. Research has also established the possibility and complexity of leader election on rings in which processors lack distinct identifiers. (In this case, randomization is required.) Also, there has been substantial work generalizing and strengthing the lower bound for election on rings and other networks under a variety of assumptions about the model. See [5] for a list of research that addresses algorithms and lower bounds related to the leader election problem.

Running an algorithm designed for an unweighted network on a weighted network will, in general, not be cost efficient. Let W be the sum of the weights of all links of a weighted ring. Peterson's classical algorithm [10], when executed on the weighted ring, will incur a cost of $\Omega(W \log n)$. In fact, all other known leader election algorithms have the same bound on complexity. The results of this paper show that this is not optimal. What is needed is a new technique for breaking the symmetry of the ring based on the weights of the edges. Such a technique is developed in this paper.

Let $\mathcal{R}$ be any ring with n_i edges having weight in $(2^{i-1}, 2^i]$. We present an algorithm for the leader election problem on unidirectional weighted rings that has cost $O(\sum_{n_i \geq 1} n_i 2^i \lg(n_i+1))$ on $\mathcal{R}$. We show that this algorithm is optimal in the following sense: given a multiset W of weights where n_i weights are in the interval $(2^{i-1}, 2^i]$ and a leader election algorithm A, we can design a ring $\mathcal{R}$ with edge weights equal to the set W such that the weighted message cost of A on $\mathcal{R}$ is $\Omega(\sum_{n_i \geq 1} n_i 2^i \lg(n_i+1))$. The matching lower bound of our cost-sensitive analysis establishes that our algorithm is optimal in the "universal" sense of Garay, Kutten, and Peleg [4]—that is, that the algorithm is optimal for any collection of weights. This universality ensures that the parameters that determine the complexity of election on a unidirectional weighted ring have been precisely identified. This is the first lower bound that applies in this strong, universal sense to cost-sensitive analysis of any problem on any weighted network.

Our algorithm for weighted rings is in some sense a generalization of the basic algorithm for the unweighted case [6]. The perspective of this algorithm facilitates an extension to the weighted case. However, the analysis in the weighted case requires completely different techniques. The new contribution of our lower bound is that it explicitly incorporates the weights into the result. The basic idea to achieve this bound is derived from the work of Pachl, Korach, and Rotem [9]. However, we need to adjust the technique to overcome the complications introduced by weighted links.

The optimal algorithm is presented in section 2, its analysis, in section 3, and the lower bound, in section 4.

2. The leader election algorithm for weighted rings.

2.1. Algorithm description. Although, in the literature, the leader election algorithms for unweighted rings are presented in a variety of ways, there is a high-level perspective that can be used to describe them all (see [5]). Initially each processor creates an *envelope* containing a *label* set to its own identifier, a *round number* (or sometimes a round parity bit), and possibly additional information, and forwards the envelope to its neighbor. Upon receipt of an envelope, a processor applies a *casualty test*, which compares the contents of the envelope with the processor's stored information, to determine whether or not to destroy the envelope. If the receiving

processor determines not to destroy the envelope, it applies a *promotion test*, to determine whether or not to increment the round number. It then updates the content of the envelope and its own information as required and forwards the envelope to its neighbor. Eventually only one envelope remains and a leader is elected. The various algorithms differ in four ways: the content of an envelope in addition to label and round number, the local information stored by each processor, the specification of the casualty test, and the specification of the promotion test.

In both the basic algorithm [6], which we refer to as the MIN-MAX algorithm, and our algorithm for weighted rings, called WEIGHTED ELECT, the label of an envelope is never changed. In MIN-MAX, each envelope contains only its label and a round number initialized to 1. Each processor stores the label and the round of the last envelope it sent. The casualty test is simply: the envelope and the receiving processor have the same round number and this round number is odd (respectively, even) and the label of the envelope is larger (respectively, smaller) than that stored by the processor. The promotion test is simply: the envelope and the receiving processor have the same round number.

One way to visualize MIN-MAX is to imagine that execution proceeds in rounds. In an odd round any envelope that directly follows an envelope with label smaller than its own label is destroyed, while in an even round any envelope that directly follows an envelope with a larger label is destroyed. Notice that in MIN-MAX, as well as in other election algorithms for unweighted rings, in every round (or sometimes in every second round) message traffic covers every link of the ring. One central idea in WEIGHTED ELECT is to accelerate processing of envelopes that have travelled a large weighted distance by promoting them to a higher round as soon as they incur a sufficient weighted cost. Algorithm WEIGHTED ELECT can be thought of as combining MIN-MAX with this idea of "early promotion by weighted distance." We will see that by using early promotion, message traffic does not necessarily cover every link in each round, thus reducing the weighted distance an envelope travels before the algorithm terminates.

The intuition is to have a processor p adopt a high round number if it sends a message over a heavy link. This causes p to destroy envelopes with lower round number that it later receives, and thus the high cost of those envelopes traveling the heavy link is avoided. It is safe for p to destroy those envelopes, since the message that p sends over the heavy link carries with it a high round number, and so can only be destroyed by processors that have adopted even higher round numbers than p. Of course, this idea must be combined with some mechanism such as the MIN-MAX algorithm, to take care of the case when many successive links have similar weights.

For algorithm WEIGHTED ELECT, in addition to the *label*, each envelope contains a *round* and a *credit*. Both are initialized as a function of the weight of the link adjacent to the processor that creates the envelope. The initial credit is proportional to this weight and the initial round number is the logarithm of this weight. The label of an envelope remains unchanged as long as the envelope survives, whereas the round and credit are adjusted during the course of the algorithm. Throughout the algorithm, each processor stores the label and the round of the last envelope that it sent. The casualty test for WEIGHTED ELECT is: the round number of the received envelope is less than that of the last envelope sent, or the casualty test of MIN-MAX holds. If an envelope is not destroyed then it may be promoted, resulting in an increased credit and a larger round. The promotion test for WEIGHTED ELECT is: the credit is less than the weight of the outgoing edge or the promotion test of MIN-MAX holds. For

```
Processor(proc-id, adj_wt):

    id ⟵ proc-id ; p ⟵ ⌈lg adj_wt⌉ ; t ⟵ 0 ; cnt ⟵ 2^(p+1) ;
    fwd_id ⟵ −∞ ; fwd_p ⟵ −1 ; fwd_t ⟵ 0 ;

    repeat

        receive(id, p, t, cnt) ;
    until Leader-test .
```

FIG. 1. *Algorithm* WEIGHTED ELECT.

any surviving envelope (whether promoted or not) the processor reduces its credit by the weight of its adjacent edge before sending the envelope forward.

The complete protocol for WEIGHTED ELECT is given in Figure 1. The protocol for each processor is parameterized by its identifier (*proc-id*) and the weight of its outgoing edge (*adj_wt*). Four consecutive rounds of WEIGHTED ELECT are grouped together to form a *phase*; hence round r is represented by an ordered pair (p, t), where p is the phase number, $t \in \{0, 1, 2, 3\}$, and $r = 4 * p + t$.

The pseudocode assumes the following three tests that are employed when an envelope containing label *id*, round (p,t), and credit *cnt* arrives at a processor that has recorded a label *fwd_id* and a round (*fwd_p*,*fwd_t*) and has an outgoing edge with weight *adj_wt*.

Casualty-test
($p <$ *fwd_p*) or
((p,t) = (*fwd_p*,*fwd_t*) and $t \in \{1, 3\}$ and *id* > *fwd_id*) or
((p,t) = (*fwd_p*,*fwd_t*) and $t \in \{0, 2\}$ and *id* < *fwd_id*).

Promotion-test
((p,t) = (*fwd_p*,*fwd_t*) and $t \in \{1, 3\}$ and *id* < *fwd_id*) or
((p,t) = (*fwd_p*,*fwd_t*) and $t \in \{0, 2\}$ and *id* > *fwd_id*) or
($p >$ *fwd_p* and *cnt* < *adj_wt*) .

Leader-test *id* = *fwd_id*.

2.2. Correctness of WEIGHTED ELECT**.** Correctness of WEIGHTED ELECT follows immediately after establishing:

safety: the algorithm never deletes all message envelopes;

progress: if there is more than one envelope then after a finite number of messages the number of envelopes is reduced; and

correct termination: the algorithm elects a leader exactly when one envelope remains.

Because the ring is unidirectional and the algorithm is deterministic and message-driven with messages processed in first-in-first-out order, the messages received by each processor and the order in which each processor processes its messages is entirely determined by the initial configuration of identifiers and edge weights. Thus the scheduler is powerless to influence the outcome of the computation. We emphasize that for *message-driven algorithms on unidirectional rings*, correctness and complexity

under any fixed scheduler implies correctness and complexity under all schedulers. Thus without loss of generality we assume a scheduler that proceeds by the round number of the envelopes. That is, an envelope with a given round number is not delivered until there does not exist an envelope of smaller round number. (This *round-driven* scheduler exists because WEIGHTED ELECT ensures that the round number of an envelope never decreases and the casualty test guarantees that the sequence of envelopes traveling any edge have nondecreasing round number.)

Suppose, contrary to safety, that some execution of WEIGHTED ELECT removes all envelopes under the round-driven scheduler and let (p, t) be the maximum round achieved. Suppose t is odd, and let S be the set of identifiers in envelopes that achieve round (p, t). According to Casualty-test, an envelope in round (p, t) with identifier i can only be destroyed by meeting a processor that either (1) last forwarded an envelope with round larger than (p, t), or (2) last forwarded an envelope with round equal to (p, t) and identifier less than i. Since (p, t) is the maximum round, case (1) is impossible. Furthermore, in case (2), the envelope in S with minimum identifier cannot be destroyed. So the envelope will be eventually promoted and its round increases contradicting that (p, t) was the maximum round. A symmetric argument applies if t is even.

Suppose, contrary to progress, that after some point, $k \geq 2$ envelopes remain alive under the round-driven scheduler. Then eventually, say, in round (p, t), each of these envelopes will receive a credit at least as large as the weight of the ring. At this point each envelope has a large enough credit to allow it to travel to the processor that promoted the envelope that precedes it. Since all undestroyed envelopes have the same round number, if t is odd (respectively, even) the envelope with maximum label (respectively, minimum label) must be destroyed, contradicting that no more envelopes are destroyed.

The algorithm cannot prematurely elect a leader because a processor will receive an envelope with *id* equal to its *fwd_id* if and only if there are no other envelopes, thus passing the Leader-test and confirming correct termination.

3. Message complexity of WEIGHTED ELECT**.** We first introduce some definitions and notation. The pth *phase* consists of all the message traffic of envelopes with round (p, t) for $t \in \{0, 1, 2, 3\}$. Since algorithm WEIGHTED ELECT never changes the label of an envelope for the duration of its existence, we use *envelope* a as an abbreviation for the envelope with label a. For an envelope a in phase p, let $\text{host}_p(a)$ denote the processor that promoted the envelope to phase p (that is, from round $(p-1, 3)$ to round $(p, 0)$), or the processor that created the envelope if it is initialized with phase p. The *weighted distance* from processor x to processor y, denoted $\delta(x, y)$, is the sum of the weights of all links between processor x and processor y, traveling in the direction of the ring.

As discussed in section 2, the scheduler cannot influence the communication complexity in a message passing unidirectional ring. Therefore, for simplicity, assume as before the round-driven scheduler, which delivers all envelopes in order of increasing round number. Under this scheduler, all undestroyed envelopes either *participate* in the round, say (p, t), or just *exist* in round (p, t) because they have been created with round number $(q, 0)$ where $q > p$ but have not yet been delivered across any link. Envelope b is the *immediate predecessor in phase* p of envelope a if, when all participating envelopes are in round $(p, 0)$ and all existing envelopes are in phase p or greater, the first envelope encountered after envelope a, traveling in the direction of the ring, is envelope b. Let envelope b be the immediate predecessor of envelope a in

phase p and suppose b is in phase $q \geq p$. Then the *horizon of envelope a in phase p* is $\delta(\text{host}_p(a), \text{host}_q(b))$.

Let n_i be the number of links with weight in $(2^{i-1}, 2^i]$ in an asynchronous ring with distinct identifiers. Let d_p denote the number of envelopes that participate in phase p. An envelope that participates in phase p is *sparse in phase p* if its horizon is greater than 2^p; otherwise, it is *dense*. Let s_p denote the number of envelopes that are sparse in phase p. Let J denote the number of phases until there are at most three remaining envelopes when WEIGHTED ELECT is run on the ring. Notice that after J phases, there can be at most three more passes of message traffic on the ring, so it suffices to bound the weighted message complexity for the first J phases.

The next three lemmas allow us to bound the number of sparse envelopes and the total number of envelopes participating in each phase as a function of the weights on the ring.

LEMMA 3.1. *The number s_p of sparse envelopes that participate in phase p satisfies $s_p \leq \sum_{i=0}^{p} n_i 2^{i-p}$.*

Proof. In phase p, any processor whose outgoing edge has weight greater than 2^p is host of an envelope in a phase $q > p$. Thus any envelope whose weighted distance to such a processor is less than 2^p cannot be sparse. The total weight of edges with weight at most 2^p is $\sum_{1=0}^{p} n_i 2^i$. These edges can accommodate at most $(\sum_{1=0}^{p} n_i 2^i)/2^p$ envelopes that are separated by a distance of at least 2^p. Thus, the number of sparse envelopes that participate in phase p is at most $\sum_{i=0}^{p} n_i 2^{i-p}$. ∎

We expect each pair of successive rounds in a phase to reduce the number of dense envelopes by at least one half. This is because in the first round any envelope meeting a processor in the same round with *fwd_id* smaller than its own *id* is eliminated, and in the next round any envelope meeting a processor in the same round with *fwd_id* larger than its own is eliminated. This is made precise in the next lemma.

LEMMA 3.2. *For $p < J$ the number d_p of envelopes that participate in phase p satisfies the recurrence:*

$$d_0 = n_0, \quad d_{p+1} \leq \frac{d_p - s_p}{4} + n_{p+1} + s_p, \qquad p \geq 0.$$

Proof. The proof relies on the following observation.

FACT 3.3. *Let x be an envelope that exists in phase $p+1$. Assume that at the beginning of phase p, x is immediately followed by k dense envelopes. Then the $\min\{k, 3\}$ dense envelopes that immediately follow x do not survive to phase $p+1$.*

The fact holds because consecutive dense envelopes have enough credit to reach the host of the next envelope with the same round number. By applying the min-max comparison for four consecutive rounds it is easily checked that if x survives for four rounds, the $\min\{k, 3\}$ dense envelopes that follow x must be eliminated.

Consider a maximal chain of dense envelopes in round $(p, 0)$. Suppose there is a nondense envelope s (a sparse envelope or an envelope with higher phase) that immediately precedes the leading dense envelope of this chain. If y is a dense envelope in this chain that survives to phase $p+1$ and is followed by at least three dense envelopes then, by Fact 3.3, we can attribute three eliminated envelopes to y. Suppose y is followed by fewer than three dense envelopes. If s exists in phase $p+1$ then we attribute to y the three eliminated envelopes that, by Fact 3.3, follow s at the beginning of phase p. If s does not survive to phase $p+1$ then in our count of surviving envelopes we can count y as eliminated instead of s.

If there is no such s then all exiting envelopes are dense and participating, and the result again follows immediately from Fact 3.3 as long as $d_p \geq 4$. Otherwise $d_p \leq 3$ and hence $p \geq J$.

In all cases at most $(d_p - s_p)/4 + s_p$ phase p envelopes survive to phase $p+1$. In addition, there are n_{p+1} new envelopes that begin in phase $p+1$. □

LEMMA 3.4. *The number d_p of envelopes that participate in phase p for $p \leq J$ satisfies $d_p < 4\sum_{i=0}^{p} n_i 2^{i-p}$.*

Proof. By Lemma 3.2, $d_p \leq (d_{p-1})/4 + n_p + s_{p-1}$. Thus, by Lemma 3.1, $d_p < (d_{p-1})/4 + n_p + \sum_{i=0}^{p-1} n_i 2^{i-p+1}$. Solving this recurrence with $d_0 = n_0$ yields: $d_p < 4\sum_{i=0}^{p} n_i 2^{i-p}$. □

The bound for d_p given by Lemma 3.4 can be less than 1, and since d_p is an integer, it must therefore be zero in this case. This reflects the situation when envelopes created by processors adjacent to light edges have all been eliminated and envelopes due to heavy edges are not yet participating. In the following theorem we exploit the fact that there can be phases with no message traffic by not charging for those phases of computation when $4\sum_{i=0}^{p} n_i 2^{i-p} < 1$.

THEOREM 3.5. *Let R be a ring with n_i edges having weight in $(2^{i-1}, 2^i]$. Then the weighted message cost of* WEIGHTED ELECT *on R is $O(\sum_{n_i \geq 1} n_i 2^i \lg(n_i + 1))$.*

Proof. Denote the worst-case weighted message cost of WEIGHTED ELECT on ring R up to phase J by $\mathrm{cost}(R)$. It suffices to bound $\mathrm{cost}(R)$ since the remaining phases have complexity $O(\sum_{n_i \geq 1} n_i 2^i)$. There are at most d_p envelopes participating in round (p,t), each of which travels at most a weighted distance of 2^{p+t+1}. Since there are four rounds per phase, phase p costs less than $d_p 2^{p+5}$. Let $\hat{n}_i$ be the least integer that is a power of 2 and satisfies $\hat{n}_i \geq n_i$. We have:

$$\begin{aligned}
\mathrm{cost}(R) &< \sum_{p=0, d_p \geq 1}^{J} d_p \cdot 2^{p+5} \\
&< \sum_{p=0, d_p \geq 1}^{J} 4\sum_{i=0}^{p} n_i 2^{i-p} \cdot 2^{p+5} \qquad \text{by Lemma 3.4} \\
&\in O\left(\sum_{p=0, d_p \geq 1}^{J} \sum_{i=0}^{p} \hat{n}_i 2^i \right).
\end{aligned}$$

We will now show that $S = \sum_{p=0, d_p \geq 1}^{J} \sum_{i=0}^{p} \hat{n}_i 2^i \in O(\sum_{n_i \geq 1} \hat{n}_i 2^i \lg(\hat{n}_i + 1))$, which implies the theorem.

Let $I = \max\{i : n_i \geq 1\}$. By Lemma 3.4, when p satisfies $I \leq p \leq J$, the number of existing envelopes in phase p is at most $4\sum_{i=0}^{p} n_i 2^{i-p} = 4\sum_{i=0}^{I} n_i 2^{i-p} \leq 4\sum_{i=0}^{I} \hat{n}_i 2^{i-p}$. Thus J (the number of phases until there are three or fewer envelopes) is at most the minimum p satisfying $(4\sum_{i=0}^{I} \hat{n}_i 2^i)/2^p < 4$.

Let A be a $(J+1)$ by $(I+1)$ matrix defined by $A(p,i) = \hat{n}_i 2^{i-p}$ for $p \geq i$ and $A(p,i) = 0$ for $p < i$. Let $D_p = 4\sum_{i=0}^{p} A(p,i)$. Then each element of the summation S can be interpreted as the corresponding element of A multiplied by an appropriate scaling factor. Specifically, $S \leq \sum_{0 \leq p \leq J, D_p \geq 1, 0 \leq i \leq I} A(p,i) \cdot 2^p$. Note that entries for any p such that $D_p < 1$ do not contribute to the sum S. Among the remaining entries of A we consider three types. Entries satisfying $A(p,i) \geq 1$ are called *whole entries* (denoted $\mathcal{W}$). Other entries are called *fractional* entries. Among fractional entries we distinguish *heavy entries* (denoted $\mathcal{H}$) and *light entries* (denoted $\mathcal{L}$), to be defined later.

CLAIM 3.6. $\sum_{A(p,i)\in\mathcal{W}} A(p,i)2^p \in O(\sum_{i=0}^{I} \hat{n}_i 2^i \lg(\hat{n}_i+1))$.

Proof. For any fixed i and $p \geq i$, $A(p,i)\cdot 2^p = \hat{n}_i 2^i$. By definition, the largest entry in column i is $A(i,i) = \hat{n}_i$, and the smallest whole entry is $A(i+\lg\hat{n}_i, i) = 1$. Therefore, there are $\lg\hat{n}_i + 1$ whole entries in column i, which, when multiplied by the corresponding scaling vector, make up exactly those terms included in the summation $\sum_{i=0}^{I} \hat{n}_i 2^i \lg(\hat{n}_i+1)$. □

Therefore, it remains to show that the contribution of the fractional entries in the summation S is of the same order.

For each i satisfying $\hat{n}_i > 0$, let level(i) be the number k satisfying $A(k,i) = 1$. That is, level(i) $= i + \lg\hat{n}_i$. Let $T_k = \{i : \text{level}(i) = k\}$ and $t_k = |T_k|$. A fractional entry $A(p,i)$ is called *heavy* if $p \leq \text{level}(i) + t_{\text{level}(i)}$. A fractional entry which is not heavy is called *light*.

The next claim states that the contribution of all heavy fractional elements to the sum S is of the same order as the contribution of whole elements.

CLAIM 3.7. *For any k such that $T_k \neq \emptyset$,*

$$\sum_{i\in T_k} \sum_{p=k+1}^{k+t_k} A(p,i)2^p \leq 3 \sum_{i\in T_k} \hat{n}_i 2^i \lg\hat{n}_i.$$

Proof. By the definition of T_k, for all $i \in T_k$, $\hat{n}_i/2^{k-i} = 1$. Thus $\hat{n}_i \cdot 2^i = 2^k$. So, $i,j \in T_k$ and $i \neq j$ implies $\hat{n}_i \neq \hat{n}_j$. Therefore, for all $i \in T_k$ the corresponding $\hat{n}_i$ are distinct and are powers of two. Hence

$$\sum_{i\in T_k} \hat{n}_i \cdot 2^i \lg\hat{n}_i = 2^k \cdot \lg\left(\prod_{i\in T_k} \hat{n}_i\right) \geq 2^k \cdot \lg(2^0 \cdot \cdots \cdot 2^{t_k-1}) > 2^k \cdot (t_k)^2/3.$$

On the other hand, for any $i \in T_k$ and for any row p, $A(p,i)\cdot 2^p = n_i 2^i = 2^k$. Hence

$$\sum_{i\in T_k} \sum_{p=k+1}^{k+t_k} A(p,i)\cdot 2^p = (t_k)^2 2^k < 3 \sum_{i\in T_k} \hat{n}_i \cdot 2^i \lg\hat{n}_i. \quad \square$$

To complete the proof we estimate the contribution of light fractional elements. First we show the following claim.

CLAIM 3.8. *For any p,*

$$\sum_{i, A(p,i)\in\mathcal{L}} A(p,i)2^p \in O(2^p).$$

Proof.

$$\sum_{i, A(p,i)\in\mathcal{L}} A(p,i)2^p = \sum_{k, k+t_k<p} \sum_{i\in T_k} A(p,i)2^p = \sum_{k, k+t_k<p} t_k 2^k.$$

Since $k < p$ we have $t_k < p-k$ and thus the last sum is bounded by $\sum_{k=1}^{p-1}(p-k)2^k \in O(2^p)$. □

By Claim 3.8, all light fractional entries that are in the same row as some whole entry contribute to the sum S approximately the same amount as that whole entry. Thus we need to take care of light fractional entries that do not belong to the same

row as a whole entry. Note that each row j that contains a whole entry can be directly followed by at most $\lg D_j$ rows that do not contain whole entries. (Any further row $p > j + \lg D_j$ that does not contain a whole entry has $D_p < 1$ and thus is not counted in the summation.) By Claim 3.8, the contribution of light fractional entries in all these rows is bounded by $\sum_{p=j+1}^{j+\lg D_j} 2^p \leq 2^{j+1+\lg D_j} \in O(D_j 2^j)$. Thus the contribution of light fractional entries that belong to a row that does not contain a whole entry is dominated by the contribution of the closest row that contains a whole entry. This concludes the proof of Theorem 3.5. □

4. Lower bound for election on weighted rings. Let W be a multiset of weights with n_i weights in the interval $(2^{i-1}, 2^i]$ (called *weight class* i). In this section we prove that if an algorithm successfully elects a leader for all unidirectional asynchronous weighted rings, then for every set of n distinct identifiers and every multiset of n weights, there exists an arrangement of these identifiers and weights on a ring of n processors such that the algorithm has weighted message cost $\Omega(\sum_{n_i \geq 1} n_i 2^i \max(\lg n_i, 1))$ on this ring. Thus we establish that the message complexity of algorithm WEIGHTED ELECT is asymptotically optimal for asynchronous unidirectional weighted rings with distinct identifiers.

We assume an asynchronous but reliable model. That is, every message is eventually received unaltered, and messages sent over one link arrive in the same order as they were sent. The proof assumes that no knowledge of ring size is known at the start of the algorithm. Also, our proof applies to message-driven algorithms only. However, a well-established argument extends message-driven lower bounds to lower bounds for algorithms that are not message-driven. See, for example, Pachl, Korach, and Rotem [9]. Also, we borrow and adapt the notation, techniques, and some terminology from that paper.

An asynchronous unidirectional weighted ring R with n processors is denoted by a sequence $R = ((id_0, w_0), \ldots, (id_{n-1}, w_{n-1}))$, called a *labeling sequence*, where id_i is the identifier of the ith processor and w_i is the weight of the link from the ith to the $(i+1)$st processor. For $i \neq j, id_i \neq id_j$, whereas w_i may or may not equal w_j. An algorithm A is a *leader election algorithm* if for every positive integer n and for every weighted ring R with n processors, when algorithm A is run on R:

(i) all messages travel clockwise around the ring;
(ii) computation halts after a finite number of messages;
(iii) upon termination, exactly one processor is in the state "leader."

For algorithm A, the *cost of* A *on ring* R, denoted $\text{cost}_A(R)$, is the total weighted cost of all messages sent by A when executed on ring R. Let W be a multiset of n weights and let I be a set of n distinct identifiers. (Elements of both W and I are assumed to be positive integers.) Let $\mathcal{R}(I, W)$ be the set of all rings $R = ((id_0, w_0), \ldots, (id_{n-1}, w_{n-1}))$ such that $\{id_0, \ldots, id_{n-1}\} = I$ and $\{w_0, \ldots, w_{n-1}\} = W$. Denote by $\text{cost}_A(I, W)$ the maximum over all rings $R \in \mathcal{R}(I, W)$ of $\text{cost}_A(R)$. The *cost of leader election for* $\mathcal{R}(I, W)$ is the minimum over all leader election algorithms A of $\text{cost}_A(I, W)$. Given these definitions, our goal is to show that for any set I of n distinct identifiers, and any multiset W of n weights where n_i weights are in weight class i, the cost of leader election for $\mathcal{R}(I, W)$ is $\Omega(\sum_{n_i \geq 1} n_i 2^i \max(\lg n_i, 1))$.

Call a ring R with edge weights taken from W *well constructed* over W if, for each i, all n_i weights in $(2^{i-1}, 2^i]$ are on consecutive links. Such a sequence of links with weights in the same weight class forms a *segment*. Let $\hat{\mathcal{R}}(I, W)$ denote that subset of $\mathcal{R}(I, W)$ that is well constructed over W.

For each ring R in $\hat{\mathcal{R}}(I, W)$, imagine barriers inserted between the segments of

R and run algorithm A on R with these barriers. That is, schedule the messages of A so that all message traffic from one segment to another segment is delayed at the receiver arbitrarily while message delay within each segment is just one time unit, and run A under this scheduler computing the weighted message cost only until all remaining messages are queued at the barriers. Clearly, this can only decrease the total cost of the message traffic; we show that the total cost of the messages sent in only this part of the execution suffices to give the lower bound. Hence, to establish the lower bound we need only show that the average cost of a segment constructed from the n_i weights in weight class i is bounded below by $\Omega(n_i 2^i \max(\lg n_i, 1))$.

First observe that every edge of the network must carry at least one message. This is because, if there is a process that does not send an initial message, then whatever conditions caused the process to not initiate could be reproduced around the ring and result in deadlock. So, for each segment with $n_i = 1$, the required bound for that segment is trivial. To achieve the bound for $n_i \geq 2$ we examine the expected message traffic that ensues within a segment. Once this is determined it is a simple matter to sum these costs, appropriately weighted, over all segments.

Define the *trace* of a message envelope created by the kth processor when it arrives at the pth processor to be the sequence $(id_k, w_k), (id_{k+1}, w_{k+1}), \ldots, (id_p, w_p)$. Because the ring is unidirectional, the trace of a message captures the maximum possible information that a message may possess. Notice that a message envelope with trace $(id_k, w_k), (id_{k+1}, w_{k+1}), \ldots, (id_p, w_p)$ has contributed a weighted cost of $\sum_{i=k}^{p-1} w_i$ to the weighted message cost of the algorithm.

If s is a sequence, then let $|s|$ denotes its length and let $C(s)$ denote the set of cyclic permutations of s. A sequence t is a *subsequence* of s if $s = utv$ for some sequences u and v.

Consider an arbitrary but fixed weight class i. Denote by D the set of all finite nonempty labelling sequences where all weights are in weight class i. For $s \in D$ and $E \subseteq D$ and positive integer k, define

$$B(s, E) = |\{t : t \in E \text{ and } t \text{ is a subsequence of } s\}| \qquad \text{and}$$

$$B_k(s, E) = |\{t : t \in E \text{ and } |t| = k \text{ and } t \text{ is a subsequence of } s\}|.$$

A set $E \subseteq D$ is *exhaustive* if the following two properties hold.

1. *Prefix property*: if $tu \in E$ and $|t| \geq 1$ then $t \in E$.
2. *Cyclic permutation property*: if $s \in D$ then $C(s) \cap E \neq \emptyset$.

For any algorithm A for unidirectional rings, define $m(s, A)$ to be the number of messages sent by A on a segment with labelling sequence s (equivalently, on a ring labelled with s when a barrier is placed between s_n and s_1). Define $E(A) \subseteq D$ to be the set of those $t \in D$ for which a message with trace t is sent when executed on a ring labelled t.

LEMMA 4.1. *For every leader election algorithm A, the set $E(A)$ is an exhaustive set satisfying $m(s, A) \geq B(s, E(A))$ for every $s \in D$.*

Proof. Suppose that $s \in E(A)$ and t is a prefix of s and $1 \leq k = |t| < |s| = n$. Then on a ring $R = p_1, \ldots, p_n$ labelled by s, a message envelope travels from p_1 to p_n. Hence on a ring $p'_1, \ldots, p'_k$ labelled by t, the envelope created by p'_1 travels to p'_k. Thus $t \in E(A)$ and the prefix property holds.

Suppose $s = s_1, \ldots, s_n \in D$, and consider a ring labelled with s. Since A is a leader election algorithm there must be one message envelope that travels the whole

ring because otherwise algorithm A could not successfully elect a leader on rings labelled with an extension of s. This message envelope has a trace of length at least n and hence has a prefix of length exactly n. Thus this prefix is a cyclic permutation of s. So $E(A)$ is exhaustive.

A similar argument confirms that if trace t is sent by A when executed on a ring labelled with t, then trace t is sent by A when executed on any sequence that contains t as a subsequence. Therefore, $m(s, A) \geq B(s, E(A))$. □

Now Lemma 4.1 is used to establish the expected weighted cost of message traffic within a segment. Let W be a multiset of n weights in $(2^{i-1}, 2^i]$. Let I be a set of n distinct integer identifiers, and consider $\mathcal{R}(I, W)$.

LEMMA 4.2. *For any leader election algorithm A, the average of $m(s, A)$ over all labelling sequences $s \in \mathcal{R}(I, W)$ is bounded below by $H_n \cdot n - n$.*

Proof.

$$\begin{aligned} ave\{m(s,A)\}_{s\in\mathcal{R}(I,W)} &= \frac{1}{|\mathcal{R}(I,W)|} \sum_{s\in\mathcal{R}(I,W)} m(s,A) \\ &\geq \frac{1}{|\mathcal{R}(I,W)|} \sum_{s\in\mathcal{R}(I,W)} B(s,E(A)) \\ &\geq \frac{1}{|\mathcal{R}(I,W)|} \sum_{k=1}^{n} \sum_{s\in\mathcal{R}(I,W)} B_k(s,E(A)). \end{aligned}$$

For fixed k and a fixed $s \in \mathcal{R}(I, W)$, there are $n-k+1$ subsequences of s with length k, so there are $|\mathcal{R}(I, W)|(n-k+1)$ length k subsequences over all $s \in \mathcal{R}(I, W)$. Partition these into $\frac{|\mathcal{R}(I,W)|(n-k+1)}{k}$ sets, where each set consists of all cyclic permutations of one sequence. By the cyclic permutation property, each set has at least one element in common with $E(A)$. Hence:

$$\begin{aligned} ave\{m(s,A)\}_{s\in\mathcal{R}(I,W)} &\geq \frac{1}{|\mathcal{R}(I,W)|} \sum_{k=1}^{n} \frac{|\mathcal{R}(I,W)|(n-k+1)}{k} \\ &= (n+1) \sum_{k=1}^{n} \frac{1}{k} - n \\ &= (n+1)H_n - n \in \Omega(n \lg n). \end{aligned}$$ □

THEOREM 4.3. *Let I be a set of n distinct identifiers, and let W be a multiset of weights with n_i weights in the interval $(2^{i-1}, 2^i]$. Then the cost of leader election for $\mathcal{R}(I, W)$ is*

$$\Omega\left(\sum_{n_i \geq 1} n_i 2^i \max(\lg n_i, 1)\right).$$

Proof. For any i such that $n_i = 1$, there is at least one initial message sent by the segment on a link of weight at least 2^{i-1}. If $n_i \geq 2$, then by Lemma 4.2, on average, $\Omega(n_i \lg n_i)$ messages are sent over the segment formed from the n_i elements of W that are in the weight class i and each message incurs a weighted cost of at least 2^{i-1}. Hence, the lower bound for each segment is $\Omega(n_i 2^i \max(\lg n_i, 1))$. Thus, the lower bound for leader election on weighted rings follows by summing over all segments. □

5. Concluding remarks. Our algorithm and lower bound together establish the asymptotic communication complexity of leader election on weighted unidirectional rings. The result is quite strong from several perspectives. First, our algorithm is universally optimal in the sense of Garay, Kutten, and Peleg [4]. That is, our lower bound is asymptotically tight for every set of identifiers and for every multiset of weights. Note that for some specially constructed rings (for example, rings with identifiers arranged in increasing order), there are leader election algorithms that are very efficient. Therefore, the universality of the lower bound cannot be further generalized from all possible sets of identifiers and weights to all possible rings. We conclude that the parameters that determine the complexity of election on a unidirectional weighted ring are precisely the number of edges in each weight class.

Also, we have shown that it is not possible to specially tune a leader election algorithm to be inexpensive for some chosen collection of weights and identifiers without it being incorrect for others. Specifically, our lower bound establishes that as long as an algorithm correctly elects a leader for all unidirectional rings, then, for every multiset W of weights and every set of identifiers I, it will be at least as expensive (asymptotically) as WEIGHTED ELECT on $\mathcal{R}(I, W)$.

There is one essential constraint on our lower bound. It applies only to those algorithms that elect a leader for *all* unidirectional weighted rings. So, for example, the proof of our lower bound does not apply if an algorithm need only work for a fixed ring size or total weight. However, having knowledge of ring size or weight while having no more specific knowledge of the arrangement of the weights on the ring seems to be an unreasonable assumption. And, as we have observed, if there is some knowledge of arrangement of weights, then this knowledge could possibly be exploited to achieve a very efficient algorithm for this arrangement.

The importance of cost-sensitive analysis of distributed algorithms was pointed out by Awerbuch, Baratz, and Peleg [1]. The cost-sensitive complexity of election on unidirectional rings is only a first step; it remains to study the cost-sensitive complexity of other problems and other networks.

Acknowledgments. We are especially grateful to two anonymous referees for their careful reading of the manuscript, their helpful comments, and their very timely response.

THE QUEUE-READ QUEUE-WRITE PRAM MODEL: ACCOUNTING FOR CONTENTION IN PARALLEL ALGORITHMS*

PHILLIP B. GIBBONS†, YOSSI MATIAS†‡, AND VIJAYA RAMACHANDRAN§

Abstract. This paper introduces the *queue-read queue-write* (QRQW) parallel random access machine (PRAM) model, which permits concurrent reading and writing to shared-memory locations, but at a cost proportional to the number of readers/writers to any one memory location in a given step. Prior to this work there were no formal complexity models that accounted for the contention to memory locations, despite its large impact on the performance of parallel programs. The QRQW PRAM model reflects the contention properties of most commercially available parallel machines more accurately than either the well-studied CRCW PRAM or EREW PRAM models: the CRCW model does not adequately penalize algorithms with high contention to shared-memory locations, while the EREW model is too strict in its insistence on zero contention at each step.

The QRQW PRAM is strictly more powerful than the EREW PRAM. This paper shows a separation of $\sqrt{\log n}$ between the two models, and presents faster and more efficient QRQW algorithms for several basic problems, such as linear compaction, leader election, and processor allocation. Furthermore, we present a work-preserving emulation of the QRQW PRAM with only logarithmic slowdown on Valiant's BSP model, and hence on hypercube-type noncombining networks, *even when latency, synchronization, and memory granularity overheads are taken into account.* This matches the best-known emulation result for the EREW PRAM, and considerably improves upon the best-known efficient emulation for the CRCW PRAM on such networks. Finally, the paper presents several lower bound results for this model, including lower bounds on the time required for broadcasting and for leader election.

1. Introduction.

The parallel random access machine (PRAM) model of computation is the most-widely used model for the design and analysis of parallel algorithms (see, e.g., [40, 39, 58]). The PRAM model consists of a number of processors operating in lock-step and communicating by reading and writing locations in a shared memory. Existing PRAM models can be distinguished by their rules regarding contention for shared memory locations. These rules are generally classified into two groups:

- *Exclusive read/write*: Each location can be read or written by at most one processor in each unit-time PRAM step.
- *Concurrent read/write*: Each location can be read or written by any number of processors in each unit-time PRAM step. For concurrent writing, the value written depends on the *write-conflict rule* of the model, e.g., in the *arbitrary concurrent-write* PRAM, an arbitrary processor succeeds in writing its value.

These two rules can be applied independently to reads and writes; the resulting models are denoted in the literature as the EREW, CREW, ERCW, and CRCW PRAM models.

In this paper, we argue that neither the *exclusive* nor the *concurrent* rules accurately reflect the contention capabilities of most commercial and research machines, and propose a new PRAM contention rule, the *queue* rule, that permits concurrent reading and writing, but at an appropriate cost:

- *Queue read/write*: Each location can be read or written by any number of processors in each step. Concurrent reads or writes to a location are serviced one at a time.

Thus the worst case time to read or write a location is linear in the number of concurrent readers or writers to the same location.

The queue rule more accurately reflects the contention properties of machines with simple, noncombining interconnection networks[1] than either the exclusive or concurrent rules. The exclusive rule is too strict, and the concurrent rule ignores the large performance penalty of high-contention steps. Indeed, for most existing machines, including the Cray T3D, IBM SP2, Intel Paragon, MasPar MP-2 (global router), MIT J-Machine, nCUBE 2S, Stanford DASH, Tera Computer, and Thinking Machines CM-5 (data network), the contention properties of the machine are well approximated by the queue-read, queue-write (QRQW) rule. For the Kendall Square KSR1, the contention properties can be approximated by the concurrent-read, queue-write (CRQW) rule. Further details are in section 3.

This paper defines the QRQW PRAM model, a variation on the standard PRAM that employs the queue rule for both reading and writing. In addition, the processors are permitted to each have multiple reads or writes in progress at a time. We show that the power of the QRQW PRAM model falls strictly between the CRCW and EREW models. We show separation results between the models by considering the 2-compaction problem, the broadcasting problem, and the problem of computing the OR function. To illustrate some of the techniques used to design low-contention algorithms that improve upon the best known zero-contention algorithms, we consider algorithms for two fundamental problems, *leader election* and *linear compaction*, under various scenarios. Finally, this paper extends the work-time framework for parallel algorithms (see, e.g., [39]) into a QRQW work-time framework that considers the contention at each step, and relates the QRQW PRAM model to the QRQW work-time framework.

The QRQW PRAM, like the other PRAM models mentioned above, abstracts away many features of real machines, including the latency or delay in accessing the shared memory, the cost of synchronizing the processors, and the fact that memory is partitioned into modules that service requests serially. A model that incorporates these features is the bulk-synchronous parallel (BSP) model of Valiant [61]. In its general form this model is parameterized by its number of processing/memory *components* p, *throughput* g, and *periodicity* L. A particular case studied by Valiant sets g to be a constant and L to be $\Theta(\log p)$; we denote this the *standard* BSP model. We show in this paper that the QRQW PRAM can be effectively emulated on the standard BSP model: A p-processor QRQW PRAM algorithm running in time t can be emulated on a $p/\log p$-

[1] In a *combining network*, when two messages destined for the same memory location meet at an intermediate node in the network, the messages are "combined" so that only one message continues toward the destination. For example, if two writes meet, then only a single write is sent on. In a *noncombining network*, messages are not combined, so that *all* messages destined for the same memory location are delivered to the home node for that location.

processor standard BSP in $O(t \log p)$ time with high probability (w.h.p.). It follows by Valiant's simulation of the standard BSP on hypercubes that the QRQW PRAM can be emulated in a work-preserving manner on parallel machines with hypercube-type, noncombining networks with only logarithmic slowdown, *even when latency, memory granularity, and synchronization overheads are taken into account.* This matches the best-known emulation for the EREW PRAM on these networks given in [61]. In contrast, work-preserving emulations for the CRCW PRAM on such networks are only known with *polynomial* slowdown (i.e., $O(p^\epsilon)$ slowdown, for a constant $\epsilon > 0$).

Note that the standard $\Theta(\log p)$ time emulation of CRCW on EREW (see, e.g., [40]) is not work preserving, in that the EREW performs $\Theta(\log p)$ times more work than the CRCW it emulates. Since we consider work-preserving speedups to be the primary goal in parallel algorithms, with fast running times the secondary goal, this emulation is unacceptable: The $\Theta(\log p)$ overhead in work ensures that the algorithms will not exhibit linear or near-linear speedups. Similarly, the best-known emulations for the CREW PRAM (or ERCW PRAM) on the EREW PRAM (or standard BSP or hypercube) require logarithmic work overhead for logarithmic slowdown or, alternatively, polynomial slowdown for constant work overhead.

Since the QRQW PRAM is strictly more powerful than the EREW PRAM, effectively emulated on hypercube-type noncombining networks (unlike the CRCW, CREW, or ERCW PRAM models), and a better match for real machines, we advocate the QRQW PRAM with its *queue*-contention rule as a more appropriate model for high-level algorithm design than a PRAM with either the *exclusive*- or *concurrent*-contention rules. The queue-contention rule can also be incorporated into lower-level shared-memory models, trading model simplicity for additional accuracy in modeling the cost of communication (e.g., explicitly modeling the communication bandwidth). In this initial paper on the queue-contention rule, we restrict our focus to high-level algorithm design on PRAM models.

In addition to the QRQW PRAM model, we define in this paper the SIMD-QRQW PRAM model, a strictly weaker model suitable for SIMD machines, in which all processors execute in lock-step and each processor can have at most one read/write in progress at a time. In a subsequent paper [30] we define the QRQW ASYNCHRONOUS PRAM model, for general asynchronous algorithms running on MIMD machines (see also [26]).

We present several algorithms and a lower bound for leader election and for computing the OR function. The lower bound is $\Omega(\log n / \log \log n)$ time for the deterministic computation of the OR function on a CRQW PRAM with arbitrarily many processors. The algorithms for both problems take linear work and $O(\log n / \log \log n)$ time with high probability. In contrast, the OR function requires $\Omega(\log n)$ expected time on a randomized CREW PRAM with arbitrarily many processors ([17], following [12]). Also presented is a linear work, $O(\sqrt{\log n})$ time w.h.p. algorithm for the linear-compaction problem. This problem has applications to automatic processor allocation for algorithms that are given in the QRQW work-time presentation. In contrast, the best linear-compaction algorithm known on the EREW PRAM is the logarithmic time prefix sums algorithm [42]. On the other hand, for the problem of broadcasting the value of a bit to n processors, we show that we can do no better on the QRQW PRAM than the simple $\Theta(\log n)$ time EREW PRAM algorithm. Specifically, we show a tight $\Omega(\log n)$ expected-time lower bound for the QRQW PRAM.

Important technical issues arise in designing algorithms for the queue models that are present in neither the concurrent nor the exclusive PRAM models. For example,

much of the effort in designing algorithms for the QRQW is in estimating the maximum contention in a step; our algorithms for leader election illustrate this point. In the QRQW, one high-contention step can dominate the running time of the algorithm: we cannot afford to underestimate the contention significantly.

In a companion paper [29], we present a number of other algorithmic results for the QRQW PRAM. Our algorithmic results include linear work, logarithmic or sublogarithmic time randomized QRQW algorithms for the fundamental problems of multiple compaction, load balancing, generating a random permutation, parallel hashing, and sorting from $U(0,1)$. These algorithms improve upon the best-known EREW algorithms for these problems, while avoiding the high-contention steps typical of CRCW algorithms. Additionally, we present new algorithms for integer sorting and general sorting.

Most of the results in [29], and some of the results in this paper, are obtained w.h.p. A probabilistic event occurs w.h.p. if, for any prespecified constant $\delta > 0$, it occurs with probability $1 - 1/n^{\delta}$, where n is the size of the input. Thus, we say a randomized algorithm runs in $O(f(n))$ time w.h.p. if for every prespecified constant $\delta > 0$, there is a constant c such that for all $n \geq 1$, the algorithm runs in $c \cdot f(n)$ steps or less with probability at least $1 - 1/n^{\delta}$.

The rest of this paper is organized as follows. Section 2 defines the QRQW PRAM and SIMD-QRQW PRAM models. Section 3 gives further motivation for the queue models, and comparison with related work. Section 4 describes the extension of the work-time framework to the QRQW models. Section 5 presents our results for realizing the QRQW PRAM on feasible networks. Section 6 gives upper and lower bounds for computing the OR and leader election under various scenarios. Section 7 presents our linear-work, sublogarithmic-time algorithm for linear compaction on a SIMD-QRQW PRAM. Section 8 presents tight $\Omega(\log n)$ expected-time lower bounds on the QRQW PRAM for broadcasting and related problems. Concluding remarks appear in section 9.

The results in this paper appeared in preliminary form in [26, 27, 28].

2. The queue models. This section defines our two QRQW models:

- the SIMD-QRQW PRAM, for algorithms running on SIMD machines, and
- the QRQW PRAM, for bulk-synchronous algorithms[2] running on MIMD machines.

In both of the QRQW models, the time cost for reading or writing a shared location, x, is proportional to the number of processors concurrently reading or writing x. This cost measure models machines in which accesses to a location queue up and are serviced one at a time, i.e., most current commercial and research machines. The SIMD-QRQW models machines in which processors synchronize at every step, waiting for all the queues to clear. The QRQW models machines in which processors synchronize less frequently, waiting for all the queues to clear only at synchronization points. In a subsequent paper [30] we define the QRQW ASYNCHRONOUS PRAM model, for general asynchronous algorithms running on MIMD machines (see also [26]). This model has an *asynchronous* queue-contention rule in which processors read and write locations at their own pace, without waiting for the queues encountered by other processors to clear. This model allows the asynchronous nature of MIMD machines to be exploited, at the cost of more complexity in the model.

[2] In a *bulk-synchronous* algorithm [61, 24, 25], synchronization among the processors is limited to global synchronization barriers involving all the processors; between such barriers, processors execute asynchronously using shared-memory values written prior to the preceding barrier.

In order to preserve the simplicity of the SIMD-QRQW PRAM and QRQW PRAM models, neither model incorporates the cost of synchronizing after a step. We note, however, that our result on a work-preserving emulation of both models on a BSP shows that the cost of synchronization can be hidden (up to a constant factor) by using a target machine with a somewhat smaller number of processors.

The complexity metric for the QRQW models will use the notion of maximum contention, defined as follows.

DEFINITION 2.1. *Consider a single step of a* PRAM*, consisting of a read substep, a compute substep, and a write substep. The* maximum contention *of the step is the maximum, over all locations x, of the number of processors reading x or the number of processors writing x. For simplicity in handling a corner case, a step with no reads or writes is defined to have maximum contention* 1.

2.1. The SIMD-QRQW PRAM model.

DEFINITION 2.2. *The* SIMD-QRQW PRAM *model is a (synchronous)* PRAM *in which concurrent reads and writes to the same location are permitted, and the* time cost *for a step with maximum contention κ is κ. If there are multiple writers to a location x in a step, an arbitrary write to x succeeds in writing the value present in x at the end of the step. The* time *of a* SIMD-QRQW PRAM *algorithm is the sum of the time costs for its steps. The* work *is its processor-time product.*

This cost measure models, for example, a SIMD machine such as the MasPar MP-1 [51] or MP-2, in which each processor can have at most one read/write in progress at a time, reads/writes to a location queue up and are serviced one at a time, and all processors await the completion of the slowest read/write in the step before continuing to the next step. Existing SIMD machines provide for the required synchronization of all processors at each step, regardless of the varying contention encountered by the individual processors. Unlike previous PRAM models, the work is not the number of operations, because with the SIMD-QRQW time metric, operations encountering nonconstant contention are charged nonconstant time.

If a PRAM model is to be used to design bulk-synchronous algorithms on MIMD machines, then the SIMD-QRQW PRAM is unnecessarily restrictive. A better model for this scenario is the QRQW PRAM, defined next.

2.2. The QRQW PRAM model.

DEFINITION 2.3. *The* QRQW PRAM *model consists of a number of processors, each with its own private memory, communicating by reading and writing locations in a shared memory. Processors execute a sequence of synchronous steps, each consisting of the following three substeps:*

1. *Read substep: Each processor i reads r_i shared-memory locations, where the locations are known at the beginning of the substep.*
2. *Compute substep: Each processor i performs c_i* RAM *operations involving only its private state and private memory.*[3]
3. *Write substep: Each processor i writes to w_i shared-memory locations (where the locations and values written are known at the beginning of the substep).*

Concurrent reads and writes to the same location are permitted in a step. In the case of multiple writers to a location x, an arbitrary write to x succeeds in writing the value present in x at the end of the step.

[3] As in the existing PRAM models, each processor is assumed to be a sequential random access machine. See, e.g., [58]. For the QRQW PRAM, a processor may perform multiple RAM operations in a compute substep, e.g., summing c_i numbers stored in its private memory, and is charged accordingly.

DEFINITION 2.4. *Consider a* QRQW PRAM *step with maximum contention* κ*, and let* $m = \max_i\{r_i, c_i, w_i\}$ *for the step, i.e., the maximum over all processors* i *of its number of reads, computes, and writes. Then the* time cost *for the step is* $\max\{m, \kappa\}$*. The* time *of a* QRQW PRAM *algorithm is the sum of the time costs for its steps. The* work *of a* QRQW PRAM *algorithm is its processor-time product.*

This cost measure models, for example, a MIMD machine such as the Tera Computer [2], in which each processor can have multiple reads/writes in progress at a time, and reads/writes to a location queue up and are serviced one at a time. Neither the EREW PRAM nor the CRCW PRAM model allows a processor to have multiple reads/writes in progress at a time, as this generalization is unnecessary when reads/writes complete in unit time. This feature, which distinguishes the QRQW PRAM from the SIMD-QRQW PRAM as well as the EREW PRAM and CRCW PRAM, enables the processors to do useful work while awaiting the completion of reads/writes that encounter contention. Nevertheless, as we show below, the CRCW PRAM can simulate the QRQW PRAM to within constant factors.

The restriction that the processors in a read substep know, at the beginning of the substep, the locations to be read reflects the intended emulation of the QRQW PRAM model on a MIMD machine in which the reads are issued in a pipelined manner, to amortize against the delay (latency) on such machines in reading the shared memory. Likewise writes in a write substep are to be pipelined in the intended emulation. On the other hand, each of the local operations performed in a compute substep can depend on compute operations in the same substep; since these operations are assumed to take constant time in the intended emulation, there is no need for pipelining (to within constant factors). The emulation inserts a barrier synchronization among all the processors between every read and write substep, so that the processors notify each other when it is safe to proceed with the next substep. This synchronization is accounted for in the emulation. A formal description of the intended emulation and its performance appears in section 5.

On existing parallel machines, there are a number of factors that determine the time to process shared-memory read and write requests, including contention in the interconnection network and at the memory modules. Often, reads and writes to *distinct* shared-memory locations may delay one another. Moreover, issued memory requests cannot be withdrawn. To reflect these realities of existing machines, the QRQW PRAM (as well as the SIMD-QRQW PRAM) does not permit processors to make inferences on the contention encountered based on the delays incurred. In addition, issued memory requests may not be withdrawn, and an algorithm has not completed until all issued memory requests have been processed. In this way, the QRQW models, although explicitly accounting only for the delays resulting from multiple requests to the *same* locations, can be efficiently emulated on models that account for these additional concerns, as shown in section 5.

As with the SIMD-QRQW PRAM, the work is not the number of operations, since operations encountering nonconstant contention may be charged nonconstant time. (In fact, the only situation where the work is a good reflection of the number of operations is when pipelining is extensively employed, i.e., when the average over i of $(r_i + c_i + w_i)$ is $\Omega(\kappa)$.)

Also, as with the SIMD-QRQW PRAM, there is no explicit metric for the number of steps in an algorithm. As we show in section 5, there is no need for such a metric in the context of the intended emulation. On the other hand, the synchronization at the end of each bulk-synchronous step is a source of overhead on existing machines,

and hence we may wish to include this additional metric when analyzing algorithms on the QRQW models.

2.3. Relations between models. The primary advantage of the QRQW PRAM model over the SIMD-QRQW PRAM model is that the QRQW permits processors each to perform a series of reads and writes in a step while incurring only a single penalty for the contention of these reads and writes. In the SIMD-QRQW, a penalty is charged after each read or write in the series; often the resulting aggregate charge for contention is far greater than the single charge under the QRQW model. On the other hand, by adding more processors to the SIMD-QRQW, we can match the time bounds (but not the work bounds) obtained for the QRQW.

OBSERVATION 2.1. *A p-processor* QRQW PRAM *algorithm running in time t can be emulated on a pt-processor* SIMD-QRQW PRAM *in time* $O(t)$.

Proof. For each QRQW processor $i \in [1..p]$, we assign a team, T_i, of t SIMD-QRQW processors, with each team having a leader, l_i. Each leader l_i maintains the entire local state of QRQW processor i during the emulation. For each team T_i, we have an auxiliary array, A_i, of size t for communications between l_i and each member of its team. Consider the jth step of a QRQW PRAM algorithm, with time cost t_j and maximum contention $k_j \leq t_j$. For each QRQW processor i, let r_i, c_i, and w_i be the number of reads, RAM operations, and writes performed by processor i in this step. Processor i is emulated as follows. (1) The leader l_i writes the r_i locations to be read to A_i, one location per cell. (2) Each member of T_i reads its cell in A_i, reads the designated location (if any) in the shared memory, and then writes the value read to its cell in A_i. (3) The leader l_i reads the values in A_i, performs the c_i RAM operations, and then writes the w_i locations and values to be written to A_i, one per cell. (4) Finally, each member of T_i reads its cell in A_i, and then writes the designated value to the designated location (if any) in the shared memory. Step 1 takes $O(r_i)$ time, step 2 takes $O(k_j)$ time, step 3 takes $O(r_i + c_i + w_i)$ time, and step 4 takes $O(k_j)$ time. Thus the overall time to emulate the jth QRQW step is $O(t_j)$, and the observation follows. □

Note that in fact only $p \cdot \tau$ processors are needed in the above emulation, where $\tau \leq t$ is the maximum time for any one step of the QRQW PRAM algorithm.

The SIMD-QRQW PRAM model permits each processor to have at most one shared-memory request outstanding at a time, as in the standard PRAM model. This places an upper bound on the number of requests that must be handled by the interconnection network of the parallel machine. For most MIMD machines, permitting only one request per processor is artificially restrictive, and the QRQW PRAM model has no such restriction. On the other hand, since there is no bound in the QRQW PRAM on the number of outstanding requests, there is a danger that QRQW PRAM algorithms will flood the network with requests beyond its capacity to efficiently process them. One approach toward alleviating this potentially serious problem is to divide steps with many shared-memory requests into a sequence of steps with fewer requests per step. In general we could indicate, for each QRQW PRAM algorithm, the maximum number of requests in any one step of the algorithm. Then when implementing the algorithm on a given parallel machine, this number could be compared with the maximum effective network capacity of the machine to determine if the memory requests can be efficiently processed by the network.

Let M_1 and M_2 be two models. We define $M_1 \preceq M_2$ to denote that any one step of M_1 with time cost $t \geq 1$ can be emulated in $O(t)$ time on M_2 using the same number of processors. For concurrent and queue writes we assume throughout this

TABLE 1
Time separation results for the QRQW. *Results on problems inducing a time separation of the* QRQW *from the* EREW *model and the* CRCW *from the* QRQW *model, including both deterministic time (*det.*) and randomized expected or w.h.p. time (*rand.*).*

paper that an arbitrary processor succeeds in the write; however, the relations stated below hold as long as both machines use the same write-conflict rule.

OBSERVATION 2.2. EREW PRAM $\preceq$ SIMD-QRQW PRAM $\preceq$ QRQW PRAM $\preceq$ CRCW PRAM.

Proof. The observation can be proved by straightforward emulation. For the CRCW emulating a QRQW step of time cost t: (1) for $j = 1, \ldots, \max_i\{r_i\}$, perform the jth read operation (if any) at each processor in one step using CR; then (2) for $j = 1, \ldots, \max_i\{c_i\}$, perform the jth compute operation (if any) at each processor; then (3) for $j = 1, \ldots, \max_i\{w_i\}$, perform the jth write operation (if any) at each processor in one step using CW. This takes time $\max_i\{r_i\} + \max_i\{c_i\} + \max_i\{w_i\} \leq 3t$. □

Let M_1 and M_2 be two models such that $M_1 \preceq M_2$. A computational problem P *induces a separation of* $O(f(n))$ *time with* $q(n)$ *processors of* M_2 *from* M_1 if there exists a function $t(n)$ such that, on inputs of length n, P can be solved on M_2 in time $O(t(n))$ with $q(n)$ processors, but P requires $\Omega(t(n) \cdot f(n))$ on M_1 if only $q(n)$ processors are available. We say that there is a *separation of* $f(n)$ *time with* $q(n)$ *processors of* M_2 *from* M_1 if there exists a problem that induces such a separation. Most of the separation results we derive in this paper hold for any $q(n) = \Omega(n)$; in such cases we omit $q(n)$ when stating the result.

Results on problems inducing a separation of the QRQW from the EREW model and the CRCW from the QRQW model appear in Table 1.

2.4. A family of queue models. The definitions of SIMD-QRQW PRAM and QRQW PRAM can be generalized so that the charge for maximum contention κ is $f(\kappa)$, a nondecreasing function of κ. When $f(\kappa) = 1$ for all κ, both models are equivalent to the CRCW PRAM. Likewise, when $f(1) = 1$ and $f(\kappa) = \infty$ for $\kappa \geq 2$, both models are equivalent to the EREW PRAM. Note that the distinction between the SIMD-QRQW PRAM and the QRQW PRAM arises only when $f(\kappa) > 1$ and is finite for some κ.

Another possible cost function is $f(\kappa) = \log \kappa$; such a function may occur in a *hypothetical* variant of combining networks, but it is not known to be relevant to any existing machines (there are no known techniques for achieving this cost function for an arbitrary set of readers/writers). The log cost function may prove to be relevant to future machines that employ an optical crossbar to interconnect the processors [34, 48]. However, in this paper, we will focus our attention on the cost function, $f(\kappa) = \kappa$, that reflects the realities of proven technologies. (For some machines that do not handle contention well, superlinear functions such as $f(\kappa) = \kappa \log \kappa$ may be appropriate; such cost functions are not considered in this paper.) Other possible variants of the model permit write-conflict rules other than *arbitrary*; however, we note that the arbitrary rule reflects the realities of most current commercial and research machines.

As the queue rule can be applied independently to reads or writes, we can also

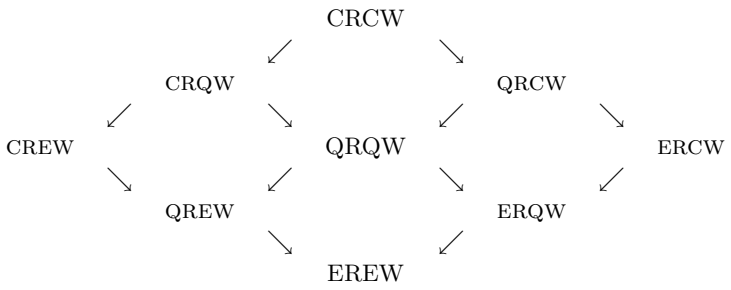

FIG. 1. *The relative power of various* PRAM *concurrency rules. The same relationships hold for the* SIMD *versions of the queue models. For concurrent write, we assume an arbitrary processor succeeds in writing. In this figure an arrow denotes that the* PRAM *model,* M_1*, at the tail of the arrow can simulate the* PRAM *model,* M_2*, at its head with at most a small constant loss in performance (and possibly some improvement), i.e.,* $M_2 \preceq M_1$*. Our results characterize more precisely the relative power of some of the concurrency rules.*

TABLE 2

*Time separation results for the hybrid queue models, including both deterministic time (*det.*) and randomized expected time or w.h.p. time (*rand.*). All results listed here hold for the* SIMD *versions as well.*

consider models such as the SIMD-CRQW or CRQW PRAM. For each such hybrid model, the PRAM version can trivially simulate the SIMD version with no loss. Figure 1 depicts the relative power of the various models immediately apparent from the definitions, extending the results in Observation 2.2 to the hybrid models. Likewise, Table 2 presents additional separation results for the hybrid models.

3. The case for QRQW. The PRAM model was introduced in 1978 [22], with the CREW contention rule. Since that time, a variety of contention rules has been proposed and studied, with the most widely studied being the EREW, CREW, and CRCW rules. Variants of the CRCW PRAM such as ARBITRARY, COLLISION, COMMON, PRIORITY, ROBUST, and TOLERANT have been proposed and studied (see, e.g., [52] for definitions); these differ in their write-conflict rules. Given the plethora of contention rules already in the literature, it is reasonable to ask if there is a need for yet another contention rule, and in particular, whether the QRQW PRAM is an important new PRAM model.

The QRQW PRAM is a fundamental departure from standard PRAM models because it is *the first* PRAM *model to properly account for contention*, as reflected in most current commercial and research machines. By permitting contention, it reflects the realities of current machines, and enables simpler and more efficient algorithms for many basic problems. By charging for contention, it reflects the realities of machines with noncombining networks, e.g., most current commercial and research machines. In the remainder of this section, we elaborate on these points and then compare

the QRQW models to related work. We begin with a critique of the exclusive and concurrent rules.

3.1. EREW is too strict. The *exclusive* contention rule is almost universally considered by PRAM proponents to be a realistic rule for parallel machines. In the EREW PRAM, it is forbidden to have two or more processors attempt to read or write the same location in the same step. We know of no existing shared-memory parallel machine with this restriction on its global communication. Moreover, the exclusive rule leads to unnecessarily slow algorithms. A simple example is the 2-compaction problem, in which there are two nonempty cells at unknown positions in an array of size n, and the contents of these cells must be moved to the first two locations of the array. An EREW PRAM requires $\Omega(\sqrt{\log n})$ time to solve the 2-compaction problem; an n-processor CREW PRAM requires $\Omega(\log \log n)$ time [20]. However, as shown in section 7, there is a trivial constant-time n-processor QRQW PRAM algorithm for this problem.

The exclusive contention rule eliminates many *randomized* algorithmic techniques. Randomization used to determine *where* a processor should read or write (e.g., random sampling, random hashing) cannot avoid some small likelihood of concurrent reading or writing and hence cannot be incorporated directly into EREW algorithms.[4] Likewise, most *asynchronous* algorithms cannot avoid scenarios in which concurrent reading or writing occurs. Hence existing ASYNCHRONOUS PRAM models (e.g., [11, 24, 54, 50]) do not enforce the exclusive rule, assuming instead a CRCW cost measure.[5]

3.2. CRCW may be too powerful. At the other extreme, the *concurrent*-contention rule may be too powerful. In the CRCW PRAM, each step takes unit time, independent of the amount of contention in the step. Thus no distinction is made between low-contention and high-contention algorithms. On parallel machines with noncombining networks, high-contention read steps or write steps can be quite slow, as each of the requests for a highly contended location is serviced one by one, creating a serial bottleneck or "hot spot" [55]. Moreover, intermediate nodes on the path to the contended destination become congested as well, so a single hot spot can even delay requests destined for other nodes in the network. If all p processors request the same location, a common occurrence in CRCW PRAM algorithms, a direct implementation of the algorithm can incur a p-fold loss in speedup due to contention, sometimes becoming no better than a sequential algorithm.

An active area of research is how to execute a CRCW step that includes high-contention reads or writes without creating hot spots. Software approaches, e.g., using sorting [61], may incur an overhead considered unacceptable in practice, even on machines that support them. This is arguably true of the MasPar MP-1, for example, where the concurrent-write primitive provided for the MP-1 is around 20 times slower than writing according to a random permutation [56]. As indicated in section 1, the asymptotically best work-preserving emulation known for simulating the CRCW PRAM on machines with noncombining networks suffers polynomial slowdown [61, 63]. Thus, the running time on the parallel machine will be a polynomial factor slower than the running time indicated by the CRCW model.

[4] These techniques can be incorporated into CRCW algorithms, and emulated on the EREW, but at logarithmic cost in time and work.

[5] An exception is the EREW variant of Gibbons' ASYNCHRONOUS PRAM model [24], which permits contention in synchronization primitives, at a cost, but enforces the exclusive rule on reads and writes occurring between synchronization points.

Hardware approaches for executing high-contention CRCW steps without hot spots incorporate combining logic into the interconnection network. Ranade's work [57] shows that any CRCW step can be simulated on certain hypercube-based networks in the same asymptotic time as an EREW step, and development of machines based on his technique have been reported (e.g., [1, 18]). It is an open question whether the system cost of supporting CRCW efficiently in hardware is justified, particularly on MIMD machines, and work continues in this area (e.g., [16]). Existing commercial machines are primarily designed to process low-contention steps efficiently; high-contention steps are slow operations.

Note that the weaknesses of the exclusive- and concurrent-contention rules apply independently to reading and writing. Thus hybrids such as the CREW PRAM or the ERCW PRAM are too strict for writing (reading, respectively) and may be too powerful for reading (writing, respectively).

3.3. Most existing machines are QRQW. Table 3 classifies some existing multiprocessors according to the concurrent-read and write capabilities of their interprocessor communication. We have included message-passing machines, as well as shared-memory ones, since they are often used to run (slightly modified versions of) shared-memory algorithms or programs. The second column indicates commercial product ($) or working prototype (P). The third column indicates synchronous (S) or asynchronous (A) machines. In the last column, ER or EW denotes that programs for the machine are forbidden from having multiple requests for a location. QR or QW denotes that multiple requests to a location may be issued, and requests are generally serviced one at a time. CR or CW denotes that multiple requests to a location may be issued, and requests are combined in the network.

A few entries do not quite fit the taxonomy and require further explanation. In the XNET of the MP-1 and MP-2, processors are limited to reading or writing values stored at nodes a given distance away in a given compass direction; each processor may broadcast a value to all intermediate nodes on the path. The control network of the CM-5 provides fast SCAN primitives [6]; such primitives provide concurrent reading and writing and more (only) for well-structured sets of requests that fit the

segmented-SCAN paradigm [7]. In bus-based machines, the bus typically services only one shared-memory location at a time; all processors requesting to read the location can be serviced at the same time without penalty. Finally, a number of these machines provide caches that permit fast concurrent rereading of shared-memory locations: once a set of processors has read a location, they may subsequently reread the location without incurring a penalty for contention, as long as no processor has written to the location in the meantime.

As seen from the table, the contention rule for most of these machines, including the Cray T3D, IBM SP2, Intel Paragon, MIT J-Machine, nCUBE 2S, Stanford DASH, and Tera Computer, is well approximated by the QRQW rule. For the synchronous MasPar MP-1 and MP-2, the contention rule is well approximated by the SIMD-QRQW rule.

For the Kendall Square KSR1, the contention rule is well approximated by the CRQW rule. The Thinking Machines CM-5 provides a second network that can be used to perform fast SCAN operations [6]. An appropriate model for this machine would be a QRQW model with unit-time SCAN operations.

Note that each of the asynchronous machines (marked *A* in Table 3) allows for general asynchronous algorithms. Thus their contention rule in its full generality is well approximated by the asynchronous queue-contention rule provided by the QRQW ASYNCHRONOUS PRAM [30] (except for the KSR1, which is well approximated by an asynchronous CRQW contention rule). On the other hand, their contention rule with respect to bulk-synchronous algorithms is well approximated by the (bulk-synchronous) queue-contention rule provided by the simpler QRQW or CRQW PRAM.

A number of these machines, such as Stanford DASH, provide caches local to each processor; on reading a shared-memory location, a copy is stored in the processor's cache for future reuse. Multiple processors with cached copies of a location may then request to read the location and will be serviced in parallel from their local caches. To maintain a single consistent value for a location, these machines typically invalidate all cached copies of the location before permitting a processor to write to the location. This fast concurrent rereading of memory locations is not modeled in the QRQW models due to the following. If the contents of a shared-memory location are stored in a private-memory location when first read by a processor, then there is no need to issue a subsequent shared-memory read for this location unless some other processor *may have* changed the value: the private copy may be used instead. Moreover, if some other processor *did* change the value, then fast rereading is not possible and there will be a penalty for high contention with or without the caches. Thus fast rereading of memory locations seems to have only a secondary effect on the contention encountered in parallel algorithms, and hence has been omitted from the model, for simplicity.

We have conducted experiments to measure the effect of contention on a 16,384 processor MasPar MP-1. The results of these experiments are given in Figure 2. The experiments show that the SIMD-QRQW rule is a far more accurate reflection of running time on the MasPar MP-1 than a CRCW contention rule. Indeed, the overall time for the read (write) step is dominated by the cost of contention at a fairly small value for the contention, and then the time grows nearly linearly with the contention. In contrast, the CRCW contention rule would predict that the overall time would not change with the contention. The differences between the left and right plots in the figure demonstrate that charging k for contention k, as in the SIMD-QRQW rule, becomes an accurate reflection of the running time only when each processor has its

MasPar running times (in milliseconds)				
contention	1024 processors		16384 processors

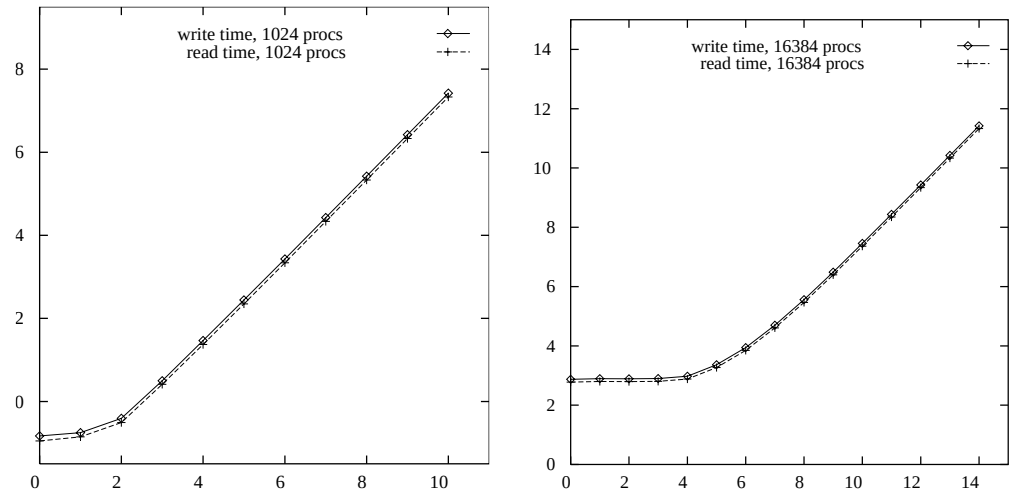

FIG. 2. *Performance measurements on the MasPar MP-*1 *for a read or write step, under increasing contention to a location. Top, timing measurements. Bottom, plot of the measurements on a* log-log *scale, showing the running time (y-coordinate) as a function of the contention in the step (x-coordinate). Results for* 2^{10} *and* 2^{14} *processors are shown. In the base experiment (contention* 1*, x-coordinate* 0*), each processor reads (writes) according to a random permutation. In the general experiment (contention* 2^i*, x-coordinate* i*), the first* 2^i *processors read (write) the same location* M*, while the remaining processors read (write) according to the original random permutation. Shown are the cumulative times of repeating the experiment on* 20 *different random permutations. In the plots, the y-coordinate depicts the base-*2 *logarithm of the number of milliseconds needed.*

The experiments show that high-contention steps are several orders of magnitude slower than random permutations, and moreover, that doubling the contention nearly doubles the running time, at least for medium- to high-contention steps. The dependence of the running time on the contention is more dramatic in the experiments with 1024 *processors than with* 16,384 *processors, for the following reason. In the* 16,384*-processor MasPar MP-*1*, each global router port is shared by* 16 *processors, creating an additional serial bottleneck. The experiments with* 1024 *processors use only one processor per port, thereby avoiding this serial bottleneck.*

own global router port; otherwise, a more complicated metric would be more accurate. Note that the MasPar MP-2, the successor of the MP-1, provides additional router

ports to help alleviate the bottleneck in the MP-1 caused by having one port for every 16 processors. Thus we would expect the MP-2 to behave more like the plot on the left, i.e., more according to the SIMD-QRQW rule.

3.4. Related work. In an early related work, Greenberg [36] considered broadcast communication schemes, such as the Ethernet, that have queues for submitted messages. More recently, Cypher [14] analyzed the performance of a maximum-finding algorithm under assumptions similar to the SIMD-QRQW PRAM. Dietzfelbinger, Kutylowski, and Reischuk [17] defined the *few-write* PRAM, that permits one-step concurrent writing of up to κ writes, where κ is a parameter of the model, as well as unlimited concurrent reading. Valiant [61] introduced the BSP model (see section 5) and studied a specialization of the model with logarithmic periodicity and constant throughput, which we call here the *standard* BSP model. In [61] it is shown that a v-processor PRAM step with contention κ can be simulated on a p-processor standard BSP in $O(v/p + \kappa \log p)$ time w.h.p. A large number of papers have studied the *Distributed Memory Machine*, in which the shared memory is partitioned into modules such that at most one memory location within each module can be accessed at a time. Concurrent reads and writes may or may not be allowed depending on the model. (See [43, 62] and the references therein.) An early example is the *Candidate Type Architecture* (*CTA*) machine model proposed by Snyder [60] which consists of a set of processors connected by a sparse communication network of unspecified topology and linked to a controller. The CTA is parameterized by the number of processors and the latency of interprocessor communication. Aumann and Rabin [3] showed that a PRAM algorithm can be simulated on a very general asynchronous parallel system that permits $O(\log n)$ contention to a location in unit time.

There have been several recent papers presenting independent work in related areas. Culler et al. [13] proposed the *LogP* model, a lower-level message-passing model in which there is limited communication bandwidth: a processor can send or receive at most one message every g cycles, where g is a parameter of the model. There is also a limit on the number of messages in the network at the same time. The LogP model permits general asynchronous algorithms. Liu, Aiello, and Bhatt [47] studied a message-passing model in which messages destined for the same processor are serviced one at a time in an arbitrary order. Their model permits general asynchronous algorithms, but each processor can have at most one message outstanding at a time. Dwork, Herlihy, and Waarts [19] defined an asynchronous shared-memory model with a *stall* metric. If several processes have reads or writes pending to a location, v, and one of them receives a response, then all the others incur a stall. Hence the charge for contention is linear in the contention, with requests to a location being serviced one at a time. Their model permits general asynchronous algorithms, but each processor can have at most one read or write outstanding at a time. Unlike their model, the QRQW models capture *directly* how the contention delays the overall running time of the algorithm, and are proposed as alternatives to other PRAM models for high-level algorithm design. Unlike each of these models, the QRQW PRAM does not explicitly limit the number of outstanding requests. The SIMD-QRQW PRAM, on the other hand, has the same restriction as the Liu, Aiello, and Bhatt [47] and Dwork, Herlihy, and Waarts [19] models, namely, one request per processor.

In contrast to many of the models mentioned above, the QRQW model focuses on the contention to locations, rather than to memory modules or processors. Any algorithm with high location contention will perform poorly on machines with non-combining networks, regardless of the number of memory modules; any lower bound

on location contention is a lower bound on memory-module contention. By focusing on locations, the QRQW model is independent of the particular layout of memory on the machine, e.g., the number of memory modules. Moreover, it is more relevant to cache-only memory architectures (COMA), such as the KSR1, that dynamically map memory locations to processors as the computation proceeds. Location contention is also a relevant metric for cache-coherence overhead, since the number of invalidates or updates that must be sent on a write is often proportional to the number of processors concurrently accessing the location being written [45]. The QRQW models, like the standard PRAM and other similar models, are true shared-memory models, providing a simple view of the shared memory as a collection of independent cells.

4. Adding contention to the work-time framework. In the *work-time* presentation, a parallel algorithm is described in terms of a sequence of steps, where each step may include any number of concurrent read, compute, or write operations [39]. In this context, the *work* is the total number of operations, and the *time* is the number of steps. This is sometimes the most natural way to express a parallel algorithm, and forms the basis of many data parallel languages (e.g., NESL [8]). For standard PRAM models, Brent's scheduling principle [10] can often be applied to obtain an efficient $O(work/p + time)$ time algorithm for a p-processor PRAM.

4.1. The QRQW work-time framework. We show here that the work-time paradigm can be used to advantage for the QRQW PRAM. It is extended into a QRQW work-time presentation by adding at each parallel step i the additional parameter k_i, the maximum contention at this step. Given an algorithm $\mathcal{A}$ in the QRQW work-time presentation, define the *work* to be the total number of operations[6] and the *time* to be the sum over all steps of the maximum contention k_i of each step (as in the SIMD-QRQW PRAM model). We note that one of the useful features of the traditional work-time presentation is that the time evaluation is independent of the work evaluation. Perhaps somewhat surprisingly, in the QRQW work-time presentation, too, the time evaluation (which is based on the contention at each step) is independent of the work evaluation: there is no benefit or loss in having steps with high contention also have high work, as long as the total contention and work remain the same. An algorithm given in the QRQW work-time presentation can be transformed into an efficient QRQW PRAM algorithm, as follows.

THEOREM 4.1. *Assume processor allocation is free. Any algorithm in the* QRQW *work-time presentation with x operations and time t (where t is the sum of the maximum contention at each step) runs in at most $x/p + t$ time on a p-processor* QRQW PRAM.

Proof. Let the number of parallel steps in the algorithm be r. Let x_i be the number of operations in the ith parallel step, and let $k_i \geq 1$ be the maximum contention in the ith parallel step, $1 \leq i \leq r$. Hence $t = \sum_{i=1}^{r} k_i$. We map the operations in the ith step uniformly onto the p QRQW PRAM processors. Thus each QRQW PRAM processor will receive at most $n_i = \lceil x_i/p \rceil$ operations. The maximum contention at any memory location remains the same as in the original work-time algorithm, i.e., at most k_i. Hence the time cost for the ith step on a p-processor QRQW PRAM is

[6] This contrasts with the *work* in a QRQW PRAM or SIMD-QRQW algorithm, which is the processor-time product.

$\max\{n_i, k_i\}$. The overall algorithm, therefore, takes time

$$\sum_{i=1}^{r} \max\{\lceil x_i/p \rceil, k_i\} \leq \sum_{i=1}^{r} ((x_i/p) + k_i) = x/p + t. \qquad \square$$

Thus Brent's scheduling principle can indeed be extended to the QRQW work-time framework.

4.2. Automatic processor allocation. The mechanism of translating an algorithm from a work-time presentation into a PRAM description is not addressed by Theorem 4.1, which assumes processor allocation is free. If the PRAM model is extended to include a unit-time SCAN operation [6], as may be appropriate for some machines such as the CM-5, then the processor allocation issue can be resolved with only small overhead. The rest of this section deals with the standard PRAM models that do not incorporate the SCAN operation.

Traditionally, the processor allocation needed to implement Brent's scheduling principle has been devised in an ad hoc manner. However, it is known that in several common situations an efficient automatic implementation is feasible, especially on the CRCW, often using linear-compaction and load-balancing algorithms as essential tools (see [52] and references therein). In this section, we adapt these techniques to the QRQW PRAM model.

Rather than tracing the details of each technique, it would be helpful to show that in general the contention parameter on the QRQW does not change the validity of these CRCW techniques. Indeed, the fact that time evaluation and work evaluation are done independently in the QRQW work-time presentation suggests that scheduling techniques on the CRCW PRAM should be useful for the QRQW PRAM as well. Next we elaborate on this issue.

Let $\mathcal{A}$ be a class of algorithms given in the QRQW work-time presentation. A QRQW *scheduling scheme* $\mathcal{S}_\mathcal{A}$ for $\mathcal{A}$ is a scheme that maps any algorithm A in $\mathcal{A}$ into a QRQW PRAM algorithm. If algorithm A has work-time bounds of w and t, then $\mathcal{S}_\mathcal{A}$ will convert A into a p-processor QRQW PRAM algorithm for some suitable number of processors p that runs in time $\tau = t + t_\mathcal{A} + (w + w_\mathcal{A})/p$ and work $\tau \cdot p$, where $t_\mathcal{A}$ and $w_\mathcal{A}$ are the overhead in time and work for the scheduling scheme $\mathcal{S}_\mathcal{A}$. The scheduling scheme $\mathcal{S}_\mathcal{A}$ is *work preserving* if $\tau \cdot p = O(w)$.

Similar definitions hold for a scheduling scheme for a class of CRCW PRAM algorithms given in the work-time presentation.

Consider a class of algorithms $\mathcal{B}$ given in a CRCW work-time presentation, and let $\mathcal{S}_\mathcal{B}$ be a scheduling scheme that adapts each algorithm B in $\mathcal{B}$ into a CRCW PRAM algorithm B'. Let $\mathcal{A}$ be the class of algorithms in the QRQW work-time presentation corresponding to $\mathcal{B}$. That is, each algorithm A in $\mathcal{A}$ is identical to an algorithm B in $\mathcal{B}$ except that the time of each parallel step is taken to be the maximum contention of that step. Thus algorithms A and B perform the same amount of work, though the running time of algorithm A could be larger. Let $\mathcal{S}_\mathcal{A}$ be a scheduling scheme on a QRQW PRAM corresponding to the CRCW PRAM scheduling scheme $\mathcal{S}_\mathcal{B}$. That is, the scheduling scheme $\mathcal{S}_\mathcal{A}$ adapts each algorithm A in $\mathcal{A}$ into a QRQW PRAM algorithm A' which, except for the scheduling overhead, is identical in execution (but not necessarily in time complexity) to the CRCW PRAM algorithm B' derived by $\mathcal{S}_\mathcal{B}$ from the algorithm B in $\mathcal{B}$ to which algorithm A corresponds.

LEMMA 4.2. *Let $w_\mathcal{A}, t_\mathcal{A}$ and $w_\mathcal{B}, t_\mathcal{B}$ be the work-time overhead of $\mathcal{S}_\mathcal{A}$ and $\mathcal{S}_\mathcal{B}$ respectively. If $\mathcal{S}_\mathcal{B}$ is work preserving on the* CRCW PRAM *and $w_\mathcal{A} = O(w_\mathcal{B})$ then*

$\mathcal{S}_{\mathcal{A}}$ is work preserving on the QRQW PRAM. *In particular, an algorithm A in $\mathcal{A}$ with work-time bounds of w and t will run optimally on a* QRQW PRAM *in time $O(w/q)$ using q processors when $q \leq w/(t + t_{\mathcal{A}})$.*

Proof. Let A correspond to a CRCW work-time algorithm B in $\mathcal{B}$ that runs in time t' with work w'. Note that $t \geq t'$ and $w = w'$ since A corresponds to B. On a p-processor CRCW PRAM, $\mathcal{S}_{\mathcal{B}}$ maps algorithm B to run in time $t' + t_{\mathcal{B}} + (w + w_{\mathcal{B}})/p$. Thus $p \cdot (t' + t_{\mathcal{B}} + (w + w_{\mathcal{B}})/p) = O(w)$ for some value of p, since $\mathcal{S}_{\mathcal{B}}$ is work preserving. This implies that $w_{\mathcal{B}} = O(w)$, and hence $w_{\mathcal{A}} = O(w)$.

Now let $\mathcal{S}_{\mathcal{A}}$ map algorithm A into a QRQW PRAM algorithm A' with $q \leq w/(t + t_{\mathcal{A}})$ processors. Then algorithm A' will run in time $\tau = t + t_{\mathcal{A}} + (w + w_{\mathcal{A}})/q$ on the q-processor QRQW PRAM, which gives the desired work-preserving schedule since

$$q \cdot \tau = q \cdot (t + t_{\mathcal{A}}) \ + \ w \ + \ w_{\mathcal{A}} \ \leq \ w + w + O(w) = O(w). \qquad \square$$

Note that we can always transform a CRCW PRAM scheduling scheme into an *equivalent* QRQW PRAM scheduling scheme simply by viewing the overhead of the CRCW scheduling scheme in the work-time framework and interpreting it as a (possibly slower) QRQW scheduling scheme with the same work overhead. This leads to the following corollary to Lemma 4.2.

COROLLARY 4.3. *Let $\mathcal{B}$ be a class of algorithms given in a* CRCW *work-time presentation and let $\mathcal{A}$ be a class of algorithms in the* QRQW *work-time presentation corresponding to $\mathcal{B}$. Let $\mathcal{S}_{\mathcal{B}}$ be a* CRCW *scheduling scheme for $\mathcal{B}$ and let $\mathcal{S}_{\mathcal{A}}$ be the equivalent* QRQW *scheduling scheme for $\mathcal{A}$. If $\mathcal{S}_{\mathcal{B}}$ is work preserving on the* CRCW PRAM *then $\mathcal{S}_{\mathcal{A}}$ is work preserving on the* QRQW PRAM.

Corollary 4.3 shows that it is always possible to derive a work-preserving QRQW scheduling scheme for a class of QRQW work-time algorithms corresponding to a class of CRCW work-time algorithms that have a work-preserving schedule. However, such a QRQW scheduling scheme can be very slow. In particular if the algorithm for the CRCW scheduling scheme has a read or write with concurrency $\Theta(w_{\mathcal{B}})$, where $w_{\mathcal{B}}$ is the work overhead of the CRCW scheduling scheme, then the work-preserving QRQW scheduling scheme degenerates into a sequential algorithm. A more useful way to apply Lemma 4.2 is to substitute a fast work-preserving QRQW PRAM algorithm for the QRQW scheduling scheme in place of the CRCW scheduling scheme.

In what follows, we give three examples of general classes of algorithms for which automatic processor allocation techniques can be applied to advantage: geometric-decaying algorithms, general task-decaying algorithms, and spawning algorithms. Processor allocation is done by a scheduling scheme that uses an algorithm for *linear (approximate) compaction*. The *linear-compaction* problem generalizes the 2-compaction problem as follows. Given k nonempty cells at unknown positions in an array of size n, with k known, move the contents of the nonempty cells to an output array of $O(k)$ cells. The linear-compaction problem can be solved by a randomized CRCW PRAM algorithm in time $T'_{lc}(n) = O(\log^* n)$ time and linear work w.h.p. [33]. In section 7 (Theorem 7.4) we show that the linear-compaction problem can be solved by a randomized SIMD-QRQW PRAM algorithm in time $T_{lc}(n) = O(\sqrt{\log n})$ and linear work w.h.p.

Sometimes the linear-compaction algorithm is used under the assumption that the number of nonempty cells is at most k. An unsuccessful termination of the algorithm is used to determine that the input consists of more than k nonempty cells. To make such a determination possible, it is necessary to employ an algorithm for computing the OR function, as well as an algorithm for the broadcasting problem. Furthermore,

recall that a subtle property of the QRQW models is that unsuccessful steps may turn out to be overly expensive if they incur (unexpected) high contention. (This is a rather significant technical issue in the algorithms of section 6.) We assume here that the number of nonempty cells never exceeds αk for some constant $\alpha > 0$, where k is the estimated upper bound. In such cases, the running time of the linear-compaction algorithm of Theorem 7.4 will increase by at most a constant factor. Let $T_{lcd}(n)$ be the running time of a linear-compaction algorithm followed by a determination of whether the algorithm was successful or not on an n-processor QRQW PRAM, and let $T''_{lcd}(n)$ be the corresponding running time on a CRQW PRAM.

In section 8 we show that on the QRQW PRAM broadcasting requires $\Omega(\log n)$ expected time. Therefore when it is necessary to determine if a run of linear compaction was unsuccessful on the QRQW PRAM, it is best to use a $\Theta(\log n)$ time EREW PRAM algorithm for prefix sums [42]. Hence, $T_{lcd}(n) = \Theta(\log n)$. Performing a broadcast on the SIMD-CRQW PRAM is trivial in constant time. In section 6 (Theorem 6.5) we show that the OR problem can be solved by a SIMD-CRQW PRAM in time $O(\log n/\log\log n)$ and linear work w.h.p. Hence, $T''_{lcd}(n) = O(\log n/\log\log n)$ w.h.p.

Task-decaying algorithms. A *task-decaying* algorithm (or simply a *decaying* algorithm) is one that starts with a collection of unit tasks. Each of these tasks progresses for a certain number of steps of the algorithm, and then dies. A task is said to be a *live* task until it dies. No other tasks are created during the course of the algorithm. The *work load* w_i is the number of live tasks at step i of the algorithm.

Geometric-decaying algorithms. A decaying algorithm in either the QRQW or the CRCW work-time presentation is *geometric-decaying* if the sequence of work loads $\{w_i\}$ is upper bounded by a decreasing geometric series. Typically the work w of such algorithms is $O(n)$, where n is the problem size.

Let $\mathcal{A}$ and $\mathcal{B}$ be the class of geometric-decaying algorithms in the QRQW and CRCW work-time presentations respectively. Using techniques from [31, 32, 53] and Lemma 4.2 we have the following theorem.

THEOREM 4.4. *Let A be a geometric-decaying algorithm in a* QRQW *work-time presentation with time t and work n. Then Algorithm A can be implemented on a p-processor* QRQW PRAM *to run in time $O(n/p)$ when $p = O(n/(t + T_{lc}(n)\log(T_{lc}(n))))$.*

Proof. Let B be a geometric-decaying algorithm in the CRCW work-time presentation to which Algorithm A corresponds. A work-preserving scheduling scheme $\mathcal{S}_{\mathcal{B}}$ that can adapt Algorithm B into a p-processor CRCW PRAM algorithm B' is given in [53]. The scheduling scheme $\mathcal{S}_{\mathcal{B}}$ consists of $\log(n/p)$ applications of an algorithm for a linear-compaction problem of size p. On the QRQW PRAM we will use a scheduling scheme $\mathcal{S}_{\mathcal{A}}$ corresponding to $\mathcal{S}_{\mathcal{B}}$. When mapping into a p-processor QRQW PRAM, scheduling scheme $\mathcal{S}_{\mathcal{A}}$ will consist of $\log(n/p)$ applications of a QRQW PRAM algorithm for the linear-compaction problem of size p. The time overhead incurred by scheduling scheme $\mathcal{S}_{\mathcal{A}}$ is $t_{\mathcal{A}} = O(T_{lc}(p)\log(n/p))$, and the work overhead is $p \cdot t_{\mathcal{A}}$. We observe, as in [53], that if $T_{lc}(p)\log(n/p) \geq n/p$, then $\log(n/p) = O(\log(T_{lc}(n)))$, and hence for $p \leq n/(T_{lc}(p)\log(T_{lc}(n)))$, scheduling scheme $\mathcal{S}_{\mathcal{A}}$ has a work overhead of $O(n)$. Therefore, by Lemma 4.2, $\mathcal{S}_{\mathcal{A}}$ maps algorithm A into a p-processor QRQW PRAM algorithm A' to run in time $O(n/p)$ provided $p = O(n/(t + T_{lc}(p)\log(T_{lc}(n))))$. □

By Theorem 4.4 and the result for linear-compaction shown in section 7 (i.e., Theorem 7.4) we obtain the following corollary.

COROLLARY 4.5. *Algorithm A in* Theorem 4.4 *can be implemented on a p-processor* QRQW PRAM *to run in time $O(n/p)$ w.h.p. when $p = O(n/(t+\sqrt{\log n}\log\log n))$.*

General task-decaying algorithms. Recall that in a task-decaying algorithm

in either the QRQW or the CRCW work-time presentation, the sequence of work loads $\{w_i\}$ is a monotonically nonincreasing series. Thus, task-decaying algorithms generalize geometric-decaying algorithms. A task-decaying algorithm is *predicted* if an approximate bound on the sequence of work loads $\{w_i\}$ is known in advance; specifically, if a sequence $\{w'_i\}$ is given such that for all i, $w'_i \geq w_i$ and $\sum_i w'_i = O(\sum_i w_i)$. Let $\mathcal{A}$ and $\mathcal{B}$ be the class of general task-decaying algorithms in the QRQW and CRCW work-time presentations respectively.

THEOREM 4.6. *Let A be a task-decaying algorithm in a* QRQW *work-time presentation with time t and work n. Then Algorithm A can be implemented to run in time $O(n/p)$ on a p-processor* QRQW PRAM *when $p = O(n/(t + T_{lcd}(n)\log(T_{lcd}(n))))$ and on a p-processor* CRQW PRAM *when $p = O(n/(t + T''_{lcd}(n)\log(T''_{lcd}(n))))$. If Algorithm A is also predicted then it can be implemented on a p-processor* QRQW PRAM *to run in time $O(n/p)$ when $p = O(n/(t + T_{lc}(n)\log(T_{lc}(n))))$.*

Proof. Let B be a predicted task-decaying algorithm in a CRCW work-time presentation to which Algorithm A corresponds. A work-preserving scheduling scheme $\mathcal{S}_{\mathcal{B}}$ that can adapt Algorithm B into a p-processor CRCW PRAM algorithm B' is given in [53]. The scheduling scheme $\mathcal{S}_{\mathcal{B}}$ is based on several applications of an algorithm for the linear-compaction problem of size p. The analysis in [53] is based on showing that the cost of all but $\log(n/p)$ applications of the linear-compaction algorithm can be amortized against the execution of Algorithm B, with only a constant factor overhead. Hence the time overhead of $\mathcal{S}_{\mathcal{B}}$ is $t_{\mathcal{B}} = O(T'_{lc}(n)\log(n/p))$. As for the geometric-decaying algorithm, the time overhead can be shown to be $t_{\mathcal{B}} = O(T'_{lc}(n)\log(T'_{lc}(n)))$.

Consider a scheduling scheme $\mathcal{S}_{\mathcal{A}}$, corresponding to $\mathcal{S}_{\mathcal{B}}$, which adapts Algorithm A to a p-processor QRQW PRAM algorithm A'. An amortization argument similar to the one used for $\mathcal{S}_{\mathcal{B}}$ implies that the cost of all but $\log(n/p)$ applications of the linear-compaction algorithm can be amortized against the execution of Algorithm A, with only a constant factor overhead. The time overhead of $\mathcal{S}_{\mathcal{A}}$ is therefore $t_{\mathcal{A}} = O(T_{lc}(n)\log(n/p))$, and hence $t_{\mathcal{A}} = O(T_{lc}(n)\log(T_{lc}(n)))$, and the work overhead is $p \cdot t_{\mathcal{A}}$. Hence for $p = O(n/(T_{lc}(n)\log(T_{lc}(n))))$ this schedule has a work overhead of $O(n)$. By Lemma 4.2 the scheduling scheme $\mathcal{S}_{\mathcal{A}}$ maps A into a p-processor QRQW PRAM in $O(n/p)$ time provided $p = O(n/(t + T_{lc}(n)\log(T_{lc}(n))))$.

If Algorithm B is not predicted then each application of the linear compaction algorithm must be followed by a detection of whether there was a successful termination. In such a case, the underestimation is by at most a factor of two. Similar arguments to the above imply that the corresponding algorithm A can be adapted to a QRQW PRAM algorithm with running time $O(n/p)$ provided $p \leq n/(t + T_{lcd}(n)\log(T_{lcd}(n)))$ and to a CRQW PRAM algorithm with running time $O(n/p)$ provided $p \leq n/(t + T''_{lcd}(n)\log(T''_{lcd}(n)))$ ∎

By the result stated above we have the following corollary.

COROLLARY 4.7. *Algorithm A in* Theorem 4.6 *can be implemented to run in time $O(n/p)$ w.h.p. on a p-processor* QRQW PRAM *when $p = O(n/(t + \log n \log\log n))$ and on a p-processor* CRQW PRAM *when $p = O(n/(t + \log n))$. If Algorithm A is predicted then it can be implemented on a p-processor* QRQW PRAM *to run in time $O(n/p)$ w.h.p. when $p = O(n/(t + \sqrt{\log n}\log\log n))$.*

Spawning algorithms. A *spawning* algorithm starts with a collection of unit tasks, and at each step of the algorithm, each task can

i. progress to the next step of the algorithm;

ii. progress to the next step of the algorithm *and* spawn another new task; or

iii. not progress to the next step and die.

The total number of tasks in a spawning algorithm may increase or decrease in each step. Thus, the spawning model generalizes the model for task-decaying algorithms. As in the task-decaying model, a spawning algorithm is *predicted* if an approximate bound on the sequence of work loads $\{w_i\}$ is known in advance; specifically, if a sequence $\{w'_i\}$ is given such that for all i, $w'_i \geq w_i$ and $\sum_i w'_i = O(\sum_i w_i)$.

THEOREM 4.8. *Let A be a spawning algorithm in a* QRQW *work-time presentation running in time t and work n, and let t' be the number of parallel steps in A. Then Algorithm A can be implemented to run in time $O(n/p)$ on a p-processor* QRQW PRAM *when $p = O(n/(t+t' \cdot T_{lcd}(n)))$ and on a p-processor* CRQW PRAM *when $p = O(n/(t+t' \cdot T''_{lcd}(n)))$. If Algorithm A is also predicted then it can be implemented to run in time $O(n/p)$ on a p-processor* QRQW PRAM *when $p = O(n/(t+t' \cdot T_{lc}(n)))$.*

Proof. Let B be a predicted spawning algorithm in a CRCW work-time presentation to which Algorithm A corresponds. Then the running time of Algorithm B is t'. A work-preserving scheduling scheme $\mathcal{S}_\mathcal{B}$ that can adapt Algorithm B into a p-processor CRCW PRAM algorithm B' is given in [52]. The scheduling scheme $\mathcal{S}_\mathcal{B}$ consists of applying an algorithm for a linear-compaction problem of size p a constant number of times after each parallel step. The time overhead of $\mathcal{S}_\mathcal{B}$ is therefore $O(t' \cdot T'_{lc}(n))$.

Consider a scheduling scheme $\mathcal{S}_\mathcal{A}$, corresponding to $\mathcal{S}_\mathcal{B}$, which adapts Algorithm A to a p-processor QRQW PRAM algorithm A'. The scheduling scheme $\mathcal{S}_\mathcal{A}$ consists of applying an algorithm for a linear-compaction problem of size p a constant number of times after each parallel step. The time overhead incurred by $\mathcal{S}_\mathcal{A}$ is thus $t_\mathcal{A} = O(t' \cdot T_{lc}(n))$ and the work overhead is $w_\mathcal{A} = p \cdot t_\mathcal{A}$. Hence by Lemma 4.2 algorithm A' runs in time $O(n/p)$ on a p-processor QRQW PRAM provided $p = O(n/(t+t' \cdot T_{lc}(n)))$.

If Algorithm B is not predicted then, as in the case of the task-decaying algorithm of Theorem 4.6, each application of the linear-compaction algorithm must be followed by a detection of whether there was a successful termination. Similar arguments to the above imply that the corresponding algorithm A can be adapted to a p-processor QRQW PRAM algorithm running in time $O(n/p)$ provided $p = O(n/(t+t' \cdot T_{lcd}(n)))$, and to a p-processor CRQW PRAM algorithm running in time $O(n/p)$ provided $p = O(n/(t+t' \cdot T''_{lcd}(n)))$. □

COROLLARY 4.9. *Algorithm A in* Theorem 4.8 *can be implemented to run in time $O(n/p)$ w.h.p. on a p-processor* QRQW PRAM *when $p = O(n/(t+t' \cdot \log n))$ and on a p-processor* CRQW PRAM *when $p = O(n/(t+t' \cdot \log n/\log\log n))$. If Algorithm A is predicted then it can be implemented to run in time $O(n/p)$ w.h.p. on a p-processor* QRQW PRAM *when $p = O(n/(t+t' \cdot \sqrt{\log n}))$.*

The spawning model can be further generalized to include a *start* operation in which one task may spawn n new tasks to begin in the next time step. This extended model is called V-PRAM in [35], where it was suggested. It was shown in [35] that the work-preserving scheme for the spawning model can be extended to the V-PRAM model as well, with the same overhead. Accordingly, Theorem 4.8 and Corollary 4.9 apply to the V-PRAM model.

A more general type of spawning algorithm, the *L-spawning algorithm*, is studied in [29]. In the L-spawning model, each task can spawn up to $L-1$ additional tasks at each step. It is shown in [29] that an L-spawning algorithm with time t, work n, and t' parallel steps can be implemented on a p-processor QRQW PRAM to run in time $O(n/p)$ w.h.p. when $p = O(n/(t+t'\sqrt{\log n}\log\log L + t'\log L))$. This implementation applies a more general load-balancing algorithm given in [29].

5. Realization on feasible networks. The BSP model was introduced by Valiant [61, 62] as a model of parallel computation that takes into account overheads incurred by latency, synchronization, and memory granularity. It consists of components that can perform local RAM computations and communicate with one another through a router which delivers messages between pairs of components. Messages to a component are serviced one at a time. The BSP provides facilities for synchronizing the components at regular intervals. There are three parameters to the model: p, the number of components, *periodicity* L, the number of time units between synchronizations, and *throughput* g, a measure of the bandwidth limitations of the router. A particular case studied by Valiant is one that sets g to be a constant and L to be $\Theta(\log p)$, and has each synchronization involve all the components; we denote this the *standard* BSP model.

A standard BSP computation consists of a sequence of supersteps, with each superstep separated from the next by a global synchronization point among all the components. In each superstep, each component sends messages, receives messages, and performs local RAM steps. Operations at a component (message initiations, message receipts, RAM operations) are assumed to take constant time. No assumption is made about the relative delivery times of messages within a superstep, and local operations may only use data values locally available to the component prior to the start of the superstep. If the operations in a superstep, including message deliveries, do not complete in L time units, additional intervals of L time units are allocated to the superstep until it completes.

The BSP model has been advocated as one that forms a bridge between software and hardware in parallel machines, that is, between abstract models for algorithm design and realistic parallel machines. This approach is supported in [61, 62] by providing a fast, work-preserving emulation of the standard BSP model on hypercube-type noncombining networks on the one hand, and a fast, work-preserving emulation of the EREW PRAM on the standard BSP on the other hand. In particular, it is shown that the EREW PRAM can be emulated in a work-preserving manner with logarithmic slowdown on the standard BSP, while the standard BSP can be emulated in a work-preserving manner with constant slowdown on, e.g., the multiport hypercube. In the multiport hypercube on p nodes, each node can receive a message on each of its $\log p$ incoming wires and route them along the appropriate outgoing wires in constant time, subject to the constraint that at most one message can be sent along each outgoing wire. These emulations show that the choice of $L = \Theta(\log p)$ and $g = \Theta(1)$ used in the standard BSP is sufficient to hide the latency, synchronization, and memory granularity overheads occurring in the emulations.

Valiant [61] shows that a v-processor PRAM step with contention κ can be simulated on a p-processor standard BSP in $O(v/p + \kappa \log p)$ time w.h.p. It follows readily from this result that a p-processor SIMD-QRQW PRAM algorithm running in time t can be emulated on a $(p/\log p)$-component standard BSP model in $O(t \log p)$ time w.h.p.

In this section we show that the more powerful QRQW PRAM can also be emulated in a work-preserving manner with only logarithmic slowdown on the standard BSP as well as on hypercube-type networks. The proof of this result is complicated by the fact that a QRQW step with time cost k may have up to $2kp$ reads and writes, whereas in the previous emulation results, the PRAM step being emulated had at most $2p$ reads and writes, independent of k. As in the previous emulations of PRAM models on the standard BSP given in [61], we apply a random hash function to map the shared memory of the PRAM onto the BSP components; this function is assumed to map

each shared-memory location to a component chosen uniformly and independently at random.

THEOREM 5.1. *A p-processor* QRQW PRAM *algorithm (or* SIMD-QRQW PRAM *algorithm) running in time t, where t is polynomial in p, can be emulated on a $(p/\log p)$-component standard* BSP *model in $O(t \log p)$ time w.h.p.*

Proof. As stated above we apply a hash function that maps the shared memory of the QRQW PRAM to the BSP components such that each shared-memory location is mapped on to a BSP component chosen uniformly and independently at random. We first show that for each QRQW step with time cost k, the number of memory requests mapped to any BSP component is $O(k \log p)$ w.h.p. Then we use this claim to argue that the time to emulate the step on the BSP is $O(k \log p)$ w.h.p., and hence the time to emulate all the QRQW steps is $O(t \log p)$ w.h.p.

Consider the ith step of the QRQW PRAM algorithm, with time cost k_i. For simplicity of exposition, we assume that each processor has exactly k_i shared-memory accesses, where an access is either a read or a write. Let $m_1, \ldots, m_d$ be the different memory locations accessed in this step, and let q_j be the number of accesses to location m_j, $1 \leq j \leq d$. For the purpose of this analysis we add $\delta p k_i$ memory accesses to this step, for a constant $\delta \geq 23$, consisting of accesses with contention k_i to locations $m_{d+1}, \ldots, m_{d'}$, where $d' = d + \delta p$. With this addition, the ith step has $v_i{}' = (\delta+1)pk_i$ concurrent accesses to d' different memory locations, and the maximum contention is k_i. We set $q_j = k_i$ for $d+1 \leq j \leq d'$ and note that $v' = \sum_{j=1}^{d'} q_j$. We now show that the bound stated in the theorem holds for this augmented problem. Clearly, this implies that the bound holds for the original problem.

As indicated earlier we assume that the memory has been randomly hashed onto the $p/\log p$ components of the BSP. Consider a fixed component C. As in [61], we define a random variable $x_j, 1 \leq j \leq d'$, where $x_j = q_j/k_i$ if m_j is hashed onto C and zero otherwise. Let $X = \sum_{j=1}^{d'} x_j$. We note that $x_j = q_j/k_i$ with probability $\log p/p$, and $k_i \cdot X$ is the number of messages sent to C in the ith step. Then

$$E(x_j) = q_j \log p/(pk_i), \quad 1 \leq j \leq d' \ .$$

Let μ be the mean of the expectations of the x_j:

$$\mu = \sum_{j=1}^{d'} (q_j \log p)/(pk_i d') = v_i{}' \log p/(pk_i d') = (\delta+1)pk_i \log p/(pk_i d') \ .$$

So $\mu = (\delta+1)\log p/d'$. By Hoeffding's inequality [37],

$$Pr(X > (\mu + z)d') \leq e^{-z^2 d'/3\mu} \ ,$$

provided $z < \min(\mu, 1-\mu)$. Let $z = \mu/2$. Then

$$Pr\ (X > 3\mu d'/2) \leq e^{-\mu d'/12} = e^{-(\delta+1)\log p/12} = 1/p^{\Theta(\delta)} \ .$$

Let $t = O(p^r)$, and let $c > 0$ be an arbitrary constant. By choosing δ sufficiently large, we have that the probability that any component receives more than $3\mu d' k_i/2 = \Theta(k_i \log p)$ messages in the ith QRQW step is less than $1/p^{r+c}$.

Each BSP component emulates $\log p$ QRQW PRAM processors. It sends $O(k_i \log p)$ "read" messages and receives $O(k_i \log p)$ (w.h.p.) such messages. In the next superstep, it sends $O(k_i \log p)$ (w.h.p.) "read reply" messages and receives $O(k_i \log p)$ such

replies. Finally, in the last superstep, it performs $O(k_i \log p)$ local RAM operations, sends $O(k_i \log p)$ "write" messages, and receives $O(k_i \log p)$ (w.h.p.) such messages, updating the values of the appropriate locations. Since the periodicity L is $\Theta(\log p)$ and the gap g is constant, the time taken to complete the ith step on the BSP is $O(k_i \log p)$ w.h.p.

Thus, with probability greater than $(1 - 1/p^c)$ the BSP completes the emulation of the $O(t)$ time augmented QRQW computation in $O(\sum_{i=1}^{m} k_i \log p)$ time, where m is the number of steps in the QRQW computation, i.e., the BSP completes the emulation in $O(t \log p)$ time w.h.p. □

Note that unlike Valiant's emulation of the EREW PRAM on the standard BSP, the emulation above may result in a rather uneven distribution of messages among the components whenever there is an uneven distribution of contention among the locations. This raises concerns regarding possible contention in routing the messages between the components. However, the (standard) BSP model ignores all issues of routing other than the number of messages sent and received at each component, and hence the proof of Theorem 5.1 addresses only these same routing issues.

Further issues in routing do arise in emulating the PRAM or BSP on models such as the multiport hypercube. Valiant defines the *slackness* of a parallel algorithm being emulated to be the ratio of the number of virtual processors in the algorithm to the number of "physical" processors in the emulating model. In [61], Valiant showed that a p-component standard BSP algorithm with slackness at least $\log p$ and running in time t can be emulated on a p-node multiport hypercube in $O(t)$ time w.h.p. Since the slackness in the emulation in Theorem 5.1 is $\log p$, we have the following theorem.

THEOREM 5.2. *A p-processor* QRQW PRAM *algorithm (or* SIMD-QRQW PRAM *algorithm) running in time t can be emulated on a $(p/\log p)$-node multiport hypercube in $O(t \log p)$ time w.h.p.*

Thus the uneven distribution of messages that may result from emulating a QRQW PRAM algorithm on the standard BSP does not prevent a fast, work-preserving emulation of the QRQW PRAM on the multiport hypercube.

6. Leader election and computing the OR. Given a Boolean array of n bits, the OR function is the problem of determining if there is a bit with value 1 among the n input bits. The *leader election* problem is the problem of electing a leader bit from among the k out of n bits that are 1 (k unknown). The output is the index in $[1..n]$ of the bit if $k > 0$, or 0 if $k = 0$. This generalizes the OR function, as long as $k = 0$ is possible.

In this section we present several randomized and deterministic algorithms for solving these problems on queue-write PRAMs. Our main result is a randomized algorithm for the two problems on the CRQW PRAM that performs linear work and runs in $O(\log n/\log\log n)$ time w.h.p. This result is somewhat surprising since it improves on the best possible time bound (which is $\Theta(\log n)$) for any deterministic or randomized CREW PRAM algorithm for the two problems.

Most of the randomized algorithms we present are of the Las Vegas type, while a few are of the Monte Carlo type. A *Las Vegas* algorithm is a randomized algorithm that always outputs a correct answer and obtains the stated bounds with some stated probability. A *Monte Carlo* algorithm, in contrast, is a randomized algorithm that outputs a correct answer with some stated probability. In the analysis of some of our randomized algorithms, we apply the Chernoff bound

$$Pr\{X \geq \beta E[X]\} \leq e^{(1-1/\beta-\ln\beta)\beta E[X]} \quad \text{for all } \beta > 1 \ ,$$

and in particular, its following corollary.

OBSERVATION 6.1. *Let X be a binomial random variable. For all $f = O(\log n)$, if $E[X] \leq 1/2^f$, then $X = O(\log n/f)$ w.h.p. Furthermore, if $E[X] \leq 1$, then $X = O(\log n/\log\log n)$ w.h.p.*

Proof. Let $\beta = c\log n/(fE[X])$ for a constant $c > \max\{2, f/\log n\}$ to be determined. Then $\beta > 1/E[X] \geq 2^f$, since $\beta E[X] = c\log n/f > 1$. By the Chernoff bound,

$$\begin{aligned} Pr\{X \geq c\log n/f\} &\leq e^{(1-1/\beta-\ln\beta)\cdot(c/f)\log n} < e^{-(c/2f)\ln\beta\log n} \\ &= e^{-(c/2f)\log\beta\cdot\ln n} = 1/n^{(c/2f)\log\beta} < 1/n^{c/2} \ . \end{aligned}$$

Hence for any $\delta > 1$, there exists a constant $c = \max\{2\delta, f/\log n\}$ such that $Pr\{X \geq c\log n/f\} < 1/n^\delta$.

If $E[X] \leq 1$, we take $\beta = c\log n/(\log\log nE[X])$, for a constant $c > 2$ to be determined. Then $\log\beta \geq \log\log n - \log\log\log n \geq 2\log\log n/3$. By the Chernoff bound,

$$\begin{aligned} Pr\{X \geq c\log n/\log\log n\} &\leq e^{(1-1/\beta-\ln\beta)\cdot(c/\log\log n)\log n} < e^{-(c/2\log\log n)\ln\beta\log n} \\ &= e^{-(c/2\log\log n)\log\beta\cdot\ln n} = 1/n^{(c/2\log\log n)\log\beta} \\ &\leq 1/n^{c/3} \ . \end{aligned}$$

Hence for any $\delta > 1$, there exists a constant $c = 3\delta$ such that $Pr\{X \geq c\log n/\log\log n\} < 1/n^\delta$. □

6.1. Deterministic algorithms. By having each processor whose input bit is 1 write the index of the bit in the output memory cell, we obtain a simple deterministic SIMD-ERQW PRAM algorithm for leader election (and similarly for the OR function) that runs in $\max\{1, k\}$ time using n processors, where k is the number of input bits that are 1 (k unknown). This is a fast algorithm if we know in advance that the value of k is small. However, for the general leader election problem, a better algorithm is the natural EREW PRAM algorithm for leader election which uses a parallel prefix algorithm to compute the location of the first 1 in the input; this takes $\Theta(\log n)$ time and $\Theta(n)$ work.

We can derive an $\Omega(\log n/\log\log n)$ lower bound for the OR function using a lower bound result of Dietzfelbinger, Kutylowski, and Reischuk [17] for the *few-write* PRAM. Recall that the few-write PRAM models are parameterized by the number of concurrent writes to a location permitted in a unit-time step. (Exceeding this number is not permitted.) Let the *κ-write* PRAM denote the few-write PRAM model that permits concurrent writing of up to κ writes to a location, as well as unlimited concurrent reading. We begin by proving a more general result for emulating the CRQW on the few-write PRAM, and then provide the OR lower bound.

OBSERVATION 6.2. *A p-processor* CRQW PRAM *deterministic algorithm running in time t can be emulated on a p-processor t-write* PRAM *in time $O(t)$.*

Proof. Since the CRQW algorithm runs in time at most t on all inputs, then the maximum write contention is at most t on all inputs. Hence the t-write PRAM can be used to emulate each write substep, and the emulation proceeds as was done for the CRCW (Observation 2.2). □

THEOREM 6.1. *Any deterministic algorithm for computing the* OR *function on a* CRQW PRAM *with arbitrarily many processors requires $\Omega(\log n/\log\log n)$ time.*

Proof. Dietzfelbinger, Kutylowski, and Reischuk [17] proved an $\Omega(\log n/\log\kappa)$ lower bound for the OR function on the κ-write PRAM. Let T be the time for the

OR function on the CRQW PRAM. Then by Observation 6.2, the OR function can be computed on the T-write PRAM in $O(T)$ time. Thus $T = \Omega(\log n / \log T)$, and hence $T \log T = \Omega(\log n)$. Now if $T = o(\log n / \log\log n)$, then $\log T = o(\log\log n)$, contradicting $T \log T = \Omega(\log n)$. Thus $T = \Omega(\log n / \log\log n)$. □

Since the ERCW PRAM can compute the OR function in constant time, Theorem 6.1 implies the following separation result.

COROLLARY 6.2. *There is an $\Omega(\log n / \log\log n)$ time separation of a deterministic* {ER,QR,CR}CW PRAM *from a deterministic* {ER,QR,CR}QW PRAM.

Cook, Dwork, and Reischuk [12] proved that any deterministic algorithm for computing the OR function on a CREW PRAM with arbitrarily many processors requires $\Omega(\log n)$ time. Dietzfelbinger, Kutylowski, and Reischuk [17] later proved a similar lower bound for randomized CREW PRAM algorithms. The difficulty in extending either of these results to the CRQW PRAM is that in the CRQW PRAM, the running time of a step may be different on different inputs. Thus in a CRQW write step with contention k for a given input I, the lower bound argument of [12, 17] will allow processors to gain knowledge about input I as a function of the maximum contention, K, for the step over *all* inputs, and K could be much larger than k.

6.2. Randomized algorithms for special cases. In this subsection, we present a series of randomized leader election algorithms, under various scenarios. First, consider the leader election problem when the value of k is known. On the SIMD-QRQW PRAM, a simple, fast, randomized algorithm for this problem is to have the k processors whose input bits are 1 write to the output cell with probability $1/k$. This runs in constant time on the SIMD-QRQW, and, as a low-contention algorithm, will run fast in practice. The failure probability can be reduced by repeating the algorithm.

OBSERVATION 6.3. *Consider the problem of electing a leader bit from among the k out of n bits that are 1, where k is known. There is a (randomized) Monte Carlo* SIMD-ERQW PRAM *algorithm that runs in $O(1)$ expected time and $O(n)$ expected work, and probability of failure less than $1/e$. There is a (randomized) Las Vegas* SIMD-CRQW PRAM *algorithm that runs in $O(1)$ expected time and $O(n)$ expected work.*

Proof. The index of each bit whose value is 1 is written into the output cell with probability $1/k$. This has constant expected contention, and the probability that no value is written is $(1-1/k)^k < 1/e$. To obtain a Las Vegas algorithm, the write step is repeated until there is at least one writer. Termination is detected by using the concurrent-read capability. The expected time is $O(1+1/e+1/e^2+1/e^3+\cdots)$, which is $O(1)$. □

The expected time for this algorithm is constant; however, we are interested in high-probability results. The next two theorems deal with high-probability randomized algorithms for the case when a good estimate for k is known, and the case when a good upper bound for the value of k is known.

Given a good estimate for *k*. In the following, we describe a fast leader election algorithm when the number of bits competing for leadership is known to within a multiplicative factor of $2^{\sqrt{\log n}}$.

THEOREM 6.3. *Consider the problem of electing a leader bit from among the k out of n bits that are 1. Let $\hat{k}$ be known to be within a factor of $2^{\sqrt{\log n}}$ of k, i.e., $\hat{k}/2^{\sqrt{\log n}} \le k \le \hat{k}2^{\sqrt{\log n}}$. There is a Monte Carlo* SIMD-ERQW PRAM *algorithm that, w.h.p., elects a leader in $O(\sqrt{\log n})$ time with $O(n)$ work. On the* SIMD-CRQW PRAM, *or if $\hat{k} \le 2^{\sqrt{\log n}}$, the same bounds can be obtained for a Las Vegas algorithm.*

Proof. We describe the algorithm for $n/\sqrt{\log n}$ processors. Let $p = \min(1, \frac{2^{c\sqrt{\log n}}}{\hat{k}})$,

for a constant $c \geq 1$ to be determined by the analysis. Let A be an array of size $m = 2^{(c+2)\sqrt{\log n}}$, initialized to all zeros. The input bits are partitioned among the processors such that each processor is assigned $\sqrt{\log n}$ bits.

Step 1. Each processor selects a leader from among its input bits that are 1, if any.

Step 2. Each processor with a leader writes, with probability p, the index of the leader bit to a cell of A selected uniformly at random.

Step 3. m of the processors participate to select a nonzero index from among those written to A.

If $\hat{k} \leq 2^{\sqrt{\log n}}$, then $p = 1$ and this is a Las Vegas algorithm. Otherwise a Las Vegas algorithm is obtained by repeating steps 2 and 3 until there is a nonzero index in A. Termination is detected by using the concurrent-read capability.

Step 1 takes $O(\sqrt{\log n})$ time. Since $m = 2^{O(\sqrt{\log n})}$, an EREW binary fanin approach can be used to obtain the same time bounds for step 3. For step 2, we will show that the contention is $O(\sqrt{\log n})$ w.h.p. Let X_i be the number of writers to cell i of A. Then

$$E[X_i] \leq kp/m \leq k2^{c\sqrt{\log n}}/\hat{k}m \leq k/\hat{k}2^{2\sqrt{\log n}} \leq 1/2^{\sqrt{\log n}} \ .$$

It follows from Observation 6.1 that the maximum contention over all cells of A is $O(\sqrt{\log n})$ w.h.p.

It remains to show that w.h.p., there is at least one writer to A (assuming that $k > 0$). If $\hat{k} \leq 2^{c\sqrt{\log n}}$, then $p = 1$ and hence there will be one writer to A for each processor that has an input bit that is 1. Otherwise $\hat{k} > 2^{c\sqrt{\log n}}$, and the probability that there are no writers to A is at most

$$\begin{aligned}(1-p)^{k/\sqrt{\log n}} &= ((1-1/(1/p))^{1/p})^{pk/\sqrt{\log n}} < (1/e)^{pk/\sqrt{\log n}}, \\ &= (1/e)^{(k/\hat{k})2^{c\sqrt{\log n}}/\sqrt{\log n}} \leq (1/e)^{2^{(c-1)\sqrt{\log n}}/\sqrt{\log n}}.\end{aligned}$$

It follows that c can be chosen so that there is at least one writer w.h.p. □

Given an upper bound on k. We next consider the case where we only have an upper bound, k_{max}, on the number of input bits that are 1; the results we obtain are not quite as good as when k is known to within a factor of $2^{\sqrt{\log n}}$, but better than the case when no bound on k (other than n) is known. The algorithm is a straightforward modification of the previous algorithm (Theorem 6.3).

THEOREM 6.4. *Consider the problem of electing a leader bit from among k out of n bits that are* 1*, given an upper bound, k_{max}, on k. There is a Las Vegas* SIMD-EROW PRAM *algorithm that runs in $O(\log k_{\max} + \sqrt{\log n})$ time with $O(n)$ work w.h.p.*

Proof. We describe the algorithm for $n/(\log k_{\max} + \sqrt{\log n})$ processors. The input bits are partitioned among the processors such that each processor is assigned $\log k_{max} + \sqrt{\log n}$ bits. If $k_{max} = \Omega(n^{\epsilon})$ for some constant $0 < \epsilon \leq 1$, apply the EREW parallel prefix algorithm, as mentioned in section 6.1, to obtain the stated bounds. Otherwise, let A be an array of size $m = k_{max} \cdot 2^{\sqrt{\log n}}$, initialized to all zeros (note that $m = O(n)$). Each processor selects a leader from among its input bits that are 1, if any. Then each processor with a leader writes to a cell of A selected uniformly at random. Finally, m of the processors participate to select a nonzero index from among those written to A. The first and third steps take $O(\log k_{max} + \sqrt{\log n})$ time. In the second step, the expected contention to a cell i in A is at most $1/2^{\sqrt{\log n}}$. It follows from Observation 6.1 that the maximum contention over all cells of A is $O(\sqrt{\log n})$ w.h.p. □

6.3. A general randomized algorithm. It is shown in [17] that the OR function on n bits requires $\Omega(\log n)$ time on a randomized CREW PRAM. (This lower bound is for randomized algorithms that have zero probability of a concurrent write, and correctly compute the OR with probability bounded away from 1/2.) In contrast to this lower bound, we show in this subsection that a randomized SIMD-CRQW PRAM can compute the OR function on n bits in $O(\log n/\log\log n)$ time and linear work w.h.p.

THEOREM 6.5. *There is a Las Vegas* SIMD-CRQW PRAM *algorithm for the leader election problem (and the* OR *function) that runs in* $O(\log n/\log\log n)$ *time and linear work w.h.p.*

Proof. We first show the time bound using $n\log\log n$ processors. We describe the algorithm for the OR function, which can be trivially modified to solve the leader election problem. Since the number, k, of contending 1-bits is unknown, we will search for the true value of k. We take larger and larger samples until we either find a sample that contains at least one input bit that is 1, or learn that all input bits are 0. We must ensure that w.h.p. there will be at least one writer (with a 1) prior to the iteration in which there are too many writers (i.e., the iteration where the contention would *not* be $O(\log n/\log\log n)$). The new algorithmic result below is a technique for amplifying probabilities on the SIMD-QRQW model so that this occurs.

1. Let $s = c\log n/\log\log n$, with $c \geq 1$ a constant determined by the analysis. Let A be an array of $s^2\log\log n$ memory cells, A' be an array of $s\log\log n$ memory cells, and A'' be an array of $\log\log n$ memory cells, each initialized to all zeros. The output is to be written in memory cell x. We assign $\log\log n$ processors to each input bit. Each processor reads its input bit. Let $p = s^2/n$.
2. Each processor with input bit 1 is active with probability p. Each such active processor writes its index to some cell i of A chosen uniformly at random, and then reads that cell. If the cell contains its index (i.e., no other processor overwrote it), then it writes its index to cell i' of A', $i' = i \bmod s\log\log n$, and then reads that cell. If the cell contains its index, then it writes its index to cell i'' of A'', $i'' = i' \bmod \log\log n$, and then reads that cell. If the cell contains its index, then it writes a 1 into memory cell x.
3. Each processor reads x. If $x = 0$, repeat steps 2 and 3 with $p = ps$. If $p \geq 1$, repeat one last time with $p = 1$ and then stop.

Note that x is set to 1 only if there is a processor with a 1. Conversely, each processor whose input bit is 1 either writes a 1 into x, writes its index in a cell of A in the iteration that x is set to 1, or stops when $x = 1$; hence the algorithm always outputs the correct answer. There are $O(\log n/\log s)$ iterations. If no processor writes to A in an iteration, then the iteration takes $O(1)$ time. Otherwise there is one last iteration in which writes to A, A', A'', and x occur.

We now analyze the contention of these last four write steps. Let p_j be the probability used at iteration j; i.e., $p_j = s^{j+1}/n$. Let k be the number of (original) input bits that are 1. Since we have a write step, $1 \leq k \leq n$. Let $t \geq 0$ be an integer such that $n/s^t \geq k > n/s^{t+1}$. Consider iteration $t+1$ if it occurs. The probability that no processor writes is at most

$$\begin{aligned}(1-p_{t+1})^{k\log\log n} &< (1/e)^{p_{t+1}k\log\log n}\\ &= (1/e)^{ks^{t+2}\log\log n/n}\\ &< (1/e)^{s\log\log n} < (1/e)^{c\log n}\\ &= (1/e)^{c'\cdot\ln n} = 1/n^{c'}\end{aligned}$$

for some constant c'. Hence, if $k > 0$, there will be no iteration $t+2$ w.h.p.

Let W be the number of active processors at iteration $t+1$, if it occurs. Then

$$E[W] = p_{t+1}k \log\log n = s^{t+2}k \log\log n/n.$$

By the choice of t, $s \geq s^{t+1}k/n > 1$, and hence $s^2 \log\log n \geq E[W] > s \log\log n$. Let X_i be the number of writers to cell i of A in iteration $t+1$. Then

$$E[X_i] = E[W]/s^2 \log\log n \leq 1.$$

By Observation 6.1, and since there are $s^2 \log\log n = o(n)$ cells, the maximum contention for this write is $O(\log n/\log\log n)$ w.h.p.

This bounds as well the contention of any iteration less than $t+1$ in which a write to A occurs (and hence is the last iteration). Since there is at most one winner from each cell of A and exactly s cells of A that map to one cell of A', the maximum contention to a cell of A' is s. Likewise, the maximum contention to a cell of A'' is s and the maximum contention to cell x is $\log\log n$.

It follows that the overall running time is $O(\log n/\log\log n)$ w.h.p.

Finally, in order to make the algorithm work optimal, we should achieve the same time bound using only $n \cdot \log\log n/\log n$ processors. For this we use an initial computation phase in which we reduce the size of the input from n to $n/\log n$. For this we divide the processors into $n/\log n$ groups of $\log\log n$ processors, and assign to each group the simple task of finding the OR of a block of $\log n$ input bits in $O(\log n/\log\log n)$ time. We then apply the algorithm described above to the reduced array of $n/\log n$ bits. This gives us the desired work-optimal randomized algorithm for the OR function on n bits in $O(\log n/\log\log n)$ time w.h.p. □

We note that the only large concurrent read in the previous algorithm is the reading of x in step 3 of the algorithm.

COROLLARY 6.6. *There is an* $\Omega(\log\log n)$ *time separation of a randomized* SIMD-CRQW-PRAM *from a randomized* CREW PRAM.

7. Linear compaction. Consider an array of size n with k nonempty cells, with k known, but the positions of the k nonempty cells not known. The *k-compaction* problem is to move the contents of the nonempty cells to the first k locations of the array. The *linear-compaction* problem is to move the contents of the nonempty cells to an output array of $O(k)$ cells. The best known EREW PRAM algorithms for both problems take $\Theta(\log n)$ time, using parallel prefix sums [42]. Even for the case $k = 2$, there is a randomized $\Omega(\sqrt{\log n})$ expected-time lower bound for the EREW PRAM ([49], following [20]), and a deterministic lower bound of $\Omega(\log\log n)$ for an n-processor CREW PRAM [20].

The simple deterministic SIMD-ERQW PRAM algorithm for leader election discussed in section 6.1 can be trivially extended to the k-compaction problem as follows.

OBSERVATION 7.1. *There is a deterministic* SIMD-ERQW PRAM *algorithm for the k-compaction problem that runs in $O(k^2)$ time with $O(n)$ work.*

Proof. The input is partitioned into subarrays of k^2 cells. Each of the n/k^2 processors reads the cells in its subarray and creates a linked list of the items in its nonempty cells. Since there are only k nonempty cells, no processor can have more than k items in its linked list. The algorithm proceeds in k rounds, in which processors attempt to place each item on their list. At round i, each processor with an unplaced item writes its index to cell i of the array. A designated processor then reads the cell, and if the index found is j, it signals processor j (by writing to a cell designated for

j), which then transfers the contents of its current item to the cell and continues to the next round with its next unplaced item (if any). All other processors continue with the same item as before. The contention in round i is at most $k - i + 1$, so the algorithm runs in $O(k^2)$ time. □

By taking $k = 2$, and recalling the lower bounds mentioned earlier for the EREW and CREW PRAM, we obtain the following two results, which are cited in Table 1 and Table 2 in section 2.

COROLLARY 7.1. *There is an $\Omega(\sqrt{\log n})$ time separation of a (deterministic or randomized)* SIMD-ERQW PRAM *from a (deterministic or randomized)* EREW PRAM.

COROLLARY 7.2. *There is a separation of $\Omega(\log \log n)$ time with n processors of a deterministic* {QR,SIMD-QR,SIMD-CR}QW PRAM *from a deterministic* {QR,SIMD-QR,CR}EW PRAM.

In the remainder of this section, we develop a SIMD-QRQW PRAM algorithm for the linear-compaction problem that runs in $O(\sqrt{\log n})$ time with linear work w.h.p. Within our algorithm, we will employ the following well-known technique for k-compaction, which runs in $O(\log n)$ time using only k processors on an EREW PRAM.

OBSERVATION 7.2. *The k-compaction problem with one processor assigned to each nonempty cell can be solved by an* EREW PRAM *algorithm in $O(\log n)$ time.*

Proof. View the n elements as leaves of a full binary tree. At the ith step we work at level i above the leaves, and inductively, for each node v at this level, we have the solution (in the form of a linked list) for the leaves in the subtrees rooted at the two children of v. To combine these solutions at v we need only to make the last distinguished element in the subtree of the left child of v as the successor of the first distinguished element in the right subtree of v. This can be performed by a constant-time EREW computation. Finally we perform list ranking on the linked list of distinguished elements (using Wyllie's pointer-jumping approach [40]) and transfer the elements to their location in the output array.

Note that the input array need not be initialized: since we have an active processor for each distinguished element, we can detect distinguished elements by a *change* in the value of a memory cell. □

To prove our SIMD-QRQW PRAM result, we start by proving the following lemma, which shows how to achieve the desired time bound. However, the algorithm performs superlinear work when k is large. We then show how to use this lemma to obtain a linear work algorithm with the same time bound.

LEMMA 7.3. *There is a Las Vegas* SIMD-QRQW PRAM *algorithm for linear compaction that runs in $O(\sqrt{\log n})$ time w.h.p. if $\sqrt{\log n}$ processors are assigned to each nonempty cell.*

Proof. Let an *item* denote a nonempty input cell. Let $r = \sqrt{\log n}$, the number of processors assigned to each item. Let A be an auxiliary array of size $m = c_1 r k 2^{c_2\sqrt{\log n}}$ for constants $c_1 \geq 2$, $c_2 \geq 1$ determined by the analysis. View the array A as partitioned into $k/\log n$ subarrays of size $m' = c_1 r 2^{c_2\sqrt{\log n}} \log n$.

1. For each item, select a subarray of A uniformly at random. Each processor assigned to the item selects a cell in that subarray uniformly at random and tries to claim that cell.
2. At this point, between zero and r cells of A have been claimed on behalf of each item. Denote an item *successful* if at least one cell of A has been claimed on its behalf. For each successful item, select one of its cells in A, and mark the rest as unclaimed.
3. In parallel for all subarrays, compact the claimed cells within each subarray

using Observation 7.2. We compact within subarrays here since, for large k, compacting all of A is too slow.

4. View the output array as partitioned into $k/\log n$ subarrays of size $c_1 \log n$. For each j, if there are n_j unclaimed cells in subarray j of the output, then the contents of (up to) n_j claimed cells in subarray j of A are transferred to output subarray j. (In the first pass of the algorithm, $n_j = c_1 \log n$, but in any subsequent pass, n_j may be smaller.) If there are more than n_j claimed cells in a subarray j, then for $i > n_j$, the item associated with the ith claimed cell in subarray j of A is denoted unsuccessful.
5. For each unsuccessful item, each of its r processors returns to step 1.

Since the processors assigned to an item repeat the algorithm until at least one of them has successfully claimed an output cell, this is a Las Vegas algorithm. (Note that processors may complete their participation in the algorithm at different times, not knowing when all processors have terminated.) Let X_j be the number of items selecting subarray j of A in step 1. Then $E[X_j] = k/\lceil k/\log n \rceil \leq \log n$. By Chernoff bounds, for $c_1 \geq 2$ defined above,

$$Pr\{X_j \geq c_1 \log n\} \leq e^{(1-1/c_1-\ln\ c_1)c_1 \log n} < e/c_1^{c_1 \log n} < 1/n^{c_1}.$$

After step 2, there is at most one claimed cell for each item, so w.h.p., there are at most $c_1 \log n$ claimed cells in a subarray. A processor tries to claim a cell in step 1 by first writing its index to the cell, then reading the cell: if it reads its index, it has claimed the cell, and it writes the contents of its input cell to the claimed cell. For each subarray j, let $Y_{j,i}$ be the number of processors selecting cell i of subarray j of A in step 1. Then $E[Y_{j,i}] \leq r \cdot c_1 \log n/m' \leq 1/2^{c_2\sqrt{\log n}}$. It follows from Observation 6.1 that the time for step 1 is $O(\sqrt{\log n})$ w.h.p.

Step 2 can be done in $O(\log r)$ time. Step 3 applies Observation 7.2, and runs in $O(\log m')$ time, which is $O(\sqrt{\log n})$ time. For step 4, for each j, the current value of n_j, as well as the index of the first unclaimed output cell in subarray j, can be broadcast in $O(\log \log n)$ time; the transferring takes constant time.

As for step 5, there are two types of unsuccessful items. As argued above, w.h.p., there are at most $c_1 \log n$ claimed cells in a subarray. It follows that the probability that an item is unsuccessful in step 1 is less than $(r \cdot c_1 \log n/m')^r = (1/2^{c_2\sqrt{\log n}})^{\sqrt{\log n}} < 1/n^{c_2}$. Moreover, it follows that, w.h.p., no cells are marked unsuccessful in step 4. So w.h.p., all cells are successful in the first pass of the algorithm. □

THEOREM 7.4. *There is a Las Vegas* SIMD-QRQW PRAM *algorithm for linear compaction that runs in $O(\sqrt{\log n})$ time with $O(n)$ work w.h.p.*

Proof. We describe the algorithm for $n/\sqrt{\log n}$ processors. Let an *item* denote a nonempty input cell. Note that we make no assumption on the distribution of the items within the input array.

1. View the n input cells as partitioned into subarrays of size $2\log^2 n$. Assign $2\log^{1.5} n$ processors per subarray. In parallel for all subarrays compact the items in each subarray, using parallel prefix.
2. For subarrays with at most $2\log n$ items, we assign $\sqrt{\log n}$ processors per item, and apply Lemma 7.3.
3. For subarrays with more than $2\log n$ items, we view the items as partitioned into blocks of size $\log n$. There are at most $2\log n$ such blocks in a subarray, so we assign $\sqrt{\log n}$ processors per block. Viewing each block as a "superitem," apply Lemma 7.3 to compact the superitems into an array of size $O(k/\log n)$.

Then we transfer the items in each block to the output array of size $O(k)$, in the obvious way.

Each of steps 1–3 takes $O(\sqrt{\log n})$ time w.h.p. □

8. Broadcasting. Given $b \in \{0, 1\}$ in a single memory location, the *broadcasting* problem is to copy b into n fixed memory locations. There is a simple linear work, $O(\log n)$ time EREW PRAM algorithm for this problem. In this section we show that this algorithm is the best possible even for the (randomized) QRQW PRAM by providing an $\Omega(\log n)$ lower bound on the expected running time of any deterministic or randomized QRQW PRAM algorithm for this problem.

Our lower bound exploits the fact that the input domain for the broadcasting problem has only two values. We show that for any problem with an input domain of size 2, a SIMD-QRQW PRAM algorithm is no faster than the best EREW PRAM algorithm for the problem, and even a QRQW PRAM algorithm is at most two times faster than the best EREW PRAM algorithm for the problem. We also show that a randomized algorithm for the problem is at most two times faster than the best deterministic algorithm for the problem. These results, in turn, imply our lower bound for broadcasting and related problems due to a lower bound for broadcasting on the EREW PRAM given by [4].

Our simulation of the SIMD-QRQW PRAM and the QRQW PRAM on the EREW PRAM results in a *nonuniform* algorithm on the EREW PRAM. An algorithm is nonuniform if it consists of different programs for different input sizes, and the program for a given input size i cannot be generated easily simply by specifying the value of i. Most algorithms used in practice are *uniform*, such that a single program works for all input sizes. A nonuniform algorithm is not desirable from a practical point of view, since the time bound for the algorithm is not guaranteed to be achieved on a given input unless we have already generated the program for that input size. However, the lower bound of [4] holds for both uniform and nonuniform algorithms (as is the case with most lower bounds), and hence our simulation result gives the desired lower bound for the SIMD-QRQW PRAM and the QRQW PRAM.

8.1. Constant-size input domain problems. We first deal with the SIMD-QRQW PRAM. We show that any SIMD-QRQW PRAM algorithm for a problem defined on a domain with only two values that runs in time T can be converted into an EREW PRAM algorithm that also runs in time T. The EREW PRAM may be nonuniform and may have a description that is of unbounded size. For an exact definition of the model see [12].

LEMMA 8.1. *Let T be the running time for an algorithm A that solves a problem P with input domain of size 2 on a* SIMD-QRQW PRAM. *Then, there exists an algorithm B that solves P in time T on an* EREW PRAM, *using the same number of processors and the same working space. Algorithm B is nonuniform and its description is of size $O(T)$ memory locations per processor.*

Proof. Assume, without loss of generality, that the input domain is $\{0, 1\}$. The lemma is proved by constructing the EREW PRAM Algorithm B from Algorithm A. Consider the ith step in Algorithm A, and let $\kappa_i(b)$ be the maximum contention in this step on input b. Let $\kappa'_i = \min\{\kappa_i(0), \kappa_i(1)\}$ (recall from Definition 2.1 that $\kappa'_i \geq 1$). Step i will be implemented in Algorithm B in at most κ'_i substeps, as described below. Therefore, the running time of algorithm B is at most $\sum_i \kappa'_i = \sum_i \min\{\kappa_i(0), \kappa_i(1)\} \leq T$. We describe first the construction for the read step.

Let $\Phi_{i,j,b}$ be the set of processors that read from memory cell j in step i on input $b \in \{0, 1\}$. Let $\Phi_{i,j} = \Phi_{i,j,0} \cap \Phi_{i,j,1}$. For processors in each set $\Phi_{i,j,b} \setminus \Phi_{i,j}$, we can

prepare a priori copies of the contents of memory cell j, $c(i,b)$, so that they can do the read operation from their appropriate copies without conflict, as described below.

For processors in each set $\Phi_{i,j}$, we serialize their computation by providing an a priori ranking from $[1..|\Phi_{i,j}|]$ to all the processors in $\Phi_{i,j}$, and scheduling the processors according to their ranks. The program for Algorithm B includes for each processor a sequence $\langle i, M(i,b), r(i,b), \phi_i, c(i,b)\rangle$, $i = 1, \ldots, T$, $b \in \{0,1\}$, where $M(i,b)$ is the memory cell from which the processor reads in step i on input b; $r(i,b)$ is the rank of the processor at step i if the processor is in $\Phi_{i,M(i,b)}$, and is null otherwise; $c(i,b)$ is the contents at step i of memory cell $M(i,b)$ if the processor is in $\Phi_{i,M(i,b),b} \setminus \Phi_{i,M(i,b)}$, and is null otherwise; and $\phi_i = \max_j |\Phi_{i,j}|$. (Note that the processor does not need to know the value of b. If, however, $M(i,0) \neq M(i,1)$ or $r(i,0) \neq r(i,1)$ then it implicitly knows the value of b at this stage; this knowledge can be made explicit by replacing the quintuple above by the sextuple $\langle i, M(i,b), r(i,b), \phi_i, c(i,b), b'\rangle$ where $b' \in \{0,1,*\}$.) This sequence can be specified in $O(T)$ memory locations, and is nonuniform. In step i, each processor whose $r(i,b)$ is not null will execute its read operation from memory location $M(i,b)$ in substep $r(i,b)$. Each processor whose $r(i,b)$ is null will read $c(i,b)$. After a total of ϕ_i substeps, all processors proceed to step $i+1$.

It remains to show how to handle the write steps. Consider a memory location j in step i, and let $\Phi_{i,j}$, $\Phi_{i,j,0}$, and $\Phi_{i,j,1}$ be defined as for the read step. On input b, it is sufficient to select a priori one processor from $\Phi_{i,j,b}$ that will do the write step to location j. If $\Phi_{i,j}$ is not empty then one of the processors in $\Phi_{i,j}$ will be arbitrarily selected. If $\Phi_{i,j}$ is empty, one of the processors in $\Phi_{i,j,b}$ will be arbitrarily selected, unless it is empty. The write operation will be executed by the selected processor at substep ϕ_i. Thus, all the read operations will be completed before the write operation is executed; moreover, there is no additional time overhead due to the execution of the write operations.

With this scheme, the ith step of Algorithm A is executed in $\phi_i \leq \kappa'_i$ steps by Algorithm B, thus giving the desired result. □

We now strengthen the above result for the SIMD-QRQW PRAM to work for the QRQW PRAM with only a constant factor increase in the running time of the simulating EREW PRAM algorithm.

LEMMA 8.2. *Let T be the running time for an algorithm A that solves a problem P with input domain of size 2 on a* QRQW PRAM. *Then, there exists an algorithm B that solves P in time $O(T)$ on an* EREW PRAM, *using the same number of processors and the same working space. Algorithm B is nonuniform and its description is of size $O(T)$ memory locations per processor.*

Proof. We show how to handle the read steps of Algorithm A; write steps are treated similarly. Consider the ith read step in Algorithm A on input b. Let the time cost of this step be t_i. Let R_k be the set of reads for processor p_k, and let M_j be the set of read requests for memory location m_j in step i on input b. Note that t_i is the maximum cardinality of the sets R_k, M_j, over all processor and memory indices k, j.

We construct a bipartite graph $B_{i,b} = (P, M, E_{i,b})$, where P contains a vertex for each processor, M contains a vertex for each memory location, and there is an edge $(p_k, m_j) \in E_{i,b}$ if and only if processor p_k reads memory location m_j in step i on input b.

The maximum degree of any vertex in the graph $B_{i,b}$ is t_i. Since $B_{i,b}$ is bipartite, it has a proper edge coloring with t_i colors (Theorem 6.1 in [9]), i.e., a mapping $c : E_{i,b} \to \{1, 2, \ldots, t_i\}$ such that for any pair of edges e, f incident on the same vertex, $c(e) \neq c(f)$. Thus for a given input b we can serialize the ith step of Algorithm A into

t_i exclusive read substeps by performing the read corresponding to the edges colored l in the lth substep.

Since the input domain is of size 2, b can take on only two values, say 0 and 1, and each processor can be in at most two different states at a given time step, no matter what the input is. In Algorithm B for each step, we run the serialization of the step on input $b = 0$ followed by the serialization of the step on input $b = 1$. If processor p_k is in a state that corresponds only to input $\hat{b} \in \{0, 1\}$ then it performs the read only in the serialization for $b = \hat{b}$. If p_k is in the same state whether $b = 0$ or $b = 1$, then p_k performs the read only in the serialization for $b = 1$. This results in a (nonuniform) EREW PRAM algorithm that performs the same computation as Algorithm A, using the same number of processors and the same working space, and runs in time $O(T)$. The length of the program is the length of the serialization, which is $O(T)$.

There was no attempt to minimize the constants in the above algorithm. Techniques similar to those applied in the proof of Lemma 8.1 can be used here to reduce the constants. □

We now show that randomization cannot help too much when the input domain is small.

LEMMA 8.3. *Let T_d be a lower bound on the time required by a deterministic algorithm to solve a problem P with input taken from a domain of size $|I|$. Then, for any randomized algorithm that solves P, the expected running time T_r on any input is bounded by $T_r \geq T_d/|I|$.*

Proof. Let T_a be the average running time for the uniform-input distribution, minimized over all possible deterministic algorithms, to solve P. Clearly, since the number of possible inputs is $|I|$, $T_a \geq T_d/|I|$. Further, by a classic result of Yao [64], $T_r \geq T_a$. (Yao's result is more general; for a short proof of this claim see [21].) Therefore, $T_r \geq T_a \geq T_d/|I|$. □

8.2. Lower bounds for broadcasting and related problems. Beame, Kik, and Kutylowski [4] showed that computing the broadcasting problem on a nonuniform EREW PRAM with unbounded program size, an unbounded number of processors, and unbounded space requires $\Omega(\log n)$ time. The results of the previous subsection give us the following theorem.

THEOREM 8.4. *Any deterministic or randomized algorithm that computes the broadcasting problem into n memory locations on a* QRQW PRAM *with an unbounded number of processors and unbounded space requires expected time $\Omega(\log n)$.*

Proof. The lower bound for deterministic algorithms follows by the lower bound in [4] and Lemma 8.2 since the size of the input domain for the broadcasting problem is 2. The lower bound for randomized algorithms follows by Lemma 8.3. □

Since a CREW PRAM can broadcast into n memory locations in constant time, Theorem 8.4 immediately implies the following separation results.

COROLLARY 8.5. *There is an $\Omega(\log n)$ time separation of a (deterministic or randomized)* {SIMD-CRQW,CRQW} PRAM *from a (deterministic or randomized)* {SIMD-QRQW,QRQW} PRAM. *The same separation result holds of a* CREW PRAM *from a queue-read, exclusive-write (*QREW*)* PRAM.

The following generalization of the broadcasting problem is used in a lower bound for load balancing given in [29].

THEOREM 8.6. *Any deterministic or randomized algorithm that broadcasts the value of a bit to any subset of k processors in a* QRQW PRAM *requires expected time $\Omega(\log k)$.*

Proof. Let Algorithm A be a QRQW algorithm that succeeds in broadcasting the

value of a bit to some subset of k processors in time t. We use Algorithm A to derive a (nonuniform) QRQW PRAM algorithm for the broadcasting problem into k (fixed) memory locations as follows. We first run Algorithm A to broadcast the value of the bit to some subset of k processors. We then transmit the value of the bit from the ith processor in the subset to the ith output memory location, $1 \leq i \leq k$. This can be performed in one step with time cost 1 since we can precompute from Algorithm A the exact indices of the k processors to which the value of the bit will be transmitted. Thus we can solve the broadcasting problem in $t+1$ steps. It follows from Theorem 8.4 that $t = \Omega(\log k)$. □

9. Conclusions. This paper has proposed a new model for shared-memory machines, the QRQW PRAM model, that takes into account the amount of contention in memory accesses. This model is motivated by the contention characteristics of currently available commercial machines. We have presented several results for this model, including a fast, work-preserving emulation of the QRQW PRAM on hypercube-type, noncombining networks, a work-time framework and some automatic processor allocation schemes for the model, several linear work, sublogarithmic time algorithms for the fundamental problems of leader election on a CRQW PRAM and linear compaction on a QRQW PRAM, and some lower bounds.

In a companion paper [29], we present many new results for the QRQW PRAM. Among the algorithmic results presented are low-contention, fast, work-optimal QRQW algorithms for multiple compaction, load balancing, generating a random permutation, and parallel hashing. These results and the results presented in this paper demonstrate the advantage of the QRQW over the EREW. Together with the penalty in running high-contention CRCW or CREW algorithms on existing machines, this supports the QRQW PRAM as a more appropriate model for high-level algorithm design.

Finally, in a related work [30] we explore the properties of the asynchronous QRQW PRAM.

Acknowledgments. Richard Cole, Albert Greenberg, Maurice Herlihy, Honghua Yang, and the anonymous referees provided useful comments on this work.

A CONSTANT-FACTOR APPROXIMATION ALGORITHM FOR THE GEOMETRIC k-MST PROBLEM IN THE PLANE*

JOSEPH S. B. MITCHELL†, AVRIM BLUM‡, PRASAD CHALASANI§, AND SANTOSH VEMPALA¶

Abstract. We show that any rectilinear polygonal subdivision in the plane can be converted into a "guillotine" subdivision whose length is at most twice that of the original subdivision. "Guillotine" subdivisions have a simple recursive structure that allows one to search for "optimal" such subdivisions in polynomial time, using dynamic programming. In particular, a consequence of our main theorem is a very simple proof that the k-MST problem in the plane has a constant-factor polynomial-time approximation algorithm: we obtain a factor of 2 (resp., 3) for the L_1 metric, and a factor of $2\sqrt{2}$ (resp., 3.266) for the L_2 (Euclidean) metric in the case in which Steiner points are allowed (resp., not allowed).

Key words. minimum spanning trees, k-MST, guillotine subdivisions, quota traveling salesman problem, prize-collecting salesman problem, bank robber (orienteering) problem, network optimization, computational geometry, dynamic programming, approximation algorithms polynomial

1. Introduction.

We introduce a new technique that can be used to obtain simple approximation algorithms for geometric network design problems. The method is based on the concept of a "guillotine subdivision." Roughly speaking, a "guillotine subdivision" is a rectilinear polygonal subdivision with the property that there exists a horizontal or vertical line (a "cut") whose intersection with the edge set is *connected* and the subdivisions on either side of the line are also guillotines. The connectedness property allows one to apply dynamic programming to optimize over guillotine subdivisions, as there is a succinct specification of how the subdivision interacts with the "cuts" that make up the boundary of a rectangle that specifies a "subproblem" of the dynamic program.

Key to our method is a theorem showing that any rectilinear polygonal subdivision can be converted into a guillotine subdivision by adding a set of edges whose total length is small (at most that of the original subdivision).

To illustrate the power of the method, we show how it can be used to give a very simple constant-factor approximation algorithm for the geometric k-MST problem, obtaining a substantially better factor than previously known. We also apply it to some related problems (the "quota TSP," "prize-collecting salesman," and "bank robber (orienteering)" problems).

A motivating application. A special case of the "quota TSP" problem is the following: you are a salesman who must sell k items. You can sell one item in each of n cities ($n \geq k$). You want to find a shortest tour that visits at least k cities, so that you can sell your quota of k items. A solution (exact or approximate) to the k-MST problem on the n cities immediately gives an approximation to the desired optimal tour (simply by doubling the tree, in the usual manner).

Related work. In the minimum-weight k-tree, or k-MST, problem, we are given a graph on n vertices with nonnegative distances on the edges and an integer $k \leq n$, and our goal is to find a tree of least total weight that spans some subset of k vertices. The k-MST problem was introduced independently by Fischetti et al. [11], Zelikovsky and Lozevanu [22], and Ravi et al. [21]. In those papers, the problem is shown to be NP-complete, and Ravi et al. give an approximation algorithm with factor $O(\sqrt{k})$. Algorithms with improved approximation factors have since been discovered: Awerbuch et al. [2] obtain factor $O(\log^2 k)$, and Rajagopalan and Vazirani [20] obtain $O(\log k)$. In the time since our work first appeared (in [6] and [18]), there have been further improvements in the approximation factors: Blum, Ravi, and Vempala [7] obtain a factor of 17, and, most recently, Garg [12] obtains a factor of 3. Cheung and Kumar [8] have also considered the problem, which they call the "quorum-cast" problem and which arises in communication networks. Note that if $k = n$, then the k-MST problem is simply the usual minimum spanning tree problem, which has efficient (polynomial-time) exact solutions; thus, the complexity of the k-MST problem arises from the fact that we must find *which* k vertices to connect with a minimum spanning tree.

In the *geometric* k-MST problem, the underlying graph is the complete graph induced by a set of points in the plane, with distances between pairs of points determined by the underlying metric space (typically, this will be Euclidean (L_2) or L_1). Specifically, we are given a set P of n points in the plane, and an integer $k \leq n$, and we are to find a subset of k points of P that has the shortest minimum spanning tree. The problem is NP-hard. Ravi et al. [21] give an approximation algorithm with ratio $O(k^{1/4})$, which was quickly improved to a factor of $O(\log k)$ by Garg and Hochbaum [13] and Mata and Mitchell [17]. Eppstein [10] has improved the approximation ratio to $O(\log k / \log \log n)$ and has given general techniques to improve the running times (as a function of n) of existing algorithms; further, he shows that the exact k-MST problem can be solved in time $2^{O(k \log k)} n + O(n \log n)$, which is simply $O(n \log n)$ for fixed k.

Note that, up to small constant factors in the approximation ratio, the k-MST problem is equivalent to the problem of finding a shortest path or shortest tour that visits k points (the k-TSP problem) or a shortest Steiner tree connecting k points.

Our contribution. Our result is a simple proof of an $O(1)$ approximation ratio for the geometric k-MST problem. We obtain a factor of 2 (resp., 3) (for the L_1 metric) or $2\sqrt{2}$ (resp., 3.266) (for the Euclidean metric) in the case that Steiner points are (resp., are not) allowed. Further, we expect that our guillotine subdivision results may yield similar improvements and simplifications to approximation algorithms for other geometric network design problems. In section 6, we mention a few applications of our method to some problems that are related to the k-MST.

This paper represents the contributions from two manuscripts: the work of Blum, Chalasani, and Vempala [6], based on the notion of a "division tree," and the improvement and simplification to it given by Mitchell [18], based on the notion of "guillotine subdivisions." We will briefly describe the original "division tree" method of Blum et al. but will only give details of the simpler method of Mitchell [18].

2. Division trees. In this section we define *division trees*, and describe a simple dynamic programming algorithm based on this notion that achieves a constant-factor approximation to the k-MST problem. The proof of the approximation guarantee appears in [6]. We do not present the proof here because in the next section we will describe a more powerful algorithm that achieves a better constant factor, and for which the proof is significantly simpler.

To define a division tree, we assume for convenience that no two points lie on the same horizontal or vertical line. In this case, we say that a spanning tree T for a set of points is a *division tree* if T satisfies the following recursive property.

> There exists some point r (the "root") such that either the vertical or the horizontal line through r splits T into two division trees. More precisely, we require both that (A) this line does not intersect any edges of T, and (B) the trees T_1 and T_2 induced by the points on either side of the line *including* r should be division trees. For the base case, if there are just two points, then the single edge is a division tree.

Given any set of n points, the following simple dynamic programming algorithm finds the subset of k points having a division tree of minimum weight.

The algorithm is most easily viewed in a recursive "memoizing" form. It returns both the desired set of k points and the *cost* of the associated division tree. The algorithm takes as input a set of points P, an integer k, and also up to four additional constraints. For each of the four sides of the bounding box of P the algorithm may be told that the point on that bounding side is "required" and must be in any set of k points the algorithm produces. At the outer loop there are no required points. Given these inputs, the algorithm considers each vertical and horizontal line that passes through some point in P and does not coincide with an edge of the bounding box. For a given such line—let p be the point in P that the line passes through—the algorithm constructs the bounding boxes B_1 and B_2 of the points on the two sides, considering p to be on both sides. It then calls itself recursively $k-1$ times for each of the two boxes B_i: in each call passing down the set of points in B_i, a new integer $k' \in [2, k]$, and the set of required points it was originally given (only considering those that lie in the box B_i) *including* the new point p. Once the algorithm receives its $k-1$ answers from each side, it simply compares to find the pair $\langle k', k-k'+1\rangle$ whose costs sum to the least amount (the reason for the "+1" is that point p lies on both sides). In the base case $k=2$, the algorithm just returns the cost of the single edge.

Because there are at most n^4 different bounding boxes, k different possibilities for the desired number of points, and 16 different settings for the "required points," the memoized procedure (or, equivalently, dynamic program) will run in polynomial time. Also, it is not too hard to see that this algorithm finds the set of k points with the lightest division tree. What is shown in [6] is that for any set of points, the division tree of minimum weight is only a constant factor more costly than the minimum spanning tree.

3. Guillotine subdivisions. We now turn to guillotine subdivisions, and our main theorem that any rectilinear subdivision of the plane can be approximated by one that is guillotine.

Consider a rectilinear polygonal subdivision S that is induced by a finite set of noncrossing horizontal and vertical (closed) line segments in the plane, whose union,

E, comprises the edges of S. We can assume (without loss of generality) that S is restricted to the unit square B (i.e., $E \subset \text{int}(B)$). Then each facet (2-face) is a bounded rectilinear polygon, possibly with holes. The *length* of S is the sum of the lengths of the edges of S.

A closed, axis-aligned rectangle W is a *window* if $W \subseteq B$. In the following definitions, we fix attention on a given window W.

A line ℓ is a *cut* for E with respect to W if $\ell \cap \text{int}(W) \neq \emptyset$. The intersection $\ell \cap (E \cap \text{int}(W))$ of a cut ℓ with $E \cap \text{int}(W)$, the *restriction* of E to the window W, consists of a discrete (possibly empty) set of subsegments of ℓ. (Some of these "segments" may be points, where ℓ crosses an edge.) The endpoints of these subsegments are called the *endpoints along* ℓ (with respect to W). (The two points where ℓ crosses the boundary of W are not considered to be endpoints along ℓ.) Let ξ be the number of endpoints along ℓ, and let the points be denoted by $p_1, \ldots, p_\xi$ in order along ℓ.

We define the *span* $\sigma(\ell)$ of ℓ (with respect to W) as follows. If $\xi = 0$, then $\sigma(\ell) = \emptyset$; otherwise, $\sigma(\ell)$ is defined to be the (possibly zero-length) line segment $p_1 p_\xi$.

A line ℓ is a *perfect cut with respect to* W if $\sigma(\ell) \subseteq E$ (which implies that $\xi = 2$, or $\xi = 1$ in case $\sigma(\ell)$ is a single point).

Finally, we say that S is a *guillotine subdivision with respect to window* W if either (1) $E \cap \text{int}(W) = \emptyset$; or (2) there exists a perfect cut ℓ, with respect to W, such that S is guillotine with respect to windows $W \cap H^+$ *and* $W \cap H^-$, where H^+, H^- are the closed halfplanes induced by ℓ. We say that S is a *guillotine subdivision* if S is guillotine with respect to the unit square B.

See Figure 3.1 for an example of a guillotine subdivision, where we illustrate the entire tree of perfect cuts. (Each perfect cut is indicated with a small arrow.)

Note that, in contrast with guillotine *rectangular* subdivisions (see [9, 17]), the guillotine subdivisions we study here are not restricted to have rectangular faces; rather, the faces of a guillotine subdivision are rectilinear polygons. In fact, it is precisely this distinction that permits us to get constant-factor approximations, while the previous method of [17] obtained logarithmic factors. For example, in order to transform a "staircase" (rectilinear) polygon into a guillotine rectangular subdivision, we must increase its total edge length by a factor of $\Omega(\log n)$; in contrast, a staircase polygon is already a guillotine subdivision according to our definition.

4. The main theorem. We now show that any rectilinear subdivision can be converted into a guillotine subdivision without increasing its length by much (at most doubling it). Our proof is inspired by the proof in [9] that any subdivision of a box (in $\Re^2$) into *rectangles* can be converted into a "guillotine" rectangular subdivision of at most twice the length by adding a new set of edges whose total length is small (charged off to the original edges of the subdivision).

THEOREM 4.1. *Let S be a rectilinear subdivision of length L with edge set E. Then there exists a guillotine subdivision S_G of length at most $2L$ whose edge set E_G contains E.*

Proof. We will convert S into a guillotine subdivision S_G by adding to E a new set of horizontal or vertical edges whose total length is at most L. The construction is recursive; at each stage, we show that there exists a cut ℓ with respect to the current window W (which initially is the box B) such that we can afford to add the span $\sigma(\ell)$ to E, while appropriately charging off the length of $\sigma(\ell)$. (Once we add $\sigma(\ell)$ to E, ℓ becomes a perfect cut with respect to W.)

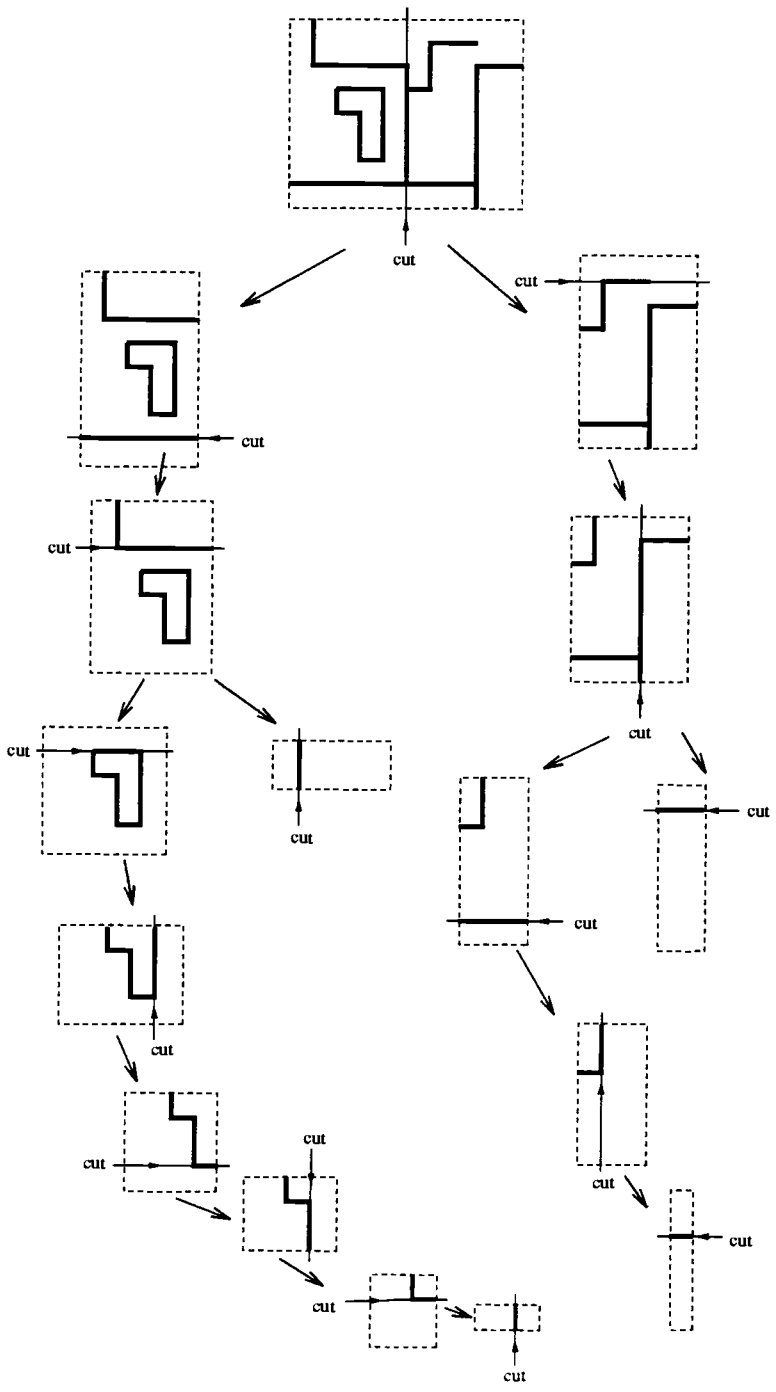

FIG. 3.1. *An example of a guillotine subdivision. Each perfect cut is indicated with a small arrow; bounding boxes (windows) are indicated with dashed rectangles.*

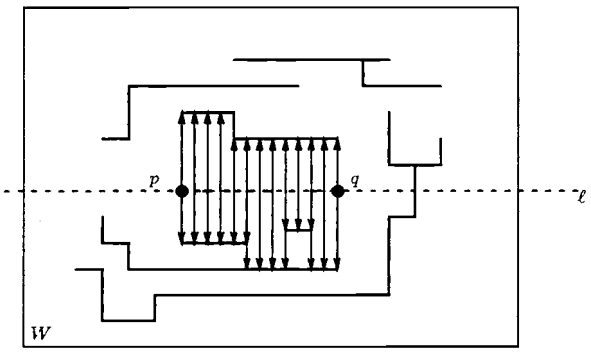

FIG. 4.1. *Subsegment $pq \subset \ell$ is dark; its length is charged to the subsegments of E that lie above or below.*

In fact, we will restrict ourselves to a special discrete set of horizontal or vertical cuts, namely, those determined by the x- or y-coordinates of original vertices V of the subdivision, or by the midpoints between consecutive x- or y-coordinates of V.

First, note that if a perfect cut (with respect to W) exists, then we can simply use it and proceed recursively on each side of the cut. Thus, we assume that no perfect cut exists with respect to a given window, W.

We say that a point p on a cut ℓ is *dark with respect to ℓ and W* if, along $\ell^\perp \cap \text{int}(W)$, there is at least one endpoint (strictly) on each side of p, where $\ell^\perp$ is the line through p that is perpendicular to ℓ.[1] We say that a subsegment of ℓ is *dark* (with respect to W) if all points of the segment are dark with respect to ℓ and W.

The important property of dark points along ℓ is the following: assume, without loss of generality, that ℓ is horizontal. Then if all points on subsegment pq of ℓ are dark, then we can charge the length of pq off to the bottoms of the subsegments $E^+ \subseteq E$ of edges that lie above pq and are vertically visible to pq, and the tops of the subsegments $E^- \subseteq E$ of edges that lie below pq and are vertically visible to pq (since we know that there is at least one edge "blocking" each point of pq from the top or bottom of W). We charge pq's length half to E^+ (charging E^+ *from below*, with $\frac{1}{2}$ units of charge) and half to E^- (charging E^- *from above*, with $\frac{1}{2}$ units of charge). In Figure 4.1 we illustrate how a dark subsegment pq has its length charged off.

We call a cut ℓ *favorable* if the dark portion of ℓ is at least as long as the span $\sigma(\ell)$. Lemma 4.2 below shows that a favorable cut always exists (even one in the special discrete set). For a favorable cut ℓ, we add its span to the edge set (charging off its length, as above) and recurse on each side of the cut in the two new windows. After a portion of E has been charged on one side, due to a cut ℓ, it will be vertically visible to the boundary of the windows on either side of ℓ and, hence, will be vertically visible to the boundary of any future windows, found deeper in the recursion, that contain the portion. Thus, *no portion of E will ever be charged more than once from each side* (top and bottom), so no portion of E will ever pay more than its total length in charge ($\frac{1}{2}$ from each side). Also, the new edges added (the spans $\sigma(\ell)$) are never themselves charged, since they lie on window boundaries and cannot therefore serve to make a portion of some future cut dark.

[1] We can think of the edges E as being "walls" that block light; then p on a line ℓ is dark if p is not illuminated when light is shone in from the boundary of W along the direction of $\ell^\perp$.

Note too that in order for a cut ℓ to be favorable, but not perfect, there must be at least one segment of E parallel to ℓ in each of the two open halfplanes induced by ℓ; thus, the recursion must terminate in a finite number of steps.

Since the total length of all spans for all favorable cuts is at most L, and the total length of all spans for all perfect cuts is at most L, we are done. □

We now prove our key lemma, which guarantees the existence of a favorable cut when there is no perfect cut. The proof of the lemma uses a particularly simple argument based on elementary calculus (reversing the order of integration).

LEMMA 4.2. *For any subdivision S, and any window W, there must be a favorable cut.*

Proof. We show that there must be a favorable cut that is either horizontal or vertical.

Let $f(x)$ denote the length of the span (with respect to W) of the vertical line through x. Then $\int_0^1 f(x)dx$ is simply the area A_x of the (x-monotone) region R_x of points of B that are dark with respect to horizontal cuts. Similarly, define $g(y)$ to be the length of the span of the horizontal line through y, and let $A_y = \int_0^1 g(y)dy$.

Assume without loss of generality that $A_x \geq A_y$. We claim that there exists a horizontal favorable cut; i.e., we claim that there exists a horizontal cut ℓ such that the length of its dark portion is at least as large as the length of its span $\sigma(\ell)$. To see this, note that A_x can be computed by switching the order of integration, "slicing" the region R_x horizontally, rather than vertically; i.e., $A_x = \int_0^1 h(y)dy$, where $h(y)$ is the length of the intersection of R_x with a horizontal line through y; i.e., $h(y)$ is the length of the dark portion of the horizontal line through y. Thus, since $A_x \geq A_y$, we get that $\int_0^1 h(y)dy \geq \int_0^1 g(y)dy \geq 0$. Thus, it cannot be that for all values of $y \in [0,1]$, $h(y) < g(y)$, so there exists a $y = y^*$ for which $h(y^*) \geq g(y^*)$. The horizontal line through this y^* is a cut satisfying the claim of the lemma. (If, instead, we had $A_x \leq A_y$, then we would get a *vertical* cut satisfying the claim.)

Finally, we note that, in the rectilinear case, f, g, and h are piecewise constant, with discontinuities corresponding to vertices V of S. Then we can always select y^* to be at a discontinuity or at a midpoint between two discontinuities. □

Remark. It is interesting to consider whether or not the factor of 2 in the theorem can be improved. We have not been able to find an example of a subdivision that cannot be made into a guillotine subdivision by the addition of edges whose total length is less than *half* that of the original subdivision. We conjecture that the factor 2 can be improved to a factor of 3/2.

5. An application to the k-MST. One application of our theorem is that it yields an algorithm along with a simple proof that it achieves a (small) constant-factor approximation of the geometric k-MST problem.

COROLLARY 5.1. *The geometric k-MST problem has a polynomial-time approximation algorithm with approximation factor 2 (allowing Steiner points) or 3 (not allowing Steiner points) in the L_1 metric. In the Euclidean metric, the approximation factors become $2\sqrt{2}$ (Steiner) or $4\sqrt{6}/3 = 3.266$ (non-Steiner).*

Proof. Let P be a set of n points in the plane. Assume that no two points of P lie on a common vertical or horizontal line (otherwise, we can perturb the points or slightly rotate the coordinate system). Let T_R be a minimum-length rectilinear Steiner k-MST for P, and let L_R^* denote its total (Euclidean) length. We can assume that T_R lies on the grid of horizontal or vertical lines through P, since T_R can easily be modified to lie on the grid, without increasing its overall length. Clearly, the length

L_R^* of T_R is the optimal length for the L_1 Steiner k-MST and is at most $\sqrt{2}$ times the length, L^*, of an optimal Euclidean Steiner k-MST.

By Theorem 4.1, there exists a guillotine subdivision S_G, with edge set E_G, of length at most $2L_R^*$ (at most $2\sqrt{2}L^*$), such that $T_R \subseteq E_G$. Thus, there exists a perfect cut ℓ (inducing closed halfplanes $\bar{H}^+$ and $\bar{H}^-$) for E_G such that $\ell \cap E_G$ is connected (a segment). When we select a favorable cut, whose existence is shown in Lemma 4.2, we can always select the cut either to pass through a point of P or to pass through, say, the midpoint of some x- or y-interval determined by consecutive coordinates of points of P; thus, the cuts will have coordinates from a *discrete* set determined by P. Proceeding recursively on each side of ℓ, we can build a tree $\mathcal{T}$ of perfect cuts.

The bounding boxes corresponding to each node of this tree have the special property that the intersection of E_G with each side of a box is *connected*; thus, we can partition the problem into subproblems, each having *constant*-size (discrete) specification, and can easily apply dynamic programming to search for an optimal guillotine subdivision that visits k of the points P and has a connected set of edges E. This yields a (rectilinear) Steiner tree connecting k points of total Euclidean length at most $2L_R^*$. If our goal is a Steiner k-MST approximation, then we are done. Otherwise, at the end we compute and output a minimum spanning tree for this subset of k points. The worst-case length of the final tree is obtained by multiplying by the Steiner ratio ($3/2$ for L_1, $2\sqrt{3}/3$ for L_2). Thus, we get an approximation factor of $2 \cdot (3/2) = 3$ (for L_1 metric) or of $2\sqrt{2} \cdot (2\sqrt{3}/3) = 4\sqrt{6}/3 = 3.266$ (for L_2 metric). We give details of the dynamic programming algorithm below. □

A dynamic programming algorithm. Let $x_1 < x_2 < \cdots < x_{2n-1}$ (resp., $y_1 < y_2 < \cdots < y_{2n-1}$) denote the sorted x (resp., y) coordinates of the n points P, as well as the $n-1$ midpoints of the intervals determined by these coordinates. We now give a dynamic programming algorithm, which is based on solving the following subproblems.

Input.

1. An integer $k' \leq k$;
2. a rectangle $R(i, i', j, j')$, defined by x_i, $x_{i'}$ $(x_{i'} > x_i)$, y_j, and $y_{j'}$ $(y_{j'} > y_j)$;
3. four "boundary segments," σ_l, σ_r, σ_b, and σ_t, which are (possibly empty or zero-length) subsegments of the four sides (left, right, bottom, top) of $R(i, i', j, j')$, each of which has endpoints determined by coordinates x_i, y_j; and,
4. a partition $\mathcal{P}$ of the set $\{\sigma_l, \sigma_r, \sigma_b, \sigma_t\}$ of boundary segments.

Objective. Compute a minimum-length guillotine subdivision S_G^* determined by some set E_G^* of horizontal or vertical line segments not lying on the boundary of rectangle $R(i, i', j, j')$, such that E_G^* covers at least k' points of P (interior to $R(i, i', j, j')$) and the edges E_G^* connect the boundary segments, according to the partition $\mathcal{P}$.

Note that there are $O(k \cdot n^4 \cdot (n^2)^4) = O(kn^{12})$ possible inputs (subproblems). Note too that an optimal solution S_G^* will necessarily be a forest, since any cycle that is formed can be broken without violating the connectivity requirements (given by $\mathcal{P}$).

The optimal value V of the above problem is 0 if $k' = 0$ and all connections among boundary segments specified by $\mathcal{P}$ are vacuously satisfied (i.e., the boundary segments that need to be connected are already connected at their endpoints (corners of the boundary box)). Otherwise, we can compute the value V recursively by adding

the values of the two subproblems obtained by splitting the problem and optimizing over all choices associated with a split:

1. $O(k)$ choices of how to partition k' among the two new subproblems;
2. $O(n)$ choices of a cut by a horizontal or vertical line (determined by some x_i or y_j);
3. $O(n^2)$ choices of new boundary segment σ on the cut; and
4. $O(1)$ choices of partitions for the two sets of boundary segments on the two new subrectangles determined by the cut subject to these partitions being consistent with the partition $\mathcal{P}$.

The polynomial time bound for solving the above recursions has a rather high exponent — $O(n^{15}k^2)$. One approach to improving this is to apply the following lemma of Eppstein [10], which is obtained by doing a simple nearest-neighbor clustering.

LEMMA 5.2 (see [10]). *If we have a time bound $T(n,k)$ for an exact or approximate geometric k-MST problem, we can solve the same problem in time $O(n\log n + nT(k^2,k)/k^2)$.*

A direct application of the above yields a time bound of $O(n\log n + nk^{30})$, which is an improvement when k is small compared with n.

Remark. Awerbuch et al. [2] discuss both "rooted" and "unrooted" versions of the k-MST problem. In the "rooted" version of the problem, we are given a specified point r, and we must use r as one of the k points in the MST. They prove that their $O(\log^2 k)$-approximation method applies to both problems, but the approximation ratio may increase by 1 for the rooted case. It is easy to see that our dynamic programming algorithm allows us also to obtain a rooted solution that is within the *same* factor of optimal as in the unrooted case, simply by specifying the appropriate constraint in the input to the dynamic program.

6. Other applications. Our methods also apply to three other problems that are related to the k-MST, and for which approximation algorithms for the graph versions have been given by Awerbuch et al. [2].

1. In the *quota-driven salesman* problem, each point of P has an associated integral value w_i, and a salesman has a given integer quota R. The objective is to find a shortest possible route (or tour) such that the sum of the values for the cities visited is at least R. It is immediate that our k-MST approximation gives an approximation for this problem too: simply replace each point of P by w_i copies of itself, at the same location in the plane. Now, simply compute an approximate solution to the k-MST, with $k = R$, and then double the tree to obtain a path or a tour.
   This algorithm runs in time polynomial in n and R. One open problem is to extend the algorithm to run in time polynomial in n and $\log R$, which holds for the algorithm of Awerbuch et al. [2].
2. In the *prize collecting salesman* problem (or, PCTSP), as studied by Balas [3] (see also [4]), the setup is the same as in the quota-driven salesman problem, except that, in addition to "values" w_i, there are nonnegative penalties associated with each point of P, and the objective function is now to minimize the sum of the distances traveled *plus* the sum of the penalties on the points *not* visited subject to satisfying the quota R. (Thus, if all penalties are 0, we simply get the quota-driven salesman problem.) As mentioned in [2], an approximation of PCTSP follows immediately from concatenating a tour obtained for the quota-driven salesman, with the 2-approximation tour given

by the algorithm of Goemans and Williamson [15] (which considers the effect of penalties but does not use the quota constraint).

3. In the *bank robber (orienteering)* problem, we are faced with essentially the dual of the quota-driven salesman problem: given a gas tank that allows one to travel a distance d, maximize the total value R of all points visited. As in [2], we can obtain an approximation for this problem, based on "guessing" the value of R, running the approximation for the quota-driven salesman for quota R, breaking the path into subpaths of length $d/2$, and then picking the subpath of highest value.
   This reduction holds only for the *unrooted* version of this problem. For the rooted version (one has a fixed root and a given distance d, and the goal is to visit as many points as possible and return to the root without running out of gas) it is unclear how to obtain any nontrivial approximation.
4. In the *minimum latency problem* (MLP), also known as the *deliveryman problem* and the *traveling repairman problem*, we are given a set of points and must find a tour that minimizes the sum of the "latencies" of all points, where the *latency* of a point p is the length of the tour from the starting point to the point p. (Thus, the latency of a point measures how long a job at that point must wait before being served by the repairman/deliveryman that is traveling along the tour.) Blum et al. [5] have given an approximation algorithm with a constant-factor bound of 128; this bound has recently been improved by Goemans and Kleinberg [14] to 29. By a direct application of Theorem 2 of [5], which states that a c-approximation for the k-MST implies an $8c$-approximation for the MLP, we see that our results immediately imply a 24-approximation algorithm for the L_1 metric MLP and a 26.13-approximation algorithm for the L_2 metric MLP for points in the plane.

In a recent application of our guillotine subdivision results, Mata and Mitchell [16] have obtained a constant-factor approximation algorithm for the following *red-blue separation* problem: given n points in the plane, each colored red or blue, find a shortest simple polygon separating red from blue. This problem is known to be NP-hard and previously had an $O(\log n)$ approximation algorithm [17].

7. Conclusion. In conclusion, we mention some of the exciting developments that have happened in the time since this paper was written. In the spring of 1996, Arora [1] announced a remarkable result—he had found a polynomial-time approximation scheme (PTAS) for the Euclidean traveling salesperson problem (TSP) as well as other geometric optimization problems such as the Steiner tree problem, the k-MST problem, etc.[2] Then, some weeks later, Mitchell [19] discovered that, in fact, a very minor variation of the method and proof given in his earlier work [18], and contained in this paper, also gives a particularly simple PTAS for geometric instances of the TSP, the k-MST, the Steiner tree problem, etc. All that must be modified is the definition of "span," from "span" to "m-span" (which links the mth endpoint with the mth-from-the-last endpoint along a cut ℓ), and, in the proof of Theorem 4.1, the notion of "darkness," from "darkness" to "m-darkness" (p is *m-dark* with respect to ℓ and W if, along $\ell^{\perp} \cap \text{int}(W)$, there are at least m endpoints (strictly) on each side of p). Here, we gave the case of $m = 1$. By allowing m to be any positive integer, the exact same proof goes through, resulting in the following extension to

[2] This means that for any fixed $\epsilon > 0$ there exists a polynomial-time algorithm that gets within a factor $(1 + \epsilon)$ of optimal.

Theorem 4.1: *for any rectilinear subdivision S with edge set E of length L and for any positive integer m, there exists an m-guillotine rectilinear subdivision S_G of length at most $(1+\frac{1}{m})L$ whose edge set E_G contains E.* (The same proof also applies to general (nonrectilinear) subdivisions, resulting in an m-guillotine subdivision of length at most $(1+\frac{\sqrt{2}}{m})L$.) See [19] for further details of the application of this extension.

Acknowledgments. We thank D. Eppstein, M. Held, S. Khuller, and C. Mata for comments and suggestions that improved this paper.

SOLVABILITY OF CONSENSUS: COMPOSITION BREAKS DOWN FOR NONDETERMINISTIC TYPES*

PRASAD JAYANTI†

Abstract. *Consensus*, which requires processes with different input values to eventually agree on one of these values, is a fundamental problem in fault-tolerant computing. We study this problem in the context of asynchronous shared-memory systems. Prior research on consensus focused on its solvability using shared objects of *specific* types. In this paper, we investigate the following general question: *Let T and T' be any two types. Consider the consensus problem among N processes. Suppose that this problem is unsolvable if processes may use only objects of any one type (T or T') for communication. Does it follow that the problem is unsolvable even if processes may use objects of both types?* Recent results imply that the answer is positive if T and T' are both deterministic types. We prove that the answer is negative even if one of T and T' is nondeterministic.

Key words. asynchronous distributed computation, consensus, wait-free algorithms, nondeterministic object type

1. Introduction.

1.1. Background. In an asynchronous system, processes progress at independent and arbitrarily varying speeds. Consequently, the view that a process holds of (any aspect of) the global state of the computation does not necessarily coincide either with the reality or with the view of another process. Thus it often becomes necessary for processes to reconcile their differences and arrive at a mutually acceptable common view. The desirable requirements of such a reconciliation are captured by the *consensus problem*, which may be stated as follows. Each process is initially given a binary input and each noncrashing process is required to eventually decide a value such that (i) no two processes decide different values, and (ii) the decision value is the input of some process.

In this paper we study the consensus problem in the shared-memory model, where asynchronous processes communicate via linearizable typed shared objects [10]. An object's type specifies the operations that may be invoked and its *sequential behavior*: one or more legal sequences of responses corresponding to each sequence of nonoverlapping operations. (The type is *nondeterministic* if there is more than one legal sequence of responses for some sequence of operations.) `register`, `queue`, `test&set`, and `compare&swap` are some examples of types. (We will use the typewriter font for types. Thus `queue` refers to the type and *queue* refers to an object of this type.)

In most systems, simple shared objects, such as registers and test&set objects, are supported in hardware, but more complex objects, such as queues and sets, must be implemented in software. Consequently there has been much research on implementing objects of one type from objects of other types. Early implementations were based

on critical sections (for example, see [6]), which are poorly suited to asynchronous systems: if one process is delayed in the critical section of an implemented object, the other processes will simply have to wait; even worse, if a process crashes in a critical section, the other processes are permanently disabled from accessing the object. To overcome this problem, Lamport advocated *wait-free implementations* [13]. A wait-free implementation has the property that every process can complete every operation on the implemented object in a finite number of its own steps, regardless of the speeds of the remaining processes.

The importance of the consensus problem became explicit when Herlihy discovered the following fundamental connection between consensus and wait-free implementations: given (i) a wait-free protocol that (repeatedly) solves the consensus problem among N processes and (ii) an unbounded array of registers, it is possible to have a wait-free implementation of an object of *any* type, where the implemented object can be shared by up to N processes [9]. Thus a consensus protocol can be regarded as a "universal" primitive.

The solvability of the consensus problem has been extensively researched. To succinctly describe these results, we use the following notation: we say that a *set $\mathcal{S}$ of types solves consensus for N processes* if there is a wait-free protocol $\mathcal{P}$ that solves the consensus problem among N processes such that *all* objects used in $\mathcal{P}$ for communication between processes are of types in $\mathcal{S}$. (There is no limit on the number of objects that $\mathcal{P}$ may use. We only require that each object be of a type in $\mathcal{S}$.) If such a protocol does not exist, we say that $\mathcal{S}$ does not solve consensus for N processes. If $\mathcal{S}$ is a singleton set $\{T\}$, we write "T solves consensus" instead of "$\{T\}$ solves consensus."

Dolev, Dwork, and Stockmeyer [7]; Loui and Abu-Amara [14]; and Chor, Israeli, and Li [4] proved that `register` does not solve consensus even for two processes. (These and most other impossibility results relating to consensus are proved using the bivalency technique introduced by Fischer, Lynch, and Paterson [8].) Loui and Abu-Amara proved that neither $\{$`test&set`, `register`$\}$ nor `2-valued read-modify-write` solves consensus for three processes, but each solves consensus for two processes [14]. They also exhibited a simple protocol to show that `3-valued read-modify-write` solves consensus for N processes for all N. Finally, Herlihy considered a host of common types—`queue`, `stack`, `fetch&add`, `move`, `compare&swap`, etc.—and analyzed, for each type T, the maximum number of processes for which $\{T,$ `register`$\}$ can solve consensus [9].

1.2. The main result. As described above, the ability of *specific types* to solve consensus has been well studied. In this paper we ask a general question: can we deduce the ability of a set of types to solve consensus simply from knowing the abilities of the individual types in the set? More specifically, consider the following compositional property of types T and T'.

PROP$_N(T, T')$. If neither T nor T' solves consensus for N processes, then $\{T, T'\}$ does not solve consensus for N processes.

For all types T, T' studied in the literature, PROP$_N(T, T')$ holds (for all N). The natural question follows.

QUESTION. Does PROP$_N(T, T')$ hold for all types T, T'?

We prove that the answer is a strong no. Specifically, we exhibit a nondeterministic type called `DAD`(∞) with the following two properties:

1. `DAD`(∞) does not solve consensus for two processes;
2. $\{$`DAD`(∞), `register`$\}$ solves consensus for N processes for any N.

From this and the known result that `register` does not solve consensus for two processes [4, 7, 14], it follows that $\text{PROP}_N(\texttt{DAD}(\infty), \texttt{register})$ is false for all $N \geq 2$.

1.3. Related results. Research relating the ability of a set of types to the abilities of the individual types in the set began with our work [11] and the work of Kleinberg and Mullainathan [12]. In [11], it is proved that the maximum number of processes for which $\{T, \texttt{register}\}$ solves consensus is reduced in general if any limit is imposed on the number of type T objects that may be used in the solution. Both [11] and [12] prove that the maximum number of processes for which a type T solves consensus is reduced in general if any limit is imposed on the number of type T objects that may be used in the solution. [11] also presents the result in this paper without proof.

Borowsky, Gafni, and Afek [2]; Peterson, Bazzi, and Neiger [16]; Chandra et al. [3] study the following question posed in [11]: If neither $\{T, \texttt{register}\}$ nor $\{T', \texttt{register}\}$ solves consensus for N processes, does it follow that $\{T, T', \texttt{register}\}$ does not solve consensus for N processes? For deterministic types T and T', [2] and [16] prove that the answer is yes. If types are nondeterministic and each process may bind to at most one "port" of each object, [3] proves that the answer is no in general. [3] also proves that if $\{T, \texttt{register}\}$ does not solve consensus for N processes, then $\{T, \texttt{register}, (N-1)-\texttt{consensus}\}$ does not solve consensus for N processes. Bazzi, Neiger, and Peterson prove that if either T is deterministic or T solves consensus for two processes, then the following holds: if T does not solve consensus for N processes then $\{T, \texttt{register}\}$ does not solve consensus for N processes [1]. Cori and Moran [5] prove a result similar to the one in [12].

2. Model and definitions.

2.1. Type. A *type* is a tuple (OP, RES, Q, δ), where OP is a set of operations, RES is a set of responses, Q is a set of states, and $\delta \subseteq Q \times OP \times Q \times RES$ is a relation known as the *sequential specification* of the type. Intuitively, if $(\sigma, op, \sigma', res) \in \delta$ it means the following: applying the operation op to an object in state σ can cause the object to move to state σ' and return the response res. δ is required to satisfy the following two properties.

1. *Totality.* For all $\sigma \in Q$ and $op \in OP$, there is at least one pair (σ', res) such that $(\sigma, op, \sigma', res) \in \delta$. (This condition ensures that it is legitimate to apply any operation in any state.)

2. *Computability.* There is a Turing machine M such that M halts on all inputs, and on input (σ, op) ($\sigma \in Q$, $op \in OP$), M computes at least one pair (σ', res) such that $(\sigma, op, \sigma', res) \in \delta$. (This condition ensures that a sequential implementation, one that is accessed by a single process, is feasible.)

A type is *deterministic* if, for all $\sigma \in Q$ and $op \in OP$, there is exactly one pair (σ', res) such that $(\sigma, op, \sigma', res) \in \delta$. Thus for deterministic types δ can be regarded as a function $\delta : Q \times OP \to Q \times RES$. A type is *nondeterministic* if it is not deterministic.

2.2. Concurrent system. We define a concurrent system informally. A formal definition, using I/O automata [15], was given in [9].

A *concurrent system* is specified by a finite set of processes $\{P_1, P_2, \ldots, P_N\}$ and a finite/infinite set of objects $\{O_1, O_2, \ldots\}$, where the following hold.

- Processes and objects have distinct names. (All names are known to all processes.)

• Each object has two attributes: a type and an initial value. (The initial value is a state of the object's type.)

• Each process is specified by a deterministic program. Some internal variables are distinguished as *input variables* and some are distinguished as write-once *output variables* (output variables are initialized to $\perp$). Each instruction of the program specifies which object to access, what operation to apply on the object, and how the object's response should alter the values of the internal variables of the program. We denote such a concurrent system as $(P_1, \ldots, P_N; O_1, O_2, \ldots)$.

A *configuration* of a concurrent system is a tuple of process and object states. Notice that the initial configuration is uniquely fixed by an assignment of values to input variables of processes. An *execution* of a concurrent system is a sequence $C_0, C_1, C_2, \ldots$ of configurations such that C_0 is an initial configuration, and C_{i+1} is the configuration that results when some process P executes a single instruction of its program in configuration C_i. We refer to the change of configuration from C_i to C_{i+1} as a *step* and associate this step with process P.

2.3. Consensus protocol. A *(binary) consensus protocol for processes* $P_1, \ldots, P_N$ is a concurrent system $(P_1, \ldots, P_N; O_1, O_2, \ldots)$, where each P_i has a binary input variable $proposal_i$ and an output variable $decision_i$ such that every infinite execution Σ has the following properties.

• *Wait-freedom.* If a process P_i has infinitely many steps in $\Sigma = C_0, C_1, C_2, \ldots$ then P_i *decides* in Σ; that is, there is a configuration C_k such that $decision_i$ has a non-$\perp$ value in C_k. (We refer to this non-$\perp$ value as P_i's *decision value* in Σ, and refer to the value of the input variable $proposal_i$ in C_0 as P_i's *proposal* in Σ.)

• *Agreement.* If P_i and P_j decide in Σ, then their decision values are the same.

• *Validity.* If P_i decides in Σ, then its decision value is the proposal of some process.

DEFINITION 2.1. *Let $\mathcal{S}$ be a set of types. We say $\mathcal{S}$* solves consensus for N processes *if there is a consensus protocol $(P_1, \ldots, P_N; O_1, O_2, \ldots)$ such that the type of each object O_i is in $\mathcal{S}$.*

DEFINITION 2.2. *We say $\mathcal{S}$* solves consensus for ∞ processes *if, for all $N \geq 1$, $\mathcal{S}$ solves consensus for N processes.*

We let CONSENSUS$(P_i, v_i, \mathcal{P})$ denote process P_i's program in consensus protocol $\mathcal{P}$ when P_i's proposal is v_i.

3. Specification of the type DAD(k). In this section we specify a family of types DAD(k), $k \in \{2, 3, 4, \ldots\} \cup \{\infty\}$. In the next two sections, we prove the following properties.[1]

1. For $k < \infty$, {DAD(k), `register`} solves consensus for k processes but not for $k + 1$ processes. {DAD(∞), `register`} solves consensus for ∞ processes.

2. For all $k \in \{2, 3, 4, \ldots\} \cup \{\infty\}$, DAD$(k)$ does not solve consensus for two processes.

The type DAD(k) is specified in Figure 1. In this specification, *choose*(S) is assumed to pick an element from set S nondeterministically and return it. Notice that the variables *upset* and *ahead*$[i]$ are stable: once true, they remain true. Similarly, once the variable *decision* assumes a binary value, its value does not subsequently change. The following is an informal description of DAD(k). This description is in-

[1] `DAD` stands for "disciplined-access demanding," a name that captures the fact that an object of this type does not return useful responses to processes unless processes show certain discipline in how they access the object.

S1. OP, the set of operations, is $\{\texttt{op}(0), \texttt{op}(1)\} \cup \{\texttt{give-decision}(i, b) \mid i \in \{0,1\}, b \in \{true, false\}\}$.

S2. RES, the set of responses, is $\{0, 1, ack\}$.
The response for $\texttt{op}(0)$ or $\texttt{op}(1)$ is always ack. The response for $\texttt{give-decision}(-,-)$ is either 0 or 1.

S3. Q, the set of states, is represented by the variables n_0, n_1, n_{gd} : `integer`; $decision \in \{\perp, 0, 1\}$; $ahead[0..1]$, $upset$: `boolean`. The state corresponding to ($n_0 = n_1 = n_{gd} = 0$; $decision = \perp$; $ahead[0..1] = upset =$ false) is known as the *fresh state*. The states of $\texttt{DAD}(k)$ are *only* those that are reachable from the fresh state by the sequential specification given in **S4**.

Informally, n_0, n_1, n_{gd} count the number of applications of $\texttt{op}(0)$, $\texttt{op}(1)$, and `give-decision`, respectively. The variable $ahead[i]$ is set to $true$ if $n_i > 0$ and $n_{\bar{i}} = 0$ when $\texttt{give-decision}(i, -)$ is applied. The variable $upset$ is set to $true$ if one of the following happens: (i) $\texttt{op}(1)$ is applied more than once ($\texttt{op}(0)$ may be applied any number of times), (ii) the total number of times that all $\texttt{give-decision}(-,-)$ operations are applied is more than k, (iii) $\texttt{give-decision}(i, -)$ is applied with no prior application of $\texttt{op}(i)$, (iv) $\texttt{give-decision}(i, true)$ is applied with no prior application of $\texttt{op}(\bar{i})$, (v) $\texttt{give-decision}(i,$ false) is applied and $ahead\ [\bar{i}] = true$. If upset, a $\texttt{DAD}(k)$ object returns 0 or 1 nondeterministically to an invocation of `give-decision`. If not upset, it sets $decision$ irrevocably and nondeterministically (if not already set) to 0 or 1 such that $n_{decision} > 0$, and returns $decision$.

S4. δ, the sequential specification, is described as follows:

```
op(i)                                   /*  i ∈ {0,1}  */
    n_i := n_i + 1
    if n_1 > 1 then upset := true
    return(ack)

give-decision(i, other-is-ahead)        /*  i ∈ {0,1},  other-is-ahead: boolean  */
    n_gd := n_gd + 1
    if (n_i > 0 ∧ n_ī = 0) then ahead[i] := true
    if (n_gd > k) ∨ (n_i = 0) ∨ (ahead[ī] ∧ ¬other-is-ahead) ∨ (n_ī = 0 ∧ other-is-ahead) then
        upset := true
    if upset then
        return(choose({0,1}))
    else if decision = ⊥ then
        decision := choose({j | n_j > 0})
    return(decision)
```

FIG. 1. *The type* $\texttt{DAD}(k)$.

tended only as an intuitive guide to, and not as a substitute for, the formal specification in Figure 1.

A $\texttt{DAD}(k)$ object supports three types of operations: $\texttt{op}(0)$, $\texttt{op}(1)$, and $\texttt{give-decision}(-,-)$. (The first parameter of `give-decision` is a 0 or 1, and the second parameter is either *true* or *false*.) The response to $\texttt{op}(0)$ or $\texttt{op}(1)$ is always *ack*. The response to $\texttt{give-decision}(-,-)$ is either 0 or 1. A $\texttt{DAD}(k)$ object requires that certain rules be observed in accessing it. If these rules are violated, the object becomes "upset." Once upset, the object remains upset forever. Below we explain (i) the conditions under which an object becomes upset and (ii) how an object computes the response (0 or 1) to a `give-decision` operation.

We say that $\texttt{op}(0)$ *is ahead of* $\texttt{op}(1)$ if, before $\texttt{op}(1)$ is applied for the first time, both $\texttt{op}(0)$ and $\texttt{give-decision}(0, -)$ are applied and are applied in that order. (It is not necessary that $\texttt{give-decision}(0, -)$ be applied immediately after $\texttt{op}(0)$). The definition of "$\texttt{op}(1)$ *is ahead of* $\texttt{op}(0)$" is symmetric. Notice that once the proposition "$\texttt{op}(i)$ is ahead of $\texttt{op}(\bar{i})$" becomes true, it remains true forever.

A DAD(k) object becomes upset if *any* of the following conditions is met. Furthermore, once upset, an object will remain upset forever.

1. op(1) is invoked more than once.

2. The total number of times that all give-decision($-,-$) operations are invoked is more than k.

3. For $i \in \{0,1\}$, give-decision($i,-$) is invoked, but op(i) has never been previously invoked (by any process).

4. For $i \in \{0,1\}$, give-decision(i, *false*) is invoked and op($\bar{i}$) is ahead of op(i).

5. For $i \in \{0,1\}$, give-decision(i, *true*) is invoked and op($\bar{i}$) has never been previously invoked (by any process).

Conditions 1 and 2 are easy to comprehend. Condition 3 states that op(i) must be invoked before give-decision($i,-$) can be invoked. Condition 4 states that if op($\bar{i}$) is ahead of op(i), then in any invocation of give-decision(i, *flag*), *flag* must be *true*. By itself, this condition is trivial to meet: whenever a process invokes give-decision($-,-$), it can always supply *true* as the second parameter. Condition 5 prevents processes from adopting such a trivial strategy. It states that if give-decision(i, *true*) is invoked, then it must be the case that op($\bar{i}$) has been previously invoked.

The operations op(0) and op(1) always get *ack* as their response. The response to an invocation INV of the give-decision operation is computed using the following rules *in the order they are specified*.

1. If the object was already upset or the current invocation INV upsets the object, the object returns 0 or 1 nondeterministically.

2. If some give-decision($-,-$) operation has previously completed and the object returned a response *res* to that operation, then the object returns *res*.

3. If op(0) has been previously invoked and op(1) has not been previously invoked, the object returns 0. Similarly, if op(1) has been previously invoked and op(0) has not been previously invoked, the object returns 1.

4. If op(0) and op(1) have both been previously invoked (and, because of rule 2, a give-decision operation has never been previously invoked), the object returns 0 or 1 nondeterministically.

The above is a complete set of rules. In particular, we do not need a rule 5 for the case when neither op(0) nor op(1) was previously invoked. This is because if neither op(0) nor op(1) was previously invoked, then the current invocation INV will upset the object, making rule 1 applicable.

The motivation for this involved specification is as follows. Consider the *name-consensus problem* for two processes P_0 and P_1 [9]. Informally, this problem requires two processes P_0 and P_1 to agree which, between them, is the winner. The nontriviality condition is that the winner must have taken at least one step. Consider the following protocol for this problem. Process P_i ($i \in \{0,1\}$) applies op(i) on $\mathcal{O}$, a DAD(k) object. P_i then applies give-decision(i, $flag_i$) on $\mathcal{O}$ (for some $flag_i$) and, if the response is j, it decides P_j to be the winner. This protocol is correct only if each process ensures that the second parameter $flag_i$ supplied while invoking give-decision does not upset $\mathcal{O}$. Thus, intuitively, DAD(k) objects are useful in solving consensus only if processes ensure that they do not upset these objects while accessing them. We have carefully specified DAD(k) so that, while solving consensus, processes can usefully access DAD(k) objects, without upsetting them, only when registers are also available. This will help us show that DAD(k) does not solve consensus but {DAD(k), register} does.

O_{dad}: DAD(k) object, initialized to the fresh state
R[0..1]: binary registers (arbitrarily initialized)
R'[0..1]: boolean registers, initialized to *false*

internal variables of process P_i
$proposal_i \in \{0, 1\}$
$decision_i \in \{\perp, 0, 1\}$, initialized to $\perp$
$d_i, winner_i \in \{0, 1\}$ (arbitrarily initialized)
$other\text{-}ahead_i$: boolean (arbitrarily initialized)

CONSENSUS($P_i, proposal_i, \mathcal{P}_n^k$) (for $1 \le i \le n-1$)

1. $d_i :=$ CONSENSUS($P_i, proposal_i, \mathcal{P}_{n-1}^k$)
2. $R[0] := d_i$
3. Apply(P_i, op(0), O_{dad})
4. $R'[0] := true$
5. $other\text{-}ahead_i := R'[1]$
6. $winner_i :=$ Apply(P_i, give-dec(0, $other\text{-}ahead_i$), O_{dad})
7. $decision_i := R[winner_i]$

CONSENSUS($P_n, proposal_n, \mathcal{P}_n^k$)

$d_n := proposal_n$
$R[1] := d_n$
Apply(P_n, op(1), O_{dad})
$R'[1] := true$
$other\text{-}ahead_n := R'[0]$
$winner_n :=$ Apply(P_n, give-dec(1, $other\text{-}ahead_n$), O_{dad})
$decision_n := R[winner_n]$

FIG. 2. $\mathcal{P}_n^k$, *consensus protocol for processes* $P_1, \ldots, P_n$.

4. {DAD(k), register} **solves consensus for** k **processes.** In this section, we exhibit a consensus protocol for k processes using only DAD(k) objects and registers. Our protocol is recursive. Let $\mathcal{P}_n^k$ ($n \le k$) denote a consensus protocol for processes $P_1, P_2, \ldots, P_n$ that uses only DAD(k) objects and registers. The base case is to derive $\mathcal{P}_1^k$, a consensus protocol for a single process P_1, and is trivial. The recursive step of deriving $\mathcal{P}_n^k$ from $\mathcal{P}_{n-1}^k$ (for all $n > 1$) is presented in Figure 2.

The protocol $\mathcal{P}_n^k$ works as follows. Processes $P_1 \ldots P_n$ split into two groups: G_0 and G_1. Group G_0 has $P_1 \ldots P_{n-1}$, and group G_1 has just P_n. Processes $P_1 \ldots P_{n-1}$ do consensus among themselves (recursively) and announce the outcome in $R[0]$. Process P_n announces its input value in $R[1]$. The rest of the protocol resolves which of the two groups is the winner. If G_0 wins, every process decides the value in $R[0]$. Similarly, if G_1 wins, every process decides the value in $R[1]$. The object O_{dad} is used to determine the winner of the two groups. Processes $P_1 \ldots P_{n-1}$ perform the operation op(0) on O_{dad}. Then they set the register $R'[0]$ to inform process P_n that op(0) has been applied on O_{dad}. Process P_n, on the other hand, performs op(1) on O_{dad}, and then sets $R'[1]$ to inform processes in G_0 that op(1) has been applied. Processes then perform the give-decision operation. The return value determines the winning group. For this strategy to work correctly, the arguments of the give-decision operation must be such that the object O_{dad} does not get upset. We urge the reader to understand how the registers $R'[0..1]$ are used to ensure that O_{dad} does not get upset. (This will be clear when we prove below that the protocol is correct.) Finally, if O_{dad} returns v, a process assumes that the group G_v won and decides the value in $R[v]$.

LEMMA 4.1. *For* $2 \le n \le k$, *the protocol* $\mathcal{P}_n^k$ *in Figure* 2 *is a correct consensus protocol for processes* $P_1, P_2, \ldots, P_n$.

Proof. The proof is by induction. Assume that $\mathcal{P}_{n-1}^k$ is correct. Consider an execution E of the consensus protocol $\mathcal{P}_n^k$ in Figure 2. The key claim is that O_{dad} does not get upset in E. This claim follows from the following simple observations.

1. op(1) is executed only once.

2. For $v \in \{0,1\}$, op(v) is executed before executing give-decision($v,-$).

3. The total number of times that all give-decision($-,-$) operations are executed is no more than n. Since $n \leq k$, the total number of times that all give-decision($-,-$) operations are executed is no more than k.

4. Suppose op(v) is ahead of op($\overline{v}$). That is, the operations op(v) and then give-decision($v,-$) are completed before the first invocation of op($\overline{v}$). Then the use of the registers $R'[0..1]$ in the protocol guarantees that when a process invokes give-decision($\overline{v}$, *other-ahead*), the second parameter, namely, *other-ahead*, is *true*.

5. Suppose no process completes the operation op(v) before some process invokes give-decision($\overline{v}$, *other-ahead*). Then the use of the registers $R'[0..1]$ in the protocol guarantees that the second parameter, namely, *other-ahead*, is *false*.

So far we have argued that O_{dad} is not upset, in E. Since O_{dad} is not upset, by the specification of DAD(k) we have the following.

1. Every give-decision operation on O_{dad} returns the same binary response. Let *winner* $\in \{0,1\}$ denote this response.

2. Some process P_j invokes op(*winner*) before O_{dad} returns *winner* for the first time to a give-decision operation.

From the protocol, it is clear that P_j writes the value d_j in $R[winner]$ before invoking op(*winner*). Furthermore, once a value is written by a process into a register $R[0]$ or $R[1]$, the value of that register never subsequently changes. For $R[0]$ this follows from the agreement property of $\mathcal{P}^k_{n-1}$, and for $R[1]$ this follows from the fact that only P_n writes $R[1]$ and writes it only once.

The above implies that, for all i, $1 \leq i \leq n$, CONSENSUS($P_i, proposal_i, \mathcal{P}^k_n$) returns d_j. Thus the protocol $\mathcal{P}^k_n$ satisfies agreement. If $j = n$, then $d_j = d_n = proposal_n$. If $j \neq n$, since $\mathcal{P}^k_{n-1}$ satisfies validity, $d_j \in \{proposal_1, proposal_2, \ldots, proposal_{n-1}\}$. Thus $\mathcal{P}^k_n$ satisfies validity. It is obvious that $\mathcal{P}^k_n$ is wait-free. This concludes the proof of correctness. □

COROLLARY 4.2. *For $k \in \{2,3,\ldots\} \cup \{\infty\}$, {DAD($k$), register} solves consensus for k processes.*

In fact, as the next lemma states, it is impossible to solve consensus for $k+1$ processes using only DAD(k) objects and registers. This lemma is however not essential for establishing our main result. The proof is therefore presented in the appendix.

LEMMA 4.3. *For $k < \infty$, {DAD(k), register} does not solve consensus for $k+1$ processes.*

Proof. It is proved by a standard bivalency argument. See the appendix. □

4.1. DAD(k) does not solve consensus for even two processes. In this section, we prove that it is impossible to solve consensus even between two processes if we may *only* use DAD(k) objects for process communication.

Impossibility results such as these are typically proved using bivalency arguments [8]. However, bivalency arguments did not appear helpful in proving this result. This is due to the fact that DAD(k) objects are not entirely powerless: after all, as we showed in the previous section, it is possible to solve consensus using DAD(k) objects if registers are also available. Our proof is based on exhibiting two indistinguishable scenarios in which processes are required to act differently. The nondeterminism of DAD(k) is exploited in keeping the scenarios indistinguishable. The details are rather involved since arguments concerning nondeterministic objects are subtle and warrant a careful treatment.

We begin with a simple lemma that will be useful later. The lemma states that it

op(i)	give-decision(i, b)

return(ack)	**if** $\sigma[decision] \in \{0,1\}$ **then**
	  return($\sigma[decision]$)
	else if $(\sigma[upset] \vee \sigma[n_0] > 0)$ **then**
	  return(0)
	else return(1)

FIG. 3. *Simulating the responses of a* DAD(k) *object whose initial state σ is a nonfresh state.*

is trivial to simulate the responses of a DAD(k) object whose initial state is not fresh. More specifically, if the initial state of a DAD(k) object O is not fresh, every process can determine the response from O to every operation locally, without invoking any operation on O or any other shared object. In the following, let $\sigma[v]$ denote the value of state variable v in state σ.

LEMMA 4.4. *Let σ be any state of* DAD(k) *different from the fresh state. Let $\mathcal{O}$ be a* DAD(k) *object whose initial state is σ. The responses from $\mathcal{O}$ to operations can be (trivially) simulated using the code in Figure* 3.

Proof. If σ is different from the fresh state, then it is easy to verify that $(\sigma[decision] \in \{0,1\}) \vee (\sigma[n_0] > 0) \vee (\sigma[n_1] > 0) \vee \sigma[upset]$. From this and the specification of DAD(k), it is obvious that the responses are correct. □

COROLLARY 4.5. *Suppose there is a consensus protocol $\mathcal{P} = (P_1, P_2; O_1, O_2, \ldots)$ where each O_i is a* DAD(k) *object. Then there is a consensus protocol $\mathcal{P}' = (P_1, P_2; O_1', O_2', \ldots)$ where each O_i' is a* DAD(k) *object initialized to the fresh state.*

Proof. The protocol $\mathcal{P}'$ is the same as $\mathcal{P}$ with one exception: if $\mathcal{P}$ employs O_i and O_i's initial state is not fresh, then $\mathcal{P}'$ does not employ O_i; instead, in $\mathcal{P}'$, each process determines the response of O_i locally, as described in the proof of Lemma 4.4. □

The next lemma states that it is impossible to solve consensus between two processes using only DAD(k) objects. The proof exploits the fact that DAD(k) objects are so weak that a process cannot use these objects to leave its "footprints" behind. Thus if a process P_0 runs to completion and decides a value before the second process P_1 even begins to run, P_1 cannot figure out that P_0 had already run and decided upon a value. This can cause P_1 to decide upon a value that is not consistent with the decision of P_0. The formal proof below elaborates this argument. However, the details are complex. We therefore present the proof in a series of easily verifiable claims.

At some places in the proof, we refer to the type det-DAD(k). The specification of det-DAD(k) is obtained by replacing every occurrence of "choose(S)" in Figure 1 by the function "min(S)." (min(S) is the minimum element in set S.) Notice that this modification makes det-DAD(k) a deterministic type.

LEMMA 4.6. *For all $k \in \{2, 3, \ldots\} \cup \{\infty\}$,* DAD($k$) *does not solve consensus for two processes.*

Proof. The proof is by contradiction. Let $(P_0, P_1; O_1, O_2, \ldots)$ be a consensus protocol $\mathcal{P}$, where each O_i is of type DAD(k). By Corollary 4.5, we can assume, without loss of generality, that the initial state of each O_i is fresh.

Recall our notation that CONSENSUS($P_i, v_i, \mathcal{P}$) denotes process P_i's program in protocol $\mathcal{P}$ when P_i's proposal is v_i. In the following, we present two scenarios, $\mathtt{S}_0$

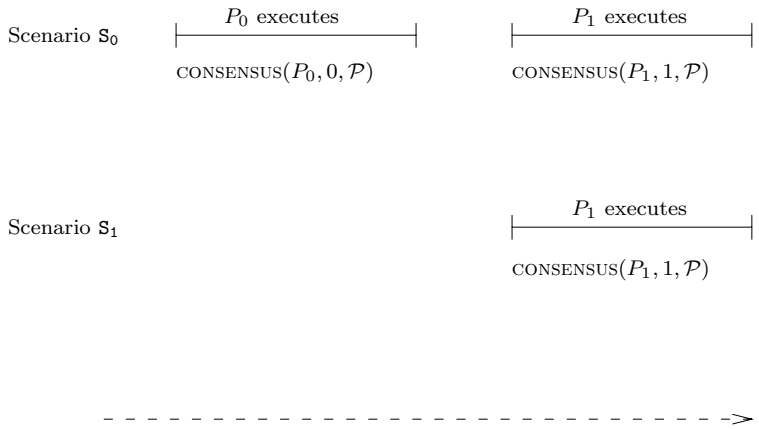

FIG. 4. *Scenarios* $\mathtt{S}_0$ *and* $\mathtt{S}_1$.

and $\mathtt{S}_1$, which are indistinguishable to P_1 but require P_1 to take different actions.

In Scenario $\mathtt{S}_0$, P_0 executes CONSENSUS$(P_0, 0, \mathcal{P})$ to completion. Assume that, during this execution of CONSENSUS$(P_0, 0, \mathcal{P})$, every object O_i $(i \geq 1)$ behaves like a $\mathtt{det\text{-}DAD}(k)$ object. We will refer to this as Assumption A1. Since $\mathcal{P}$ satisfies validity, at the completion of CONSENSUS$(P_0, 0, \mathcal{P})$, P_0 decides 0. Of $O_1, O_2, \ldots$ let $\mathcal{S}$ be the set of objects that are in the fresh state in scenario $\mathtt{S}_0$ at the completion of CONSENSUS$(P_0, 0, \mathcal{P})$.

We now do two things: (i) we continue scenario $\mathtt{S}_0$ by letting P_1 execute CONSENSUS$(P_1, 1, \mathcal{P})$, and (ii) we start a new scenario, call it scenario $\mathtt{S}_1$, by letting P_1 execute CONSENSUS$(P_1, 1, \mathcal{P})$. (See Figure 4 for a depiction of scenarios $\mathtt{S}_0$ and $\mathtt{S}_1$.) Assume that, in both scenarios, each object in $\mathcal{S}$ behaves deterministically, consistent with the type $\mathtt{det\text{-}DAD}(k)$. We will refer to this as Assumption A2.

We prove the following statement by induction on i: the objects in $\{O_1, O_2, \ldots\} - \mathcal{S}$ can choose among the nondeterministic alternatives (when applicable) such that for all $i \geq 0$, P_1 cannot distinguish scenario $\mathtt{S}_0$ from scenario $\mathtt{S}_1$ in its first i steps. The base case for $i = 0$ is trivial. To prove the induction step, assume the hypothesis for $i \leq m$.

Consider the $(m+1)$th step. Let *oper* be the operation that P_1 performs in this step in scenario $\mathtt{S}_0$, and let O be the object on which it performs *oper*. From the induction hypothesis and the fact that the protocol $\mathcal{P}$ is deterministic, it follows that P_1 performs *oper* on O in its $(m+1)$th step in scenario $\mathtt{S}_1$ also.

Suppose *oper* $\in \{\mathtt{op}(0), \mathtt{op}(1)\}$. Then the response is *ack* in either scenario. Thus $\mathtt{S}_0$ and $\mathtt{S}_1$ remain indistinguishable to P_1 after $m+1$ steps. Hence the induction step is proved.

Suppose instead that *oper* is $\mathtt{give\text{-}decision}(-,-)$. We make a case analysis to prove the induction step.

Case 0. $O \in \mathcal{S}$.

We claim that O is in the fresh state in both $\mathtt{S}_0$ and $\mathtt{S}_1$ just before P_1 begins executing CONSENSUS$(P_1, 1, \mathcal{P})$. For $\mathtt{S}_0$, this follows from the definition of $\mathcal{S}$; and for

$\mathtt{S}_1$, this follows from the fact that every object is initialized to the fresh state. By Assumption A2, O behaves deterministically (consistent with the type $\mathtt{det\text{-}DAD}(k)$) in both scenarios. The above facts, together with induction hypothesis, guarantee that O is in the same state in both scenarios at the end of m steps of P_1 and, therefore, O returns the same response to *oper* in both scenarios. Thus $\mathtt{S}_0$ and $\mathtt{S}_1$ remain indistinguishable to P_1 after $m+1$ steps. Hence the induction step is proved.

Case 1. Case 0 does not apply and the following holds: in at least one of $\mathtt{S}_0$ and $\mathtt{S}_1$, O is upset in the first $m+1$ steps of P_1.

Let $\mathtt{S}_i$ be a scenario in which O is upset in the first $m+1$ steps of P_1. By the specification of $\mathtt{DAD}(k)$, O is free to return 0 or 1 to *oper* in scenario $\mathtt{S}_i$. Suppose that O uses this freedom and returns the same response to *oper* in $\mathtt{S}_i$ as it does in $\mathtt{S}_{\overline{i}}$. Then $\mathtt{S}_0$ and $\mathtt{S}_1$ remain indistinguishable to P_1 after $m+1$ steps. Hence the induction step is proved.

Case 2. Neither Case 0 nor Case 1 applies. In other words, O is not in the fresh state in scenario $\mathtt{S}_0$ just before P_1 calls CONSENSUS$(P_1, 1, \mathcal{P})$ and, in both $\mathtt{S}_0$ and $\mathtt{S}_1$, O is not upset at the end of $m+1$ steps of P_1.

Our proof that the induction step holds for this case proceeds as follows. First, we make claims (C1 to C11 below) and show that the induction step holds if *any* of the claims is false. Then we show that if all of claims C1 to C11 are true, the induction step must hold.

Let σ_0^k and σ_1^k denote the state of O at the end of k steps of P_1 in scenarios $\mathtt{S}_0$ and $\mathtt{S}_1$, respectively.

C1. $\sigma_1^m[n_{gd}] = 0$.[2] In other words, P_1 does not apply a `give-decision` operation on O in its first m steps in scenario $\mathtt{S}_1$.

Suppose that the claim is false. Let $k \leq m$ be the smallest integer such that $\sigma_1^k[n_{gd}] = 1$. That is, `give-decision` is applied on O for the first time by P_1 in its kth step in scenario $\mathtt{S}_1$. Since O is not upset in $\mathtt{S}_1$, it follows that $\sigma_1^k[\mathit{decision}] \in \{0,1\}$, and this value is the response from O in the kth step of P_1 in scenario $\mathtt{S}_1$. Let $d = \sigma_1^k[\mathit{decision}]$. By inductive hypothesis, the response from O in the kth step of P_1 in scenario $\mathtt{S}_0$ is also d. Since O is not upset in scenario $\mathtt{S}_0$, this implies that $\sigma_0^k[\mathit{decision}] = d$. From the specification of $\mathtt{DAD}(k)$, it is clear that once the state variable *decision* assumes a non-$\perp$ value, its value does not subsequently change. Thus we have $\sigma_0^m[\mathit{decision}] = d$ and $\sigma_1^m[\mathit{decision}] = d$. From this and the fact that O is not upset in either scenario, we conclude that the response from O to *oper* is d in both scenarios. Thus $\mathtt{S}_0$ and $\mathtt{S}_1$ remain indistinguishable to P_1 after $m+1$ steps. Hence the induction step is proved.

C2. There is a $v \in \{0,1\}$ such that $\sigma_1^m[n_v] > 0$ and $\sigma_1^m[n_{\overline{v}}] = 0$. In other words, P_1 applies $\mathtt{op}(v)$ but not $\mathtt{op}(\overline{v})$ in its first m steps in $\mathtt{S}_1$. (This v is fixed in the remainder of this proof.)

Assume that the claim is false. Then either $\sigma_1^m[n_0] = \sigma_1^m[n_1] = 0$ or $\sigma_1^m[n_0] > 0$ and $\sigma_1^m[n_1] > 0$. Suppose $\sigma_1^m[n_0] = \sigma_1^m[n_1] = 0$. Then by the specification of $\mathtt{DAD}(k)$, when P_1 applies $\mathit{oper} \equiv \mathtt{give\text{-}decision}(-,-)$ in the $(m+1)$th step in $\mathtt{S}_1$, it upsets O. This contradicts the case we are considering.

Suppose $\sigma_1^m[n_0] > 0$ and $\sigma_1^m[n_1] > 0$. Since $\sigma_1^m[n_{gd}] = 0$ (by C1), by the specification of $\mathtt{DAD}(k)$, O is free to return either 0 or 1 in $\mathtt{S}_1$. Suppose that O uses this freedom and returns the same response to *oper* in $\mathtt{S}_1$ as it does in $\mathtt{S}_0$. Then $\mathtt{S}_0$ and $\mathtt{S}_1$ remain indistinguishable to P_1 after $m+1$ steps. Thus the induction step holds.

[2]Recall our notation that $\sigma[v]$ denotes the value of the state variable v in state σ.

C3. P_1 applies $\texttt{op}(v)$ on O at least once in its first m steps in $\texttt{S}_0$.

This claim follows from C2 and the induction hypothesis.

C4. $oper \equiv \texttt{give-decision}(v, false)$.

Suppose $oper \equiv \texttt{give-decision}(\overline{v}, -)$ or $oper \equiv \texttt{give-decision}(v, true)$. Since $\sigma_1^m[n_{\overline{v}}] = 0$ (by C2), O will be upset in $\texttt{S}_1$ when *oper* is invoked in the $(m+1)$th step. This contradicts the case we are considering.

So far we made the following claims for the case in consideration (Case 2): there is some $v \in \{0, 1\}$ such that, in both $\texttt{S}_0$ and $\texttt{S}_1$, P_1 applies $\texttt{op}(v)$ on O but not $\texttt{op}(\overline{v})$ in its first m steps and applies $\texttt{give-decision}(v, \text{false})$ in its $(m+1)$th step.

C5. $\sigma_0^m[ahead[\overline{v}]] = false$.

Suppose $\sigma_0^m[ahead[\overline{v}]] = true$. Then when P_1 applies $oper \equiv \texttt{give-decision}(v, \text{false})$ (guaranteed by C4) in its $(m+1)$th step in $\texttt{S}_0$, it upsets O. This contradicts the case we are considering.

C6. $v = 1$ implies $\sigma_0^0[n_{gd}] = 0$. In other words, if $v = 1$, then P_0 never applied a `give-decision` operation on O in $\texttt{S}_0$.

Suppose $v = 1$ and P_0 applied $\texttt{give-decision}(1, -)$ on O in $\texttt{S}_0$. Since O is not upset in $\texttt{S}_0$, it follows that P_0 applied $\texttt{op}(1)$ on O before applying $\texttt{give-decision}(1, -)$. By C3 and the assumption that $v = 1$, P_1 applied $\texttt{op}(1)$ in $\texttt{S}_0$. Thus $\texttt{op}(1)$ was applied at least twice on O in $\texttt{S}_0$. By the specification of $\texttt{DAD}(k)$, O would be upset in $\texttt{S}_0$. This contradicts the case we are considering.

Suppose $v = 1$ and P_0 applied $\texttt{give-decision}(0, -)$ on O in $\texttt{S}_0$. Since O is not upset in $\texttt{S}_0$, it follows that P_0 applied $\texttt{op}(0)$ on O before applying $\texttt{give-decision}(0, -)$. By C5 and the assumption that $v = 1$, $\sigma_0^m[ahead[0]] =$ false. This implies that P_0 applied $\texttt{op}(1)$ on O before applying $\texttt{give-decision}(0, -)$. By C3 and the assumption that $v = 1$, P_1 applied $\texttt{op}(1)$ in $\texttt{S}_0$. Thus $\texttt{op}(1)$ was applied at least twice on O in $\texttt{S}_0$. By the specification of $\texttt{DAD}(k)$, O would be upset in $\texttt{S}_0$. This contradicts the case we are considering.

C7. $v = 0$.

Suppose $v = 1$. Then we can infer the following: (1) $\sigma_1^m[n_{gd}] = 0$ (by C1); (2) $\sigma_0^m[n_{gd}] = 0$ (by C1, induction hypothesis, and C6); (3) $\sigma_1^m[n_1] > 0$ (by C2); (4) $\sigma_0^m[n_1] > 0$ (by C3). These four facts, together with the specification of $\texttt{DAD}(k)$, imply that O is free to return 1 to *oper* in both $\texttt{S}_0$ and $\texttt{S}_1$. Suppose that O does this. Then $\texttt{S}_0$ and $\texttt{S}_1$ remain indistinguishable to P_1 after $m+1$ steps. Thus the induction step holds.

The claims made so far assert that, in both $\texttt{S}_0$ and $\texttt{S}_1$, P_1 applies $\texttt{op}(0)$ on O, but not $\texttt{op}(1)$, in its first m steps, and applies $\texttt{give-decision}(0, \text{false})$ in its $(m+1)$th step. Furthermore, $\texttt{op}(1)$ is not ahead of $\texttt{op}(0)$ in scenario $\texttt{S}_0$.

C8. O returns 0 to *oper* (in the $(m+1)$th step of P_1) in scenario $\texttt{S}_1$.

Claims C2 and C7 imply that $\sigma_1^m[n_0] > 0$ and $\sigma_1^m[n_1] = 0$. Further, by the case we are considering, O is not upset in the first $m+1$ steps of P_1 in scenario $\texttt{S}_1$. The above facts imply that the only legal response that O can return to *oper* is 0.

C9. If P_0 applied $\texttt{give-decision}(1, -)$ on O (in $\texttt{S}_0$), it did so only after applying $\texttt{op}(0)$ on O.

Suppose P_0 applied $\texttt{give-decision}(1, -)$ on O (in scenario $\texttt{S}_0$). Since O is not upset in $\texttt{S}_0$, this implies that P_0 applied $\texttt{op}(1)$ on O before applying $\texttt{give-decision}(1, -)$. If P_0 did not apply $\texttt{op}(0)$ before applying `give-`

`decision`$(1,-)$, then this application of `give-decision`$(1,-)$ would set $ahead[1]$ to *true*. This, together with the fact that $ahead[1]$ is stable, implies that $\sigma_0^m[ahead[1]] = true$. This contradicts the conjunction of C5 and C7.

C10. Every application of the operation `give-decision`$(-,-)$ on O by P_0 in scenario $\mathtt{S}_0$ gets the response 0.

Consider the earliest application e of `give-decision`$(w,-)$ on O by P_0 in $\mathtt{S}_0$. If $w = 1$, C9 implies that P_0 applies `op`(0) before e. If $w = 0$, the fact that O is not upset in $\mathtt{S}_0$ implies that P_0 applies `op`(0) before e. Thus we conclude that P_0 applies `op`(0) before e. This, together with Assumption A1, implies that e returns 0. From this and the fact that O is not upset in $\mathtt{S}_0$, it follows that every application of `give-decision`$(-,-)$ on O in $\mathtt{S}_0$ returns the response 0.

C11. P_0 never applies `give-decision`$(-,-)$ on O (in $\mathtt{S}_0$).

Suppose that the claim is false. Then, from C10 and the fact that O is not upset in $\mathtt{S}_0$, it follows that O returns 0 to *oper* in the $(m+1)$th step of P_1 in scenario $\mathtt{S}_0$. Thus, by C8, $\mathtt{S}_0$ and $\mathtt{S}_1$ remain indistinguishable to P_1 after $m+1$ steps. Hence the induction step is proved.

From the above claims we deduce the following facts: (F1) $\sigma_1^m[n_0] > 0$. This follows from C2 and C7. (F2) $\sigma_0^m[n_0] > 0$. This follows from F1 and induction hypothesis. (F3) $\sigma_0^m[n_{gd}] = 0$. This follows from C1, induction hypothesis, and C11. From F2, F3, and the specification of `DAD`(k), it is clear that O is free to return 0 to *oper* (in the $(m+1)$th step of P_1) in scenario $\mathtt{S}_0$. Suppose that it does. Then, by C8, $\mathtt{S}_0$ and $\mathtt{S}_1$ remain indistinguishable to P_1 after $m+1$ steps. Thus the induction step holds. This completes the proof of the induction step for Case 2.

We have proved the induction step for all cases. We therefore conclude that no matter how many steps P_1 takes, scenarios $\mathtt{S}_0$ and $\mathtt{S}_1$ can remain indistinguishable to P_1.

Since $\mathcal{P}$ is a wait-free protocol, CONSENSUS$(P_1, 1, \mathcal{P})$ terminates in $\mathtt{S}_0$ after a finite number of steps, with P_1 deciding some value $val \in \{0,1\}$. Since $\mathtt{S}_0$ and $\mathtt{S}_1$ are indistinguishable to P_1, CONSENSUS$(P_1, 1, \mathcal{P})$ terminates in $\mathtt{S}_1$ after exactly the same number of steps, with P_1 deciding val. If $val = 0$, the protocol does not satisfy the validity property in $\mathtt{S}_1$. If $val = 1$, the protocol does not satisfy the agreement property in $\mathtt{S}_0$. Thus $\mathcal{P}$ is not a correct consensus protocol. This completes the proof of the lemma. □

We conclude this section with some observations on Lemma 4.6 and its proof above. Nondeterminism occurs at two different places in the specification of `DAD`(k)(see the *choose* statement on lines 6 and 8 of the `give-decision` procedure in Figure 1). The proof of Lemma 4.6 exploits both occurrences, the first occurrence in proving the induction step for Case 1 and the second occurrence in proving the induction step for Case 2 (see the proofs of claims C2 and C7 and the conclusion of Case 2).

Is it possible to eliminate *either* occurrence of nondeterminism from the specification of `DAD`(k) and still prove Lemma 4.6? The answer appears to be no. Specifically, if either occurrence of the *choose* function is replaced with the deterministic function min (or max), it can be shown that Lemma 4.6 does not hold.

Lemma 4.6 states that the binary consensus problem for two processes is not solvable using `DAD`(k) objects. It is easy to show that binary consensus for N processes is solvable using objects of type T if and only if name-consensus for N processes is solvable using objects of type T. (The name-consensus problem is described earlier in section 3.) It follows that the name-consensus problem for two processes is also not solvable using `DAD`(k) objects alone.

5. The main theorem and conclusion. Recall from section 1.2 the property PROP$_N$ defined for pairs of types. From Lemma 4.6, Corollary 4.2, and the fact that `register` does not solve consensus for two processes [4, 7, 14], we conclude that, for $N \geq 2$, PROP$_N$(`DAD`(∞), `register`) is false. Thus we have Theorem 5.1.

THEOREM 5.1. *For $N \geq 2$,* PROP$_N$ *is not a property of all types.*

The type `DAD`(∞), which we have used to prove the above theorem, is nondeterministic. It is natural to ask if there are deterministic types T and T' for which PROP$_N(T, T')$ is false (for some N). Interestingly, the answer is negative. This follows from two recent results, as we explain below.

For all deterministic types T, T' and for all $N \geq 2$, if neither $\{T,$ `register`$\}$ nor $\{T',$ `register`$\}$ solves consensus for N processes, then $\{T, T',$ `register`$\}$ does not solve consensus for N processes [2, 16]. For all types T, if T is deterministic or T solves consensus for two processes, the following is true: if T does not solve consensus for N processes (for some N), then $\{T,$ `register`$\}$ does not solve consensus for N processes [1]. Together, these two results have the following straightforward implications.

1. If PROP$_N(T, T')$ is false, then at least one of T and T' is nondeterministic.
2. If PROP$_N(T, T')$ is false and one of T and T' is `register`, then the other type does not solve consensus for two processes.

Thus it is not surprising that the type `DAD`(∞) identified in this paper both is nondeterministic and does not solve consensus for two processes.

Appendix A. We prove that it is impossible to solve consensus for $k+1$ processes using only `DAD`(k) objects and registers. This impossibility result follows from a straightforward bivalency argument. The intuition behind why consensus is impossible for $k+1$ processes, but not for k processes, is as follows. As we have seen, a `DAD`(k) object supports two kinds of operations: `op` and `give-decision`. The operation `op`(i) does not return any useful information to the invoking process. This is due to the fact that the response of `op`(i) is always *ack*. The operation `give-decision` does return useful information but only to the first k invocations of the operation. Thereafter, its response is nondeterministic and hence is not helpful. Thus k processes may gain useful information from a `DAD`(k) object but $k+1$ processes cannot. We now proceed to give a formal proof of impossibility.

Let `det-DAD`(k) be the type obtained by replacing every occurrence of "choose(S)" in Figure 1 by the function "min(S)." (min(S) is the minimum element in set S.) Thus `det-DAD`(k) is a deterministic restriction of `DAD`(k). We prove below that `det-DAD`(k) objects and registers do not suffice to solve consensus for $k+1$ processes. This trivially implies that `DAD`(k) objects and registers do not suffice to solve consensus for $k+1$ processes.

As mentioned, the proof uses a simple bivalency argument. Since bivalency arguments are standard, our definitions and the proof are informal. A configuration C of a consensus protocol is *v-valent* (for $v \in \{0, 1\}$) if there is no execution from C in which $\overline{v}$ is decided upon by some process. In other words, once the protocol is in configuration C, no matter how processes are scheduled, no process decides $\overline{v}$. A configuration is *monovalent* if it is either 0-valent or 1-valent. A configuration is *bivalent* if it is not monovalent. If E is a finite execution of a consensus protocol $\mathcal{P}$ started in configuration C, $E(C)$ denotes the configuration at the end of the execution E.

LEMMA A.1. *For all $k \in \{2, 3, \ldots\}$,* $\{$`det-DAD`(k), `register`$\}$ *does not solve consensus for $k+1$ processes.*

Proof. Suppose that there is a consensus protocol $\mathcal{P} = (P_1, \ldots, P_{k+1}; O_1, O_2, \ldots)$, where each O_i is either a `det-DAD`(k) object or a register. Let C_0 be an initial configuration of $\mathcal{P}$ such that, for some processes P_l and P_m, $proposal_l = 0$ and $proposal_m = 1$.

When P_l runs by itself from C_0, the validity and the wait-freedom properties of $\mathcal{P}$ require that P_l decides $proposal_l = 0$. Similarly, when P_m runs by itself from C_0, it decides $proposal_m = 1$. Thus C_0 is bivalent. Let E be a finite execution from C_0 such that (1) $C_{crit} = E(C_0)$ is bivalent; and (2) for all P_i, if P_i takes a step from C_{crit}, the resulting configuration is monovalent. (If such E does not exist, it is easy to see that there is an infinite execution E' in which no process decides. Thus some process takes infinitely many steps in E' without deciding, contradicting the fact that $\mathcal{P}$ is a wait-free protocol.) Let S_v be the set of processes whose step from C_{crit} results in a v-valent configuration. Since C_{crit} is bivalent, neither S_0 nor S_1 is empty. Furthermore, $S_0 \cap S_1 = \emptyset$ and $|S_0 \cup S_1| = k + 1 \geq 3$ (since $k \geq 2$). Without loss of generality, assume that $|S_0| \geq 2$ and $|S_1| \geq 1$. In particular, let $S_0 = \{P_1^0, P_2^0, \ldots, P_r^0\}$ and $S_1 = \{P_1^1, P_2^1, \ldots, P_s^1\}$, where $r \geq 2$ and $s \geq 1$.

By a standard argument, the enabled step of every process in configuration C_{crit} must be on the same object O. Furthermore, again by a standard argument, O is not a register. Thus the enabled step of every process in configuration C_{crit} is on O, an object of type `det-DAD`(k). Let s_2^0 and s_1^1 denote the enabled steps of P_2^0 and P_1^1, respectively, in configuration C_{crit}. Consider the following scenarios $\mathtt{S_0}$ and $\mathtt{S_1}$, each starting from the configuration C_{crit}.

- In scenario $\mathtt{S_0}$, P_2^0 takes the step s_2^0. Then P_1^1 takes a step. Let D_0 be the resulting configuration. Clearly D_0 is a 0-valent configuration.
- In scenario $\mathtt{S_1}$, P_1^1 takes the step s_1^1. Then P_2^0 takes a step. Let D_1 be the resulting configuration. Clearly D_1 is a 1-valent configuration.

Processes P_2^0 and P_1^1 have to distinguish scenario $\mathtt{S_0}$ from scenario $\mathtt{S_1}$, since they must decide 0 in (every extension of) $\mathtt{S_0}$, and decide 1 in (every extension of) $\mathtt{S_1}$. Observe that unless the operation applied by P_2^0 (resp., P_1^1) in step s_2^0 (resp., s_1^1) is a `give-decision` operation, it must eventually apply a `give-decision` operation on O in order to distinguish $\mathtt{S_0}$ from $\mathtt{S_1}$. Thus we extend scenarios $\mathtt{S_0}$ and $\mathtt{S_1}$, currently in configurations D_0 and D_1, respectively, as follows.

1. First, if the operation applied by P_2^0 on O in step s_2^0 is not a `give-decision` operation, run P_2^0 (in both scenarios) exactly until P_2^0 completes a step in which it applies a `give-decision` operation on O.
2. Then if the operation applied by P_1^1 on O in step s_1^1 is not a `give-decision` operation, run P_1^1 (in both scenarios) exactly until P_1^1 completes a step in which it applies a `give-decision` operation on O.

A process $P \in \{P_1, \ldots, P_{k+1}\} - \{P_1^0, P_2^0, P_1^1\}$ has to distinguish scenario $\mathtt{S_0}$ from scenario $\mathtt{S_1}$, since P must decide 0 in (every extension of) $\mathtt{S_0}$, and decide 1 in (every extension of) $\mathtt{S_1}$. Observe, however, that P cannot distinguish $\mathtt{S_0}$ from $\mathtt{S_1}$ until it applies a `give-decision` operation on O. Thus we extend scenarios $\mathtt{S_0}$ and $\mathtt{S_1}$ as follows.

- For each $P \in \{P_1, \ldots, P_{k+1}\} - \{P_1^0, P_2^0, P_1^1\}$, run P (in both scenarios) exactly until P completes a step in which it applies a `give-decision` operation on O.

We make the following observations: (1) the process P_1^0 is in the same state in scenarios $\mathtt{S_0}$ and $\mathtt{S_1}$; (2) every object except O is in the same state in $\mathtt{S_0}$ and $\mathtt{S_1}$; (3) in both $\mathtt{S_0}$ and $\mathtt{S_1}$, a `give-decision` operation is applied on O at least k times (once by each process in $\{P_1, \ldots, P_{k+1}\} - \{P_1^0\}$). The third observation, together with the

specification of det-DAD(k), implies that every subsequent give-decision operation on O returns 0 in either scenario. Extend scenarios $\mathtt{S}_0$ and $\mathtt{S}_1$ by letting P_1^0 run by itself. By the above observations, P_1^0 cannot distinguish $\mathtt{S}_0$ from $\mathtt{S}_1$, no matter how many steps it takes. Yet it must decide 0 in $\mathtt{S}_0$, and 1 in $\mathtt{S}_1$. This is impossible. Hence the lemma is proved. □

A LOWER BOUND FOR INTEGER MULTIPLICATION WITH READ-ONCE BRANCHING PROGRAMS*

STEPHEN PONZIO†

Abstract. We prove that read-once branching programs computing integer multiplication require size $2^{\Omega(\sqrt{n})}$. This is the first nontrivial lower bound for multiplication on branching programs that are not oblivious. By the appropriate problem reductions, we obtain the same lower bound for other arithmetic functions.

Key words. multiplication, read-once, branching programs, BDD, verification

1. Introduction and background.

It is well known that many functions, some of them very simple, cannot be computed by read-once branching programs of polynomial size [We88, Za84, Du85, We87, BHST87, Ju88, Kr88]. Interest in whether integer multiplication can be so computed has been created by recent developments in the field of digital design and hardware verification.

1.1. Hardware verification and branching programs.

The central problem of verification is to check whether a combinational hardware circuit has been correctly designed. One approach to verification often employed today is to independently convert both the circuit description and the function specification to a common intermediate representation and then test whether the two representations are equivalent (e.g., [We94]). The use of restricted branching programs as the intermediate representation has made this approach feasible and very popular—several software packages are available for implementing this very strategy [Kr94, Br92].

DEFINITION 1. *A* branching program *is a directed acyclic graph with a distinguished root node and two sink nodes. The sink nodes are labeled* 1 *and* 0 *and each nonsink node is labeled with an input variable* x_i, $i \in \{1, \ldots, n\}$, *and has two outgoing edges labeled* 0 *and* 1.

A branching program computes a Boolean function $f : \{0,1\}^n \to \{0,1\}$ in the natural manner: each assignment of Boolean values to the variables x_i defines a unique path through the graph from the root to one of the sinks; the label of that sink defines the value of the function on that input. The *size* of a branching program is its number of nodes.

The hardware circuit to be verified is assumed to be an ordinary combinational single-output circuit, built up from a standard basis of Boolean functions such as $\{\wedge, \vee, \neg\}$. The typical algorithm for constructing the intermediate representation from the circuit is to work bottom-up through the circuit, from the inputs to the output, combining the representations appropriately at each gate. Thus, the algorithm need only compute a representation for $f \wedge g$, $f \vee g$, and $\neg f$, when given representations for f and g. In the literature, these are called the "synthesis operations."

1.2. Ordered binary decision diagrams (OBDDs) and multiplication. Because it is NP-complete to determine whether two general branching programs are equivalent, the intermediate representation is chosen to be a restricted class of branching programs for which both the synthesis operations and the equivalence test are tractable.[1] The chosen class, which has led to the success of this verification technique, is *oblivious read-once* branching programs also known as *ordered binary decision diagrams*, or *OBDDs*.

DEFINITION 2. *A branching program is* read-once *if on every path from the source to a sink, each variable appears at most once as the label of a vertex.*

DEFINITION 3. *A branching program is* oblivious *if on every path from the source to a sink, the variables appear in the same order.*

Thus, any oblivious branching program may be leveled so that all nodes at a given level are labelled with the same variable. An OBDD will have n levels, with a variable ordering that is a permutation of the variables.

It is easy to verify that two OBDDs obeying the same ordering of the variables are easily tested for equivalence: Construct an OBDD to compute their exclusive-or using standard finite automata product constructions for conjunction and disjunction; then test for a path from source to sink. (In general, there do not exist polynomial-size constructions for conjunction and disjunction if the two OBDDs do not obey the same ordering—see section 1.4.)

Although OBDDs are easily manipulated, they are clearly a very weak model of computation. For the purposes of hardware verification, however, they are usually powerful enough: OBDDs can compute in polynomial size integer addition, symmetric Boolean functions, and many of the benchmark functions [BF85] used by the verification community. But multiplication is a very important exception—for this function Byrant [Br91] proved that exponential size is required.

DEFINITION 4. Integer multiplication *is the Boolean function* $\mathbf{MULT} : \{0,1\}^{2n} \to \{0,1\}$ *that computes the middle bit in the product of two* n*-bit integers. That is,* $\mathbf{MULT}(x,y) = z_{n-1}$ *where* $x = x_{n-1}\cdots x_0$ *and* $y = y_{n-1}\cdots y_0$ *and* $xy = z = z_{2n-1}\cdots z_0$.

(The middle bit is the "hardest" bit, in the sense that if it can be computed by read-once branching programs (or circuits, etc.) of size $s(n)$, then any other bit can be computed with size at most $s(2n)$.) This is a serious limitation to the usefulness of OBDDs, since the hardware to be tested typically contains circuits that perform multiplication. Today, the largest multipliers that can be checked using this method have 12-bit inputs; ideally, circuit designers would like to check multipliers of 32 or even 64 bits.

1.3. Other oblivious models: Extensions to OBDDs. Thus, despite the success of this approach, there has also been great effort expended to find another model that is likewise manipulated but with greater computational power [SDG94, SW95, e.g.]. For example, the various extensions to OBDDs that have been considered include

- "k-OBDDs," where the variable ordering is a single permutation repeated k times consecutively [BSSW93, BHR95, Kr91];

[1] Of course efficient (polynomial time) algorithms for the individual synthesis operations do not imply that the resulting bottom-up algorithm for computing a representation is efficient. Despite this problem, researchers have been content with the bottom-up algorithm as long as each synthesis operation can be performed efficiently.

- "k-IBDDs," where the variable ordering is k consecutive permutations, possibly different [JABFA92, BSSW95];
- OBDDs with various kinds of nondeterministic branching nodes ($\vee$-nodes, $\wedge$-nodes, $\oplus$-nodes) [Me89, SDG94, Ge94, and others].

Recently proposed alternative models include "graph-driven BDDs" [SW95] and "binary moment diagrams" [BC94]. The latter are not branching programs and do not *compute* a function, but they do allow polynomial-size representation of multiplication. Also, in [AM88] lower bounds are proved for any oblivious programs of linear length, regardless of the order in which variables are read.

From the proof of Bryant's lower bound for OBDDs [Br91], it follows by a simple communication complexity argument that **Mult** cannot be computed in polynomial-size by k-OBDDs [Kr91, BSSW93] or the various nondeterministic OBDDs [Ge94]. Incorporating results from [AM88], [Ge94] extends the lower bound to arbitrary linear-length oblivious programs. Indeed, all of these oblivious models have been found too weak to compute **Mult** in polynomial size. It is therefore natural to consider *nonoblivious* programs, the simplest of these being read-once programs.

1.4. Nonoblivious programs. Unfortunately, (nonoblivious) read-once programs are not as easily manipulated as OBDDs. It is not known how to test equivalence in polynomial time, though there is a randomized (co-RP) algorithm [BCW80]. (There is also a deterministic algorithm to test the equivalence of an OBDD and a read-once program [FHS78].) Moreover, the synthesis operations are *provably intractable*—there exist functions f and g that each have polynomial-size read-once programs but whose conjunction $f \wedge g$ requires exponential-size read-once programs. For example, determining whether a $0,1$-matrix is a permutation matrix requires exponential-size read-once programs (even nondeterministic) [KMW91], whereas the rowwise and columnwise criteria (that each has one 1) are each computable with small OBDDs. Despite their relative recalcitrance, read-once programs have been considered by some researchers for possible use in hardware verification [GM94]. Very little was known about the complexity of multiplication.

There has been great success in proving lower bounds on the size of read-once programs, even for some very simple functions [Ma76, Du85, Za84, We87, SS93]. For example, it was proved in [Za84] (see also [We87]) that determining whether a graph on n nodes is an $n/2$-clique (with no further edges) requires size $2^{\Omega(n)}$. Until the time of this writing, the only asymptotically optimal lower bound was found in [BHST87], which proves a bound of $2^{\Omega(n^2)}$ for computing the parity of the number of triangles in a graph on n nodes. Very recently, Savicky and Zak [SZ96] proved a lower bound of $2^{n-3\sqrt{n}}$, the best to date. Exponential lower bounds for explicit functions have also been proved for nondeterministic read-once branching programs [Ju89, KMW91, BRS93]. Lower bounds for read-k-times programs (where each variable appears at most k times on each path)[2] are proved in [Ok91, BRS93, Ju92].

1.5. The decision problem. Although it is not directly related to the issue of verification, another Boolean function that has been considered is the decision problem $\textbf{Dmult}(x, y, z) = 1$ if $xy = z$. Note that it is not readily apparent which problem is "harder", **Mult** or **Dmult**: On the one hand, **Dmult** seems to require

[2]These are often called "syntactic" read-k-times, an apparently (though not proven) more severe restriction than "semantic" read-k-times where the limitation applies only to paths from source to sink that are traversed by some input—that is, paths that contain no contradictory literals along them. No superpolynomial bounds are known for semantic read-k-times programs for any $k \geq 2$.

practically computing all the bits of xy; however, an algorithm for **DMULT** has the advantage of inspecting all the bits of z, the putative product. (An easy reduction in [FSS84] shows **MULT** $\notin$ AC^0, but is was not until [Bu92] that **DMULT** $\notin$ AC^0 was proved.)

A simple argument [We94] shows that computing **DMULT** with read-once programs is as hard as factoring: To factor a given integer n, instantiate it as z in the read-once branching program and construct a factor by instantiating the bits of x one at a time, maintaining the satisfiability (source-to-sink connectivity) of the branching program. Jukna [Ju94] proves a lower bound of $2^{n^{1/4}/k^{2k}}$ for **DMULT** on nondeterministic read-k-times branching programs, but this does not yield results for **MULT**.

1.6. Our results. In this paper, we prove that any read-once branching programs for **MULT** have size $2^{\Omega(\sqrt{n})}$. This is the first superpolynomial lower bound for multiplication on nonoblivious branching programs.

We begin by describing in section 2 a paradigm for read-once lower bounds, recognized and distilled by Simon and Szegedy [SS93], in Lemma 1. For ease of presentation we first prove a lower bound of $2^{\Omega(\sqrt[3]{n})}$ in section 3 and then extend the proof to achieve $2^{\Omega(\sqrt{n})}$ in section 4. In section 5, we define *read-once reductions*[3] in order to deduce similar lower bounds for other arithmetic functions.

2. A paradigm for read-once lower bounds. Let f be a Boolean function, $f : \{0,1\}^n \to \{0,1\}$, and let $X = \{x_0, \ldots, x_{n-1}\}$ be its n binary input variables. Let $\mathcal{F}$ be a filter on X. (That is, $\mathcal{F} \subseteq 2^X$ and $\mathcal{F}$ is closed upward—if $S \in \mathcal{F}$, then all supersets of S are in $\mathcal{F}$.)[4] The filter $\mathcal{F}$ gives us a way of partitioning 2^X into "large" sets (in $\mathcal{F}$) and "small" sets (not in $\mathcal{F}$). A subset $B \subset X$ is said to be in the *boundary* of $\mathcal{F}$ if $B \notin \mathcal{F}$ but $B \cup \{x_i\} \in \mathcal{F}$ for some x_i. By setting the values of $\overline{B} = X \setminus B$, we naturally induce a function on B, the unset bits of X. The lemma is stated below in the form we will need it; it appears in [SS93] in slightly more generalized form.

LEMMA 1 (see [SS93]). *If for any B in the boundary of $\mathcal{F}$ at most $2^{|\overline{B}|}/L$ settings to $\overline{B}$ induce the same subfunction on B, then any read-once branching program computing f has size at least L.*

For completeness, we now provide a proof of this lemma.

Proof. The idea is that $\mathcal{F}$ defines a "frontier" of edges in the branching program—a cut containing exactly one edge from each source-to-sink path—in which every edge allows only a fraction $1/L$ of the inputs in $\{0,1\}^n$ to pass through it. Since the path of every input passes through some frontier edge, there must be at least L such edges. Having fan-out 2 and only one root, the program also has at least L nodes (the frontier edges lead to the leaves of an embedded binary tree which has $L-1$ distinct internal nodes, not counting the two sinks of the program).

In order to define the frontier, we first associate with each node of the program the set of variables appearing in the subprogram rooted there—that is, those variables appearing on nodes that are reachable from the given node. Clearly, moving down any path, the variable-sets of later nodes are subsets of the variable-sets of earlier nodes. The frontier is defined to be those edges leading from nodes with "large" sets of variables to nodes with "small" sets. "Large" sets are those that are in the filter $\mathcal{F}$ and "small" are not. Clearly there is exactly one frontier edge on each source-to-sink path, since the root has the variable-set $X \in \mathcal{F}$ (assuming f depends on all variables)

[3] Similar reductions have recently been considered also in [BW95].

[4] This differs from the usual definition of *filter* for infinite sets because we do not require that $(S \in \mathcal{F}) \wedge (T \in \mathcal{F}) \Longrightarrow (S \cap T) \in \mathcal{F}$.

and the sinks have the variable-set $\emptyset \notin F$ (for proper filters $\mathcal{F}$). Each frontier edge is thus naturally associated with a set $B \subset X$ in the boundary of $\mathcal{F}$.

Suppose boundary set B is associated with a given frontier edge. Because the program is read-once, these variables do not appear on any path from the root to this edge. In fact, the inputs $x \in \{0,1\}^n$ that reach this edge are characterized exactly by their settings to $\overline{B}$. Each setting to $\overline{B}$ that reaches this edge clearly induces the same subfunction on B, as defined by the subprogram rooted there. Since at most $2^{|\overline{B}|}/L$ settings to $\overline{B}$ give the same subfunction on B, at most $(2^{|\overline{B}|}/L) \cdot 2^{|B|} = 2^n/L$ inputs in $\{0,1\}^n$ may pass through this frontier edge. The lower bound follows. □

3. A lower bound of $2^{\Omega(\sqrt[3]{n})}$. In this section, we prove a weaker bound with an easier proof that includes the main ideas.

THEOREM 1. *Read-once branching programs for* **MULT** *require size* $2^{\Omega(\sqrt[3]{n})}$.

Proof. Let $m = \sqrt[3]{n}/4$ and let X and Y denote the sets of variables $X = \{x_0, \ldots, x_{n-1}\}$ and $Y = \{y_0, \ldots, y_{n-1}\}$. Define the filter

$$\mathcal{F} = \{V \subset (X \cup Y) : |V \cap X| > n - m \text{ and } |V \cap Y| > n - m\}.$$

The resulting "frontier" of the branching program (as defined in Lemma 1) roughly speaking marks the threshold where at most m bits of X and at most m bits of Y have been read. (In order for this notion to be strictly correct, "have been read" must be interpreted to mean "appear on any path from the root.")

We will show that for any B in the boundary of $\mathcal{F}$, at most $2^{|\overline{B}|-m}$ settings to $\overline{B}$ give the same subfunction on B. By Lemma 1, this gives the desired lower bound of 2^m. Fix any B in the boundary of $\mathcal{F}$ and let $S = \overline{B}$. Think of S as being the variables already read by the branching program. Since B is in the boundary of $\mathcal{F}$, either $|S \cap X| = m$ or $|S \cap Y| = m$ (but not both). We will show that there is a subset $S' \subset S$ of size at least m such that if two settings to S differ on S' then they induce different subfunctions on $\overline{S} = B$. Thus at most $2^{|S|-m}$ settings to $S = \overline{B}$ induce the same subfunction on $\overline{S} = B$, as desired. We will show that the two subfunctions are different by explicitly demonstrating a single setting to the bits of $\overline{S}$ where the induced subfunctions of **MULT** differ.

Suppose without loss of generality that $|S \cap X| = m$ (and therefore $|S \cap Y| < m$). Let $i \in \{0, \ldots, n-1\}$ be the smallest index such that $y_i \notin S$. Let

$$S' = \{y_0, \ldots, y_{i-1}\} \cup \left(S \cap \{x_0, \ldots, x_{n-1-i}\}\right).$$

Note that because $\{y_0, \ldots, y_{i-1}\} \subseteq S$ and $|S \cap X| = m$, we have $|S'| \geq m$.

Let us adopt the following notation for the integers obtained from partial settings to the variables. For a setting α to $W \subseteq X \cup Y$ (i.e., $\alpha : W \to \{0,1\}$), let x_α denote the integer that is represented in binary when the variables of $X \cap W$ have the value given by α and the variables of $X \cap \overline{W}$ are each 0. Define y_α similarly. For a single variable $z \notin W$, let "$\alpha + z$" denote the setting to $W \cup \{z\}$ that further sets $z = 1$. For two settings α and τ to disjoint subsets W and V, let "$\alpha \cup \tau$" denote the setting equal to α on W and to τ on V. Finally, let $(x)_i$ denote the ith bit in the binary representation of integer x, so $x = \sum_{i=0}^{n-1} (x)_i \, 2^i$.

Let α and β be two settings to S that differ on some bit in S'. Our goal is thus to find a setting τ to the bits of $\overline{S}$ so that $(x_{\alpha\cup\tau} y_{\alpha\cup\tau})_{n-1} \neq (x_{\beta\cup\tau} y_{\beta\cup\tau})_{n-1}$.

We proceed in two stages, according to Lemmas 2 and 3. First we ensure, by setting to 1 (if necessary) a single variable z of $\overline{S}$, that the two products $x_{\alpha+z} y_{\alpha+z}$

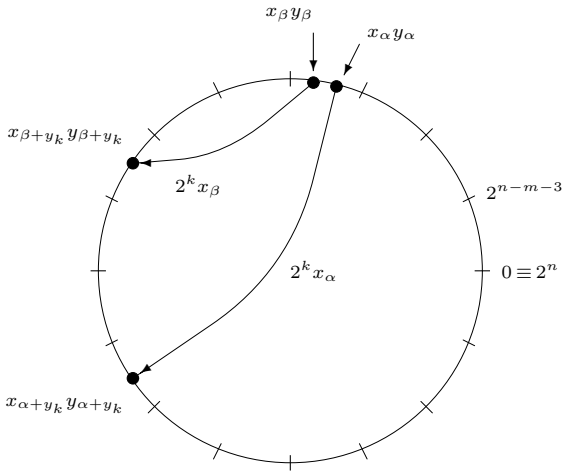

FIG. 1. *The integers modulo 2^n. In order for $x_{\beta+y_k} y_{\beta+y_k}$ and $x_{\alpha+y_k} y_{\alpha+y_k}$ to fall into different segments, we must choose k so that $2^k(x_\alpha - x_\beta)$ has large magnitude.*

and $x_{\beta+z}y_{\beta+z}$ differ in a "high-order" bit—a bit position in the range $[n-m-3, n-1]$ (we aren't concerned with bit positions higher than the middle). In the second stage, we set to 1 a pair of variables of $\overline{S}$, one in X and one in Y, so that the resulting product differs in a *higher* high-order bit position. We iterate this second stage, repeatedly setting a pair of variables until the resulting products differ in bit position $n-1$. It follows that α and β induce different subfunctions on $\overline{S}$—the subfunctions differ when $\overline{S}$ has z and the pairs from the second stage all set to 1 and the remaining bits of $\overline{S}$ set to 0.

LEMMA 2. *If for all $i \in [n-m-3, n-1]$ we have $(x_\alpha y_\alpha)_i = (x_\beta y_\beta)_i$, then there is a single variable $z \in \overline{S}$ such that*

$$(x_{\alpha+z}y_{\alpha+z})_i \neq (x_{\beta+z}y_{\beta+z})_i$$

for some $i \in [n-m-3, n-1]$.

LEMMA 3. *Let $T \subset X \cup Y$, and α and β be two settings to T. Let d be the greatest index in $[0, n-2]$ such that $(x_\alpha y_\alpha)_d \neq (x_\beta y_\beta)_d$. If $d \geq n-m-3$ and $\max(|T \cap X|, |T \cap Y|) = t \leq 3m$, then there are two variables, $x_u \in X \cap \overline{T}$ and $y_v \in Y \cap \overline{T}$, such that*

$$(x_{\alpha'}y_{\alpha'})_{d+1} \neq (x_{\beta'}y_{\beta'})_{d+1}$$

where $\alpha' = \alpha + x_u + y_v$ and $\beta' = \beta + x_u + y_v$.

Theorem 1 now follows from these lemmas as outlined above. Notice that Lemma 3 is first applied with $t \leq m+1$, and since we must apply Lemma 3 at most $m+3$ times, each time setting one more variable of X and Y, we maintain $t \leq 2m+4 \leq 3m$ as required. □

We now give the proofs of Lemmas 2 and 3.

Proof of Lemma 2. The settings α and β differ on $S' \subseteq S$; suppose first that they differ in a bit of $S' \cap X$.

The proof is most easily explained by picturing the integers modulo 2^n on a circle. Partition the circle into 2^{m+3} equal-sized segments according to the values

of the $m+3$ highest bits, so each segment contains 2^{n-m-3} consecutive integers, as depicted in Figure 1. The hypothesis of the lemma is that $x_\alpha y_\alpha$ and $x_\beta y_\beta$ fall into the same segment. If we set bit $y_k \in \overline{S} \cap Y$ to 1, we obtain the products $x_{\alpha+y_k} y_{\alpha+y_k} = x_\alpha y_\alpha + x_\alpha 2^k$ and $x_{\beta+y_k} y_{\beta+y_k} = x_\beta y_\beta + x_\beta 2^k$. The product $x_{\alpha+y_k} y_{\alpha+y_k}$ is obtained by a translation of $2^k x_\alpha$ along the circle from $x_\alpha y_\alpha$, and $x_{\beta+y_k} y_{\beta+y_k}$ is obtained by a translation of $2^k x_\beta$ from $x_\beta y_\beta$. If, modulo 2^n, their difference $2^k(x_\alpha - x_\beta)$ is at least 2^{n-m-2}, or two segments long, and at most $2^n - 2^{n-m-2}$, or "negative two" segments long, then it is clear that the translates $x_{\alpha+y_k} y_{\alpha+y_k}$ and $x_{\beta+y_k} y_{\beta+y_k}$ fall into different segments. It follows that the products $x_{\alpha+y_k} y_{\alpha+y_k}$ and $x_{\beta+y_k} y_{\beta+y_k}$ differ in a high-order bit position.

It only remains to show how to choose $y_k \in \overline{S} \cap Y$ so that $2^{n-m-2} \leq 2^k(x_\alpha - x_\beta) \leq 2^n - 2^{n-m-2}$ modulo 2^n. Let $\overline{x} = x_\alpha - x_\beta$. It is useful now to think in terms of the table generated by the usual grade-school algorithm for multiplying $\overline{x}$ by y, as shown in Figure 2.

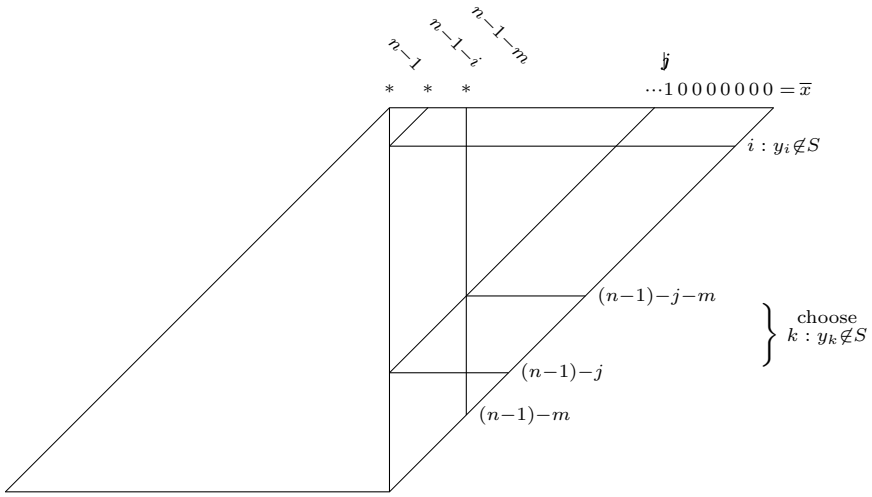

FIG. 2. *The table generated by the grade-school algorithm for multiplying $\overline{x} = x_\alpha - x_\beta$ by y. We choose a bit y_k to set to 1 so that the least significant 1 in $\overline{x}$ is shifted into a "high-order" bit position.*

In this table, the rows are the partial products, indexed by $y_0, \ldots, y_{n-1}$. The diagonals are indexed by $\overline{x}_{n-1}, \ldots, \overline{x}_0$. Since α and β differ in a bit of $S' \cap X \subseteq \{x_0, \ldots, x_{n-1-i}\}$, the difference $\overline{x} = x_\alpha - x_\beta$ must have a 1 somewhere in the range of bit positions $[0, n-1-i]$. Let j be the position of the least significant 1 in $\overline{x}$, so that either there is a 0 in position $j-1$, or $j = 0$. We now choose any variable of $\overline{S} \cap Y$ with index k in the range $[(n-1)-j-m, (n-1)-j]$. This range must contain a variable $y_k \in \overline{S} \cap Y$ because if $(n-1)-j-m \geq 0$, the range has at least $m+1$ elements while $|S \cap Y| < m$; if, however, $(n-1)-j-m < 0$, we may choose $k = i$ (by definition $y_i \notin S$), which lies in the range $[0, n-1-j]$ since $j \leq n-i-1$. This ensures that $2^k \overline{x}$ has a 1 in position $j+k$ and a 0 in position $j+k-1$, where $n-1-m \leq j+k \leq n-1$. It follows that modulo 2^n, we have $2^{n-m-1} \leq 2^k \overline{x} \leq 2^n - 1 - 2^{n-m-2}$ (the upper bound attained if all bits except bit $j+k-1$ are 1's and $j+k = n-1-m$). This satisfies the desired bounds.

If α and β differ in a bit of $S' \cap Y \subseteq \{y_0, \ldots, y_{i-1}\}$ the proof is essentially the same. We have to choose $x_k \in \overline{S} \cap X$ so that $2^{n-m-2} \leq 2^k(y_\alpha - y_\beta) \leq 2^n - 2^{n-m-2}$ modulo 2^n. In this case, we know $\overline{y} = y_\alpha - y_\beta$ has a 1 in the range $[0, i-1]$. Again

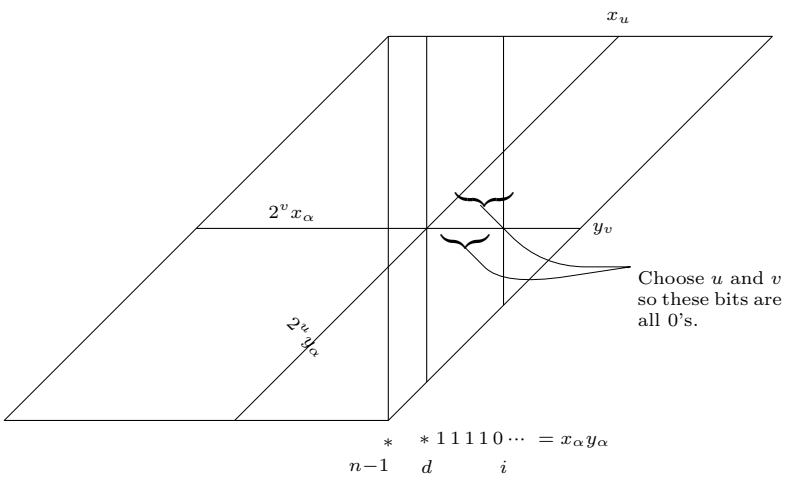

FIG. 3. *In Lemma* 3*, we choose* x_u *and* y_v *to set to* 1 *so that* $u+v=d$ *and also so that the products* $2^u y_\alpha$ *and* $2^v x_\alpha$ *have* 0*'s in bit positions* $d-1,\ldots,i-1$ *so that when added to* $x_\alpha y_\alpha + 2^d$*, they do not cause a carry to propagate into position* $d+1$*.*

letting j be the least significant 1 of $\overline{y}$ in this range, we simply choose k anywhere in the range $[(n-1)-j-m, n-1-j]$. Now for sure $(n-1)-j-m \geq 0$ and the range always has $m+1$ elements, since $j \leq i-1 \leq m = \sqrt[3]{n}/4$. It follows as before that $2^k\overline{y}$ satisfies the desired inequality. This completes the proof. □

We restate Lemma 3 for convenience.

LEMMA 3. *Let* $T \subset X \cup Y$*, and* α *and* β *be two settings to* T*. Let* d *be the greatest index in* $[0, n-2]$ *such that* $(x_\alpha y_\alpha)_d \neq (x_\beta y_\beta)_d$*. If* $d \geq n-m-3$ *and* $\max(|T\cap X|, |T\cap Y|) = t \leq 3m$*, then there are two variables* $x_u \in X \cap \overline{T}$ *and* $y_v \in Y \cap \overline{T}$ *such that*

$$(x_{\alpha'} y_{\alpha'})_{d+1} \neq (x_{\beta'} y_{\beta'})_{d+1}$$

where $\alpha' = \alpha + x_u + y_v$ *and* $\beta' = \beta + x_u + y_v$*.*

Proof of Lemma 3. We will consider all pairs of variables (x_u, y_v) such that $u+v=d$. We want $(x_{\alpha'} y_{\alpha'})_{d+1} \neq (x_{\beta'} y_{\beta'})_{d+1}$, where

$$\begin{aligned} x_{\alpha'} y_{\alpha'} &= (x_\alpha + 2^u)(y_\alpha + 2^v) \\ &= \left(x_\alpha y_\alpha + 2^d\right) + \left(2^v x_\alpha + 2^u y_\alpha\right), \\ \text{and } \; x_{\beta'} y_{\beta'} &= (x_\beta + 2^u)(y_\beta + 2^v) \\ &= \left(x_\beta y_\beta + 2^d\right) + \left(2^v x_\beta + 2^u y_\beta\right). \end{aligned}$$

Since d is the highest bit in which $x_\alpha y_\alpha$ and $x_\beta y_\beta$ differ, clearly $\left(x_\alpha y_\alpha + 2^d\right)_{d+1} \neq \left(x_\beta y_\beta + 2^d\right)_{d+1}$. We will choose u and v so that the addition of the cross terms $2^v x_\alpha + 2^u y_\alpha$ to $x_\alpha y_\alpha + 2^d$ does not affect bits d or $d+1$ of $x_\alpha y_\alpha + 2^d$ (and similarly for β). In order to do this, we choose u and v so that the cross terms have 0's in bit positions d and $d+1$ and, furthermore, in the addition of the two integers, there is no carry bit into position d.

To accomplish this, we first find the largest bit position i less than d where $x_\alpha y_\alpha$ has a 0 (so positions $i+1$ through $d-1$ are all 1's). We will choose u and v so that $2^v x_\alpha$ and $2^u y_\alpha$ each has 0's in positions $i-1$ through $d+1$. It follows that their sum

then has 0's in positions i through $d+1$, and so, when added to $x_\alpha y_\alpha + 2^d$ which has a 0 in position i, causes no carry into any position $i+1$ through d (see Figure 3). We will choose u and v so that the same conditions hold for β as well.

A simple counting argument now shows that there exist u and v as desired. First, we claim that $x_\alpha y_\alpha$ (and $x_\beta y_\beta$) has 1's in at most t^2 bit positions, so that $i \geq (d-1) - t^2$. In general, if the binary representations of integers p and q have $w(p)$ and $w(q)$ 1's in them, respectively, then clearly $p+q$ has at most $w(p)+w(q)$ 1's in it. Recall α sets at most t bits in X or Y. We may therefore view $x_\alpha y_\alpha$ as the addition of at most t shifts of x_α, and the claim follows.

We require $(2^v x_\alpha)_j = (2^v x_\beta)_j = 0$ in at most t^2+4 positions j: $j = d+1,\ d,\ d-1,\ \ldots,\ i,\ i-1$. There are at most t bit positions in which either x_α or x_β has a 1, and for each such 1, there are at most t^2+4 "bad" values of $v \in [0, n-1]$ that shift the 1 to a position we require to be 0. Thus, x_α and x_β rule out at most $t(t^2+4)$ values of v. Furthermore, there are up to t variables of Y that are in T, making a total of $t(t^2+4)+t$ values of v that we may not choose. Similarly, a total of at most $t(t^2+4)+t$ values of u are ruled out by y_α, y_β, and T. The number of pairs (x_u, y_v) in which either x_u or y_v has been ruled out is thus at most

$$2(t^3+5t) \leq 2\left(27m^3+15m\right) \leq 2\left(\frac{27n}{64} + \frac{15\sqrt[3]{n}}{4}\right)$$

since $t \leq 3m$ and $m = \sqrt[3]{n}/4$. There are at least $d+1 \geq n-m-2$ pairs (x_u, y_v) such that $u+v=d$. Thus we retain at least

$$n - \frac{\sqrt[3]{n}}{4} - 2 - \left(\frac{54}{64}n + \frac{30}{4}\sqrt[3]{n}\right) = \Omega(n)$$

good pairs satisfying the desired requirements for x_u and y_v. □

4. Improving the bound to $2^{\Omega(\sqrt{n})}$. We can improve the lower bound to $2^{\Omega(\sqrt{n})}$ by analyzing more closely how we iterate Lemma 3 in the proof of the theorem. There we needed $m = O(\sqrt[3]{n})$, because in Lemma 3 we used $t^2 = O(m^2)$ as an upper bound on the number of consecutive 1's to the right of position d in $x_\alpha y_\alpha$ or $x_\beta y_\beta$. We then required 0's in these $O(m^2)$ positions in the cross terms $2^v x_\alpha + 2^u y_\alpha$ and $2^v x_\beta + 2^u y_\beta$. Since each of the $O(m)$ 1's in x_α may then rule out $O(m^2)$ values of v, we needed $O(m^3) < n$ in order not to rule out all values of v. In order to allow $m = O(\sqrt{n})$, we will reduce to $O(m)$ the number of positions in which we require 0's in the cross terms. For the rest of this section, we let $m = \sqrt{n}/3$.

Depending on exactly what $x_\alpha y_\alpha$ and $x_\beta y_\beta$ look like, we may not need to require more than a few 0's in the cross terms. For example, if $x_\alpha y_\alpha$ and $x_\beta y_\beta$ look like[5]

$$\begin{aligned} x_\alpha y_\alpha &= \cdots \underset{d}{1}0 \cdots \\ x_\beta y_\beta &= \cdots \underset{d}{0}0 \cdots \end{aligned},$$

then we need to require 0's in the cross terms in only four positions: $d+1$ through $d-2$. This is sufficient to ensure that the addition of $2^v x_\alpha + 2^u y_\alpha$ to $x_\alpha y_\alpha + 2^d$ does not generate a carry into position d and does not affect bits d or $d+1$ of $x_\alpha y_\alpha + 2^d$. The same holds for β and we get $(x_{\alpha'} y_{\alpha'})_{d+1} \neq (x_{\beta'} y_{\beta'})_{d+1}$. With only these four positions

[5]Here and henceforth, "$\cdots$" denotes an arbitrary string of 0's and 1's; thus $x_\alpha y_\alpha = \cdots \underset{d}{1}0 \cdots$ has a 1 in bit d, a 0 in bit $d-1$, and may have any values in other bit positions.

required to be 0's, the total number of v's ruled out by x_β and x_α is proportional to the number of 1's they contain, which is $O(m)$. Similarly, the cases

$$\begin{array}{l} x_\alpha y_\alpha = \cdots \underset{d}{1} 1 \cdots \\ x_\beta y_\beta = \cdots \underset{d}{0} 0 \cdots \end{array} \quad \text{and} \quad \begin{array}{l} x_\alpha y_\alpha = \cdots \underset{d}{1} 1 \cdots \\ x_\beta y_\beta = \cdots \underset{d}{0} 1 \cdots \end{array}$$

can be handled with only a few constraints by choosing $u + v = d - 1$ (this will be proved in Lemma 6). In fact, there is really only one case in which we need to require $(2^v x_\beta + 2^u y_\beta)$ or $(2^v x_\alpha + 2^u y_\alpha)$ to have many 0's, which follows.

DEFINITION 5. *Let d be the greatest index less than n in which $(x_\alpha y_\alpha)_d \neq (x_\beta y_\beta)_d$. We say that $x_\alpha y_\alpha$ and $x_\beta y_\beta$ are* k-bad *if $d \geq n - m - 4$ and the products look like*

$$\begin{array}{rcl} x_\alpha y_\alpha & = & \cdots \underset{d}{1} 0 \cdots\cdots \\ x_\beta y_\beta & = & \cdots \underset{d}{0} 1\,1\,1\,1\,\underset{\substack{\uparrow \\ n-m-6}}{1}\underbrace{1\,1\,1\,1\,1}_{k}\cdots \end{array}$$

or vice versa (exchanging α and β).

In this case, say $x_\beta y_\beta = \cdots \underset{d}{0} 1\,1\,1\,1\,\underset{\substack{\uparrow \\ n-m-6}}{1}\underbrace{1\,1\,1\,1\,1}_{k}\cdots$, we must require $2^v x_\beta + 2^u y_\beta$ to be 0 in the positions of each of these 1's in order to prevent a carry into position $d+1$ when we add it to $x_\beta y_\beta + 2^d$. In order to allow $m = O(\sqrt{n})$, we will ensure that the products are not k-bad for $k > m + 4$. Then the number of v's ruled out by each 1 of x_α and x_β is $2m + 10$, and as long as the number of 1's in x_α or x_β is $O(m)$, the total number of v's ruled out is $O(m^2)$.

We will first show that we may begin with products that differ in a high-order bit but are not 1-bad and then prove a version of Lemma 3 in which each application allows the "badness" to grow by at most 1.

LEMMA 5. *For any two settings α and β to S that differ on a bit of S', there are three (or fewer) variables $x_u, y_v, z \in \overline{S}$ ($x_u \in X$ and $y_v \in Y$) such that for $\alpha' = \alpha + x_u + y_v + z$ and $\beta' = \beta + x_u + y_v + z$, the products $x_{\alpha'} y_{\alpha'}$ and $x_{\beta'} y_{\beta'}$ differ in a high-order bit (in the range $[n - m - 4, n - 1]$) and, moreover, are not* 1*-bad.*

LEMMA 6. *Let $T \subset X \cup Y$, and let α and β be two settings to T. Let d be the greatest index in $[0, n-2]$ such that $(x_\alpha y_\alpha)_d \neq (x_\beta y_\beta)_d$. Suppose $d \geq n - m - 4$ and $\max(|T \cap X|, |T \cap Y|) = t \leq 2m + 5$ and also that $x_\alpha y_\alpha$ and $x_\beta y_\beta$ are not k-bad for some $k \leq m + 4$. Then there are two variables, $x_u, y_v \in \overline{T}$ ($x_u \in X$ and $y_v \in Y$), such that*

$$(x_{\alpha'} y_{\alpha'})_{d+1} \neq (x_{\beta'} y_{\beta'})_{d+1}$$

for $\alpha' = \alpha + x_u + y_v$ and $\beta' = \beta + x_u + y_v$, and, moreover, $x_{\alpha'} y_{\alpha'}$ and $x_{\beta'} y_{\beta'}$ are not $(k+1)$-bad.

We now have Theorem 2.

THEOREM 2. *Read-once branching programs for* **MULT** *require size $2^{\Omega(\sqrt{n})}$.*

Proof. The proof is exactly the same as the proof of Theorem 1 except for the lemmas. We start with products that differ in a high-order bit but are not 1-bad, as provided by Lemma 5. The number of variables in X or Y set in these products is at most $m + 2$. We obtain a difference in bit $n - 1$ by iterating Lemma 5 at most $m + 3$ times, each time setting at most one variable in X and in Y. This maintains $t \leq (m + 2) + (m + 3)$ and $k \leq 1 + (m + 3)$ as required. □

We now give the proofs of Lemmas 5 and 6.

Proof of Lemma 5. Either $x_\alpha y_\alpha$ and $x_\beta y_\beta$ differ (modulo 2^n) by at least 2^{n-m-3} or they do not. If they do, then they must differ in a high-order bit (in the range $[n-m-4, n-1]$). If not, we proceed just as in Lemma 2 to find a variable z such that $x_{\alpha+z}y_{\alpha+z}$ and $x_{\beta+z}y_{\beta+z}$ differ by at least 2^{n-m-3}. In order to avoid overly cumbersome notation, let us abuse notation slightly by calling these products $x_\alpha y_\alpha$ and $x_\beta y_\beta$, even though they should possibly be called $x_{\alpha+z}y_{\alpha+z}$ and $x_{\beta+z}y_{\beta+z}$.

Now that we know the products differ in a high-order bit, it remains to ensure that they are not 1-bad. Assume they are. Let d be the greatest index less than n of a bit position in which $x_\alpha y_\alpha$ and $x_\beta y_\beta$ differ.

First, we claim that if the products are 1-bad, then in fact $d \geq n-m-2$. Because if, say, $d = n-m-3$, then the products look like[6]

$$x_\alpha y_\alpha = \cdots 1\,0 \cdots$$
$$x_\beta y_\beta = \cdots \underset{d}{0}\,1\,1\,1\,\underset{n-m-6}{1} \cdots$$

and therefore they differ modulo 2^n by at most $2^{n-m-4}+2^{n-m-7}-1$ (since they agree in bits $d+1$ through $n-1$), but we know they differ by at least 2^{n-m-3}. Furthermore, by the same reasoning, not only is $d \geq n-m-2$, but $x_\alpha y_\alpha$ must have a 1 in some position between $d-2$ and $n-m-4$ inclusive (note that $(x_\alpha y_\alpha)_{d-1} = 0$ or else the products are not 1-bad). For otherwise, the products look like

$$x_\alpha y_\alpha = \cdots \underset{d}{1}\,0\,0\,0\,0\,0 \cdots$$
$$x_\beta y_\beta = \cdots \underset{d}{0}\,1\,1\,1\,1\,1\,1\,\underset{n-m-6}{1} \cdots$$

and again they differ modulo 2^n by at most $2^{n-m-4}+2^{n-m-7}-1$, a contradiction.

So we are reduced to the case that the products are 1-bad, differ in position $d \geq n-m-2$, and $x_\alpha y_\alpha$ has a 1 in some position between $d-2$ and $n-m-4$. Let ℓ be the highest index of a 1 in this range: $x_\alpha y_\alpha = \cdots \underset{d}{1}\,0\,0\,0\,\underset{\ell}{1} \cdots$. We will find a pair of variables (x_u, y_v) with $u+v = n-m-6$ so that the cross terms $2^v x_\alpha, 2^v x_\beta, 2^u y_\alpha, 2^u y_\beta$ all have 0's in positions $n-m-8$ through $n-1$. Then $(2^{u+v}+2^v x_\alpha + 2^u y_\alpha)$ and $(2^{u+v}+2^v x_\beta + 2^u y_\beta)$ both look like $\cdots \underset{n-1}{0}\,0\,0\,0\,0\,0\,0\,0\,\underset{n-m-6}{1}\,0 \cdots$. We see that $x_{\alpha'}y_{\alpha'}$ looks like either $\cdots \underset{d}{1}\,0\,0\,0\,\underset{\ell}{1} \cdots$ or $\cdots \underset{d}{1}\,0\,0\,1\,\underset{\ell}{0} \cdots$, depending on whether there is a carry into position ℓ when $2^{u+v}+2^v x_\alpha + 2^u y_\alpha$ is added to $x_\alpha y_\alpha$. Meanwhile,

$$x_{\beta'}y_{\beta'} = \begin{array}{ll} & \cdots \underset{d}{0}\,1\,1\,1\,1\,1\,1\,1\,1 \cdots \\ + & \cdots 0\,0\,0\,0\,0\,0\,0\,1\,0 \cdots \\ \hline \end{array}$$

looks like $\cdots \underset{d}{1}\,0\,0\,0\,0\,0\,0\,0\,\underset{n-m-6}{0} \cdots$ or $\cdots \underset{d}{1}\,0\,0\,0\,0\,0\,0\,0\,\underset{n-m-6}{1} \cdots$ depending on whether there is a carry into position $n-m-6$ in this addition.

Since $x_{\beta'}y_{\beta'}$ has 0's in positions ℓ ($\leq d-2$) and $\ell-1$ ($\geq n-m-5$), we see that $x_{\alpha'}y_{\alpha'}$ and $x_{\beta'}y_{\beta'}$ look like

$$x_{\alpha'}y_{\alpha'} = \cdots \underset{d}{1}\,0\,0\,0\,0\,\underset{d'}{1} \cdots$$
$$x_{\beta'}y_{\beta'} = \cdots \underset{d}{1}\,0\,0\,0\,0\,\underset{d'}{0}\,0 \cdots,$$

[6]Without loss of generality, let us assume that in position d, $x_\alpha y_\alpha$ has a 1 and $x_\beta y_\beta$ has a 0.

where d' is either ℓ or $\ell+1$. Furthermore, the products agree in all higher bits up to $n-1$ because by the definition of d, $x_\alpha y_\alpha$ and $x_\beta y_\beta$ agree in bits $d+1$ through $n-1$, and we chose x_u and y_v so that the cross terms have 0's in these positions. Since $\ell \geq n-m-4$, it follows that $x_{\alpha'}y_{\alpha'}$ and $x_{\beta'}y_{\beta'}$ differ in a high-order bit and are not even 1-bad.

A counting argument like that for Lemma 3 shows that we may choose x_u and y_v as needed. We require the cross terms to have 0's in at most $m+8$ positions. Since at most $m+1$ bits are set to 1 in x_α or x_β, the total number of values v that we may not choose is $(m+1)(m+8)+(m+1)$. The same number of values u are ruled out, making a total of at most $2(m+1)(m+9) = 2\frac{n}{9} + O(\sqrt{n})$ pairs (x_u, y_v) that are ruled out. Since there are $n-m-5$ pairs to choose from initially, we retain $\Omega(n)$ pairs. □

Proof of Lemma 6. We have four possible cases (up to switching α and β):

$$\begin{array}{lllll} x_\alpha y_\alpha = & (1)\ \cdots \underset{d}{1}0\cdots & (2)\ \cdots \underset{d}{1}1\cdots & (3)\ \cdots \underset{d}{1}1\cdots & (4)\ \cdots \underset{d}{1}0\cdots \\ x_\beta y_\beta = & \cdots \underset{d}{0}0\cdots & \cdots \underset{d}{0}0\cdots & \cdots \underset{d}{0}1\cdots & \cdots \underset{d}{0}1111110\cdots \end{array}$$

Case 1. $x_\alpha y_\alpha = \cdots \underset{d}{1}0\cdots$
$x_\beta y_\beta = \cdots \underset{d}{0}0\cdots.$

It is sufficient to choose (x_u, y_v) so that $u+v=d$ and each of the cross terms $2^v x_\beta$, $2^u y_\beta$, $2^v x_\alpha$, and $2^u y_\alpha$ has 0's in positions $d-3$ through $d+1$. Then the sums $2^v x_\beta + 2^u y_\beta$ and $2^v x_\alpha + 2^u y_\alpha$ have 0's in positions $d-2$ through $d+1$. Adding these to $x_\alpha y_\alpha$ and $x_\beta y_\beta$, respectively, therefore, causes no carry into position d and thus the addition of $2^{u+v} = 2^d$ causes a carry into bit $d+1$ for α but not for β. Since $x_\alpha y_\alpha$ and $x_\beta y_\beta$ agree in bits $d+1$ through $n-1$, this carry bit causes them to differ in bit $d+1$ and possibly higher bits as well.

We now verify that $x_{\alpha'}y_{\alpha'}$ and $x_{\beta'}y_{\beta'}$ are not 1-bad. We know that $2^{u+v} + 2^v x_\beta + 2^u y_\beta$ looks like $\cdots 0\underset{d}{1}00\cdots$. Thus

$$x_{\beta'}y_{\beta'} = \begin{array}{ll} & \cdots \underset{d}{0}0\cdots \\ + & \cdots 0100\cdots \\ \hline \end{array}$$

looks like either $\cdots \underset{d}{1}0\cdots$ or $\cdots \underset{d}{1}10\cdots$, depending on whether there is a carry into position $d-1$. Thus $x_{\beta'}y_{\beta'}$ does not have a string of 1's extending past position $d-1 \geq n-m-5$ and cannot make the products even 1-bad. Since the products differ in position $d+1$ or higher and $x_{\alpha'}y_{\alpha'}$ has a 0 in position d, the products cannot be 1-bad due to a string of 1's in $x_{\alpha'}y_{\alpha'}$.

To prove that we can choose (x_u, y_v) as desired, we argue as in the proof of Lemma 3. The number of positions required to be 0 is 5, ruling out $5t$ values of v. Of the $d+1 = n - O(\sqrt{n})$ pairs (x_u, y_v) such that $u+v=d$, the number of pairs ruled out is at most $2(5t+t) = 12t \leq 12(2m+5) = O(\sqrt{n})$, so there are $n-o(n)$ remaining pairs to choose from.

Case 2. $x_\alpha y_\alpha = \cdots \underset{d}{1}1\cdots$
$x_\beta y_\beta = \cdots \underset{d}{0}0\cdots$

Case 3. $x_\alpha y_\alpha = \cdots \underset{d}{1}1\cdots$
$x_\beta y_\beta = \cdots \underset{d}{0}1\cdots$

It is sufficient to choose (x_u, y_v) as in Case 1 except that $u+v=d-1$. Adding 2^{d-1} will cause a carry to propagate into position $d+1$ for α but not for β, causing them to differ in bit $d+1$ and possibly higher bits as well. The counting argument for choosing (x_u, y_v) is exactly the same as in Case 1 except that there is one fewer pair (x_u, y_v) with $u+v=d-1$.

It only remains to show that in fact $x_{\alpha'}y_{\alpha'}$ and $x_{\beta'}y_{\beta'}$ are not 1-bad. Now $2^{u+v}+2^v x_\alpha + 2^u y_\alpha$ looks like $\cdots \underset{d}{0}\,0\,1\,0\cdots$ and so does $2^{u+v}+2^v x_\beta + 2^u y_\beta$. Thus

$$x_{\alpha'}y_{\alpha'} = \begin{array}{r} \cdots \underset{d}{1}\,1\cdots \\ +\quad \cdots 0\,0\,1\,0\cdots \\ \hline \end{array},$$

and we see that it has a 0 in bit d.

Looking now at $x_{\beta'}y_{\beta'}$, we see that in Case 2,

$$x_{\beta'}y_{\beta'} = \begin{array}{r} \cdots \underset{d}{0}\,0\cdots \\ +\quad \cdots 0\,0\,1\,0\cdots \\ \hline \end{array}$$

looks like either $\cdots \underset{d}{0}\,1\cdots$ or $\cdots \underset{d}{1}\,0\cdots$, depending on whether there is a carry into position $d-1$. In Case 3,

$$x_{\beta'}y_{\beta'} = \begin{array}{r} \cdots \underset{d}{0}\,1\cdots \\ +\quad \cdots 0\,0\,1\,0\cdots \\ \hline \end{array}$$

looks like either $\cdots \underset{d}{1}\,0\cdots$ or $\cdots \underset{d}{1}\,1\,0\cdots$, depending on whether there is a carry into position $d-1$. In any case, $x_{\beta'}y_{\beta'}$ does not have a string of 1's extending past $d-2 \geq n-m-6$, and so $x_{\alpha'}y_{\alpha'}$ and $x_{\beta'}y_{\beta'}$ are not even 1-bad.

Case 4. $x_\alpha y_\alpha = \cdots \underset{d}{1}\,0\cdots,$

$$x_\beta y_\beta = \cdots \underset{d}{0}\,1\,1\,1\,1\overbrace{1\,1\,1\,1}^{k-1}\,0\cdots.$$
$$\qquad\qquad\qquad\qquad\quad \underset{n-m-6}{\uparrow}$$

Without loss of generality, let us say that $x_\beta y_\beta$ contains the maximum number, $k-1$, of consecutive 1's extending past position $n-m-6$. We choose (x_u, y_v) so that $u+v=d$ and the cross terms $2^v x_\alpha$, $2^u y_\alpha$, $2^v x_\beta$, and $2^u y_\beta$ have 0's in positions $(n-m-6)-(k+2)$ through $n-1$. This will ensure that from 2^d we get a carry into position $d+1$ for α' but not for β', causing the products to differ in bit $d+1$ and possibly higher bits as well.

The sum $2^v x_\beta + 2^u y_\beta$ has 0's in positions $(n-m-6)-(k+1)$ through $n-1$, so

$$x_{\beta'}y_{\beta'} = \begin{array}{r} \cdots \underset{d}{0}\,1\,1\,1\,1\overbrace{1\,1\,1\,1}^{k-1}\,0\cdots \\ +\quad \cdots 0\,1\,0\,0\,0\,0\,0\,0\,0\,0\,0\,0\cdots \\ \hline \end{array}$$

looks like either

$$\cdots \underset{d}{1}\,1\,1\,1\,1\overbrace{1\,1\,1\,1}^{k-1}\,0\cdots \quad \text{or} \quad \cdots \underset{d}{1}\,1\,1\,1\,1\overbrace{1\,1\,1\,1}^{k-1}\,1\,0\cdots,$$

depending on whether there is a carry into position $(n-m-6)-k$. So $x_{\beta'}y_{\beta'}$ has at most k 1's extending past position $n-m-6$. The pair of products cannot be worse than k-bad due to a longer string of 1's in $x_{\alpha'}y_{\alpha'}$ since the products differ in position $d+1$ or higher and $x_{\alpha'}y_{\alpha'}$ has a 0 in position d. Thus $x_{\alpha'}y_{\alpha'}$ and $x_{\beta'}y_{\beta'}$ are at worst k-bad.

The number of positions in which we require $2^v x_\alpha$ or $2^u x_\beta$ to be 0 is $m+6+k+2 \leq 2m+12$. Together, x_α and x_β may rule out $t(2m+12)$ values v in addition to the t variables y_v already in T. Taking into account the same number of values u ruled out by y_α and y_β, there are at most $2(t(2m+12)+t)$ pairs (x_u, y_v) that could be ruled out. Of the $d+1 = n - O(\sqrt{n})$ possible pairs (x_u, y_v) with $u+v=d$, a total of at most

$$2(2m+5)(2m+13) = 8\frac{n}{9} + O(\sqrt{n})$$

pairs are ruled out, leaving $\frac{n}{9} - O(\sqrt{n}) = \Omega(n)$ pairs to choose from. □

5. Problem reductions. With the suitable reductions, we may deduce similar lower bounds for other Boolean functions. Clearly a read-once program for a function g will yield a read-once program for f if there is an appropriate one-to-one substitution of the variables of f for the variables of g. This substitution need not be onto the entire set of g's variables—some of them may be fixed to 0 or 1. This is exactly a one-to-one *projection reduction*, which we shall call a *read-once reduction* as discussed in the following definitions.

DEFINITION 6 (see [SV81]). *A function f is* projection reducible *to a function g, written $f \leq_{\text{proj}} g$, if for all n there is a polynomially bounded function $p(n)$ and a mapping $\sigma_n : \{y_1, \ldots, y_{p(n)}\} \to \{0, 1, x_1, \ldots, x_n, \overline{x_1}, \ldots, \overline{x_n}\}$ such that*

$$f_n(x_1, \ldots, x_n) = g_{p(n)}(\sigma(y_1), \ldots, \sigma(y_{p(n)})).$$

In other words, $f \leq_{\text{proj}} g$ if any algorithm (circuit or branching program) for $g(y_1, \ldots, y_{p(n)})$ can be used as a black box for f simply by substituting the inputs to f (and $0, 1$) for the inputs to g so that the output of the algorithm is that of f. These reductions were used in the study of constant-depth reducibility [CSV84]—clearly, given that $f \leq_{\text{proj}} g$, if $g \in \text{AC}^0$ then $f \in \text{AC}^0$.

DEFINITION 7. *A function f is* read-once reducible *to a function g, written $f \leq_{r\text{-}o} g$, if there is a projection reduction σ from f to g such that for all k and $i \neq j$,*

$$\sigma(y_i) \in \{x_k, \overline{x_k}\} \Longrightarrow \sigma(y_j) \notin \{x_k, \overline{x_k}\}.$$

That is, each of f's inputs x_i is substituted for no more than one input y_j of g. It follows that a polynomial-size read-once branching program for $f(x_1, \ldots, x_n)$ is obtained by relabeling and reducing the nodes of a polynomial-size read-once program for $g(y_1, \ldots, y_{p(n)})$. We remark that the same holds for read-once *formulas* (e.g., [KLNSW93, Gu77]).

5.1. Reductions to other arithmetic functions. Projection reductions have been used to deduce tight lower bounds on the depth of polynomial-size threshold circuits. It was originally proved in [HMPST93] that **INNER-PRODUCT-MODULO-2** cannot be computed in polynomial-size by threshold circuits of depth 2. It was also noted there that the projection reduction to multiplication (first given in [FSS84], from **PARITY** to **MULT**) shows that **MULT** obeys the same lower bound. Wegener [We93] gives projection reductions from **MULT** to squaring and inversion in order

to show that these functions also require depth 3 polynomial-size threshold circuits. Our lower bound for the middle bit of multiplication implies a lower bound for the appropriate bit of these two functions. We will phrase the reductions of [We93] in terms of the following Boolean functions:

- **SQUARING** : $\{0,1\}^n \to \{0,1\}$; computes "the" middle bit (here, bit n rather than bit $n-1$, which we chose for **MULT**) in the square of an n-bit integer:

$$\textbf{SQUARING}(z) = (z^2)_n.$$

- **INVERSION** : $\{0,1\}^n \to \{0,1\}$; computes the ones' bit in the reciprocal of an n-bit number between 0 and 1:

$$\textbf{INVERSION}(x) = y_0,$$

  where x represents the number $0\,.\,x_1x_2\cdots x_n = \sum_i x_i 2^{-i}$ and $y = y_n \cdots y_0 = \sum_i y_i 2^i$ is the integral part of $1/x$. (Note that $1 < y \le 2^n$.) Define the function to be 0 if all x_i are 0.

Wegener actually shows that

$$\textbf{MULT} \le_{\text{proj}} \textbf{SQUARING} \le_{\text{proj}} \textbf{INVERSION},$$

except that the reductions are given for all bits of multiplication, squaring, and inversion. We provide the reductions here in order to verify that each reduction is in fact read-once and also because we are working instead with Boolean versions of these functions. The polynomial $p(n)$ of the reduction is linear in both cases, implying that if each bit of the function is computable with a read-once program of size $f(n)$, then **MULT** is computable with a read-once program of size $f(cn)$ for some constant c. This gives the following corollaries to Theorem 2.

COROLLARY 1. *Read-once branching programs for* **SQUARING** *require size* $2^{\Omega(\sqrt{n})}$.

Proof. The reduction $\textbf{MULT} \le_{\text{r-o}} \textbf{SQUARING}$ is given by mapping the n-bit inputs x, y (of **MULT**) to the $(3n+2)$-bit input $z = x2^{2(n+1)} + y$ (of **SQUARING**), so that $z^2 = x^2 2^{4(n+1)} + xy2^{2(n+1)+1} + y^2$. The middle bit of the product xy is found in the middle bit of z^2: $(xy)_{n-1} = (z^2)_{3n+2}$. It is clear that the mapping σ is injective since

$$\sigma(z_i) = \begin{cases} y_i & \text{if } 0 \le i < n, \\ 0 & \text{if } n \le i < 2(n+1), \\ x_{i-2(n+1)} & \text{if } 2(n+1) \le i < 2(n+1)+n. \end{cases} \qquad \square$$

COROLLARY 2. *Read-once branching programs for* **INVERSION** *require size* $2^{\Omega(\sqrt{n})}$.

Proof. The reduction $\textbf{SQUARING} \le_{\text{r-o}} \textbf{INVERSION}$ essentially reduces the problem of computing the square of an n-bit integer m to the problem of computing $1/(1-x) = 1 + x + x^2 + x^3 + \cdots$ where

$$1 - x = 1 - m\,2^{-4n} - 2^{-10n},$$

which is a $10n$-bit number slightly less than 1. The proof in [We93] shows that the product m^2 lies in bit positions $-6n-1$ through $-8n$ in $1/(1-x)$, its middle bit being in position $-7n$. By instead computing the inverse of $2^{-7n}(1-x)$, a $17n$-bit number, we find the middle bit of m^2 in position 0.

For example, working in decimal, we may compute 5^2 (so $n = 1$) by calculating

$$10^{-7}(1 - 5 \cdot 10^{-4} - 10^{-10})^{-1} = 10005002.50225\cdots$$

from which we may recover the middle digit, 2, of 25 in position in position 0.

To see that the mapping σ is injective, simply notice that $1-x = 1-2^{-10n}-m\,2^{-4n}$ has 1's in all positions -1 through $-10n$, except in positions $-3n-1$ through $-4n$, where it has exactly the complements of the bits of m. The number $2^{-7n}(1-x)$ is similar, with extra 0's on the left. □

6. Further work. We doubt that $2^{\Theta(\sqrt{n})}$ is the true read-once complexity of **Mult** (Bryant's lower bound for OBDDs is $2^{n/8}$ [Br91]), but the simple counting technique used in our proof seems limited to this lower bound. It is curious that many of the lower bounds for read-once programs achieve only $2^{\Omega(\sqrt{n})}$ if n is the number of input bits—only the lower bounds of [BHST87] and [SZ96] achieve a fully exponential lower bound of $2^{\Omega(n)}$. This limitation is most likely an artifact of the proofs, but it is not well understood. In addition to improving the bound, it may also be possible to extend the argument using the framework of [BRS93] to show that a similar bound holds for nondeterministic read-once programs or for read-k-times programs.

Acknowledgments. Thanks to Mikael Goldmann for pointing out the reductions in [We93], to Mauricio Karchmer and Ravi Sundaram for discussions, and to Allan Borodin for his seminar in which I learned of this problem. Thanks also to the referees for catching several small errors in the first version.

TOTAL COLORING WITH $\Delta + \text{poly}(\log \Delta)$ COLORS*

HUGH HIND†, MICHAEL MOLLOY‡, AND BRUCE REED§

Abstract. We provide a polynomial time algorithm which finds a total coloring of any graph with maximum degree Δ, Δ sufficiently large, using at most $\Delta + 8\log^8 \Delta$ colors. This improves the best previous upper bound on the total chromatic number of $\Delta + 18\Delta^{1/3}\log(3\Delta)$.

Key words. total coloring, algorithms, probabilistic method

1. Introduction. A *total coloring* of a graph G is an assignment of colors to its vertices and edges so that no two adjacent vertices have the same color, no two adjacent edges have the same color, and no edge has the same color as one of its endpoints. A k total coloring is a total coloring which uses at most k colors. The *total chromatic number,* $\chi''(G)$, is the least number of colors required for a total coloring of G.

This concept was introduced independently by Behzad [3] and Vizing [15], who each conjectured that any graph with maximum degree Δ has a $\Delta + 2$ total coloring. Note that if it is true, this conjecture is tight because every such graph requires at least $\Delta + 1$ colors and there are some graphs such as $K_{\Delta+1}$, Δ odd, which require $\Delta + 2$ colors. Kilakos and Reed [11] have shown that the fractional total chromatic number of such a graph is at most $\Delta + 2$.

The first $\Delta + o(\Delta)$ bound on the total chromatic number of such a graph was $\Delta + 2\sqrt{\Delta}$, due to Hind [7]. More recently, Häggkvist and Chetwynd (see [10]) have reported a bound of $\Delta + 18\Delta^{1/3}\log(3\Delta)$. In this paper we tighten the bound to $\Delta + 8\log^8 \Delta$ (all logarithms have base e).

THEOREM 1. *For sufficiently large Δ, if G has maximum degree Δ then $\chi''(G) \leq \Delta + 8\log^8 \Delta$.*

Our proof is probabilistic and makes use of the Lovász local lemma. The proof can be made constructive, providing an $O(n^3 \log^{O(1)} n)$ randomized algorithm and a polytime deterministic algorithm to find such a total coloring.

The total chromatic number conjecture is reminiscent of Vizing's theorem which states that if G has maximum degree Δ then the edge chromatic number of G, $\chi'(G)$ is either Δ or $\Delta + 1$. It is also reminiscent of the list coloring conjecture. In fact, a slightly weaker form of the total coloring conjecture follows from the list coloring conjecture.

The *list edge chromatic number* of a graph G, $\chi'_\ell(G)$, is the minimum number r with the following property: for any mapping $f : E(G) \to \mathcal{S}$ where $\mathcal{S}$ is a collection of sets of colors each of size r, G has a proper edge coloring where for each edge e,

the color of e lies in $f(e)$. The list coloring conjecture is that $\chi_\ell^{'}(G) = \chi^{'}(G)$.

Recall that for any graph G, $\chi(G) \leq \Delta + 1$. Now consider any $\Delta + 1$ coloring $c : V(G) \to \{1, \ldots, \Delta + 1\}$. For each edge $e = (u, v)$ define $f(e)$ to be the set $\{1, \ldots, \Delta + 3\} - \{c(u), c(v)\}$. Now the size of $f(e)$ is $\Delta + 1$ for each e, and so if the list coloring conjecture holds, then we can use such a coloring to provide a $\Delta + 3$ total coloring of G. Therefore, the list coloring conjecture implies $\chi^{''}(G) \leq \Delta + 3$.

Inspired by this implication, we say that a proper vertex coloring is *extendible* to a t total coloring if there is a total coloring of size t whose restriction to $V(G)$ is that vertex coloring. Thus, we have seen that the list coloring conjecture implies that every $\Delta + 1$ vertex coloring of G is extendible to a $\Delta + 3$ total coloring of G. Hind [8] has shown that there exist graphs that have a $\Delta + 1$ vertex coloring which is not extendible to a $\Delta + 2$ total coloring.

In [9] we define a proper vertex coloring to be *β-frugal* if no vertex has more than β members of any color class in its neighbourhood. We prove the following theorem.

THEOREM 2. *Every graph G with maximum degree $\Delta \geq \Delta_0 = \mathrm{e}^{10^7}$ has a $\log^5 \Delta$-frugal $(\Delta + 1)$ vertex coloring.*

In this paper, we show that every $\log^5 \Delta$-frugal $(\Delta+1)$ vertex coloring is extendible to a $\Delta + 8 \log^8 \Delta$ total coloring, thus proving Theorem 1.

The idea behind our proof is simple. We begin by presenting the basic ideas. For ease of exposition, let us assume for now that G is Δ-regular. Consider any $\log^5 \Delta$-frugal $(\Delta + 1)$ vertex coloring of G with color classes $S_1, \ldots, S_{\Delta+1}$. If we could find an edge disjoint sequence of matchings $M_1, \ldots, M_{\Delta+1}$ such that M_i misses all of S_i and covers all of $V(G) - S_i$ (i.e., M_i is a perfect matching of $G - S_i$), then this would give us a $\Delta + 1$ total coloring. (Note that since every vertex is missed by exactly one matching here, then $\cup M_i = E(G)$.) Of course, this is not always possible as there are some graphs with $\chi^{''} \geq \Delta + 2$. For example, we will fail if $|V(G) - S_i|$ is odd for any i. Thus we will have to allow our matchings to miss a few more vertices. Essentially, we will show that we can find sets $X_1, \ldots, X_{\Delta+1}$ with the following two properties:

1. each vertex lies in at most $\log^8 \Delta$ of these sets; and
2. for each $1 \leq i \leq \Delta + 1$, we can find a matching M_i in $G_i = G - \cup_{1 \leq j \leq i-1} M_i$ which misses all of S_i and meets all of $V(G) - S_i - X_i$.

Therefore, the color classes $C_i = S_i \cup M_i$ will provide a total coloring of all but $E(G_{\Delta+2})$. By condition 1, $G_{\Delta+2}$ has maximum degree at most $\log^8 \Delta$ and so it can be edge colored with at most $\log^8 \Delta + 1$ colors thus providing a $\Delta + \log^8 \Delta + 2$ total coloring of G.

We have oversimplified things here. In fact, our argument is more intricate. In the next section we will fill in the details, including the manner in which we choose our sets X_i. For now, we will simply say that we choose them randomly and make use of the following two tools. The first is due to Lovász and appears in [4]. The second can be found in [6].

The local lemma. *Suppose $\mathcal{A} = A_1, \ldots, A_n$ is a list of random events such that for each i, $\mathbf{Pr}(A_i) \leq p$ and A_i is mutually independent of all but at most d other events in $\mathcal{A}$. If $\mathrm{e}p(d + 1) < 1$ then $\mathbf{Pr}(\wedge_{i=1}^n \bar{A}_i) > 0$.*

The Chernoff bounds. *Suppose $B(n, p)$ is the sum of n independent Bernoulli variables each equal to 1 with probability p. Then for any $0 < a < \frac{1}{6}np$ we have the following:*

$$\mathbf{Pr}(B(n, p) - np > a) < \mathrm{e}^{-a^2/3np}$$

and

$$\mathbf{Pr}(B(n,p) - np < -a) < \mathrm{e}^{-a^2/2np}.$$

For the remainder of this paper, we assume $\Delta \geq \mathrm{e}^{10^7}$. For each vertex v, $N(v)$ denotes the neighbourhood of v. We usually omit all $\lfloor, \rfloor$ and $\lceil, \rceil$ signs.

2. The details. Our main task will be to prove the following.

LEMMA 3. *Suppose G is a graph with maximum degree at most $D \geq 8\log^8 \Delta$. Suppose further that we are given $S_1, S_2, \ldots, S_{\frac{D}{2}} \subseteq V(G)$ such that for all $v \in V(G), 1 \leq i \leq \frac{D}{2}$, $|N(v) \cap S_i| \leq \log^5 \Delta$. Then there exists a sequence of edge-disjoint matchings in G, $M_1, \ldots, M_{\frac{D}{2}}$ such that*

1. *M_i misses S_i;*
2. *$G' = G - \cup_{i=1}^{\frac{D}{2}} M_i$ has maximum degree at most $\frac{D}{2} + 2\log^7 \Delta$.*

Repeated iterations of Lemma 3 will prove Theorem 1.

Proof of Theorem 1. Take $S_1, \ldots, S_{\Delta+1}$ to be the color classes of any $\log^5 \Delta$-frugal $\Delta + 1$ coloring of G, as guaranteed by Theorem 2. Set $G_0 = G$, $\Delta_0 = \Delta$, and repeatedly apply Lemma 1 until $\Delta_j < 8\log^8 \Delta$, setting $G_{j+1} = G'$, $\Delta_{j+1} = \Delta_j/2 + 2\log^7 \Delta \leq \frac{\Delta}{2^j} + 4\log^7 \Delta$, and choosing $S_1^{(j)}, \ldots, S_{\Delta_j/2}^{(j)}$ from previously unused members of $\{S_1, \ldots, S_{\Delta+1}\}$, all the while forming color classes from the pairs $S_i \cup M_i$. As there are at most $\log \Delta$ iterations, $\sum \Delta_i/2 \leq \Delta - 4\log^8 \Delta + \log \Delta(4\log^7 \Delta) < \Delta + 1$, and so we will have produced fewer than $\Delta + 1$ color classes. Therefore, an $8\log^8 \Delta$ edge coloring of the final G' will provide our $\Delta + 8\log^8 \Delta$ total coloring. □

We prove Lemma 3 by choosing random sets X_i, which we allow M_i to miss as described in the introduction. As mentioned earlier, it is important that no vertex appears in very many sets X_i, as that will cause its degree in G' to be too high. In order to ensure this, we will divide $\{1, \ldots, D/2\}$ into $\log^7 \Delta$ subsequences, and we will insist that no vertex falls into two sets from the same subsequence.

Specifically, we set $\alpha_j = \lfloor j \times \frac{D}{\log^7 \Delta} \rfloor$, $j = 0, \ldots, \lceil \frac{1}{2}\log^7 \Delta \rceil$, and we set $A_j = \{\alpha_{j-1}+1, \ldots, \alpha_j\}$. We will choose $X_1, \ldots, X_{D/2}$ such that for $i_1, i_2 \in A_j$, $X_{i_1} \cap X_{i_2} = \emptyset$.

For $i \in A_j$, we define $D_i = D - (i-1) + 2(j-1)$. We set $G_1 = G$, and for $1 \leq i \leq D/2$ we will find a matching M_i in $G_i = G - \cup_{j=1}^{i-1} M_i$ such that

1. M_i misses S_i;
2. M_i meets every vertex of degree at least D_i in $V(G) - S_i - X_i$.

We will see how to find X_i and M_i later, but first note that this will be enough to prove Lemma 3.

CLAIM 1. *For each $i \geq 2$, if M_{i-1} exists, then G_i has maximum degree at most $D_i + 2$.*

Proof. In what follows, we only discuss $k \leq i$ and j such that $\alpha_{j-1} \leq i$. Consider any vertex v. We denote by $\deg_k(v)$ the degree of v in G_k. We will see by induction on j that $\deg_{\alpha_{j-1}+1}(v) \leq D_{\alpha_{j-1}+1}$ and that for all k with $\alpha_{j-1} + 1 \leq k \leq \alpha_j$, $\deg_k(v) \leq D_k + 2$. The first condition holds for $j = 1$. To see that for each j, the first condition implies the second condition as well as the first condition for $j+1$, consider the first (if any) $k \in A_j$ such that $\deg_k(v) = D_k$, and note that $\deg_{k'}(v) \geq D_{k'}$ for all $k \leq k' \leq \alpha_j$, and so v can be missed by at most two matchings M_{k_1}, M_{k_2} before $\alpha_j + 1$, corresponding to $v \in X_{k_1}$ and $v \in S_{k_2}$. Therefore, $\deg_{k'}(v) \leq D_{k'} + 2$ for each $k \leq k' \leq \alpha_j$, and $\deg_{\alpha_j+1}(v) \leq D_{a_j+1}$ as $D_{a_j+1} = D_{a_j} + 1$. □

Therefore, $G_{D/2}$ has maximum degree at most $D_{D/2} + 2 \leq D/2 + 2\log^7 \Delta$ as required.

It only remains to choose X_i and M_i. This is done via the following two lemmas.

LEMMA 4. *Suppose G_i has maximum degree at most $D_i + 2$ where $D_i \geq \log^8 \Delta$, and suppose further that there exists a set $R \subseteq V(G)$ such that for any $v \in V(G)$, $|N(v) \cap R| \leq \frac{3D}{\log \Delta}$. Then there exists $X_i \subseteq V(G) - R$ such that for all $v \in V(G)$,*

1. $|N(v) - X_i| \leq D_i - \log^6 \Delta$;
2. $|N(v) \cap X_i| \leq 3 \log^6 \Delta$.

LEMMA 5. *Suppose G_i has maximum degree at most $D_i + 2$ and suppose further that we have $S_i, X_i \subseteq V(G)$ such that for each $v \in V(G)$,*

1. $|N(v) \cap S_i| \leq \log^5 \Delta$;
2. $|N(v) - X_i| \leq D_i - \log^6 \Delta$;
3. $|N(v) \cap X_i| \leq 3 \log^6 \Delta$.

Then there exists a matching M_i such that

1. *M_i misses S_i;*
2. *M_i meets every vertex of degree at least D_i in $V(G) - S_i - X_i$.*

Using these lemmas, along with Claim 1, it is now straightforward to prove Lemma 3 in the manner discussed earlier.

Proof of Lemma 3. For $i = 1, \ldots, D/2$, we choose X_i via Lemma 4 by setting $R = \cup_{k \in A_j, k<i} X_k$ where $i \in A_j$, noting that $|N(v) \cap R| \leq |A_j| \times 3 \log^6 \Delta \leq \frac{3D}{\log \Delta}$, and we choose M_i via Lemma 3. The result now follows as in the earlier discussion. ∎

We now complete the proof of Theorem 1 by proving Lemmas 4 and 5.

Proof of Lemma 4. We will choose X_i randomly. For each $v \in V(G) - R$, we place v in X_i with probability $p_i = \frac{2 \log^6 \Delta}{D_i + 2}$. For each $v \in V(G)$ define E_v to be the event that v violates one of the required conditions. Note that by the Chernoff bounds,

$$\begin{aligned}
\mathbf{Pr}(E_v) &\leq \mathbf{Pr}(|B(D_i + 2, p_i) - 2 \log^6 \Delta| > \tfrac{1}{3} \log^6 \Delta) \\
&\qquad + \mathbf{Pr}(|B(D_i - \tfrac{3D}{\log \Delta}, p_i) - p_i \times (D_i - \tfrac{3D}{\log \Delta})| > \tfrac{1}{6} \log^6 \Delta) \\
&\leq 2\mathrm{e}^{-\log^6 \Delta/54} + 2\mathrm{e}^{-\log^6 \Delta/108} \\
&< \Delta^{-3}.
\end{aligned}$$

Furthermore, each event E_v is mutually independent of all but at most Δ^2 other events. Therefore, our result follows from the local lemma as $\mathrm{e}\Delta^{-3}(\Delta^2 + 1) < 1$. ∎

Proof of Lemma 5. Suppose that such a matching does not exist. Then by a well-known extension of Tutte's theorem, there exist disjoint $T, Q \subset V(G_i) - S_i$ with $T \cap X_i = \emptyset$ such that each $v \in T$ has degree at least D_i in G; the subgraph induced by T has at least $|Q| + 1$ odd components $C_1, C_2, \ldots, C_{|Q|+1}$; and there are no edges from T to $G - (Q \cup S_i)$. (One way to see this is form G_i' by deleting S_i from G_i and then adding an edge between every pair of nonadjacent vertices that each have degree less than D_i in G_i. If $|G_i'|$ is odd, then add a vertex that is adjacent to every vertex of degree less than D_i in G_i. Now apply Tutte's theorem (see, e.g., [12]) to G_i'.)

For any disjoint $A, B \subseteq V(G_i)$, denote by $E(A, B)$ the set of edges with one endpoint in each of A, B.

CLAIM 2. *For each $1 \leq i \leq |Q| + 1$, $|E(C_i, Q)| \geq D_i - \log^5 \Delta$.*

Proof.

Case 1. $|C_i| \leq D_i/3$.

$|E(C_i, Q \cup S_i)| \geq D_i |C_i| - \binom{|C_i|}{2}$, and $|E(C_i, S_i)| \leq |C_i| \log^5 \Delta$. Therefore, $|E(C_i, Q)| \geq |C_i|(D_i - \log^5 \Delta) - \binom{|C_i|}{2} \geq D_i - \log^5 \Delta$.

Case 2. $|C_i| > D_i/3$.

For each $v \in C_i$, $|E(\{v\}, X_i)| \geq \log^6 \Delta$ and $|E(\{v\}, S_i)| \leq \log^5 \Delta$. Therefore, $|E(C_i, Q)| \geq |C_i|(\log^6 \Delta - \log^5 \Delta) \geq D_i - \log^5 \Delta$. □

CLAIM 3. *For each* $v \in Q$, $|E(\{v\}, T)| \leq D_i - \log^6 \Delta$.

Proof. This follows from the fact that $T \cap X_i = \emptyset$. □

Therefore, we have $(|Q| + 1)(D_i - \log^5 \Delta) \leq |E(T, Q)| \leq |Q|(D_i - \log^6 \Delta)$. Thus $D_i \leq \log^5 \Delta$ which contradicts $D \geq 8 \log^8 \Delta$. □

3. An efficient algorithm. We note here that our proof can be made algorithmic using the techniques developed by Beck [2], at the price of increasing our lower bound on Δ. Set $n = |V(G)|$.

In [9] the present authors provide an $O(n^3 \log^{O(1)} n)$ randomized algorithm and a polytime deterministic algorithm to find a $\log^5 \Delta$-frugal $(\Delta + 1)$-coloring of G. After doing this, we must find the set X_i guaranteed by Lemma 2 and the matching M_i guaranteed by Lemma 3 fewer than Δ times, and finally we must find the $8 \log^8 \Delta$ edge coloring used in the proof of Theorem 1. The latter step can be done in $O(n^4)$ steps, or we can find a $16 \log^8 \Delta$ edge coloring in $O(n^2)$ steps. Each M_i can be found in $O(n^{2.5})$ steps, as in [5] or [13]. It only remains to find X_i.

This can be done in $O(n^2 \log^{O(1)} n)$ steps using an algorithm essentially the same as that in section 4 of [2]. The only modification required is to allow for sampling with probability p_i here rather than with probability $\frac{1}{2}$ as in [2]. This can be done in a straightforward manner as described in [9].

Thus we have a $O(n^{2.5} \log^{O(1)} n)$-time randomized algorithm and a polytime deterministic algorithm for finding a $\Delta + 16 \log^8 \Delta$ total coloring of G.

4. Remarks. It is worth noting that by being more careful with our calculations, both here and in [9], and raising our lower bound on Δ, we can find a $\log^3 \Delta$-frugal $(\Delta + 1)$-coloring for any graph with maximum degree Δ sufficiently large, and we can find a $\Delta + \log^4 \Delta$ total coloring. However, these techniques do not appear to be sufficient to get a bound any lower than $\Delta + \text{poly}(\log \Delta)$.

Alon [1] has shown how to modify the technique of [2] to produce parallel algorithms. This does not seem to apply here.

Recently, Molloy and Reed [14] have improved the upper bound on the total chromatic number to $\Delta + C$ for a large constant C. The proof uses a different, much more complicated technique and does not appear to yield an efficient algorithm for finding such a coloring.

Acknowledgments. We would like to thank two anonymous referees for several improvements.

COMPUTING COMPONENTS AND PROJECTIONS OF CURVES OVER FINITE FIELDS*

JOACHIM VON ZUR GATHEN† AND IGOR SHPARLINSKI‡

Abstract. This paper provides an algorithmic approach to some basic algebraic and combinatorial properties of algebraic curves over finite fields: the number of points on a curve or a projection, its number of absolutely irreducible components, and the property of being "exceptional."

Key words. curves over finite fields, computational algebraic geometry, approximation algorithms

1. Introduction. Let $\mathbb{F}_q$ be a finite field with q elements, $f \in \mathbb{F}_q[x,y]$ a bivariate polynomial of total degree n over $\mathbb{F}_q$, and $\mathcal{C} = \{f = 0\} = \{(u,v) \in \mathbb{F}_q^2 \colon f(u,v) = 0\} \subseteq \mathbb{F}_q^2$ the plane curve defined by f over $\mathbb{F}_q$. In this paper we present some algorithms to compute approximations to the curve size $\#\mathcal{C}$ and to the number r_i^* of points with exactly i preimages under the projection to a coordinate axis. Since this task generalizes Weil's estimate of $\#\mathcal{C}$, it might be called a "computational Weil estimate."

In [7], a "strip-counting" method was introduced. It is based on the general principle that the behavior of a curve can be deduced from its behavior over a wide enough vertical strip.

To be specific, let $S \subseteq \mathbb{F}_q$, $i \in \mathbb{N}$, and $\mathcal{C}(S)$ be the set of $(u,v) \in S \times \mathbb{F}_q$ with $f(u,v) = 0$. Furthermore, $R_i(S)$ is the set of $u \in S$ for which there are exactly i values $v \in \mathbb{F}_q$ with $f(u,v) = 0$, $r_i(S) = \#R_i(S)$, $M(S)$ is the number of triples $(u,v,w) \in S^2 \times \mathbb{F}_q$ with $f(u-v,w) = 0$, and $t_i(S)$ is the number of pairs $(u,v) \in S^2$ for which there are exactly i values $w \in \mathbb{F}_q$ satisfying $f(u-v,w) = 0$.

The basic idea now is that for some properties of curves, we can find reasonably small sets S such that the above parameters are not too hard to compute, and give information about some of the global parameters we are interested in.

A completely different approach, pioneered in [19], leads to deterministic algorithms for computing the size of $\mathcal{C} \subseteq \mathbb{F}_p^2$ with time polynomial in $\log p$ (and exponential in the degree); see [17], [11]. A method for higher-dimensional varieties is in [12].

If the set S is given in some reasonable sense, e.g., if we have an efficient way to enumerate all elements of S, then we can compute $\#\mathcal{C}(S)$ and all $r_i(S)$ for $0 \le i \le n$ in time $O\tilde{}(|S| n \log q)$ (see Lemma 2.5 below). Thus $\#\mathcal{C}$ and r_i^* may be computed in exponential time of order $O\tilde{}(nq)$ by this "brute force" algorithm. Here, we use the "soft-Oh" notation: $A = O\tilde{}(B)$ if and only if $A = B(\log B + 2)^{O(1)}$.

Continuing the work in [7], we show that for certain small sets S, the numbers $q\#\mathcal{C}(S)/\#S$ or $qM(S)/\#S^2$, and $qr_i(S)/\#S$ or $qt_i(S)/\#S^2$ are rather good approx-

imations to the curve size $\#\mathcal{C}$ and the projection statistics r_i^*, respectively. (The quality of these approximations is described in detail below.) In particular, to estimate $\#\mathcal{C}$, this is true for random sets of cardinality of order n^3, for any set of size of order $n^2q^{1/2}$, and for a random shift of any set of size of order n^4. The latter is a positive answer to Question 7.2 of [7] and is an example of reducing the number of random choices required in probabilistic algorithms. These results motivate the strip-counting terminology, in that it is sufficient to count points in the strip $S \times \mathbb{F}_q$ over S.

We consider mainly the case of finite prime fields, but we also show how some results can be generalized to the case of general finite fields, and outline some difficulties that do not allow us to generalize all results.

From $r_i(S)$ and $t_i(S)$ for $0 \le i \le n$ (or their approximations) we can compute (or estimate) the numbers $\#\mathcal{C}(S)$ and $M(S)$, respectively, as

$$\#\mathcal{C}(S) = \sum_{1 \le i \le n} r_i(S)i, \quad M(S) = \sum_{1 \le i \le n} t_i(S)i. \tag{1.1}$$

A connection in the opposite direction is given in Lemma 2.2 below.

The more general problem about the number of $u \in \mathbb{F}_q$ for which the polynomial $f(u, y) \in \mathbb{F}_q[y]$ has a given "factorization pattern" can be reduced to calculating analogues of r_i^* in extensions of the ground field $\mathbb{F}_q$.

For a curve of the form $f(x, y) = x - h(y)$, with $h(y) \in \mathbb{F}_q[y]$, $r_0^* = 0$ is equivalent to h being a permutation polynomial over $\mathbb{F}_q$.

Throughout the paper, we use the following terminology. Let K be an algebraic closure of $\mathbb{F}_q$ and $\mathcal{X} \subseteq K^{m+1}$ be an algebraic curve over K, defined over $\mathbb{F}_q$, and $\mathcal{C} = \mathcal{X} \cap \mathbb{F}_q^{m+1}$ the $\mathbb{F}_q$-rational points on $\mathcal{X}$. Since we are only interested in set-theoretic (counting) properties of $\mathcal{C}$ (and not sheaf-theoretic ones), we assume that $\mathcal{X}$ is reduced and without embedded points; $\mathcal{X}$ may be reducible and have singular points. Most of our results deal with the case $m = 1$, where we assume that $\mathcal{C}$ (and $\mathcal{X}$) are given by some polynomial $f \in \mathbb{F}_q[x, y]$, as $\mathcal{C} = \{f = 0\}$. Since the curve is reduced, f is squarefree. In the proofs, certain fiber products of $\mathcal{C}$ occur. A further assumption, without loss of generality, is that $\mathcal{C} \subseteq \mathbb{F}_q^2$ contains no vertical lines; this is defined in section 2. We denote by σ the number of absolutely irreducible components, i.e., the number of irreducible components of $\mathcal{C}$ over K that are defined over $\mathbb{F}_q$, and we use parameters λ_i defined in (2.3), via the fiber power of the curve. Lemmas 2.1 and 2.3 show that we automatically get approximations of order $O(q^{1/2})$ (for n fixed) to $\#\mathcal{C}$ and r_i^*, respectively, from approximations to σ and λ_i. So we shall mainly concentrate on algorithms to compute the latter parameters. Moreover, it also follows from those lemmas that in order to determine σ and r_i^*, it is enough to get approximations to $\#\mathcal{C}$ and to r_i^* with absolute errors less than $q/2$ and $q/2n!$, respectively. We consider the following three important special cases: $\sigma = 0$ ("exceptional curves"), $\sigma = 1$ ("almost absolutely irreducible curves"), and $\lambda_0 = 0$ ("almost permutation curves").

Our algorithms address a fairly difficult problem and have the following properties:

- they are easy to state and implement;
- their proofs of correctness rely on deep results from arithmetical algebraic geometry.

Table 1 below summarizes our algorithmic results.

2. Some general results. We start by collecting some facts about curves over finite fields. The following inequality is a consequence of the famous Weil result and Lemma 2.2 of [7], which gives a bound for the number of points on intersections

TABLE 1

Computing various parameters for a curve in $\mathbb{F}_q^2$ of degree n: absolutely irreducible components, *λ_i (see (2.3)),* exceptional, one component, *and $\lambda_0 = 0$. The* time *is the number of operations in $\mathbb{F}_q$, and* random *the number of random elements; both in the $O^{\sim}$-sense. If random is* 0, *we have a deterministic algorithm. For all probabilistic algorithms, the error probability is at most δ, and $q \geq$ indicates the lower bound on q, in the $O^{\sim}$-sense. The* condition *is either Condition A from section* 4, *or that the field size be a prime p.*

of absolutely irreducible curves and for the number of points on irreducible but not absolutely irreducible curves.

LEMMA 2.1. *Let $\mathcal{C} \subseteq \mathbb{F}_q^{m+1}$ be a curve of degree n over $\mathbb{F}_q$ with σ absolutely irreducible components defined over $\mathbb{F}_q$. Then*

$$\bigl|\#\mathcal{C} - \sigma q\bigr| \leq n^2 q^{1/2}.$$

Proof. Let $\mathcal{C}_1, \ldots, \mathcal{C}_\tau$ be the irreducible components of $\mathcal{C}$ over $\mathbb{F}_q$, with $\mathcal{C}_i$ absolutely irreducible if and only if $i \leq \sigma$. From the proof of Lemma 2.2 in [7], we find

$$\begin{aligned}
|\#\mathcal{C} - \sigma q| &\leq \Biggl|\#\mathcal{C} - \sum_{1 \leq i \leq \sigma} \#\mathcal{C}_i\Biggr| + \sum_{1 \leq i \leq \sigma} \bigl|\#\mathcal{C}_i - q\bigr| \\
&< \sum_{1 \leq i < j \leq \sigma} n_i n_j + \sum_{\sigma < i \leq \tau} n_i^2/4 + q^{1/2} + \sum_{1 \leq i \leq \sigma} n_i^2 \\
&\leq \Biggl(\sum_{1 \leq i \leq \tau} n_i\Biggr)^2 q^{1/2} \leq n^2 q^{1/2}. \qquad \square
\end{aligned}$$

Let $\mathcal{C} \subset \mathbb{F}_q^{m+1}$ be a curve. Throughout this paper, we assume that $\mathcal{C}$ is *without vertical components*, i.e., no absolutely irreducible component of $\mathcal{C}$ is contained in a hyperplane $\{a\} \times \mathbb{F}_q^m$, for some $a \in \mathbb{F}_q$. For a plane curve $\mathcal{C} = \{f = 0\}$, with $f = \sum_i f_i y^i \in \mathbb{F}_q[x, y]$ and all $f_i \in \mathbb{F}_q[x]$, this is the case if and only if $\gcd(f_0, f_1, \ldots) = 1$. In that case, we also say that $\mathcal{C}$ is *without vertical lines*. For the computational problems we consider, the general case is easily reduced to this (slightly) restricted one.

Furthermore, let $i \in \mathbb{N}$ and $S \subseteq \mathbb{F}_q$. We consider the difference map $\delta\colon S^2 \to \mathbb{F}_q$ with $\delta(u_1, u_2) = u_1 - u_2$, and denote by id the identity on $\mathbb{F}_q^m$. We define the following:

$$\begin{aligned}
\mathcal{C}(S) &= \mathcal{C} \cap (S \times \mathbb{F}_q^m) \;=\; \{(u, v)\colon (u, v) \in \mathcal{C},\ u \in S\} \subseteq \mathbb{F}_q^{m+1}, \\
R_i(S) &= \{u \in S\colon \#\mathcal{C}(\{u\}) = i\}, \\
r_i(S) &= \#R_i(S), \\
\mathcal{C}^\delta(S) &= (\delta \times \mathrm{id})^{-1}(\mathcal{C}) = \{(u_1, u_2, v)\colon (u_1 - u_2, v) \in \mathcal{C},\ u_1, u_2 \in S\},
\end{aligned}$$

$$M(S) = \#\mathcal{C}^{\delta}(S),$$
$$t_i(S) = \#\delta^{-1}(R_i(S)).$$

We also set $r_i^* = r_i(\mathbb{F}_q)$ and $t_i^* = t_i(\mathbb{F}_q)$. All these definitions coincide with the ones in the introduction if $\mathcal{C}$ is a plane curve. For a plane curve $\mathcal{C}$ given by $f \in \mathbb{F}_q[x,y]$ and $1 \le k \le n$, we define the curve $\mathcal{C}_k \subseteq \mathbb{F}_q^{k+1}$ as the closure of

$$\begin{aligned} S_k \;=\; & \{(u, v_1, \dots, v_k) \in \mathbb{F}_q^{k+1} : \\ & f(u,v_1) = \cdots = f(u,v_k) = 0,\ v_i \neq v_j \text{ for } 1 \le i < j \le k\}. \end{aligned} \tag{2.1}$$

To define this closure of S_k, we take the set X of all points in K^{k+1} satisfying the equations and inequalities in (2.1), its (Zariski-) closure $\overline{X}$ (i.e., all points satisfying all polynomials over K that vanish on X), and then $\mathcal{C}_k = \overline{X} \cap \mathbb{F}_q^{k+1}$. The geometry of $\mathcal{C}_2$ and the equations defining it as a complete intersection are described in detail in [8] and an example is given below. $\mathcal{C}_k$ is the k-fold fiber power of $\mathcal{C}$ along the first projection; it may be empty. Applying Bézout's theorem to the equations in (2.1), we find deg $\mathcal{C}_k \le n^k$; in fact, deg $\mathcal{C}_k \le n(n-1)\cdots(n-k+1)$. It can, of course, also be defined for curves in $\mathbb{F}_q^{m+1}$ with $m > 1$. The following statement is essentially Lemma 3.2 of [7].

LEMMA 2.2. *For a plane curve $\mathcal{C} \subseteq \mathbb{F}_q^2$ without vertical lines and of degree n, $S \subseteq \mathbb{F}_q$, and $0 \le i \le n$, we have*

$$r_i(S) = \frac{1}{i!} \sum_{i \le k \le n} \frac{(-1)^{i+k}\, \#\mathcal{C}_k(S)}{(k-i)!}, \tag{2.2}$$
$$t_i(S) = \frac{1}{i!} \sum_{i \le k \le n} \frac{(-1)^{i+k}\, \#\mathcal{C}_k^{\delta}(S)}{(k-i)!}.$$

In view of these expressions, we consider the number σ_k of absolutely irreducible components defined over $\mathbb{F}_q$ of $\mathcal{C}_k$, with $\sigma_0 = 1$, and for $0 \le i \le n$ set

$$\lambda_i = \frac{1}{i!} \sum_{i \le k \le n} \frac{(-1)^{i+k}\sigma_k}{(k-i)!} \in \mathbb{Q}. \tag{2.3}$$

LEMMA 2.3. *Let $\mathcal{C} \subseteq \mathbb{F}_q^2$ be a curve without vertical lines given by $f \in \mathbb{F}_q[x,y]$ of degree n, and $\lambda_0, \dots, \lambda_n$ as above. Then for $0 \le i \le n$, we have $n!\lambda_i \in \mathbb{Z}$, and*

$$|r_i^* - \lambda_i q| \le 2n^{2n} q^{1/2}. \tag{2.4}$$

Proof. Noting that $\mathcal{C}_k$ is of degree at most n^k and using σ_k as above, we find from Lemmas 2.1 and 2.2 that

$$\begin{aligned} \left| r_i^* - q\lambda_i \right| &= \frac{1}{i!} \left| \sum_{i \le k \le n} \frac{(-1)^{i+k}(\#\mathcal{C}_k - \sigma_k q)}{(k-i)!} \right| \\ &\le \frac{q^{1/2}}{i!} \sum_{i \le k \le n} \frac{n^{2k}}{(k-i)!} \le \frac{q^{1/2}(n^2)^{n+1} - 1}{n^2 - 1} \le 2n^{2n} q^{1/2} \end{aligned}$$

for $n \ge 2$; the case $n = 1$ is trivial. Furthermore $i!(k-i)!$ divides $n!$ for all $0 \le i \le k \le n$. ∎

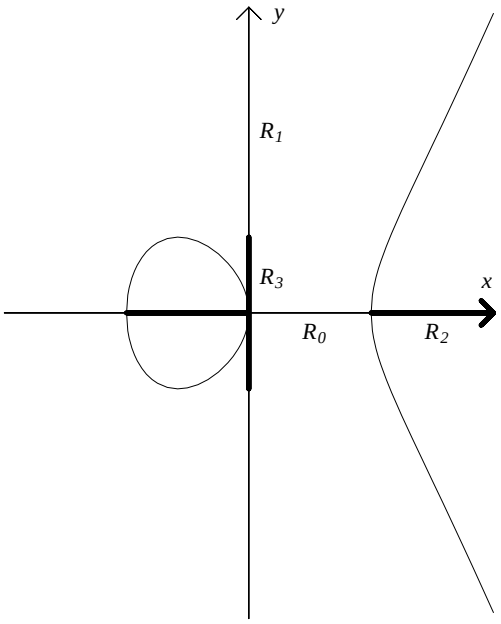

FIG. 1. *The elliptic curve $y^2 = x^3 - x$ over $\mathbf{R}$, the sets R_0 and R_2 for the first projection, and the sets R_1 and R_3 for the second projection.*

EXAMPLE 2.4. *We take the (irreducible) elliptic curve $\mathcal{C} = \{f = 0\}$ of degree $n = 3$ given by $f = y^2 - x^3 + x \in \mathbb{F}_q[x, y]$, where $q = 1019$ is prime. Figure* 1 *gives the picture over $\mathbb{R}$. Then $\mathcal{C}_2$ is given by the equations*

$$-u^3 + u = v_1^2, v_1 + v_2 = 0.$$

The latter equation comes from eliminating u and dividing the result $v_1^2 - v_2^2$ by $v_1 - v_2$. Thus $\mathcal{C}_2$ is isomorphic to $\mathcal{C}$ and irreducible, and $\sigma_2 = 1$. Furthermore, $\mathcal{C}_3 = \emptyset$ and $\sigma_3 = 0$, so that

$$\lambda_0 = \frac{1}{2}, \quad \lambda_1 = 0, \quad \lambda_2 = \frac{1}{2}, \quad \lambda_3 = 0.$$

For the two sets $S_1 = \mathbb{F}_q$ and $S_2 = \{0, 1, 2, \ldots, 49\}$ we find

i	$r_i(S_1) = r_i^*$	$\#\mathcal{C}_i(S_1)$	$r_i^* - \lambda_i q$	$r_i(S_2)$	$\#\mathcal{C}_i(S_2)$
0	508	1019	-1.5	26	50
1	3	1019	3	2	2
2	508	1016	-1.5	22	22
3	0	0	0	0	0

Of course, (2.2) *could have been used to predict the r_i^* approximately. The pessimistic bound* (2.4) *actually holds with the error term $3 < 46{,}541.95 \approx 2n^{2n}q^{1/2}$. As expected from the picture of the curve $\{y^2 = x^3 - x\}$ over $\mathbb{R}$, there are (almost) no points with* 1 *or* 3 *preimages under the first projection. The other two possibilities, of* 0 *or* 2 *preimages, occur equally often. The three points with one preimage are $0, 1, -1$.*

It is instructive to also look at the projection of $\mathcal{C}$ onto the y-axis. To preserve terminology, we thus take $f = x^2 - y^3 + y$. Then $\mathcal{C}_2$ is

$$\mathcal{C}_2 = \{(u, v_1, v_2) \in \mathbb{F}_q^3 \colon f(u, v_1) = 0, v_1^2 + v_1 v_2 + v_2^2 - 1 = 0\}. \tag{2.5}$$

$\mathcal{C}_2$ is irreducible, and $\sigma_2 = 1$. For $\mathcal{C}_3$, we have to add the equation

$$v_1 + v_2 + v_3 = 0$$

to those in (2.5); *thus $\mathcal{C}_3 \cong \mathcal{C}_2$ and $\sigma_3 = 1$. We find*

$$\lambda_0 = \frac{1}{3}, \lambda_1 = \frac{1}{2}, \lambda_2 = 0, \lambda_3 = \frac{1}{6},$$

and with S_1 and S_2 as above, we have

i	$r_i(S_1) = r_i^*$	$\#\mathcal{C}_i(S_1)$	$r_i^* - \lambda_i q$	$r_i(S_2)$	$\#\mathcal{C}_i(S_2)$
0	340	1019	0.33	14	50
1	508	1019	−1.5	24	60
2	2	1020	2	0	72
3	169	1020	−0.83	12	72

Again, (2.4) *holds with the bound* $2 < 46{,}541.95$. *This example shows how the λ_i's comprise in a concise way reasonably good information about the projection statistics of the curve. Note that in the picture over $\mathbb{R}$ the set corresponding to R_0 is empty.*

We denote by $\mathsf{M}(n)$ the Boolean complexity of multiplication of two n-bit numbers. The currently best estimate [18] of this function is

$$\mathsf{M}(n) = O(n \log n \operatorname{loglog} n).$$

As in the proof of Lemma 2.5 of [7], we find the following result.

LEMMA 2.5. *Let $\mathcal{C} \subseteq \mathbb{F}_q^2$ be without vertical lines and given by $f \in \mathbb{F}_q[x, y]$ of degree n, and $u \in \mathbb{F}_q$. Then $\#\mathcal{C}(\{u\})$ can be computed with $O(\mathsf{M}(n) \log(nq))$ arithmetic operations in $\mathbb{F}_q$.*

3. Counting with random elements. Throughout this section, $\mathcal{C}$ is a plane curve without vertical lines. We extend our notions $\mathcal{C}(S)$, $R_i(S)$, $r_i(S)$ to a sequence $S = (s_1, \ldots, s_h)$ of elements of $\mathbb{F}_q$ in the obvious way, e.g., we set $\#\mathcal{C}(S) = \sum_{1 \le i \le h} \#\mathcal{C}(\{s_i\})$. In particular, when S is a sequence of random elements of $\mathbb{F}_q$, $\#\mathcal{C}(S)$ and $r_i(S)$ are random variables. We state our algorithms in this section for a sequence of h random elements, because for a computer implementation such a sequence is slightly more natural than a random subset of size h; the results also hold for such a random subset.

The following bound on the difference between a sample mean and the true expected value is a direct consequence of the general result of [13] (see also Theorem 7.2 of [7]) and the trivial bounds $\#\mathcal{C} \le nq$ and $r_i^* \le q$.

LEMMA 3.1. *Let S be a sequence of h independently and uniformly distributed random elements of $\mathbb{F}_q$, $0 \le i \le n$, and $\delta > 0$. Then the following hold with probability at least $1 - \delta$:*

$$\begin{aligned} |\#\mathcal{C} - q\#\mathcal{C}(S)h^{-1}| &\le \left(2n(n+1)q\#\mathcal{C} \log(2n/\delta)h^{-1}\right)^{1/2} \\ &\le nq\left(2(n+1)\log(2n/\delta)h^{-1}\right)^{1/2}, \end{aligned}$$

$$|r_i^* - qr_i(S)h^{-1}| \le 2\left(qr_i^* \log(2/\delta)h^{-1}\right)^{1/2} \le 2q\left(\log(2/\delta)h^{-1}\right)^{1/2}.$$

ALGORITHM 3.2. *Components.*
Input: $f \in \mathbb{F}_q[x,y]$ *of degree* n, *and* $\delta > 0$.
Output: *An estimate of the number of absolutely irreducible components of* $\mathcal{C} = \{f = 0\}$ *defined over* $\mathbb{F}_q$.

1. *Set* $h = \lceil 72n^2(n+1)\log(2n/\delta)\rceil$.
2. *Choose a sequence* S *of* h *random independently uniformly distributed elements of* $\mathbb{F}_q$.
3. *Compute* $\#\mathcal{C}(S)$.
4. *Return the nearest integer to* $\#\mathcal{C}(S)/h$.

THEOREM 3.3. *Assume that* $q \geq 36n^4$. *Then Algorithm* 3.2 *outputs the number* σ *of absolutely irreducible components correctly with probability at least* $1-\delta$. *It uses* $O(n^3\log(n/\delta))$ *random elements and* $O(n^3\mathsf{M}(n)\log(n/\delta)\log(nq))$ *arithmetic operations in* $\mathbb{F}_q$.

Proof. The cost bound follows from Lemma 2.5, and Lemmas 2.1 and 3.1 show that

$$|\sigma - \#\mathcal{C}(S)h^{-1}| \leq n^2 q^{-1/2} + n\left(2(n+1)\log(2n/\delta)h^{-1}\right)^{1/2} \leq 1/6 + 1/6 = 1/3$$

with probability at least $1-\delta$. □

We call a curve $\mathcal{C}$ over $\mathbb{F}_q$ *exceptional* (over $\mathbb{F}_q$) if and only if none of the irreducible components of $\mathcal{C}$ defined over $\mathbb{F}_q$ is absolutely irreducible. In particular, a plane curve $\mathcal{C} = \{f = 0\}$ with $f \in \mathbb{F}_q[x,y]$ is exceptional if and only if none of the irreducible factors of f over $\mathbb{F}_q$ is absolutely irreducible. This notion plays a central role in the study of permutation polynomials: $g \in \mathbb{F}_q[x]$ is a permutation polynomial if and only if $(g(x)-g(y))/(x-y)$ is exceptional provided that $q \geq 16(\deg g)^4$ [4], [5].

ALGORITHM 3.4. *Exceptional test.*
Input: $f \in \mathbb{F}_q[x,y]$ *of degree* n, *and* $\delta > 0$.
Output: *YES if* f *is exceptional, and NO otherwise.*

1. *Set* $h = \lceil 16n(n+1)\log(2n/\delta)\rceil$.
2. *Choose a sequence* S *of* h *random independently uniformly distributed elements of* $\mathbb{F}_q$.
3. *Compute* $\#\mathcal{C}(S)$.
4. *If* $\#\mathcal{C}(S) \leq n^2/4$ *then return YES else return NO.*

THEOREM 3.5. *Assume that* $q \geq 4n^4$. *If* f *is exceptional, Algorithm* 3.4 *answers correctly. If* f *is not exceptional, Algorithm* 3.4 *answers correctly with probability at least* $1-\delta$. *It uses* $O(n^2\log(n/\delta))$ *random elements and* $O(n^2\mathsf{M}(n)\log(n/\delta)\log(nq))$ *arithmetic operations in* $\mathbb{F}_q$.

Proof. Let σ be the required number of components. If $\sigma = 0$, then $\#\mathcal{C} \leq n^2/4$; see Lemma 5.2(ii) of [7] for an example. Thus the algorithm answers correctly in this case. It is sufficient to estimate the probability that $\#\mathcal{C}(S) \leq n^2$ when $\sigma \geq 1$. From Lemma 2.1 we get

$$\#\mathcal{C} \geq q - n^2 q^{1/2} \geq q/2.$$

Assuming that $\delta \leq 1$, Lemma 3.1 implies that with probability at least $1-\delta$ we have

$$\begin{aligned}\#\mathcal{C}(S) &\geq \frac{h\#\mathcal{C}}{q} - \frac{h}{q}\left(2n(n+1)q\#\mathcal{C}\log(2n/\delta)h^{-1}\right)^{1/2} \\ &\geq \frac{h\#\mathcal{C}}{q}\left(1 - \left(\frac{q}{\#\mathcal{C}}\cdot\frac{1}{8}\right)^{1/2}\right) \;\geq\; \frac{h}{2}\left(1 - \left(\frac{1}{4}\right)^{1/2}\right) \;=\; \frac{h}{4} \;>\; n^2. \qquad \square\end{aligned}$$

ALGORITHM 3.6.
Input: $f \in \mathbb{F}_q[x,y]$ *of degree* n, *and* $\delta > 0$.
Output: *YES if* $\mathcal{C} = \{f = 0\}$ *has exactly one absolutely irreducible component defined over* $\mathbb{F}_q$, *and NO otherwise.*

1. *Return NO if* f *is exceptional, using Algorithm* 3.4 *with input* $(f, \delta/2)$.
2. *Set* $h = \lceil 90n(n+1)\log(4n/\delta)\rceil$.
3. *Choose a sequence* S *of* h *random independent uniformly distributed elements of* $\mathbb{F}_q$.
4. *Compute* $\#\mathcal{C}(S)$.
5. *If* $\#\mathcal{C}(S) \le 17h/12$ *then return YES else return NO.*

THEOREM 3.7. *Let* $q \ge 16n^4$. *With probability at least* $1-\delta$, *Algorithm* 3.6 *decides correctly whether* $\mathcal{C}$ *has exactly one absolutely irreducible component defined over* $\mathbb{F}_q$. *It uses* $O(n^2\log(n/\delta))$ *random elements and* $O(n^2\mathsf{M}(n)\log(n/\delta)\log(nq))$ *arithmetic operations in* $\mathbb{F}_q$.

Proof. Let σ be the number of components. The cost estimate follows from Lemma 2.5. We may assume that $\sigma \ge 1$, and have to bound the error probability. If $\sigma = 1$, then we get from Lemma 2.1 that

$$\#\mathcal{C} \le q + n^2 q^{1/2} \le 5q/4,$$

and from Lemma 3.1 that

$$\begin{aligned}\#\mathcal{C}(S) &\le h\#\mathcal{C}/q + \frac{h}{q}\left(2n(n+1)q\#\mathcal{C}\log(4n/\delta)h^{-1}\right)^{1/2}\\ &\le \frac{5h}{4} + h\left(\frac{5}{4\cdot 45}\right)^{1/2} = \frac{17h}{12}\end{aligned}$$

with probability at least $1-\delta/2$. Otherwise,

$$7q/4 \le 2q - n^2q^{1/2} \le \#\mathcal{C} \le 2q + n^2q^{1/2} \le 9q/4,$$

and with probability at least $1-\delta/2$

$$\begin{aligned}\#\mathcal{C}(S) &\ge \frac{h\#\mathcal{C}}{q} - \frac{h}{q}\left(2n(n+1)q\#\mathcal{C}\cdot\log(4n/\delta)h^{-1}\right)^{1/2}\\ &\ge \frac{7h}{4} - h\cdot\left(\frac{9}{4\cdot 45}\right)^{1/2} = \frac{(35-2\sqrt{5})h}{20} > \frac{17h}{12}.\end{aligned}$$

□

Our next algorithm computes the rational numbers $\lambda_0,\dots,\lambda_n$. In view of (2.3), this is equivalent to calculating $\sigma_0,\dots,\sigma_n$ up to a triangular system of linear equations; we do not know a direct easy way to compute these σ_i's.

ALGORITHM 3.8.
Input: $f \in \mathbb{F}_q[x,y]$ *of degree* n, *and* $\delta > 0$.
Output: *The parameters* $\lambda_0,\dots,\lambda_n$ *of* $\mathcal{C} = \{f = 0\}$ *as defined in* (2.3).

1. *Set* $h = \lceil 144(n!)^2\log(2/\delta)\rceil$.
2. *Choose a sequence* S *of* h *random independently uniformly distributed elements of* $\mathbb{F}_q$.
3. *For* $i = 1,\dots,n$ *do steps* 4, 5, 6.
4. *Compute* $r_i(S)$.
5. *Compute the nearest integer* Λ_i *to* $n!r_i(S)/h$.
6. Return $\Lambda_i/n!$.

THEOREM 3.9. *If $q \geq 144n^{4n}(n!)^2$, then Algorithm* 3.8 *computes the parameters $\lambda_0, \ldots, \lambda_n$ of $\mathcal{C} = \{f = 0\}$ correctly with probability at least $1 - \delta$. It uses $O((n!)^2 \log(\delta^{-1}))$ random elements, and $O((n!)^2 \mathsf{M}(n) \log(\delta^{-1}) \log(nq))$ arithmetic operations in $\mathbb{F}_q$.*

Proof. From Lemmas 2.3 and 3.1, we find that with probability at least $1 - \delta$

$$|\lambda_i - r_i(S)h^{-1}| \leq 2n^{2n}q^{-1/2} + 2\big(\log(2/\delta)h^{-1}\big)^{1/2} < 1/6n! + 1/6n! < 1/3n!,$$

and in this case the output is correct. The cost estimate follows from Lemma 2.5. □

Together with Lemma 2.3, this gives an estimate for the r_i's, and, with (1.1) for $S = \mathbb{F}_q$, also for $\#\mathcal{C}$.

Let us now consider the special case of testing if $\lambda_0 = 0$. For a curve of the form $f = y - g(x)$ with $g \in \mathbb{F}_q[x]$, the condition $\lambda_0 = 0$ implies $r_0 = 0$ (at least for q large enough), i.e., that h is a permutation polynomial (see [5] for details).

ALGORITHM 3.10.
Input: *$f \in \mathbb{F}_q[x, y]$ of degree n, and $\delta > 0$.*
Output: *YES if $\lambda_0 = 0$ for $\mathcal{C} = \{f = 0\}$, else NO.*

1. *Set $h = \lceil 256(n!)^2 \log(2/\delta) \rceil$.*
2. *Choose a sequence S of h random independently uniformly distributed elements of $\mathbb{F}_q$.*
3. *Compute $\#\mathcal{C}(S)$.*
4. *Return YES if $\#\mathcal{C}(S) \leq h/4n!$, else NO.*

THEOREM 3.11. *If $q \geq 256n^{4n}(n!)^2$, then the output of Algorithm* 3.10 *is correct with probability at least $1 - \delta$. It uses $O(n! \log(\delta^{-1}))$ random elements and $O(n! \mathsf{M}(n) \log(\delta^{-1}) \log(nq))$ arithmetic operations in $\mathbb{F}_q$.*

Proof. The cost estimate follows from Lemma 2.5. To bound the error probability, we have from Lemma 2.3 that

$$\lambda_0 q - q/8n! \leq \lambda_0 q - 2n^{2n}q^{1/2} \leq r_0^* \leq \lambda_0 q + 2n^{2n}q^{1/2} \leq \lambda_0 q + q/8n!.$$

If $\lambda_0 = 0$, then we find from Lemma 3.1 that with probability at least $1 - \delta$

$$r_0(S) \leq hr_0^*/q + 2\big(h \log(2/\delta)\big)^{1/2} \leq h/8n! + h/8n! = h/4n!.$$

Now suppose that $\lambda_0 \neq 0$. Then $|\lambda_0| \geq 1/n!$. Furthermore, $\lambda_0 < 0$ would imply that $0 \leq r_0^* \leq -q/n! + q/8n! < 0$. Thus $\lambda_0 \geq 1/n!$, and with probability at least $1 - \delta$

$$r_0(S) \geq hr_0^*/q - 2\big(h \log(2/\delta)\big)^{1/2} \geq 7h/8n! - h/8n! = 3h/4n!. \qquad \square$$

4. Counting in additive strips. In this section, we continue to study properties of curves in additive strips. Our main tool is the bound from [1] on exponential sums along a curve. The various estimates we obtain give methods for approximating $\#\mathcal{C}$ and the r_i's, at least when q is large relative to n.

For integers a and h, we denote by $A(a, h)$ the interval

$$A(a, h) = \{(a + j) \bmod p \colon 0 \leq j < h\} \subseteq \mathbb{F}_q,$$

where $p = \operatorname{char} \mathbb{F}_q$, and for a curve $\mathcal{C} \subseteq \mathbb{F}_q^{m+1}$, we write

$$\mathcal{C}(a, h) = \mathcal{C}(A(a, h)), \qquad r_i(a, h) = r_i(A(a, h)),$$

$$M(a,h) = M(A(a,h)), \qquad t_i(a,h) = t_i(A(a,h)).$$

It follows from Lemma 2.1 of [7] that if x is not a constant along any absolutely irreducible component of $\mathcal{C}$ and $n = \deg\ \mathcal{C}$, then for any integers a and $h \le p$,

$$\bigl|\#\mathcal{C}(a,h) - h\#\mathcal{C}/p\bigr| \le 2n^2 p^{1/2}\log p. \tag{4.1}$$

Let K be an algebraic closure of $\mathbb{F}_q$. We will repeatedly use the following assumption on a curve $\mathcal{C} \subseteq \mathbb{F}_q^{m+1}$, which arises in Bombieri's work.

HYPOTHESIS A. *For every absolutely irreducible component $\mathcal{D}$ of $\mathcal{C}$ and every rational function g on K^{m+1}, x is different from $g^p - g$ on $\mathcal{D}$, where $p = \operatorname{char}\mathbb{F}_q$.*

In general, given the equations for $\mathcal{C}$, it seems not easy to check whether $\mathcal{C}$ satisfies Hypothesis A. If $x = g^p - g = \prod_{u\in\mathbb{F}_p}(g-u)$, then each $g-u$ has the same poles as x, and in particular the degree of the pole divisor of x is divisible by p. Thus

$$\deg\mathcal{C} < p \quad\Longrightarrow\quad \mathcal{C} \text{ satisfies Hypothesis A;} \tag{4.2}$$

see also Lemma 4 of [2].

Below we show that for the parameter $\#\mathcal{C}^\delta(S)$ a slightly stronger result than (4.1) holds for an arbitrary set $S \subseteq \mathbb{F}_q$.

LEMMA 4.1. *Let $\mathcal{C} = \mathbb{F}_q^{m+1}$ be a curve without vertical components and of degree n satisfying Hypothesis A, $S \subseteq \mathbb{F}_q$, and $h = \#S$. Then*

$$\bigl|\#\mathcal{C}^\delta(S) - h^2\#\mathcal{C}/q\bigr| < 2n^2 h q^{1/2}.$$

Proof. Let χ be a nontrivial additive character of $\mathbb{F}_q$. Then

$$\bigl|\#\mathcal{C}^\delta(S)\bigr| = \frac{1}{q}\sum_{(a,b)\in\mathcal{C}}\ \sum_{u,v\in S}\ \sum_{\lambda\in\mathbb{F}_q}\chi\bigl(\lambda(a-u+v)\bigr) = h^2\#\mathcal{C}/q + t/q,$$

where $a \in \mathbb{F}_q$ and $b \in \mathbb{F}_q^m$ in the sum, and

$$t = \sum_{\lambda\in\mathbb{F}_q^\times}\ \sum_{(a,b)\in\mathcal{C}}\chi(\lambda a)\sum_{u,v\in S}\chi(\lambda(u-v)).$$

The bound of [1, Theorem 6] implies that for $\lambda \in \mathbb{F}_q^\times$,

$$\Bigl|\sum_{(a,b)\in\mathcal{C}}\chi(\lambda a)\Bigr| \le (n^2-n)q^{1/2} + n^2 < 2n^2 q^{1/2}.$$

Therefore

$$\begin{aligned} t &< 2n^2 q^{1/2}\Bigl|\sum_{\lambda\in\mathbb{F}_q^\times}\ \sum_{u,v\in S}\chi(\lambda(u-v))\Bigr| \\ &= 2n^2 q^{1/2}\Bigl|\sum_{u,v\in S}\ \sum_{\lambda\in\mathbb{F}_q}\chi\bigl(\lambda(u-v)\bigr) - h^2\Bigr|. \end{aligned}$$

Since the inner sum equals 0 when $u \ne v$ and q otherwise, we get

$$t < 2n^2 h q^{3/2}. \qquad \square$$

We note that this lemma is nontrivial for sets of cardinality $h \ge 2n^2q^{1/2}$, while the above-mentioned result from [7] works only in case of a prime field $\mathbb{F}_q = \mathbb{F}_p$ and needs $h \ge 2n^2p^{1/2}\log p$.

For $w \in \mathbb{F}_q$ and $S \subseteq \mathbb{F}_q$, we denote by S_w the w-shift of S:

$$S_w = \{w + u : u \in S\}.$$

The following lemma shows that $q\#\mathcal{C}(S_w)/h$ is a good approximation to $\#\mathcal{C}$ for almost all w-shifts of any set $S \subseteq \mathbb{F}_q$ with $\#S \gg n^3$.

LEMMA 4.2. *Let $\mathcal{C} \subseteq \mathbb{F}_q^{m+1}$ be a curve without vertical components and of degree n satisfying Hypothesis A, $w \in \mathbb{F}_q$, $S \subseteq \mathbb{F}_q$, $h = \#S$, and*

$$s = \frac{1}{q}\sum_{w\in\mathbb{F}_q}\big(\#\mathcal{C}(S_w) - h\#\mathcal{C}/q\big)^2.$$

Then $s \le 4n^4h$, and if $q \ge n^2$, then $s \le n^4h$.

Proof. Let χ be a nontrivial additive character on $\mathbb{F}_q$. We have, as in the proof of the previous lemma,

$$\#\mathcal{C}(S_w) - h\#\mathcal{C}/q = \frac{1}{q}\sum_{\lambda\in\mathbb{F}_q^\times}\sum_{(a,b)\in\mathcal{C}}\chi(\lambda a)\sum_{u\in S}\chi\big(-\lambda(w+u)\big),$$

where $a \in \mathbb{F}_q$ and $b \in \mathbb{F}_q^m$. Hence

$$\sum_{w\in\mathbb{F}_q}\big|\#\mathcal{C}(S_w) - h\#\mathcal{C}/q\big|^2 = tq^{-2},$$

where

$$\begin{aligned} t &= \sum_{w\in\mathbb{F}_q}\Big|\sum_{\lambda\in\mathbb{F}_q^\times}\sum_{(a,b)\in\mathcal{C}}\chi(\lambda a)\sum_{u\in S}\chi\big(-\lambda(w+u)\big)\Big|^2 \\ &= \sum_{\lambda_1,\lambda_2\in\mathbb{F}_q^\times}\sum_{(a_1,b_1),(a_2,b_2)\in\mathcal{C}}\chi(\lambda_1a_1 - \lambda_2a_2)\sum_{u_1,u_2\in S}\chi(-\lambda_1u_1 + \lambda_2u_2) \\ &\quad\times\sum_{w\in\mathbb{F}_q}\chi\big(w(-\lambda_1+\lambda_2)\big). \end{aligned}$$

Since the last sum equals 0 when $\lambda_1 \ne \lambda_2$ and q otherwise, we find from Theorem 6 of [1] that

$$\begin{aligned} t &= q\sum_{\lambda\in\mathbb{F}_q^\times}\sum_{(a_1,b_1),(a_2,b_2)\in\mathcal{C}}\chi\big(\lambda(a_1-a_2)\big)\sum_{u_1,u_2\in S}\chi\big(\lambda(-u_1+u_2)\big) \\ &= q\sum_{\lambda\in\mathbb{F}_q^\times}\Big|\sum_{(a,b)\in\mathcal{C}}\chi(\lambda a)\Big|^2\sum_{u_1,u_2\in S}\chi\big(\lambda(-u_1+u_2)\big) \\ &\le q\big((n^2-n)q^{1/2}+n^2\big)^2\sum_{\lambda\in\mathbb{F}_q^\times}\sum_{u_1,u_2\in S}\chi\big(\lambda(u_1-u_2)\big) \\ &\le 4n^4q^2\Big|\sum_{\lambda\in\mathbb{F}_q}\sum_{u_1,u_2\in S}\chi(\lambda(u_1-u_2)) - h^2\Big|. \end{aligned}$$

We can replace 4 by 1 if $n^2 \le q$. The sum is zero when $u_1 \neq u_2$ and q otherwise, so that

$$t \le 4n^4q^2(qh - h^2) \le 4n^4hq^3. \qquad \square$$

COROLLARY 4.3. *Let $\mathcal{C} \subseteq \mathbb{F}_q^{m+1}$ be a curve without vertical components and of degree n satisfying Hypothesis A, $\delta > 0$, $S \subseteq \mathbb{F}_q$, and $h = \#S$. Then*

$$\big|\#\mathcal{C}(S_a) - h\#\mathcal{C}/q\big| \le 2\delta^{-1/2}n^2h^{1/2}$$

holds with probability at least $1 - \delta$ for random $a \in \mathbb{F}_q$.

LEMMA 4.4. *Let p be a prime, $\mathcal{C} \subseteq \mathbb{F}_p^2$ be a plane curve without vertical lines of degree n satisfying Hypothesis A, $0 \le i \le n$, $p > n^n$, and $a, h \in \mathbb{N}$ with $h \le p$. Then*

$$|t_i(a,h) - h^2r_i^*/p| \le 3n^{2n}hp^{1/2},$$
$$|r_i(a,h) - \ hr_i^*/p| \le 3n^{2n}p^{1/2}\log p.$$

Proof. For $1 \le k \le n$, we have deg $\mathcal{C}_k \le n^k < p$, and thus $\mathcal{C}_k$ satisfies Hypothesis A, by (4.2). Lemma 4.1 implies that

$$\big|\#\mathcal{C}_k^\delta(a,h) - h^2\#\mathcal{C}_k/p\big| \le 2n^{2k}hp^{1/2}.$$

Let $0 \le i \le n$. From Lemma 2.2, we have

$$|t_i(a,h) - h^2t_i^*/p| \le \frac{1}{i!}\sum_{i\le k\le n}\frac{\big|\#\mathcal{C}_k^\delta(a,h) - h^2\#\mathcal{C}_k/p\big|}{(k-i)!}$$
$$\le\ \frac{1}{i!}\sum_{i\le k\le n}\frac{2n^{2k}hp^{1/2}}{(k-i)!} \le 2n^{2n}hp^{1/2}\frac{n^2}{n^2-1}\ \le\ 3n^{2n}hp^{1/2}.$$

Using (4.1), the second bound follows in a similar way. $\square$

We next show that for almost all a a much stronger bound than the second estimate in Lemma 4.4 holds.

LEMMA 4.5. *Let $p > n^n$ be a prime, $\mathcal{C} \subseteq \mathbb{F}_p^2$ a plane curve without vertical lines and of degree n, $0 \le i \le n$, and $h \le p$. Then*

$$\frac{1}{p}\sum_{0\le a<p}\big(r_i(a,h) - hr_i^*/p\big)^2 \le 8n^{4n}h.$$

Proof. For $0 \le k \le n$, we have deg $\mathcal{C}_k \le n^k < p$, and $\mathcal{C}_k$ satisfies Hypothesis A by (4.2). Using Lemma 4.2, we find

$$\sum_{0\le a<p}\big(r_i(a,h) - hr_i^*/p\big)^2 \le \frac{1}{i!^2}\sum_{0\le a<p}\Big(\sum_{i\le k\le n}\frac{\big(\#\mathcal{C}_k(a,h) - h\#\mathcal{C}_k/p\big)}{(k-i)!}\Big)^2$$
$$\le \sum_{i\le k\le n}\ \sum_{0\le a<p}\big(\#\mathcal{C}_k(a,h) - h\#\mathcal{C}_k/p\big)^2$$
$$\le 4ph\sum_{i\le k\le n}n^{4k}\ \le\ 8n^{4n}ph. \qquad \square$$

COROLLARY 4.6. *Let $p > n^n$ be a prime, $\mathcal{C} \subseteq \mathbb{F}_p^2$ a plane curve without vertical lines and of degree n, $0 < \delta < 1$, and $h \le p$. Then*

$$|r_i(a,h) - hr_i^*/p| \le n^{2n}(8h\delta^{-1})^{1/2}$$

holds with probability at least $1-\delta$ *for a random element* $a \in \mathbb{F}_p$.

It was proved in [7] that the number of absolutely irreducible components of a plane curve $\mathcal{C} \subseteq \mathbb{F}_p^2$ of degree n can be determined with $O(n^2\mathsf{M}(n)p^{1/2}\log^2 p)$ arithmetic operations in $\mathbb{F}_p$. A similar result is true for r_i, namely, we can find the parameters λ_i as in (2.3) with $O(n!n^{2n}\mathsf{M}(n)p^{1/2}\log^2 p)$ arithmetic operations in $\mathbb{F}_p$. Indeed, choose

$$h = \lceil 18n!n^{2n}p^{1/2}\log p\rceil.$$

Setting $\Lambda_i = \lambda_i n! \in \mathbb{Z}$, we find from Lemmas 4.4 and 2.3

$$\begin{aligned}|n!\,r_i(0,h)h^{-1} - \Lambda_i| &\le n!h^{-1}|r_i(0,h) - hr_i^*p^{-1}| + n!p^{-1}|r_i^* - \lambda_i p|\\ &\le n!h^{-1}\cdot 3n^{2n}p^{1/2}\log p + n!p^{-1}\cdot 2n^{2n}p^{1/2}\\ &\le 1/6 + 1/6 \;=\; 1/3,\end{aligned}$$

if $p \ge 144n^{4n}(n!)^2$. Thus we may determine Λ_i as the nearest integer to $n!r_i(0,h)h^{-1}$.

Below we show how to improve this method and partially generalize it to the case of arbitrary finite fields.

ALGORITHM 4.7. *Deterministic components.*
Input: $f \in \mathbb{F}_q[x,y]$ *of degree* $n \le q^{1/4}/4$, *and a basis* $\omega_1,\dots,\omega_k$ *of* $\mathbb{F}_q$ *over* $\mathbb{F}_p$, *where* $p = \operatorname{char}\mathbb{F}_q$ *and* $q = p^k$.
Output: *The number of absolutely irreducible components of* $\mathcal{C} = \{f = 0\}$ *defined over* $\mathbb{F}_q$.

1. *Set* $H = \lceil 12n^2q^{1/2}\rceil$.
2. *Compute integers* l, h_0, *and* h *such that*

$$p^{l-1} \le H < p^l, \quad (h_0-1)p^{l-1} \le H < h_0p^{l-1}, \quad h = \min\{(p-1)/2, h_0\}.$$

3. *Set*

$$S = \{a_1\omega_1 + \cdots + a_l\omega_l \colon a_1,\dots,a_{l-1} \in \mathbb{F}_p,\ a_l \in A(0,h)\}.$$

4. *Compute* $M(S)$.
5. *Return the nearest integer to* $M(S)/\#S^2$.

THEOREM 4.8. *Let* $q > 256n^4$, *and* $\mathcal{C} \subseteq \mathbb{F}_q^2$ *be a plane curve without vertical lines and of degree* n *satisfying Hypothesis A. Algorithm* 4.7 *correctly computes the number of absolutely irreducible components of* $\mathcal{C}$. *It uses* $O(n^2\mathsf{M}(n)q^{1/2}\log q)$ *arithmetic operations in* $\mathbb{F}_q$.

Proof. Since $H \le 8n^2q^{1/2} + 1 < 16n^2q^{1/2} \le q$, we have $l \le k$. Using $\delta\colon S^2 \to \mathbb{F}_q$, and that $l \ge 1$, $h_0 \ge 2$, we find

$$H/2 \le \#S \le \#\delta(S^2) \le 2\#S \le 4H,$$

and for any $a = a_1\omega_1 + \cdots + a_l\omega_l \in \delta(S^2)$, with $-h < a_l < h$, the number $\#\delta^{-1}(\{a\})$ of $(u_1,u_2) \in S^2$ with $a = u_1 - u_2$ is equal to $p^{l-1}(h - |c_l|)$. Using Lemma 2.5, we can compute $M(S)$ in $O(\mathsf{M}(n)\#S\cdot\log q)$ or $O(n^2\mathsf{M}(n)q^{1/2}\log q)$ arithmetic operations in $\mathbb{F}_q$. From Lemmas 2.1 and 4.1, we get

$$\begin{aligned}\left|\sigma - M(S)/\#S^2\right| &\le |\sigma - \#\mathcal{C}/q| + \left|\#\mathcal{C}/q - M(S)/\#S^2\right|\\ &< n^2q^{-1/2} + 2n^2q^{1/2}/\#S \;\le\; 1/16 + 1/3 \;=\; 19/48 < 1/2. \qquad \square\end{aligned}$$

ALGORITHM 4.9. *Components.*
Input: *A curve* $\mathcal{C} \subseteq \mathbb{F}_q^2$ *without vertical lines, given by* $f \in \mathbb{F}_q[x,y]$ *of degree* n *satisfying Hypothesis A, and* $\delta > 0$.
Output: *An estimate of the number of absolutely irreducible components of* $\mathcal{C}$ *defined over* $\mathbb{F}_q$.

1. *Set* $H = \lceil 288\,\delta^{-2} n^4 \rceil$.
2. *Determine the set* $S \subseteq \mathbb{F}_q$ *as in Algorithm* 4.7.
3. *Choose* $a \in \mathbb{F}_q$ *at random.*
4. *Compute* $\#\mathcal{C}(S_a)$.
5. *Return the nearest integer to* $\#\mathcal{C}(S_a)/\#S^2$.

THEOREM 4.10. *If* $q > 36n^4$, *then Algorithm* 4.9 *computes the number of absolutely irreducible components of* $\mathcal{C}$ *correctly with probability at least* $1-\delta$. *It uses one random element and* $O(n^4 \mathsf{M}(n) \delta^{-2} \log q)$ *arithmetic operations in* $\mathbb{F}_q$.

Proof. The cost estimate follows from the fact that $\#\mathcal{C}(S_a)$ can be computed in $O(\mathsf{M}(n)\#S \cdot \log q)$ or $O(\delta^{-2} n^4 \mathsf{M}(n) \log q)$ arithmetic operations in $\mathbb{F}_q$. Corollary 4.3 implies that

$$\left|\#\mathcal{C}(S_a) - \#S \cdot \#\mathcal{C}/q\right| \le 2\delta^{-1} n^2 (\#S)^{1/2}$$

with probability at least $1-\delta$. From Lemma 2.1 we obtain

$$\begin{aligned} \left|\sigma - \#\mathcal{C}(S_a)/\#S\right| &\le |\sigma - \#\mathcal{C}/q| + \left|\#\mathcal{C}/q - \#\mathcal{C}(S_a)/\#S\right| \\ &\le\ n^2 q^{-1/2} + 2\delta^{-1} n^2 (\#S)^{-1/2} \le 1/6 + 1/6\ =\ 1/3 \end{aligned}$$

with probability at least $1-\delta$. □

ALGORITHM 4.11. *Parameters* λ_i.
Input: *A curve* $\mathcal{C} \subseteq \mathbb{F}_q^2$ *without vertical lines and given by* $f \in \mathbb{F}_p[x,y]$ *of degree* n, *and* $\delta > 0$.
Output: *The parameters* λ_i *for* $0 \le i \le n$.

1. *Set* $h = \lceil 12 n! n^{2n} p^{1/2} \rceil$.
2. *For* $0 \le i \le n$, *compute* $t_i(0,h)$.
3. *For* $0 \le i \le n$, *let* Λ_i *be the nearest integer to* $t_i(0,h) n!/h^2$, *and return* $\lambda_i = \Lambda_i / n!$.

THEOREM 4.12. *Let* $p > 576 (n!)^2 n^{4n}$ *be a prime. Then Algorithm* 4.11 *computes* λ_i *for* $0 \le i \le n$. *It uses* $O(n! n^{2n} \mathsf{M}(n) p^{1/2} \log p)$ *arithmetic operations in* $\mathbb{F}_p$.

Proof. Set $S = A(0,h)$, and let $0 \le i \le n$. It follows from Lemmas 2.3 and 4.4 that

$$\begin{aligned} \left|\lambda_i - t_i(0,h)/h^2\right| &\le |\lambda_i - r_i^*/p| + \left|r_i^*/p - t_i(0,h)/h^2\right| \\ &\le 2n^{2n} p^{-1/2} + 3n^{2n} p^{1/2} h^{-1} \\ &< 1/24n! + 1/4n!\ =\ 7/(24n!). \end{aligned}$$

Thus the algorithm works correctly. Since $12 n! n^{2n} p^{1/2} < p/2$, we have $h \le (p+1)/2$, and for $-h < a < h$ the number of $u_1, u_2 \in \mathbb{N}$ with $a = u_1 - u_2$ and $0 \le u_1, u_2 < h$ is equal to $h - |a|$. Using this fact and Lemma 2.5, we can compute $t_i(0,h)$ in $O(\mathsf{M}(n) h \log p)$ or $O(n! n^{2n} \mathsf{M}(n) p^{1/2} \log q)$ arithmetic operations in $\mathbb{F}_p$. □

ALGORITHM 4.13. *Parameters* λ_i.
Input: *A curve* $\mathcal{C} \subset \mathbb{F}_q^2$ *without vertical lines and given by* $f \in \mathbb{F}_q[x,y]$ *of degree* n, *and* $\delta > 0$.
Output: *An estimate of the parameters* λ_i *for* $0 \le i \le n$.

1. *Set* $h = \lceil 288(n!)^2 n^{4n} \delta^{-1} \rceil$.
2. *Choose* $a \in \mathbb{F}_p$ *at random.*
3. *For* $0 \le i \le n$, *compute* $r_i(a,h)$ *and the nearest integer* Λ_i *to* $n! r_i(a,h)/h$, *and return* $\lambda_i = \Lambda_i / n!$.

THEOREM 4.14. *Let* $p > 144(n!)^2 n^{4n}$ *be a prime,* $\mathcal{C} \subseteq \mathbb{F}_p^2$ *a plane curve of degree* n *without vertical lines, and* $\delta > 0$. *Algorithm* 4.13 *computes* λ_i *for* $0 \le i \le n$ *correctly with probability at least* $1 - \delta$. *It uses one random element and* $O((n!)^2 n^{4n} \mathsf{M}(n) \delta^{-1} \log p)$ *arithmetic operations in* $\mathbb{F}_p$.

Proof. The algorithm uses $O(\mathsf{M}(n) h \log p)$ or $O((n!)^2 n^{4n} \mathsf{M}(n) \delta^{-1} \log p)$ arithmetic operations in $\mathbb{F}_p$. Let $0 \le i \le n$. It follows from Corollary 4.6 that

$$|r_i(a,h) - h r_i^*/p| \le n^{2n} (8h\delta^{-1})^{1/2}$$

with probability at least $1 - \delta$. If this inequality holds, we find from Lemma 2.3 that

$$\begin{aligned} |\lambda_i - r_i(a,h)/h| &\le |\lambda_i - r_i^*/p| + |r_i^*/p - r_i(a,h)/h| \\ &\le 2n^{2n} p^{-1/2} + n^{2n} (8/h\delta)^{1/2} \\ &\le 1/6n! + 1/6n! = 1/3n!. \end{aligned}$$

Then $\lambda_i = \Lambda_i / n!$ is the correct answer. □

5. Distribution of points in multiplicative strips. In the previous sections we did not succeed in computing the projection distribution parameters r_i in an arbitrary finite field, as we have to know the behavior of x along absolutely irreducible components of the fiber product curves $\mathcal{C}_k$. Instead of additive strips, we consider in this section multiplicative strips that may help us in some cases.

Our main tool is the bound from [15] on multiplicative character sums along an algebraic curve, rather than Bombieri's bound that we used before.

For $\lambda \in \mathbb{F}_q^\times$ and integers a and h, we denote by $M(\lambda, a, h)$ the multiplicative interval

$$M(\lambda, a, h) = \{\lambda^{a+t} : 1 \le t \le h\} \subseteq \mathbb{F}_q^\times,$$

and given a curve $\mathcal{C} \subseteq \mathbb{F}_q^{m+1}$, we let

$$\mathcal{C}(\lambda, a, h) = \mathcal{C}(M(\lambda, a, h)).$$

We prove some analogues of Lemma 2.1 of [7] and Lemma 4.2 of this paper. The following condition on a curve $\mathcal{C} \subseteq \mathbb{F}_q^{m+1}$ is used in Perel'muter's theorem.

HYPOTHESIS B. *The first coordinate function* x *is not a power* g^e *of a rational function* g *on any absolutely irreducible component of* $\mathcal{C}$, *where* g *is defined over an algebraic closure of* $\mathbb{F}_q$, *and* $e \ge 2$ *is an integer.*

THEOREM 5.1. *Let* $\mathcal{C} \subseteq \mathbb{F}_q^m$ *be a curve of degree* n *without vertical components and satisfying Hypothesis B,* $\lambda \in \mathbb{F}_q^\times$ *be of order* τ, *and* a *and* $h \le \tau$ *be integers. Then*

$$\left| \#\mathcal{C}(\lambda, a, h) - h \#\mathcal{C}/q \right| \le 2n^2 q^{1/2} \log q.$$

Proof. Let $\theta \in \mathbb{F}_q$ be a primitive element such that $\lambda = \theta^{(q-1)/\tau}$.

Denote by $\operatorname{ind} u$ the index of $u \in \mathbb{F}_q^\times$ in base θ, i.e., the smallest nonnegative integer t with $u = \theta^t$, so that

$$\operatorname{ind}(\lambda^{a+t}) \equiv (q-1)(a+t)\tau^{-1} \bmod (q-1).$$

Then

$$\#\mathcal{C}(\lambda,a,h)=\frac{1}{q-1}\sum_{(u,v)\in\mathcal{C}}\sum_{1\le t\le h}\sum_{0\le s\le q-2}\exp\biggl(\frac{2\pi is(\operatorname{ind}\,u-(q-1)(a+t)\tau^{-1})}{q-1}\biggr)$$
$$=\frac{1}{q-1}\sum_{0\le s\le q-2}\sum_{(u,v)\in\mathcal{C}}\chi_s(u)\sum_{1\le t\le h}\exp(-2\pi is(a+t)/\tau),$$

where $u\in\mathbb{F}_q$ and $v\in\mathbb{F}_q^m$ in the sums. For $0\le s\le q-2$, define a multiplicative character χ_s on $\mathbb{F}_q$ by

$$\chi_s(u)=\exp[2\pi is\operatorname{ind}\,u/(q-1)],$$

for $u\in\mathbb{F}_q^\times$, and set $\chi_s(0)=0$. Separating the term corresponding to $s=0$ we get

$$\begin{aligned}\#\mathcal{C}(\lambda,a,h)\ &=\ \frac{h}{q-1}(\#\mathcal{C}-E)\\ &+\frac{1}{q-1}\sum_{1\le s\le q-2}\sum_{(u,v)\in\mathcal{C}}\chi_s(u)\sum_{1\le t\le h}\exp(-2\pi is(a+t)/\tau),\end{aligned}\tag{5.1}$$

where

$$E=\sum_{(0,v)\in\mathcal{C}}1=\#(\mathcal{C}\cap\{x=0\})\le n,$$

by Bézout's theorem. Theorem 2 of [15] implies that for any s

$$\biggl|\sum_{(u,v)\in\mathcal{C}}\chi_s(x)\biggr|\le(n^2-3n)q^{1/2}+n^2.$$

Since $h\le q-1$, we have

$$\begin{aligned}&\bigl|\#\mathcal{C}(\lambda,a,h)-h\#\mathcal{C}/(q-1)\bigr|\\ &\le\frac{hn}{q-1}+\frac{(n^2-3n)q^{1/2}+n^2}{q-1}\sum_{1\le s\le q-2}\biggl|\sum_{1\le t\le h}\exp(2\pi is(a+t)/\tau)\biggr|\\ &\le n+\frac{(n^2-3n)q^{1/2}+n^2}{\tau}\sum_{1\le s<\tau}\biggl|\sum_{1\le t\le h}\exp(-2\pi ist/\tau)\biggr|.\end{aligned}$$

Using the well-known inequality

$$\sum_{1\le s<\tau}\biggl|\sum_{1\le t\le h}\exp(2\pi ist/\tau)\biggr|\le\tau\log\tau,$$

we get

$$\bigl|\#C(\lambda,a,h)-h\#\mathcal{C}/(q-1)\bigr|\le n+\bigl((n^2-3n)q^{1/2}+n^2\bigr)\log\tau.$$

Taking into account that $\#\mathcal{C}\le nq$ and thus

$$\biggl|\frac{h\#C}{q-1}-\frac{h\#C}{q}\biggr|=\frac{h\#C}{q(q-1)}\le n,\tag{5.2}$$

we obtain finally that

$$\begin{aligned}\bigl|\#\mathcal{C}(\lambda,a,h) - h\#\mathcal{C}/q\bigr| &\le n + n + \bigl((n^2-3n)q^{1/2}+n^2\bigr)\log\tau\\ &\le 2n + \bigl((n^2-3n)q^{1/2}+n^2\bigr)\log\tau\\ &\le 2n^2q^{1/2}\log q. \qquad \square\end{aligned}$$

THEOREM 5.2. *Let $\mathcal{C}\subseteq\mathbb{F}_q^m$ be a curve without vertical components and of degree $n\ge 2$ satisfying Hypothesis B, $\lambda\in\mathbb{F}_q^\times$ be of order τ, and $h\le\tau$. Then*

$$\sum_{0\le a\le q-2}\bigl(\#\mathcal{C}(\lambda,a,h) - h\#\mathcal{C}/q\bigr)^2 \le 8n^4qh.$$

Proof. Using the notation of the previous proof, we have

$$(q-1)\left|\frac{\#\mathcal{C}}{q} - \frac{\#\mathcal{C}-E}{q-1}\right| = \left|\frac{-\#\mathcal{C}}{q}+E\right| \le n,$$

$$\begin{aligned}&\sum_{0\le a\le q-2}\bigl(\#\mathcal{C}(\lambda,a,h) - h\#\mathcal{C}/q\bigr)^2\\ &\le 2\sum_{0\le a\le q-2}\left[\#\mathcal{C}(\lambda,a,h) - \frac{h(\#\mathcal{C}-E)}{q-1}\right]^2 + 2\sum_{0\le a\le q-2}\left[\frac{h\#\mathcal{C}}{q} - \frac{h(\#\mathcal{C}-E)}{q-1}\right]^2\\ &\le 2W + 2n^2h^2/(q-1),\end{aligned}$$

where

$$\begin{aligned}W &= \sum_{0\le a\le q-2}\left[\#\mathcal{C}(\lambda,a,h) - \frac{h(\#\mathcal{C}-E)}{q-1}\right]^2\\ &= (q-1)^{-2}\sum_{0\le a\le q-2}\left|\sum_{1\le s\le q-2}\sum_{(u,v)\in\mathcal{C}}\chi_s(u)\sum_{1\le t\le h}\exp(2\pi is(a+t)/\tau)\right|^2,\end{aligned}$$

by (5.1). Using $|\alpha|^2=\alpha\bar\alpha$ for $\alpha\in\mathbb{C}$, we have

$$\begin{aligned}W = (q-1)^{-2}&\sum_{1\le s_1,s_2\le q-2}\sum_{(u_1,v_1),(u_2,v_2)\in\mathcal{C}}\chi_{s_1}(u_1)\chi_{s_2}(u_2^{-1})\\ &\cdot\sum_{1\le t_1,t_2\le h}\exp(2\pi i(s_1t_1-s_2t_2)/\tau)\sum_{0\le a\le q-2}\exp(2\pi ia(s_1-s_2)/\tau).\end{aligned}$$

Noting that the inner sum equals 0 when $s_1\ne s_2$ and $q-1$ otherwise, we get

$$\begin{aligned}W &= (q-1)^{-1}\sum_{1\le s\le q-2}\sum_{(u_1,v_1),(u_2,v_2)\in\mathcal{C}}\chi_s(u_1u_2^{-1})\sum_{1\le t_1,t_2\le h}\exp(2\pi is(t_1-t_2)/\tau)\\ &= (q-1)^{-1}\sum_{1\le s\le q-2}\left|\sum_{(u,v)\in\mathcal{C}}\chi_s(u)\right|^2\left|\sum_{1\le t\le h}\exp(2\pi ist/\tau)\right|^2.\end{aligned}$$

Theorem 2 of [15] yields

$$W \le \frac{\bigl((n^2-3n)q^{1/2}+n^2\bigr)^2}{q-1}\sum_{1\le s\le q-2}\left|\sum_{1\le t\le h}\exp(2\pi ist/\tau)\right|^2.$$

Taking into account the equality

$$\sum_{0\le s\le q-2}\Big|\sum_{1\le t\le h}\exp(2\pi ist/\tau)\Big|^2=\sum_{1\le t_1,t_2\le h}\ \sum_{0\le s\le q-2}\exp(2\pi is(t_1-t_2)/\tau)=h(q-1),$$

we obtain

$$W\le\frac{\big((n^2-3n)q^{1/2}+n^2\big)^2}{q-1}\cdot\big(h(q-1)-h^2\big),$$

$$\sum_{0\le a\le q-2}\big(\#\mathcal{C}(\lambda,a,h)-h\#\mathcal{C}/q\big)^2\le 2n^2h^2/(q-1)+2\big((n^2-3n)q^{1/2}+n^2\big)^2h$$

$$\le 2n^2h\big(1+((n-3)q^{1/2}+n)^2\big)\le 2n^2h(nq^{1/2}+n)^2\ \le\ 8n^4hq. \qquad \square$$

We now show that Hypothesis B is not a severe restriction, in that it is satisfied after a generic linear transformation. This is most naturally shown for a projective curve over an algebraically closed field $\mathbb{K}$.

So let $\mathcal{X}\subseteq\mathbb{P}_{\mathbb{K}}^{m+1}$ be a reduced curve of degree n, possibly reducible or singular, $\mathbb{H}\cong\mathbb{P}_{\mathbb{K}}^{m+1}$ the space of hyperplanes in $\mathbb{P}_{\mathbb{K}}^{m+1}$, and for $\mathcal{H}\in\mathbb{H}$, let $l_{\mathcal{H}}$ be the rational linear function whose zero set is $\mathcal{H}$. We say that $\mathcal{H}\in\mathbb{H}$ *intersects* $\mathcal{X}$ *transversally* if and only if $\#(\mathcal{X}\cap\mathcal{H})=n$. The following facts are well known.

FACT 5.3. *Let $\mathcal{X}$ be as above, and $\mathcal{H}\in\mathbb{H}$.*

(i) *If no component of $\mathcal{X}$ is contained in $\mathcal{H}$, then $\#(\mathcal{X}\cap\mathcal{H})\le n$.*
(ii) *If $\mathcal{H}$ does not contain a tangent line to $\mathcal{X}$ or a singular point of $\mathcal{X}$, then $\mathcal{H}$ intersects $\mathcal{X}$ transversally.*
(iii) *There is a proper closed subvariety $E\subseteq\mathbb{H}$ of degree at most $n(n-1)$ such that $\mathcal{H}$ intersects $\mathcal{X}$ transversally if $\mathcal{H}\in\mathbb{H}\setminus E$.*
(iv) *If $\mathcal{H}$ intersects $\mathcal{X}$ transversally, then $l_{\mathcal{H}}$ is not a power g^e of a rational function g on any absolutely irreducible component of $\mathcal{X}$, with $e\ge 2$.*

For a plane curve, (iii) follows from, e.g., Proposition 5.2.2 of [3]. For a curve $\mathcal{C}\subseteq\mathbb{F}_q^{m+1}$, Fact 5.3 implies that almost all linear transformations of $\mathcal{C}$ satisfy Hypothesis B. We only make this explicit for $m=1$. We need the fact that there exists a line (over $\mathbb{K}$) through the origin which is not a tangent to $\mathcal{C}$; this is true for all curves except the "strange" conic in characteristic two (see [10, Theorem IV.3.9]).

PROPOSITION 5.4. *Let $f\in\mathbb{F}_q[x,y]$ be squarefree of degree n, with either $n\ne 2$ or $\operatorname{char}\mathbb{F}_q\ne 2$, and for $\alpha\in\mathbb{F}_q$, let*

$$\mathcal{C}_\alpha=\{f(x,y+\alpha x)=0\}=\{(a,b)\in\mathbb{F}_q^2\colon f(a,b+\alpha a)=0\}.$$

Then there exists $E\subseteq\mathbb{F}_q$ with $\#E\le n(n-1)$ and such that $\mathcal{C}_\alpha$ satisfies Hypothesis B for all $\alpha\in\mathbb{F}_q\setminus E$.

In order to design algorithms from the above results, we have to construct wide enough multiplicative strips or, equivalently, to find elements $\lambda\in\mathbb{F}_q^*$ of sufficiently large order, as in [9]; certainly a primitive root is sufficient. Results about the construction, distribution, and density of primitive roots can be found in [14]; see [22] for a survey and also [6], [16], [20], [21] for the currently best results in this area.

BIPARTITE EDGE COLORING IN $O(\Delta m)$ TIME*

ALEXANDER SCHRIJVER†

Abstract. We show that a minimum edge coloring of a bipartite graph can be found in $O(\Delta m)$ time, where Δ and m denote the maximum degree and the number of edges of G, respectively. It is equivalent to finding a perfect matching in a k-regular bipartite graph in $O(km)$ time.

By sharpening the methods, a minimum edge coloring of a bipartite graph can be found in $O((p_{\max}(\Delta) + \log \Delta)m)$ time, where $p_{\max}(\Delta)$ is the largest prime factor of Δ. Moreover, a perfect matching in a k-regular bipartite graph can be found in $O(p_{\max}(k)m)$ time.

Key words. bipartite, edge-coloring, complexity, timetabling, perfect, matching

1. Introduction.

In a classical paper, König [9] showed that the edges of a bipartite graph G can be colored with $\Delta(G)$ colors, where $\Delta(G)$ is the maximum degree of G. (In this paper, "coloring" edges presumes that edges that have a vertex in common obtain different colors.)

König's proof is essentially algorithmic, yielding an $O(nm)$ time algorithm (n and m denote the numbers of vertices and edges, respectively, of the graph). As was shown by Gabow [4], the $O(\sqrt{n}m)$ bipartite matching algorithm of Hopcroft and Karp [8] implies an $O(\sqrt{n}m \log \Delta)$ bipartite edge-coloring algorithm. This was improved by Cole and Hopcroft [1] to $O(m \log m)$ by extending methods of Gabow and Kariv [5], [6].

Fixing the maximum degree Δ, the methods found as yet are superlinear (albeit slightly). In this paper we give a linear-time method for fixed or bounded Δ. More precisely, we give an $O(\Delta m)$ method for bipartite edge coloring. It implies (in fact, is equivalent to) finding a perfect matching in a k-regular bipartite graph in $O(km)$ time.

Ultimately one would hope for an $O(m \log k)$ (or even $O(m)$) algorithm finding a perfect matching in a k-regular bipartite graph and for an $O(m \log \Delta)$ algorithm for bipartite edge coloring (the first algorithm implies the second, by a method of Gabow [4] — see below). We did not find such algorithms, although our methods can be extended to obtain some supporting results.

In particular, define, for any natural number k,

$$\phi(k) := \sum_{i=1}^{t} \frac{p_i}{\prod_{j=1}^{i-1} p_j}, \tag{1}$$

where $p_1 \leq \cdots \leq p_t$ are primes with $k = p_1 \cdot \ldots \cdot p_t$. We give an $O((\phi(\Delta) + \log \Delta)m)$ bipartite edge-coloring algorithm. Note that in $\phi(\Delta) + \log \Delta$, the term $\phi(\Delta)$ dominates if Δ is prime, while $\log \Delta$ dominates if Δ is a power of 2. Note also that $\phi(\Delta) \leq 2p_{\max}(\Delta)$, where $p_{\max}(\Delta)$ denotes the largest prime factor in Δ. So

fixing the maximum prime factor of Δ, there is an $O(m \log \Delta)$ bipartite edge-coloring algorithm.

Moreover, we give an $O(\phi(k)m)$ algorithm finding a perfect matching in a k-regular bipartite graph. So bounding the maximum prime factor of k, there is a linear-time perfect matching algorithm for k-regular bipartite graphs.

The proof idea is an extension of the following idea of Gabow [4] to find a perfect matching in a 2^t-regular bipartite graph G in linear time. First find an Eulerian orientation of G (taking $O(m)$ time), and consider those edges that are oriented from vertex-color class I to vertex-color class II (in the 2-vertex coloring of G). This gives a 2^{t-1}-regular subgraph of G. Repeating this, we end up with a 1-regular subgraph of G, being a perfect matching in G. The time is $O(m + \frac{1}{2}m + \frac{1}{4}m + \cdots) = O(m)$.

One can similarly find a 2^t-edge coloring in $O(tm)$ time. In extending this method to prime factors other than 2 we use some techniques of [10] for estimating the number of perfect matchings and edge colorings of bipartite graphs.

In this paper, all graphs may have multiple edges.

2. Some practical motivation. As is well known, bipartite edge coloring can be applied in timetabling. A pure instance of timetabling consists of a set of teachers, a set of classes, and a list L of pairs (t, c) of a teacher t and a class c, indicating that teacher t has to teach class c during a time slot (say, an hour) within the time span of the schedule (say, a week). A pair (t, c) may occur several times in the list, indicating the number of hours the pair t, c should meet weekly.

A timetable then is an assignment of the pairs in the list to hours, from a set H of possible hours, in such a way that no teacher t and no class c occurs in two pairs that are assigned to the same hour. This clearly is a bipartite edge-coloring problem, and by König's theorem, there is a timetable if and only if $|H|$ is not smaller than the number of times that any teacher t or any class c occurs in L. So by the result of Cole and Hopcroft [1] a timetable can be found in $O(|L| \log |L|)$ time, and by our theorem, it can be found also in $O(|H| \cdot |L|)$ time. (In practice, several additional constraints are put on a timetable, making the problem usually NP-complete—cf. Even, Itai, and Shamir [3].)

In many countries, schools are merging, yielding an increase in size, including in numbers of teachers and of classes. So the list L grows. However, the number of hours during a week does not grow. This gives that, in this interpretation, the algorithm is linear in the size of the school.

Moreover, often H is built up from smaller units (say, days), implying that $|H|$ does not have large prime factors. ($|H|$ typically has prime factors 2, 3, and 5 only, and sometimes 7.) This gives that applying the $O(\phi(|H|+\log |H|)|L|)$-time algorithm can be fruitful. Similarly, the method is not very sensitive to doubling or tripling the time span (say to two or three weeks).

3. An $O(\Delta m)$ bipartite edge-coloring algorithm. Basic in the edge-coloring algorithm (as in [4]) is a subroutine finding a matching that covers all maximum-degree vertices, and that hence can serve as our first color. To this end we show Theorem 1.

THEOREM 1. *A perfect matching in a k-regular bipartite graph can be found in $O(km)$ time.*

Proof. Let $G = (V, E)$ be a k-regular bipartite graph. For any function $w : E \longrightarrow \mathcal{Z}_+$, let E_w be the set of edges with $w(e) > 0$. For any $F \subseteq E$, denote $w(F) := \sum_{e \in F} w(e)$ and let χ^F be the incidence vector of F.

Initially set $w(e) := 1$ for each edge e. Next apply the following iteratively:

(2) Find a circuit C in E_w. Let $C = M \cup N$ for matchings M and N with $w(M) \geq w(N)$. Reset $w := w + \chi^M - \chi^N$.

Note that, at any iteration, the equality $w(\delta(v)) = k$ is maintained for all $v \in V$ (where $\delta(v)$ is the set of edges incident with v).

To see that the process terminates, first note that at any iteration the sum

$$\sum_{e \in E} w(e)^2 \tag{3}$$

increases by

$$\sum_{e \in M} ((w(e)+1)^2 - w(e)^2) + \sum_{e \in N} ((w(e)-1)^2 - w(e)^2) = 2w(M) + |M| - 2w(N) + |N|, \tag{4}$$

which is at least $|C|$ (as $w(M) \geq w(N)$). Moreover, (3) is bounded, since $w(e) \leq k$ for each edge e. So the process terminates.

At termination, we have that the set E_w is a forest and hence is a perfect matching (since $w(e) = k$ for each end edge e of E_w). This implies that at termination the sum (3) is equal to $\frac{1}{2}nk^2 = km$.

Now by depth first search we can find a circuit C in (2) in $O(|C|)$ time on average. Indeed, keep a path P of edges e with $0 < w(e) < k$. Let v be the last vertex of P. Choose an edge $e = vu$ incident with v but not in P. If u does not occur in P, we reset $P := P \cup \{e\}$ and iterate. If u does occur in P, let C be the circuit in $P \cup \{e\}$, and apply (2) to C. Next reset $P := P \setminus C$, and iterate.

If $P = \emptyset$, choose any edge e with $0 < w(e) < k$, and set $P := \{e\}$. If no such edge e exists, we are done. □

For k smaller than $\sqrt{\log n}$, the $O(km)$ bound is asymptotically better than the $O(m + n \log n (\log k)^2)$ bound proved by Cole and Hopcroft [1]. (An algorithm related to, but different from, the algorithm described in Theorem 1 was proposed by Csima and Lovász [2], giving an $O(n^2 k \log k)$ time bound.)

By applying a technique of Gabow [4], one can derive from Theorem 1 the following stronger statement:

COROLLARY 1a. *A k-edge coloring of a k-regular bipartite graph can be found in $O(km)$ time.*

Proof. If k is odd, first find a perfect matching M, remove M from G, and apply recursion (M will serve as color).

If k is even, find an Eulerian orientation of G. Let $k' = \frac{1}{2}k$. Then split G into two k'-regular graphs $G_1 = (V, E_1)$ (with E_1 the set of edges oriented from vertex-color class I to vertex-color class II) and $G_2 = (V, E_2)$ (with $E_2 := E \setminus E_1$). Find recursively k'-edge colorings of G_1 and G_2. The union of the two colorings is a k-edge coloring of G.

The time is bounded as follows. Starting with G, we can find M (if k is odd), find the Eulerian orientation, and split G into G_1 and G_2, in time ckm for some constant c. Then the whole recursion takes time $2ckm$. This can be shown inductively, as $2ckm = ckm + 2ck'm' + 2ck'm'$, where $m' = |E(G_1)| = |E(G_2)| = \frac{1}{2}m$. □

This implies the sharper statement as shown in Corollary 1b.

COROLLARY 1b. *A $\Delta(G)$-edge-coloring of a bipartite graph $G = (V, E)$ can be found in $O(\Delta(G)m)$ time.*

Proof. Let $k := \Delta(G)$. First iteratively merge any two vertices in the same color class of G if each has degree at most $\frac{1}{2}k$. The final graph H will have at most two vertices of degree at most $\frac{1}{2}k$, and moreover, $\Delta(H) = k$ and any k-edge coloring of H yields a k-edge coloring of G. Next make a copy H' of H, and join each vertex v of H by $k - d_H(v)$ parallel edges with its copy v' in H' (where $d_H(v)$ is the degree of v in H). This gives the k-regular graph G', with $|E(G')| = O(|E(G)|)$. By Corollary 1a we can find a k-edge coloring of G' in $O(k|E(G')|)$ time. This gives a k-edge coloring of H and hence a k-edge coloring of G. □

4. Toward an $O(m \log \Delta)$ method. The results of section 3 can be sharpened by using divisibility properties of $\Delta(G)$. First we sharpen Corollary 1a. We repeat the definition of $\phi(k)$ for any natural number k:

$$\phi(k) := \sum_{i=1}^{t} \frac{p_i}{\prod_{j=1}^{i-1} p_j}, \tag{5}$$

where $p_1 \leq \cdots \leq p_t$ are primes with $k = p_1 \cdot \ldots \cdot p_t$.

THEOREM 2. *A k-edge coloring of a k-regular bipartite graph $G = (V, E)$ can be found in $O((\phi(k) + \log k)m)$ time.*

Proof. Let $k = pk'$ with p prime. Split each vertex v into k' new vertices $v_1, \ldots, v_{k'}$, and distribute the edges incident with v over $v_1, \ldots, v_{k'}$ in such a way that each vertex v_i is incident with exactly p edges. This gives the p-regular graph $\tilde{G}$. Find a p-edge-coloring of $\tilde{G}$. The colors give a partition of E into classes $E_1, \ldots, E_p$ in such a way that each graph $G_j = (V, E_j)$ is k'-regular. Next find a k'-edge coloring of G_p, yielding perfect matchings $M_1, \ldots, M_{k'}$.

Now we apply the following iteratively. We have a partition of E into perfect matchings $M_1, \ldots, M_{\alpha k'}$ and k'-regular graphs $E_1, \ldots, E_{p-\alpha}$. (Initially, $\alpha = 1$.) Let $q := \min\{\alpha, p - \alpha\}$. Choose r such that $qk' + r$ is a power of 2 and such that $r \leq qk'$. Let $E' := M_1 \cup \cdots \cup M_r \cup E_1 \cup \cdots \cup E_q$. Then $G' := (V, E')$ is a $qk' + r$-regular graph. Next $qk' + r$-edge-color G', yielding colors $N_1, \ldots, N_{qk'+r}$. Now replace $M_1, \ldots, M_r$ by $N_1, \ldots, N_{qk'+r}$ and $E_1, \ldots, E_{p-\alpha}$ by $E_{q+1}, \ldots, E_{p-\alpha}$ and iterate. We stop if $\alpha = p$.

So at any iteration, α is replaced by $\alpha + q$. Moreover, at any iteration except possibly the last iteration, we have $q = \alpha$. So at any iteration except possibly the last one, q is twice as large as at the previous iteration.

By [4], the work in the iteration takes time $O(|E'| \log(qk' + r)) = O(|E'| \log k)$, since $qk' + r$ is a power of 2 and since $qk' + r \leq k$. Since $|E'| = \frac{1}{2}(qk' + r)n \leq qk'n$, over all iterations the work is $O((1 + 2 + 2^2 + \cdots + 2^{\log p})k'n \log k) = O(pk'n \log k) = O(m \log k)$.

To this time bound we must add the time needed to obtain $G_1, \ldots, G_p$, which takes $O(pm)$ time by Corollary 1b, since it amounts to p-edge coloring the p-regular graph $\tilde{G}$, having m edges, and the time needed to edge color G_p, which takes (by induction) $O((\phi(k') + \log k')m')$ time, where $m' = m/p$ is the number of edges of G_p. Since $\phi(k) = p + \phi(k')/p$, we have the required time bound. □

This gives Corollary 2a.

COROLLARY 2a. *A $\Delta(G)$-edge coloring of a bipartite graph G can be found in $O((\phi(\Delta(G)) + \log \Delta(G))m)$ time.*

Proof. It is proved directly from Theorem 2 by the method of Corollary 1b. □

Note that

$$\phi(k) \leq 2p_{\max}(k) \tag{6}$$

(where $p_{\max}(k)$ is the largest prime factor of k). This follows inductively, since if $k = pk'$, with p the smallest prime factor of k, then $\phi(k) = p + \phi(k')/p \leq p_{\max}(k) + (2p_{\max}(k')/p) \leq 2p_{\max}(k)$. This implies Corollary 2b.

COROLLARY 2b. *A $\Delta(G)$-edge coloring of a bipartite graph G can be found in $O((p_{\max}(\Delta(G)) + \log \Delta(G))m)$ time.*

Proof. The proof follows directly from Corollary 2a with (6). □

Note that in performing this method one does not need to apply deep number-theoretic algorithms to find the prime factorization of k. Indeed, the factors $p_1, \ldots, p_t$ can be found in $O(\phi(k)k)$ time, since the smallest prime factor p can be found in time $O(pk)$ by trying $i = 2, 3, \ldots$ as divisor of k (for each i taking $O(k)$ time), until we reach p. Next we can apply recursion to $k' := k/p$, taking recursively $O(\phi(k')k')$ time. This gives $O(\phi(k)k)$ time overall, since $\phi(k) = p + \phi(k')/p$.

A sharpening can be obtained also for finding perfect matchings in k-regular bipartite graphs.

THEOREM 3. *A perfect matching in a k-regular bipartite graph G can be found in $O(\phi(k)m)$ time.*

Proof. Write $k = pk'$ with p the smallest prime factor of k. Make the graph $\tilde{G}$ as in the proof of Theorem 2. So $\tilde{G}$ is p-regular. Find a perfect matching M in $\tilde{G}$. It gives a k'-regular subgraph $G' = (V, E')$ of G. In G' we find recursively a perfect matching.

Finding perfect matching M in $\tilde{G}$ takes time $O(pm)$ by Theorem 1. Finding matching N in G' takes time $O(\phi(k')m/p)$ by induction (as G' is k'-regular and has m/p edges). Since $\phi(k) = p + \phi(k')/p$, the whole process takes $O(\phi(k)m)$ time. □

COROLLARY 3a. *A matching covering all maximum-degree vertices in a bipartite graph can be found in $O(\phi(\Delta)m)$ time.*

Proof. The proof follows directly from Theorem 3, using the technique of Corollary 1b. □

By (6), Theorem 3 can be stated in a weaker form as Corollary 3b.

COROLLARY 3b. *A perfect matching in a k-regular bipartite graph can be found in $O(p_{\max}(k)m)$ time.*

Proof. The proof follows directly from Theorem 3, using (6). □

5. Some open questions. It would be surprising if divisibility properties of the maximum degree $\Delta(G)$ of a bipartite graph G would determine the complexity of edge coloring G. However, our results are blocked by the primes. If $\Delta(G)$ is a prime, we do not have anything better than an $O(\Delta(G)m)$-time algorithm. So the main problem is to "break" a prime. More precisely,

(7) Is there an $O(m \log k)$ algorithm for finding a perfect matching in a k-regular bipartite graph?

The method of Cole and Hopcroft [1] gives an $O(m + n \log n \log^2 k)$ algorithm to find a perfect matching in any k-regular bipartite graph. If there would be an $O(m \log k)$ perfect matching algorithm for k-regular bipartite graphs, there exists an $O(m \log \Delta)$ bipartite edge-coloring algorithm (by methods like in Theorem 2 above), thus answering our second question:

(8) Is there an $O(m \log \Delta)$ algorithm for bipartite edge coloring?

Similar methods as used for proving Theorem 2 give an approximative method, namely, a bipartite $(\Delta + \lfloor \log(\Delta - 1) \rfloor)$-edge-coloring algorithm, with time bound $O(m \log \Delta)$. Indeed, let $G = (V, E)$ be a bipartite graph of maximum degree Δ. In $O(m)$ time we can split E into E' and E'' such that both $G' = (V, E')$ and $G'' = (V, E'')$ have maximum degree at most $\Delta' := \lceil \frac{1}{2}\Delta \rceil$. We may assume that $|E'| \leq \frac{1}{2}m$. Let $t := \Delta' + \lfloor \log(\Delta' - 1) \rfloor$. Then t-edge color G' recursively, giving colors $M_1, \ldots, M_t$. Choose $s \leq t$ such that $\Delta' + s$ is a power of 2. Next $(\Delta' + s)$-edge color the graph H made by $M_1 \cup \cdots \cup M_s \cup E''$. With the remaining $M_{s+1}, \ldots, M_t$ it gives an edge coloring of G with

$$(\Delta' + s) + (t - s) = 2\Delta' + \lfloor \log(\Delta' - 1) \rfloor \leq \Delta + \lfloor \log(\Delta - 1) \rfloor \tag{9}$$

colors. Since the number of edges in G' is at most $\frac{1}{2}m$ and since edge coloring H takes $O(m \log(\Delta' + s)) = O(m \log \Delta)$ time, this gives an $O(m \log \Delta)$ time bound.

The nonbipartite case is NP-complete, by the well-known result of Holyer [7]: it is NP-complete to decide if a 3-regular graph can be 3-edge colored. However, it is not difficult to see that a 3-regular graph can be 4-edge colored in *linear* time. Actually, any graph of maximum degree 3 can be 4-edge colored in $O(m)$ time.

By Vizing's theorem, each simple graph G can be $(\Delta(G) + 1)$-edge colored. (If $\Delta(G) \leq 3$ we can delete the condition that G be simple.) This prompts the question:

(10) Is there an $O(\Delta m)$-time $(\Delta+1)$-edge coloring algorithm for simple graphs?

Of course, the stronger question is to ask for an $O(m \log \Delta)$ algorithm.

ROW-MAJOR SORTING ON MESHES*

JOP F. SIBEYN†

Abstract. In all recent near-optimal sorting algorithms for meshes, the packets are sorted with respect to some snake-like indexing. In this paper we present deterministic algorithms for sorting with respect to the more natural row-major indexing.

For 1-1 sorting on an $n \times n$ mesh, we give an algorithm that runs in $2 \cdot n + o(n)$ steps, matching the distance bound, with maximal queue size five. It is considerably simpler than earlier algorithms. Another algorithm performs k-k sorting in $k \cdot n/2 + o(k \cdot n)$ steps, matching the bisection bound.

Furthermore, we present *uniaxial* algorithms for row-major sorting. We show that 1-1 sorting can be performed in $2\frac{1}{2} \cdot n + o(n)$ steps. Alternatively, this problem is solved with maximal queue size five in $4\frac{1}{3} \cdot n$ steps, without any additional terms.

1. Introduction.

Various models for parallel machines have been considered. One of the best-studied machines with a fixed interconnection network is the *mesh*. In this model the processing units (PUs) form an array of size $n \times n$ and are connected by a two-dimensional grid of communication links.

Problems. The problems concerning the exchange of packets among the PUs are called *communication problems*. The packets must be sent to their destinations such that at most one packet traverses any wire during a single step. Quality measures are *run time*, which is the maximum number of steps T a packet may need to reach its destination, and *queue size* Q, the maximum number of packets any PU may have to store.

Routing is the basic communication problem. In this problem the packets have a known destination. The routing problem in which every PU is the source and destination of k packets is called the k-k *routing* problem. 1-1 routing is commonly known as *permutation routing*.

Sorting is, next to routing, one of the most considered communication problems. Several variants of the problem have been studied. In the 1-1 sorting problem, each PU initially holds a single packet, where each packet contains a key drawn from a totally ordered set. The packets have to be rearranged such that the packet with the key of rank i is moved to the PU with index i for all i. In the k-k sorting problem, each PU is the source and destination of k packets.

Scattering is a weak variant of sorting: the packets should be rearranged such that as few as possible packets with the same key stand in the same column. It is a subroutine of many deterministic algorithms for other communication problems, and often their queue size linearly depends on the quality of the scattering algorithm. Scattering can be performed by sorting the packets in row-major order.

TABLE 1
Run times for k-k sorting in row-major order. For large n, the lower-order terms are omitted.

	Uniaxial		Biaxial
k	All n	Large n	Large n
1	$4\frac{1}{3} \cdot n$	$2\frac{1}{2} \cdot n$	$2 \cdot n$
2	$5\frac{1}{4} \cdot n$	$3 \cdot n$	$2\frac{1}{2} \cdot n$
k	$(7/4 \cdot k + 6) \cdot n$	$k \cdot n$	$k/2 \cdot n$

Models and indexings. The model in which the PUs can communicate with all their neighbors at the same time, sending and receiving up to four packets in a single step, is called the *MIMD* model. Alternatively the PUs may send only in a specific direction during any step. This is called the *SIMD* model. In a *half-MIMD* all PUs can either send and receive packets along the horizontal or along the vertical connections. Algorithms running on a half-MIMD are called *uniaxial*. Algorithms for the MIMD will be called *biaxial*.

If MIMD algorithms are directly run on an SIMD, they are slowed down by a factor of four. Half-MIMD algorithms are slowed down by a factor of two only. Because in many cases half-MIMD algorithms are hardly slower than MIMD algorithms, it may be advantageous to design half-MIMD algorithms. Another feature is that on an MIMD two of these algorithms can be perfectly overlapped. This is a basic observation underlying many algorithms involving some kind of "coloring" [12, 10, 21, 6].

Several recent sorting algorithms [2, 11, 8] were designed for (blocked) snake-like row-major indexings. However, in many cases it is desirable to have the packets in the more natural row-major or column-major order. Furthermore, sorting in snake-like order is unsuitable for scattering.

In the "one-packet" model considered by Schnorr and Shamir [18], the best-known upper bound for row-major sorting is higher than for sorting in snake-like row-major order. In our model a PU may hold a constant number of packets and packets may be copied. The results of this paper demonstrate that in this model, sorting in row-major order is not substantially harder than sorting in snake-like order.

Results. This paper gives numerous new results for row-major sorting, summarized in Table 1. The queue sizes for 1-1 and 2-2 sorting range between four and nine, and in the k-k sorting from k to $k+2$.

Theoretically the results for large n are the most appealing. So far, the fastest biaxial row-major sorting algorithm has $T = 2\frac{1}{4} \cdot n + o(n)$ and $Q = \mathcal{O}(1)$. It was recently designed by Krizanc and Narayanan [9]. However, this algorithm works only for the subproblem that all the keys are 0 or 1 (though some extension seems possible). The first near-optimal sorting algorithm,[1] $T = 2 \cdot n + o(n)$, was presented by Kaklamanis and Krizanc [2]. The algorithm is randomized and sorts the packets in blocked snake-like row-major order. Kaufmann, Sibeyn, and Suel [8] came up with a deterministic version. These algorithms are considerably more involved than the algorithm of this paper, and have queue sizes around 20. The best uniaxial row-major sorting algorithm so far appears to be a modification of the algorithm of Schnorr and Shamir [18]. It takes $4 \cdot n + o(n)$ steps. The first near-optimal algorithm for k-k sorting was discovered by Kaufmann and Sibeyn [7]. Then in [11] by Kunde and slightly later also in [8], deterministic versions of this randomized algorithm were described. All

[1] An algorithm is called near-optimal if its time consumption equals a lower-bound plus lower-order terms.

these algorithms use blocked snake-like row-major indexings. In this paper we present the first near-optimal algorithm for k-k sorting in row-major order.

Most current communication algorithms strive for $T = \alpha \cdot n + o(n)$, with α as small as possible. This completely neglects the fact that actual meshes tend to be of fairly moderate sizes, for which the $o(n)$ often dominates. In this paper we also aim for algorithms with a routing time without hidden terms. A sorting time that can be expressed as $T \leq \alpha \cdot n$ for all n also has theoretical relevance in recursive or divide-and-conquer algorithms, where the effective size of the network decreases, and this α may be decisive for the overall performance [21].

The remainder of the paper is organized as follows. In section 3 we give the algorithms for uniaxial row-major sorting for all n. Then we introduce in section 4 the "desnakification" of the k-k sorting algorithm for large n. This powerful technique is then applied in section 5 and culminates in the near-optimal 1-1 sorting algorithm.

2. Preliminaries.

Basics of routing and sorting. We speak of *edge contention* when several packets residing in a PU have to be routed over the same connection. Contentions are resolved using a priority scheme. We apply the *farthest-first strategy*, which gives priority to the packet that has to go farthest. For one-dimensional sorting we apply a suitable variant of an odd-even transposition sort. For the analysis of the routing on higher-dimensional meshes we need the "routing lemma" for routing a distribution of packets on a one-dimensional mesh [15, 7], and the corresponding result on sorting. Define for a given distribution of packets over the PUs $h_{\text{right}}(i,j) = \#\{$*packets passing from left to right through both* P_i and $P_j\}$, where P_i denotes the PU with index i. Define $h_{\text{left}}(j,i)$ analogously.

LEMMA 1. *Routing a distribution of packets on a linear array with n PUs, using the farthest-first strategy, takes* $\max_{i<j}\{\max\{h_{right}(i,j), h_{left}(j,i)\} + j - i - 1\}$ *steps. This bound is sharp. When the packets are evenly distributed, then the same bound can be achieved for sorting.*

Because of the distance a packet may have to go, $2 \cdot n - 2$ steps is a lower bound for any general routing or sorting problem on the two-dimensional mesh. We call this the *distance bound*. Because of the number of packets that may have to pass from one half of the mesh into the other half over only n connections, $k \cdot n/2$ steps is a lower bound for any k-k routing or sorting problem. This is called the *bisection bound*.

A 0-1 *distribution* is a distribution of packets that all have key 0 or 1. In a 0-1 distribution a row is called *dirty* if it contains both zeros and ones. In our analysis we frequently use the "0-1 lemma" (see [13]), which states that under light conditions a sorting algorithm is correct if it sorts any 0-1 distribution.

Indexings. The PU at position (i,j) is denoted $P_{i,j}$. Here $0 \leq i,j \leq n-1$, and position $(0,0)$ lies in the upper-left corner. In the row-major indexing, $P_{i,j}$ has index $i \cdot n + j$; in the column-major indexing, it has index $i + j \cdot n$; and in the reversed row-major indexing, it has index $i \cdot n + (n-j)$. In the snake-like row-major indexing, the indexing of the odd rows is reversed. For a given indexing the PU with index i, $0 \leq i \leq n^2 - 1$, is denoted P_i. A row i is said to be *sorted rightward* if the packets stand in increasing order from $P_{i,0}$ to $P_{i,n-1}$. Analogously, rows can be sorted *leftward* and columns *downward* or *upward*.

For k-k sorting there are several natural ways to index the $k \cdot n^2$ destination locations. In a *layered* indexing, location r in P_i has index $r \cdot n^2 + i$. Our default is a *nonlayered* indexing, under which location r in P_i, $0 \leq r < k$, $0 \leq i < n^2$, has index

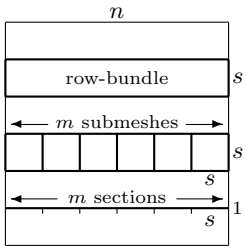

FIG. 2. *Subdivisions for the case $s = n/6$, $m = 6$.*

$k \cdot i + r$. A nonlayered row-major indexing is an indexing as if we have an $n \times k \cdot n$ mesh with row-major indexing. In our row-major sorting we use a *semilayered* indexing, under which location $P_{i,j}$ has index $(i + r) \cdot n + j$. This is as if we have an $n \times k \cdot n$ mesh with row-major indexing. These indexings are illustrated in Figure 1.

DEFINITION 1. *An indexing is* continuous *if for all i, $0 \leq i \leq n-2$, P_i is adjacent to P_{i+1} in the mesh. An indexing is* piecewise continuous *with parameter s if for every i, $0 \leq i < n^2$, there is an interval $\mathcal{I}_i \subset [0, n^2 - 1]$, with $i \in \mathcal{I}_i$ and $\#\mathcal{I}_i \geq s$, such that P_j is adjacent to P_{j+1} for all $j, j + 1 \in \mathcal{I}_i$.*

The row-major indexing is piecewise continuous with parameter n, but not continuous. The snake-like row-major indexing is continuous. One of the achievements of this paper is to show that for near-optimal sorting a *piecewise*-continuous indexing suffices.

Subdivisions. The mesh is divided into regular $s \times s$ submeshes. Let $m = n/s$. The submeshes $B_{i,j}$, $0 \leq i, j \leq m-1$, are indexed as the PUs starting with $(0, 0)$ in the upper-left corner. *Row-bundle i* consists of the PUs in $\cup_{j=0}^{m-1} B_{i,j}$. *Column-bundle j* consists of $\cup_{i=0}^{m-1} B_{i,j}$. *Section l*, S_l, $0 \leq l \leq m \cdot n - 1$, consists of the PUs with index in $\{s \cdot l, \ldots, s \cdot (l + 1) - 1\}$. Under a row-major indexing the sections regularly subdivide the rows and the submeshes. All subdivisions are depicted in Figure 2.

DEFINITION 2. *An* m-way merge *is a procedure that turns m^2 sorted submeshes into a sorted $n \times n$ mesh.*

3. Uniaxial sorting for small n.

This section is practically the most important. We present a variety of sorting algorithms that have no additional terms in their time consumptions.

3.1. Powers of two.

LEMMA 2. *On 2×2 meshes, uniaxial sorting in arbitrary order takes three steps, with queue size two.*

Proof. Perform gossiping (all-to-all routing) along rows and then along columns. This takes three steps. The PUs that finally should hold the packets with rank 0 and

1 need to conserve only the two smallest packets, the other PUs only the two largest packets. □

3.1.1. Larger n. For $n = 2^l$, $l > 1$, we use an optimized merge-sort algorithm combining several recent techniques and adding some new ideas. The first merge-sort algorithm with the optimal time *order* was given by Thompson and Kung [19]. Initially we have four sorted $n/2 \times n/2$ submeshes: those in the left half in row-major order; those in the right half in reversed row-major order. Then we perform the following.

ALGORITHM MERGE.

1. In the left half, shift the packets $n/4$ steps to the right. In the right half, shift the packets $n/4$ steps to the left.

2. In the central $n/2$ columns, sort the packets downward.

3. Copy the smallest packet in every $P_{i,j}$, $0 < i \leq n-1$, $n/4 \leq j \leq 3/4 \cdot n - 1$, to $P_{i-1,j}$. Copy the largest packet in every $P_{i,j}$, $0 \leq i < n-1$, $n/4 \leq j \leq 3/4 \cdot n - 1$, to $P_{i+1,j}$.

4. In every row, sort the section of the row that lies in the central $n/2$ columns. If this submesh is going to be the right half of a larger mesh in the next merge, then the sorting is leftward, otherwise rightward.

5. Throw away the packets in $P_{i,j}$ with $j \in [n/4, 3/8 \cdot n - 1] \cup [5/8 \cdot n, 3/4 \cdot n - 1]$. For any $P_{i,j}$, with $3/8 \cdot n \leq j \leq 5/8 \cdot n - 1$, send the packet with rank r, $0 \leq r \leq 3$, to $P_{i,4\cdot(j-3/8\cdot n)+r}$.

We analyze the routing time and the correctness of MERGE. Step 1 takes $n/4$ steps, step 2 can be performed in n steps, and step 3 takes a single step. This step can easily be made to coincide with the last step of the sorting. Its purpose is expressed by the following lemma.

LEMMA 3. *After step* 2 *all packets that actually should be in a row can be found either in the row itself, or among the smallest packets of the row below, or among the largest packets of the row above.*

Proof. First we consider a modified problem. Suppose that initially four $n/2 \times n/2$ submeshes stand above each other in an $2 \cdot n \times n/2$ mesh. Two of these submeshes are sorted in row-major order, the other two in reversed row-major order. Consider a 0-1 distribution. It is easy to check that after sorting the columns of this mesh, there are at most two dirty rows. These dirty rows can be resolved as follows: copy every row to the row above and the row below; sort the rows; spread the packets from the central $n/3$ columns. In the real problem every two rows of the high and narrow mesh are compressed in one row in which every PU in the center holds two packets. □

LEMMA 4. *Step* 4 *can be performed in* $3/4 \cdot n$ *steps.*

Proof. For the number of required steps we analyze the worst possible 0-1 distributions after step 2. These are of the form given on the left in Figure 3. After step 3 this gives a distribution as on the right in Figure 3. According to Lemma 1, sorting this row takes $3/4 \cdot n$ steps. □

Finally, step 5 takes $3/8 \cdot n$ steps.

LEMMA 5. MERGE *takes at most* $2^3/_8 \cdot n$ *steps.*

3.1.2. Improvement by overlapping. In MERGE, steps 4 and 5 involve routing along the same axis. So, we might overlap these steps, without impairing the uni-axiality of the algorithm. The central observation is that the packets to throw away are known well before the end of step 4. After throwing them away, we can proceed with a combination of odd-even transposition sort and routing packets outward: in

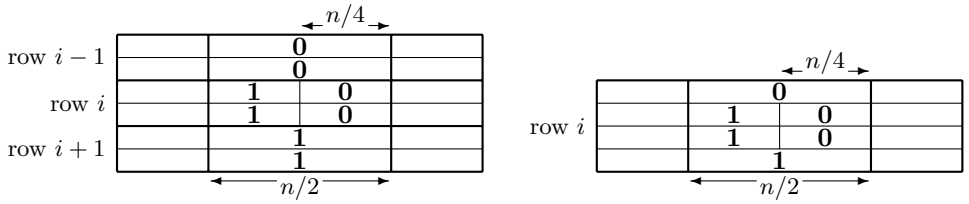

FIG. 3. *Left: worst case distribution after step* 2; *right: situation after step* 3.

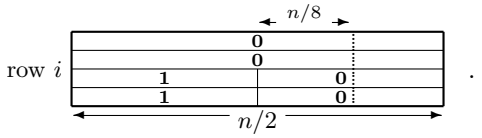
the same step that we are sure which packets to throw away, we also know the largest surviving packet. One step later we know the second largest, and so on. Without further comparison these packets can be routed to their destinations, reducing the maximal distance the packets may have to travel after the end of the sorting.

LEMMA 6. *In step* 4 *all packets that will be thrown away have reached their destination region in* $5/8 \cdot n$ *steps.*

Proof. We consider the packets that will be thrown away on the high side in some row i. Assume that the sorting is rightward. If there are more than $n/2$ candidates (because a critical key occurs more than once), then some of these packets stand more to the right than necessary. So, let there be precisely $n/2$ packets with key 1, while all the others have key 0. According to Lemma 1 we must analyze how far the ones can stand to the left. Notice that a row that holds both zeros and ones is a dirty row. There are at most two dirty rows. This gives the following worst case:



It takes $n/8 + n/2$ steps until all ones have drifted into the region on the right. □

After $t = 5/8 \cdot n$ we would like to discard in every row i the packets that do not belong in it. Suppose that the sorting is rightward. $P = P_{i,5/8 \cdot n-1}$ is the rightmost PU that preserves its packets, and $P' = P_{i,5/8 \cdot n}$ is the leftmost PU of the section in which the the largest packets are thrown away. If the transposition sort works without making copies, the packets continue to move back and forth. In that case Lemma 6 guarantees only that all packets to throw away have *reached* their destination regions, not that they actually reside there! Thus, P' has to operate carefully, to prevent it throwing away the wrong packets. A solution is to let P' throw away its largest packet after step $t-1$. Then in step t it keeps a copy of its smallest packet p', which it sends to P. After step t P' throws away all its packets, except for p when it has a smaller key than p'.

Notice that the smaller of p and p', p' say, is the largest of all surviving packets: the destination of p' is in $P_{i,n-1}$. Thus, p' can be sent toward its destination, while the sorting in the central part of the row continues. It is easy to check that the second, third, ..., largest packet ultimately arrives in P in step $t+1$, $t+2$, ... (consider a worst case distribution in which the largest surviving packets reside as far to the left as possible). So, P continues to send its largest packets to the right without receiving packets from there. It sends its smallest packets leftward as long as it holds more than one packet. After this its left neighbor takes over its role of "frontier" PU. After the sorting has finished, all packets are routed as in step 5 of MERGE-m. This concludes our description of the modified steps 4 and 5. We summarize the main points:

4′. For all i, $0 \leq i < n$, until step $5/8 \cdot n$, sort the packets in the central $n/2$ PUs of

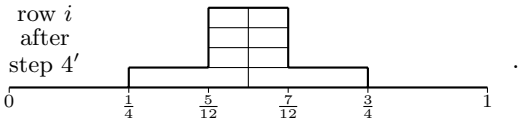
row i. Throw away the packets that stand outside the central $n/4$ columns. A PU that holds more than one packet continues to sort. A PU in the left (right) half that holds only one packet sends this packet leftward (rightward).

5′. Route the packets in row i to their destinations.

Step 4′ takes as long as before: the sorting is influenced in no way by the action going on in the periphery. On the other hand, step 5′ is substantially cheaper than step 5.

LEMMA 7. *Step 5′ can be performed in $n/4$ steps.*

Proof. Suppose that the sorting is rightward. In step 4′, the packets that do not belong in some row i are thrown away after $5/8 \cdot n$ steps. The remaining packets stand concentrated in the central $n/4$ PUs. From now on the packets spread out of this region without delay until the end of the sorting after $3/4 \cdot n$ steps. Then the situation is as follows (omitting factors n):



Because the packets are properly arranged by now, none of them still has to travel farther than $n/4$ steps. □

Combining Lemma 7 with the earlier results gives the following.

LEMMA 8. *The improved version of* MERGE *takes at most $2^{1}/_{4} \cdot n$ steps. The queue size is at most four.*

3.1.3. Sorting. Starting with sorted 2×2 meshes, MERGE can be used repeatedly for sorting on an $n \times n$ mesh. Call this algorithm SORT. We have the following result.

THEOREM 1. *For all $n = 2^l$,* SORT *performs row-major sorting on an $n \times n$ mesh in $4^{1}/_{2} \cdot n$ steps.* SORT *is uniaxial, and the queue size is four.*

Proof. Summing the number of steps required for all merges, we find that the sorting takes less than $3 + 2^{1}/_{4} \cdot (4 + 8 + \cdots + n) < 2^{1}/_{4} \cdot n \cdot \sum_{i=0} 2^{-i}$ steps. □

3.2. Powers of two, three, ... We derived an efficient 1-1 sorting algorithm for $n = 2^l$. However, in practice, processor networks may not have different side lengths. Furthermore, some algorithms in which sorting is used as a subroutine, e.g., the algorithms of [21], specifically require that $n = m^l$ for some $m \neq 2$. In principle we could use SORT by rounding n up to the nearest power of 2. But this might give sorting times that are almost twice as large as necessary. In this section we present m-way merge algorithms, which perform well for $m \leq 5$. By combining them, we can efficiently sort $n \times n$ meshes for arbitrary n.

***m* × *m* meshes.** The following algorithm efficiently sorts an $m \times m$ mesh in row-major order:

1. In all rows i, concentrate the packets in $P_{i,\lfloor m/2 \rfloor}$.
2. Sort the packets in column $\lfloor m/2 \rfloor$ downwards.
3. In all rows i, spread the packets over the row.

LEMMA 9. *Uniaxial sorting on $m \times m$ meshes can be performed in $m^2/2 + m$ steps, for m even, and $m \cdot (m+1)/2$ steps, for m odd. The queue size is m.*

Proof. Steps 1, 2, and 3 take $\lfloor m/2 \rfloor$, $m \cdot \lfloor m/2 \rfloor$, and $\lfloor m/2 \rfloor$ steps, respectively. □

TABLE 2
Run times and queue sizes of uniaxial row-major sorting algorithms for $n = 2 \cdot m^l$.

m	2	3	4	5	6
Q	2	5	6	9	10
T	$5\frac{1}{2} \cdot n$	$4\frac{1}{3} \cdot n$	$4\frac{1}{2} \cdot n$	$4.61 \cdot n$	$4.65 \cdot n$

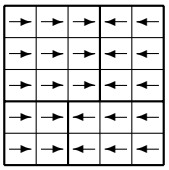


FIG. 4. *For merging* 25 *sorted submeshes, the rightward (leftward) arrows indicate submeshes that are sorted in (reversed) row-major order.*

Larger n. For performing an m-way merge for $m \geq 3$, we can proceed as in MERGE: wipe all submeshes together, sort the columns, etc. However, for algorithms of this type the number of dirty rows equals $\lceil m^2/2 \rceil$, which leads to long queues, and rapidly growing time to resolve them with increasing m. It is better to first sort the row-bundles, then to merge the sorted row-bundles. In this way the number of dirty rows is limited to $\lceil m/2 \rceil$. For $m \geq 3$ this approach is faster. Proceeding along these lines, we get the following theorem.

THEOREM 2. *For all $n = 2 \cdot m^l$, uniaxial row-major sorting on $n \times n$ meshes can be performed with the time consumptions and queue sizes given in Table* 2.

Proof. For numbers of the form $2 \cdot m^l$, first the 2×2 submeshes are sorted, then we repeatedly perform an m-way merge. At the start of an m-way merge the $n/m \times n/m$ submeshes are appropriately sorted. For even m, in every row-bundle $m/2$ submeshes are sorted in row-major order and $m/2$ in reversed row-major order. For odd m, $\lceil m/2 \rceil$ submeshes are sorted in row-major order in the highest $\lceil m/2 \rceil$ row-bundles, and $\lfloor m/2 \rfloor$ in the lowest $\lfloor m/2 \rfloor$ row-bundles. The other submeshes are sorted in reversed row-major order. See Figure 4 for an example. Then we sort the row-bundles and subsequently the column-bundles. The complete algorithm and its analysis can be found in [20]. Again a reduction of the routing time is achieved by overlapping the phases, as was done in section 3.1.2. □

Sorting on $n \times n$ meshes for arbitrary n can be performed by approximating n by the closest number of the form $2^{l_2} \cdot 3^{l_3} \cdot 5^{l_5}$, and then using the basic two-, three-, and five-way merges in the optimal order, performing the most efficient ones in the final merges, when the submeshes are large. In this way we get the following result.

THEOREM 3. *Uniaxial row-major sorting on $n \times n$ meshes can be performed in less than $4.75 \cdot n$ steps for all n. The queue size is at most nine.*

Proof. The result follows by estimating the maximum factor between n and the smallest $n' > n$ that can be written as $n' = 2^{l_2} \cdot 3^{l_3} \cdot 5^{l_5} \cdot 7^{l_7} \geq n$. Here $l_7 \leq 1$, and if $l_2 = 0$, then $l_5 + l_7 \leq 1$. The sorting is performed in the time required for an $n' \times n'$ mesh. Details are given in [20]. □

3.3. k-k sorting. We present an algorithm for uniaxial k-k sorting in row-major order. Asymptotically optimal performance is achieved by the uniaxial version of the algorithm of section 4, which requires $\max\{4 \cdot n, k \cdot n\} + \mathcal{O}((k \cdot n)^{5/6})$. But the algorithm presented here is far better for small n. We assume that $n = 2^l$.

Four $n/2 \times n/2$ submeshes are sorted in semilayered row-major order on the left,

TABLE 3
Run times and queue sizes for uniaxial k-k sorting in row-major order.

k	T	Q
2	$5\frac{1}{4} \cdot n$	4
3	$7 \cdot n$	5
4	$8\frac{2}{3} \cdot n$	6
k	$(7/4 \cdot k + 6) \cdot n$	$k + 2$

and semilayered reversed row-major order on the right. The merging is almost the same as MERGE of section 3.1.

ALGORITHM KKMERGE.

1. $P_{i,j}$, $0 \le i, j < n$, sends its packets with rank r, $0 \le r < k$, such that $\text{odd}(k \cdot i + r + j)$, to $P_{i,(j+n/2) \bmod n}$.

2. In all columns, sort the packets downward.

3. In every $P_{i,j}$, $0 < i \le n-1$, $0 \le j \le n-1$, copy the smallest packet to $P_{i-1,j}$. In every $P_{i,j}$, $0 \le i < n-1$, $0 \le j \le n-1$, copy the largest packet to $P_{i+1,j}$.

4. Sort the rows. If this submesh is going to be the left half of a larger mesh in the next merge, then the sorting is rightward, otherwise leftward.

5. In every row, throw away the n packets with the smallest and the n packets with the largest indices. If this is the final merge step, then spread the remaining $k \cdot n$ packets that stand in every row. Else route the packets to the destinations as given by step 1 of the next merge, and continue with step 2.

Analyzing the algorithm step by step, and partially overlapping step 4 and step 5, we obtain (see [20]) the following lemma.

LEMMA 10. *An intermediate application of* KKMERGE *can be performed in* $(5 \cdot k^2 + 14 \cdot k + 4 - \min\{k^2, 2 \cdot k + 8\})/(4 \cdot k + 8) \cdot n$ *and the final application in* $(2 \cdot k^2 + 12 \cdot k + 4)/(4 \cdot k + 8) \cdot n$ *steps.*

Let KKSORT1 be the k-k sorting algorithm based on KKMERGE.

THEOREM 4. *For all* $k \ge 2$, KKSORT1 *performs uniaxial* k-k *sorting in row-major order on* $n \times n$ *meshes in* $(7 \cdot k^2 + 26 \cdot k + 8 - \min\{k^2, 2 \cdot k + 8\})/(4 \cdot k + 8) \cdot n$ *steps, with queue size* $k + 2$.

Proof. We start with sorted PUs. It takes $k/2$ steps to obtain the situation at the beginning of step 2 of the merge in 2×2 meshes. Thus, the general estimate for k-k sorting on $n \times n$ meshes is $k/2 + (5 \cdot k^2 + 14 \cdot k + 4 - \min\{k^2, 4 \cdot k + 12\})/(4 \cdot k + 8) \cdot (2 + 4 + \cdots + n/2) + (2 \cdot k^2 + 12 \cdot k + 4)/(4 \cdot k + 8) \cdot n$. □

From Theorem 4 we computed the results in Table 3. For small n they are extremely competitive, even though asymptotically uniaxial k-k sorting can be performed almost twice as fast. Applying KKMERGE for $k = 1$ gives a good alternative for $n = 2^l$: $T = 5 \cdot n$ and $Q = 2$.

3.4. Minimizing the queue sizes. It may be desirable to have minimal queue size even at the expense of slightly more routing steps. For example, if in an algorithm, which has $Q = q$ for some structural reason, some local sorting operations are used as subroutines, then we do not want to take Q larger just because of this sorting (see [5]). In this section we give a general idea for minimizing the queue sizes of the presented algorithms.

General idea. The core of all presented algorithms consists of steps of the following type:

1. Rearrange the packets within the rows.

2. Sort (sections of) the columns.
3. Copy the q smallest packets of every PU to its upper neighbor, and the q largest to its lower neighbor.
4. Sort sections of width s of the rows. Throw away the $q \cdot s$ smallest and largest packets.

The queue size depends on the degree of concentration c after step 1, and the number q: $Q = c + 2 \cdot q$. The degree of concentration is an essential feature of the algorithm and was chosen carefully to minimize its run time. q equals the number of dirty rows minus one. However, there is no need to clean away all dirt in a single operation. Repeating the following steps instead of steps 3 and 4, we can obtain $Q = c$. An additional advantage is that no packets are copied anymore. We assume that the sorting is rightward.

3′. In every section, spread the $s/2$ smallest packets over the leftmost $s/2$ PUs, and the $s/2$ largest packets over the $s/2$ rightmost PUs. Call these packets *active*. Compensate for the concentration in the middle by pushing the packets that follow (precede) the actives in rank rightward (leftward). Shift the actives in the right half one row down.
4′. Sort the actives in every section. Shift the rightmost $s/2$ actives one row up. Sort the sections.

The number of iterations of steps 3′ and 4′ follows from the distribution that arises after step 2. Before the first application the packets in every row should be sorted. As the algorithm is given we get $Q = c+1$ in the right halves of the sections in row 0. In order to get $Q = c$, we should shift one nonactive packet up from every PU in the right half of row 0 at the end of step 3′. These are returned in step 4′.

LEMMA 11. *One iteration of steps* 3′ *and* 4′ *on a section of length* s *in which every PU holds* c *packets takes* $3/2 \cdot s - s/c + 3$ *steps.*

Proof. The spreading in step 3′ takes $s/2 - s/(2 \cdot c)$ steps. For sorting the actives it is essential that the packets in each half are already sorted. Therefore it can be performed in $s/2 + 1$ steps with an ordinary odd-even transposition sort without making copies (if this is desirable), and with one step fewer if copying is allowed. Sorting the sections takes as much as the spreading: no packet has to travel more than $s/2 - s/(2 \cdot c)$, and no connection is heavily loaded. □

***k*-*k* sorting.** For the k-k merge, it can be shown that steps 3′ and 4′ need to be performed only once. This means that at little extra cost, the queue size of the k-k sorting algorithm can be reduced to k.

1-1 sorting. In our machine model a packet that only passes a PU is not inserted into its queue but transferred directly from its in-buffer to its out-buffer. In addition, it is possible to compare a buffered packet with a queued one, and to exchange them. In such a model the given algorithm can be applied for 1-1 sorting with $T = 5\frac{1}{2} \cdot n + \log n$ and $Q = 1$. Alternatively, the algorithm can be applied for sorting in the *one-packet model* in which every PU holds one packet at all times and the connections act as comparators. The algorithm of Schnorr and Shamir [18] requires approximately $4 \cdot n + 20 \cdot n^{2/3}$ steps for sorting in row-major order. For all mesh sizes smaller than 1000×1000, our result gives a significant improvement over this.

LEMMA 12. *For* $k = 1$, *the queue size of* MERGEKK *can be reduced to* 1. *An intermediate application takes* $3\frac{1}{4} \cdot n + 1$, *the final application* $2\frac{1}{4} \cdot n + 1$ *steps.*

Proof. Because the packets within the submeshes are already sorted, step 2 takes only $3/4 \cdot n$ steps. Sorting the sections takes $n - 1$, steps 3′ 1, and Step 4′, without

the final sorting, $n/2 + 1$ steps. In the final merge no more steps are needed. In an intermediate merge packets still may travel a distance n. □

THEOREM 5. KKSORT1 *performs uniaxial* 1-1 *sorting in row-major order on* $n \times n$ *meshes in* $5^1/_2 \cdot n + \log n$ *steps with queue size* 1.

Applying a technique called "vibration" [1, 14], the same bound can be achieved for "hot-potato" sorting (a paradigm in which no queuing is allowed). The hot-potato routing algorithms in [3, 4] apply such a sorting as a subroutine.

4. *k*-*k* sorting for large *n*. Earlier algorithms for k-k sorting [7, 11, 8] work according to the following basic scheme:

1. Route all packets to random destinations.
2. Estimate the ranks of the packets by local comparisons.
3. Route all packets to their preliminary destinations.
4. Rearrange the packets locally to bring them to their final destinations.

In the version of [8], the mesh is divided into $s \times s$ submeshes with $s = n^{2/3}/k^{1/3}$, and the randomization of step 1 is replaced by sorting the packets in the submeshes and unshuffling them regularly over the submeshes. Step 2 is performed by sorting within the submeshes. Step 4 is performed by sorting pairs of adjacent submeshes. On an MIMD the total sorting time is $k \cdot n/2 + \mathcal{O}(k^{2/3} \cdot n^{2/3})$. As the algorithm is given, step 4 requires that the indexing is continuous. In this section we introduce a novel technique, *desnakification*, to handle the final local sorting such that piecewise-continuous indexings are allowed.

The continuity of the indexing is required for sorting together pairs of submeshes with consecutive indices. Sorting such pairs of submeshes is necessary because the estimate of the rank in step 2 is accurate only up to one submesh. So, it may happen that after step 3, a packet with destination in submesh B_i actually resides in the preceding submesh B_{i-1} or the succeeding submesh B_{i+1}. However, this is easy to overcome: send for all packets p, of which the destination submesh is not uniquely determined, a copy to both submeshes in which its destination may lie. Now it is sufficient to sort within the submeshes. If for B_i the numbers cl of packets that actually belong in B_{i-1} and ch of packets that belong in B_{i+1} are exactly known, then the smallest cl and largest ch packets in B_i are thrown away, and the remaining packets are redistributed within B_i. All this is very similar to the way dirty rows are resolved in the algorithms of section 3. The only possible problem is that routing the copies might slow down the algorithm.

We work the desnakification out in detail for biaxial sorting. In order to bound the number of copies, we must take the submeshes larger than in [8]. The optimal choice is $s = n^{5/6}/k^{1/6}$ and $m = n/s = k^{1/6} \cdot n^{1/6}$. We suppose that the indexing is piecewise continuous with parameter s. For the sake of a simple exposition we assume that the mesh is divided into sections of length s, each of which is fully contained in a single submesh. The algorithm proceeds as follows.

ALGORITHM KKSORT2.

1. In each submesh, sort the packets. The intermediate destination of a packet p with rank r, $0 \le r < k \cdot s^2$, lies in submesh $r \bmod m^2$. If $r \bmod (2 \cdot m^2) < m^2$, then color p white, else black.

2. In each submesh rearrange the white (black) packets such that those with intermediate destinations in column-bundle l (row-bundle l), $0 \le l < m$, stand in the columns (rows) $[l \cdot s/m, (l+1) \cdot s/m - 1]$ of the submesh.

3. From column-bundle j, $0 \le j < m$, route the white packets with intermediate destinations in column-bundle l, $0 \le l < m$, as a block to the columns $[j \cdot s/m, (j+1) \cdot s/m - 1]$ of column-bundle l. Route the black packets analogously.

4. In each submesh rearrange the white (black) packets such that those with intermediate destinations in row-bundle l (column-bundle l), $0 \le l < m$, stand in the rows (columns) $[l \cdot s/m, (l+1) \cdot s/m - 1]$ of the submesh.

5. From row-bundle i, $0 \le i < m$, route the white packets with intermediate destinations in row-bundle l, $0 \le l < m$, as a block to the rows $[i \cdot s/m, (i+1) \cdot s/m - 1]$ of row-bundle l. Route the black packets analogously.

6. In each submesh, sort the packets. The preliminary destination of a packet p with rank r, $0 \le r < k \cdot s^2$, lies in section S_l, with $l = \lfloor r \cdot m^2/(s \cdot k) \rfloor$. If $\lfloor (r \cdot m^2 - m^4)/(s \cdot k) \rfloor = l - 1$, then create a copy p' of p with preliminary destination in S_{l-1}. If $\lfloor (r \cdot m^2 + m^4)/(s \cdot k) \rfloor = l + 1$, then create a copy p' of p with preliminary destination in S_{l+1}. If r is even, then color p (and p') white, else black.

7, 8, 9, 10. Like steps 2, 3, 4, and 5, respectively, for the preliminary destinations.

11. Route the packets within the submeshes to the sections of their preliminary destinations.

12. In each section, sort the packets.

13. In each section S_l, $0 \le l \le m \cdot n - 1$, throw away the m^4 packets with the smallest keys (except for S_0), and the m^4 packets with the largest keys (except for $S_{m \cdot n - 1}$). Redistribute the remaining $k \cdot s$ packets within S_l.

If packets have the same key, then special care should be taken not to throw away both copies of a packet, while keeping both copies of another packet. A solution is to take the index of the PU where a packet started as an additional comparison criterion, to assure that all packets have different keys. The algorithm can be made uniaxial by leaving out the coloring, and applying only uniaxial local operations.

THEOREM 6. *Let* $s = n^{5/6}/k^{1/6}$. KKSORT2 *performs biaxial* k*-*k *sorting with respect to a piecewise-continuous indexing with parameter* s *in* $\max\{4 \cdot n, k \cdot n/2\} + \mathcal{O}(k \cdot s)$ *steps. The queue size is* $k + 2$.

Proof. The following facts imply the correctness of KKSORT2. In step 6, the estimate of the global rank of a packet p with rank r within its submesh, $r \cdot m^2$, is accurate up to m^4. Hence, the index of the destination PU of p is accurate up to m^4/k. Thus after step 11, a (copy of a) packet resides in its destination section. After step 11 there are m^4 packets in S_l, $0 < l \le m \cdot n - 1$, that belong in S_{l-1}, because from each of the m^2 submeshes precisely m^2 copies of packets with estimated destination in S_{l-1} are sent to S_l. Likewise there are m^4 packets in S_l, $0 \le l < m \cdot n - 1$, that belong in S_{l+1}.

For the time analysis, only the four main steps, steps 3, 5, 8, and 10, are of importance. The other steps can be performed in $\mathcal{O}(k \cdot s) = \mathcal{O}(k^{5/6} \cdot n^{5/6})$ steps. Step 3 and step 5 are very regular. It is easy to check that no connection has to transfer more than $k \cdot n/8$ packets, and that packets travel less than n steps. At the beginning of step 8, there are in every submesh exactly m^3 packets and $2 \cdot m^2$ copies of packets with destination in any section S_l, $0 < l < m \cdot n - 1$ (m^2 copies for $l = 0$ or $l = m \cdot n - 1$). Because the sections are fully contained in the submeshes, this implies that every submesh holds $m^3 \cdot n$ packets and $2 \cdot m^2 \cdot n$ copies of packets with destination in any column-bundle. This means that step 7 can be performed such that the PUs in the columns $[l \cdot s/m, (l + 2 \cdot k/m) \cdot s/m - 1]$ all hold $k + 1$ packets and the PUs in all other columns hold exactly k packets. Clearly step 8 now takes $(1 + 2/m) \cdot k \cdot n/8 = k \cdot n/8 + s/4$. Performing step 9 appropriately, the same bound can be shown for step 10.

A PU never holds more than $k/2$ packets and one copy of both colors, and thus $Q \le k + 2$. □

5. 1-1 sorting for large n. We start with a uni-axial algorithm for 1-1 sorting in row-major order. It runs in $2^1/_2 \cdot n + o(n)$ steps. Asymptotically this is much faster then the algorithms of section 3. This algorithm is obtained by combining our new insight in merge sorting and the desnakification technique, with old knowledge about sorting with splitters. In section 5.2 it is turned into a near-optimal biaxial algorithm. Without loss of generality, we assume that all packets have different keys.

5.1. Uniaxial sorting. The mesh is divided into $s \times s$ submeshes. In the algorithm of this section $s = n^{5/6}$, and $m = n/s = n^{1/6}$. We distinguish packets and *splitters*. The splitters are copies of a small subset of the packets. They are broadcast and the packets estimate their ranks by comparison with the splitters. This widely known idea (going back to work of Reischuck [16] and Reif and Valiant [17]) has been used for randomized [15, 7, 2] and deterministic [8] sorting on meshes. In the k-k sorting algorithm of section 4 we do not need splitters because the packets are fully distributed over the mesh, and thus reliable estimates of the ranks of the packets can be obtained by local comparison among the packets themselves. In the case of 1-1 sorting this does not lead to efficient algorithms. The splitters allow us to spread the necessary information rapidly, while the packets are involved in more useful operations.

Algorithm. First we give the algorithm for selecting and routing the splitters.

ALGORITHM SPLITTER-ROUTE.

1. In every submesh, sort the packets. Copy the packets with ranks $i \cdot m^2$, $0 \le i \le s^2/m^2 - 1$. These are the splitters.

2. In every submesh $B_{i,j}$, $0 \le i, j < m$, rearrange the splitters such that they stand in the positions (i', j') of $B_{i,j}$, with $i \cdot s/m \le i' < (i+1) \cdot s/m$ and $j \cdot s/m \le j' < (j+1) \cdot s/m$.

3. Send the splitters along the rows. A splitter starting in position (i', j') of $B_{i,j}$ drops copies in the positions (i', j') of $B_{i,l}$, for all $0 \le l < m$.

4. Send the splitters along the columns. A splitter starting in position (i', j') of $B_{i,j}$ drops copies in the positions (i', j') of $B_{l,j}$ for all $0 \le l < m$.

LEMMA 13. SPLITTER-ROUTE *takes* $2 \cdot n + \mathcal{O}(s)$ *steps to complete. No connection has to transfer more than* $\mathcal{O}(s)$ *packets. Finally, each PU holds precisely one splitter, and all splitters are available in every* $s \times s$ *submesh.*

Proof. Step 1 and step 2 take $\mathcal{O}(s)$ steps, step 3 and step 4 take less than n steps. The rearrangement is such that the splitters in $B_{i,j}$ stand in "subsubmesh" (i, j). After the broadcast these splitters occupy the subsubmeshes (i, j) in all submeshes: the splitters from different submeshes fit perfectly next to each other. This arrangement also assures that during step 3 and step 4 a connection has to transfer at most $m/2 \cdot s/m = s/2$ splitters. □

When splitters and packets want to use the same connection, priority is given to the splitters. By the lemma this delays the packets by at most $\mathcal{O}(s)$. For the packets we perform a kind of m-way merge algorithm.

ALGORITHM 11SORT.

1. In every submesh, sort the packets in row-major order.

2. In every submesh $B_{i,j}$, $0 \le i, j < m$, shift the packets in row l, $0 \le l < s$, to row l of $B_{i,(j+l) \bmod (m/2)}$, and copies to row l of $B_{i,(j+l) \bmod (m/2)+m/2}$.

3. In all columns, sort the packets downward.

4. In every submesh, determine for every packet its "rank," the number r, $0 \le r \le s^2$, of splitters that are smaller. The preliminary destination of a packet p with

rank r lies in section S_l, with $l = \lfloor r \cdot m^2/s \rfloor$. If $\lfloor (r \cdot m^2 - m^4)/s \rfloor = l-1$, then create a copy p' of p with preliminary destination in S_{l-1}. If $\lfloor (r \cdot m^2 + m^4)/s \rfloor = l+1$, then create a copy p' of p with preliminary destination in S_{l+1}. Discard the splitters and the (copies of) packets that have preliminary destination in the other half of the mesh.

5. In every submesh, sort the packets in column-major order on their preliminary destination column-bundles.

6. In every row, route the packets to the first PUs in their preliminary destination column-bundles that hold less than two packets.

7. In each submesh, sort the packets in row-major order on their preliminary destination section.

8. In every column, route the packets to the sections of their preliminary destinations.

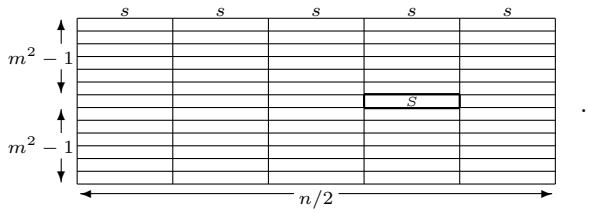
9. In every section, sort the packets.

10. In every section S_l, $0 < l \leq m \cdot n - 1$, throw away the m^4 packets with the smallest keys, and in each S_l, $0 \leq l < m \cdot n - 1$, throw away the m^4 packets with the largest keys. Redistribute the remaining $k \cdot s$ packets within S_l.

After step 3, there are in a 0-1 distribution at most m^2 dirty rows. For a general distribution this means that a packet resides at most $m^2 - 1$ rows away from its destination row. These three steps take $2 \cdot n + \mathcal{O}(s)$ steps, just as in SPLITTER-ROUTE. So, we may assume that after step 3 the splitters are available in the submeshes. Step 4, ..., step 10 resemble the final steps of KKSORT2 for $k = 1$.

Analysis. As the algorithm is given, it is not entirely correct. It is *not* true that, as in KKSORT2, exactly m^4 packets must be thrown away on both sides of every section: 11SORT orders the packets, but the sections do not necessarily hold exactly s packets. Fortunately, the numbers of packets that must be thrown away in a section on the low and high sides, respectively, can be determined.

Consider some section S and the sections from which it may receive packets after step 3:



$(2 \cdot m^2 - 1) \cdot n/2$ packets are stored in these sections, among which are the s packets with destination in S. After step 8, these s packets all reside in S, but also some packets that do not belong in S. How can we figure out which packets to keep, and which packets to throw away? Suppose that S is the lth section, $(m^2 - 1) \cdot n/s \leq l < m^2 \cdot n/s$, in the involved (whole) rows. Then finally S should hold the packets with ranks r, $l \cdot s \leq r < (l+1) \cdot s$, from among the $(2 \cdot m^2 - 1) \cdot n$ packets. Analogously to the merge algorithms of section 3, we could copy *all* packets to S, sort them, and throw away the smallest $l \cdot s$ packets and the largest $(2 \cdot m^2 - 1) \cdot n - (l+1) \cdot s$ packets. This gives a correct but very inefficient algorithm. However, it is not necessary to copy all packets to S. It is sufficient, if for each contributing section i, the counters, the numbers $under_{S,i}$ and $over_{S,i}$ of packets that are *not* sent to S because they are definitely too small or definitely too large, respectively, are known in S. The counters can easily be determined in step 4. They can be transferred to S during the subsequent

steps, in parallel with the packets. As every section sends and receives only $\mathcal{O}(m^3)$ counters in total, they can be routed without causing substantial delay. The numbers $Under_S = \sum_i under_{S,i}$ and $Over_S = \sum_i over_{S,i}$ can be computed in step 9. Finally, in step 10, the smallest $l \cdot s - Under_S$ packets and the largest $(2 \cdot m^2 - 1) \cdot n - (l+1) \cdot s - Over_S$ packets in S are thrown away, leaving exactly the s packets belonging in S. Now we get the following result.

THEOREM 7. *Uniaxial* 1-1 *sorting in row-major order can be performed in* $2^1/_2 \cdot n + \mathcal{O}(n^{5/6})$ *steps. The queue size is five.*

Proof. Let $s = n^{5/6}$. For the routing time and correctness, we only have to prove that step 6 can be performed in $n/2 + \mathcal{O}(s)$ steps. All other steps can be performed in $\mathcal{O}(s)$ steps.

The estimate of the rank of a packet, $r \cdot m^2$, is accurate up to m^4. This means that for some section S_l, only a packet (or its copy) with actual destination in some PU P_k, with $k \in [l \cdot s - 2 \cdot m^4, (l+1) \cdot s + 2 \cdot m^4]$, may get preliminary destination in S_l. Hence, at most $s^2 + 4 \cdot m^4 \cdot s$ packets have preliminary destination in any submesh $B_{i,j}$. By the sorting in step 5, they are distributed almost optimally over the rows of row-bundle i: at most $s + \mathcal{O}(m^4)$ packets stand in any row. The $m^2 \cdot s$ packets with destination in $B_{i-1,j}$ and $B_{i+1,j}$ that may stand in row-bundle i have no serious influence. This shows that step 6 can be performed as specified: no PU in $B_{i,j}$ has to receive more than two packets.

We consider the routing time of step 6. For a rightward-moving packet p, residing in some PU $P_{i,j}$ and moving to column l, with $j, l < n/2$, we are interested in the number h_l of packets within row i that go to some column k, with $k \geq l$. By the above analysis, we know that $h_l \leq n/2 - l + \mathcal{O}((n/2 - l)/s \cdot m^4) \leq n/2 - l + \mathcal{O}(s)$. p is delayed at most h_l times, and hence p finishes step 6 within $n/2 + \mathcal{O}(s)$ steps.

A PU may hold up to four (copies of) packets during step 4 and step 5. In addition step 4 can be organized such that a PU holds at most one splitter or counter. Hence, $Q \leq 5$. □

Other indexings. The algorithm is not suited for sorting with respect to any piecewise-continuous indexing: it is essential that after step 3 the packets do not have to make another long vertical move. However, the algorithm *is* correct for any piecewise indexing in which the pieces are scrambled within the rows.

2-2 sorting. For uniaxial 2-2 sorting, only step 2 has to be modified: the packets are not copied, but distributed evenly over the rows. For biaxial 2-2 sorting, we essentially apply two orthogonal versions of 11SORT. This gives the following theorem (details are provided in [20]).

THEOREM 8. *Uniaxial* 2-2 *sorting in row-major order can be performed in* $3 \cdot n + \mathcal{O}(n^{5/6})$ *steps. The queue size is five. Biaxially it takes* $2^1/_2 \cdot n + \mathcal{O}(n^{5/6})$ *steps, with a queue size of nine.*

5.2. Near-optimal biaxial sorting. Essentially 11SORT consists of three main routing phases: horizontal, vertical, and horizontal (step 2, step 3, and step 6). These phases take n, n, and $n/2$ steps, respectively. The connections between the left and right halves are not used anymore after step $n/2$. Thus it may happen that a packet p_1 that stands in column 0 after phase 1 is routed to a preliminary destination in column $n/2 - 1$ in phase 3. This is unnecessary: a copy of p_1 stands in column $n/2$. In a uniaxial algorithm this observation does not lead to a faster algorithm: there may be a packet p_2, after phase 1 in column $n/2 - 1$ and with preliminary destination in column 0, which has to travel $n/2$ steps in phase 3. On the other hand, in a

biaxial algorithm, it is possible to coalesce the phases. Then p_2 can start phase 3 after $3/2 \cdot n + \mathcal{O}(s)$ steps, and will reach its preliminary destination after $2 \cdot n + \mathcal{O}(s)$ steps.

We work out these ideas. Only step 4 is changed: instead of discarding the packets that have their destinations in the other half, we now perform the following.

In all columns j, $0 \leq j < n/2$, discard the (copies of) packets that have preliminary destination in some column j', with $j' \geq 2 \cdot j$. For $n/2 \leq j < n$, discard the packets with $j' < 2 \cdot j - n$.

Notice that by this rule again exactly one of the copies of a packet reaches every possible destination section. The steps are coalesced. Most importantly, this means that step 3 begins in column j after $n/2 + |n/2 - j|$ steps, and step 6 after $3/2 \cdot n + |n/2 - j|$ steps.

THEOREM 9. *Biaxial* 1-1 *sorting in row-major order can be performed in* $2 \cdot n + \mathcal{O}(n^{5/6})$ *steps. The queue size is five.*

Proof. A packet that starts step 6 after $2 \cdot n - d + \mathcal{O}(s)$ steps has to travel at most d steps to reach the column-bundle of its preliminary destination. We check this for a packet p that is routed in step 2 to some column j, with $j < n/2$. p starts step 6 after $2 \cdot n - j + \mathcal{O}(s)$ steps. In step 4 the preliminary destination of p is determined. p survives only when it goes to some column l, with $l < 2 \cdot j$: p has to travel at most j steps. By a refinement of the analysis in the proof of Theorem 7, it can be shown that p is not delayed more than $2 \cdot j - l$ times. Hence, step 7 can start in all submeshes after $2 \cdot n + \mathcal{O}(s)$ steps. □

In fact this algorithm is still *locally* uniaxial: every PU uses only horizontal or vertical connections.

6. Conclusion. We presented novel uniaxial and biaxial row-major algorithms for sorting on two-dimensional meshes. A tremendous improvement is our near-optimal algorithm for 1-1 sorting: it is much simpler than the earlier algorithm, it is suited for more useful indexings, it is locally uniaxial, and it has queue size five.

Future research could address (1) the optimality of the uniaxial sorting algorithm with run time $2\frac{1}{2} \cdot n + o(n)$ steps; (2) a further development of the merge-sort idea to obtain even faster sorting for all n.

ROBUST PROXIMITY QUERIES: AN ILLUSTRATION OF DEGREE-DRIVEN ALGORITHM DESIGN*

GIUSEPPE LIOTTA†, FRANCO P. PREPARATA‡, AND ROBERTO TAMASSIA‡

Abstract. In the context of methodologies intended to confer robustness to geometric algorithms, we elaborate on the exact-computation paradigm and formalize the notion of degree of a geometric algorithm as a worst-case quantification of the precision (number of bits) to which arithmetic calculation have to be executed in order to guarantee topological correctness. We also propose a formalism for the expeditious evaluation of algorithmic degree. As an application of this paradigm and an illustration of our general approach where algorithm design is driven also by the degree, we consider the important classical problem of proximity queries in two and three dimensions and develop a new technique for the efficient and robust execution of such queries based on an implicit representation of Voronoi diagrams. Our new technique offers both low degree and fast query time and for 2D queries is optimal with respect to both cost measures of the paradigm, asymptotic number of operations, and arithmetic degree.

Key words. geometric computing, robustness, arithmetic precision, proximity queries

1. Introduction.

The increasing demand for efficient and reliable geometric software libraries in key applications such as computer graphics, geographic information systems, and computer-aided manufacturing is stimulating a major renovation in the field of computational geometry. The inadequacy of the traditional simplified framework has become apparent, and it is being realized that, in order to achieve an effective technology transfer, new frameworks and models are needed to design and analyze geometric algorithms that are efficient in a practical realm.

The real-RAM model with its implicit infinite-precision requirement has proved unrealistic and needs to be replaced with a realistic finite-precision model where geometric computations can be carried out either exactly or with a guaranteed error bound. This has motivated a great deal of research on the subject of robust computational geometry (see, e.g., [4, 12, 11, 19, 27, 28, 31, 36, 34, 39, 48, 54, 58, 21, 30, 32]). For an early survey of the different approaches to robust computational geometry the reader is referred to [38].

To a first, rough approximation, robustness approaches are of two main types: perturbing and nonperturbing. Perturbing approaches transform the given problem into one that is intended not to suffer from well-identified shortcomings; nonperturbing approaches are based on the notion of "exact" (rather than "approximate") computations, with the assumption that (bounded-length) input data are error-free. In this category falls the exact geometric computation paradigm independently advocated by

Yap [59] and by the Saarbrücken school [10], and so does our approach. Within this paradigm, we introduce the notion of *degree* of an algorithm, which describes, up to a small additive constant, the arithmetic precision (i.e., number of bits) needed by the exact-computation paradigm. Namely, if the coordinates of the input points of a degree-d geometric algorithm are b-bit integers, then, as we shall substantiate below, the algorithm may be required in some instances to perform arithmetic computations with bit precision $d(b + O(1))$.

Theoretical analysis and experimental results show that multiprecision numerical computations take up most of the CPU time of exact geometric algorithms (see, e.g., [41, 49]). Thus, we believe that, in defining the efficiency of a geometric algorithm, the degree should be considered as important as the asymptotic time complexity and should correspondingly play a major role in the design stage. In fact, the principal thrust of this paper is to present algorithm degree as a major design criterion for geometric computation. Research along these lines involves reexamining the entire rich body of computational geometry as we know it today.

In this paper, we consider as a test case a problem area, geometric proximity, which plays a major role in several applications and has recently attracted considerable attention because, due to its demands of high precision for exact computation, it is particularly appropriate in assessing effectiveness of robust approaches (see, e.g., [9, 11, 20, 29, 31, 27, 55, 32]). In particular we shall illustrate the role played by the degree criterion if one wishes to comply with the standard exact-computation paradigm.

To illustrate the approach, we recall that Voronoi diagrams are the search structures which permit answering a proximity query without evaluating all query/site distances. Therefore, given the set of sites, their Voronoi diagram is computed and supplied as a planar subdivision to a point location procedure. Assuming that the coordinates of all input data (also called *primitive* points) are b-bit integers, the coordinates of the points computed by the algorithm (referred to here as *derived* points, e.g., the vertices of a Voronoi diagram of points and segments) must be stored with a representation scheme that supports rational or algebraic numbers as data types (through multiprecision integers). Specifically, the coordinates (x, y) of a Voronoi vertex are rational numbers given by the ratio of two determinants (of respective orders 3 and 2) whose entries are integers of well-defined maximum modulus. The fundamental operation used by any point location algorithm is the point-line discrimination, which consists of determining whether the query point q is to the left or to the right of an edge between vertices v_1 and v_2. For the case of the Voronoi diagram $V(S)$, this is equivalent to evaluating the sign of a 3×3 determinant whose rows are the homogeneous coordinates of q, v_1, and v_2, a computation that needs about $6b$ bits of precision. This should be compared with the $O(n)$-time brute-force method that computes the (squares of the) distances from q to all the sites of S, and executes arithmetic computations with only $2b$ bits of precision (which is optimal).

Guided by the low-degree criterion, in this paper we present a technique—complying with the exact-computation paradigm—which uses a new point location data structure for Voronoi diagrams, such that the test operations executed in the point location procedure are distance comparisons, and are therefore executed with optimal $2b$ bits of precision. Hence, our approach reconciles efficiency with robustness and supports an object-oriented programming style where access to the geometry of Voronoi diagrams in point location queries is encapsulated in a small set of geometric test primitives. It must be pointed out that distance comparisons have already been used nontrivially for proximity search (extremal-search method [26]). However, we shall show that the latter method fails to achieve optimal degree because the search

is based on predicates requiring $4b$ bits of precision; moreover, the high overhead of the search technique (which uses the hierarchical polytope representation [22]) casts some doubts on the practicality of the method.

The main results of this work are summarized in Table 1. Considering, for the time being, the degree as a measure of complexity, we show that previous methods exhibit a sharp tradeoff between degree and query time. Namely, low degree is achieved by the slow brute-force search method, while fast algorithms based on point location in a preprocessed Voronoi diagram or on the extremal-search method have high degree. Our new technique gives instead both low degree and fast query time and is optimal with respect to both cost measures for queries in sets of 2D point sites.

The rest of this paper is organized as follows. In section 2, the concept of degree of a geometric algorithm is defined and a simple formalism to compute such degree is introduced. Such formalism is used in section 3 to analyze the performance of basic proximity primitives. In section 4, we consider the following fundamental proximity queries for a set of point sites in the plane: nearest neighbor search, k-nearest neighbors search, and circular range search. We show that the existing methods for efficiently answering such queries have degree either 6 (point location in explicit Voronoi diagram) or 4 (extremal-search method), and we present our new technique, based on implicit Voronoi diagrams, which achieves optimal degree 2. In sections 5–6, we extend our approach to nearest neighbor search queries in a set of 3D point sites and in a set of point and segment sites in the plane, respectively. Practical improvements are presented in section 7. Finally, further research directions are discussed in section 8.

2. Degree of geometric algorithms and problems. The numerical computations of a geometric algorithm are basically of two types: tests (predicates) and constructions. The two types of computations have clearly distinct roles. Tests are associated with branching decisions in the algorithm that determine the flow of control, whereas constructions are needed to produce the output data of the algorithm.

Approximations in the execution of constructions are acceptable, since approximate results are perfectly tolerable, provided that the error magnitude does not exceed the resolution required by the application. On the other hand, approximations in the execution of tests may produce an incorrect branching of the algorithm. Such event may have catastrophic consequences, giving rise to *structurally* incorrect results. The exact-computation paradigm therefore requires that tests be executed with total accuracy.

We shall therefore characterize geometric algorithms on the basis of the complexity of their test computations. Any such computation consists of evaluating the sign of an *algebraic expression* over the input variables, constructed using an adequate set of operators such as $\{+, -, \times, \div, \sqrt[2]{}, \ldots\}$. As we shall show below, the expressions under consideration are equivalent to multivariate polynomials.

Here we make the reasonable assumption that input data be *dimensionally consistent*, i.e., that if an entity with the physical dimension of a length is represented with b bits, then one with the dimension of an area be represented with $2b$ bits, and so on. Under the hypothesis of dimensional consistency (where point coordinates are b-bit entries), a polynomial expressing a test is homogeneous because all of its monomials must have the same physical dimension.

A *primitive variable* is an input variable of the algorithm and has conventional arithmetic degree 1. The arithmetic degree of a polynomial expression E is the common arithmetic degree of its monomials. The arithmetic degree of a monomial is the sum of the arithmetic degrees of its variables.

DEFINITION 1. *An algorithm has* degree d *if its test computations involve the evaluation of multivariate polynomials of arithmetic degree at most* d. *A problem* Π *has* degree d *if any algorithm that solves* Π *has degree at least* d.

Remark 1. Recently, Burnikel [9] has independently defined the notion of *precision of an algorithm*, which is equivalent to our notion of degree of an algorithm. Also, our definition of degree is related to that of *depth of derivation* proposed by Yap [58, 59]. Given a set of numbers, any number x of the set has depth 0. A number has depth at most d if it can be obtained by executing a rational operation on numbers with depth $d-1$ or it is the result of a root extraction from a degree-k polynomial whose coefficients have depth at most $d-k$. An algorithm has *depth* d if it performs only rational operations such that all the intermediate computed numbers have depth of derivation at most d with respect to the set of input numbers. Clearly, d is the least possible integer such that all the intermediate computed values have depth of derivation at most d. A problem has *depth* d if it can be solved by an algorithm with rational bounded depth d. Despite the relatedness of the notions of depth and degree, the latter seems more appropriate to our analysis, where we aim at minimizing the number of bits needed for computing an exact value, independently of its (possibly very high) depth.

Motivated by a standard feature of geometric algorithms, we also make the assumption that every multivariate polynomial of degree d used in tests depends upon a set of size s (a small constant) of primitive variables. Therefore, a multivariate polynomial has $O(s^d)$ distinct monomials with bounded integer coefficients, so that the maximum value of the multivariate polynomial is expressible with at most $db + d \log s$ bits. A consequence of Definition 1 and of the above assumption is the following fact, which justifies our use of the degree of an algorithm to characterize the precision required in test computations.

LEMMA 1. *If an algorithm has degree* d *and its input variables are* b*-bit integers, then all the test computations can be carried out with* $d(b + O(1))$ *bits.*

Typically the support of a geometric test is not naturally expressed by a multivariate polynomial but, rather, by a pair (E_1, E_2) of expressions involving the four arithmetic operations, powering, and the extraction of square roots, and the test consists of comparing the magnitudes of E_1 and E_2. Such expressions always have a physical dimension (a length, an area, a volume, etc.), so that if they have the form of ratios, the degree of the numerator exceeds that of the denominator.

Expressions such as E_1 and E_2 can be viewed as a binary tree, whose leaves represent input variables and whose internal nodes are of two types: binary nodes,

which are labeled with an operation from the set $\{+, -, \times, \div\}$, and unary nodes, which are labeled either with a power or with a square root extraction (notice that we restrict ourselves to this type of radical). If no radical appears in the trees of E_1 and E_2, then the test is trivially equivalent to the evaluation of the sign of a polynomial, since E_i is a rational function of the form $\frac{N_i}{D_i}$ ($i = 1, 2$, N_i, D_i are not both trivial polynomials and $D_i \neq 0$) and

$$E_1 \geq E_2 \Longleftrightarrow (-1)^{\sigma(D_1)+\sigma(D_2)}(N_1 D_2 - N_2 D_1) \geq 0,$$

where $\sigma(E) = 1$ if $E < 0$ and $\sigma(E) = 0$ if $E \geq 0$. (Note that the above predicate implies the inductive assumption that the signs of lower-degree expressions N_1,N_2, D_1, and D_2 are known.) Suppose now that at least one of the trees of E_1 and E_2 contains radicals. We prune the tree so that the pruned tree contains no radicals except at its leaves (notice that pruned subtrees may themselves contain radicals). Then N_i and D_i ($i = 1, 2$) can be viewed as polynomials whose variables are the radicals and whose coefficients are (polynomial) functions of nonradicals. Given a polynomial E in a set of radicals, for any radical R in this set, we can express E as $E = E''R + E'$ where neither E'' nor E' contains R. Then

$$E \geq 0 \Longleftrightarrow E''R \geq -E'.$$

The resulting expression $(E''^2 R^2 - E'^2)$ does not contain R. Therefore, by this device, referred to as *segregate and square*, we can eliminate one radical. This shows that by the four rational operations we can reduce the sign test to the computation of the signs of a collection of multivariate polynomials.

We now present a very simple, but useful, formalism that enables us to rapidly evaluate the degree of the multivariate polynomial which uniquely determines the sign of the original algebraic expression.

The terms involved in the formal manipulations are of two types: generic and specific. *Generic* terms have the form α^s (for a formal variable α and an integer s), representing an unspecified multivariate polynomial of degree s over primitive variables. *Specific* terms have the form ρ_j, for some integer index j, representing a specified expression involving the operators $\{+, -, \times, \div, \sqrt{\ }\}$. The terms are members of a free commutative semiring; i.e., addition and multiplication are associative and commutative, addition distributes over multiplication, and specific terms can be factored out. Besides these conventional algebraic rules, we have a set of *rewriting rules* of the form $A \rightarrow B$, meaning that the sign of A is *unambiguously determined* by the sign of B and by the signs of terms in A, which are inductively assumed to be known. This induction is either on the degree of the terms or, in case of addition of (same degree) terms, on the number of the latter.

We have seven rules, whose correctness can be proved with elementary algebra. Rule 1 performs genericization, i.e., a specific term ρ_j, which is known to be a polynomial of degree s over primitive variables, can be rewritten as α^s. Rules 2–4 involve generic terms, which reflect the fact that the only relevant feature of a polynomial is its degree. Finally, rules 5–7 concern specific terms. The role of specific terms is that we wish to keep track of their structure (that is, their definition) in order to exploit it when computing least common multiples or multiplying radicals together. Again, the R.H.S. of a rule gives the highest degree of the polynomials whose signs unambiguously determine the sign of the L.H.S. Recall that the stated hypothesis of nonnegative dimensionality implies that the degree of a numerator is never smaller

than that of its denominator. The rules are

$$\begin{array}{lccc}
(1) & \rho_j & \longrightarrow & \alpha^s \\
(2) & \alpha^s\alpha^r & \longrightarrow & \alpha^{s+r} \\
(3) & \alpha^s + \alpha^s & \longrightarrow & \alpha^s \\
(4) & -\alpha^s & \longrightarrow & \alpha^s \\
(5) & \frac{\rho_j}{\rho_i} \pm \frac{\rho_h}{\rho_i} & \longrightarrow & \rho_j \pm \rho_h \\
(6) & \frac{\rho_j}{\rho_i} \pm \frac{\rho_h}{\rho_k} & \longrightarrow & \rho_j\rho_k \pm \rho_i\rho_h \\
(7) & \rho_i \pm \rho_j & \longrightarrow & \rho_i^2 - \rho_j^2.
\end{array}$$

A discussion on how to compute the sign of an algebraic expression of the type considered by rule (7) can also be found in [57].

The preceding discussion establishes the following theorem.

THEOREM 1. *Rules* (1)–(7) *are adequate to evaluate the degree of multivariate polynomials whose sign, collectively, unambiguously determines the sign of an arbitrary algebraic expression involving square roots.*

While the above rules represent an adequate formalism for obtaining an upper bound to the degree of an algorithm, more subtle is the corresponding lower-bound question. In other words, given a predicate $\mathcal{P}$ that is essential to the solution of a given problem, what is the inherent degree of $\mathcal{P}$? Suppose that predicate $\mathcal{P}$ is expressed by a polynomial P of degree d, and we must decide whether the value of P is positive, negative, or zero. Can we answer this question by computing a discrete (ternary) function f of analogous evaluations of irreducible polynomials $P_1, \ldots, P_k$ of maximum degree smaller than d? Clearly, f changes value only when some P_j changes sign (exactly, when the value of P_j passes by 0). Thus, a 0 of P corresponds to a 0 of some P_j. Moreover, as the arguments of P_j vary while P_j remains 0, so does f and hence P. Therefore, P vanishes at all points for which P_j vanishes and, for a well-known theorem of polynomial algebra (see, e.g., [8, pp. 212–216]), we conclude that P_j is a factor of P. This is summarized as follows.

THEOREM 2. *The degree of the problem of evaluating a predicate expressed by a polynomial P is the maximum arithmetic degree of the factors of P that change sign over their domain.*

3. Basic proximity queries. In this section we use the formalism introduced above to analyze the degree of some geometric tests that answer basic proximity queries. We end the section by establishing a lower bound on the degree of the nearest neighbor search problem. In the proofs, we assume that a line r is represented by the coefficients of its equation. However, the results still hold if line r is represented by two of its points.

We start with the point-to-lines distance test; i.e., given two lines r_1 and r_2 on the plane and a query point q, determine whether q is closer to r_1 than to r_2.

LEMMA 2. *The* point-to-lines distance test *can be solved with degree* 6.

Proof. Let the equation of r_i be $a_ix + b_iy + c_i = 0$ $(i = 1, 2)$ and let $q \equiv (x_q, y_q)$. Then the test is to study the sign of $\frac{|a_1x_q+b_1y_q+c_1|}{\sqrt{a_1^2+b_1^2}} - \frac{|a_2x_q+b_2y_q+c_2|}{\sqrt{a_2^2+b_2^2}}$. By using the proposed notation, and with obvious meaning for ρ_1 and ρ_2, this test becomes (each arrow being superscripted with the rules used)

$$\frac{\alpha^2}{\rho_1} - \frac{\alpha^2}{\rho_2} \quad \longrightarrow^{(6)} \alpha^2\rho_2 - \alpha^2\rho_1 \quad \longrightarrow^{(7)} \alpha^4\rho_2^2 - \alpha^4\rho_1^2 \quad \longrightarrow^{(1)}$$
$$\alpha^4\alpha^2 - \alpha^4\alpha^2 \quad \longrightarrow^{(4,3)} \alpha^6. \qquad \square$$

The following lemmas describe the degree of other proximity primitives that will be useful in the rest of the paper. We omit the proofs of such lemmas, since they

are either straightforward or have been already proved in [9]. However, it is worth mentioning that the proofs in [9] can be substantially simplified by using the proposed notation.

Let p be a point and r a line in the plane. The point-to-point-line distance test determines whether a query point q is closer to p or to r.

LEMMA 3. *The* point-to-point-line distance test *can be solved with degree* 4.

Let p_1 and p_2 be two distinct points of the plane and let q be a query point. The point-to-points distance test determines whether q is closer to p_1 or to p_2.

LEMMA 4. *The* point-to-points distance test *can be solved with degree* 2.

The above lemma can be easily extended to any space of dimension d.

Another fundamental proximity primitive is the incircle test, that is, testing whether the circle determined by three distinct sites (points and/or segments) of the plane contains a given query site. The incircle test is a basic operation for many algorithms that construct the Voronoi diagram of the sites (see, e.g., [37, 41, 33, 3]). The degree of the incircle test has been extensively studied by Burnikel [9] and by Burnikel, Mehlhorn, and Schirra [11]. Following the notation of Burnikel [9], an incircle test is conveniently expressed as a quadruple $(a_1, a_2, a_3; a_4)$, where each $a_i \in \{p, l\}$ $(i = 1, \ldots, 4)$ is either a point or a line on the plane (a segment is seen by Burnikel as given by the pair of its endpoints and by the underlying line) and we test whether a_4 intersects the circle determined by a_1,a_2, and a_3.

The following lemma is proved observing that the incircle test $(p_1, p_2, p_3; p_4)$ can be answered by determining the sign of a 4×4 determinant that is an arithmetic degree-4 multivariate polynomial.

LEMMA 5 (see [9]). *The* incircle test $(p_1, p_2, p_3; p_4)$ *can be solved with degree* 4.

Lemma 5 can be easily extended to any dimension $d > 2$. We describe such a test as $(p_1, \ldots, p_{d+1}; p_{d+2})$, where points $p_1, \ldots, p_{d+1}$ determine a d-dimensional sphere and p_{d+2} is the query point.

LEMMA 6. *The* insphere test $(p_1, \ldots, p_{d+1}; p_{d+2})$ *in any fixed dimension* $d \geq 2$ *can be solved with degree* $d + 2$.

For the construction of the Voronoi diagram of a set of points and segments in the plane Burnikel shows that the most demanding test in terms of degree is the incircle test $(l_1, l_2, l_3; l_4)$ [9].

LEMMA 7 (see [9]). *The* incircle test $(l_1, l_2, l_3; l_4)$ *can be solved with degree* 40.

While the above lemmas provide an upper bound on the degree of a proximity problem, the next theorem gives a lower bound.

THEOREM 3. *The nearest neighbor search problem for a point set has degree* 2 *in any fixed dimension* $d \geq 2$.

Proof. We show the proof for the case $d = 2$. The proof for any other values of d is analogous. Let $p_1 \equiv (x_1, y_1)$, $p_2 \equiv (x_2, y_2)$, and $q \equiv (x_q, y_q)$ be three points in the plane. In order to determine which of p_1 and p_2 is the point nearest to q, a point-to-points distance test must be performed.

This is equivalent to the evaluation of the sign of the difference $d(p_1, q) - d(p_2, q)$, which, in turn, is equivalent to the evaluation of the sign of the polynomial $d^2(p_1, q) - d^2(p_2, q)$. This shows that this computation has degree at most 2. On the basis of Theorem 2, for the degree to be less than 2, polynomial $d^2(p_1, q) - d^2(p_2, q)$ should be factorable as the product of two degree-1 polynomials. We show below that this is not possible.

Suppose, for a contradiction, that there exist constants $a', a'', b', b'', c', c'', d', d'', e, e'', f', f''$ such that

$$d^2(p_1, q) - d^2(p_2, q) = x_1^2 + y_1^2 - x_2^2 - y_2^2 - 2x_1x_q + 2x_2x_q - 2y_1y_q + 2y_2y_q$$
$$= (a'x_1 + b'y_1 + c'x_2 + d'y_2 + e'x_q + f'y_q) \cdot (a''x_1 + b''y_1 + c''x_2 + d''y_2 + e''x_q + f''y_q).$$

The above equality implies $e'e'' = 0$, since there cannot be a term $e'e''x_q^2$. However, e' and e'' are not simultaneously 0, because there are nonzero terms having x_q as a factor. Assume w.l.o.g. that $e'' \neq 0$. Observe that $d'e'' = 0$ because there is no term $d'e''y_2y_q$; this implies $d' = 0$. However, we must also have $d'd'' = -1$ because of the term $-y_2^2$, a contradiction. □

Observe that an optimal degree algorithm for the nearest neighbor search problem in a planar point set can be easily obtained with the brute-force approach, where one computes all the distances between the query point and all other points and reports the point at minimum distance. However, such algorithm is both computationally inefficient (it requires quadratic time) and does not support repetitive-mode queries. In section 4 we present an optimal degree algorithm, complying with the exact-computation paradigm, whose query time and space are optimal.

4. Proximity queries for point sites in the plane. In this section, under our standard assumption that all input parameters — such as coordinates of sites and query points — are represented by b-bit integers, we consider the following proximity queries on a set S of point sites in the plane:

nearest neighbor search: given query point q, find a site of S whose Euclidean distance from q is less than or equal to that of any other site;

k-nearest neighbors search: given query point q, find k sites of S whose Euclidean distances from q are less than or equal to that of any other site;

circular range search: given query points q and r, find the sites of S that are inside the circle with center q passing through r.

It is well known that such queries are efficiently solved by performing point location in the Voronoi diagram (possibly of higher order) $V(S)$ of the sites [51]. For nearest neighbor search, the alternative extremal-search method [26] also exists.

We begin by examining in section 4.1 the geometric test primitives used by the theoretically optimal and practically efficient point location methods. We identify three fundamental geometric test primitives for accessing the geometry of a planar map, and we introduce the concepts of "native" and "ordinary" point location methods. In section 4.2, we show that the "conventional" approach of accessing the explicitly computed Voronoi diagram $V(S)$ of the sites causes point location queries, and hence proximity queries, to have degree at least 6. We also analyze the extremal-search method and show that it has degree 4. In sections 4.3–4.4, we describe our new implicit representation of Voronoi diagrams for point sites in the plane, which allows us to perform proximity queries with optimal degree 2.

4.1. Test primitives and methods for planar point location. The *chain method* [44], the *bridged-chain method* [25], the *trapezoid method* [50], the *subdivision refinement method* [42], and the *persistent search tree method* [53] are popular deterministic techniques for point location in a planar map that combine theoretical efficiency with good performance in practice (see, e.g., [24, 51]). Namely, denoting with n the size of the map, all the above point location methods require $O(n \log n)$ preprocessing time. The query time is $O(\log^2 n)$ for the chain method and $O(\log n)$ for the other methods. The space used is $O(n \log n)$ for the trapezoid method and $O(n)$ for the other methods. For monotone maps, the preprocessing time is $O(n)$ for the chain method and the bridged-chain method, and $O(n \log n)$ for the other methods. The *randomized-incremental method* [35] also exists. Such a method is specialized for point location in Voronoi diagrams, uses expected space $O(n)$, and has expected query time $O(\log^2 n)$.

By a careful examination of the query algorithms used in the point location methods presented in the literature, it is possible to clearly separate the primitive opera-

tions that access the geometry of the map from those that access only the topology. We say that a point location method is *native* for a class of maps if it performs point location queries in a map M of the class by accessing the geometry of M exclusively through the following three geometric test primitives that discriminate the query point with respect to the vertices and edges of M:

above-below(q, v) determine whether query point q is vertically above or below vertex v.

left-right(q, v) determine whether query point q is horizontally to the left or to the right of vertex v.

left-right(q, e) determine whether query point q is to the left or to the right of edge e; this operation assumes that edge e is not horizontal and its vertical span includes q.

Test primitive left-right(q, v) is typically used only in degenerate cases (e.g., in the presence of horizontal edges).

Some point location methods work on modified versions of the original subdivision by means of auxiliary geometric objects introduced in the preprocessing (e.g., triangulation or regularization edges). We say that a point location method is *ordinary* for a class of maps if it performs point location queries in a map M of the class by accessing the geometry of M through the three geometric test primitives described above for the native methods and through left-right(q, e) tests such that e is a fictitious edge connecting two vertices of M.

Now, we analyze the chain method [44] for point location in a monotone map M. A binary tree represents a balanced recursive decomposition of map M by means of vertically monotone polygonal chains covering the edges of M, called *separators*. A point location query consists of traversing a root-to-leaf path in this tree, where at each node we determine whether the query point q is to the left or to right of the separator associated with the node. The discrimination of point q with respect to a separator σ is performed in two steps:

1. we find the edge e of σ whose vertical span includes point q by means of binary search on the y coordinates of the vertices of σ, which consists of performing a sequence of a logarithmic number of above-below(q, v) tests;
2. we discriminate q with respect to σ by performing test left-right(q, e).

In the special case that separator σ has horizontal edges, the discrimination of point q with respect to σ uses also test primitive left-right(q, v). Hence, the chain method is native for monotone maps. For a map M that is not monotone, fictitious "regularization" edges are added to M and the point location in M is reduced to point location in the resulting refinement M' of M. Hence, the chain method is ordinary for general maps.

In the bridged-chain method [25], the technique of *fractional cascading* [17, 18] is applied to the sets of y-coordinates of the separators. Fractional cascading establishes "bridges" between the separator of a node and the separators of its children such that there are $O(1)$ vertices between any two consecutive bridges. Hence, except for the separator of the root, step 1 can be executed with $O(1)$ above-below(q, v) tests for the vertices between two consecutive bridges. The bridged-chain method is ordinary for general maps and native for monotone maps.

A similar analysis shows that all efficient point-location methods described in the literature are ordinary for general maps. More specifically, we have the following lemma.

LEMMA 8. *The trapezoid method and the persistent search tree method are native for general maps. The chain method and the bridged-chain method are ordinary for general maps and native for monotone maps. The subdivision refinement method*

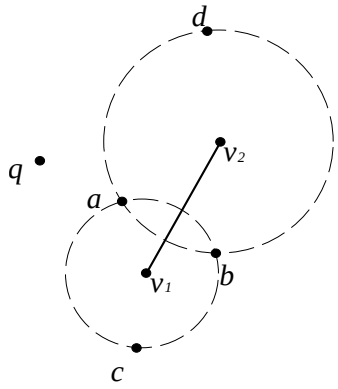

FIG. 1. *Illustration for Lemma* 9.

is ordinary for general maps. The randomized-incremental method is ordinary for Voronoi diagrams.

Hence, all the known planar point location methods described in the literature are ordinary for Voronoi diagrams.

4.2. Explicit Voronoi diagrams. Let S be a set of n point sites in the plane, where each site is a primitive point with b-bit integer coordinates. The Voronoi diagram $V(S)$ of S is said to be *explicit* if the coordinates of the vertices of $V(S)$ are computed and stored with exact arithmetic, i.e., as rational numbers (pairs of integers).

LEMMA 9. *The* left-right(q, e) *test primitive in an explicit Voronoi diagram of point sites in the plane has degree* 6.

Proof. Let $e \equiv (v_1, v_2)$ be a Voronoi edge such that $v_1 \equiv (x_1, y_1)$ is equidistant from three sites $a \equiv (x_a, y_a)$, $b \equiv (x_b, y_b)$, $c \equiv (x_c, y_c)$ and $v_2 \equiv (x_2, y_2)$ is equidistant from three sites $b \equiv (x_b, y_b)$, $c \equiv (x_c, y_c)$, and $d \equiv (x_d, y_d)$. See Figure 1. In an explicit Voronoi diagram, test primitive left-right(q, e) that determines whether query point $q \equiv (x_q, y_q)$ is to the left or to the right of edge $e \equiv (v_1, v_2)$ is equivalent to evaluating the sign of the following determinant:

$$\Delta = \begin{vmatrix} x_q & y_q & 1 \\ x_1 & y_1 & 1 \\ x_2 & y_2 & 1 \end{vmatrix} = \begin{vmatrix} x_q & y_q & 1 \\ \frac{X_1}{2W_1} & \frac{Y_1}{2W_1} & 1 \\ \frac{X_2}{2W_2} & \frac{Y_2}{2W_2} & 1 \end{vmatrix} = \frac{1}{4W_1W_2} \begin{vmatrix} x_q & y_q & 1 \\ X_1 & Y_1 & 2W_1 \\ X_2 & Y_2 & 2W_2 \end{vmatrix} = \frac{\Delta'}{4W_1W_2},$$

where

$$X_1 = \begin{vmatrix} x_a^2 + y_a^2 & y_a & 1 \\ x_b^2 + y_b^2 & y_b & 1 \\ x_c^2 + y_c^2 & y_c & 1 \end{vmatrix}, \quad Y_1 = \begin{vmatrix} x_a & x_a^2 + y_a^2 & 1 \\ x_b & x_b^2 + y_b^2 & 1 \\ x_c & x_c^2 + y_c^2 & 1 \end{vmatrix}, \quad W_1 = \begin{vmatrix} x_a & y_a & 1 \\ x_b & y_b & 1 \\ x_c & y_c & 1 \end{vmatrix}$$

and X_2, Y_2, and W_2 have similar expressions obtained replacing in the above determinants x_c with x_d and y_c with y_d. Evaluating the sign of Δ is equivalent to evaluating the signs of W_1, W_2 and of Δ'.

By using the notation introduced in section 2, we can rewrite X_i and Y_i as α^3, and W_i as α^2 $(i = 1, 2)$. Hence, Δ' is a degree-6 multivariate polynomial since it can be rewritten as

$$\alpha(\alpha^3\alpha^2 - \alpha^3\alpha^2) - \alpha(\alpha^3\alpha^2 - \alpha^3\alpha^2) + \alpha^3\alpha^3 - \alpha^3\alpha^3 \quad \longrightarrow^{(2,3,4)} \quad \alpha^6 + \alpha^6 \quad \longrightarrow^{(3)} \quad \alpha^6.$$

Although the explicit representation approach leads to Lemma 9, it should be noted that determinant Δ is a reducible polynomial,[1] one factor being the (always positive) incircle test polynomial of degree 4 for the four sites. □

An algorithm for proximity queries on a set S of point sites in the plane is said to be *conventional* if it computes the explicit Voronoi diagram $V(S)$ of S and then performs point location queries on $V(S)$ with an ordinary method. Note that the class of conventional proximity query algorithms includes all the efficient algorithms presented in the literature. A conventional proximity query algorithm needs to perform test primitive left-right(q, e). Thus, by Lemma 9 we have the following theorem.

THEOREM 4. *Conventional algorithms for the following proximity query problems on a set of point sites in the plane have degree at least* 6*:*

- *nearest neighbor query,*
- *k-nearest neighbor query,*
- *circular range query.*

We observe that a degree-6 algorithm implies that a k-bit arithmetic unit can handle with native precision queries for points in a grid of size at most $2^{k/6} \times 2^{k/6}$. For example, if $k = 32$, the points that can be treated with single-precision arithmetic belong to a grid of size at most 64×64.

The *extremal-search method* [26], also designed for proximity queries, reduces the nearest neighbor search problem for a set S of 2D point sites to the following extremal-search problem. Let $\mathcal{P}$ be the paraboloid with equation $z = x^2 + y^2$, and let S' be the set of 3D points obtained by lifting S to $\mathcal{P}$. Given a query point q in the plane, let $\vec{r}$ be the unit vector orthogonal to the plane tangent to $\mathcal{P}$ at the lifted query point $q' \equiv (x_q, y_q, x_q^2 + y_q^2)$. The extremal-search problem for S' and query vector $\vec{r}$ consists of determining the first site s' of S' hit by a plane orthogonal to $\vec{r}$ translating from infinity toward S'. Projecting s' down onto the xy-plane gives the nearest neighbor s of q in S.

The extremal-search method makes use of 3D geometric primitives that guide the search through a data structure embodying the Dobkin–Kirkpatrick hierarchical representation [22] of the convex hull of S'. Such 3D geometric primitives in turn can be reduced to the following 2D geometric primitives:

- point-to-points distance test for q and a site of S, which has degree 2;
- the identification of suitably defined "extremal edges" of the Delaunay triangulation of a subset of S with respect to q.

The second primitive evaluates the sign of determinants of the type

$$\Delta = \begin{vmatrix} x_a & y_a & x_a^2 + y_a^2 \\ x_b & y_b & x_b^2 + y_b^2 \\ x_q & y_q & x_q^2 + y_q^2 \end{vmatrix},$$

where $a \equiv (x_a, y_a)$ and $b \equiv (x_b, y_b)$ are sites of S. By using the methodology introduced in section 2, we can show that Δ is a degree-4 multivariate polynomial. Thus, we have Theorem 5.

THEOREM 5. *The extremal-search method for the nearest neighbor query problem on a set of point sites in the plane has degree at least* 4.

4.3. Implicit Voronoi diagrams. Let S be a set of n point sites in the plane, and recall our assumption that each site or query point is a primitive point with b-bit integer coordinates. We say that a number s is a *semi-integer* if it is a rational number of the type $s = m/2$ for some integer m. The *implicit Voronoi diagram* $V^*(S)$ of S is a representation of the Voronoi diagram $V(S)$ of S that consists of a topological

[1] K. Mehlhorn suggested that Δ was likely to be reducible.

component and of a geometric component. The topological component of $V^*(S)$ is the planar embedding of $V(S)$, represented by a suitable data structure (e.g., doubly connected edge lists [51] or the data structure of [37]). The geometric component of $V^*(S)$ stores the following geometric information for each vertex and edge of the embedding:

- For each vertex v of $V(S)$, $V^*(S)$ stores semi-integers $x^*(v)$ and $y^*(v)$ that approximate the x- and y-coordinates $y(v)$ of v. We provide the definition of $y^*(v)$ below. The definition of $x^*(v)$ is analogous.

$$y^*(v) = \begin{cases} y(v), & 0 \le y(v) \le 2^b - 1,\ y(v) \text{ integer}, \\ \lfloor y(v) \rfloor + \frac{1}{2}, & 0 \le y(v) \le 2^b - 1,\ y(v) \text{ not integer}, \\ 2^b - \frac{1}{2}, & y(v) > 2^b - 1, \\ 0, & y(v) < 0. \end{cases}$$

  Note that semi-integers $x^*(v)$ and $y^*(v)$ can be stored with $(b+1)$-bits.
- For each nonhorizontal edge e of $V(S)$, $V^*(S)$ stores the pair of sites $\ell(e)$ and $r(e)$ such that e is a portion of the perpendicular bisector of $\ell(e)$ and $r(e)$, and $\ell(e)$ is to the left of $r(e)$.

Equipped with the above information, the three test primitives for point location can be performed in the implicit Voronoi diagram $V^*(S)$ as follows:

above-below(q, v) compare the y-coordinate of q with $y^*(v)$;

left-right(q, v) compare the x-coordinate of q with $x^*(v)$;

left-right(q, e) compare the Euclidean distances of point q from sites $\ell(e)$ and $r(e)$.

Since the query point q is by assumption a primitive point whose coordinates are b-bit integers, we have that $y(q) \le y(v)$ if and only if $y(q) \le y^*(v)$, where testing the latter inequality has degree 1. Similar considerations apply to testing $x(q) \le x(v)$. This proves the correctness of our implementation of above-below(q, v) and left-right(q, v).

The correctness of the above implementation of test left-right(q, e) follows directly from the definition of Voronoi edges. Thus, in an implicit Voronoi diagram, test left-right(q, e) can be implemented with a point-to-points distance test that has degree 2 (Lemma 4).

Hence, we obtain the following lemmas.

LEMMA 10. *Test primitives* above-below(q, v) *and* left-right(q, v) *in an implicit Voronoi diagram of point sites in the plane can be performed in* $O(1)$ *time and with degree* 1.

LEMMA 11. *Test primitive* left-right(q, e) *in an implicit Voronoi diagram of point sites in the plane can be performed in* $O(1)$ *time and with degree* 2.

In order to execute a native point location algorithm in an implicit Voronoi diagram, we only need to redefine the implementation of the three test primitives. By having encapsulated the geometry in the test primitives, no further modifications are needed. Hence, by Lemmas 10–11 we obtain Lemma 12.

LEMMA 12. *For any native method on a class of maps that includes Voronoi diagrams, a point location query in an implicit Voronoi diagram has optimal degree* 2 *and has the same asymptotic time complexity as a point location query in the corresponding explicit Voronoi diagram.*

In order to compute the implicit Voronoi diagram $V^*(S)$, we begin by constructing the Delaunay triangulation of S, denoted $DT(S)$, by means of the $O(n \log n)$-time algorithm of [37], which has degree 4 because its most expensive operation in terms of the degree is the incircle test (see Lemma 5). The topological structure of $V(S)$ and the sites $\ell(e)$ and $r(e)$ for each edge e of $V(S)$ are immediately derived from $DT(S)$

by duality. Next, we compute the approximations $x^*(v)$ and $y^*(v)$ for each vertex v of $V(S)$ by means of integer division. For effective procedures that perform the integer division, see, e.g., *LEDA* [46]. Let a, b, and c be the three sites of S that define vertex v. Adopting the same notation as in the proof of Lemma 9, the y-coordinate $y(v)$ of v is given by the ratio $y(v) = \frac{Y_1}{2W_1}$, where Y_1 is a polynomial of degree 3 and W_1 is a polynomial of degree 2, and similarly for $x(v)$. Hence, the computation of $x^*(v)$ and $y^*(v)$ involves an integer represented by at most $3(b + O(1))$ bits. We summarize the above analysis as follows.

LEMMA 13. *The implicit Voronoi diagram of n point sites in the plane can be computed in $O(n \log n)$ time, $O(n)$ space, and with degree* 4.

THEOREM 6. *Let S be a set of n point sites in the plane. There exists an $O(n)$-space data structure for S, based on the implicit Voronoi diagram $V^*(S)$, that can be computed in $O(n \log n)$ time with degree* 5*, and supports nearest neighbor queries in $O(\log n)$ time with optimal degree* 2.

Proof. We perform point location in the implicit Voronoi $V^*(S)$ diagram of S using a native method for monotone maps with optimal space and query time such as the bridged-chain method or the persistent search tree method. The space requirement and the query degree and time follow from the performance of these methods and from Lemma 12.

Regarding the preprocessing time, by Lemma 13, the construction of the implicit Voronoi $V^*(S)$ takes $O(n \log n)$ time with degree 4. In order to construct the point location data structure, we also need an additional test primitive that consists of comparing the y-coordinates of two Voronoi vertices. For example, this primitive is used to establish bridges in the bridged-chain method (see section 4.1) and to sort the vertices by y-coordinate in the persistent location method. By using the same notation as in Lemma 9, comparing the y-coordinates of the Voronoi vertices is equivalent to evaluating the sign of multivariate polynomials of the form $\frac{Y_i}{2W_i} - \frac{Y_j}{2W_j}$, where $\frac{Y_i}{2W_i}$ and $\frac{Y_j}{2W_j}$ represent the y-coordinates of two different Voronoi vertices. Such multivariate polynomials have degree 5, since they can be rewritten as

$$\frac{\rho_i}{\rho_j} - \frac{\rho_h}{\rho_k} \quad \longrightarrow^{(6)} \quad \rho_i\rho_k - \rho_h\rho_j \quad \longrightarrow^{(1)} \quad \alpha^3\alpha^2 - \alpha^3\alpha^2 \quad \longrightarrow^{(2,3,4)} \quad \alpha^5. \qquad \square$$

Remark 2. It must be pointed that for the problem under consideration similar results could be obtained by carrying out tests with limited accuracy, and therefore risking to mistakenly select a Voronoi site adjacent to the correct one in critical situations (when the query point is very close to the separating edge): such indeterminacy could be remedied by an additional test comparing the distances of the query point from the two competing sites. Although effective, such ad hoc solution would not fit the exact-computation paradigm, whereas our method fully complies with it. $\square$

4.4. Implicit higher-order Voronoi diagrams. In this section, we introduce implicit higher-order Voronoi diagrams for point sites in the plane, and we extend the results of section 4.3 to k-nearest neighbors and circular range search queries.

The definition of the *implicit order-k Voronoi diagram* $V_k^*(S)$ of set S of point sites in the plane is analogous to that given in section 4.3 for Voronoi diagrams. A vertex v of $V_k(S)$ is represented by its approximate coordinates $x^*(v)$ and $y^*(v)$, and a nonhorizontal edge e of $V_k(S)$ stores the pair of sites $\ell(e)$ and $r(e)$ such that e is a portion of the perpendicular bisector of $\ell(e)$ and $r(e)$, and $\ell(e)$ is to the left of $r(e)$.

Lemmas 10–11 immediately hold also for $V_k(S)$, and we obtain Lemma 14.

LEMMA 14. *For any native method for monotone maps, a point-location query in an implicit order-k Voronoi diagram has optimal degree* 2 *and has the same asymptotic time complexity as a point location query in an explicit order-k Voronoi diagram.*

The order-k Voronoi diagram $V_k(S)$ for a set S of n point sites has $O(k(n-k))$ vertices, edges, and faces and can be obtained from the order $k-1$ implicit Voronoi diagram $V_{k-1}(S)$ by intersecting each face of $V_{k-1}(S)$ with the (order-1) Voronoi diagram of a suitable subset of the vertices of S [43]. As shown in [43, 16], $V_k(S)$ can be computed in $O(k(n-k)\sqrt{n}\log n)$ time. Since the construction is based on iteratively computing Voronoi diagrams by using the incircle test, which is the most expensive operation in terms of degree, the overall degree of the preprocessing is 4 (Lemma 5). Hence, we obtain Lemma 15.

LEMMA 15. *The implicit order-k Voronoi diagram of n point sites in the plane can be computed in $O(k(n-k)\sqrt{n}\log n)$ time, $O(k(n-k))$ space, and with degree* 4.

Point location in the order-k Voronoi diagram solves k-nearest neighbors queries. Hence, by Theorem 3 and Lemmas 14–15, we obtain Theorem 7.

THEOREM 7. *Let S be a set of n point sites in the plane and k an integer with $1 \le k \le n-1$. There exists an $O(k(n-k))$-space data structure for S, based on the implicit order-k Voronoi diagram $V_k^*(S)$, that can be computed in $O(k(n-k)\sqrt{n}\log n)$ time with degree* 5 *and supports k-nearest neighbors queries in $O(\log n + k)$ time with optimal degree* 2.

Circular range search queries in a set S of n point sites can be reduced to a sequence of 2^i-nearest neighbors queries in $V_{2^i}(S)$, $i = 0, \ldots, \log n$ [7]. This approach yields a data structure with $O(n^3)$ space and preprocessing time, and $O(\log n \log\log n + k)$ query time, where k is the size of the output. Hence, with analogous reasoning as above, we obtain the following theorem.

THEOREM 8. *Let S be a set of n point sites in the plane. There exists an $O(n^3)$-space data structure for S, based on implicit order-k Voronoi diagrams, that can be computed in $O(n^3)$ time with degree* 5 *and supports circular range search queries in $O(\log n \log\log n + k)$ time with optimal degree* 2.

The space and preprocessing time of Theorems 7–8 and the query time of Theorem 8 can be improved while preserving the same degree bounds by more complicated procedures along the lines suggested in [1, 2, 15].

5. Proximity queries for point sites in 3D space. In this section, we consider the following proximity query on a set S of point sites in 3D space:

nearest neighbor search: given query point q, find a site of S whose Euclidean distance from q is less than or equal to that of any other site.

We recall our assumption that the sites and query points are primitive points represented by b-bit integers.

As for the 2D case, such a query is efficiently answered by performing point location in the 3D Voronoi diagram of S. Test primitives and methods for spatial point location are described in section 5.1. Section 5.2 shows that "conventional" algorithms require degree 8. A degree-3 algorithm based on "implicit" 3D Voronoi diagrams is then given in section 5.3.

5.1. Test primitives and methods for spatial point location. There are only two known efficient spatial point location methods for cell-complexes that are applicable to 3D Voronoi diagrams: the *separating surfaces method* [14, 56], which extends the chain method [44], and the *persistent planar location method* [52], which extends the persistent search tree method [53]. Let N be the number of facets of a cell-complex C. The query time is $O(\log^2 N)$ for both methods. The space used is $O(N)$ for the separating surfaces method and $O(N \log^2 N)$ for the persistent planar location method. Both methods are restricted to convex cell-complexes. The separating surfaces method is further restricted to acyclic convex cell-complexes, where the dominance relation among cells in the z-direction is acyclic.

As in section 4.1, we can separate the primitive operations that access the geometry of the cell-complex from those that access only the topology. We say that a point location method is *native* for a class of 3D cell-complexes if it performs point locations queries in a cell-complex C of the class by accessing the geometry of C exclusively through the following three geometric test primitives that discriminate the query point with respect to the vertices and edges of C:

above-below(q, v) compares the z-coordinate of the query point q with the z-coordinate of vertex v.

left-right(q, v) compares the x-coordinate of the query point q with the x-coordinate of vertex v.

front-rear(q, v) compares the y-coordinate of the query point q with the y-coordinate of vertex v.

left-right(q_{xy}, e_{xy}) compares the xy-projection q_{xy} of the query point q with the xy-projection of edge e_{xy}. This operation assumes that e_{xy} is not parallel to the x-axis and its y-span includes q_{xy}.

above-below(q, f) determines whether query point q is above or below a facet f; this operation assumes that facet f is not parallel to the z-axis and that the xy-projection of f contains the xy-projection of q.

Test primitives above-below(q, v) and left-right(q, v) are used only in degenerate cases (e.g., in the presence of facets parallel to the z-axis and in cases where e_{xy} is horizontal).

Now, we analyze the separating surfaces method for spatial point location [14, 56] in acyclic cell-complexes. *Separating surfaces* are the 3D analogue of separators of monotone maps. Their existence is guaranteed by the acyclicity of the cell-complex. Thus, a point location query consists of traversing a root-to-leaf path in the *separating surface tree*, where at each node we determine whether the query point q is to above or below the separating surface associated with the node. The discrimination of point q with respect to a separating σ is performed in two steps:

1. By means of a planar point location query for the xy-projection q_{xy} of q in the xy projection of σ, we find the facet f of σ whose xy projection contains q_{xy}. If an ordinary point location method is used, this step uses primitives front-rear(q, v), left-right(q, v), and left-right(q_{xy}, e_{xy}).
2. We discriminate q with respect to σ by performing test above-below(q, f).

In the special cases that cell-complex C has facets parallel to the z-axis, the discrimination of point q with respect to σ uses also test primitives above-below(q, v). Thus, the separating surfaces method is native for acyclic convex cell-complexes.

A similar analysis shows that also the persistent planar location method is native for convex cell-complexes. More specifically, we have Lemma 16.

LEMMA 16. *The separating surfaces method is native for acyclic convex cell-complexes. The persistent planar location method is native for convex cell-complexes.*

Hence, all the known spatial point location methods described in the literature are native for 3D Voronoi diagrams.

5.2. Explicit Voronoi diagrams. Let S be a set of n point sites in 3D, where each site is a primitive point with b-bit integer coordinates. The 3D Voronoi diagram $V(S)$ of S is said to be *explicit* if the coordinates of the vertices of $V(S)$ are computed and stored with exact arithmetic, i.e., as rational numbers (pairs of integers).

LEMMA 17. *The* left-right(q_{xy}, e_{xy}) *test primitive in an explicit Voronoi diagram of point sites in* 3D *space has degree* 8.

Proof. The reasoning is the same as in the proof of Lemma 9. Let $e_{x,y} \equiv (v_1, v_2)$, where v_1 and v_2 are the xy-projections of two adjacent vertices u and v of $V(S)$; let u be equidistant from the four primitive sites $a \equiv (x_a, y_a)$, $b \equiv (x_b, y_b)$, $c \equiv (x_c, y_c)$, and

$d \equiv (x_d, y_d)$, and v from $a \equiv (x_a, y_a)$, $b \equiv (x_b, y_b)$, $c \equiv (x_c, y_c)$, and $h \equiv (x_h, y_h)$. In an explicit Voronoi diagram, test primitive $\mathsf{left\text{-}right}(q_{xy}, e_{xy})$ that determines whether query point $q \equiv (x_q, y_q)$ is to the left or to the right of edge $e \equiv (v_1, v_2)$ is equivalent to evaluating the sign of the following determinant:

$$\Delta = \begin{vmatrix} x_q & y_q & 1 \\ x_1 & y_1 & 1 \\ x_2 & y_2 & 1 \end{vmatrix} = \begin{vmatrix} x_q & y_q & 1 \\ \frac{X_1}{2W_1} & \frac{Y_1}{2W_1} & 1 \\ \frac{X_2}{2W_2} & \frac{Y_2}{2W_2} & 1 \end{vmatrix} = \frac{1}{4W_1W_2} \begin{vmatrix} x_q & y_q & 1 \\ X_1 & Y_1 & 2W_1 \\ X_2 & Y_2 & 2W_2 \end{vmatrix} = \frac{\Delta'}{4W_1W_2},$$

where

$$X_1 = \begin{vmatrix} x_a^2+y_a^2+z_a^2 & y_a & z_a & 1 \\ x_b^2+y_b^2+z_b^2 & y_b & z_b & 1 \\ x_c^2+y_c^2+z_c^2 & y_c & z_c & 1 \\ x_d^2+y_d^2+z_d^2 & y_d & z_d & 1 \end{vmatrix}, \quad Y_1 = \begin{vmatrix} x_a & x_a^2+y_a^2+z_a^2 & z_a & 1 \\ x_b & x_b^2+y_b^2+z_b^2 & z_b & 1 \\ x_c & x_c^2+y_c^2+z_c^2 & z_c & 1 \\ x_d & x_d^2+y_d^2+z_d^2 & z_d & 1 \end{vmatrix},$$

$$W_1 = \begin{vmatrix} x_a & y_a & z_a & 1 \\ x_b & y_b & z_b & 1 \\ x_c & y_c & z_c & 1 \\ x_d & y_d & z_d & 1 \end{vmatrix},$$

and X_2, Y_2, and W_2 have similar expressions obtained replacing in the above determinants x_d with x_h, y_d with y_h, and z_d with z_h.

Evaluating the sign of Δ is equivalent to evaluating the signs of W_1, W_2 and of Δ'.

By using the notation introduced in section 2, we can rewrite X_i and Y_i as α^4, and W_i as α^3 $(i = 1, 2)$. Hence, Δ' is a degree-8 multivariate polynomial since it can be rewritten as

$$\alpha(\alpha^4\alpha^3 - \alpha^4\alpha^3) - \alpha(\alpha^4\alpha^3 - \alpha^4\alpha^3) + \alpha^4\alpha^3 - \alpha^4\alpha^4 \quad \longrightarrow^{(2,3,4)} \quad \alpha^8 + \alpha^8 \quad \longrightarrow^{(3)} \alpha^8. \qquad \square$$

An algorithm for nearest neighbor queries on a set S of point sites in 3D space is said to be *conventional* if it computes the explicit 3D Voronoi diagram $V(S)$ of S and then performs point location queries on $V(S)$ with a native method. Recall that the class of conventional nearest neighbor query algorithms includes the two efficient algorithms presented in the literature. A conventional proximity query algorithm needs to perform test primitive $\mathsf{left\text{-}right}(q_{xy}, e_{xy})$. Thus, by Lemma 17, we have Theorem 9.

THEOREM 9. *Conventional algorithms for the nearest neighbor query problem on a set of point sites in* 3D *space have degree at least* 8.

5.3. Implicit Voronoi diagrams. The definition of the implicit 3D Voronoi diagram $V^*(S)$ of a set of S of point sites in 3D space is a straightforward extension of the definition for 2D Voronoi diagrams given in section 4.3. Namely, $V^*(S)$ stores the topological structure of the 3D Voronoi diagram $V(S)$ of S (e.g., the data structure of [23]) and the following geometric information for each vertex and facet:

- For each vertex v of $V(S)$, $V^*(S)$ stores the semi-integer $(b+1)$-bit approximations $x^*(v)$, $y^*(v)$, and $z^*(v)$ of the x-, y-, and z-coordinates of v.
- For each facet f of $V(S)$ that is not parallel to any of three Cartesian planes, $V^*(S)$ stores the pair of sites $\ell(f)$ and $r(f)$ such that f is a portion of the perpendicular bisector of $\ell(f)$ and $r(f)$, and $\ell(f)$ is below $r(f)$.

The tests $\mathsf{above\text{-}below}(q, v)$, $\mathsf{left\text{-}right}(q, v)$, $\mathsf{front\text{-}rear}(q, v)$ can be implemented comparing the x-, y-, and z-coordinate of query point q with $x(v)^*$, $y(v)^*$, and $z(v)^*$, respectively. With the same reasoning as for the 2D case (see section 4.3), it is easy to see that such implementations are correct.

LEMMA 18. *Test primitives* above-below(q, v), left-right(q, v), front-rear(q, v) *in an implicit Voronoi diagram of* 3D *point sites can be performed in* $O(1)$ *time and with degree* 1.

Test primitive above-below(q, f) is implemented by comparing the Euclidean distances of point q from the two sites $\ell(e)$ and $r(e)$ of which f is the perpendicular bisector with a point-to-points distance test. The implementation is correct by the definition of Voronoi facet. Thus, by Lemma 4, we have Lemma 19.

LEMMA 19. *Test primitive* above-below(q, f) *in an implicit Voronoi diagram of* 3D *point sites can be performed in* $O(1)$ *time and with degree* 2.

Finally, test left-right(q_{xy}, e_{xy}) is implemented by determining the sign of the equation of the line that contains edge e_{xy} when computed at point q_{xy}.

LEMMA 20. *Test primitive* left-right(q_{xy}, e_{xy}) *in an implicit Voronoi diagram of* 3D *point sites can be performed in* $O(1)$ *time and with degree* 3.

Proof. The line containing the oriented edge e_{xy} is the projection on the xy-plane of the intersection of two planes containing two facets of the 3D Voronoi diagram. Let $a_i x + b_i y + c_i z + d_i = 0$ be the equation of one such plane $(i = 1, 2)$. The projection of their intersection on the xy-plane is

$$\begin{vmatrix} a_1 & c_1 \\ a_2 & c_2 \end{vmatrix} x + \begin{vmatrix} b_1 & c_1 \\ b_2 & c_2 \end{vmatrix} y + \begin{vmatrix} d_1 & c_1 \\ d_2 & c_2 \end{vmatrix} = 0.$$

Test left-right(q_{xy}, e_{xy}) consists of determining the sign of

$$\begin{vmatrix} a_1 & c_1 \\ a_2 & c_2 \end{vmatrix} x_q + \begin{vmatrix} b_1 & c_1 \\ b_2 & c_2 \end{vmatrix} y_q + \begin{vmatrix} d_1 & c_1 \\ d_2 & c_2 \end{vmatrix},$$

which is a multivariate polynomial having arithmetic degree 3, since it can be rewritten as

$$\alpha\alpha^2 + \alpha\alpha^2 + \alpha^3 \longrightarrow^{(2,3)} \alpha^3. \qquad \square$$

In order to execute a native point location algorithm in an implicit 3D Voronoi diagram, we only need to redefine the implementation of the five test primitives. By having encapsulated the geometry in the test primitives, no further modifications are needed. Hence, by Lemmas 18–20 we obtain Lemma 21.

LEMMA 21. *For any native method on a class of cell-complexes that includes* 3D *Voronoi diagrams, a point location query in an implicit* 3D *Voronoi diagram has degree* 3 *and has the same asymptotic time complexity as a point location query in an explicit* 3D *Voronoi diagram.*

The Voronoi diagram of n point sites in 3D space is an acyclic convex cell-complex with $N = O(n^2)$ facets. Hence, using the separating surfaces method on the implicit 3D Voronoi diagram yields the following result.

The implicit Voronoi diagram $V^*(S)$ of a set S of n points in 3D space can be constructed by computing the 3D Delaunay triangulation with the incremental algorithm by Joe [40], whose time complexity and storage is $O(n^2)$ (see also [49]). Since the most demanding operation of the algorithm in terms of degree is the 3D insphere test, from Lemma 6 we have that the degree of the algorithm that computes $V(S)$ is 5. As in the planar case, the topological structure of $V(S)$ and the sites $\ell(f)$ and $r(f)$ for each edge e of $V(S)$ are immediately derived from $DT(S)$ by duality. We then compute the approximations $x^*(v)$, $y^*(v)$, and $z^*(v)$ for each vertex v of $V(S)$ by means of integer division. Let a, b, c, and d be the four sites of S that define vertex v. Adopting the same notation as in the proof of Lemma 17, the x-coordinate $x(v)$ of v is given by the ratio $x(v) = \frac{X_1}{2W_1}$, where X_1 is a variable of arithmetic degree 4

and W_1 is a variable of arithmetic degree 3; this is similar for $y(v)$ and $z(v)$. We summarize the above analysis as follows.

LEMMA 22. *The implicit Voronoi diagram of a set of n point sites in* 3D *space can be computed in $O(n^2)$ time and space and with degree* 5.

Lemmas 21 and 22 lead to the following theorem.

THEOREM 10. *Let S be a set of n point sites in* 3D *space. There exists an $O(n^2)$-space data structure for S that can be computed in $O(n^2)$ time with degree* 7 *and supports nearest neighbor queries in $O(\log^2 n)$ time with degree* 3.

Proof. We perform point location in the implicit Voronoi $V^*(S)$ diagram of S using the separating surfaces method. The space requirement and the query degree and time follow from the performance of these methods and from Lemma 21.

Regarding the preprocessing time, by Lemma 22, the construction of the implicit Voronoi $V^*(S)$ takes $O(n^2)$ time with degree 5. In order to construct the point-location data structure, we also need an additional test primitive that consists of comparing the y-coordinates of two Voronoi vertices. For example, this primitive is used to establish bridges between the vertices of the different separating chains if the bridged-chain method (see section 4.1) is applied to locate the xy-projection of the query point into the xy-projection of a separating surface. Comparing the y-coordinates of the Voronoi vertices is equivalent to evaluating the sign of multivariate polynomials of the form $\frac{Y_i}{2W_i} - \frac{Y_j}{2W_j}$, where $\frac{Y_i}{2W_i}$ and $\frac{Y_j}{2W_j}$ represent the y-coordinates of two different Voronoi vertices (see also the proof of Lemma 17). Such multivariate polynomials have degree 7, since they can be rewritten as

$$\frac{\rho_i}{\rho_j} - \frac{\rho_h}{\rho_k} \quad \longrightarrow^{(6)} \quad \rho_i\rho_k - \rho_h\rho_j \quad \longrightarrow^{(1)} \quad \alpha^4\alpha^3 - \alpha^4\alpha^3 \quad \longrightarrow^{(2,3,4)} \quad \alpha^7. \qquad \square$$

Although the algorithm for nearest neighbor queries proposed in this section has nonoptimal degree 3, it is a practical approach for the important application scenario where the primitive points are pixels on a computer screen. On a typical screen with about $2^{10} \times 2^{10}$ pixels, our nearest neighbor query can be executed with the standard integer arithmetic of a 32-bit processor.

6. Proximity queries for point and segment sites in the plane. In this section, we consider the following proximity query on a set S of point and segment sites in the plane:

nearest neighbor search: given query point q, find a site of S whose Euclidean distance from q is less than or equal to that of any other site.

As for the other queries studied in the previous sections, such a query is efficiently solved by performing point location in the Voronoi diagram of the set of point and segment sites [51].

The test primitives needed by such an approach are described in section 6.1. Section 6.2 shows that the "conventional" approach requires degree 64. A degree-6 algorithm based on "implicit" Voronoi diagrams is then given in section 6.3.

6.1. Test primitives and methods. The Voronoi diagram $V(S)$ of a set S of point and segment sites is a map whose edges are either straight-line segments or arcs of parabolas. Hence, in general $V(S)$ is neither convex nor monotone. In order to perform point location in $V(S)$, we refine $V(S)$ into a map with monotone edges as follows. If edge e of $V(S)$ is an arc of parabola whose point p of maximum (or minimum) y-coordinate is not a vertex, we split e into two edges by inserting a fictitious vertex at point p. We call the resulting map the *extended Voronoi diagram* $V'(S)$ of S.

The persistent search tree method and the trapezoid method can be used as native methods on the extended Voronoi diagram, where the test primitives are the same as

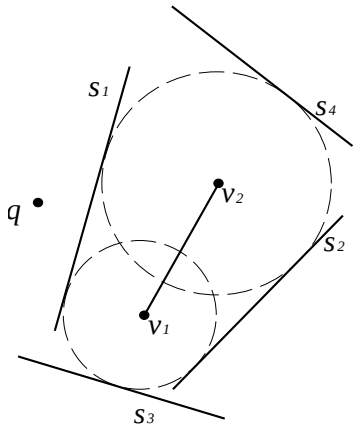

FIG. 2. *Illustration for Lemma* 24.

those defined in section 4.1 for point sites. If we want to use the chain method or the bridged-chain method, we need to do a further refinement that transforms the map into a monotone map by adding vertical fictitious edges emanating from the fictitious vertices previously inserted along the parabolic edges.

LEMMA 23. *The trapezoid method and the persistent search tree method are native, and the chain method and the bridged-chain method are ordinary for extended Voronoi diagrams of point and segment sites.*

6.2. Explicit Voronoi diagrams. Let S be a set of n points and segment sites. The extended Voronoi diagram $V'(S)$ of S is said to be *explicit* if the coordinates of the vertices of $V'(S)$ are computed and stored with exact arithmetic, i.e., as algebraic numbers [10, 59].

In the following lemma, we analyze the degree of test primitive $\mathsf{left\text{-}right}(q, e)$ for a straight-line edge e of an explicit extended Voronoi diagram.

LEMMA 24. *The* $\mathsf{left\text{-}right}(q, e)$ *test primitive for a straight-line edge* e *in an explicit extended Voronoi diagram of point and segment sites in the plane has degree* 64.

Proof. Let $e \equiv (v_1, v_2)$, such that $v_1 \equiv (x_1, y_1)$ is equidistant from three segments s_1, s_2, and s_3 and v_2 is from three segments s_1, s_2, and s_4. See Figure 2.

We show that the test $\mathsf{left\text{-}right}(q, e)$ for determining whether the query point $q \equiv (x_q, y_q)$ is to the left or to the right of (v_1, v_2) has degree 64. Namely, let $a_i x + b_i y + c_i = 0$ $(i = 1, 2, 3, 4)$ be the equation of the line containing segment s_i. In an explicit Voronoi diagram, test primitive $\mathsf{left\text{-}right}(q, e)$, determines whether query point $q \equiv (x_q, y_q)$ is to the left or to the right of edge $e \equiv (v_1, v_2)$, is equivalent to evaluating the sign of the following determinant:

$$\Delta = \begin{vmatrix} x_q & y_q & 1 \\ x_1 & y_1 & 1 \\ x_2 & y_2 & 1 \end{vmatrix} = \begin{vmatrix} x_q & y_q & 1 \\ \frac{X_1}{W_1} & \frac{Y_1}{W_1} & 1 \\ \frac{X_2}{W_2} & \frac{Y_2}{W_2} & 1 \end{vmatrix} = \frac{1}{W_1 W_2} \begin{vmatrix} x_q & y_q & 1 \\ X_1 & Y_1 & W_1 \\ X_2 & Y_2 & W_2 \end{vmatrix} = \frac{\Delta'}{W_1 W_2},$$

where

$$X_1 = \begin{vmatrix} b_1 & c_1 & \sqrt{a_1^2 + b_1^2} \\ b_2 & c_2 & \sqrt{a_2^2 + b_2^2} \\ b_3 & c_3 & \sqrt{a_3^2 + b_3^2} \end{vmatrix}, \quad Y_1 = \begin{vmatrix} a_1 & c_1 & \sqrt{a_1^2 + b_1^2} \\ a_2 & c_2 & \sqrt{a_2^2 + b_2^2} \\ a_3 & c_3 & \sqrt{a_3^2 + b_3^2} \end{vmatrix},$$

$$W_1 = \begin{vmatrix} b_1 & a_1 & \sqrt{a_1^2 + b_1^2} \\ b_2 & a_2 & \sqrt{a_2^2 + b_2^2} \\ b_3 & a_3 & \sqrt{a_3^2 + b_3^2} \end{vmatrix},$$

and X_2, Y_2, and W_2 have similar expressions obtained by substituting in the above determinants a_3 with a_4, b_3 with b_4, and c_3 with c_4. Evaluating the sign of Δ is equivalent to evaluating the signs of W_1, W_2 and of Δ'. In the rest of this proof we show that evaluating the sign of Δ' is a computation with degree 64. By using the same technique, one can easily see that evaluating the signs of W_1 and W_2 is a computation with degree 12.

We have

$$\Delta' = x_q(Y_2W_1 - Y_1W_2) - y_q(X_1W_2 - X_2W_1) + (X_2Y_1 - X_1Y_2). \tag{1}$$

By using the notation introduced in section 2, we can rewrite X_1, and Y_1 as $\alpha^3\rho_1 + \alpha^3\rho_2 + \alpha^3\rho_3$, W_1 as $\alpha^2\rho_1 + \alpha^2\rho_2 + \alpha^2\rho_3$, X_2 and Y_2 as $\alpha^3\rho_1 + \alpha^3\rho_2 + \alpha^3\rho_4$, and W_2 as $\alpha^2\rho_1 + \alpha^2\rho_2 + \alpha^2\rho_4$, where $\rho_i = \sqrt{a_i^2 + b_i^2}$ $(i = 1, \ldots, 4)$. Considering that x_q and y_q are expressions of type α and applying repeatedly Rules (1) and (2), we obtain the expression

$$\alpha^8 + \alpha^6\rho_1\rho_2 + \alpha^6\rho_1\rho_3 + \alpha^6\rho_1\rho_4 + \alpha^6\rho_2\rho_3 + \alpha^6\rho_2\rho_4 + \alpha^6\rho_3\rho_4.$$

By means of the rewriting rules of section 2 we have

$$\begin{array}{ll}
\alpha^8 + \alpha^6\rho_1\rho_2 + \alpha^6\rho_1\rho_3 + \alpha^6\rho_1\rho_4 + \alpha^6\rho_2\rho_3 + \alpha^6\rho_2\rho_4 + \alpha^6\rho_3\rho_4 & \longrightarrow^{(7)} \\
(\alpha^8 + \alpha^6\rho_2\rho_3 + \alpha^6\rho_2\rho_4 + \alpha^6\rho_3\rho_4)^2 - (\alpha^6\rho_1\rho_2 + \alpha^6\rho_1\rho_3 + \alpha^6\rho_1\rho_4)^2 & \longrightarrow^{(1,2,3,4)} \\
\alpha^{16} + \alpha^{14}\rho_2\rho_3 + \alpha^{14}\rho_2\rho_4 + \alpha^{14}\rho_3\rho_4 & \longrightarrow^{(7)} \\
(\alpha^{16} + \alpha^{14}\rho_2\rho_3)^2 - (\alpha^{14}\rho_2\rho_4 + \alpha^{14}\rho_3\rho_4)^2 & \longrightarrow^{(1,2,3,4)} \\
\alpha^{32} + \alpha^{30}\rho_2\rho_3 & \longrightarrow^{(7)} \\
\alpha^{64} - \alpha^{64} & \longrightarrow^{(3,4)} \\
\alpha^{64}. &
\end{array}$$

□

An algorithm for proximity queries on a set S of point and segment sites in the plane is said to be *conventional* if it computes the explicit extended Voronoi diagram $V'(S)$ of S and then performs point location queries on $V'(S)$ with a native method. Note that the class of conventional proximity query algorithms includes all the efficient algorithms presented in the literature. A conventional proximity query algorithm needs to perform test primitive left-right(q, e). Thus, by Lemma 24 we conclude Theorem 11.

THEOREM 11. *Conventional algorithms for the nearest neighbor query problem on a set of point and segment sites in the plane have degree at least* 64.

Our analysis shows that performing point location in an explicit Voronoi diagram of points and segments is not practically feasible due to the high degree.

6.3. Implicit Voronoi diagrams. The definition of the implicit Voronoi diagram $V^*(S)$ of a set of S of point and segment sites is a straightforward extension of the definition for Voronoi diagrams of point sites given in section 4.3. Namely, $V^*(S)$ stores the topological structure of the extended Voronoi diagram $V'(S)$ of S (e.g., the data structure of [23]) and the following geometric information for each vertex and edge:

- For each vertex v of $V'(S)$, $V^*(S)$ stores the semi-integer $(b+1)$-bit approximations $x^*(v)$ and $y^*(v)$ of the x- and y-coordinates of v.
- For each nonhorizontal edge e of $V'(S)$, $V^*(S)$ stores the pair of sites $\ell(e)$ and $r(e)$ such that e is a portion of the bisector of $\ell(e)$ and $r(e)$, and $\ell(e)$ is to the left of $r(e)$.

In the implicit Voronoi diagram $V^*(S)$ of S, test left-right(q, e) is implemented by comparing the distances of query point q from sites $\ell(e)$ and $r(e)$ with one of the

following tests, depending on the type (point or line) of sites $\ell(e)$ and $r(e)$: point-to-lines distance test, point-to-point-line distance test, or point-to-points distance test. Thus, by Lemmas 2–4, we have Lemma 25.

LEMMA 25. *For any native method on a class of maps that includes extended Voronoi diagrams of point and segment sites in the plane, a point location query in an implicit Voronoi diagram has degree* 6 *and has the same asymptotic time complexity as a point location query in an explicit Voronoi diagram.*

The implicit Voronoi diagram can be constructed in $O(n \log n)$ expected running time by using the randomized incremental algorithm of [11]. The most demanding operation is incircle test for three segments, which has degree 40 by Lemma 7 (see also [9]). By a similar analysis as the one shown in sections 4 and 5, it is not hard to show that both the y-ordering of the vertices of $V(S)$ and the semi-integer approximation of the vertex coordinates can be performed without affecting the computational cost and the degree of the computation of $V(S)$.

LEMMA 26. *The implicit Voronoi diagram of a set of n point and segment sites in the plane can be computed in $O(n \log n)$ expected time, $O(n)$ space, and degree* 40.

Lemmas 25 and 26 lead to the following theorem.

THEOREM 12. *Let S be a set of n point and segment sites in the plane. There exists an $O(n)$-space data structure for S that can be computed in $O(n \log n)$ expected time with degree* 40 *and supports nearest neighbor queries in $O(\log n)$ time with degree* 6.

7. Simplified implicit Voronoi diagrams. In this section, we describe a modification of implicit Voronoi diagrams of point sites that allows us to reduce the degree of the preprocessing task from 5 to 4 when the sites are in the plane (see Theorems 6–8), and from 7 to 5 when the sites are in 3D space (see Theorem 10). This modification also has a positive impact on the space requirement of the data structure and on the running time of point location queries.

Let $V(S)$ be the Voronoi diagram of a set S of point sites in the plane. We recall our standard assumption that all input parameters — such as coordinates of sites and query points — are represented as b-bit integers.

An *island* of $V(S)$ is a connected component of the map obtained from $V(S)$ by removing all the vertices with integer y-coordinate and all the edges containing a point with integer y-coordinate. Note that for any two vertices v_1 and v_2 of an island, $y^*(v_1) = y^*(v_2) = m + \frac{1}{2}$ for some integer m, where $y^*(v)$ is the semi-integer approximation defined in section 4.3.

The *simplified implicit Voronoi diagram* $V^\circ(S)$ of S is a representation of the Voronoi diagram $V(S)$ of S that consists of a topological component and a geometric component. The topological component of $V^\circ(S)$ is the planar embedding obtained from $V(S)$ by contracting each island of $V(S)$ into an *alias vertex*. The geometric component of $V^\circ(S)$ stores the following geometric information for each vertex and edge of the embedding:

- For each vertex v that is also a vertex of $V(S)$, $V^\circ(S)$ stores the $(b+1)$-bit semi-integers approximations $x^*(v)$ and $y^*(v)$.
- For each alias vertex a, which is associated with an island of $V(S)$, $V^\circ(S)$ stores semi-integer $y^*(a)$ such that $y^*(a) = y^*(v)$ for each vertex v of the island.
- For each nonhorizontal edge e that is also an edge of $V(S)$, $V^\circ(S)$ stores the pair of sites $\ell(e)$ and $r(e)$ such that e is a portion of the perpendicular bisector of $\ell(e)$ and $r(e)$, and $\ell(e)$ is to the left of $r(e)$.

The space requirement of the simplified implicit Voronoi diagram is less than or equal to that of the implicit Voronoi diagram, since each island is represented

by a single alias vertex storing only its semi-integer y-approximation. We can show examples where the simplified implicit Voronoi diagram of n point sites has $O(n)$ fewer vertices and edges than the corresponding implicit Voronoi diagram.

The following lemmas extend Lemmas 12–13 and can be proved with similar techniques.

LEMMA 27. *For any native method on a class of maps that includes monotone maps, a point location query in a simplified implicit Voronoi diagram has optimal degree* 2 *and executes a number of operations less than or equal to a point location query in the corresponding explicit Voronoi diagram.*

LEMMA 28. *The simplified implicit Voronoi diagram of n point sites in the plane can be computed in* $O(n \log n)$ *time,* $O(n)$ *space, and with degree* 4.

The main advantage of the simplified implicit Voronoi diagram with respect to the degree cost measure is that the additional test primitive needed in the preprocessing that consists of comparing the y-coordinates of two Voronoi vertices (see the proof of Theorem 6) is now reduced to the comparison of two $(b + 1)$-bit semi-integers, and thus has degree 1. Hence, the preprocessing for point location using a native method for monotone maps has degree 1.

By the above discussion and Lemmas 27–28, we obtain the following theorem that improves upon Theorem 6.

THEOREM 13. *Let S be a set of n point sites in the plane. There exists an* $O(n)$*-space data structure for S, based on the simplified implicit Voronoi diagram* $V^{\circ}(S)$*, that can be computed in* $O(n \log n)$ *time with degree* 4 *and supports nearest neighbor queries in* $O(\log n)$ *time with optimal degree* 2.

Using a similar approach, we can define simplified implicit order-k Voronoi diagrams for point sites in the plane and simplified implicit Voronoi diagrams for point sites in 3D space. This reduces the degree of the preprocessing from 5 to 4 in Theorems 7–8 and from 7 to 5 in Theorem 10.

8. Further research directions. Within the proposed approach, this paper only addresses the issue of the degree of test computations and illustrates its impact on algorithmic design in relation to a central problem in computational geometry. However, several important related problems need further investigation and will be reported on in the near future.

First, the methodological framework described in section 2 should be extended to the computation of the degree of other classes of geometric primitives. Recently, motivated in part by a preliminary version of this paper [45], Burnikel et al. [13] have presented a new separation bound for arithmetic expressions involving square roots.

Also, since the degree of an algorithm expresses worst-case computational requirement occurring in degenerate or near-degenerate instances, special attention must be devoted to the development of a methodology that reliably computes the sign of an expression with the least expenditure of computational resources. This involves the use of "arithmetic filters," possibly families of filters, of progressively increasing power that, depending upon the values of primitive variables, carefully adjust the computational effort (see, e.g., [4, 11, 29, 41]).

Next, one should carefully analyze the precision adopted in executing constructions, so that the outputs are within the precision bounds required by the application. In addition, each construction algorithm should be accompanied by a verification algorithm, which not only checks for topological compliance of the output with the generic member of its class (as, e.g., a Voronoi diagram must have the topology of a convex map) as illustrated in [54] but more specifically verifies its topological agreement with the structure emerging from the tests executed by the algorithm [47].

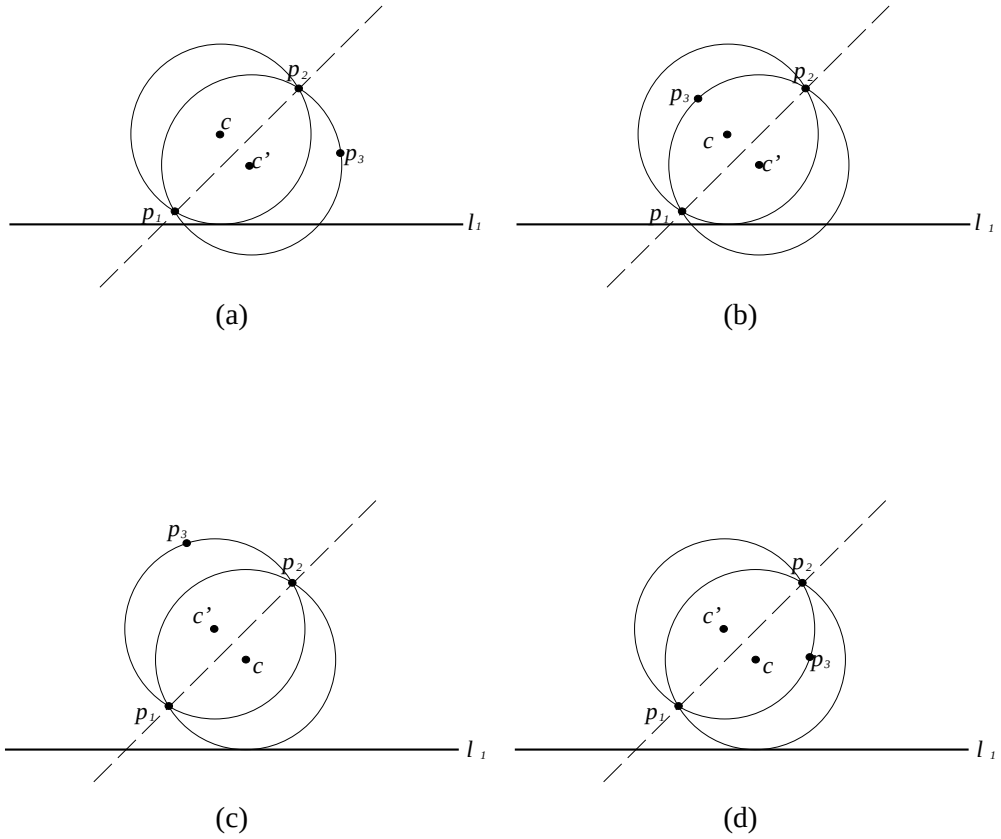

FIG. 3. *Different cases for test* $(p_1, p_2, l_1; p_3)$.

Beyond these general methodological issues, the investigation reported in these pages leaves some interesting open problems such as answering nearest neighbor queries in subquadratic time and optimal degree for a set of points in 3D space or improving the efficiency of the preprocessing stage in computing the implicit Voronoi diagram of a set of sites.

We mention, in this respect, how the degree can impact the design of geometric primitives adopted in existing algorithms for Voronoi diagrams of point and segment sites. Let $(a_1, a_2, a_3; a_4)$, with a_i either a point or a segment, denote the incircle test, where a_4 is tested for intersection with circle(a_1, a_2, a_3). Specifically, consider $(p_1, p_2, l_1; p_3)$, which can be answered with degree 12 [9]. We show that it can be more efficiently executed as follows. First perform the test $(p_1, p_2, p_3; l_1)$. Let c and c' be the centers of circle(p_1, p_2, l_1) and circle(p_1, p_2, p_3), respectively. Two cases are possible: either circle(p_1, p_2, p_3) intersects l_1 or it does not. In the first case, p_3 is inside circle(p_1, p_2, l_1) if and only if c' and p_3 lie on opposite sides of line $\overline{p_1 p_2}$ through p_1 and p_2 (see Figures 3(a) and 3(b)). In the second case the answer to test $(p_1, p_2, l_1; p_3)$ depends on which side of $\overline{p_1 p_2}$ point p_3 lies (see Figures 3(c) and 3(d)). Thus, test $(p_1, p_2, l_1; p_3)$ is reduced to test $(p_1, p_2, p_3; l_1)$ that can be executed with degree 8 (see [9]) and at most two other left-right tests of lower degree.

Finally, an important issue for future research deals with the experimental comparison between point location algorithms in implicit Voronoi diagrams and traditional point location algorithms in explicit Voronoi diagrams. We are currently implementing *GeomLib*, an object-oriented library for robust geometric computing that will

be accessible through the world wide web by using the architectural framework of *Mocha* [6, 5].

Acknowledgment. The authors wish to thank the referees for several useful suggestions.

FAILURE DETECTION AND RANDOMIZATION: A HYBRID APPROACH TO SOLVE CONSENSUS*

MARCOS KAWAZOE AGUILERA† AND SAM TOUEG†

Abstract. We present a consensus algorithm that combines unreliable failure detection and randomization, two well-known techniques for solving consensus in asynchronous systems with crash failures. This hybrid algorithm combines advantages from both approaches: it guarantees deterministic termination if the failure detector is accurate, and probabilistic termination otherwise. In executions with no failures or failure detector mistakes, the most likely ones in practice, consensus is reached in only two asynchronous rounds.

Key words. algorithms, reliability, agreement problem, asynchronous systems, Byzantine generals' problem, consensus problem, crash failures, failure detection, fault-tolerance, message passing, processor failures, randomized algorithms

1. Introduction.

1.1. Motivation.

A well-known result by Fischer, Lynch, and Paterson [14] is that *consensus* cannot be solved in asynchronous systems with failures, even if communication is reliable; at most one process may fail, and it can only fail by crashing. Since this seminal paper, there has been intense research seeking to "circumvent" this negative result (e.g., [4, 5, 6, 7, 10, 13, 22]).

One promising approach is the use of unreliable failure detection [2, 3, 6, 7, 11, 16, 17, 18, 19, 20, 21, 23]. Roughly speaking, this approach assumes that each process has access to a local failure detector module that gives some (possibly inaccurate) information on which processes may have failed. It turns out that consensus can be solved with unreliable failure detectors that make an infinite number of mistakes, provided that they satisfy some minimum properties [6, 7].

In particular, [7] presents a consensus algorithm with the following features. Even if the information provided by the failure detectors is completely wrong, the algorithm never violates safety; i.e., no two processes ever decide differently. During "good" periods, when the failure detectors are reasonably accurate, processes reach consensus within few asynchronous rounds; on the other hand, when a "bad" period occurs, i.e., when failure detectors lose their accuracy, the consensus algorithm may stop making progress until the bad period is over. Such an algorithm is useful because, in practice, good periods tend to be long while bad ones tend to be rare and short. However, long bad periods do occasionally occur, and each time this happens the consensus algorithm of [7] can be delayed for a long time.

In this paper, we seek an algorithm that terminates quickly when failure detection is accurate (i.e., during good periods) and that makes progress and terminates, albeit more slowly, even if failure detection is inaccurate (i.e., during bad periods). We

†Computer Science Department, Cornell University, Ithaca, NY 14853-7501 (aguilera@cs.cornell.edu, sam@cs.cornell.edu).

achieve this goal by combining failure detection with *randomization*—another technique that was used to solve consensus in asynchronous systems [4]. In this hybrid approach, randomization "kicks in" as a back-up to failure detection when failure detectors are inaccurate. Further discussion of the relative merits of failure detection, randomization, and this hybrid approach is postponed until section 7.

The idea of combining randomization and failure detection to solve consensus in asynchronous systems first appeared in [12]. A related idea, namely, combining randomization and deterministic algorithms to solve consensus in *synchronous* systems, was explored in [15, 25]. A brief comparison with our results is given in section 8.

1.2. Main result. We focus on two of the major techniques to circumvent the impossibility of consensus in asynchronous systems: randomization and unreliable failure detection. The first one assumes that each process has a local random number generator (denoted *R-oracle*) that provides *random bits* [4]. The second technique assumes that each process has a local failure detector module (denoted *FD-oracle*) that provides *a list of processes suspected to have crashed* [7]. Each approach has some advantages over the other, and we seek to combine advantages from both.

With a randomized consensus algorithm, every process can query its local R-oracle and use the oracle's random bit to determine its next step. With such an algorithm, termination is achieved with probability 1, within a finite expected number of steps (for a survey of randomized consensus algorithms see [8]).

With a failure detector based consensus algorithm, every process can query its local FD-oracle (which provides a list of processes that are suspected to have crashed) to determine the process's next step. Consensus can be solved with FD-oracles that make an infinite number of mistakes. In particular, consensus can be solved with FD-oracles that satisfy two properties, *strong completeness* and *eventual weak accuracy*. Roughly speaking, the first property states that every process that crashes is eventually suspected by every correct process, and the second one states that some correct process is eventually not suspected. These properties define the weakest class of failure detectors that can be used to solve consensus [6].

In this paper we describe a hybrid consensus algorithm with the following properties. Every process has access to both an R-oracle and an FD-oracle. If the FD-oracle satisfies the above two properties, the algorithm solves consensus (no matter how the R-oracle behaves). If the FD-oracle loses its accuracy property but the R-oracle works, the algorithm still solves consensus, albeit "only" with probability 1. In executions with no failures or failure detector mistakes, the most likely ones in practice, an optimized version of this algorithm reaches consensus in only two asynchronous rounds.

2. Informal model. Our model of asynchronous computation is patterned after the one in [14] and its extension in [6]. We only sketch its main features here. We consider *asynchronous* distributed systems in which there is no bound on message delay, clock drift, or the time necessary to execute a step. To simplify the presentation of our model, we assume the existence of a discrete global clock. This is merely a fictional device: the processes do not have access to it. We take the range $\mathcal{T}$ of the clock's ticks to be the set of natural numbers $\mathbf{N}$.

The system consists of a set of n *processes*, $\Pi = \{p_0, p_1, \ldots, p_{n-1}\}$. Every pair of processes is connected by a reliable communication channel. Up to f processes can fail by *crashing*. A failure pattern indicates which processes crash, and when they crash during an execution. Formally, a *failure pattern* F is a function from $\mathbf{N}$ to 2^{Π}, where $F(t)$ denotes the set of processes that have crashed through time t.

Once a process crashes, it does not "recover"; i.e., $\forall t : F(t) \subseteq F(t+1)$. We define $\text{crashed}(F) = \bigcup_{t \in \mathbf{N}} F(t)$ and $\text{correct}(F) = \Pi - \text{crashed}(F)$. If $p \in \text{crashed}(F)$ we say *p crashes (in F)* and if $p \in \text{correct}(F)$ we say *p is correct (in F)*.

Each process has access to two oracles: a failure detector, henceforth denoted the FD-oracle, and a random number generator, henceforth denoted the R-oracle. When a process queries its FD-oracle, it obtains a list of processes.[1] When it queries its R-oracle, it obtains a bit. The properties of these oracles are described in the two next sections.

A distributed algorithm $\mathcal{A}$ is a collection of n deterministic automata (one for each process in the system) that communicates by sending messages through reliable channels. The execution of $\mathcal{A}$ occurs in *steps* as follows. For every time $t \in \mathcal{T}$, at most one process takes a step. Each step consists of receiving a message, querying the FD-oracle, querying the R-oracle, changing state, and optionally sending a message to one process. We assume that messages are never lost. That is, if a process does not crash, it eventually receives every message sent to it.

A schedule is a sequence $\{s_j\}_{j \in \mathbf{N}}$ of processes and a sequence $\{t_j\}_{j \in \mathbf{N}}$ of strictly increasing times. A schedule indicates which processes take a step and when they take a step; for each j, process s_j takes a step at time t_j. A schedule is *consistent (with respect to a failure pattern F)* if a process does not take a step after it has crashed (in F). A schedule is *fair (with respect to a failure pattern F)* if each process that is correct (in F) takes an infinite number of steps. We consider only schedules that are consistent and fair.

2.1. FD-oracles. Every process p has access to a local FD-oracle module that outputs a list of processes that are suspected to have crashed. If some process q belongs to such list, we say that p *suspects* q.[2] FD-oracles can make mistakes: it is possible for a process p to be suspected by another even though p did not crash or for a process to crash and never be suspected. FD-oracles can be classified according to properties that limit the extent of such mistakes. We focus on one of the eight classes of FD-oracles defined in [7], namely, the class of *eventually strong* failure detectors, denoted $\diamond S$. An FD-oracle belongs to $\diamond S$ if and only if it satisfies two properties:

Strong completeness. Eventually every process that crashes is permanently suspected by *every* correct process (formally, $\exists t \in \mathcal{T}, \forall p \in \text{crashed}(F), \forall q \in \text{correct}(F), \forall t' \geq t : p \in \text{FD}_q^{t'}$, where $\text{FD}_q^{t'}$ denotes the output of q's FD-oracle module at time t').

Eventual weak accuracy. There is a time after which some correct process is never suspected by any correct process (formally, $\exists t \in \mathcal{T}, \exists p \in \text{correct}(F), \forall t' \geq t, \forall q \in \text{correct}(F) : p \notin \text{FD}_q^{t'}$).

It is known that $\diamond S$ is the weakest class of FD-oracles that can be used to solve consensus [6].

2.2. R-oracles. Each process has access to a local R-oracle module that outputs one bit each time it is queried. We say that the R-oracle is *random* if it outputs an independent random bit for each query. For simplicity, we assume a uniform distribution; i.e., a random R-oracle outputs 0 and 1, each with probability 1/2.

2.3. Adversary power. When designing fault-tolerant algorithms, we often assume that an intelligent adversary has some control on the behavior of the system;

[1] In general, the output of a failure detector is not restricted to be a list of processes [6, 1].

[2] In general, processes do not have to agree on the list of suspects at any one time or ever.

e.g., the adversary may be able to control the occurrence and the timing of process failures, the message delays, and the scheduling of processes. Adversaries may have limitations on their computing power and on the information that they can obtain from the system. Different algorithms are designed to defeat different types of adversaries [8].

We now describe the adversary that our hybrid algorithm defeats. The adversary has unbounded computational power and full knowledge of all process steps that already occurred. In particular, it knows the contents of all past messages, the internal state of all processes in the system,[3] and all the previous outputs of both the R-oracle and FD-oracle. With this information, at any time in the execution, the adversary can dynamically select which process takes the next step, which message this process receives (if any), and which processes (if any) crash. The adversary, however, operates under the following restrictions: the final schedule must be consistent and fair, every message sent to a correct process must be eventually received, and at most f processes may crash over the entire execution.

In addition to the above power, we allow the adversary to initially select *one* of the two oracles to control and possibly corrupt. If the adversary selects to control the R-oracle, it can predict and even determine the bits output by that oracle. For example, the adversary can force some local R-oracle module to always output 0 or it can dynamically adjust the R-oracle's output according to what the processes have done so far.

If the adversary selects to control the FD-oracle, it can ensure that the FD-oracle does not satisfy eventual weak accuracy. In other words, at *any* time the adversary can include *any* process (whether correct or not) in the output of the local FD-oracle module of any process. The adversary, however, does not have the power to disrupt the strong completeness property of the FD-oracle. This is not a limitation in practice; most failure detectors are based on time-outs and eventually detect all process crashes.

If the adversary does not control the R-oracle, then the R-oracle is random. If the adversary does not control the FD-oracle, then the FD-oracle is in $\diamond S$. We stress that the algorithm does *not* know which one of the two oracles (FD-oracle or R-oracle) is controlled by the adversary.

3. The consensus problem. In the *uniform binary consensus* problem, every process p has some *initial value* $v_p \in \{0, 1\}$ and must *decide* on a value such that we have the following:

Uniform agreement. If processes p and p' decide v and v', respectively, then $v = v'$;

Uniform validity. If some process decides v, then v is the initial value of some process;

Termination. Every correct process eventually decides some value.

For probabilistic consensus algorithms, Termination is weakened to the following:

Termination with probability 1. With probability 1, every correct process eventually decides some value.

4. Hybrid consensus algorithm. The hybrid consensus algorithm shown in Figure 4.1 combines Ben-Or's algorithm [4] with failure-detection and the rotating coordinator paradigm used in [7]. With this paradigm, we assume that all processes have a priori knowledge that during phase k, one selected process, namely, $p_{k \bmod n}$,

[3] This is in contrast to the assumptions made by several algorithms, e.g., those that use cryptographic techniques.

Every process p executes the following:

```
0   procedure consensus(v_p)                          {v_p is the initial value of process p}
        x ← v_p                                       {x is p's current estimate of the decision value}
        k ← 0
        while true do
            k ← k + 1                                 {k is the current phase number}
5           c ← p_{k mod n}                           {c is the current coordinator}
            send (R, k, x) to all processes
            wait for messages of the form (R, k, *) from n − f processes      {"*" can be 0 or 1}
            if received more than n/2 (R, k, v) with the same v
            then send (P, k, v) to all processes
10          else send (P, k, ?) to all processes
            wait for messages of the form (P, k, *) from n − f processes      {"*" can be 0, 1 or ?}
            if received at least f + 1 (P, k, v) with the same v ≠ ? then decide v
            if at least one (P, k, v) with v ≠ ? then x ← v else x ← ?
            send (S, k, x) to c
15          if p = c then
                wait for messages of the form (S, k, *) from n − f processes
                if received at least one (S, k, v) with v ≠ ?
                then send (E, k, v) to all processes
                else
20                  random_bit ← R-oracle                                 {query R-oracle}
                    send (E, k, random_bit) to all processes
            wait until receive (E, k, v_coord) from c or c ∈ FD-oracle    {query FD-oracle}
            if received (E, k, v_coord)
            then x ← v_coord
25          else if x = ? then x ← R-oracle                               {query R-oracle}
```

FIG. 4.1. *Hybrid consensus algorithm.*

is the coordinator. The algorithm works under the assumption that a majority of processes are correct (i.e., $n > 2f$). It is easy to see that this requirement is necessary for any algorithm that solves consensus in asynchronous systems with crash failures, even if all processes have access to a random R-oracle and an FD-oracle that belongs to $\diamond S$.

In the hybrid algorithm, every message contains a tag (R, P, S, or E), a phase number, and a value which is either 0 or 1 (for messages tagged P or S, it could also be "?"). Messages tagged R are called *reports*; those tagged with P are called *proposals*; those with tag S are called *suggestions (to the coordinator)*; and those with tag E are called *estimates (from the coordinator)*. When p sends (R, k, v), (P, k, v), or (S, k, v), we say that p *reports*, *proposes*, or *suggests* v in phase k, respectively. When the coordinator sends (E, k, v), we say that the coordinator sends estimate v in phase k.

Each execution of the **while** loop is called a *phase*, and each phase consists of four asynchronous rounds. In the first round (lines 4 to 7), processes report to each other their current estimate (0 or 1) for a decision value.

In the second round (lines 8 to 13), if a process receives a majority of reports for the *same* value then it proposes that value to all processes, otherwise it proposes "?". Note that it is impossible for one process to propose 0 and another process to propose 1 in the same phase. At the end of the second round, if a process receives

$f + 1$ proposals for the same value different than ?, then it decides that value. If it receives at least one value different than ?, then it adopts that value as its new estimate, otherwise it adopts ? for an estimate.

In the third round (lines 14 to 16), processes suggest their estimates to the current coordinator.

In the fourth round (lines 17 to 25), if the coordinator receives a value different than ?, then it sends that value as its estimate. Otherwise, the coordinator queries the R-oracle and sends the random value that it obtains as its estimate. Processes wait until they receive the coordinator's estimate or until their FD-oracle suspects the coordinator. If a process receives the coordinator's estimate, it adopts it. Otherwise, if its current estimate is ?, it adopts a random value obtained from its R-oracle.

To simplify the presentation, the algorithm in Figure 4.1 does not include a halt statement. Moreover, once a correct process decides a value, it will keep deciding the same value in all subsequent phases. However, it is easy to modify the algorithm so that every process decides at most once and halts at most one round after deciding.

5. Proof of correctness. The hybrid algorithm shown in Figure 4.1 always satisfies the safety properties of consensus. This holds no matter how the FD-oracle or the R-oracle behaves, that is, even if these oracles are totally under the control of the adversary. On the other hand, the algorithm satisfies liveness properties only if the FD-oracle satisfies strong completeness. Strong completeness is easy to achieve in practice: most failure detectors use time-out mechanisms, and every process that crashes eventually causes a time-out and, therefore, a permanent suspicion.

Assume that there is a majority of correct processes (i.e., $n > 2f$). We show the following theorem.

THEOREM 5.1.
(Safety) The hybrid algorithm always satisfies uniform validity and uniform agreement.
(Liveness) Suppose that the FD-oracle *satisfies strong completeness.*
- *If the* FD-oracle *satisfies eventual weak accuracy, i.e., it is in* $\diamond S$*, then the algorithm satisfies termination.*
- *If the* R-oracle *is random, then the algorithm satisfies termination with probability* 1.

Proof. We say that *process p starts phase k* if process p completes at least $k - 1$ iterations of the **while** loop. We say that *process p reaches line n in phase k* if process p starts phase k and p executes past line $n - 1$ in that phase. We say that v *is k-locked* if every process that starts phase k does so with its variable x set to v. When ambiguities may arise, a local variable of a process p is subscripted by p; e.g., x_p is the local variable x of process p. □

We first show the safety properties.

LEMMA 5.2. *Suppose* $k > 0$. *Then* (1) *it is impossible for a process to propose* 0 *and another one to propose* 1 *in the same phase k; and* (2) *it is impossible for a process to suggest* 0 *and another to suggest* 1 *in the same phase k.*

Proof. We prove (1) by contradiction: suppose that two processes p and q propose 0 and 1, respectively, in phase k. Thus, p received more than $n/2$ reports for 0 and q received more than $n/2$ reports for 1 in phase k. But then there is a process that reports 0 to p and 1 to q in phase k, and this is impossible. This proves (1).

Now (2) follows from (1) since if a process suggests $v \neq ?$ in phase k, then v was proposed in phase k. □

LEMMA 5.3. *If some process decides v in phase $k > 0$, then v is $(k+1)$-locked.*

Proof. Suppose some process p decides v in phase $k > 0$ (note that $v \neq ?$), and let q be any process that starts phase $k+1$. From the algorithm, p receives at least $f+1$ proposals for v in phase k (line 12). Let r be any process that suggests a value in line 14 of phase k. Before suggesting (line 14), r waits for $n-f$ proposals in line 11. Because p receives $f+1$ proposals for v, r must have received at least one proposal for v. Moreover, by Lemma 5.2, r does not receive any proposals for $\bar{v}$.[4] So r sets x_r to v in line 13 and suggests v in phase k. Thus, (1) q sets x_q to v in line 13, and (2) the coordinator of phase k can only receive suggestions for v. In particular, the coordinator does not receive ?. So, if the coordinator sends an estimate in phase k (line 18), that estimate is also v. If q receives that estimate (line 22), then q resets x_q to v in line 24. Otherwise q does not modify x_q (because x_q is different than ?). In either case, q starts phase $k+1$ with $x_q = v$. □

LEMMA 5.4. *If a value v is k-locked for some $k > 0$, then every process that reaches line* 13 *in phase k decides v in phase k.*

Proof. Suppose v is k-locked for some $k > 0$. Then all reports sent in line 6 of phase k are for v. Since $n-f > n/2$, every process that proposes some value in phase k proposes v in line 9. Consider a process p that reaches line 13 in phase k. Clearly, p receives $n-f$ proposals (line 11) for v in phase k. Since $n-f \geq f+1$, p decides v in phase k. □

COROLLARY 5.5. *If some process decides v in phase $k > 0$, then every process that reaches line* 13 *in phase $k+1$ decides v in phase $k+1$.*

Proof. The corollary is proved by Lemmas 5.3 and 5.4. □

COROLLARY 5.6. (uniform agreement). *If some processes p and p' decide v and v' in phase $k > 0$ and $k' > 0$, respectively, then $v = v'$.*

Proof. For $k = k'$ the result follows from Lemma 5.2 and the fact that a process can decide a value in a phase only if that value was proposed in the same phase. Assume that $k < k'$. Since p' decides in phase k', then p' reaches line 13 in every phase r, $k < r \leq k'$. Since p decides v in phase k, by Corollary 5.5, p' decides v in phase $k+1 \leq k'$. By additional applications of Corollary 5.5, we conclude that p' decides v in phase k'. Each process can decide at most once per phase, so $v = v'$. □

COROLLARY 5.7. (uniform validity). *If some process p decides v, then v is the initial value of some process.*

Proof. Note $v \in \{0, 1\}$. If the initial values of all processes are not identical, then v is clearly the initial value of some process. Now, suppose all processes have the same initial value w. Thus, w is 1-locked. From Lemma 5.4, p decides w, and from Corollary 5.6, $w = v$. □

From now on we assume that the FD-oracle satisfies strong completeness, and proceed to prove the liveness properties.

LEMMA 5.8. *Every correct process starts every phase $k > 0$.*

Proof. The detailed proof is by a simple but tedious induction on k. We describe only the central idea here. In each phase, there are four **wait** statements that can potentially block processes (lines 7, 11, 16, 22). It is not possible for a correct process to be blocked forever in any of the first three **wait** statements because at least $n-f$ processes are correct and send the messages that this process is waiting for. Consider the fourth **wait** statement. Either the coordinator c sends its estimate to all processes or c crashes. In the first case, every correct process receives this estimate. In the

[4] We denote by $\bar{v}$ the binary complement of bit v.

(c) the coordinator did not query the R-oracle in line 20 of phase k
then return 1
else return 0

FIG. 5.1. *Favorable coin toss algorithm.*

second case, c eventually appears on the list of suspects; i.e., $c \in$ *FD-oracle* (because the *FD-oracle* satisfies strong completeness). So no correct process waits forever at the fourth **wait** statement of a phase. □

COROLLARY 5.9. *If a value v is k-locked for some $k > 0$, then every correct process decides v in phase k.*

Proof. The corollary is proved immediately from Lemmas 5.4 and 5.8. □

COROLLARY 5.10. *If some process decides v in phase $k > 0$, then every correct process decides v in phase $k + 1$ (and thus in all subsequent phases).*

Proof. The corollary is proved immediately from Corollary 5.5 and Lemma 5.8. □

LEMMA 5.11 (termination). *If the* FD-oracle *satisfies eventual weak accuracy, then every correct process decides.*

Proof. If the FD-oracle satisfies eventual weak accuracy, then there is a time t_0 after which (1) some correct process p_m is never suspected by any correct process and (2) only correct processes take steps (faulty ones crash before t_0). Let k_i be the value of variable k of process p_i at time t_0. Let $\hat{k}$ be the smallest phase after $\max_i\{k_i\}$ such that p_m is the coordinator of phase $\hat{k}$. Let q and r be arbitrary processes that start phase $\hat{k} + 1$. Note that this occurs after time t_0, so neither q nor r suspect the coordinator p_m in phase $\hat{k}$. Thus, q and r set x_q and x_r to p_m's estimate in line 24. Since this estimate is different from ? and unique for phase $\hat{k}$, we have $x_q = x_r = v$ for some $v \neq ?$ at the beginning of phase $\hat{k} + 1$. So v is $(\hat{k} + 1)$-locked. Therefore, by Corollary 5.9, all correct processes decide v in phase $\hat{k} + 1$. □

We now proceed to show that if the R-oracle is random, then the algorithm satisfies termination with probability 1. For $k > 0$, let τ_k be the first time that any process receives $n - f$ proposals in phase k. From Lemma 5.8, for every $k > 0$, some process receives $n - f$ proposals in phase k, so τ_k is well defined. Note that in our algorithm no process queries the R-oracle in phase k before time τ_k.

A process starts a phase with its variable x set to either 0 or 1 (never to ?). For each $k > 0$, we say that a value $v \in \{0, 1\}$ *is k-major at time t* if by time t more than $n/2$ processes have started phase k with their variable x set to v. Clearly, for each $k > 0$ and all times t and t', it is impossible for 0 to be k-major at t and 1 to be k-major at t'.

We say that *a process p R-gets v in phase k at time t* if either

1. in phase k at time t, p obtains v from the R-oracle in line 25 and sets x_p to v; or

2. in phase k, the coordinator obtains v from the R-oracle in line 20 and sends v as its estimate to all processes, and p receives this estimate and sets x_p to v in line 24 at time t.

Intuitively, a process p R-gets v if p sets x_p to v, and p obtained v from an R-oracle query (directly, or indirectly through the coordinator).

LEMMA 5.12. *For every $k \geq 1$, if at time t a process p starts phase $k+1$ with x_p set to some value $v \in \{0,1\}$, then v is k-major at time t or p R-gets v in phase k.*

Proof. Consider phase k. Suppose p did not R-get v. Let t' be the last time p updates x_p in phase k. Note that $t' < t$. Then, at time t', either (a) p receives the estimate from the coordinator and the coordinator obtained that estimate from one of its non-? suggestions; or (b) p sets x_p in line 13. In both cases, more than $n/2$ processes must have reported v in phase k before time t'. Therefore, more than $n/2$ processes have started phase k by time t' (and thus by time t) with their variable x set to v. □

An immediate consequence of Lemma 5.12 is that for every $k \geq 1$, if v is never k-major and no process R-gets v in phase k, then $\bar{v}$ is $(k+1)$-locked.

For the rest of the proof, we group pairs of phases into *epochs* as follows: *epoch* r consists of phases $2r$ and $2r+1$.[5] We will define the concept of a "lucky" epoch—one in which processes toss coins that cause the termination of the algorithm (no matter what the adversary does). To do so, we first define function *FavorableToss*(r, u), given in Figure 5.1. We say that *epoch r is lucky* if, for every process p and any time u, if p queries the R-oracle in epoch r at time u, then p obtains *FavorableToss*(r, u) from the R-oracle. Note that if p queries the R-oracle in epoch r at time u, this occurs after at least one process receives $n - f$ proposals in phase $2r$. Thus, $\tau_{2r} \leq u$, so the value of *FavorableToss*(r, u) depends only on what occurred in the system up to time u.

LEMMA 5.13. *If the R-oracle is random, then the probability that some epoch is lucky is* 1.

Proof. The result is immediate from the following observation: for every $r \geq 1$, (a) the probability that epoch r is lucky is at least $2^{-(2n+2)}$ (because in each phase there are at most $n+1$ queries to the R-oracle, and the R-oracle is random), and (b) for any $r' \neq r$, the events "epoch r is lucky" and "epoch r' is lucky" are independent (because epochs r and r' consist of disjoint sets of phases). □

LEMMA 5.14. *For every $r \geq 1$, if epoch r is lucky, then some value is $(2r+1)$-locked or $(2r+2)$-locked.*

Proof. Throughout the proof of this lemma, fix some arbitrary $r \geq 1$ and assume that epoch r is lucky. Let $k = 2r$; recall that epoch r consists of phases k and $k+1$. Since epoch r is lucky, if any process R-gets a value v at time t and in phase $j = k$ or $j = k+1$, then $v =$ *FavorableToss*(r, u) for some time u, $\tau_j \leq u \leq t$ (value v was obtained either directly from the R-oracle or indirectly through the coordinator).

Case 1. Suppose some value v is k-major at time τ_k. By the definition of *FavorableToss*, for any u such that $\tau_k \leq u$, *FavorableToss*$(r, u) = v$. So, if a process R-gets a value in phase k, that value is v. Note that $\bar{v}$ is not k-major at any time. By Lemma 5.12, v is $(k+1)$-locked.

Case 2. Now assume that no value is k-major at time τ_k.

Case 2.1. Suppose that no value is k-major before time τ_{k+1}. Then for any u, $\tau_k \leq u$, we have *FavorableToss*$(r, u) = 0$. By Lemma 5.12, every process p that starts phase $k+1$ before time τ_{k+1} does so with x_p set to some value that p R-got in phase k, and such value can only be 0. So all reports (and thus all proposals) sent in phase $k+1$

[5] Phase 1 is not part of any epoch.

before time τ_{k+1} are for 0. From the definition of τ_{k+1}, there are at least $n-f$ such proposals for 0 in phase $k+1$. By an argument similar to the one in the proof of Lemma 5.3, value 0 is $(k+2)$-locked.

Case 2.2. Now assume some value v is k-major before time τ_{k+1}.

Case 2.2.1. Suppose $v=0$. Since 1 is never k-major, then for any time u such that $\tau_k \le u$, we have $\mathit{FavorableToss}(r,u) = 0$. So all processes that R-get a value in phase k R-get 0. By Lemma 5.12, value 0 is $(k+1)$-locked.

Case 2.2.2. Now assume $v=1$. For any time u, $\tau_k \le u < \tau_{k+1}$, we have $\mathit{FavorableToss}(r,u)=0$. Let S be the processes that R-get a value in phase k before time τ_{k+1}; clearly, all processes in S R-get 0.

Case 2.2.2.1. Suppose $|S| \ge n/2$. Then, for any time u, $\tau_k \le u$, $\mathit{FavorableToss}(r,u)=0$. So, all processes that R-get in phase $k+1$ R-get 0. Note that $|S| \ge n/2$ implies that 1 can never be $(k+1)$-major. By Lemma 5.12, value 0 is $(k+2)$-locked.

Case 2.2.2.2. Now assume that $|S| < n/2$.

Case 2.2.2.2.1. Suppose that the coordinator of phase k does not query the R-oracle in line 20 of phase k before time τ_{k+1}. Then, for any u such that $\tau_{k+1} \le u$, we have $\mathit{FavorableToss}(r,u)=1$. So, if the coordinator queries the R-oracle in line 20 of phase k, it obtains 1 from the R-oracle. Therefore, all processes that R-get a value at or after time τ_{k+1} in phase k R-get 1. Thus, exactly $|S| < n/2$ processes R-get 0 in phase k. Since 1 is k-major, from Lemma 5.12 we conclude that value 0 can never be $(k+1)$-major. Since no process queries the R-oracle in phase $k+1$ before time τ_{k+1}, all processes that R-get a value in phase $k+1$ R-get 1. By Lemma 5.12, value 1 is $(k+2)$-locked.

Case 2.2.2.2.2. Now assume that the coordinator of phase k queries the R-oracle in line 20 of phase k before time τ_{k+1}. Then the coordinator obtains 0 from the R-oracle. So, for any $u \ge \tau_k$, we have $\mathit{FavorableToss}(r,u)=0$. Since the coordinator queries the R-oracle in line 20, it received $n-f$ suggestions for ? in line 16, and this occurred before time τ_{k+1}. Thus, $n-f$ processes have set their variable x to ? in line 13 in phase k before time τ_{k+1}. Note that if any such process starts phase $k+1$, then it R-gets a value in phase k and that value is 0, and thus, any such process starts phase $k+1$ with its variable x set to 0. Therefore, at most $n-(n-f)=f<n/2$ processes start phase $k+1$ with their variable x set to 1. So 1 can never be $(k+1)$-major. All processes that R-get in phase $k+1$ R-get 0. By Lemma 5.12, value 0 is $(k+2)$-locked. □

LEMMA 5.15 (termination with probability 1). *If the R-oracle is random, then the probability that all correct processes decide is* 1.

Proof. The lemma is proved immediately from Lemmas 5.13 and 5.14 and Corollary 5.9. □

The proof of Theorem 5.1 is now complete: Uniform validity and uniform agreement were shown in Corollaries 5.7 and 5.6, respectively. Termination was proved in Lemma 5.11, and termination with probability 1 was shown in Lemma 5.15. □

From the proof of Lemma 5.13, it is easy to see that the expected number of rounds for termination is $O(2^{2n})$. However, it can be shown that, as in [4], termination is reached in constant expected number of rounds if $f = O(\sqrt{n})$. In section 7, we outline a similar hybrid algorithm that terminates in constant expected number of rounds, even for $f = O(n)$.

$c \leftarrow p_0$ {p_0 is the first coordinator}
if $p = c$ **then send** $(E, 0, v_p)$ to all processes {if p is the first coordinator}

wait until receive $(E, 0, v\_coord)$ **from** c **or** $c \in$*FD-oracle* {query FD-oracle}
if received $(E, 0, v\_coord)$
then send $(P, 0, v\_coord)$ **to** all processes
else send $(P, 0, ?)$ **to** all processes

wait for messages of the form $(P, 0, *)$ **from** $n - f$ processes {"$*$" can be 0, 1 or ?}
if received at least $f + 1$ $(P, 0, v)$ with the same $v \neq ?$ **then** decide v
if received at least one $(P, 0, v)$ with $v \neq ?$ **then** $x \leftarrow v$

FIG. 6.1. *Optimization for the hybrid algorithm.*

6. An optimization. The algorithm in Figure 4.1 was designed to be simple rather than efficient, because our main goal here is to demonstrate the viability of a "robust" hybrid approach (one in which termination can occur in more than one way: by "good" failure detection or by "good" random draws). The following optimization suggests that such hybrid algorithms can also be efficient in practice.

In many systems, failures are rare, and failure detectors can be tuned to seldom make mistakes (i.e., erroneous suspicions). The algorithm in Figure 4.1 can be optimized to perform particularly well in such systems. The optimized version ensures that all correct processes decide by the end of two asynchronous rounds when the first coordinator does not crash and no process erroneously suspects it.[6]

This optimization is obtained by inserting some extra code between lines 2 and 3 of the hybrid algorithm. This code, given in Figure 6.1, consists of a phase (phase 0) with two asynchronous rounds. In the first round, p_0 sends a message to all processes; in the second round, every process sends a message to all processes. We claim that (1) the optimization code preserves the correctness of the original algorithm; and (2) processes decide quickly in the absence of failures and erroneous suspicions. To see (1), note the following:

1. No correct process blocks during the execution of the optimization code (phase 0); i.e., all correct processes start phase 1.

2. Any process p that starts phase 1 does so with x_p set to the initial value of some process.

3. If some process decides v in phase 0, then v is 1-locked. Thus, (by Corollary 5.9) all correct processes decide v in phase 1.

To see (2), note that if p_0 is correct and no process suspects p_0, then all processes wait for its estimate v and propose v in phase 0; so every process receives $n - f$ proposals for v and, thus, decides v in phase 0. Thus, we have the following theorem.

THEOREM 6.1. *Theorem* 5.1 *holds for the optimized hybrid algorithm. Moreover, in executions with no crashes or false suspicions, all processes decide in two rounds.*

7. Discussion. In practice, many systems are well behaved most of the time: few failures actually occur, and most messages are received within some predictable time. Failure detector based algorithms (whether "pure" ones like in [7] or hybrid ones like in this paper) are particularly well suited to take advantage of this: (time-out based) failure detectors can be tuned so that the algorithms perform optimally

[6] Actually, decision occurs in two rounds even if up to $n - 2f - 1$ processes erroneously suspect it.

when the system behaves as predicted, and performance degrades gracefully as the system deviates from its "normal" behavior (i.e., if failures occur or messages take longer than expected). For example, the optimized version of our hybrid algorithm solves consensus in only two asynchronous rounds in the executions that are most likely to occur in practice, namely, runs with no failures or erroneous suspicions.

The above discussion suggests that using this hybrid approach is better than using the randomized approach alone. In fact, randomized consensus algorithms for asynchronous systems tend to be inefficient in practical settings.[7] Typically, their performance depends more on "luck" (e.g., many processes happen to start with the same initial value or happen to draw the same random bit) than on how "well behaved" the underlying system is (e.g., on the number of failures that actually occur during execution). The fact that randomized algorithms are extremely "robust," i.e., they do not depend on how the system behaves, may also be an inherent source of inefficiency.

Note that our hybrid algorithm terminates with probability 1 even if the FD-oracle is completely inaccurate (in fact, even if every process suspects every other process all the time). So it is more robust than algorithms that are simply failure detector based.

An important remark is now in order about the expected termination time of our hybrid algorithm. We developed this algorithm by combining Ben-Or's randomized algorithm [4] with the failure detection ideas in [7]. We selected Ben-Or's algorithm because it is the simplest and thus the most appropriate to illustrate this approach, even though its expected number of rounds is exponential in n for $f = O(n)$. By starting from an efficient randomized algorithm, due to Chor, Merritt, and Shmoys [9], we can obtain a hybrid algorithm that terminates in constant expected number of rounds, as we now briefly explain.

Roughly speaking, the randomized asynchronous consensus algorithm in [9] is obtained from Ben-Or's algorithm by replacing each coin toss with the toss of a "weakly global coin" computed by a *coin_toss* procedure. We can do exactly the same: replace the coin tosses of the algorithm in Figure 4.1 with those obtained by using the *coin_toss* procedure. More precisely, in each phase, every process (a) invokes this procedure between the second and third rounds (i.e., between lines 13 and 14) to obtain a random bit, and (b) uses this random bit rather than querying the R-oracle (in lines 20 and 25).[8]

As in [9], this modified hybrid algorithm terminates[9] in constant expected number of rounds for $f \leq n\ (3 - \sqrt{5})\ /\ 2 \approx 0.38n$. But also as in [9], and in contrast to the algorithm in section 4, it assumes that the adversary cannot see the internal state of processes or the content of messages. With the optimization of Figure 6.1, this modified hybrid algorithm also terminates in two rounds in failure-free and suspicion-free runs.

8. Related work. The idea of combining randomization with a deterministic consensus algorithm appeared in [15] and was further developed in [25]. These works, however, assume that the system is *synchronous* and do not use failure detectors.

Dolev and Malki were the first to combine randomization and unreliable failure

[7] Algorithms that assume that processes a priori agree on a long sequence of random bits [22, 24] are more efficient than others. But this assumption may be too strong for some systems.

[8] As in [9], another simple modification is necessary: the addition of a "synchronization round" just before the *coin_toss* procedure. In this round, processes broadcast "wait" messages, then wait until $n - f$ such messages are received.

[9] Provided, of course, that the FD-oracle satisfies strong completeness.

detection to solve consensus in asynchronous systems with process crashes [12]. That work differs from ours in many respects:

1. In contrast to our algorithm, those in [12] require that both R-oracle and FD-oracle always work correctly.

2. In our hybrid algorithm, safety is always preserved; even if the failure detector continuously misbehaves, no two processes ever decide differently. In contrast, with the hybrid algorithms given in [12], if at any point the failure detector loses its accuracy property, processes may decide differently.

3. Our goal is to use randomization to improve failure detector based algorithms. We use randomization as a "back-up" to ensure termination in the occasional "bad" periods when the failure detector loses its accuracy property.

Two goals of [12] are to use failure detection to increase the resiliency of randomized consensus algorithms, and to ensure their deterministic termination. The hybrid consensus algorithms given in [12] achieve the first goal by increasing the resiliency from $f < n/2$ to $f < n$, but not the second one. It is stated, however, that a future version of the paper will give an algorithm that achieves both goals.

4. The two hybrid algorithms in [12] use failure detectors that are stronger than $\diamond S$ (the failure detector that we use). The first algorithm—which supposes that the same sequence of random bits is shared by all the processes, as in [22]—assumes that some correct process is *never* suspected by any process. The second algorithm—which drops the assumption of a common sequence of bits—assumes that $\Omega(n)$ correct processes are never suspected by any process. Both algorithms reach consensus in constant expected time.

Acknowledgments. We are grateful to Vassos Hadzilacos; some of our proofs are based on his lecture notes. We would also like to thank the anonymous referees for their valuable comments.

AVERAGE PROFILE OF THE GENERALIZED DIGITAL SEARCH TREE AND THE GENERALIZED LEMPEL–ZIV ALGORITHM*

GUY LOUCHARD†, WOJCIECH SZPANKOWSKI‡, AND JING TANG§

Abstract. The goal of this research is threefold: (i) to analyze generalized digital search trees, (ii) to derive the average profile (i.e., phrase length) of a generalization of the well-known parsing algorithm due to Lempel and Ziv, and (iii) to provide analytic tools to analyze asymptotically certain partial differential functional equations often arising in the analysis of digital trees. In the generalized Lempel–Ziv parsing scheme, one partitions a sequence of symbols from a finite alphabet into phrases such that the new phrase is the shortest substring seen in the past by at most $b-1$ phrases ($b=1$ corresponds to the original Lempel–Ziv scheme). Such a scheme can be analyzed through a generalized digital search tree in which every node is capable of storing up to b strings. In this paper, we investigate the depth of a randomly selected node in such a tree and the length of a randomly selected phrase in the generalized Lempel–Ziv scheme. These findings and some recent results allow us to compute the average redundancy of the generalized Lempel–Ziv code and compare it to the ordinary Lempel–Ziv code, leading to an optimal value of b. Analytic techniques of (precise) analyses of algorithms are used to establish most of these conclusions.

Key words. generalized Lempel–Ziv parsing scheme, generalized digital search trees, average redundancy, partial differential functional equations, singularity analysis, asymptotic expansions, depoissonization, Mellin transform

1. Introduction.

The heart of several universal data compression schemes is the parsing algorithm due to Lempel and Ziv [23] (e.g., it is used in the UNIX `compress` command and in a CCITT standard for data compression for modems). It is a dictionary-based algorithm that partitions a sequence into phrases (blocks) of variable sizes such that a new block is the shortest substring not seen in the past as a phrase. Such a new phrase is coded by giving the location of the prefix (that occurred before as a phrase) and the value of the last symbol; that is, the Lempel–Ziv code consists of pairs $(\texttt{pointer}, \texttt{symbol})$ (details can be found in many textbooks, e.g., [3, 36]). For example, the sequence `ababbababaaaaaaaaac` is parsed into (`a`)(`b`)(`ab`)(`ba`)(`bab`)(`aa`)(`aaa`)(`aaaa`)(`c`), and its code becomes `0a0b1b2a4b1a6a7a0c` (e.g., the pair `6a` indicates that this phrase (`aaa`) consists of the sixth phrase as a prefix that occurred before, appended by `a`). Observe that there is no need for a separator between phrases. Let us compute the length of this code in bits, assuming a ternary alphabet $\Sigma = \{\texttt{a}, \texttt{b}, \texttt{c}\}$. There are nine phrases; thus we need up to four $(= \lceil \log_2 9 \rceil)$ bits to code each pointer. Every terminal symbol requires two $(= \lceil \log_2 3 \rceil)$ bits and there are nine phrases in the code; hence the total length of the code is $9 \cdot 4 + 9 \cdot 2 = 54$ bits.

It is known that the original Lempel–Ziv scheme does not cope very well with some sequences; e.g., those containing a long string of repeated symbols. To somewhat remedy this situation, Louchard and Szpankowski [27] introduced a generalization of the Lempel–Ziv parsing scheme: It parses a sequence into phrases such that the next phrase is the shortest phrase seen in the past by *at most* $b-1$ phrases ($b=1$ corresponds to the original Lempel–Ziv algorithm). For example, the sequence above is parsed with $b=2$ as follows: (a)(b)(a)(b)(ba)(ba)(baa)(aa)(aa)(aaa)(c), which has seven *distinct* phrases and eleven phrases. The code for this new algorithm consists of either (i) (pointer, symbol) when pointer refers to the *first* previous occurrence of the prefix of the phrase and symbol is the value of the last symbol of this phrase or (ii) just (pointer) if the phrase has occurred as a whole previously (i.e., it is the second, third, ..., or bth occurrence of this phrase). For example, the code for the previously parsed sequence becomes, for $b=2$, 0a0b122a33a1a55a0c (e.g., the phrase 2a occurs for the first time as a new phrase hence 2 refers to the second distinct phrase appended by a, while code 5 represents a phrase that has its second occurrence as the fifth distinct phrase). Observe that this code is of length 47 bits since there are 11 phrases, each requiring up to $\lceil \log_2 7 \rceil = 3$ bits, and seven symbols needing 14 additional bits (i.e., $47 = 11 \cdot 3 + 7 \cdot 2 = 47$). We saved 7 bits! But the reader may verify that the same sequence requires only 46 bits for $b=3$ (so only 1 additional bit is saved), while for $b=4$ the bit count increases again to 52. This example suggests that $b=3$ is (at least local) optimum for the above sequence. Can one draw similar conclusions "on average" for a typical sequence (i.e., generated randomly)? We shall provide an answer to this and other questions in this paper.

Our goal is to investigate the probabilistic behavior of a *typical phrase length*, that is, the length of a randomly selected phrase. As already observed in Louchard and Szpankowski [26] (cf. [15]), the Lempel–Ziv algorithm can be modeled in two ways, namely, as a *digital tree model* or a *Lempel–Ziv model*. In the former, one constructs the Lempel–Ziv sequence from m (probabilistically) independent strings (of possibly infinite lengths). For example, let $m=4$ sequences be given: $X_1 = 0000\ldots$, $X_2 = 1010\ldots$, $X_3 = 1111\ldots$, and $X_4 = 0101\ldots$. Then, for $b=1$ the Lempel–Ziv sequence (0)(1)(11)(01) is of length $L_4 = 6$ and a typical (i.e., randomly selected) phrase is of average length $1\frac{1}{2}$. In the Lempel–Ziv model there is only *one sequence* of fixed length, say, n, and one partitions the sequences according to the Lempel–Ziv algorithm as described above. Clearly, these models are related as already observed in [15, 26]. We shall study both models in this paper.

Let us have a closer look at the *digital tree model* (cf. [26] for a more detailed description). To justify its name we shall show how the Lempel–Ziv parsing (of m strings) can be constructed by building an associated digital search tree (cf. [6, 20, 29]). In this case, we consider an extension of digital search trees called *b-digital search tree*, or (for short) b-DST (cf. [8, 29]) which is built from a fixed number, say, m, of strings. Hereafter, we consider only the binary alphabet $\Sigma = \{0, 1\}$, but an extension to any finite alphabet is straightforward. This tree is constructed as follows: In addition to m given strings, we consider b empty strings that are stored in the root of the tree. The remaining m strings are stored in an available space in a node which is not full, i.e., containing less than b strings. The search for an available space follows the prefix structure of a string. The rule is simple: if the next symbol in a string is 1 we move to the left; otherwise we move to the right until either we find a node with less than b strings or, if all nodes are full on this path, we create a new node. The details of such a construction can be found in [8, 20, 29].

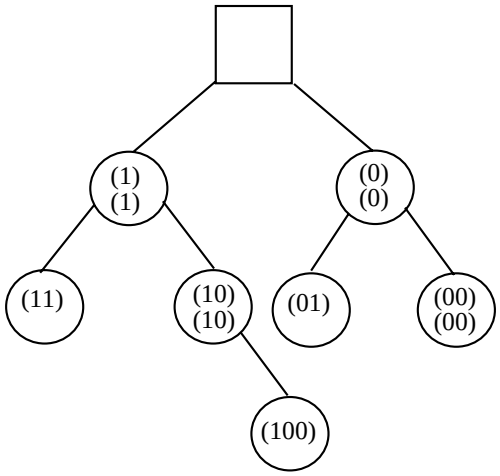

FIG. 1. *A* 2*-digital search tree representation of the generalized Lempel–Ziv parsing for the string* 1100101000100010011.

Now, we briefly discuss the *Lempel–Ziv model*. We recall that now we deal with a single sequence of fixed length n which is partitioned according to the Lempel–Ziv algorithm. As already discussed in [1, 26, 15], digital trees also can be used to construct the Lempel–Ziv parsing. Indeed, let us first append the string with b empty phrases that are stored in the root of the associated b-digital search tree. All other phrases are stored in internal nodes and they are constructed on-line in the course of building the associated b-DST. When a new phrase is created, the search starts at the root and proceeds down the tree as directed by the input symbols of the string exactly in the same manner as in the b-digital tree construction until either we find a node with less than b phrases or we create a new node. In Figure 1 we show the 2-DST constructed from the sequence 1100101000100010011. Observe that for a fixed length string, the number of nonroot nodes in the associated digital tree is a random variable that is equal to the number of distinct phrases of the generalized Lempel–Ziv scheme.

In this paper, we study both models in a probabilistic framework in which every string is generated according to the Bernoulli model; that is, *symbols are generated in an independent manner with* 0 *and* 1 *occurring, respectively, with probability* p *and* $q = 1-p$. If $p = q = 0.5$, the Bernoulli model is *symmetric*; otherwise it is *asymmetric*.

Digital trees appear in a variety of computer and communications applications including searching, sorting, dynamic hashing, codes, conflict resolution protocols for multiaccess communications, and data compression (cf. [6, 8, 20, 29, 26, 27, 15, 39]). Thus, better understanding of their behavior is desirable and could lead to some algorithmic improvements. One parameter that is of interest to these applications is the depth of a randomly (uniformly) selected node (i.e., the length of the path from the root to the chosen node). It can represent the search time for a key word or the length of a phrase in the generalized Lempel–Ziv algorithm (cf. Figure 1). In this paper, we fully characterize the probabilistic behavior of the depth in a b-digital search tree under the digital tree model. We derive asymptotic expansions for the mean and the variance, as well as for large deviations and the limiting distribution of the depth. In particular, we prove that the depth appropriately normalized is asymptotically normally distributed in the asymmetric Bernoulli model.

The *Lempel–Ziv model* is somewhat more intricate since there is some unpleasant dependency between consecutive phrases. Fortunately, Louchard and Szpankowski [26] proved that this dependency is not too strong (cf. (24) in section 2 of this paper), and one can infer the probabilistic behavior of the length of a randomly selected phrase from the depth of a randomly selected node in a b-DST built from a fixed number of nodes (i.e., in the digital tree model). In addition, using another recent finding of Louchard and Szpankowski [28] (concerning redundancy of the ordinary Lempel–Ziv code, i.e., for $b = 1$; cf. Savari [35]), we are able to compute the average redundancy of the generalized Lempel–Ziv code. The average redundancy measures how far the code is from being optimal for a given source of information (thus it requires a precise asymptotic expansion for the average length of the Lempel–Ziv sequence in the digital tree model). This allows us to determine theoretically the optimal value of b that minimizes the average length of the generalized Lempel–Ziv code (cf. Theorem 2.3 and the discussion thereafter).

We believe our contribution is also of a methodological nature: We establish our results in a consistent manner by a technique that belongs to the toolkit of the analytic analysis of algorithms. More precisely, Flajolet and Richmond [8] had already observed that b-digital trees are harder to analyze than ordinary ($b = 1$) digital search trees. The difficulty boils down ultimately to a solution of the following general recurrence in x_n. Let $x_1, \ldots, x_b$ be given. Then, for a given sequence a_n and a constant u,

$$x_{n+b} = a_n + u \sum_{k=0}^{n} \binom{n}{k} p^k (1-p)^{n-k} (x_k + x_{n-k}), \qquad n \geq 0 \tag{1}$$

(cf. recurrence (4) in section 2), which can be reduced to the following partial differential functional equation in terms of the Poisson generating function of x_n defined as $\widetilde{X}(z) = \sum_{n\geq 0} x_n \frac{z^n}{n!} e^{-z}$:

$$\sum_{i=0}^{b} \binom{b}{i} \frac{\partial^i \widetilde{X}(z)}{\partial z^i} = \widetilde{A}(z) + u(\widetilde{X}(pz) + \widetilde{X}(qz)), \tag{2}$$

where $q = 1 - p$ (cf. (6) in section 2 and (30) and(31) in section 3).

The above recurrence can be solved exactly for $b = 1$ (cf. [38]), but attempts at extensions to $b > 1$ have partially failed. Flajolet and Richmond [8] (cf. also [12]) used a new technique to solve this recurrence for $p = 1/2$ (i.e., symmetric Bernoulli model). Unfortunately, this technique seems to be restricted to the symmetric Bernoulli model since some sums involved in the asymmetric Bernoulli model (i.e., $p \neq 1/2$) cease to be harmonic sums. To circumvent this difficulty we devise another approach that is asymptotic in nature. In order to accomplish this, we use some other techniques such as analytical poissonization and depoissonization, singularity analysis, and Mellin transforms.

In passing, we should mention that differential functional equations such as (2) were discussed as early as 1924 by Flamant [10], who provided an iterative solution. Our approach is completely different, and we present an asymptotic solution as $z \to \infty$ (which suffices to obtain an asymptotic solution of the original recurrence). Finally, during the course of the analysis we face a problem of numerical evaluation of some constants involving Mellin transforms. These constants are somewhat important since they carry the information about the dependence of b on the final solution. We propose here a method to evaluate numerically such constants (cf. section 3.3) that is of its

own interest and can be applied to other problems. We should mention that similar numerical problems can be encountered in other analyses (cf. [18]).

Digital search trees for $b = 1$ have been analyzed in the past in the case of a *fixed* number of independent strings (cf. [6, 14, 19, 20, 21, 24, 31, 32, 33, 38, 39]). Much less is known about b-digital search trees. As mentioned, the first nontrivial analysis of the size of such trees for the symmetric Bernoulli model was proposed by Flajolet and Richmond [8]. The variance of the size and the internal path length—still for the symmetric model—was discussed by Hubalek [12]. To the best of our knowledge, b-DST have not yet been analyzed for the asymmetric Bernoulli model. In a companion paper, Louchard [25] presents an alternative probabilistic approach to obtain some of our results. He gets the limiting distribution (without the rate of convergence) but not the large deviation results and precise evaluation of the moments (see section 4.2 for the derivation of the asymptotic distribution in the symmetric case using this approach). In [25] Louchard also evaluates the average number of nodes in a b-digital search tree, thus directly extending the Flajolet and Richmond result [8] to the asymmetric Bernoulli model.

For the original Lempel–Ziv parsing algorithm ($b = 1$) mostly only first-order asymptotics (e.g., leading terms in almost sure convergence) have been analyzed (cf. [41, 22, 23]), with exceptions being the work by Aldous and Shields [1] and recent works of Louchard and Szpankowski [26] and Jacquet and Szpankowski [14] (see also [30, 35, 39]). Finally, Gilbert and Kadota [11] analyzed numerically the number of possible messages composed of m parsed phrases, as well as the length of a phrase in the digital tree model.

The paper is organized as follows: In the next section, we present our main results concerning the digital tree model and the generalized Lempel–Ziv scheme. Proofs are deferred to sections 3 and 4, where in the former we treat the asymmetric Bernoulli model and in the latter the symmetric case. The proofs are analytic with the exception of the distribution in the symmetric Bernoulli model discussed in section 4.2.

2. Main results. We consider a b-digital tree built over m statistically independent words. Let $D_m(i) = D_i(i)$ be the depth of the ith string (of infinite length) in such a tree, that is, the length of a path from the root to a node containing the ith string. In a variety of applications, one is interested in the *typical* depth D_m, defined as the depth of a randomly selected string; that is,

$$\Pr\{D_m = k\} = \frac{1}{m}\sum_{i=1}^{m} P\{D_m(i) = k\}. \tag{3}$$

As argued in Louchard and Szpankowski [26], the depth D_m is closely related to the length of a randomly selected phrase in the generalized Lempel–Ziv parsing scheme. We denote it D_n^{LZ}, where n is the length of the string to be parsed. Our goal is to study moments and distribution of D_m and D_n^{LZ} and their dependence upon parameter b.

2.1. Digital tree model. We now concentrate on the depth D_m in a b-DST built over a *fixed* number, say, m, of independent strings generated according to an asymmetric Bernoulli model (with 0 and 1 occurring, respectively, with probability p and $q = 1-p$). Let B_m^k be the *expected* number of strings on level k of a randomly built b-digital search tree. From the above we immediately obtain $\Pr\{D_m = k\} = B_m^k/m$; thus one can alternatively study the average B_m^k, which is further called *the average profile*. Let $B_m(u) = \sum_{k\geq 0} B_m^k u^k$ be the generating function of the average profile.

A digital tree is a recursive structure. Suppose that there are $m+b$ strings to store. The root of such a tree contains b strings, and the remaining m strings are split between the left subtree and the right subtree. If i strings go to the left subtree, then its average profile is characterized by $uB_i(u)$, while $uB_{m-i}(u)$ is the generating function for the right subtree. Finally, the probability that i strings end up in the left subtree is equal to the probability that i out of m strings start with 0, and this is equal to $\binom{m}{i}p^iq^{m-i}$. Thus we have the following recurrence for $m \geq 0$:

$$B_{m+b}(u) = b + u\sum_{i=0}^{m}\binom{m}{i}p^iq^{m-i}\left(B_i(u) + B_{m-i}(u)\right) \tag{4}$$

with initial conditions

$$B_i(u) = i \qquad \text{for} \qquad i = 0, 1, \ldots, b-1. \tag{5}$$

For $b = 1$ the above recurrence can be solved exactly as discussed in [37] (cf. [26]). Unfortunately, for $b > 1$ the recurrence becomes too complicated and no exact solution is known. This had been noted by Flajolet and Richmond [8] who developed a special technique to deal with such recurrences for $b > 1$. Unfortunately again, the technique of [8] was designed for the symmetric Bernoulli model and becomes very intricate for the asymmetric Bernoulli models. The reason is that some sums occurring in the solution of (4) cease to become harmonic sums in the asymmetric case.

In view of this, we approach the general recurrence (4) from a different "angle." First of all, we "poissonize" the model; that is, we introduce the Poisson transform (or Poisson generating function) as

$$\widetilde{B}(u,z) = \sum_{i=0}^{\infty} B_i(u)\frac{z^i}{i!}e^{-z}.$$

Then, the recurrence becomes a slightly more manageable differential functional equation, namely,

$$\left(1+\frac{\partial}{\partial z}\right)^b \widetilde{B}(u,z) = b + u\left(\widetilde{B}(u,pz) + \widetilde{B}(u,qz)\right), \tag{6}$$

where $(1+\frac{\partial}{\partial z})^b f(z) \stackrel{\text{def}}{=} \sum_{i=0}^{b}\binom{b}{i}\frac{\partial^i f(z)}{\partial z^i}$. We shall study $\widetilde{B}(u,z)$ for $z \to \infty$ in a cone around the real axis and u in a compact set around $u = 1$. This will suffice to recover asymptotics of $B_m(u)$, as discussed in section 3.2.

In passing, we should point out that $\widetilde{B}(u,z)$ represents the average profile in the so-called Poisson model in which the fixed number of strings is replaced by a random number of strings according to a Poisson distribution with mean z. To take full advantage of this new model, however, we shall postulate that z is a complex variable. After "depoissonization" (cf. section 3.2) we expect that $B_m(u) \sim \widetilde{B}(u,m)$.

In the next section, we use the Mellin transform [9], singularity analysis [7], and the depoissonization lemma [16, 34] to solve (6) and to prove the following main result. Below, we write log for natural logarithm.

THEOREM 2.1 (asymmetric Bernoulli model).

(i) *Let D_m be the typical depth in a b-digital tree built over m statistically independent strings under the* asymmetric *Bernoulli model. Then*

$$ED_m = \frac{1}{h_1}\log m + \frac{1}{h_1}\left(\frac{h_2}{2h_1} + \gamma - 1 - H_{b-1} - \Delta(b,p) + \delta_1(m,b)\right) + O\left(\frac{\log m}{m}\right), \tag{7}$$

$$\text{Var } D_m = \frac{h_2 - h_1^2}{h_1^3}\log m + O(1), \tag{8}$$

where $h_1 = -p\log p - q\log q$ is the entropy of the Bernoulli(p) distribution, $h_2 = p\log^2 p + q\log^2 q$, and $\gamma = 0.577\ldots$ is the Euler constant, while $H_{b-1} = \sum_{i=1}^{b-1}\frac{1}{i}$, $H_0 = 0$ are harmonic numbers. The constant $\Delta(b,p)$ can be computed as follows (see Table 1, *section* 3.3, *for numerical values):*

$$\Delta(b,p) = \sum_{n=2b+1}^{\infty} \bar{f}_n \sum_{i=1}^{b} \frac{(i+1)b!}{(b-i)!n(n-1)\ldots(n-i-1)} < \infty, \tag{9}$$

where $\bar{f}_n$ is given recursively by

$$\begin{cases} f_{m+b} = m + \displaystyle\sum_{i=0}^{m}\binom{m}{i}p^i q^{m-i}(f_i + f_{m-i}), & m > 0, \\ f_0 = f_1 = \cdots = f_b = 0, & \\ \bar{f}_{m+b} = f_{m+b} - m > 0, & m \geq 1. \end{cases}$$

Finally, $\delta_1(x,b)$ is a fluctuating function with a small amplitude (cf. (48)*) when $(\log p)/(\log q)$ is rational, and for any fixed b $\lim_{x\to\infty}\delta_1(x,b) = 0$ otherwise.*

(ii) *Let $G_m(u)$ be the probability generating function of D_m (i.e., $G_m(u) = Eu^{D_m}$), $\mu_m = ED_m$, and $\sigma_m = \sqrt{\text{Var } D_m}$. Then, for complex τ,*

$$e^{-\tau\mu_m/\sigma_m}G_m(e^{\tau/\sigma_m}) = e^{\frac{\tau^2}{2}}\left(1 + O\left(\frac{1}{\sqrt{\log m}}\right)\right). \tag{10}$$

Thus, the limiting distribution of $\frac{D_m - \mu_m}{\sigma_m}$ is normal, and it converges in moments (i.e., in mean of any order) to the appropriate moments of the standard normal distribution. Also, there exist positive constants A and $\alpha < 1$ (that may depend on p and b) such that, uniformly in k for large m,

$$\Pr\left\{\left|\frac{D_m - c_1\log m}{\sqrt{c_2\log m}}\right| > k\right\} \leq A\alpha^k, \tag{11}$$

where $c_1 = 1/h_1$ and $c_2 = (h_2 - h_1^2)/h_1^3$.

The *symmetric* Bernoulli model must be treated differently since we shall prove below that Var $D_m = O(1)$, and hence a central limit theorem may not hold. We use the Flajolet and Richmond [8] technique to establish an asymptotic distribution in this case (cf. section 4.1). Using a probabilistic approach we also establish the exact distribution of D_m (cf. section 4.2). Both results are summarized in Theorem 2.2 below.

Before we present our findings, we must introduce some additional notation. Let

$$Q(t) = \prod_{k=0}^{\infty}(1 + t2^{-k}), \tag{12}$$

and for integer s and complex z we define

$$H(s) = \frac{\partial^s}{\partial z^s}\left(\frac{1}{Q^b(-z)}\right)\Big|_{z=1}; \tag{13}$$

$$R_i(s) = -\frac{\partial^s}{\partial z^s}\left(\prod_{k=1}^{i}(1 - z2^k)^{-b}\right)\Big|_{z=1}, \qquad R_0(s) = -1. \tag{14}$$

THEOREM 2.2 (symmetric Bernoulli model).

(i) *Let us consider the symmetric Bernoulli model (with $p = q = 1/2$). The mean value ED_m is given by* (7)*, while the variance becomes*

$$\begin{aligned}\operatorname{Var} D_m = {} & \frac{1}{12} + \frac{1}{L^2}\left(1 + \frac{\pi^2}{6}\right) + \frac{1}{L^2}\left(J''(0) - (J'(0))^2\right) \\ & + \frac{1}{L}\delta_2(\log_2 m) - [\delta_1^2]_0 + O\left(\frac{\log^2 m}{m}\right),\end{aligned} \tag{15}$$

where $L = h_1 = \log 2$. Then

$$J'(0) = \int_0^1 \left(\frac{1}{Q(t)^b} - 1\right)\frac{dt}{t} + \int_0^\infty \frac{1}{Q(t)^b}\frac{dt}{t} \tag{16}$$

and

$$J''(0) = -\frac{\pi^2}{3} + 2\int_0^1 \left(\frac{1}{Q(t)^b} - 1\right)\frac{\log t}{t}dt + 2\int_0^\infty \frac{1}{Q(t)^b}\frac{\log t}{t}dt, \tag{17}$$

where $J(s)$ is defined in (68) *of section* 4.1*, $\delta_2(\cdot)$ is a periodic function with mean* 0 *and period* 1*, and $[\delta_1^2]_0$ is a very small constant (e.g., $[\delta_1^2]_0 \le 10^{-10}$ for $b = 1$). More precisely, as in Hubalek* [12] *with $\chi_k = 2k\pi i/L$ for $k = \pm 1, \pm 2, \ldots,$*

$$[\delta_1^2]_0 = \frac{1}{L^2}\sum_{k\ne 0}\frac{I(\chi_k)I(-\chi_k)}{\Gamma(2 + \chi_k)\Gamma(2 - \chi_k)},$$

where $\Gamma(\cdot)$ is Euler's gamma function, and

$$I(\chi_k) = \frac{1}{\chi_k} + \int_0^1 \left(Q^{-b}(t) - 1\right)t^{\chi_k - 1}dt + \int_1^\infty Q^{-b}(t)t^{\chi_k}dt,$$

where $I(s)$ is defined in (67) *of section* 4.1.

(ii) *The exact distribution of D_m is given by*

$$\begin{aligned}m\Pr\{D_m \le j\} = {} & b - \frac{1}{(b-1)!}\sum_{k=1}^{j}(1 - 2^k)^{-b} \\ & \times \frac{\partial^{b-1}}{\partial z^{b-1}}\left(\frac{z^{2b}}{(z-1)^2}(z^{-b} - z^{-m})\prod_{1\le\ell\le j:\ell\ne k}\left(\frac{2^{-\ell}z}{1 - (1 - 2^{-\ell})z}\right)^b\right)\Bigg|_{z=(1-2^{-k})^{-1}}\end{aligned} \tag{18}$$

for any positive integer j.

(iii) *Now let* $j = \lfloor \log_2 m \rfloor + \kappa$ *for a fixed integer* κ*, and define* $\{\log_2 m\} = \log_2 m - \lfloor \log_2 m \rfloor$*. Then the "asymptotic distribution" of* D_m *can be expressed as*

$$\lim_{m\to\infty} \Big| \Pr\{D_m \le \lfloor \log_2 m \rfloor + \kappa\} - \sum_{\substack{\ell+s+t=b-1 \\ \ell,s,t \,\ge\, 0}} \frac{(s+1)}{\ell!} \sum_{i=0}^{\infty} \frac{K_i(t) e^{-2^{-(\kappa-\{\log_2 m\}-i)}}}{2^{-(\ell-1)(i-(\kappa-\{\log_2 m\}))}}$$

$$- \sum_{s+t=b-1} (s+1) \sum_{i=0}^{\infty} K_i(t) \left(e^{-2^{-(\kappa-\{\log_2 m\}-i)}} - 1 \right) 2^{\kappa-\{\log_2 m\}-i} \Big| = 0,$$

where $K_i(t) = \sum_{s_1+s_2=t} \frac{(-1)^t}{s_1! s_2!} R_i(s_2) H(s_1)$*. Observe that the limiting distribution of* D_m *does not exist due to the term* $\{\log_2 n\}$*.*

In passing it should be noted that the "asymptotic distribution" established in part (iii) above resembles a "mixture" of double exponential distributions (i.e., $e^{-2^{-x}}$), as in the case $b = 1$. An intuitive explanation for different behavior in the symmetric case is given in [26], but this follows basically from the fact that Var $D_m = O(1)$. We should also point out that numerical values of $J'(0)$ and $J''(0)$ can be found in Hubalek [12].

2.2. Lempel–Ziv model. The situation is similar, but *not* the same, in the *Lempel–Ziv model*, in which a sequence of *fixed length* n is parsed into random number of phrases. Let M_n denote the number of *full* phrases produced by the algorithm (the last incomplete phrase is ignored). We should mention that for $b > 1$ the number of full *distinct* phrases, M'_n, is not equal to the total number of full phrases M_n. Also let $D_n^{LZ}(i)$ be the length of the ith phrase in the Lempel–Ziv model, where $1 \le i \le M_n$. By the *typical* phrase length D_n^{LZ} we mean the length of a randomly selected phrase (i.e., conditioned on M_n each phrase has probability $1/M_n$ of being selected).

The typical depth D_n^{LZ} in the Lempel–Ziv model can be estimated as follows (cf. [26]):

$$\Pr\{D_n^{LZ} = k\} = \sum_{m=m_L}^{m_U} \Pr\{D_n^{LZ} = k | M_n = m\} \Pr\{M_n = m\}, \tag{19}$$

where m_L and m_U are lower and upper bounds for the number of phrases. It is easy to see that there exist constants $\alpha_1 > 0$ and $\alpha_2 < \infty$ such that $m_L = \alpha_1 \sqrt{n/b} \le M_n \le \alpha_2 (n/b)/\log_2(n/b) = m_U$. Indeed, the minimum number of phrases occurs only for two strings: either all 0s or all 1s, and then $n = \sum_{i=1}^{M_n} D_n^{LZ}(i) \le b \sum_{i=1}^{M_n} i$, whence the lower bound $m_L = \Omega(\sqrt{n/b})$. For the upper bound, we consider a complete binary tree with the internal path length equal to n. Naturally, the number of nodes in such a tree is $O((n/b)/\log_2(n/b))$.

To estimate the probabilities appearing in (19) one seeks the limiting distribution of M_n. This is a difficult problem even for $b = 1$, and only recently Jacquet and Szpankowski [14] "cracked" it by showing that M_n appropriately normalized weakly converges to the standard normal distribution. The case $b > 1$ is still unsolved; however, the technique of [14] can handle this case, too. To see this, we first reduce the problem to another one on the digital tree model. Indeed, observe that the following relationship between M_n (Lempel–Ziv model) and $L_m = \sum_{i=1}^{m} D_m(i)$ (digital tree model) takes place:

$$M_n = \max \left\{ m : \; L_m = \sum_{i=1}^{m} D_m(i) \le n \right\},$$

which immediately implies

$$\Pr\{M_n \geq m\} = \Pr\{L_m \leq n\}. \tag{20}$$

The above relationship is known as the *renewal equation*, and from Theorem 17.3 of [2], we conclude the central limit theorem for M_n knowing it holds for L_m. The latter is easier to handle but far from trivial; see [14] for details.

One finds a similar situation for the case $b > 1$; thus a central limit theorem for the internal path length L_m should hold. The exponential generating function $L(z,u) = \sum_{m=0}^{\infty} Eu^{L_m} \frac{z^m}{m!}$ of the probability generating function of L_m satisfies the following partial-functional differential equation:

$$\frac{\partial^b L(z,u)}{\partial z^b} = L(pzu,u)L(qzu,u). \tag{21}$$

The arguments from [14] can be extended to $b > 1$, after some tedious labor, and one can solve (21) asymptotically . We formulate our conclusions in a form of a fact that follows from [14] but without providing any detailed derivation.

FACT 1. *Consider the asymmetric Bernoulli model. Let* $c_1 = 1/h_1$ *and* $c_2 = (h_2 - h_1^2)/h_1^3$.
(i) *The path length* L_m *in a* b*-digital search tree possesses the following limiting distribution*

$$\frac{L_m - EL_m}{\sqrt{\text{Var } L_m}} \to N(0,1), \tag{22}$$

where $N(0,1)$ *denotes the standard normal distribution,* $EL_m = mED_m$, Var $L_m = c_2 m \log m + O(m)$, *and the convergence is also in moments.*

(ii) *The number of phrases* M_n *of the generalized Lempel–Ziv parsing scheme satisfies the following*

$$\frac{M_n - EM_n}{\sqrt{\text{Var } M_n}} \to N(0,1), \tag{23}$$

where $EM_n \sim nh_1/\log n$ *and* Var $M_n \sim c_2 h_1^3 n/\log^2 n$. *Moreover, all moments of* M_n *converge to the appropriate moments of the normal distribution.*

Having settled this, we can return to evaluating the limiting distribution of the phrase length D_n^{LZ}. According to (19), one needs to estimate the conditional probability $\Pr\{D_n^{LZ} = k | M_n = m\}$. It is tempting to assume that it is equal to $\Pr\{D_m = k\}$ (the latter refers to the probability distribution of the depth in the digital tree model). But this is *untrue* due to the fact that in the Lempel–Ziv model we consider *only* those digital search trees whose internal path length is fixed and equal to n. Clearly, this restriction affects the depth of a randomly selected phrase. A mathematical form of this dependency is actually written down in (20). We can use exactly the same arguments as in Louchard and Szpankowski [26] (cf. section III-B of [26]) to show that, for $b > 1$,

$$\Pr\{D_n^{LZ} = k | M_n = m\} = \left(1 + O\left(\sqrt{(\log n)/n}\right)\right) \Pr\{D_m = k\} \tag{24}$$

holds as long as $k = O(ED_m) = O(\log m)$. This would particularly imply (using Fact 1(ii)) that, for complex ϑ,

$$Ee^{\vartheta D_n^{LZ}} \sim Ee^{\vartheta D_{nh_1/\log n}}$$

asymptotically as $n \to \infty$ (cf. [26] for details).

In summary, the second main result concerning the Lempel–Ziv model is presented below (for simplicity we formulate it only for the asymmetric case).

THEOREM 2.3. *Consider the asymmetric Bernoulli model. Let D_n^{LZ} be the length of a randomly selected phrase in the generalized Lempel–Ziv scheme that partitions a string of length n. Then*

$$\frac{D_n^{LZ} - c_1 \log(nh_1/\log n)}{\sqrt{c_2 \log(nh_1/\log n)}} \to N(0,1). \tag{25}$$

More precisely, for complex ϑ,

$$e^{-\vartheta c_1 \sqrt{\log(nh_1/\log n)}} E\left(e^{\vartheta D_n^{LZ}/\sqrt{\log(nh_1/\log n)}}\right) = e^{c_2\vartheta^2/2}\left(1 + O\left(1/\sqrt{\log(n/\log n)}\right)\right). \tag{26}$$

Furthermore, there exist two positive constants A' and $\alpha_1 < 1$ such that

$$\Pr\left\{\left|\frac{D_m^{LZ} - c_1 \log(nh_1/\log n)}{\sqrt{c_2 \log(nh_1/\log n)}}\right| > k\right\} \le A'\alpha_1^k \tag{27}$$

uniformly in k for large m, where $c_1 = 1/h_1$ and $c_2 = (h_2 - h_1^2)/h_1^3$ as before.

The symmetric Bernoulli model can be handled in a similar manner, but its formulation is too complicated to be presented in a compact form. It is described by a similar formula as for the digital tree model with m replaced by $n/\log_2 n$. Naturally, the limiting distribution does not exist as such but some limiting theorem can be formulated, as in the case of the digital tree model (cf. Theorem 2.2(iii)).

Finally, in order to find an optimal b that possibly asymptotically minimizes the generalized Lempel–Ziv code length, we shall deal with the *average redundancy* $\bar{r}_n$ defined as

$$\bar{r}_n = \frac{E\ell_n - nh_1}{n},$$

where ℓ_n is the length of the generalized Lempel–Ziv code and the expectation is taken with respect to the underlying probability measure. As explained in section 1, the data compression code for the generalized Lempel–Ziv scheme consists of pairs of numbers, one being a pointer to the previous occurrence of the prefix of the phrase and the second number either containing the last symbol of a new phrase in the case it is the first phrase among b identical phrases or otherwise being empty. Clearly, the length ℓ_n of such a code depends on two parameters, namely, the number of phrases M_n and the number of *distinct* phrases M_n', and it can be computed (for a binary alphabet) as

$$\ell_n = M_n \log M_n' + \log 2 \cdot \sum_{i=1}^{M_n} I_i, \tag{28}$$

where I_i is equal to 1 if the ith phrase consists of a previously occurring prefix and an additional symbol and 0 otherwise (in the case of a general alphabet Σ of size $|\Sigma|$ the $\log 2$ factor in the second term of (28) should be replaced by $\log|\Sigma|$). In the above, for simplicity of presentation, the length ℓ_n is expressed in nats instead of bits since we use natural logarithm $\log M_n'$ instead of $\log_2 M_n'$. We should also point out that a particular implementation of the algorithm may lead to a slightly different formula

for ℓ_n but here we ignore these differences, concentrating only on the mathematical analysis.

It is not difficult to see (especially, if one considers the associated digital tree, as discussed in section 1), that

$$E\sum_{i=1}^{M_n} I_i = EM'_n.$$

Thus, $\ell_n = E(M_n \log M'_n) + \log 2 \cdot EM'_n$. But, as in [28], we notice that $E(M_n \log M'_n) = (EM_n) \log EM'_n + O(1/\log n)$. To estimate EM_n we observe that it is related to the internal path length in the associated digital tree, and $EL_m = mED_m$ (cf. (20)). As in Louchard and Szpankowski [28], we conclude that $EM_n \sim x_n$, where x_n is a solution of $EL_{x_n} = n$; that is,

$$x_n = \frac{nh_1}{\log n}\left(1 + \frac{\log\log n}{\log n} + \frac{A - \log h_1}{\log n} + O\left(\frac{(\log\log n)^2}{\log^2 n}\right)\right).$$

Here $-A$ is h_1 times the $\Theta(1)$ term in (7) of Theorem 2.1(i); that is,

$$A = 1 + H_{b-1} + \Delta(b,p) - \frac{h_2}{2h_1} - \gamma - \delta_1(m,b).$$

In a similar fashion we can estimate EM'_n; however, one should observe that M'_n is related to the size of the associated b-DST. More precisely, if S_m is the size of a b-DST built from m strings, then $M'_n = S_{M_n} - 1$ (since we count only nonroot nodes). However, according to Flajolet and Richmond [8] (symmetric case) and Louchard [25] (asymmetric case),

$$ES_m = m\,(q_0(b) + \delta_2(m,b)) + O(1),$$

where $q_0(b)$ is a constant that can be computed explicitly. For example, Flajolet and Richmond [8] proved that

$$q_0(b) = \frac{1}{\log 2}\int_0^\infty \left(\frac{1+t}{Q(t)}\right)^b \frac{dt}{1+t},$$

where, as in (12), $Q(t) = \prod_{j=0}^\infty (1 + t2^{-j})$. In particular, $q_0(1) = 1$, and the authors of [8] computed $q_0(2) = 0.5747$, $q_0(3) = 0.4069$, and so on. For large b, one derives that $q_0(b) \sim 1/(b \log 2)$. In summary, $EM'_n \sim x_n(q_0(b) + \delta_2(n,b))$.

Putting everything together, and using the approach from [28], we finally arrive at the following formula for the average redundancy of the generalized Lempel–Ziv code:

$$\bar{r}_n(b) = h_1 \frac{1 - \gamma - \frac{h_2}{2h_1} + \Delta(b,p) + H_{b-1} + q_0(b)\log 2 + \log q_0(b) - \delta(n,b)}{\log n} + O\left(\frac{\log\log n}{\log^2 n}\right),$$

where $\delta(\cdot)$ is a fluctuating function with a small amplitude, and the other quantities are defined as above.

It may be interesting to compare the average redundancy for different values of b hoping that there exists an optimal value of b. For example, for the symmetric Bernoulli model with a binary alphabet, we obtain

$$\bar{r}_n(1) = \frac{2.27 + \delta(n)}{\log_2 n} + O\left(\frac{\log\log n}{\log^2 n}\right),$$
$$\bar{r}_n(2) = \frac{1.98 + \delta(n)}{\log_2 n} + O\left(\frac{\log\log n}{\log^2 n}\right),$$
$$\bar{r}_n(3) = \frac{1.89 + \delta(n)}{\log_2 n} + O\left(\frac{\log\log n}{\log^2 n}\right),$$
$$\bar{r}_n(\infty) = \frac{1.71 + \delta(n)}{\log_2 n} + O\left(\frac{\log\log n}{\log^2 n}\right).$$

Furthermore, some recent preliminary experimental results (cf. [13]) carried out on structured ASCII files indicate that a practical saving can be achieved for $b > 1$, and this is particularly true for large alphabets (e.g., image), as already indicated in section 1. We should point out that these experimental findings are very sensitive to implementation issues. For example, a particular implementation can add $\Omega(M_n)$ bits which contribute $\Omega(1/\log n)$ to the expected redundancy $\bar{r}_n$. Observe that the leading term of $\bar{r}_n$ is only of order $\Omega(1/\log n)$.

3. Analysis of the asymmetric Bernoulli model. In this section, we prove Theorem 2.1 concerning the digital tree model in the asymmetric Bernoulli model. After establishing recurrences for the mean and variance, we proceed to derive the asymptotics of these quantities. We first deal with the Poisson model (section 3.1), and then depoissonize the results (section 3.2). Special attention is devoted to computing a certain constant arising in the analysis (section 3.3). Finally, we show how to derive the limiting distribution for D_m (section 3.4).

3.1. Analysis of moments in the Poisson model. As defined in section 2.1, $B_m(u)$ is the generating function of the average profile B_m^k. Observe that $B_m(1) = m$, and $ED_m = B_m'(1)/m$, and $B_m''(1)/m = E\{D_m(D_m-1)\} = \mathrm{Var}D_m - ED_m + (ED_m)^2$. Thus,

$$\text{Var } D_m = \frac{B_m''(1)}{m} + \frac{B_m'(1)}{m} - \left(\frac{B_m'(1)}{m}\right)^2. \tag{29}$$

We will use the above formulas to derive asymptotics of ED_m and Var D_m as $m \to \infty$.

Our approach is analytic, and as mentioned in the previous section, we first derive the mean and the second factorial moment of the average profile in the Poisson model, that is, the first and the second derivative with respect to u at $u = 1$ of $\widetilde{B}(u, z)$. Since $\widetilde{B}(u, z)$ is analytic (jointly in u and z), one immediately obtains

$$\left(1 + \frac{\partial}{\partial z}\right)^b \widetilde{B}_u(u, z) = \left(\widetilde{B}(u, pz) + \widetilde{B}(u, qz)\right) + u\left(\widetilde{B}_u(u, pz) + \widetilde{B}_u(u, qz)\right),$$
$$\left(1 + \frac{\partial}{\partial z}\right)^b \widetilde{B}_{uu}(u, z) = 2\left(\widetilde{B}_u(u, pz) + \widetilde{B}_u(u, qz)\right) + u\left(\widetilde{B}_{uu}(u, pz) + \widetilde{B}_{uu}(u, qz)\right).$$

Let $\widetilde{B}_u(1, z) = \widetilde{X}(z)$, $\widetilde{B}_{uu}(1, z) = \widetilde{W}(z)$, which suffice to compute the mean and the variance of D_m, as previously indicated. Then

$$\left(1+\frac{\partial}{\partial z}\right)^b \widetilde{X}(z) = z + \widetilde{X}(pz) + \widetilde{X}(qz), \tag{30}$$

$$\left(1+\frac{\partial}{\partial z}\right)^b \widetilde{W}(z) = 2\left(\widetilde{X}(pz) + \widetilde{X}(qz)\right) + \left(\widetilde{W}(pz) + \widetilde{W}(qz)\right). \tag{31}$$

Our goal is now to solve (30) and (31) asymptotically (as $z \to \infty$ in a cone around $\Re(z) > 0$). It is well known that equations like these are amiable to attack by the Mellin transform. To recall, for a function $f(x)$ of real x, we define its Mellin transform $F(s)$ as

$$F(s) = \mathcal{M}[f(t); s] = \int_0^\infty f(t) t^{s-1} dt.$$

In some of our arguments (e.g., depoissonization in section 3.2 and singularity analysis in section 4.1), we could use either Mellin transform of a complex variable function $f(z)$ or an analytic continuation argument. It is known (cf. [5, 16]) that as long as $\arg(z)$ belongs to some cone around the real axis, the Mellin transform $F(s)$ of a function $f(x)$ of a real argument and its corresponding function of a complex argument is the same. Therefore, we work most of the time with the Mellin transform of a function of real variable as defined above.

Now let

$$X(s) = \mathcal{M}[\widetilde{X}(t); s] = \Gamma(s)\gamma(s), \tag{32}$$

$$Y(s) = \mathcal{M}[\widetilde{W}(t); s] = \Gamma(s)\beta(s), \tag{33}$$

where $\Gamma(s)$ is the classical gamma function, and we aim to compute $\gamma(s)$ and $\beta(s)$. They exist in a proper strip as proved in the following lemma.

LEMMA 3.1. *The following is true:* (i) $X(s)$ *exists for* $\Re(s) \in (-b-1, -1)$, *and* $Y(s)$ *is defined for* $\Re(s) \in (-2b-1, -1)$.

(ii) *Furthermore,* $\gamma(-1-i) = 0$ *for* $i = 1, \ldots, b-1$, $\gamma(-1-b) = (-1)^{b+1}$, *and* $\beta(-1-i) = 0$ *for* $i = 1, \ldots, b$, *and* $\gamma(s)$ *has simple poles at* $s = -1, 0, 1, \ldots$

Proof. By recurrence (4), we have $B_i(u) = i$ for $i = 0, 1, \ldots, b$ and thus $B_i(u) = b + (i-b)u$ for $i = 1+b, \ldots, 2b$. Taking derivatives, we obtain $\frac{\partial B_i(u)}{\partial u} = 0$ for $i = 0, 1, \ldots, b$ and $\frac{\partial B_i(u)}{\partial u} = i - b$ for $i = b, 1+b, \ldots, 2b$. Furthermore, the second derivative becomes $\frac{\partial^2 B_i(u)}{\partial u^2} = 0$ for $i = 0, 1, \ldots, 2b$. Hence, for $z \to 0$,

$$\begin{aligned}
\widetilde{X}(z) &= \left(z^{(b+1)}/(b+1)! + 2z^{(b+2)}/(b+2)! + 3z^{(b+3)}/(b+3)! + O(z^{b+4})\right) e^{-z} \\
&= z^{(b+1)}/(b+1)! + O(z^{b+2}) \quad \text{as} \quad z \to 0, \\
\widetilde{W}(z) &= O(z^{2b+1}) \quad \text{as} \quad z \to 0.
\end{aligned}$$

However, for $z \to \infty$ we conclude from (30) and (31) that $\widetilde{X}(z) = O(z \log z)$ and $\widetilde{W}(z) = O(z \log^2 z)$. Thus, the first part of the lemma is proven. Part (ii) follows directly from the lemma below and (38). ∎

LEMMA 3.2. *Let* $\{f_n\}_{n=0}^\infty$ *be a sequence of real numbers, and suppose that its Poisson generating function* $\widetilde{F}(z) = \sum_{n=0}^\infty f_n \frac{z^n}{n!} e^{-z}$ *is an entire function. Furthermore, let its Mellin transform* $F(s)$ *have the factorization* $F(s) = \mathcal{M}[\widetilde{F}(z); s] = \Gamma(s)\gamma(s)$, *and assume that* $F(s)$ *exists for* $\Re(s) \in (-2, -1)$ *while* $\gamma(s)$ *is analytic for* $\Re(s) \in (-\infty, -1)$. *Then*

$$\gamma(-n) = \sum_{k=0}^{n} \binom{n}{k} (-1)^k f_k \quad \textit{for} \quad n \geq 2. \tag{34}$$

Proof. Let a sequence $\{g_n\}_{n=0}^{\infty}$ be such that $\widetilde{F}(z) = \sum_{n=0}^{\infty} g_n \frac{z^n}{n!}$, that is (cf. [8]),

$$g_n = \sum_{k=0}^{n} \binom{n}{k} (-1)^{n-k} f_k, \qquad n \geq 0.$$

Now define, for some fixed $N \geq 2$, the function $\widetilde{F}_N(z) = \sum_{n=0}^{N-1} g_n \frac{z^n}{n!}$. Due to our assumptions, we can analytically continue $F(s)$ to the whole complex plane except $s = -2, -3, \ldots$ In particular, for $\Re(s) \in (-N, -N+1)$, we have

$$F(s) = \mathcal{M}[\widetilde{F}(z) - \widetilde{F}_N(z); s].$$

(The above is true since a polynomial in z such as $\widetilde{F}_N(z)$ can only shift the fundamental strip of the Mellin transform but cannot change its value [9].) As $s \to -N$, due to the assumed factorization $F(s) = \Gamma(s)\gamma(s)$, we have

$$F(s) = \frac{1}{s+N} \frac{(-1)^N}{N!} \gamma(-N) + O(1);$$

thus, by the inverse Mellin transform, we have

$$\widetilde{F}(z) - \widetilde{F}_N(z) = \frac{(-1)^N}{N!} \gamma(-N) z^N + O(z^{N+1}) \quad \text{as} \quad z \to 0. \tag{35}$$

But

$$\widetilde{F}(z) - \widetilde{F}_N(z) = \sum_{i=N}^{\infty} g_n \frac{z^n}{n!} = g_N \frac{z^N}{N!} + O(z^{N+1}). \tag{36}$$

Thus, by comparing (35) and (36), we prove that

$$\gamma(-N) = (-1)^N g_N = \sum_{k=0}^{N} \binom{N}{k} (-1)^k f_k \quad \text{for} \quad N \geq 2. \qquad \square$$

Now we are in a position to compute the Mellin transforms of $\widetilde{X}(z)$ and $\widetilde{W}(z)$. From (30) and (31), after taking Mellin transforms and using (32) and (33), we obtain

$$\sum_{i=0}^{b} \binom{b}{i} (-1)^i \gamma(s-i) = (p^{-s} + q^{-s})\gamma(s),$$

$$\sum_{i=0}^{b} \binom{b}{i} (-1)^i \beta(s-i) = 2(p^{-s} + q^{-s})\gamma(s) + (p^{-s} + q^{-s})\beta(s),$$

and, by Lemma 3.1, $\gamma(s)$ exists at least in $\Re(s) \in (-b-1, -1)$, while $\beta(s)$ is well defined in the strip $\Re(s) \in (-2b-1, -1)$. To simplify the above equations, we define, for any function $g(s)$,

$$\widehat{g}(s) = \sum_{i=1}^{b} \binom{b}{i} (-1)^{i+1} g(s-i), \tag{37}$$

provided $g(s-1),\dots,g(s-b)$ exist. Then

$$\gamma(s)=\frac{1}{1-p^{-s}-q^{-s}}\sum_{i=1}^{b}\binom{b}{i}(-1)^{i+1}\gamma(s-i)=\frac{1}{1-p^{-s}-q^{-s}}\widehat{\gamma}(s), \tag{38}$$

$$\begin{aligned}\beta(s)&=\frac{1}{1-p^{-s}-q^{-s}}\sum_{i=1}^{b}\binom{b}{i}(-1)^{i+1}\beta(s-i)+\frac{2(p^{-s}+q^{-s})}{1-p^{-s}-q^{-s}}\gamma(s)\\&=\frac{1}{1-p^{-s}-q^{-s}}\widehat{\beta}(s)+\frac{2(p^{-s}+q^{-s})}{(1-p^{-s}-q^{-s})^2}\widehat{\gamma}(s).\end{aligned} \tag{39}$$

Now let s_k, $k=0,\pm1,\pm2,\dots$, be roots of $1-p^{-s}-q^{-s}=0$. Observe that $s_0=-1$. Actually, s_k were studied quite intensively in the past, and the following is well known (e.g., see [15] for further references).

LEMMA 3.3. *Let s_k for $k=\dots,-2,-1,0,1,2,\dots$ all be solutions of $1-p^{-s}-q^{-s}=0$.*

(i) *Then*

$$-1\le\Re(s_k)\le\sigma_0,$$

where σ_0 is a positive solution of $1+q^{-s}=p^{-s}$.

(ii) *If $\Re(s_k)=-1$ and $\Im(s_k)\neq0$, then $(\log p)/(\log q)$ must be rational. Furthermore, if $\frac{\log p}{\log q}=\frac{r}{t}$, where $\gcd(r,t)=1$ for integers r,t, then*

$$s_k=-1+\frac{2kr\pi i}{\log p}$$

for all integers k.

Observe now that at $s=s_k$ we have

$$\frac{1}{1-p^{-s}-q^{-s}}=-\frac{1}{h(s_k)}\frac{1}{s-s_k}+\frac{h_2(s_k)}{2h^2(s_k)}+O(s-s_k), \tag{40}$$

where

$$h(t)=-p^{-t}\log p-q^{-t}\log q, \tag{41}$$

$$h_2(t)=p^{-t}\log^2 p+q^{-t}\log^2 q. \tag{42}$$

Expanding $\Gamma(s)\widehat{\gamma}(s)$ around $s=s_k$, we find

$$\Gamma(s)\widehat{\gamma}(s)=\Gamma(s_k)\widehat{\gamma}(s_k)+\left(\Gamma(s_k)\widehat{\gamma}'(s_k)+\Gamma'(s_k)\widehat{\gamma}(s_k)\right)(s-s_k)+O((s-s_k)^2).$$

Therefore, since $X(s)=\Gamma(s)\gamma(s)=\frac{1}{1-p^{-s}-q^{-s}}\Gamma(s)\widehat{\gamma}(s)$, we derive around $s=s_k\neq-1$ to obtain

$$\begin{aligned}X(s)=&-\frac{1}{s-s_k}\frac{\Gamma(s_k)}{h(s_k)}\widehat{\gamma}(s_k)+\frac{h_2(s_k)}{2h^2(s_k)}\Gamma(s_k)\widehat{\gamma}(s_k)\\&-\frac{1}{h(s_k)}\left(\Gamma(s_k)\widehat{\gamma}'(s_k)+\Gamma'(s_k)\widehat{\gamma}(s_k)\right)+O(s-s_k).\end{aligned} \tag{43}$$

In a similar manner, from (39) we have

$$\begin{aligned} Y(s) &= -\frac{1}{s-s_k}\frac{\Gamma(s_k)}{h(s_k)}\widehat{\beta}(s_k) + 2\Gamma(s_k)\left(\frac{1}{h^2(s_k)}\frac{1}{(s-s_k)^2} - \frac{h_2(s_k)-h^2(s_k)}{h^3(s_k)}\frac{1}{s-s_k}\right) \\ &\quad \times\ (\widehat{\gamma}(s_k) + (s-s_k)\widehat{\gamma}'(s_k)) + \frac{2\Gamma'(s_k)\widehat{\gamma}(s_k)}{h^2(s_k)}\frac{1}{s-s_k} + O(1) \\ &= \frac{2\Gamma(s_k)\widehat{\gamma}(s_k)}{h^2(s_k)}\frac{1}{(s-s_k)^2} + \left(\frac{2\Gamma'(s_k)\widehat{\gamma}(s_k)}{h^2(s_k)} - \frac{\Gamma(s_k)}{h(s_k)}\widehat{\beta}(s_k)\right. \\ &\quad \left. - 2\Gamma(s_k)\frac{h_2(s_k)-h^2(s_k)}{h^3(s_k)}\widehat{\gamma}(s_k) - \frac{2\Gamma(s_k)\widehat{\gamma}'(s_k)}{h^2(s_k)}\right)\frac{1}{s-s_k} + O(1). \end{aligned} \tag{44}$$

However, from (40) and (38) at $s = s_0 = -1$, we find

$$\begin{aligned} \gamma(s) &= \left(-\frac{1}{h_1}\frac{1}{s+1} + \frac{h_2}{2h_1^2}\right)(\widehat{\gamma}(-1) + (s+1)\widehat{\gamma}'(-1)) + O(s+1) \\ &= -\frac{1}{h_1}\frac{1}{s+1} + \frac{h_2}{2h_1^2} - \frac{\widehat{\gamma}'(-1)}{h_1} + O(s+1), \end{aligned} \tag{45}$$

$$\begin{aligned} \beta(s) &= \left(-\frac{1}{h_1}\frac{1}{s+1} + \frac{h_2}{2h_1^2}\right)\left(\widehat{\beta}(-1) + (s+1)\widehat{\beta}'(-1)\right) \\ &\quad + 2\left(\frac{1}{h_1^2}\frac{1}{(s+1)^2} - \frac{h_2-h_1^2}{h_1^3}\frac{1}{s+1}\right)(\widehat{\gamma}(-1) + (s+1)\widehat{\gamma}'(-1)) + O(1) \\ &= \frac{2}{h_1^2}\frac{1}{(s+1)^2} + \left(-2\frac{h_2-h_1^2}{h_1^3} + 2\widehat{\gamma}'(-1)\frac{1}{h_1^2}\right)\frac{1}{s+1} + O(1). \end{aligned} \tag{46}$$

In the above equation, we used the fact that $\widehat{\gamma}(-1) = 1$ and $\widehat{\beta}(-1) = 0$, which follows directly from Lemma 3.1. Observe now that $\Gamma(s) = -\frac{1}{s+1} + (\gamma - 1) + O(s+1)$; hence the Laurent expansion of $X(s)$ at $s = -1$ is

$$X(s) = \Gamma(s)\gamma(s) = \frac{1}{h_1}\frac{1}{(s+1)^2} - \left(\frac{h_2}{2h_1^2} - \frac{1}{h_1}\widehat{\gamma}'(-1) + \frac{\gamma-1}{h_1}\right)\frac{1}{s+1} + O(1). \tag{47}$$

In order to derive the asymptotic expansion of $\widetilde{X}(z)$ for large z, we use well-known arguments (cf. [4, 6, 9, 14, 26, 29]) of the inverse Mellin transform; that is,

$$\widetilde{X}(z) = \frac{1}{2\pi i}\int_{-\frac{3}{2}-i\infty}^{-\frac{3}{2}+i\infty} X(s)z^{-s}ds.$$

(The evaluation of this integral is quite standard (e.g., see [29]): we extend the line of integration to a big rectangle right to the integration line, and observe that bottom and top lines contribute negligibly because the gamma function decreases exponentially with the increase in the magnitude of the imaginary part, and the right side positioned at, say, d, contributes x^{-d} for $d \to \infty$.) However, to estimate the error term we must note, as observed in Lemma 3.1, that $\gamma(s)$ has additional simple poles at $s = 0, 1, \ldots$. The pole at $s = 0$ is a double pole of $X(s) = \Gamma(s)\gamma(s)$, and thus its contribution to $\widetilde{X}(z)$ is $O(\log z)$. Putting everything together, we finally arrive at

$$\widetilde{X}(z) = \frac{1}{h_1} z \log z + \left(\frac{h_2}{2h_1^2} - \frac{1}{h_1} \widehat{\gamma}'(-1) + \frac{\gamma - 1}{h_1} \right) z + \sum_{k \neq 0} \frac{\Gamma(s_k) \widehat{\gamma}(s_k)}{h(s_k)} z^{-s_k} + O(\log z). \tag{48}$$

Similarly, at $s = -1$,

$$Y(s) = -\frac{2}{h_1^2} \frac{1}{(s+1)^3} + \frac{2}{h_1} \left(\frac{h_2 - h_1^2}{h_1^2} - \frac{1}{h_1} \widehat{\gamma}'(-1) + \frac{\gamma - 1}{h_1} \right) \frac{1}{(s+1)^2} + O\left(\frac{1}{s+1} \right).$$

In addition, there is a double pole at $s = 0$; hence, by the inverse Mellin transform and Lemma 3.3, we obtain

$$\widetilde{W}(z) = \frac{1}{h_1^2} z \log^2 z + \frac{2}{h_1} \left(\frac{h_2 - h_1^2}{h_1^2} - \frac{1}{h_1} \widehat{\gamma}'(-1) + \frac{\gamma - 1}{h_1} \right) z \log z + 2 \sum_{k \neq 0} \frac{\Gamma(s_k) \widehat{\gamma}(s_k)}{h^2(s_k)} z^{-s_k} \log z + O(z)$$

for $z \to \infty$, where $O(z)$ comes from the term $O((s+1)^{-1})$. This formula will allow us to infer asymptotics of the variance of D_m.

3.2. Depoissonization. The above asymptotic formulas concern the behavior of the Poisson mean and the second factorial moment as $z \to \infty$. More precisely, we must restrict the growth of z to a cone $S_\theta = \{z : \ |\arg(z)| \leq \theta\}$ for some $|\theta| < \pi/2$. But our original goal was to derive asymptotics of the mean ED_m and the variance $\operatorname{Var} D_m$ in the Bernoulli model. To infer Bernoulli model behavior from its Poisson model asymptotics, we must apply the so-called *depoissonization lemma*. This lemma basically says that $mED_m \sim \widetilde{X}(m)$ and $mED_m(D_m - 1) \sim \widetilde{W}(m)$ under some weak conditions that are easy to verify in our case. The reader is referred to [16, 34] for more details about the depoissonization lemma. For completeness, however, we review some depoissonization results that are useful for our problem.

Let us consider a more general problem: For a random variable X_n, we define g_n as a functional of the distribution of X_n (e.g., $g_n = EX_n$ or $g_n = EX_n^2$, etc.) or, in general, we assume that g_n is a sequence of n. We may also need to consider the generating function $G_n(u) = Eu^{X_n}$ for a complex u, which can be viewed as such a g_n (with a parameter u belonging to a compact set). Define the Poisson transform of g_n as $\widetilde{G}(z) = \sum_{n=0}^{\infty} g_n \frac{z^n}{n!} e^{-z}$ (or, more generally, $\widetilde{G}(z,u) = \sum_{n=0}^{\infty} G_n(u) \frac{z^n}{n!} e^{-z}$ for u in a compact set). Assume that we know the asymptotics of $\widetilde{G}(z)$ for z large and belonging to a cone $S_\theta = \{z : |\arg(z)| \leq \theta\}$ for some $|\theta| < \pi/2$. How can we infer asymptotics of g_n from $\widetilde{G}(z)$? One possible answer is given in the depoissonization lemma below (cf. [16, 34]):

LEMMA 3.4 (depoissonization lemma).

(i) *Let $\widetilde{G}(z)$ be the Poisson transform of a sequence g_n that is assumed to be an entire function of z. We postulate that for $0 < |\theta| < \pi/2$ the following two conditions simultaneously hold for some numbers $A, B, \xi > 0$, β, and $\alpha < 1$:*

(I) *For $z \in S_\theta$,*

$$|z| > \xi \Rightarrow |\widetilde{G}(z)| \leq B|z|^\beta \Psi(|z|), \tag{49}$$

where $\Psi(z)$ is a slowly varying function (e.g., $\Psi(z) = \log^d z$ for some $d > 0$).

(O) *For $z \notin S_\theta$,*

$$|z| > \xi \Rightarrow |\widetilde{G}(z)e^z| \le A\exp(\alpha|z|). \tag{50}$$

Then, for large n,

$$g_n = \widetilde{G}(n) + O(n^{\beta-1}\Psi(n)) \tag{51}$$

or, more precisely,

$$g_n = \widetilde{G}(n) - \frac{1}{2}\widetilde{G}''(n) + O(n^{\beta-2}\Psi(n)).$$

(ii) *If conditions* (I) *and* (O) *hold for $\widetilde{G}(z,u)$ for u belonging to a compact set $\mathcal{U}$, then*

$$G_n(u) = \widetilde{G}(n,u) + O(n^{\beta-1}\Psi(n)) \tag{52}$$

for large n and uniformly in $u \in \mathcal{U}$.

To apply the above lemma to $\widetilde{X}(z)$ and $\widetilde{W}(z)$, one must check conditions (I) and (O). But condition (I) inside the cone S_θ is automatically satisfied due to the asymptotics of $\widetilde{X}(z)$ and $\widetilde{W}(z)$ just derived. Formally, we must use either complex variable Mellin transform or analytic continuation to establish $\widetilde{X}(z) = O(z\log z)$ and $\widetilde{W}(z) = O(z\log^2 z)$. Thus, it suffices to check condition (O) outside the cone[1] (in fact, the arguments below work fine also for verifying condition (I)).

We consider only $\widetilde{X}(z)$ since $\widetilde{W}(z)$ can be treated in a similar manner. Let $X(z) = \widetilde{X}(z)e^z$. Then, functional equation (30) transforms into

$$X^{(b)}(z) = X(zp)e^{zq} + X(zq)e^{zp} + ze^z,$$

where $X^{(b)}(z)$ denotes the bth derivative of $X(z)$. Observe that the above equation can be represented alternatively as

$$X(z) = \underbrace{\int_0^z \int_0^{w_1} \cdots \int_0^{w_{b-1}}}_{b \text{ times}} + \left(X(w_1 p))e^{w_1 q} + X(w_1 q)e^{w_1 p} + w_1 e^{w_1}\right) dw_b \cdots dw_2 dw_1, \tag{53}$$

where the integration is along lines in the complex plane.

We now prove $|X(z)| \le e^{\alpha|z|}$ for $z \notin S_\theta$ for $\alpha < 1$. We use induction over the so-called *increasing domains* defined as follows (cf. [16, 29]): For all positive integers $m \ge 1$ and constants $\xi, \delta > 0$, let

$$\mathcal{F}_m = \{z = \rho e^{i\vartheta} : \ \rho \in [\xi\delta, \xi\nu^{-m}], \ \ 0 \le \vartheta < 2\pi\},$$

where $\max\{p,q\} \le \nu < 1$ and $\delta \le \min\{p,q\}$. The point to observe is that if $z \in \mathcal{F}_{m+1} - \mathcal{F}_m$, then $zp, zq \in \mathcal{F}_m$, provided $|z| \ge \xi$, which is assumed to hold.

To carry out the induction, we first define $\bar{\mathcal{F}}_m = \mathcal{F}_m \cap \bar{S}_\theta$, where $\bar{S}_\theta$ denotes points in the complex plane outside S_θ. Since $X(z)$ is bounded for $z \in \bar{\mathcal{F}}_1$, the initial step of induction holds. Let us now assume that for some $m > 1$ and for $z \in \bar{\mathcal{F}}_m$ we have

[1]Recently, Jacquet and Szpankowski [17] proved that if an analytic continuation of g_n has a polynomial growth, then condition (O) from Lemma 3.4 is automatically satisfied.

$|X(z)| \le e^{\alpha|z|}$ with $\alpha < 1$. We intend to prove that $|X(z)| \le e^{\alpha|z|}$ for $z \in \bar{\mathcal{F}}_{m+1}$. Indeed, let $z \in \bar{\mathcal{F}}_{m+1}$. If also $z \in \bar{\mathcal{F}}_m$, then the proof is completed. So let us now assume that $z \in \bar{\mathcal{F}}_{m+1} - \bar{\mathcal{F}}_m$. Then since $zp, zq \in \bar{\mathcal{F}}_m$, we can use our induction hypothesis together with the integral equation (53) to obtain the following estimate for $|z| > \xi$ where ξ is large enough:

$$|X(z)| \le |z|^{b+1} \left(e^{|z|(p\alpha + q\cos\theta)} + e^{|z|(q\alpha + p\cos\theta)} + e^{|z|\cos\theta} \right).$$

Let us now define $1 > \alpha > \cos\theta$ such that the following three inequalities are simultaneously fulfilled:

$$\begin{aligned} |z|^b e^{|z|(p\alpha + q\cos\theta)} &\le \frac{1}{3} e^{\alpha|z|}, \\ |z|^b e^{|z|(q\alpha + p\cos\theta)} &\le \frac{1}{3} e^{\alpha|z|}, \\ |z|^{b+1} e^{|z|\cos\theta} &\le \frac{1}{3} e^{\alpha|z|}. \end{aligned}$$

Then for $z \in \bar{\mathcal{F}}_{m+1}$ we have $|X(z)| \le e^{\alpha|z|}$, as needed to verify condition (O) of the depoissonization lemma.

Hence we can apply the depoissonization lemma to $\widetilde{X}(z)$, and using our previous asymptotics on $\widetilde{X}(z)$, we immediately obtain

$$\begin{aligned} ED_m &= \frac{\widetilde{X}(m)}{m} + O\left(\frac{\log m}{m}\right) \\ &= \frac{1}{h_1}\log m + \frac{h_2}{2h_1^2} - \frac{1}{h_1}\widehat{\gamma}'(-1) + \frac{\gamma - 1}{h_1} + \sum_{k \ne 0} \frac{\Gamma(s_k)\widehat{\gamma}(s_k)}{h(s_k)} m^{-1-s_k} + O\left(\frac{\log m}{m}\right). \end{aligned}$$

Another application of the depoissonization lemma leads to a formula on the second factorial moment:

$$\begin{aligned} ED_m(D_m - 1) = \frac{\widetilde{W}(m)}{m} + O(1) &= \frac{1}{h_1^2}\log^2 m \\ &\quad + 2\frac{1}{h_1}\left(\frac{h_2 - h_1^2}{h_1^2} - \frac{1}{h_1}\widehat{\gamma}'(-1) + \frac{\gamma - 1}{h_1}\right)\log m \\ &\quad + 2\sum_{k \ne 0} \frac{\Gamma(s_k)\widehat{\gamma}(s_k)}{h^2(s_k)} m^{-1-s_k}\log m + O(1). \end{aligned}$$

Finally, after computing $(ED_m)^2$ we arrive at

$$\begin{aligned} \operatorname{Var} D_m &= ED_m(D_m - 1) + ED_m - (ED_m)^2 \\ &= \frac{h_2 - h_1^2}{h_1^3}\log m + 2\sum_{k \ne 0} \frac{\Gamma(s_k)\widehat{\gamma}(s_k)}{h(s_k)} \left(\frac{1}{h(s_k)} - \frac{1}{h_1}\right) m^{-1-s_k}\log m + O(1). \end{aligned}$$

If $\Re(s_k) = -1$ for all k, then by Lemma 3.3 one can prove that $h(s_k) = h_1$ (cf. [15]). If $\Re(s_k) > -1$, then $m^{-1-s_k}\log m = o(1)$. Therefore, $\operatorname{Var} D_m = \frac{h_2 - h_1^2}{h_1^3}\log m + O(1)$. From Lemma 3.3 we know that $\Re(s_k) = -1$ whenever $(\log p)/(\log q)$ is rational; otherwise $\Re(s_k) > -1$. In summary, to complete the proof of Theorem 2.1(i) we must evaluate the constant $\widehat{\gamma}'(-1)$, which we discuss next.

3.3. Evaluation of some constants. In several applications (e.g., the computation of the average code redundancy discussed at the end of section 2) the second-order term of ED_m (i.e., the leading term of $ED_m - h_1^{-1}\log m$) plays a very important role. Therefore, knowing its value, or providing a numerical algorithm to compute it, is of prime interest. In the previous subsection, we showed that the value of this term depends on $\widehat{\gamma}'(-1)$, which can be also expressed as

$$\widehat{\gamma}'(-1) = \sum_{i=1}^{b} \binom{b}{i} (-1)^{i+1} \gamma'(-1-i),$$

where $\gamma(s)\Gamma(s) = \mathcal{M}[\widetilde{X}(t); s]$ and $\widetilde{X}(z) = \sum_{n=0}^{\infty} f_n \frac{z^n}{n!} e^{-z}$. We recall from Theorem 2.1 that f_n is defined as

$$\begin{cases} f_{m+b} = m + \displaystyle\sum_{i=0}^{m} \binom{m}{i} p^i q^{m-i} (f_i + f_{m-i}), \quad m \geq 0, \\ f_0 = f_1 = \cdots = f_b = 0, \\ \bar{f}_{m+b} = f_{m+b} - m, \quad m \geq 1. \end{cases}$$

Clearly, $\bar{f}_i > 0$ for any $i > b+1$ since $f_i \geq i - b$ for $i \geq b$.

To compute $\widehat{\gamma}'(-1)$ we must find $\gamma(s)$ in terms of computable quantities such as f_n. We proceed as follows:

$$\gamma(s) = \frac{1}{\Gamma(s)} \mathcal{M}\left[\sum_{n=b+1}^{\infty} f_n \frac{z^n}{n!} e^{-z}; s\right] = \sum_{n=b+1}^{\infty} \frac{f_n}{n!} \frac{\Gamma(s+n)}{\Gamma(s)}$$

$$= \sum_{n=b+1}^{\infty} \frac{f_n}{n!} s(s+1)\dots(s+n-1). \tag{54}$$

We assume above that $\Re(s) \in (-b-1, -1)$ to ensure the existence of the Mellin transform and the convergence of the series. Then one easily derives

$$\gamma'(s) = \sum_{n=b+1}^{\infty} \frac{f_n}{n!} s(s+1)\cdots(s+n-1) \sum_{i=0}^{n-1} \frac{1}{s+i}, \qquad s \notin \{-2, -3, \dots, -b\}. \tag{55}$$

After some algebra, we arrive at the following:

$$\gamma'(-k) = (-1)^k \sum_{n=b+1}^{\infty} \frac{f_n}{n!} k!(n-k-1)! \quad \text{for} \quad k = 2, \dots, b,$$

$$\gamma'(-b-1) = (-1)^b H_{b+1} + (-1)^{b+1} \sum_{n=b+2}^{\infty} \frac{f_n}{n!} (b+1)!(n-b-2)!.$$

Let us first assume that $b > 1$. Then, to estimate $\widehat{\gamma}'(-1)$, we proceed as follows:

$$\widehat{\gamma}'(-1) = \sum_{i=1}^{b} \binom{b}{i} (-1)^{i+1} \gamma'(-i-1)$$

$$= -H_{b+1} + \frac{1}{b+1} \sum_{i=1}^{b-1} \frac{i+1}{b-i} + \sum_{i=1}^{b} \binom{b}{i} \sum_{n=b+2}^{\infty} \frac{f_n}{n!} (i+1)!(n-i-2)!$$

$$= -H_{b+1} - H_{b-1} - \frac{b-1}{b+1} + \sum_{n=b+2}^{\infty} (n-b+\bar{f}_n) \sum_{i=1}^{b} \frac{(i+1)b!}{(b-i)!n(n-1)\dots(n-i-1)}$$
$$= -\frac{1}{b} - \frac{b}{b+1} + A + \Delta(b,p),$$

where

$$\Delta(b,p) = \sum_{n=b+2}^{\infty} \bar{f}_n \sum_{i=1}^{b} \frac{(i+1)b!}{(b-i)!n(n-1)\dots(n-i-1)},$$
$$A = \sum_{n=b+2}^{\infty} (n-b) \sum_{i=1}^{b} \frac{(i+1)b!}{(b-i)!n(n-1)\dots(n-i-1)}.$$

The above series converge since the summands are $O(\log n/n^2)$. Finally, observe that $\bar{f}_{m+b} = 0$ for $m = 1, 2, \dots, b$ and $\bar{f}_i > 0$ for $i > 2b$; hence

$$\Delta(b,p) = \sum_{n=b+2}^{\infty} \bar{f}_n \sum_{i=1}^{b} \frac{(i+1)b!}{(b-i)!n(n-1)\dots(n-i-1)}$$
$$= \sum_{n=2b+1}^{\infty} \bar{f}_n \sum_{i=1}^{b} \frac{(i+1)b!}{(b-i)!n(n-1)\dots(n-i-1)}.$$

After a long and tedious algebra (cf. [40]), we can prove that $A = H_b + b(1+b)^{-1}$. Hence $\widehat{\gamma}'(-1) = H_{b-1} + \Delta(b,p)$ as presented in Theorem 2.1, and this completes the proof of part (i) of Theorem 2.1 for $b > 1$.

For $b = 1$ we have

$$\widehat{\gamma}'(-1) = \gamma'(-2) = -H_2 + \Delta(1,p) + \sum_{n=3} \frac{2}{n(n-2)} = \Delta(1,p),$$

since the above series is equal to $3/2$, which is canceled by $-H_2 = -3/2$. Thus Theorem 2.1 is also proved for $b = 1$. Actually, in this case we may also conclude from [38] that

$$\Delta(1,p) = -\sum_{k=1}^{\infty} \frac{p^{k+1}\log p + q^{k+1}\log q}{1 - p^{k+1} - q^{k+1}}.$$

In Table 1 we present numerical values of $\Delta(b,p)$ and $ED_m - \frac{1}{h_1}(\log m - \delta(m,b))$ as a function of b. While $\Delta(b,p)$ is relatively easy to compute numerically, we must point out that the rate of convergence for this series is only $O(\log N/N)$, where N is the cutoff value of the series computation.

3.4. Limiting distribution. In this section, we will prove part (ii) of Theorem 2.1; that is, we establish the central limit theorem for D_m. We recall that $\widetilde{B}(u,z) = \sum_{i=0}^{\infty} B_i(u)\frac{z^i}{i!}e^{-z}$ and that

$$\left(1 + \frac{\partial}{\partial z}\right)^b \widetilde{B}(u,z) = b + u\left(\widetilde{B}(u,pz) + \widetilde{B}(u,qz)\right). \tag{56}$$

TABLE 1
Numerical values of $\Delta(b,p)$ *and* $ED_m - \frac{1}{h_1}\log m$ *for* $p = 0.3$

For some function $\omega(u,s)$, let the Mellin transform of $\widetilde{B}(u,z)$ be given by

$$Z(u,s) = \mathcal{M}\left(\widetilde{B}(u,z) - z; s\right) = \Gamma(s)\omega(u,s). \tag{57}$$

The existence of the Mellin transform $Z(u,s)$ is proved in the lemma below.

LEMMA 3.5. (i) *The Mellin* $Z(u,s)$ *exists for* $\Re(s) \in (-b-1,-1)$.
(ii) *For* $i = 1,\dots,b-1$ *we have* $\omega(u,-1-i) = 0$ *and* $\omega(u,-1-b) = (-1)^{b+1}(u-1)$.

Proof. The proof uses the same arguments as in Lemma 3.1. In particular,

$$\begin{aligned}\widetilde{B}(u,z) &= \left(z + z^2 + z^3/2! + \cdots + z^b/(b-1)! + (u+b)z^{b+1}/(b+1)! + O(z^{b+2})\right)e^{-z}\\ &= z + (u-1)z^{b+1}/(b+1)! + O(z^{b+2}).\end{aligned}$$

Thus as $z \to 0$ one obtains $\widetilde{B}(u,z) - z = O(z^{(b+1)})$. For fixed u, we also have $\widetilde{B}(u,z) = O(z\log z)$ for $z \to \infty$. Therefore, part (i) is proved. Part (ii) follows from Lemma 3.2. □

The plan for this section is similar to the previous one. We first use the Mellin transform technique to derive asymptotics of $\widetilde{B}(z,u) - z$ for $z \to \infty$ in a cone S_θ and then depoissonize this result by Lemma 3.4. We start with taking the Mellin transform to (56). After some algebra, we obtain

$$\sum_{i=0}^{b}\binom{b}{i}(-1)^i\omega(u,s-i) = u(p^{-s}+q^{-s})\omega(u,s),$$

which further leads to

$$\omega(u,s) = \frac{1}{1-u(p^{-s}+q^{-s})}\widehat{\omega}(u,s).$$

Now let $s_k(u), k = 0,\pm1,\pm2,\dots,$ be the roots of the equation $1-u(p^{-s}+q^{-s}) = 0$ for fixed u. Then, for $s = s_k(u)$,

$$\frac{1}{1-u(p^{-s}+q^{-s})} = \frac{1}{s-s_k(u)}\frac{u^{-1}}{-h(s_k(u))}.$$

In addition, one must consider two poles of the gamma function $\Gamma(s)$ at $s_{-1} = -1$ and $s_0 = 0$. The latter pole contributes $O(1)$, and the former $-z\omega(u,-1)$. But, by Lemma 3.5, we know that $\omega(u,-1) = 1$; thus the total contribution of these two poles is $-z + O(1)$.

Summing up, we have

$$\widetilde{B}(u,z)7 = \frac{u^{-1}}{h(s_0(u))}\Gamma(s_0(u))\widehat{\omega}(u,s_0(u))z^{-s_0(u)} + \sum_{k\neq 0}\frac{u^{-1}}{h(s_k(u))}\Gamma(s_k(u))\widehat{\omega}(u,s_k(u))z^{-s_k(u)} + O(1).$$

We now set $u = e^t$ for complex t in the vicinity of 0. Algebra similar to that in [14, 26] leads to the following for $t \to 0$:

$$\begin{aligned} s_0(t) &= -1 - \frac{t}{h_1} - \frac{\alpha t^2}{2} + O(t^3), \\ \Gamma(s_0(t)) &= \frac{h_1}{t} + O(t^2), \\ \frac{e^{-t}}{h(s_0(t))} &= \frac{1}{h_1} + O(t), \\ \widehat{\omega}(t,s_0(t)) &= e^t - 1 + O(t^2) = t + O(t^2). \end{aligned} \tag{58}$$

The rest is a matter of depoissonization. But the depoissonization conditions (I) and (O) of Lemma 3.4 are easy to verify for u belonging to a compact set around $u = 1$, as we already showed in the case of $\widetilde{X}(z)$. Thus, an application of (52) provides the following estimate:

$$B_m(t) = \frac{1}{h_1}\frac{h}{t}\widehat{\omega}(t,s_0(t))m^{-s_0(t)} + e^{-t}\sum_{k\neq 0}\frac{1}{h(s_k(t))}\Gamma(s_k(t))\widehat{\omega}(u,s_k(t))m^{-s_k(t)} + O(\log m),$$

since $B(z,u) = O(z\log z)$. Then the generating function $G_m(t) = Ee^{tD_m}$ becomes

$$\begin{aligned} G_m(t) &= \frac{B_m(t)}{m} \\ &= \frac{1}{t}\widehat{\omega}(t,s_0(t))m^{-1-s_0(t)} + e^{-t}\sum_{k\neq 0}\frac{1}{h(s_k(t))}\Gamma(s_k(t))\widehat{\omega}(u,s_k(t))m^{-1-s_k(t)} \\ &\quad + O\left(\frac{\log m}{m}\right) \\ &= \frac{1}{t}(t-1)m^{-1-s_0(t)} + e^{-t}\sum_{k\neq 0}\frac{1}{h(s_k(t))}\Gamma(s_k(t))\widehat{\omega}(u,s_k(t))m^{-1-s_k(t)} \\ &\quad + O\left(\frac{\log m}{m}\right) \\ &= m^{-1-s_0(t)} + e^{-t}\sum_{k\neq 0}\frac{1}{h(s_k(t))}\Gamma(s_k(t))\widehat{\omega}(u,s_k(t))m^{-1-s_k(t)} + O\left(\frac{\log m}{m}\right). \end{aligned}$$

As the final step, we set $t = \frac{\tau}{\sigma_m}$ for some fixed τ and $\sigma_m = \operatorname{Var} D_m$. Then, using (58) $m^{-1-s_0(t)} = e^{\tau\mu_m/\sigma_m + \tau^2/2}$, as well as

$$e^{-\tau\mu_m/\sigma_m}G_m(e^{\tau/\sigma_m}) = e^{-\tau\mu_m/\sigma_m}$$
$$\times \left(\frac{1}{t}te^{\tau\mu_m/\sigma_m+\frac{\tau^2}{2}} + e^{-t}m^{-1-s_0(t)}\sum_{k\neq 0}\frac{1}{h(s_k(t))}\Gamma(s_k(t))\widehat{\omega}(u,s_k(t))m^{s_0(t)-s_k(t)} + O\left(\frac{\log m}{m}\right)\right)$$
$$= e^{\frac{\tau^2}{2}}\left(1+O\left(\sum_{k\neq 0}\frac{1}{h(s_k(t))}\Gamma(s_k(t))\widehat{\omega}(u,s_k(t))m^{s_0(t)-s_k(t)}\right)\right)$$
$$= e^{\frac{\tau^2}{2}}\left(1+O\left(\frac{1}{\sqrt{\log m}}\right)\right)$$

since, as in [14], we prove that (cf. [40])

$$\sum_{k\neq 0}\frac{1}{h(s_k(t))}\Gamma(s_k(t))\widehat{\omega}(u,s_k(t))m^{s_0(t)-s_k(t)} = O(t) = O\left(\frac{1}{\sqrt{\log m}}\right)$$

for $t = \tau/\sigma_m = O(1/\sqrt{\log m})$.

To complete the proof of part (ii) of Theorem 2.1, we must show that the above expression implies the convergence of moments. But this is standard (cf. [16]) and can be argued as follows: Let $D'_m = (D_m - \mu_n)/\sigma_m$. We just proved that $G_m(t) = E(e^{tD'_m}) \to e^{t^2/2}$ on t belonging to a real interval around $t = 0$. Hence $G_m(t)$ is bounded in the vicinity of $t = 0$ since $|E(e^{tD'_m})| \le E(e^{\Re(t)D'_m})$, which further implies that $G_m(t)$ is uniformly bounded around $t = 0$. By *Ascoli's theorem* we can select a subsequence from $G_m(t)$ that converges to a continuous function which must be analytic and equal to e^{t^2} inside the real interval (by uniqueness of analytic continuation). Since analytic functions that are uniformly bounded on a compact set must have all derivatives, we conclude the convergence in moments of D'_m, as desired. In summary, part (ii) of Theorem 2.1 and hence the theorem as a whole is proven.

4. Analysis of the symmetric Bernoulli model. In this section we prove Theorem 2.2 concerning the asymptotic behavior of a b-digital search tree in the unbiased (symmetric) Bernoulli model.

4.1. The variance. The average value ED_m follows directly from (7). But, in the symmetric case, $h_2 = h_1^2 = \log 2$, and therefore from (8) we deduce that Var $D_m = O(1)$. Our goal is to compute it precisely. In this case, an extension of a Flajolet and Richmond technique [8] works fine, and we apply it in this subsection. We follow Hubalek [12] to derive our results. We omit most of the detailed calculations, which can be found in [8, 12].

First, we observe that (6), our differential functional equation, in this case becomes

$$\left(1+\frac{\partial}{\partial z}\right)^b \widetilde{B}(u,z) = b + 2u\widetilde{B}(u,z/2).$$

The coefficients of $\widetilde{B}(u,z)$ can be computed by solving a linear recurrence of type (1). Unfortunately, there is no easy way to solve such a recurrence unless $b = 1$ (cf. [20, 38]). To circumvent this difficulty, Flajolet and Richmond [8] reduced it to a certain functional equation on an *ordinary* generating function that is easier to solve. We proceed along this path.

Let $\widetilde{B}(u,z) = \sum_{k=0}^{\infty} g_k(u)\frac{z^k}{k!}$, and $G(u,z) = \sum_{k=0}^{\infty} g_k(u)z^k$. We also define an ordinary generating function of $B_k(u)$ as $F(u,z) = \sum_{k=0}^{\infty} B_k(u)z^k$. Observe that $B_n(u) = \sum_{k=0}^{n} \binom{n}{k} g_k(u)$; hence as in [8] we obtain

$$F(u,z) = \frac{1}{1-z} G\left(u, \frac{z}{1-z}\right). \tag{59}$$

Indeed,

$$\begin{aligned}\frac{1}{1-z} G\left(u, \frac{z}{1-z}\right) &= \sum_{m=0}^{\infty} g_m(u) z^m \frac{1}{(1-z)^{m+1}} = \sum_{m=0}^{\infty} g_m(u) z^m \sum_{j=0}^{\infty} \binom{m+j}{j} z^j \\ &= \sum_{n=0}^{\infty} z^n \sum_{k=0}^{n} \binom{n}{k} g_k(u) = F(u,z).\end{aligned}$$

Certainly, (59) further implies that

$$F_u^{(n)}(u,z) = \frac{1}{1-z} G_u^{(n)}\left(u, \frac{z}{1-z}\right),$$

where $f_u^{(k)}(z,u)$ denotes the kth derivative of $f(z,u)$ with respect to u. Then

$$G(u,z)(1+z)^b = z(1+z)^b - z^{b+1} + 2uz^b G\left(u, \frac{z}{2}\right), \tag{60}$$

$$G'_u(u,z)(1+z)^b = 2z^b G\left(u, \frac{z}{2}\right) + 2uz^b G'_u\left(u, \frac{z}{2}\right), \tag{61}$$

$$G''_u(u,z)(1+z)^b = 4z^b G'_u\left(u, \frac{z}{2}\right) + 2uz^b G''_u\left(u, \frac{z}{2}\right). \tag{62}$$

In order to compute the variance, we compute $L^{\underline{1}}(z) := G'_u(u,z)|_{u=1}$ and $L^{\underline{2}}(z) := G''_u(u,z)|_{u=1}$ and then use (59). From (61) and (62) we immediately obtain

$$\begin{aligned}L^{\underline{1}}(z)(1+z)^b &= z^{b+1} + 2z^b L^{\underline{1}}\left(\frac{z}{2}\right), \\ L^{\underline{2}}(z)(1+z)^b &= 4z^b L^{\underline{1}}\left(\frac{z}{2}\right) + 2z^b L^{\underline{2}}\left(\frac{z}{2}\right).\end{aligned}$$

Iterating these equations we easily find (cf. [8, 12])

$$L^{\underline{1}}(z) = \sum_{k=0}^{\infty} \frac{(2z^b)(2(\frac{z}{2})^b)\cdots(2(\frac{z}{2^k})^b)}{\left((1+z)(1+\frac{z}{2})\cdots(1+\frac{z}{2^k})\right)^b} \frac{z}{2^{k+1}}, \tag{63}$$

$$L^{\underline{2}}(z) = \sum_{k=0}^{\infty} \frac{(2z^b)(2(\frac{z}{2})^b)\cdots(2(\frac{z}{2^k})^b)}{\left((1+z)(1+\frac{z}{2})\cdots(1+\frac{z}{2^k})\right)^b} 2L^{\underline{1}}(\frac{z}{2^{k+1}}). \tag{64}$$

The next step is to transform the above sums (63) and (64) into certain harmonic sums (cf. [9]). For this, we set $z = 1/t$ and define $Q(t) = \prod_{k=0}^{\infty}(1+\frac{t}{2^k})$. Then (63) and (64) become

$$\frac{tL^{\underline{1}}(\frac{1}{t})}{\left(Q(\frac{t}{2})\right)^b} = \sum_{k=0}^{\infty} \frac{1}{\left(Q(2^k t)\right)^b}, \tag{65}$$

$$\frac{tL^{\underline{2}}(\frac{1}{t})}{\left(Q(\frac{t}{2})\right)^b} = 2\sum_{k=0}^{\infty} \frac{2^{k+1} tL^{\underline{1}}(\frac{1}{2^{k+1}t})}{\left(Q(\frac{2^{k+1}t}{2})\right)^b}. \tag{66}$$

Both sums are of the form $\sum_{k\geq 0}\lambda_k f(\mu_k x)$ for some function $f(\cdot)$ and sequences λ_k, μ_k; that is, they are the so-called *harmonic sums* (cf. [9]). It is well known that the Mellin transform of such a sum is $F(s)\sum_{k\geq 0}\lambda_k\mu_k^{-s}$ (where $F(s)$ is the Mellin transform of f). In our case, we have

$$\mathcal{M}\left[\frac{tL^1(\frac{1}{t})}{Q^b(\frac{t}{2})};s\right] = \frac{1}{1-2^{-s}}I(s),$$
$$\mathcal{M}\left[\frac{tL^2(\frac{1}{t})}{Q^b(\frac{t}{2})};s\right] = \frac{2^{1-s}}{(1-2^{-s})^2}I(s),$$

where

$$I(s) = \int_0^\infty \frac{t^{s-1}}{Q^b(t)}dt = \frac{\pi}{\sin\pi s}J(s), \tag{67}$$

$$J(s) = \frac{1}{2\pi i}\int_{\mathcal{H}} \frac{(-t)^{s-1}}{Q^b(t)}dt \tag{68}$$

with $\mathcal{H}$ being the Hankel contour (cf. [9, 12]).

The rest is easy. Applying standard arguments of the inverse Mellin transform we can derive asymptotic expansions of $L^1(\frac{1}{t})$ and $L^2(\frac{1}{t})$ as $t\to 0$. We find

$$L^1(\frac{1}{t}) = \frac{1}{t}k(t) + bk(t) + O(t\log t^{-1}),$$
$$L^2(\frac{1}{t}) = \frac{1}{t}K(t) + bK(t) + O(t\log^2 t^{-1}),$$

where

$$k(t) = \frac{1}{L}\log\frac{1}{t} + \frac{1}{2} + \frac{J'(0)}{L} - \frac{1}{L}\sum_{k=0}\frac{I(s_k)}{s_k}t^{-s_k},$$
$$K(t) = \frac{1}{L^2}\log^2\frac{1}{t} + \frac{2J'(0)}{L^2}\log\frac{1}{t} - \left(\frac{1}{6} + \frac{J''(0)}{L^2} - \frac{\pi^2}{3L^2}\right) + 8bt$$
$$- \frac{2}{L^2}\sum_{k=0}\frac{I(s_k)}{s_k}t^{-s_k}\log\frac{1}{t} + \frac{2}{L^2}\sum_{k=0}\left(\frac{I(s_k)}{s_k^2} - \frac{I'(s_k)}{s_k}\right)t^{-s_k},$$

with $s_k = 2\pi ik/\log 2$ for $k = 0, \pm 1, \ldots$ being the roots of $1-2^{-s}=0$, and $L = \log 2$. Finally, applying the *singularity analysis* of Flajolet and Odlyzko [7], after somewhat tedious algebra we prove (15).

4.2. Exact and limiting distribution. We need another approach to establish exact and asymptotic distributions in the symmetric case since, as shown above, Var $D_m = O(1)$. We also point out that—even if it is possible in principle—using recurrence (5) or functional equation (6) may be quite troublesome. Therefore we devised another, more combinatorial and probabilistic approach.

Let us fix $j \geq 1$, and consider a *particular path*, say, $\mathcal{P}$, from the root to a node at level j on $\mathcal{P}$. Let $T_{j,r}$ be the number of strings needed to be added to the tree (after the first b) to ensure that a node at level j contains exactly r strings ($1 \leq r \leq b$). Since the first b strings are stored in the root, we observe the following:

$\Pr\{T_{j,r} \leq m-b\} =$

$\Pr\{$node at level j contains at least r strings when m strings are in the tree$\}$.

Note that $P[j,r] := \Pr\{\text{exactly } r \text{ strings are in a node at level } j \text{ when } m \text{ strings are added}\} = \Pr\{T_{j,r} \le m-b\} - \Pr\{T_{j,r+1} \le m-b\}$.

Then the distribution of D_m can be computed as

$$\Pr\{D_m = j\} = \frac{2^j}{m} \sum_{r=1}^{b} P[j,r] \cdot r = \frac{2^j}{m} \sum_{r=1}^{b} \Pr\{T_{j,r} \le m-b\}. \tag{69}$$

In view of the above equation, to compute the exact distribution of D_m one needs the distribution of $T_{r,j}$. But the number of strings, say, X_i, that one must insert into the tree in order to fill up a node at level $i < j$ on the path $\mathcal{P}$ (when the node on $\mathcal{P}$ at level $i-1$ is full) is distributed as the sum of b independent random variables geometrically distributed with success probability $\pi(i) = 2^{-i}$. Let $X_i(z) = Ez^{X_i}$ be the probability generating function. Then

$$X_i(z) = \left(\frac{\pi(i)z}{1-(1-\pi(i))z} \right)^b \quad \text{for} \quad i < j.$$

Similarly, the probability generating function for the number of strings needed to get exactly r strings in a given node at level j (when the node on $\mathcal{P}$ at level $j-1$ is full) is given by

$$X_j(z) = \left(\frac{\pi(j)z}{1-(1-\pi(j))z} \right)^r.$$

Summing up, the probability generating function $T_{j,r}(z)$ of $T_{j,r}$ is

$$T_{j,r}(z) = X_j(z) \prod_{i=1}^{j-1} X_i(z). \tag{70}$$

To compute the required probabilities, we first use the Cauchy formula,

$$\Pr\{T_{j,r} = \ell\} = \frac{1}{2\pi i} \oint \frac{T_{j,r}(z)}{z^{\ell+1}}\, dz,$$

and then the residue theorem. The calculations are rather straightforward but quite tedious. We find

$$\begin{aligned} m\Pr\{D_m \le j\} = b - \frac{1}{(b-1)!} \sum_{k=1}^{j} \left(\frac{\pi(k)}{\pi(k)-1} \right)^b \frac{\partial^{b-1}}{\partial z^{(b-1)}} \Bigg\{ \frac{z^{2b}}{(z-1)^2} (z^{-b} - z^{-m}) \\ \times \prod_{v=1, v\ne k}^{j} \left(\frac{\pi(v)z}{1-(1-\pi(v))z} \right)^b \Bigg\}_{z=z^*(k)}, \end{aligned} \tag{71}$$

where $z^*(k) = (1-\pi(k))^{-1}$. This leads to (18) for the exact distribution for D_m.

The asymptotic formula of part (iii) of Theorem 2.2 follows from the above after some algebra that we summarize below. We set throughout this derivation $j = \log_2 m + \eta$, with $\eta = O(1)$, and $k = j + O(1)$, which we justify. After substituting $\eta = \kappa - \{\log_2 m\}$, we prove part (iii) of Theorem 2.2.

Let us now analyze (71). The term involving z^{-m} in (71) becomes

$$H_1 := \frac{\pi^b(k)}{m(b-1)!(\pi(k)-1)^b} \frac{\partial^{b-1}}{\partial z^{b-1}} \left(z^{-(m-2b)} (z-1)^{-2} \varphi_1(z) \varphi_2(z) \right) |_{z=z^*(k)},$$

where

$$\varphi_1(z) = \prod_{v=1}^{k-1} \left(\frac{\pi(v)z}{1-(1-\pi(v))z} \right)^b,$$
$$\varphi_2(z) = \prod_{v=k+1}^{j} \left(\frac{\pi(v)z}{1-(1-\pi(v))z} \right)^b.$$

After using Leibniz's rule for differentiation, we obtain

$$\sum_{\ell+s+s_1+s_2=b-1} \binom{b-1}{\ell, s, s_1, s_2} \left(\frac{(-1)^{\ell+s-b}\pi^b(k)(m-2b)_\ell(-1)^s(s+1)!(1-\pi(k))^{m-3b+\ell+2+s}}{(m(b-1)!\pi(k))^{2+s}} \right)$$

$$\times \left(\varphi_1^{(s_1)}(z)\varphi_2^{(s_2)}(z) \right) |_{z^*(k)}, \tag{72}$$

where $f^{(k)}(z)$ denotes the kth derivative of $f(z)$, and $(m)_\ell = m(m-1)\cdots(m-\ell+1)$.

Now let $j = \log_2 m + \eta$ and $i = j - k$ where $i = O(1)$. We obtain

$$\frac{(\pi(k))^{\ell-1}(m-2b)_\ell}{m} \sim (m\pi(k))^{\ell-1} = \frac{2^{i(\ell-1)}}{2^{\eta(\ell-1)}} \tag{73}$$

and

$$(1-\pi(k))^{m-3b+\ell+2+s} \sim e^{-2^{-(\eta-i)}}.$$

To compute the derivatives of $\varphi_1(z)$ and $\varphi_2(z)$, we observe, for example, that for any integer r,

$$Y := \frac{\partial^r}{\partial z^r} \left(\frac{\pi(v)}{1-(1-\pi(v))z} \right)^b = \frac{(\pi(v))^b(1-\pi(v))^r(b)_r}{1-(1-\pi(v)z)^{b+r}}.$$

Setting $z = z^*(k)$ and $v = k + O(1)$, we find

$$Y \sim \frac{(b)_r}{(\pi(k))^r(1-2^{-u})^{b+r}2^{ur}} \qquad \text{in the } \varphi_1 \text{ case,} \tag{74}$$

where $u = k - v > 0$, and

$$Y \sim \frac{(b)_r 2^{ur}}{(\pi(k))^r(1-2^u)^{b+r}} \qquad \text{in the } \varphi_2 \text{ case.} \tag{75}$$

To deal with expressions like (74) or (75), we define

$$H(s) = \frac{\partial^s}{\partial z^s} \prod_{k=1}^{\infty} \left(\frac{1}{1-\pi(k)z} \right)^b |_{z=1},$$

and with $R(0,s) = -1$,

$$R(i,s) = -\frac{\partial^s}{\partial z^s} \prod_{k=1}^{i} \left(\frac{1}{1-\frac{z}{\pi(k)}} \right)^b \Bigg|_{z=1},$$

which are (13) and (14) from section 2.

These expressions are the b-equivalent of $Q^{-1}(t)$ (cf. (12)) and function $|R_i|$ used in [24, 26] (cf. (30) of [26]) parametrized by s. Clearly $R(i,s)$ decreases exponentially with i and $H(s)$ is uniformly bounded, which justifies our choice $k = j + O(1)$ for asymptotic analysis. Moreover, any term $(1-\pi(v))^r$ $(v < k)$ leads to a contribution $(1-2^{u-k})^r 2^{-ur}(1-2^{-u})^{-r}$. The sum of all these contributions is $O(1)$, which shows that we can asymptotically take $(1-\pi(v)) \sim 1$.

Let us return to (71). We can extract a term $(\pi(k))^{b-2-s-s_1-s_2} = (\pi(k))^{\ell-1}$ and, with (73), after summing over k we obtain

$$H_1 \sim \sum_{l+s+s_1+s_2=b-1} \frac{(-1)^{s_1+s_2}}{l!s_1!s_2!} \sum_{i=0}^{\infty} (s+1) R(i,s_2) H(s_1) \frac{2^{i(\ell-1)}}{2^{\eta(\ell-1)}} e^{-2^{-(\eta-i)}}.$$

Similar analysis is valid for the term at z^{-b} of (71). Finally, after substituting $\eta = \kappa - \{\log_2 m\}$, we prove part (iii) of Theorem 2.2, which completes the proof of Theorem 2.2.

Acknowledgment. We thank Philippe Jacquet (INRIA, France) and Helmut Prodinger (TU Wien) for many valuable comments regarding this research. We are particularly obliged to one of the referees whose very careful reading of the paper allowed us to eliminate some inaccuracies and led to a better presentation of our results.

THE MAXIMUM PARTITION MATCHING PROBLEM WITH APPLICATIONS*

CHI-CHANG CHEN† AND JIANER CHEN‡

Abstract. Let $\mathcal{S} = \{C_1, C_2, \ldots, C_k\}$ be a collection of pairwise disjoint subsets of $U = \{1, 2, \ldots, n\}$ such that $\bigcup_{i=1}^{k} C_i = U$. A *partition matching* of $\mathcal{S}$ consists of two subsets $\{a_1, \ldots, a_m\}$ and $\{b_1, \ldots, b_m\}$ of U together with a sequence of distinct partitions of $\mathcal{S}$: $(\mathcal{A}_1, \mathcal{B}_1), \ldots, (\mathcal{A}_m, \mathcal{B}_m)$ such that a_i is contained in a subset in the collection $\mathcal{A}_i$ and b_i is contained in a subset in the collection $\mathcal{B}_i$ for all $i = 1, \ldots, m$. An efficient algorithm is developed that constructs a maximum partition matching for a given collection $\mathcal{S}$. The algorithm can be used to construct optimal parallel routing between two nodes in interconnection networks.

1. Introduction.

Matching is one of the most extensively studied areas in computer science, since it is interesting from a combinatorial point of view and has wide applications as well. Examples of matching are the maximum graph matching problem [15], maximum graph adjacency matching problem [7], stable marriage problem [10], and three-dimensional matching problem [9].

In this paper, we introduce a new maximum matching problem, study its computational complexity, and demonstrate its applications in interconnection networks. Let $\mathcal{S} = \{C_1, C_2, \ldots, C_k\}$ be a collection of subsets of the universal set $U = \{1, 2, \ldots, n\}$ such that $\bigcup_{i=1}^{k} C_i = U$ and $C_i \cap C_j = \phi$ for all $i \neq j$. A *partition matching* (of order m) of $\mathcal{S}$ consists of two ordered subsets $L = \{a_1, a_2, \ldots, a_m\}$ and $R = \{b_1, b_2, \ldots, b_m\}$ of m elements of U (the subsets L and R may not be disjoint), together with a sequence of m distinct partitions of $\mathcal{S}$: $(\mathcal{A}_1, \mathcal{B}_1), (\mathcal{A}_2, \mathcal{B}_2), \ldots, (\mathcal{A}_m, \mathcal{B}_m)$ such that for all $i = 1, \ldots, m$, a_i is contained in a subset in the collection $\mathcal{A}_i$ and b_i is contained in a subset in the collection $\mathcal{B}_i$. The *maximum partition matching* problem is to construct a partition matching of order m for a given collection $\mathcal{S}$ with m maximized.

The maximum partition matching problem can be formulated in terms of the three-dimensional matching problem as follows: given an instance $\mathcal{S} = \{C_1, C_2, \ldots, C_k\}$ of the maximum partition matching problem, we construct an instance M for the three-dimensional matching problem such that a triple (a, b, P) is contained in M if and only if a and b are elements in U, and $P = (\mathcal{A}, \mathcal{B})$ is a partition of $\mathcal{S}$ such that a is contained in a set in $\mathcal{A}$ and b is contained in a set in $\mathcal{B}$. Unfortunately, the number of partitions of the collection $\mathcal{S}$ can be as large as 2^n; thus the above reduction is not polynomial-time bounded. Moreover, the three-dimensional matching problem is NP-hard [9].

We will present an algorithm of running time $O(n^2 \log n)$ that solves the maximum partition matching problem. We first show that when the number of subsets in the collection $\mathcal{S}$ is sufficiently large, a maximum partition matching can be constructed from a simpler "prematching" on the elements in U. For the case that the number of subsets in the collection $\mathcal{S}$ is small, we develop a greedy algorithm that uses a "chain justification" technique and finds a maximum partition matching. A sophisticated combinatorial analysis is given to prove the correctness of the algorithm.

The maximum partition matching problem arises in connection with the parallel routing problem in interconnection networks. We show how the above algorithm can be applied to construct an optimal parallel routing in star networks, which have received considerable attention recently and have been shown to be an attractive alternative to the widely used hypercube networks [1]. In particular, we present an efficient algorithm that constructs between two arbitrary nodes in the n-dimensional star network a maximum number of node-disjoint *shortest* paths, which can be further used to construct between the two nodes $n-1$ node-disjoint paths of minimum bulk length (the *bulk length* of $n-1$ node-disjoint paths between two nodes is defined to be the length of the longest path among the $n-1$ paths). Note that these two problems on general graphs are NP-hard [8, 9]. These results significantly improve the previous parallel routing results in star networks [6, 11, 13, 14].

We introduce necessary terminology that is used in the rest of our discussion.

Let $M = \langle L, R, (\mathcal{A}_1, \mathcal{B}_1), \ldots, (\mathcal{A}_m, \mathcal{B}_m)\rangle$ be a partition matching of the collection $\mathcal{S}$, where $L = \{a_1, \ldots, a_m\}$ and $R = \{b_1, \ldots, b_m\}$. We will say that the partition $(\mathcal{A}_i, \mathcal{B}_i)$ *left-pairs* the element a_i and *right-pairs* the element b_i. An element a is said to be *left-paired* if it is in the set L. Otherwise, the element a is *left-unpaired*. Similarly, we define *right-paired* and *right-unpaired* elements. The collections $\mathcal{A}_i$ and $\mathcal{B}_i$ are called the *left-collection* and *right-collection* of the partition $(\mathcal{A}_i, \mathcal{B}_i)$. The partition matching M may also be written as $M[(a_1, b_1), \ldots, (a_m, b_m)]$ if the partitions $(\mathcal{A}_1, \mathcal{B}_1), \ldots, (\mathcal{A}_m, \mathcal{B}_m)$ are implied. The partition matching $M[(a_1, b_1), \ldots, (a_m, b_m)]$ is *maximum* if m is the largest among all partition matchings of $\mathcal{S}$.

A permutation $u = a_1 a_2 \cdots a_n$ of the elements in the set $U = \{1, 2, \ldots, n\}$ can be given by a product of disjoint cycles [2], which will be called the *cycle structure* of the permutation. A $\pi[1, i]$ *transposition* on u is to exchange the positions of a_1 and a_i in u. More specifically, $\pi[1, i](u) = a_i a_2 a_3 \cdots a_{i-1} a_1 a_{i+1} \cdots a_n$. It is sometimes more convenient to write the transposition $\pi[1, i](u)$ as $\pi[a_i](u)$ to indicate that the transposition exchanges the position of the first symbol and the symbol a_i in u. Let us consider how a transposition changes the cycle structure of a permutation. Write u in its cycle structure

$$u = (a_1^{(1)} \cdots a_{n_1}^{(1)}\ 1)(a_1^{(2)} \cdots a_{n_2}^{(2)}) \cdots (a_1^{(k)} \cdots a_{n_k}^{(k)}).$$

Now suppose we apply the transposition $\pi[1, i]$ on u. There are two cases.

If a_i is not in the cycle containing the symbol 1, then $\pi[1, i]$ "merges" the cycle containing 1 with the cycle containing a_i. More precisely, suppose that $a_i = a_1^{(2)}$ (note that each cycle can be cyclically permuted and the order of the cycles is not important). Then the permutation $\pi[1, i](u)$ will have the cycle structure

$$\pi[1, i](u) = (a_1^{(2)} \cdots a_{n_2}^{(2)} a_1^{(1)} \cdots a_{n_1}^{(1)}\ 1)(a_1^{(3)} \cdots a_{n_3}^{(3)}) \cdots (a_1^{(k)} \cdots a_{n_k}^{(k)}).$$

If a_i is in the cycle containing the symbol 1, then $\pi[1, i]$ "splits" the cycle. More precisely, suppose that $a_i = a_j^{(1)}$, $j > 1$ (note that $a_1^{(1)} = a_1$ and we assume $i > 1$).

Algorithm. PREMATCHING

INPUT: The collection $\mathcal{S} = \{C_1, \ldots, C_k\}$ of subsets of U, with $2^k \geq 2n$.
OUTPUT: A partition matching M in $\mathcal{S}$.

1. $\mathcal{T} = \mathcal{S}$;
2. **while** $\mathcal{T}$ contains more than one set
   but does not consist of exactly three singular sets **do**
   Pick two sets C and C' of largest cardinality in $\mathcal{T}$;
   Pick an element a in C and an element a' in C';
   Pick two unused partitions of $\mathcal{S}$ of the forms $(\mathcal{A} \cup \{C\}, \mathcal{B} \cup \{C'\})$, and $(\mathcal{B} \cup \{C'\}, \mathcal{A} \cup \{C\})$, where $\mathcal{A} \cup \mathcal{B} = \mathcal{S} - \{C, C'\}$;
   Use the partition $(\mathcal{A} \cup \{C\}, \mathcal{B} \cup \{C'\})$ to left-pair a and right-pair a';
   Use the partition $(\mathcal{B} \cup \{C'\}, \mathcal{A} \cup \{C\})$ to left-pair a' and right-pair a;
   $C = C - \{a\}$; $C' = C' - \{a'\}$;
   If any of the sets C and C' is an empty set now, then delete it from the collection $\mathcal{T}$;
3. **if** $\mathcal{T}$ consists of exactly three singular sets $C_1 = \{a_1\}$, $C_2 = \{a_2\}$, and $C_3 = \{a_3\}$
   then Pick three unused partitions of $\mathcal{S}$ of the forms $(\mathcal{A}_1 \cup \{C_1\}, \mathcal{B}_1 \cup \{C_2\})$, $(\mathcal{A}_2 \cup \{C_2\}, \mathcal{B}_2 \cup \{C_3\})$, and $(\mathcal{A}_3 \cup \{C_3\}, \mathcal{B}_3 \cup \{C_1\})$ to left-pair a_1 and right-pair a_2, left-pair a_2 and right-pair a_3, and left-pair a_3 and right-pair a_1, respectively.

FIG. 2.1. *The algorithm* PREMATCHING.

Then $\pi[1, i](u)$ will have the cycle structure

$$\pi[1, i](u) = (a_1^{(1)} \cdots a_{j-1}^{(1)})(a_j^{(1)} \cdots a_{n_1}^{(1)} 1)(a_1^{(2)} \cdots a_{n_2}^{(2)}) \cdots (a_1^{(k)} \cdots a_{n_k}^{(k)}).$$

Note that if a symbol a_i is in a single symbol cycle in a cycle structure of a permutation $u = a_1 a_1 \cdots a_n$, then the symbol is in its "correct" position, i.e., $a_i = i$, and that if a symbol is in a cycle containing more than one symbol, then the symbol is not in its correct position. Denote by ε the identity permutation $\varepsilon = 12 \cdots n$.

2. Partition matching via element prematching. For the rest of this paper, we assume that $U = \{1, 2, \ldots, n\}$ and that $\mathcal{S} = \{C_1, C_2, \ldots, C_k\}$ is a collection of pairwise disjoint subsets of U such that $\bigcup_{i=1}^{k} C_i = U$.

A necessary condition for two subsets $\{a_1, a_2, \ldots, a_m\}$ and $\{b_1, b_2, \ldots, b_m\}$ of U to form a partition matching for the collection $\mathcal{S}$ is that a_i and b_i belong to different subsets in the collection $\mathcal{S}$ for all $i = 1, 2, \ldots, m$. This motivates the following definition.

DEFINITION 2.1. *Two subsets* $\{a_1, a_2, \ldots, a_m\}$ *and* $\{b_1, b_2, \ldots, b_m\}$ *of* U *form an* element prematching $P = \{(a_i, b_i) \mid 1 \leq i \leq m\}$ *if* a_i *and* b_i *do not belong to the same subset in the collection* $\mathcal{S}$ *for all* $i = 1, 2, \ldots, m$. *The element prematching* P *is* maximum *if* m *is the largest among all element prematchings of* $\mathcal{S}$.

The following lemma follows directly from Definition 2.1.

LEMMA 2.2. *Let* $\{a_1, a_2, \ldots, a_m\}$ *and* $\{b_1, b_2, \ldots, b_m\}$ *be a maximum element prematching of* $\mathcal{S}$. *If the subsets* $\{a_1, a_2, \ldots, a_m\}$ *and* $\{b_1, b_2, \ldots, b_m\}$ *also form a partition matching* M *of* $\mathcal{S}$, *then* M *is a maximum partition matching.*

We show in this section that when the number of subsets in the collection $\mathcal{S}$ is sufficiently large, a maximum partition matching in $\mathcal{S}$ can be constructed via a maximum element prematching. Consider the algorithm PREMATCHING in Figure 2.1. We say that a set is *singular* if it consists of a single element.

The rest of this section is for a proof of correctness and complexity analysis of the algorithm PREMATCHING.

LEMMA 2.3. *Let $P = \{(a_i, b_i) \mid 1 \le i \le m\}$ be the set of pairs constructed by the algorithm* PREMATCHING. *Then P forms a maximum element prematching for the collection $\mathcal{S}$.*

Proof. Since for each pair (a_i, b_i) constructed by the algorithm PREMATCHING, the elements a_i and b_i are from different sets in $\mathcal{S}$, the set P forms an element prematching. We show that this element prematching P is maximum.

Denote by $|C_i|$ the cardinality of the set C_i. Without loss of generality, we assume $|C_1| \ge |C_2| \ge \cdots \ge |C_k|$. There are two cases.

Case 1. $|C_1| > n/2$. Because in an element prematching each pair (a, b) must have either $a \in \cup_{i=2}^{k} C_i$ or $b \in \cup_{i=2}^{k} C_i$, a maximum element prematching can have at most $2\sum_{i=2}^{k} |C_i|$ pairs.

On the other hand, in case $|C_1| > n/2$ the algorithm PREMATCHING actually constructs $2\sum_{i=2}^{k} |C_i|$ pairs: Since $|C_1| > \sum_{i=2}^{k} |C_i|$, in each execution of the body of the **while** loop in step 2 the set C_1 always has the largest cardinality. Thus, the algorithm always picks an element a in C_1 and an element b in $\bigcup_{i=2}^{k} C_i$ and then makes the pairs (a, b) and (b, a). The loop will stop when all elements in $\bigcup_{i=2}^{k} C_i$ have been used, which results in exactly $2\sum_{i=2}^{k} |C_i|$ pairs. Thus, the lemma is true for this case.

Case 2. $|C_1| \le n/2$. In this case we show that the algorithm PREMATCHING always constructs an element prematching with n pairs (thus maximum).

If $\mathcal{S}$ consists of only two sets C_1 and C_2, then since $|C_1| \ge |C_2|$, $|C_1| \le n/2$, and $|C_1| + |C_2| = n$, we must have $|C_1| = |C_2|$. Now it becomes trivial to verify in this case that the algorithm PREMATCHING constructs a maximum element prematching with n pairs.

Thus we assume that the collection $\mathcal{S}$ contains at least three sets. We prove the lemma for this case by induction on the size n of the universal set U. When $n = 3$, the collection $\mathcal{S}$ consists of exactly three singular sets, and step 3 of the algorithm shows how an element prematching with three pairs can be constructed. Now assume that $n > 3$. Note that after the first execution of the body of the **while** loop in step 2, the collection $\mathcal{T}$ becomes

$$\mathcal{T}' = \{C_1', C_2', C_3, \ldots, C_k\},$$

where $C_1' = C_1 - \{a\}$, $C_2' = C_2 - \{a'\}$, and $|C_1'| + |C_2'| + |C_3| + \cdots + |C_k| = n - 2$. We show that the largest set in $\mathcal{T}'$ contains at most $(n-2)/2$ elements.

If C_1' is still the largest set, then from $|C_1| \le n/2$ we have $|C_1| \le \sum_{i=2}^{k} |C_i|$. Consequently, $|C_1'| \le |C_2'| + |C_3| + \cdots + |C_k|$, i.e., $|C_1'| \le (n-2)/2$. On the other hand, if C_1' is no longer the largest set, then C_3 must be the largest set in $\mathcal{T}'$, and before the first execution of the body of the **while** loop in step 2 we have $|C_1| = |C_2| = |C_3|$. Thus, $|C_3| \le n/3$. Note that $|C_3|$ is an integer; thus $|C_3| \le n/3$ implies $|C_3| \le (n-2)/2$ for all $n > 3$.

Thus, the collection $\mathcal{T}'$ consists of k subsets of the universal set $U - \{a, a'\}$ of $n - 2$ elements, and the largest set in $\mathcal{T}'$ contains no more than $(n-2)/2$ elements. Note that the algorithm PREMATCHING applies the same strategy on the collection $\mathcal{T}'$. By the inductive hypothesis, the algorithm constructs an element prematching P' with $n - 2$ pairs for the collection $\mathcal{T}'$. Combining this with the pairs (a, a') and (a', a) constructed in the first execution of the body of the **while** loop in step 2, we obtain an element prematching with n pairs for the collection $\mathcal{S}$.

Combining all these analyses, we conclude with the lemma. ∎

To complete the correctness proof for the algorithm PREMATCHING, we need only to show that for each pair (a, a') constructed by the algorithm, there is always a distinct partition of $\mathcal{S}$ that implements the pairing. By the assumption of the algorithm, we have $2^k \geq 2n$.

We first consider step 2 of the algorithm PREMATCHING. Suppose that at some moment the algorithm needs a partition to left-pair an element $a \in C$ and right-pair an element $a' \in C'$. Note that each execution of the body of the **while** loop uses two partitions of the forms $(\mathcal{A}, \mathcal{B})$ and $(\mathcal{B}, \mathcal{A})$. Thus each execution of the body of the **while** loop can use at most one partition whose left-collection contains C and whose right-collection contains C'. Consequently, less than $\lfloor n/2 \rfloor$ partitions whose left-collection contains C and whose right-collection contains C' have been used. Since $2^k \geq 2n$ and there are $2^{k-2} \geq n/2$ partitions of $\mathcal{S}$ whose left-collection contains C and whose right-collection contains C', we conclude that there is always an unused partition P that can be used to left-pair the element a and right-pair the element a'.

The proof proceeds similarly for step 3. For example, suppose we want to left-pair the element $a_3 \in C_3$ and right-pair the element $a_1 \in C_1$. There are $2^{k-2} \geq n/2$ total partitions of $\mathcal{S}$ whose left-collection contains C_3 and whose right-collection contains C_1, of which at most $(n-3)/2$ have been used (by step 2). Also note that no partition that is used to left-pair a_1 and right-pair a_2 or left-pair a_2 and right-pair a_3 in step 3 has C_3 in its left-collection and C_1 in its right-collection. Therefore, there is always an unused partition that can be used to left-pair a_3 and right-pair a_1.

This shows that the algorithm PREMATCHING constructs a partition matching in the collection $\mathcal{S}$. Combining this with Lemmas 2.2 and 2.3, we have the following theorem.

THEOREM 2.4. *Let $\mathcal{S} = \{C_1, C_2, \ldots, C_k\}$ be a collection of nonempty subsets of the universal set $U = \{1, 2, \ldots, n\}$ such that $\bigcup_{i=1}^{k} C_i = U$ and $C_i \cap C_j = \phi$ for $i \neq j$. If $2^k \geq 2n$, then the algorithm* PREMATCHING *constructs a maximum partition matching in $\mathcal{S}$.*

The algorithm PREMATCHING can be implemented to have running time $O(n^2)$. For this, we represent each partition of $\mathcal{S}$ by a binary number of k bits and assume that simple arithmetic operations on k-bit binary numbers take constant time. With this representation, testing whether a set C_i is in the left-collection or in the right-collection of a partition P takes constant time. We keep a list $\mathcal{L}$ for the used partitions, sorted by their k-bit binary representations. When a pair (C_i, C_j) of sets is given and we need to find a partition whose left-collection contains C_i and whose right-collection contains C_j (this kind of partitions will be called "partitions pairing (C_i, C_j)" in the following description), we go through the list $\mathcal{L}$ to identify all used partitions pairing (C_i, C_j) in $\mathcal{L}$. Let $\mathcal{L}'$ be the (sorted) sublist containing all used partitions pairing (C_i, C_j) in $\mathcal{L}$. Note that given a partition P pairing (C_i, C_j), we can construct the "next" partition pairing (C_i, C_j) by a special "adding 1" operation on P; this adding 1 operation first deletes the ith bit b_i and the jth bit b_j from P, then adds 1 to the resulting number, and finally reinserts the bits b_i and b_j back into the ith and jth positions, respectively. The adding 1 operation can be implemented by a constant number of arithmetic operations; thus it takes constant time. Therefore, by going through the sublist $\mathcal{L}'$ we can find a "gap" between two consecutive partitions P_1 and P_2 in $\mathcal{L}'$; i.e., P_2 is not the partition pairing (C_i, C_j) next to the partition P_1, so the partition pairing (C_i, C_j) next to the partition P_1 is unused. However, if there is no gap between any two consecutive partitions in $\mathcal{L}'$, the partition pairing (C_i, C_j) next to the last partition in $\mathcal{L}'$ is unused. In any case, the constructed unused partition is

used to pair (C_i, C_j) and is added to the list $\mathcal{L}$ (by scanning the list $\mathcal{L}$ and inserting the partition into a proper position in $\mathcal{L}$). In conclusion, in time $O(n)$ we can find an unused partition to pair two given elements and update the list $\mathcal{L}$. Consequently, the algorithm PREMATCHING runs in time $O(n^2)$.

3. Maximum partition matching: General case. According to Theorem 2.4, we only have to investigate maximum partition matchings for collections of k subsets in U such that $2^k < 2n$. We shall show in this section that a maximum partition matching for such collections can be constructed by a greedy strategy.

Suppose we have constructed a partition matching $M = M[(a_1, b_1), \ldots, (a_h, b_h)]$ and want to expand this matching. The partitions of the collection $\mathcal{S}$ then can be classified into two classes: h of the partitions are used to pair the h pairs (a_i, b_i), $i = 1, \ldots, h$, and the remaining $2^k - h$ partitions are unused. Now if there is an unused partition $P = (\mathcal{A}, \mathcal{B})$ such that there is a left-unpaired element a in $\mathcal{A}$ and a right-unpaired element b in $\mathcal{B}$, then we simply pair the element a with the element b using the partition P, thus expanding the partition matching M.

Now suppose that there is no such unused partition; i.e., for all unused partitions $(\mathcal{A}, \mathcal{B})$, either $\mathcal{A}$ contains no left-unpaired elements or $\mathcal{B}$ contains no right-unpaired elements. This case may not necessarily imply that the current partition matching is the maximum. For example, suppose that $(\mathcal{A}, \mathcal{B})$ is an unused partition such that there is a left-unpaired element a in $\mathcal{A}$ but no right-unpaired elements in $\mathcal{B}$. Assume further that there is a *used* partition $(\mathcal{A}', \mathcal{B}')$ that pairs elements (a', b') such that the element b' is in $\mathcal{B}$ and there is a right-unpaired element b in $\mathcal{B}'$. Then we can let the partition $(\mathcal{A}', \mathcal{B}')$ pair the elements (a', b) and let the partition $(\mathcal{A}, \mathcal{B})$ pair the elements (a, b'), thus expanding the partition matching M. An explanation of this process is that the used partitions have been incorrectly used to pair elements; thus, to construct a maximum partition matching, we must re-pair some of the elements. To further investigate this relation, we need to introduce a few notations.

For a used partition P of $\mathcal{S}$, we underline a set in the left-collection (respectively, the right-collection) of P to indicate that an element in the set is left-paired (respectively, right-paired) by the partition P. The sets will be called the *left-paired set* and the *right-paired set* of the partition P, respectively.

DEFINITION 3.1. *A used partition P is* directly left-reachable *from a partition $P_1 = (\mathcal{A}_1, \mathcal{B}_1)$ if the left-paired set of P is contained in $\mathcal{A}_1$ (the partition P_1 can be either used or unused). The partition P is* directly right-reachable *from a partition $P_2 = (\mathcal{A}_2, \mathcal{B}_2)$ if the right-paired set of P is contained in $\mathcal{B}_2$. A partition P_s is* left-reachable *(respectively,* right-reachable*) from a partition P_1 if there are partitions $P_2, \ldots, P_{s-1}$ such that P_i is directly left-reachable (respectively, directly right-reachable) from P_{i-1} for all $i = 2, \ldots, s$.*

The left-reachability and the right-reachability are transitive relations.

Let $P_1 = (\mathcal{A}_1, \mathcal{B}_1)$ be an unused partition such that there are no left-unpaired elements in $\mathcal{A}_1$, and let $P_s = (\mathcal{A}_s, \mathcal{B}_s)$ be a partition left-reachable from P_1 and there is a left-unpaired element a_s in $\mathcal{A}_s$. We show how we can use a *chain justification* to make a left-unpaired element for the collection $\mathcal{A}_1$.

By Definition 3.1, there are used partitions $P_2, \ldots, P_{s-1}$ such that P_i is directly left-reachable from P_{i-1} for $i = 2, \ldots, s$. We can further assume that P_i is *not* directly left-reachable from P_{i-2} for $i = 3, \ldots, s$—otherwise we simply delete the partition P_{i-1} from the sequence. Thus, these partitions can be written as

$$P_1 = (\{C_1\} \cup \mathcal{A}'_1, \mathcal{B}_1), \qquad P_2 = (\{\underline{C_1}, C_2\} \cup \mathcal{A}'_2, \mathcal{B}_2),$$
$$P_3 = (\{\underline{C_2}, C_3\} \cup \mathcal{A}'_3, \mathcal{B}_3), \qquad \ldots,$$
$$P_{s-1} = (\{\underline{C_{s-2}}, C_{s-1}\} \cup \mathcal{A}'_{s-1}, \mathcal{B}_{s-1}),$$
$$P_s = (\{\underline{C_{s-1}}, C_s\} \cup \mathcal{A}'_s, \mathcal{B}_s),$$

where $\mathcal{A}'_1, \ldots, \mathcal{A}'_s$ are subcollections of $\mathcal{S}$ without an underlined set.

We can assume that the left-unpaired element a_s in $\mathcal{A}_s = \{\underline{C_{s-1}}, C_s\} \cup \mathcal{A}'_s$ is in a nonunderlined set C_s in $\mathcal{A}_s$—otherwise, we consider the sequence $P_1, P_2, \ldots, P_{s-1}$ instead. We modify the partition sequence into

$$P_1 = (\{C_1\} \cup \mathcal{A}'_1, \mathcal{B}_1), \qquad P_2 = (\{C_1, \underline{C_2}\} \cup \mathcal{A}'_2, \mathcal{B}_2),$$
$$P_3 = (\{C_2, \underline{C_3}\} \cup \mathcal{A}'_3, \mathcal{B}_3), \qquad \ldots,$$
$$P_{s-1} = (\{C_{s-2}, \underline{C_{s-1}}\} \cup \mathcal{A}'_{s-1}, \mathcal{B}_{s-1}),$$
$$P_s = (\{C_{s-1}, \underline{C_s}\} \cup \mathcal{A}'_s, \mathcal{B}_s).$$

The interpretation is as follows: We use the partition P_s to left-pair the left-unpaired element a_s (the right-paired element in the right-collection $\mathcal{B}_s$ is unchanged). Thus, the element a_{s-1} in the set C_{s-1} the partition P_s used to left-pair becomes left-unpaired. We then use the partition P_{s-1} to left-pair the element a_{s-1} and leave an element a_{s-2} in the set C_{s-2} left-unpaired. Then we use the partition P_{s-2} to left-pair a_{s-2}, ... At the end, we use the partition P_2 to left-pair an element a_2 in the set C_2 and leave an element a_1 in the set C_1 left-unpaired. Therefore, this process makes an element in the left-collection $\mathcal{A}_1 = \{C_1\} \cup \mathcal{A}'_1$ of the partition P_1 left-unpaired.

The above process will be called a *left-chain justification*. Thus, given an unused partition $P_1 = (\mathcal{A}_1, \mathcal{B}_1)$ in which the left-collection $\mathcal{A}_1$ has no left-unpaired elements and given a used partition $P_s = (\mathcal{A}_s, \mathcal{B}_s)$ left-reachable from P_1 such that the left-collection $\mathcal{A}_s$ of P_s has a left-unpaired element, we can apply the left-chain justification that keeps all used partitions in the partition matching M and makes a left-unpaired element for the partition P_1. A process called *right-chain justification* for right-collections of the partitions can be described similarly. This motivates the algorithm Greedy Expanding in Figure 3.1.

Theorem 3.2. *The algorithm* Greedy Expanding *runs in time* $O(n^2 \log n)$.

Proof. For each set C_i, we keep a counter for the number of left-unpaired elements in C_i and a counter for the number of right-unpaired elements in C_i, so that checking whether a partition has an unpaired element can be done in time $O(k)$.

To test left-reachabilities in each execution of Cases 1–4, we let v_i be the collection of all used partitions whose left-paired set is C_i, for $i = 1, \ldots, k$. Note that if a partition in v_i is directly left-reachable from a partition P, then the left-collection of P contains C_i; thus *all* partitions in v_i are left-reachable from P. If v_i contains a used partition whose left-collection contains a left-unpaired element, then we "label" v_i by such a partition (if there is more than one such partition, pick any one of them). We construct a directed graph G whose vertices are v_1, ..., v_k. There is an edge from vertex v_i to vertex v_j in G if and only if all partitions in v_j are directly left-reachable from a partition in v_i. The graph G contains at most $O(k^2)$ edges and can be constructed in time $O(nk)$ by scanning the partitions in each vertex in G.

For each set C_i in $\mathcal{S}$, in time $O(k^2)$ we can find all vertices v_j in the graph G such that there is a path in G from v_i to v_j. If any v_j of these vertices is labeled by a partition, then we associate the set C_i with the vertex v_j (if there is more than one such vertex, pick any one of them).

Algorithm. GREEDY EXPANDING

INPUT: A collection $\mathcal{S} = \{C_1, \ldots, C_k\}$ of pairwise disjoint subsets of U, with $2^k < 2n$.
OUTPUT: A partition matching M_{exp} in $\mathcal{S}$.

Start with $M_{exp} = \emptyset$ and repeat the following steps until no more changes.

1. **Case 1.** There is an unused partition $P = (\mathcal{A}, \mathcal{B})$ that has a left-unpaired element a in $\mathcal{A}$ and a right-unpaired element b in $\mathcal{B}$
Then pair the two elements (a, b) by the partition P and add P to the matching M_{exp};
2. **Case 2.** There is an unused partition $P = (\mathcal{A}, \mathcal{B})$ that has a right-unpaired element b in $\mathcal{B}$ but no left-unpaired elements in $\mathcal{A}$, and there is a used partition $P' = (\mathcal{A}', \mathcal{B}')$ left-reachable from P and the collection $\mathcal{A}'$ has a left-unpaired element
Then use the left-chain justification to make a left-unpaired element a for the collection $\mathcal{A}$, pair the two elements (a, b) by the partition P, and add P to the matching M_{exp};
3. **Case 3.** There is an unused partition $P = (\mathcal{A}, \mathcal{B})$ that has a left-unpaired element a in $\mathcal{A}$ but no right-unpaired elements in $\mathcal{B}$, and there is a used partition $P' = (\mathcal{A}', \mathcal{B}')$ right-reachable from P and the collection $\mathcal{B}'$ has a right-unpaired element
Then use the right-chain justification to make a right-unpaired element b for the collection $\mathcal{B}$, pair the two elements (a, b) by the partition P, and add P to the matching M_{exp};
4. **Case 4.** There is an unused partition $P = (\mathcal{A}, \mathcal{B})$ that has no left-unpaired elements in $\mathcal{A}$ and no right-unpaired elements in $\mathcal{B}$, and there are two used partitions $P' = (\mathcal{A}', \mathcal{B}')$ left-reachable from P and $P'' = (\mathcal{A}'', \mathcal{B}'')$ right-reachable from P such that $\mathcal{A}'$ has a left-unpaired element and $\mathcal{B}''$ has a right-unpaired element
Then use the left-chain justification to make a left-unpaired element a for $\mathcal{A}$, and use the right-chain justification to make a right-unpaired element b for $\mathcal{B}$, then pair the two elements (a, b) by the partition P, and add P to the matching M_{exp}.

FIG. 3.1. *The algorithm* GREEDY EXPANDING.

The above preprocessing takes time $O(nk + k^3)$.

Let $P = \{\mathcal{A}, \mathcal{B}\}$ be an unused partition. It is easy to verify that for any collection v_j, *all* partitions in v_j are left-reachable from P if and only if there is a set C_i in $\mathcal{A}$ such that there is a path from v_i to v_j in the graph G. In particular, a used partition whose left-collection contains a left-unpaired element is left-reachable from P if and only if a set C_i in $\mathcal{A}$ is associated with a vertex v_j in G labeled by a used partition $P' = \{\mathcal{A}', \mathcal{B}'\}$, where $\mathcal{A}'$ contains a left-unpaired element. Therefore, the conditions in Cases 1–4 in the algorithm GREEDY EXPANDING for each unused partition P can be tested in time $O(k)$. When a set C_i in $\mathcal{A}$ is associated with a vertex v_j labeled by a used partition $P' = \{\mathcal{A}', \mathcal{B}'\}$, the actual left-reachability path from P to P' can be constructed by first finding a path p in the graph G from vertex v_i to vertex v_j and then searching the partitions in each of the vertices on the path p. Thus such a left-reachability path from the unused partition P to the used partition P' can be constructed in time $O(nk + k^2)$.

The right-reachability can be handled similarly.

Since there are at most $2^k < 2n$ partitions, we conclude that each execution of the loop (Cases 1–4) takes time bounded by $O(nk + k^3) = O(n \log n)$ since $k = O(\log n)$. Since each execution of the loop adds at least one partition to the partition matching M_{exp}, the total running time of the algorithm GREEDY EXPANDING is bounded by $O(n^2 \log n)$. □

After execution of the algorithm GREEDY EXPANDING, we obtain a partition matching M_{exp}. For each partition $P = (\mathcal{A}, \mathcal{B})$ not included in M_{exp}, either $\mathcal{A}$ has no

left-unpaired elements and no used partition left-reachable from P has a left-unpaired element in its left-collection or $\mathcal{B}$ has no right-unpaired elements and no used partition right-reachable from P has a right-unpaired element in its right-collection.

DEFINITION 3.3. *Define L_{free} to be the set of partitions P not used by M_{exp} such that the left-collection of P has no left-unpaired elements and no used partition left-reachable from P has a left-unpaired element in its left-collection, and define R_{free} to be the set of partitions P' not used by M_{exp} such that the right-collection of P' has no right-unpaired elements and no used partition right-reachable from P' has a right-unpaired element in its right-collection.*

According to the algorithm GREEDY EXPANDING, each partition not used by M_{exp} is either in the set L_{free} or in the set R_{free}. The sets L_{free} and R_{free} may not be disjoint.

DEFINITION 3.4. *Define L_{reac} to be the set of partitions in M_{exp} that are left-reachable from a partition in L_{free}, and define R_{reac} to be the set of partitions in M_{exp} that are right-reachable from a partition in R_{free}.*

According to Definition 3.3 and Definition 3.4, if a used partition P is in the set L_{reac}, then all elements in its left-collection are left-paired, and if a used partition P is in the set R_{reac}, then all elements in its right-collection are right-paired.

We first show that if L_{reac} and R_{reac} are not disjoint, then we can construct a maximum partition matching from the partition matching M_{exp} constructed by the algorithm GREEDY EXPANDING.

LEMMA 3.5. *If the sets L_{reac} and R_{reac} contain a common partition and the partition matching M_{exp} has less than n pairs, then there is a set C_0 in $\mathcal{S}$, $|C_0| \leq n/2$ such that either all elements in each set $C \neq C_0$ are left-paired and every used partition whose left-paired set is not C_0 is contained in L_{reac} or all elements in each set $C \neq C_0$ are right-paired and every used partition whose right-paired set is not C_0 is contained in R_{reac}.*

Proof. Let the partition $P = (\mathcal{A}, \mathcal{B})$ be in the intersection of L_{reac} and R_{reac}. Therefore, all elements in $\mathcal{A}$ are left-paired and all elements in $\mathcal{B}$ are right-paired. Since there are totally n elements in $\mathcal{A} \cup \mathcal{B}$, one of $\mathcal{A}$ and $\mathcal{B}$ has at least $n/2$ elements.

Suppose that $\mathcal{A}$ has at least $n/2$ elements, which are all left-paired. Since M_{exp} has less than n pairs, there is a set C_0 that contains left-unpaired elements. In particular, C_0 is not contained in the collection $\mathcal{A}$. Thus, $|C_0| \leq n/2$.

Let $P_1, \ldots, P_t$ be the partitions in M_{exp} that are used to left-pair the elements in $\mathcal{A}$. Thus, $t \geq n/2$. Since the left-paired set of each P_i is also contained in $\mathcal{A}$, by Definition 3.1 P_i is directly left-reachable from $P = (\mathcal{A}, \mathcal{B})$. Now $P \in L_{reac}$. Thus, we also have $P_i \in L_{reac}$ for $i = 1, \ldots, t$. In particular, all elements in the left-collection of each P_i have been left-paired. Consequently, the set C_0 is not contained in the left-collection of any of these partitions $P_1, \ldots, P_t$.

Suppose that there is another set $C \neq C_0$ in $\mathcal{S}$ that also is not contained in the left-collection of any of the partitions $P_1, \ldots, P_t$. Then, since the total number of partitions whose left-collections do not contain the sets C_0 and C is 2^{k-2}, we get $2^{k-2} \geq t$. However, this would contradict the facts that $t \geq n/2$ and $2^k < 2n$.

Therefore, the set C_0 is the only set in $\mathcal{S}$ that is not contained in the left-collection of any of the partitions $P_1, \ldots, P_t$. In particular, the set C_0 is the only set that contains left-unpaired elements. All elements in each set $C \neq C_0$ are left-paired.

Now let P' be a used partition whose left-paired set $C \neq C_0$. Since the set C must be contained in the left-collection of some partition P_i among $\{P_1, \ldots, P_t\}$, by the definition of the left-reachability, the partition P' is left-reachable from the

partition P_i. Since the partition P_i is in L_{reac}, we conclude that the partition P' is also in L_{reac}.

Thus, we have proved that if the left-collection $\mathcal{A}$ of the partition $P = (\mathcal{A}, \mathcal{B})$ in the intersection of L_{reac} and R_{reac} has at least $n/2$ elements, then there is a set C_0 in $\mathcal{S}$, $|C_0| \leq n/2$, such that all elements in each set $C \neq C_0$ are left-paired and every used partition whose left-paired set is not C_0 is in the set L_{reac}.

In case the right-collection $\mathcal{B}$ of the partition P has at least $n/2$ elements, we can prove in a completely similar way that there is a set C_0 in $\mathcal{S}$, $|C_0| \leq n/2$, such that all elements in each set $C \neq C_0$ are right-paired and every used partition whose right-paired set is not C_0 is in R_{reac}. □

Now we are ready for the following theorem.

THEOREM 3.6. *If L_{reac} and R_{reac} have a common partition, then the collection $\mathcal{S}$ has a maximum partition matching of n pairs, which can be constructed in linear time from the partition matching M_{exp} constructed by the algorithm* GREEDY EXPANDING.

Proof. If M_{exp} has n pairs, then M_{exp} is already a maximum partition matching. Thus we assume that M_{exp} has less than n pairs. According to Lemma 3.5, we can assume, without loss of generality, that all elements in each set C_i, $i = 2, \ldots, k$, are left-paired and that every used partition whose left-paired set is not C_1 is in L_{reac}. Moreover, $|C_1| \leq \sum_{i=2}^{k} |C_i|$.

Let $t = \sum_{i=2}^{k} |C_i|$ and $d = |C_1|$. Then we can assume that M_{exp} consists of the partitions

$$P_1, \ldots, P_t, P_{t+1}, \ldots, P_{t+h},$$

where $P_1, \ldots, P_t$ are used by M_{exp} to left-pair the elements in $\cup_{i=2}^{k} C_i$, and $P_{t+1}, \ldots, P_{t+h}$ are used by M_{exp} to left-pair the elements in C_1, $h < d$. Moreover, all partitions $P_1, \ldots, P_t$ are in the set L_{reac}. Thus, the set C_1 must be contained in the right-collection in each of the partitions $P_1, \ldots, P_t$.

We ignore the partitions $P_{t+1}, \ldots, P_{t+h}$ and use the partitions $P_1, \ldots, P_t$ to construct a maximum partition matching of n pairs. Note that $\{P_1, \ldots, P_t\}$ also forms a partition matching in the collection $\mathcal{S}$.

Consider the algorithm PARTITION FLIPPING given in Figure 3.2, where *flipping* a partition $(\mathcal{A}, \mathcal{B})$ gives the partition $(\mathcal{B}, \mathcal{A})$.

We must prove that the algorithm PARTITION FLIPPING correctly constructs a partition matching with n pairs.

Step 1 of the algorithm is always possible: Since C_1 is contained in the right-collection of each partition P_i, $i = 1, \ldots, t$, and $t \geq d$ for each right-unpaired element b in C_1, we can always pick a partition P_i that right-pairs an element in $\cup_{i=2}^{k} C_i$ and let P_i right-pair the element b. We keep doing this replacement until all d elements in C_1 get right-paired. At this point, the number of partitions in $\{P_1, \ldots, P_t\}$ that right-pair elements in $\cup_{i=2}^{k} C_i$ is exactly $t - d$.

Step 3 is always possible since the partitions $P_1, \ldots, P_t$ left-pair all elements in $\cup_{i=2}^{k} C_i$.

Now we verify that the sequence $\{P_1, \ldots, P_t, P'_1, \ldots, P'_d\}$ is a partition matching in $\mathcal{S}$.

No two partitions P_i and P_j can be identical since $\{P_1, \ldots, P_t\}$ is supposed to be a partition matching in $\mathcal{S}$. No two partitions P'_i and P'_j can be identical since they are obtained by flipping two different partitions in $\{P_1, \ldots, P_t\}$. No partition P_i is identical to a partition P'_j because P_i has C_1 in its right-collection whereas P'_j has C_1 in its left-collection. Therefore, the partitions $P_1, \ldots, P_t$, $P'_1, \ldots, P'_d$ are all distinct.

Algorithm. PARTITION FLIPPING

INPUT: A partition matching $\{P_1, \ldots, P_t\}$ that left-pairs all elements in $\cup_{i=2}^{k} C_i$, $t = \sum_{i=2}^{k} |C_i|$, and the set C_1 is contained in the right-collection of each partition P_i, $i = 1, \ldots, t$, $d = |C_1| \leq t$.

OUTPUT: A maximum partition matching in $\mathcal{S}$ with n pairs.

1. If not all elements in the set C_1 are right-paired by $P_1, \ldots, P_t$, replace a proper number of right-paired elements in $\cup_{i=2}^{k} C_i$ by the right-unpaired elements in C_1 so that all elements in C_1 are right-paired by $P_1, \ldots, P_t$;
2. Suppose that the partitions $P_1, \ldots, P_{t-d}$ right-pair $t - d$ elements $b_1, \ldots, b_{t-d}$ in $\cup_{i=2}^{k} C_i$, and that $P_{t-d+1}, \ldots, P_t$ right-pair the d elements in C_1;
3. Suppose that $\overline{P}_1, \ldots, \overline{P}_{t-d}$ are the $t - d$ partitions in $\{P_1, \ldots, P_t\}$ that left-pair the elements $b_1, \ldots, b_{t-d}$;
4. Flip each of the d partitions in $\{P_1, \ldots, P_t\} - \{\overline{P}_1, \ldots, \overline{P}_{t-d}\}$ to get d partitions $P'_1, \ldots, P'_d$ to left-pair the d elements in C_1. The right-paired element of each P'_i is the left-paired element before the flipping;
5. $\{P_1, \ldots, P_t, P'_1, \ldots, P'_d\}$ is a partition matching in $\mathcal{S}$ with n pairs.

FIG. 3.2. *The algorithm* PARTITION FLIPPING.

Each of the partitions $P_1, \ldots, P_t$ left-pairs an element in $\cup_{i=2}^{k} C_i$, and each of the partitions $P'_1, \ldots, P'_d$ left-pairs an element in C_1. Thus, all elements in the universal set U get left-paired in $\{P_1, \ldots, P_t, P'_1, \ldots, P'_d\}$.

Finally, the partitions $P_1, \ldots, P_t$ right-pair all elements in C_1 and the elements $b_1, \ldots, b_{t-d}$ in $\cup_{i=2}^{k} C_i$. Now, by our selection of the partitions, the partitions $P'_1, \ldots, P'_d$ precisely right-pair all the elements in $\cup_{i=2}^{k} C_i - \{b_1, \ldots, b_{t-d}\}$. Thus, all elements in U also get right-paired in $\{P_1, \ldots, P_t, P'_1, \ldots, P'_d\}$.

This leads to the conclusion that the sequence $\{P_1, \ldots, P_t, P'_1, \ldots, P'_d\}$ is a maximum partition matching in the collection $\mathcal{S}$.

The running time of the algorithm PARTITION FLIPPING is obviously linear. □

Now we consider the case when L_{reac} and R_{reac} have no common partitions.

THEOREM 3.7. *If L_{reac} and R_{reac} have no common partitions, then the partition matching M_{exp} constructed by the algorithm* GREEDY EXPANDING *is a maximum partition matching.*

Proof. Let W_{other} be the set of used partitions in M_{exp} that belong to neither L_{reac} nor R_{reac}. Then

$$L_{free} \cup R_{free} \cup L_{reac} \cup R_{reac} \cup W_{other}$$

is the set of all partitions of the collection $\mathcal{S}$, and

$$L_{reac} \cup R_{reac} \cup W_{other}$$

is the set of partitions contained in the partition matching M_{exp}. Since all sets L_{reac}, R_{reac}, and W_{other} are pairwise disjoint, the number of partitions in M_{exp} is precisely

$$|L_{reac}| + |R_{reac}| + |W_{other}|.$$

Now consider the set $W_L = L_{free} \cup L_{reac}$. Let U_L be the set of elements that appear in the left-collection of a partition in W_L. We have the following situations:

1. Every $P \in L_{reac}$ left-pairs an element in U_L.
2. Every element in U_L is left-paired.

Algorithm. GENERAL MAXIMUM PARTITION MATCHING

INPUT: A collection $\mathcal{S} = \{C_1, \ldots, C_k\}$ of pairwise disjoint subsets of $U = \{1, 2, \ldots, n\}$.
OUTPUT: A maximum partition matching M in $\mathcal{S}$.

1. **Case 1.** $2^k \geq 2n$
   call the algorithm PREMATCHING to construct a maximum partition matching;
2. **Case 2.** $2^k < 2n$
   call the algorithm GREEDY EXPANDING to construct a partition matching M_{exp}; compute L_{reac} and R_{reac};
   if L_{reac} and R_{reac} have a common partition
   then call the algorithm PARTITION FLIPPING to construct a maximum partition matching
   else M_{exp} is a maximum partition matching.

FIG. 3.3. *The algorithm* GENERAL MAXIMUM PARTITION MATCHING.

3. If an element a in U_L is left-paired by a partition P, then $P \in L_{reac}$. (*Proof.* Let the element a be in the set C. Then the set C is the left-paired set of the partition P. Since the element a is in U_L, the set C is also contained in the left-collection of a partition P' that is in either L_{free} or L_{reac}. The partition P is left-reachable from P'; thus, it must be in L_{reac}.)

Therefore, the partitions in L_{reac} precisely left-pair the elements in U_L. This gives $|L_{reac}| = |U_L|$. Since there are only $|U_L|$ elements that appear in the left-collections in partitions in $L_{free} \cup L_{reac}$, we conclude that the partitions in $W_L = L_{free} \cup L_{reac}$ can be used to left-pair at most $|U_L| = |L_{reac}|$ elements in *any partition matching* in the collection $\mathcal{S}$.

Similarly, the partitions in the set $W_R = R_{free} \cup R_{reac}$ can be used to right-pair at most $|R_{reac}|$ elements in *any partition matching* in the collection $\mathcal{S}$.

Therefore, any partition matching in the collection $\mathcal{S}$ can include at most $|L_{reac}|$ partitions in the set W_L, at most $|R_{reac}|$ partitions in the set W_R, and at most all partitions in the set W_{other}. Consequently, a maximum partition matching in $\mathcal{S}$ consists of at most

$$|L_{reac}| + |R_{reac}| + |W_{other}|$$

partitions. Since the partition matching M_{exp} constructed by the algorithm GREEDY EXPANDING contains just this many partitions, M_{exp} is a maximum partition matching in the collection $\mathcal{S}$. □

We summarize all the discussions above into the following theorem.

THEOREM 3.8. *The maximum partition matching problem can be solved in time* $O(n^2 \log n)$.

Proof. The problem is solved by the algorithm GENERAL MAXIMUM PARTITION MATCHING given in Figure 3.3. The correctness of the algorithm has been proved by Theorems 2.4, 3.6, and 3.7. To construct the sets L_{reac} and R_{reac}, we use an algorithm similar to the one described for the algorithm GREEDY EXPANDING. That is, we first compute all the used partitions reachable from each set C_i and then use this information to examine each unused partition. This can be done in time $O(n^2 \log n)$, and we leave the detailed verification to interested readers. □

4. Parallel routing in star networks. In this section, we show an application of maximum partition matching in parallel routing in star networks.

The star network [1] has received considerable attention from researchers recently as a graph model for interconnection networks. It has been shown to be an attractive

alternative to the widely used hypercube model. Like the hypercube, the star network has rich structural and symmetric properties as well as fault tolerant characteristics. Moreover, it has a smaller diameter and degree while being comparable to a hypercube with the same number of vertices.

Formally, the *n-dimensional star network* (or simply *the n-star network*) is an undirected graph consisting of $n!$ nodes labeled with the $n!$ permutations on symbols $1, 2, \ldots, n$. There is an edge between a node u to a node v if and only if there is a transposition $\pi[1, i]$, $2 \leq i \leq n$, such that $\pi[1, i](u) = v$. The n-star network is an $(n-1)$-connected and vertex symmetric Cayley graph [1].

Parallel routing, i.e., finding parallel node-disjoint paths between two nodes in a star network, has been investigated recently [6, 11, 13, 14]. Since the n-star network is vertex symmetric, a parallel routing between two arbitrary nodes can be mapped to a parallel routing between a node and the identity node ε. Let $\text{dist}(u)$ define the distance from the node u to ε. Day and Tripathi [6] and Jwo, Lakshmivarahan, and Dhall [11] have shown that for any node u there are $n-1$ node-disjoint paths connecting u and ε such that no path has length larger than $\text{dist}(u) + 4$. An algorithm was described in [11] to construct the maximum number of node-disjoint paths of length $\text{dist}(u)$ between the nodes u and ε. Unfortunately, the algorithm runs in exponential time in the worst case. Moreover, the algorithm seems to contain a serious bug. For example, the algorithm always constructs an even number of shortest paths from a node u to ε, whereas a star network may have an odd number of node-disjoint shortest paths between a node u and ε (see our discussion in the next section).

Let $u = a_1 a_2 \cdots a_n$ be a node in the n-star network (i.e., u is a permutation on $1, \ldots, n$). Suppose that the cycle structure of u is $u = c_1 \cdots c_k e_1 \cdots e_m$, where c_i are cycles of length at least 2 and e_j are cycles of length 1. If we further let $l = \sum_{i=1}^{k} |c_i|$, then the shortest distance from u to the identity node ε is given by the formula [1]

$$\text{dist}(u) = \begin{cases} l + k, & \text{if } a_1 = 1, \\ l + k - 2, & \text{if } a_1 \neq 1. \end{cases}$$

From this formula, we can derive an upper bound on the number of node-disjoint shortest paths from u to ε. We distinguish two cases. Recall that $\pi[1, i]$ is the transposition on permutations that exchanges the positions of the first symbol and the ith symbol and that $\pi[a]$ is the transposition on permutations that exchanges the positions of the first symbol and the symbol a.

Suppose $a_1 = 1$ in the node $u = a_1 a_2 \cdots a_n$ with cycle structure $c_1 \cdots c_k e_1 \cdots e_m$. If $a \neq 1$ is in a single symbol cycle e_i, then by the discussion in section 1 and the above formula, it is not hard to show that $\text{dist}(\pi[a](u)) = \text{dist}(u) + 1$; i.e., the edge from u to $\pi[a](u)$ does not lead to a shortest path from u to ε. Thus, in this case the total number of node-disjoint shortest paths from u to ε is bounded by $l = \sum_{i=1}^{k} |c_i|$. It is also easy to see that if a is in a cycle c_i of length of at least 2, then $\text{dist}(\pi[a](u)) = \text{dist}(u) - 1$.

Suppose $a_1 \neq 1$. We further assume that in the cycle structure $c_1 \cdots c_k e_1 \cdots e_m$ of u, we have $c_1 = (a_1^{(1)} a_2^{(1)} \cdots a_d^{(1)})$, where $a_1 = a_1^{(1)}$ and $a_d^{(1)} = 1$. Let a be an element in the cycle c_1 such that $a \neq a_1$ and $a \neq a_2^{(1)}$. Then by the discussion in section 1 and the above formula, $\text{dist}(\pi[a](u)) = \text{dist}(u) + 1$; i.e., the edge from u to $\pi[a](u)$ does not lead to a shortest path from u to ε. Similarly, if a is in a single symbol cycle e_j, then the edge from u to $\pi[a](u)$ does not lead to a shortest path from u to ε. Thus, in this case the total number of node-disjoint shortest paths from u to ε is bounded

by $1 + \sum_{i=2}^{k} |c_i|$. It is also easy to see that if $a = a_2^{(1)}$ or if a is in a cycle c_i of length at least 2, $i > 1$, then $\text{dist}(\pi[a](u)) = \text{dist}(u) - 1$.

We summarize the above discussion in the following lemma.

LEMMA 4.1. *Let $u = a_1 a_2 \cdots a_n$ be a node in the n-star network with a cycle structure $u = c_1 \cdots c_k e_1 \cdots e_m$, where c_i are cycles of length at least 2 and e_j are cycles of length 1.*

If $a_1 = 1$, then the number of node-disjoint paths of length dist(u) from u to ε is bounded by $\sum_{i=1}^{k} |c_i|$.

If $a_1 \neq 1$, then the number of node-disjoint paths of length dist(u) from u to ε is bounded by $1 + \sum_{i=2}^{k} |c_i|$ (we assume that the symbol 1 is contained in cycle c_1).

The above discussion also tells us that on a shortest path from a node v to ε, from each node $u = a_1 a_2 \cdots a_n$ on the path, with a cycle structure $u = c_1 \cdots c_k e_1 \cdots e_m$, to the next node on the path, we must perform one of the following two operations:

Rule 1. If $a_1 = 1$, then merge the single symbol cycle $\{1\}$ into a cycle c_i of length at least 2. This corresponds to applying a transposition $\pi[a]$ with $a \in c_i$.

Rule 2. In the case $a_1 \neq 1$, assume that $c_1 = (a_1^{(1)} a_2^{(1)} \cdots a_d^{(1)})$, where $a_1 = a_1^{(1)}$ and $a_d^{(1)} = 1$. Then either merge the cycle c_1 with a cycle c_i, $i > 1$ (this corresponds to applying the transposition $\pi[a]$, where $a \in c_i$), or delete the symbol a_1 from cycle c_1 (this corresponds to applying the transposition $\pi[a_2^{(1)}]$ and putting a_1 in a single symbol cycle).

Remark. Thus, a transposition $\pi[a]$ is never applied along the shortest path if $a \neq 1$ is in a single symbol cycle. Consequently, once a symbol $a \neq 1$ is in a single symbol cycle, it will stay in the single symbol cycle forever along the shortest path.

Now we are ready to discuss parallel routing on the n-star network. Again suppose that $u = a_1 a_2 \cdots a_n$ is a node of the n-star network and we want to construct a maximum number of node-disjoint shortest paths from the node u to the identity node ε in the n-star network.

If $a_1 = 1$, then by the above analysis there are at most $l = \sum_{i=1}^{k} |c_i|$ node-disjoint shortest paths. In fact, it is not very hard to construct l node-disjoint shortest paths from such a node u to ε [6, 11]. We will not discuss this case here. Interested readers are referred to [6, 11].

We will concentrate on the other case, which is more difficult.

Problem A (parallel routing (hard case)). Given a node $u = a_1 a_2 \cdots a_n$ in the n-star network, where $a_1 \neq 1$, with a cycle structure $c_1 \cdots c_k e_1 \cdots e_m$, where $c_1 = (a_1^{(1)} \cdots a_d^{(1)})$, $a_1^{(1)} = a_1$, and $a_d^{(1)} = 1$, construct a maximum number of node-disjoint shortest paths (of length dist(u)) in the n-star network from the node u to the identity node ε.

We first derive another upper bound for the number of node-disjoint shortest paths from the node u to ε in terms of the maximum partition matching of the cycles $c_2, \ldots, c_k$, regarding $c_2, \ldots, c_k$ as sets of symbols.

LEMMA 4.2. *Let u be the node described in Problem* A. *Then the number of node-disjoint shortest paths from u to ε cannot be larger than 2 plus the number of partitions of a maximum partition matching in $\mathcal{S} = \{c_2, \ldots, c_k\}$.*

Proof. Let $P_1, \ldots, P_s$ be s node-disjoint shortest paths from u to ε. For each path P_i, let u_i be the first node on P_i such that the symbol 1 is in the first position in the permutation u_i. The node u_i is obtained by repeatedly applying Rule 2, starting from the node u. It is easy to prove by induction that for any node v from u to u_i on the path P_i, the only possible cycle of length larger than 1 in v that is not in $\{c_2, \ldots, c_k\}$

is the one that contains the symbol 1. In particular, the node u_i must have a cycle structure of the form

$$u_i = c'_1 \cdots c'_{k_i} e'_1 \cdots e'_{m_i},$$

where c'_i are cycles of length at least 2, e'_j are cycles of length 1, and $\mathcal{B}_i = \{c'_1, \ldots, c'_{k_i}\}$ is a subcollection of $\mathcal{S} = \{c_2, \ldots, c_k\}$.

Assume that the first edge on P_i is from u to $\pi[b_i](u)$. By the discussion of Lemma 4.1, b_i is either $a_2^{(1)}$ or one of the symbols in $\cup_{i=2}^{k} c_i$. Moreover, by Rule 2, once b_i is contained in the cycle containing the symbol 1, it will stay in the cycle containing the symbol 1 until it is put into a single symbol cycle. In particular, the symbol b_i is not in the set $\cup_{j=1}^{k_i} c'_j$.

Now consider the last edge on the path P_i, which must be from a node w_i with cycle structure $(d_i 1)$ to the identity node ε. Since the symbol d_i is in a cycle of length larger than 1 in w_i, by the remark, d_i is also in a cycle of length larger than 1 in the node u_i; that is, $d_i \in \cup_{j=1}^{k_i} c'_j$. The only exception is $d_i = a_{d-1}^{(1)}$ (in this case $u_i = \varepsilon$).

Now we let $\mathcal{A}_i = \mathcal{S} - \mathcal{B}_i$. Then we can conclude that except at most two paths P_1 and P_2, each P_i, $i \geq 3$, of the other paths $P_3, \ldots, P_s$ must start with an edge $\{u, \pi[b_i](u)\}$, where b_i is in $\mathcal{A}_i$, and end with an edge $\{w_i, \varepsilon\}$, where w_i has a cycle structure $(d_i 1)$ and $d_i \in \mathcal{B}_i$ (the two exceptional paths P_1 and P_2 may start with the edge $\{u, \pi[a_2^{(1)}](u)\}$ or end with the edge $\{w, \varepsilon\}$, where w has a cycle structure $(a_{d-1}^{(1)} 1)$).

Now since the s paths $P_1, \ldots, P_s$ are node-disjoint, the symbols $b_3, \ldots, b_s$ are all pairwise distinct, and the symbols $d_3, \ldots, d_s$ are also pairwise distinct. Moreover, since all nodes $u_3, \ldots, u_s$ are pairwise distinct, the collections $\mathcal{B}_3, \ldots, \mathcal{B}_s$ of cycles are also pairwise distinct. Consequently, the partitions $(\mathcal{A}_3, \mathcal{B}_3)$, …, $(\mathcal{A}_s, \mathcal{B}_s)$ form a partition matching of the collection $\mathcal{S} = \{c_2, \ldots, c_k\}$.

This leads us to conclude that s cannot be larger than 2 plus the number of partitions in a maximum partition matching of the collection $\mathcal{S} = \{c_2, \ldots, c_k\}$, thus proving the lemma. □

Now we show how we construct a maximum number of node-disjoint shortest paths from the node u to the identity node ε in the n-star network. We first show how to route a single shortest path from u to ε, given a partition $(\mathcal{A}, \mathcal{B})$ of the collection $\mathcal{S} = \{c_2, \ldots, c_k\}$ and a pair of symbols b and d, where b is in $\mathcal{A}$ and d is in $\mathcal{B}$. We also allow b to be $a_2^{(1)}$—in this case, d must be in $\cup_{i=2}^{k} c_i$, and $\mathcal{A} = \phi$ and $\mathcal{B} = \mathcal{S}$. Similarly, we allow d to be $a_{d-1}^{(1)}$—in this case, b must be in $\cup_{i=2}^{k} c_i$, and $\mathcal{B} = \phi$ and $\mathcal{A} = \mathcal{S}$. Consider the algorithm Single Routing given in Figure 4.1. Since the algorithm Single Routing starts with the node u and applies only transpositions described in Rules 1 and 2, we conclude that the algorithm Single Routing constructs a shortest path from the node u to the node ε.

Now we are ready to describe the final algorithm. Consider the algorithm Optimal Parallel Routing given in Figure 4.2.

Theorem 4.3. *Algorithm* Optimal Parallel Routing *constructs a maximum number of node-disjoint shortest paths from the node u to the identity node ε in time $O(n^2 \log n)$.*

Proof. From Lemmas 4.1 and 4.2, we know that the number of shortest paths constructed by the algorithm Optimal Parallel Routing matches the maximum number of node-disjoint shortest paths from u to ε. What remains is to show that all these paths are node-disjoint.

Algorithm. SINGLE ROUTING

INPUT: A partition $(\mathcal{A}, \mathcal{B})$ of $\mathcal{S} = \{c_2, \ldots, c_k\}$, and two symbols b in $\mathcal{A}$ and d in $\mathcal{B}$. b can be $a_2^{(1)}$ with $\mathcal{A} = \phi$, and d can be $a_{d-1}^{(1)}$ with $\mathcal{B} = \phi$.

OUTPUT: A shortest path from u to ε starting with the edge $\{u, \pi[b](u)\}$ and ending with the edge $\{w, \varepsilon\}$, where w has a cycle structure $(d1)$.

1. **if** $b \neq a_2^{(1)}$
   apply $\pi[b]$ to u to merge the cycle in $\mathcal{A}$ that contains b into the cycle c_1; then merge in an arbitrary order the rest of the cycles in $\mathcal{A}$ into the cycle containing the symbol 1;
2. repeatedly delete symbols in the cycle containing the symbol 1 until the symbol 1 is put into a single symbol cycle;
3. **if** $d \neq a_{d-1}^{(1)}$
   suppose that the cycle C containing d in $\mathcal{B}$ is $(d' \cdots d)$. Apply $\pi[d']$ to merge $(d' \cdots d)$ with the single symbol cycle $\{1\}$; then merge in an arbitrary order the rest of the cycles in $\mathcal{B}$ into the cycle containing the symbol 1;
4. repeatedly delete symbols in the cycle containing the symbol 1 until you reach the node ε.

FIG. 4.1. *The algorithm* SINGLE ROUTING.

Algorithm. OPTIMAL PARALLEL ROUTING

INPUT: The node u in the n-star network, as described in Problem A.

OUTPUT: A maximum number of node-disjoint shortest paths from u to ε.

1. Construct a maximum partition matching $M[(b_1, d_1), \ldots, (b_s, d_s)]$ in the collection $\mathcal{S} = \{c_2, \ldots, c_k\}$ with the partitions $(\mathcal{A}_1, \mathcal{B}_1)$, …, $(\mathcal{A}_s, \mathcal{B}_s)$ of $\mathcal{S}$;
2. **if** $s = \sum_{i=2}^{k} |c_i|$
   then construct $s + 1$ node-disjoint shortest paths as follows.
   2.1. Call the algorithm SINGLE ROUTING with the partition $(\phi, \mathcal{S})$ of $\mathcal{S}$ and the symbol pair $(a_2^{(1)}, d_1)$;
   2.2. Call the algorithm SINGLE ROUTING with the partition $(\mathcal{S}, \phi)$ of $\mathcal{S}$ and the symbol pair $(b_1, a_{d-1}^{(1)})$;
   2.3. For $i = 2$ to s, call the algorithm SINGLE ROUTING with the partition $(\mathcal{A}_i, \mathcal{B}_i)$ of $\mathcal{S}$ and the symbol pair (b_i, d_i);
3. **if** $s < \sum_{i=2}^{k} |c_i|$
   then construct $s + 2$ node-disjoint shortest paths as follows.
   3.1. Let b_0 be a left-unpaired symbol and d_0 be a right-unpaired symbol in the partition matching constructed in step 1.
   3.2. Call the algorithm SINGLE ROUTING with the partition $(\phi, \mathcal{S})$ of $\mathcal{S}$ and the symbol pair $(a_2^{(1)}, d_0)$;
   3.3. Call the algorithm SINGLE ROUTING with the partition $(\mathcal{S}, \phi)$ of $\mathcal{S}$ and the symbol pair $(b_0, a_{d-1}^{(1)})$;
   3.4. For $i = 1$ to s, call the algorithm SINGLE ROUTING with the partition $(\mathcal{A}_i, \mathcal{B}_i)$ of $\mathcal{S}$ and the symbol pair (b_i, d_i).

FIG. 4.2. *The algorithm* OPTIMAL PARALLEL ROUTING.

Suppose that the algorithm OPTIMAL PARALLEL ROUTING constructs h shortest paths P_1, P_2, …, P_h from node u to node ε, where $h = s + 1$ or $h = s + 2$ depending on whether $s = \sum_{i=2}^{k} |c_i|$, and suppose that the path P_i is constructed by calling the algorithm SINGLE ROUTING on partition $(\mathcal{A}_i, \mathcal{B}_i)$ of $\mathcal{S}$ and symbol pair (b_i, d_i) for all $i = 1, \ldots, h$. Note that if $\mathcal{A}_i = \phi$, then we have $b_i = a_2^{(1)}$, and if $\mathcal{B}_i = \phi$, then we have $d_i = a_{d-1}^{(1)}$. Now fix an i and consider the path P_i, which is constructed from the partition $(\mathcal{A}_i, \mathcal{B}_i)$ and the symbol pair (b_i, d_i). Let $\mathcal{A}_i = \{c_2^{(i)}, \ldots, c_l^{(i)}\}$ and $\mathcal{B}_i = \{c_{l+1}^{(i)}, \ldots, c_k^{(i)}\}$, where if $\mathcal{A}_i \neq \phi$, then the cycle $c_2^{(i)}$ is of form $c_2^{(i)} = (b_i * * b_i')$,

and if $\mathcal{B}_i \neq \phi$, then the cycle $c_{l+1}^{(i)}$ is of form $c_{l+1}^{(i)} = (* *\ d_i)$, where we use "$* *$" to represent the irrelevant part of a cycle structure. Finally, recall that the cycle c_1 has the form $c_1 = (a_1^{(1)} * * a_{d-1}^{(1)} 1)$.

The interior nodes of the path P_i can be split into three segments: $I_1^{(i)}$, $I_2^{(i)}$, and $I_3^{(i)}$. The first segment $I_1^{(i)}$ corresponds to nodes constructed in step 1 of the algorithm SINGLE ROUTING that first merges cycle $c_2^{(i)}$ into cycle c_1, obtaining a cycle of the form $(b_i * * b_i' a_1^{(1)} * * a_{d-1}^{(1)} 1)$, and then merges cycles $c_3^{(i)}, \ldots, c_l^{(i)}$ into the cycle containing symbol 1. Therefore, all nodes in this segment are of the form

$$(* *\ b_i * * b_i' a_1^{(1)} * * a_{d-1}^{(1)} 1) * *.$$

The second segment $I_2^{(i)}$ corresponds to the nodes constructed by step 2 of the algorithm SINGLE ROUTING that deletes symbols in the cycle containing the symbol 1. All nodes in this segment are of the form

$$(* *\ 1) c_{l+1}^{(i)} \cdots c_k^{(i)} * *.$$

The third segment $I_3^{(i)}$ corresponds to the nodes constructed by steps 3 and 4 of the algorithm SINGLE ROUTING, which first merges the cycle $c_{l+1}^{(i)}$ into the single symbol cycle $\{1\}$, obtaining a cycle of form $(* *\ d_i 1)$, then merges the cycles $c_{l+2}^{(i)}, \ldots, c_k^{(i)}$, and then deletes symbols in the cycle containing the symbol 1. Therefore, all nodes in this segment should have the form

$$(* *\ d_i 1) * *.$$

In case $\mathcal{A}_i = \phi$, we have $b_i = a_2^{(1)}$ and the segment $I_1^{(i)}$ is empty, and in case $\mathcal{B}_i = \phi$, we have $d_i = a_{d-1}^{(1)}$ and the segment $I_3^{(i)}$ is empty.

We now show that any two shortest paths P_i and P_j, $i \neq j$, constructed by the algorithm OPTIMAL PARALLEL ROUTING are node-disjoint. Let v be a node on the path P_i.

Suppose that $v = (* *\ b_i * * b_i' a_1^{(1)} * * a_{d-1}^{(1)} 1) * *$ is a node on the first segment $I_1^{(i)}$ of the path P_i. The node cannot be on the first segment $I_1^{(j)}$ of the path P_j since all nodes on $I_1^{(j)}$ are of form $(* *\ b_j * * b_j' a_1^{(1)} * * a_{d-1}^{(1)} 1) * *$ and $b_i \neq b_j$ (thus $b_i' \neq b_j'$). Moreover, the node v cannot be on the second or the third segment of P_j since the cycle structure of a node on the second or the third segment of P_j has more single symbol cycles (note that each execution of step 2 of the algorithm SINGLE ROUTING creates a new single symbol cycle in the cycle structure).

If $v = (* *\ 1) c_{l+1}^{(i)} \cdots c_k^{(i)} * *$ is on the second segment $I_2^{(i)}$ of the path P_i, then v cannot be on the second segment $I_2^{(j)}$ of P_j since each node on $I_2^{(j)}$ is of form $(* *\ 1) c_{f+1}^{(j)} \cdots c_k^{(j)} * *$ and

$$\mathcal{B}_i = \{c_{l+1}^{(i)}, \ldots, c_k^{(i)}\} \neq \mathcal{B}_j = \{c_{f+1}^{(j)}, \ldots, c_k^{(j)}\}.$$

The node v cannot be on the third segment $I_3^{(j)}$ of P_j either since each node on the segment $I_3^{(j)}$ is of form $(* *\ d_j 1) * *$, where $d_j \in \cup_{i=2}^{k} c_i$, while the cycle containing the symbol 1 in the node v is either a single symbol cycle or of form $(* *\ a_{d-1}^{(1)} 1)$, where $a_{d-1}^{(1)}$ is in c_1.

Finally, if $v = (** \ d_i 1) **$ is on the third segment of the path P_i, then v cannot be on the third segment of P_j because $d_i \neq d_j$.

By symmetry, the above analysis shows that the two shortest paths P_i and P_j constructed by the algorithm Optimal Parallel Routing must be node-disjoint.

The running time of the algorithm Optimal Parallel Routing is dominated by step 1 of the algorithm, which takes time $O(n^2 \log n)$ according to Theorem 3.8. Thus, the algorithm Optimal Parallel Routing runs in time $O(n^2 \log n)$. □

5. Conclusion and remarks. We have presented an efficient algorithm for the maximum partition matching problem. By a nontrivial reduction, we have shown that finding the maximum number of node-disjoint shortest paths between two given nodes in the star networks can be reduced to the maximum partition matching problem. This gives the first correct and efficient algorithm for constructing the maximum number of node-disjoint shortest paths between two given nodes in the star networks.

The problem of constructing the maximum number of node-disjoint shortest paths between two given nodes in the star networks was previously investigated in [11], which presents an algorithm (Algorithm 3.2 in [11]) that claims to find the maximum number of node-disjoint shortest paths between two given nodes in the star networks. For each node $u = c_1 \cdots c_k e_1 \cdots e_m$, the algorithm in [11] runs in time exponential in k, thus in time exponential in n in the worst case (when $k = \Theta(n)$). More seriously, the algorithm seems based on an incorrect observation that claims that when $k > 1$, the maximum number of node-disjoint shortest paths from u to ε is always even (see the paragraph following Lemma 3.11 in [11]). Therefore, in case $k > 1$, the algorithm in [11] always produces an even number of node-disjoint shortest paths from the node u to ε. The incorrectness of this can be shown as follows. Consider a node $u = c_1 \cdots c_k e_1 \cdots e_m$ in the n-star network, where $k > 1$. It is easy to make the node u satisfy the following conditions: (1) $|c_2| \geq |c_i|$ for $i = 3, \ldots, k$ and $|c_2| \leq \sum_{i=3}^{k} |c_i|$; (2) the number $s = \sum_{i=2}^{k} |c_i|$ is even; and (3) $k - 1$ is at least as large as $\log(2s)$. Now, according to the discussion in section 2, we can construct a partition matching of order s for the collection $\{c_2, \ldots, c_k\}$. Moreover, by step 2 of the algorithm Optimal Parallel Routing, the maximum number of node-disjoint shortest paths from u to ε is $s + 1$, which is an odd number. A concrete example of this construction in the n-star network can be found in [3].

Finally, we describe how the algorithm Optimal Parallel Routing can be used to construct, between two nodes in the n-star network, $n - 1$ node-disjoint paths of minimum bulk length. Let G be an h-connected graph. By Menger's theorem [12], for any pair of nodes u and v in G there are h node-disjoint paths connecting u and v. The *bulk length* of h node-disjoint paths connecting u and v in G is defined to be the length of the longest path among the h paths. The *bulk distance* between the two nodes u and v is defined to be the minimum bulk length over all groups of h node-disjoint paths connecting u and v. Clearly, the bulk distance between two nodes u and v is at least as large as the distance between u and v, which is defined to be the length of the shortest path connecting u and v. In general, the problem of computing the bulk distance between two given nodes in a graph is NP-hard [8, 9].

The bulk distance problem on the star networks has been studied recently [4, 5, 6, 11, 13, 14]. Since the n-star network is $(n - 1)$-connected and vertex symmetric [1], the bulk distance problem on two arbitrary nodes in the n-star network can be converted to the problem of finding $n - 1$ node-disjoint paths of minimum bulk length from the node u to the identity node ε. Let $\mathrm{dist}(u)$ and $B\mathrm{dist}(u)$ be the distance and bulk distance, respectively, between the node u and the identity node ε in the

n-star network. It has been shown that $B\text{dist}(u)$ is equal to $\text{dist}(u)$ plus an even number [6]. Day and Tripathi [6] have developed an algorithm that constructs $n-1$ node-disjoint paths between u and ε with bulk length $\text{dist}(u)+4$. Thus, we always have $B\text{dist}(u) \leq \text{dist}(u)+4$. The authors of the present paper [4, 5] have established a sufficient and necessary condition for the node u to have bulk distance $\text{dist}(u)+4$ and have developed an $O(n^2 \log n)$ time algorithm to construct $n-1$ node-disjoint paths between u and ε of bulk length $\text{dist}(u)+2$ when the bulk distance of u is less than $\text{dist}(u)+4$.

Combining these results and the results in the present paper, we obtain an $O(n^2 \log n)$ time algorithm that constructs $n-1$ node-disjoint paths of bulk length $B\text{dist}(u)$ between any node u and the identity node ε in the n-star network, as follows. We first check whether the bulk distance $B\text{dist}(u)$ is $\text{dist}(u)+4$, using the formula given in [4, 5]. If $B\text{dist}(u) = \text{dist}(u)+4$, then we apply the algorithm given in [6] to construct $n-1$ node-disjoint paths of bulk length $\text{dist}(u)+4 = B\text{dist}(u)$ from u to ε. If the bulk distance of u is less than $\text{dist}(u)+4$, then we apply the algorithm Optimal Parallel Routing in the present paper to find the maximum number of node-disjoint shortest paths. If the algorithm returns $n-1$ such shortest paths, then these paths are the $n-1$ node-disjoint paths of bulk distance $\text{dist}(u)$ between u and ε. If the algorithm returns less than $n-1$ such shortest paths, then we know that the bulk distance of u is $\text{dist}(u)+2$ so the algorithm developed in [4] can be applied to construct $n-1$ node-disjoint paths of bulk length $\text{dist}(u)+2$. This completes the description of the algorithm that always constructs $n-1$ node-disjoint paths of bulk length $B\text{dist}(u)$ between a node u and the identity node ε in the n-star network. The running time of the algorithm is clearly $O(n^2 \log n)$.

We would like to make a few remarks on the complexity of the above algorithm. The bulk distance problem on general graphs is NP-hard [9]. Thus, it is very unlikely that the bulk distance problem can be solved in time polynomial in the size of the input graph. On the other hand, our algorithm solves the bulk distance problem in time $O(n^2 \log n)$ on the n-star network. Note that the n-star network has $n!$ nodes. Therefore, the running time of our algorithm is actually a polynomial of the logarithm of the size of the input star network. Moreover, our algorithm is almost optimal (differs at most by a $\log n$ factor) since the following lower bound can be easily observed—the distance $\text{dist}(u)$ from u to ε can be as large as $\Theta(n)$. Thus, constructing $n-1$ node-disjoint paths from u to ε takes time at least $\Theta(n^2)$ in the worst case.

Acknowledgments. The authors would like to thank Professor Eva Tardos for her thorough and valuable comments and useful discussion on an earlier version of this paper. The authors are grateful to Professor Jonathan Gross for informing them of the recent discovery by Galil and Yu on graph bulk distance [8]. The authors also thank Professor Laxmi Bhuyan, Professor Don Friesen, Professor Mi Lu, and Dr. Xiangdong Yu for their comments and discussion. Finally, the authors express their sincere thanks to the referees, whose critical comments and suggestions were important for removing possible bugs and confusion in a previous version and have greatly improved the presentation of the paper.

OPTIMAL BIDDING ALGORITHMS AGAINST CHEATING IN MULTIPLE-OBJECT AUCTIONS*

MING-YANG KAO†, JUNFENG QI‡, AND LEI TAN§

Abstract. This paper studies some basic problems in a multiple-object auction model using methodologies from theoretical computer science. We are especially concerned with situations where an adversary bidder knows the bidding algorithms of all the other bidders. In the two-bidder case, we derive an optimal randomized bidding algorithm, by which the disadvantaged bidder can procure at least half of the auction objects despite the adversary's a priori knowledge of his algorithm. In the general k-bidder case, if the number of objects is a multiple of k, an optimal randomized bidding algorithm is found. If the $k-1$ disadvantaged bidders employ that same algorithm, each of them can obtain at least $1/k$ of the objects regardless of the bidding algorithm the adversary uses. These two algorithms are based on closed-form solutions to certain multivariate probability distributions. In situations where a closed-form solution cannot be obtained, we study a restricted class of bidding algorithms as an approximation to desired optimal algorithms.

1. Introduction.

This paper investigates some basic problems in auction theory. Broadly speaking, an auction is a market mechanism with explicit or implicit rules for allocating resources and determining prices on the basis of bids from market participants [4, 11, 13, 19]. Auctions are frequently used to price various types of assets. For instance, the U.S. Treasury raises funds by auctioning T-bonds and T-notes, while the Department of the Interior sells mineral rights on federally owned properties via auction. Economists are interested in auctions as an efficient way to price and allocate goods which have no standard market value. Auctions are believed to be the simplest and most familiar means of price determination for multilateral trading without intermediary market makers [11, 13, 19].

In typical auctions, there are one seller and a group of competing buyers who bid to possess the auction objects. Procurements describe situations in which a single buyer wishes to purchase objects from a set of potential suppliers. There are four basic forms of auctions in use [11, 13, 15]. In an *English auction* or *ascending bid auction*, the price of an object is successively raised until only one bidder remains and wins the object. In a *Dutch auction*, which is the converse of an English auction, an initial high price is subsequently lowered until a bidder accepts the current price. In a *first-price sealed-bid auction*, potential buyers submit sealed bids for an object. The highest bidder is awarded the object and pays the amount of his bid. In a *second-price sealed-bid auction*, the highest bidder wins the object but pays a price equal to the

second-highest bid. While there are many other forms of auctions, these four are of the greatest interest.

Previous literature on auction theory mainly studied bidding behavior under the assumption that the objective of bidders is to maximize expected profits in the absence of any budget constraints. Such work concentrates on the allocation of a single object to one of many bidders. Each bidder has a *valuation*, which is his estimate of the value of the object. In the *independent private valuation* (IPV) model, each bidder knows his valuation for the object ex ante. Each bidder's valuation is assumed to be drawn independently from the same probability distribution. In the *common value* (CV) model, it is assumed that bidders obtain imperfect estimates of the value of the object. The bidders all assign the same value to the object ex post. Both models are well studied in auction theory [14, 15, 16, 17].

Very little work in computer science has been conducted on problems related to auctions. Neither auction mechanisms nor bidding algorithms have been formally studied. Nevertheless, computer scientists have realized the importance of auctions as an efficient method of resource allocation [4]. Gagliano, Fraser, and Schaefer [10] applied auction techniques to the allocation of decentralized network resources. Yang, Barash, and Upton [20] proposed an auction-based scheme in which task and resource allocations are determined through negotiations among system entities.

Our work investigates some basic issues of automated negotiation mechanisms which are emerging in electronic commerce and other applications of software agents for resource allocation. For the purpose of maximizing transaction volume and speed [6], we focus on the simultaneous auction of several objects and propose a *multiple-object auction* model. This model further differs from the IPV and CV models in two significant aspects. In this model, each bidder faces a binding budget constraint which is identical to all the bidders. Such constraints can be used to enforce fairness of some form when their compliance is verifiable. Our model also addresses security concerns in electronic transaction environments. We explicitly recognize the possibility that electronically transmitted information about bids may be legitimately or illegitimately revealed against the wishes of their bidders. The IPV and CV models assume that no bidder has such informational advantage on bids or bidding algorithms over other bidders [9]. The assumptions of our model are specified as follows:

- There are a total of k bidders, $\mathcal{B}_1, \mathcal{B}_2, \ldots, \mathcal{B}_k$, each of whom has the same total resource to devote toward winning objects. We normalize this amount to be 1. Assume that $k \geq 2$.
- A total of n objects are auctioned. Assume that $n \geq k$. Each bidder's goal is to maximize the number of objects he wins. The objects are therefore of equal value to a bidder.
- Each bidder submits a sequence of n bids simultaneously for the n objects. Each object is won by the highest bidder at the price of his bid. If m bidders submit the same highest bid for an object, each wins the object with probability $1/m$. (The results of our bidding algorithms in sections 2 and 3 are not affected by the specific tie-breaking rules that are used.) For technical reasons, no zero bid is allowed. (This restriction is used only in section 4.)
- Some bidders may know the bidding algorithms of others. The information structure can be characterized by a directed graph in which an arc from a bidder $\mathcal{B}_i$ to another bidder $\mathcal{B}_j$ means that $\mathcal{B}_i$ knows $\mathcal{B}_j$'s algorithm. For instance, in Figure 1.1, $\mathcal{B}_4$ knows the algorithms of $\mathcal{B}_1$ and $\mathcal{B}_2$; $\mathcal{B}_3$ knows

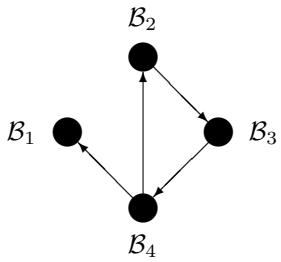

FIG. 1.1. *A graph of information structure.*

$\mathcal{B}_4$'s; $\mathcal{B}_2$ knows $\mathcal{B}_3$'s; $\mathcal{B}_1$ knows only his own. The bidders all compete noncooperatively. We assume that each bidder knows the number of bidders and that of objects.

We analyze the performance of a number of bidding algorithms with which bidders can assign their bids. Almost all the bidding algorithms in this paper are randomized ones. We first study the case of two bidders, i.e., $k = 2$, and then extend the results to the case of multiple bidders. In the two-bidder case, let $\mathcal{B}$ and $\mathcal{A}$ denote the bidders. We assume that $\mathcal{A}$ knows $\mathcal{B}$'s bidding algorithm, while $\mathcal{B}$ does not know $\mathcal{A}$'s; i.e., $\mathcal{B}$ is a disadvantaged bidder and $\mathcal{A}$ an adversary. Here, $\mathcal{A}$ is an oblivious adversary, because although $\mathcal{A}$ knows $\mathcal{B}$'s bidding algorithm, he does not know the outcome of the random choices that $\mathcal{B}$ makes. We give an optimal randomized bidding algorithm for $\mathcal{B}$ by which he can procure at least one half of the objects despite $\mathcal{A}$'s a priori knowledge of his bidding algorithm. The main difficulty with obtaining this optimal bidding algorithm is finding a closed-form solution to a desired multivariate probability distribution [1, 5, 7, 12, 18].

We next study the case where there are more than two bidders, and an adversary bidder knows the bidding algorithms of all the others. If the number of objects is a multiple of the number of bidders, an optimal randomized bidding algorithm is found. If all the disadvantaged bidders employ that same bidding algorithm, each of them can obtain at least $1/k$ of the objects regardless of the bidding algorithm the adversary uses. This bidding algorithm is also based on a closed-form solution to a desired multivariate probability distribution.

When the number of objects is not a multiple of the number of bidders, a closed-form solution of a desired probability distribution cannot be obtained. Motivated by this, we study a class of bidding algorithms to approximate desired optimal algorithms. A bidding algorithm in this class computes an initial sequence of bids, and the actual bid sequence is a random permutation of the initial sequence.

Section 2 describes the optimal bidding algorithm for the disadvantaged bidder in the two-bidder case. In section 3, the optimal randomized bidding algorithm from section 2 is generalized for the multiple-bidder case. In section 4, a class of bidding algorithms are introduced to approximate desired optimal algorithms when a closed-form solution cannot be determined. Section 5 concludes the paper.

For brevity, let $W(\mathcal{B}_i)$ denote the expected number of objects that $\mathcal{B}_i$ wins with a bidding algorithm that is explicitly or implicitly specified.

2. The two-bidder case. This section studies the two-bidder case. We assume that $\mathcal{A}$ knows $\mathcal{B}$'s bidding algorithm, while $\mathcal{B}$ does not know $\mathcal{A}$'s. We give an optimal

randomized bidding algorithm for $\mathcal{B}$ such that $W(\mathcal{B}) = n/2$ despite $\mathcal{A}$'s informational advantage. Since this problem is a zero-sum game, this bound of $n/2$ would be straightforward if von Neumann's min-max theorem were applicable. However, our problem has an infinite pure strategy space, and it is not immediately clear that the min-max theorem is applicable [2, 3, 8, 9, 19].

2.1. $\mathcal{B}$'s optimal bidding algorithm. The following lemma gives an upper bound for the expected number of objects $\mathcal{B}$ can win.

LEMMA 2.1. $W(\mathcal{B}) \leq \frac{n}{2}$.

Proof. Since $\mathcal{A}$ knows $\mathcal{B}$'s bidding algorithm, $\mathcal{A}$ can perform at least as well as $\mathcal{B}$ by employing the same algorithm. Then this lemma follows from the fact that our auction is a zero-sum game. □

Lemma 2.2 describes the marginals of a desired multivariate probability distribution with which $\mathcal{B}$ can form an optimal bidding algorithm.

LEMMA 2.2. *Assume that $\mathcal{B}$ draws his bid sequence $b_1, b_2, \ldots, b_n$ from an n-dimensional probability distribution such that each b_i has the same marginal probability distribution $F_2(b_i)$, where*

$$F_2(b_i) = \begin{cases} \frac{n}{2} \cdot b_i, & b_i \in [0, \frac{2}{n}], \\ 1, & b_i \in (\frac{2}{n}, 1], \end{cases} \tag{2.1}$$

subject to $\sum b_i = 1$. Then, $\mathcal{A}$'s optimal bidding algorithm wins exactly $n/2$ objects on average.

Proof. Let $a_1, a_2, \ldots, a_n$ be $\mathcal{A}$'s optimal bids for the n objects, respectively. $\mathcal{A}$'s probability of winning the ith object is $F_2(a_i)$. Since $\mathcal{B}$'s bids are within $[0, 2/n]$, it is not to $\mathcal{A}$'s advantage to bid over $2/n$. Hence $a_i \leq 2/n$ and $F_2(a_i) = \frac{n}{2} a_i$. $\mathcal{A}$'s optimal bids maximize $W(\mathcal{A})$ as follows:

$$\begin{aligned} \max_{\substack{\sum a_i = 1, \\ 0 \leq a_i \leq \frac{2}{n}}} W(\mathcal{A}) &= \max_{\substack{\sum a_i = 1, \\ 0 \leq a_i \leq \frac{2}{n}}} F_2(a_1) + F_2(a_2) + \cdots + F_2(a_n) \\ &= \max_{\substack{\sum a_i = 1, \\ 0 \leq a_i \leq \frac{2}{n}}} \frac{n}{2} \cdot (a_1 + \cdots + a_n) = \frac{n}{2}. \end{aligned}$$ □

Lemma 2.4 systematically constructs a bid sequence for $\mathcal{B}$ which satisfies the conditions given in Lemma 2.2. We define two additional functions for Lemma 2.4. Let

$$s(v) = \frac{81}{2} \cdot \frac{v}{2 - 3v}. \tag{2.2}$$

Let $h(x, y, z)$ be the function defined on $\{(x, y, z) | 0 \leq x, y, z \leq \frac{1}{3}\}$ such that

$$h(x, y, z) = s(|x - y| + |y - z| + |z - x|). \tag{2.3}$$

LEMMA 2.3. *The function $h(x, y, z)$ is a joint probability density function of x, y and z.*

Proof. Note that $h(x, y, z) \geq 0$. To show that *h(x,y,z)* is a joint probability density function, we need only verify that the integral of *h(x,y,z)* over $\{(x, y, z) | 0 \leq x, y, z \leq \frac{1}{3}\}$ is 1. Let

$$r(x, y) = \int_0^{1/3} h(x, y, z)\, dz. \tag{2.4}$$

Consider the case $x \geq y$. Then

$$\begin{aligned} &\text{if } x \geq y \geq z, \quad h(x,y,z) = s(2(x-z));\\ &\text{if } x \geq z \geq y, \quad h(x,y,z) = s(2(x-y));\\ &\text{if } z \geq x \geq y, \quad h(x,y,z) = s(2(z-y)). \end{aligned}$$

Hence if $x \geq y$,

$$r(x,y) = \int_0^y s(2(x-z))\,dz + \int_y^x s(2(x-y))\,dz + \int_x^{1/3} s(2(z-y))\,dz, \tag{2.5}$$

which equals

$$\frac{9}{2}\left(2\ln(1-3(x-y)) - \ln(3y(1-3x)) - \frac{1-6(x-y)}{1-3(x-y)}\right). \tag{2.6}$$

By symmetry, if $y \geq x$,

$$r(x,y) = \frac{9}{2}\left(2\ln(1-3(y-x)) - \ln(3x(1-3y)) - \frac{1-6(y-x)}{1-3(y-x)}\right).$$

It can be verified that

$$\int_0^{1/3}\int_0^{1/3} r(x,y)\,dxdy = 1.$$

Thus,

$$\int_0^{1/3}\int_0^{1/3}\int_0^{1/3} h(x,y,z)\,dxdydz = 1. \qquad \square$$

LEMMA 2.4. *$\mathcal{B}$ can use the following procedure to draw his bids $b_1, b_2, \ldots, b_n$ such that $\sum b_i = 1$ and the marginal probability distribution of each b_i is as described by (2.1).*

Case 1: *$n = 2m$ is even. $\mathcal{B}$ draws b_1 from the probability distribution F_2 and sets $b_i = b_1$ and $b_{m+i} = \frac{2}{n} - b_1$ for $i = 1, \ldots, m$.*

Case 2: *$n = 2m+1$ is odd. $\mathcal{B}$ draws b_1 from F_2 and then sets $b_i = b_1$ and $b_{m-1+i} = \frac{2}{n} - b_1$ for $i = 1, \ldots, m-1$. For the remaining three bids $b_{2m-1}, b_{2m}, b_{2m+1}$, $\mathcal{B}$ draws (x,y,z) according to h in (2.3) and sets*

$$b_{2m-1} = \frac{3}{n}\left(x - y + \frac{1}{3}\right), \quad b_{2m} = \frac{3}{n}\left(y - z + \frac{1}{3}\right), \quad b_{2m+1} = \frac{3}{n}\left(z - x + \frac{1}{3}\right). \tag{2.7}$$

Proof. Note that $\sum_{i=1}^n b_i = 1$, whether n is even or odd.

Case 1. This lemma is correct since if a random variable X is drawn from the uniform probability distribution on $[0, \frac{2}{n}]$, then $\frac{2}{n} - X$ has the same probability distribution.

Case 2. The proof of Case 1 shows that the marginal probability distribution of each b_i is F_2 for $i = 1, \ldots, 2m-2$. It remains to show that $b_{2m-1}, b_{2m}, b_{2m+1}$ are also distributed the same way. Because these three random variables are symmetric to each other in (2.7), we discuss only b_{2m-1} in detail. Let $t = x - y + \frac{1}{3}$. Since x and y are defined on $[0, \frac{1}{3}]$, t is defined on $[0, \frac{2}{3}]$. We have two cases: $t \in [0, \frac{1}{3}]$ and

$t \in [\frac{1}{3}, \frac{2}{3}]$. The two cases are symmetric, and we discuss only the latter. Let *G(t)* denote the probability distribution of *t*. Then

$$G(t) = 1 - \int\int_{u-v+\frac{1}{3}\geq t, 0\leq u,v\leq \frac{1}{3}} r(u,v)\,dvdu = 1 - \int_{t-1/3}^{1/3}\int_{0}^{u-t+1/3} r(u,v)\,dvdu.$$

Since $u \geq u-t+1/3$, $r(u,v)$ can take the form of (2.6), and we can obtain $G(t) = \frac{3}{2}t$. Since $b_{2m-1} = \frac{3}{n}t$, F_2 is the probability distribution of b_{2m-1}. □

THEOREM 2.5. *The bidding algorithm given in Lemma* 2.4 *is optimal for* $\mathcal{B}$ *and ensures* $\mathcal{B}$ *at least* $n/2$ *objects in expected terms.*

Proof. Lemma 2.1 gives an upper bound for $W(\mathcal{B})$. Lemmas 2.2 and 2.4 give an upper bound for $W(\mathcal{A})$, which in turn gives a matching lower bound for $W(\mathcal{B})$ because $W(\mathcal{B}) + W(\mathcal{A}) = n$. □

2.2. Deriving the joint probability density function $h(x, y, z)$. The most difficult step of obtaining the function h is guessing that *x,y,* and *z* appear together as $|x-y|+|y-z|+|z-x|$. It is worthwhile to show the derivation of the function s in (2.2) that gives the joint probability density function *h(x,y,z).* As in (2.4), let *r(x,y)* be the probability distribution of *(x,y).* Also let $t = x - y + \frac{1}{3}$. Since $t = \frac{n}{3}b_{2m-1}$ needs to be uniformly distributed over $[0, \frac{2}{3}]$, we need to have

$$1 - \int_{t-1/3}^{1/3}\int_{0}^{u-t+1/3} r(u,v)\,dvdu = \frac{3}{2}t \quad \text{for all } t \in \left[\frac{1}{3}, \frac{2}{3}\right] \tag{2.8}$$

and

$$\int_{0}^{t}\int_{u-t+1/3}^{1/3} r(u,v)\,dvdu = \frac{3}{2}t \quad \text{for all } t \in \left[0, \frac{1}{3}\right].$$

These two cases are symmetric, and we discuss only the case given by (2.8) in detail. For notational simplicity, let

$$s(2v) = q(v), \quad \int^{u} q(v)\,dv = p(u), \quad r_2(x,y) = \frac{\partial r(x,y)}{\partial y}.$$

Differentiating (2.8) with respect to t twice, we obtain

$$\int_{t-1/3}^{1/3} r_2\left(u, u-t+\frac{1}{3}\right)\,du + r\left(t-\frac{1}{3}, 0\right) = 0. \tag{2.9}$$

Since $x \geq y$ in (2.8), the following is derived from (2.5):

$$r_2(u,v) = -(u-v)q'(u-v) - q\left(\frac{1}{3} - v\right) + q(u-v).$$

Then

$$\begin{aligned}\int_{t-1/3}^{1/3} & r_2\left(u, u-t+\frac{1}{3}\right)\,du \\ &= -\left(t-\frac{1}{3}\right)\left(\frac{2}{3}-t\right)q'\left(t-\frac{1}{3}\right) + p\left(t-\frac{1}{3}\right) - p\left(\frac{1}{3}\right) + q\left(t-\frac{1}{3}\right)\left(\frac{2}{3}-t\right).\end{aligned} \tag{2.10}$$

We obtain from (2.5)

$$r\left(t-\frac{1}{3},0\right)=\left(t-\frac{1}{3}\right)q\left(t-\frac{1}{3}\right)+p\left(\frac{1}{3}\right)-p\left(t-\frac{1}{3}\right). \tag{2.11}$$

Setting $w=t-\frac{1}{3}$, we can derive the following differential equation from (2.9), (2.10), and (2.11):

$$w(1-3w)q'(w)=q(w).$$

The solution to the differential equation is

$$q(w)=c\frac{3w}{1-3w},$$

where c is a constant. Therefore

$$s(v)=c\frac{3v}{2-3v}.$$

Since *h(x,y,z)* is a probability density function for $(x,\ y,\ z)$, c is set to $\frac{27}{2}$ to satisfy

$$\int_0^{1/3}\int_0^{1/3}\int_0^{1/3}h(x,y,z)\,dxdydz=1.$$

3. The multiple-bidder case. This section generalizes the results in section 2 to give an optimal randomized bidding algorithm for the case of multiple bidders. We assume that the bidding algorithms of $k-1$ bidders are known to a single adversary bidder $\mathcal{A}$. If all the $k-1$ disadvantaged bidders employ our bidding algorithm, each of them wins at least a fraction $1/k$ of the objects regardless of the bidding algorithm the adversary uses.

LEMMA 3.1. *Assume that each of the $k-1$ disadvantaged bidders independently draws his bid sequence $b_1,b_2,\ldots,b_n$ from an n-dimensional probability distribution such that each b_i has the same marginal probability distribution $F_k(b_i)$, where*

$$F_k(b_i)=\begin{cases}\left(\frac{n}{k}\cdot b_i\right)^{\frac{1}{k-1}} & \text{if } b_i\in[0,\frac{k}{n}],\\ 1 & \text{if } b_i\in(\frac{k}{n},1],\end{cases} \tag{3.1}$$

subject to $\sum b_i=1$. Then, $W(\mathcal{A})$ is at most n/k.

Proof. Let $b_{i,j}$ denote the bid on the ith object of the jth disadvantaged bidder. Let a_i be $\mathcal{A}$'s bid on the ith object. Because the bids of the $k-1$ disadvantaged bidders are within $[0,k/n]$, $\mathcal{A}$ has no incentive to bid over k/n. Thus $a_i\le k/n$ and $F(a_i)=\left(\frac{n}{k}\cdot a_i\right)^{\frac{1}{k-1}}$. Since bids from different disadvantaged bidders are independent,

$$\begin{aligned}&\text{Prob}\{a_i\text{wins the } i\text{th object}\}\\ &=\text{Prob}\{b_{i,1}\le a_i\}\cdot\text{Prob}\{b_{i,2}\le a_i\}\cdots\text{Prob}\{b_{i,k-1}\le a_i\}\\ &=(F_k(a_i))^{k-1}\\ &=\frac{n}{k}\cdot a_i.\end{aligned}$$

From the fact that $\sum a_i\le 1$, $\mathcal{A}$ wins exactly n/k objects on average. ∎

It appears quite difficult to find a closed-form solution to a joint probability distribution whose marginals are as described by (3.1).

CONJECTURE 3.2. *There exists an n-dimensional joint probability distribution such that its marginal probability distribution of every component is as described by* (3.1)*, while the components from all dimensions sum to* 1.

For $k = 2$, this conjecture has been proved in section 2. If n is a multiple of k, we prove this conjecture as follows. Let

$$e(b_1, b_2, \ldots, b_k) = \begin{cases} (b_1 b_2 \cdots b_k)^{\frac{1}{k-1}-1}, & b_1 + b_2 + \cdots + b_k = 1,\ b_i > 0, \\ 0 & \text{otherwise.} \end{cases}$$

Let

$$\alpha = \int_{b_1+\cdots+b_k=1} e(b_1, b_2, \ldots, b_k) db_1 db_2 \cdots db_{k-1}.$$

Normalizing e by using α, we have

$$g(b_1, b_2, \ldots, b_k) = \begin{cases} \frac{(b_1 b_2 \cdots b_k)^{\frac{1}{k-1}-1}}{\alpha}, & b_1 + b_2 + \cdots + b_k = 1,\ b_i > 0, \\ 0 & \text{otherwise.} \end{cases} \tag{3.2}$$

With this normalization, g is a probability density function of $(b_1, b_2, \ldots, b_k)$. For example, if $n = k = 3$, the probability density function shown in (3.2) is

$$g(b_1, b_2, b_3) = \begin{cases} \frac{1}{2\pi\sqrt{b_1 b_2 b_3}}, & b_1 + b_2 + b_3 = 1,\ b_i > 0, \\ 0 & \text{otherwise.} \end{cases}$$

The following lemma proves Conjecture 3.2 for the case $n = k$.

LEMMA 3.3. *If $n = k$ and the bid sequence $b_1, b_2, \ldots, b_n$ is drawn from the n-dimensional joint probability distribution in* (3.2)*, then the marginal probability distribution for each b_i is as described by* (3.1).

Proof. Because $b_1, b_2, \ldots, b_k$ are symmetric for g, we need only show that the probability distribution of b_k is as described in (3.1). Let

$$b_i = (1 - b_k) u_{k-i},\ i = 2, \ldots, k-1.$$

Then

$$db_i = (1 - b_k) du_{k-i}.$$

Let

$$\alpha' = \int_{u_1+\cdots+u_{k-1}=1} (u_1 u_2 \cdots u_{k-1})^{\frac{1}{k-1}-1} du_{k-2} du_{k-3} \cdots du_1.$$

Note that $\alpha = (k-1) \cdot \alpha'$. The probability distribution of b_k equals

$$\int_{\substack{0 \le w \le b_k \\ b_1+b_2+\cdots+b_{k-1}+w=1}} g(b_1, \ldots, b_{k-1}, w) db_2 \cdots db_{k-1} dw$$

$$= \frac{1}{\alpha} \cdot \int_0^{b_k} \int_0^{1-w} \int_0^{1-w-b_{k-1}} \cdots \int_0^{1-w-\cdots-b_3}$$

$$
\begin{aligned}
&((1-b_2-\cdots-w)b_2b_3\cdots w)^{\frac{1}{k-1}-1}db_2\ db_3\cdots db_{k-1}dw\\
&=\frac{1}{\alpha}\cdot\int_0^{b_k} w^{\frac{1}{k-1}-1}\int_0^1\int_0^{1-u_1}\cdots\int_0^{1-u_1-\cdots-u_{k-3}}\\
&\quad(u_1u_2\cdots u_{k-2}(1-u_1-\cdots-u_{k-2}))^{\frac{1}{k-1}-1}\,du_{k-2}\cdots du_2\,du_1\,dw\\
&=\frac{1}{\alpha}\cdot\int_0^{b_k}\alpha' w^{\frac{1}{k-1}-1}\,dw\\
&=\frac{\alpha'}{\alpha}(k-1)a^{\frac{1}{k-1}}\\
&=F_k(b_k).\qquad\square
\end{aligned}
$$

The following lemma extends Lemma 3.3 to the case $n = k{\cdot}m$ for some integer.

LEMMA 3.4. *If $n = k{\cdot}m$ for some integer m, there exists a procedure to generate a bid sequence $b_1, b_2, \ldots, b_n$ such that the probability distribution for each b_i can be described by* (3.1)*, and the bids b_i sum to* 1.

Proof. If $m = 1$, the lemma is the same as Lemma 3.3. If $m > 1$, we divide the objects into m groups of k objects each and employ Lemma 3.3 to obtain bids for the first group. We then set the bids for the other $m-1$ groups to the corresponding bids for the first group. We scale every bid by a factor of $\frac{1}{m}$ so that the bids sum to 1. This gives the desired probability distribution. □

THEOREM 3.5. *If $n = k{\cdot}m$ for some integer m and the disadvantaged bidders all employ the bidding algorithm characterized by Lemma* 3.4*, then each can obtain at least n/k objects in expected terms, which is optimal.*

Proof. From Lemmas 3.1 and 3.4 and the fact that our game is a zero-sum game, the $k-1$ disadvantaged bidders win $\frac{k-1}{k}{\cdot}n$ objects in total. Since they all use the same bidding algorithm, by symmetry each of them wins n/k objects. This upper bound of n/k is also a lower bound since the adversary can always win at least n/k objects by employing the same bidding algorithm as the disadvantaged bidders. □

4. Position-randomized bidding algorithms. In section 3, an optimal randomized bidding algorithm for the bidders with informational disadvantage is derived for the case where the number of objects is a multiple of that of bidders. This algorithm is based on a closed-form solution to a desired multivariate probability distribution. If n is not a multiple of k, a closed-form solution cannot be obtained with our current techniques. Motivated by this, we consider situations where all the bidders are restricted to a class of bidding algorithms called *position-randomized bidding algorithms*. A position-randomized bidding algorithm consists of two steps. Step 1 deterministically selects an initial sequence of n bids. Step 2 permutes the sequence. The ith element of the final sequence is the actual bid for the ith object. As in section 3, we assume that all the disadvantaged bidders adopt an identical bid sequence at step 1 and the same probability distribution at step 2. A position-randomized bidding algorithm can be considered as an approximation to optimal bidding algorithms desired for resolving Conjecture 3.2 in section 3.

The next lemma examines how probability distributions chosen at step 2 affect the expected numbers of objects bidders win.

LEMMA 4.1. *For a given initial bid sequence $a_1, a_2, \ldots, a_n$ of $\mathcal{A}$ and a given initial bid sequence $b_1, b_2, \ldots, b_n$ of the disadvantaged bidders,*

- *W_1 denotes the expected number of objects $\mathcal{A}$ wins by using the uniform probability distribution while the disadvantaged bidders may use any arbitrary probability distribution;*

- *W_2 denotes the expected number of objects $\mathcal{A}$ wins without permuting his initial bid sequence while the disadvantaged bidders employ the uniform probability distribution;*
- *W_3 denotes the expected number of objects $\mathcal{A}$ wins using any given probability distribution while the disadvantaged bidders employ the uniform probability distribution.*

If $a_1, a_2, \ldots, a_n$ are all different from $b_1, b_2, \ldots, b_n$, then $W_1 \geq W_2 = W_3$.

Proof. For each a_i,

- $W_{1,i}$ denotes the expected number of objects a_i wins if $\mathcal{A}$ uses the uniform probability distribution while the disadvantaged bidders may use any arbitrary probability distribution;
- $W_{2,i}$ denotes the expected number of objects a_i wins if $\mathcal{A}$ does not permute his initial bid sequence and the disadvantaged bidders employ the uniform probability distribution;
- $W_{3,i}$ denotes the expected number of objects a_i wins if $\mathcal{A}$ uses a given probability distribution and the disadvantaged bidders employ the uniform probability distribution.

Since $W_j = W_{j,1} + \cdots + W_{j,n}$ for $j \in \{1, 2, 3\}$, it suffices to prove that $W_{1,i} \geq W_{2,i} = W_{3,i}$. Without loss of generality, assume that $b_1 \leq b_2 \leq \cdots \leq b_n$. Let p be the largest index such that $b_p < a_i$; if no such b_p exists, let $p = 0$. Since $a_i < b_j$ for $j = p+1, \ldots, n$,

$$W_{2,i} = \left(\frac{p}{n}\right)^{k-1}.$$

To calculate $W_{3,i}$, let $Q_{q,r}$ be the probability that $\mathcal{A}$ places a_q on the rth object. Then

$$\begin{aligned} W_{3,i} &= \sum_{r=1}^{n} \text{Prob}\{a_i \text{ wins the } r\text{th object}\} \\ &= \sum_{r=1}^{n} Q_{i,r} \left(\frac{p}{n}\right)^{k-1}. \end{aligned}$$

Since $\sum_{r=1}^{n} Q_{i,r} = 1$,

$$W_{2,i} = W_{3,i}.$$

To calculate $W_{1,i}$, let $P_{q,r}$ be the probability that a disadvantaged bidder places b_q on the rth object. Then

$$\begin{aligned} W_{1,i} &= \sum_{r=1}^{n} \frac{1}{n} \cdot \text{Prob}\{a_i \text{ wins the } r\text{th object}\} \\ &= \sum_{r=1}^{n} \frac{1}{n} (P_{1,r} + P_{2,r} + \cdots + P_{p,r})^{k-1}. \end{aligned}$$

Since $\sum_{r=1}^{n} P_{q,r} = 1$ for each q, by Hödel's inequality

$$W_{1,i} \geq W_{2,i}. \qquad \square$$

Since $W_1 \geq W_3$ in Lemma 4.1, the disadvantaged bidders should always use the uniform probability distribution at step 2. Since $W_2 = W_3$, we may assume that $\mathcal{A}$

does not permute his initial bid sequence whenever the disadvantaged bidders use the uniform probability distribution. We next use Lemma 4.1 to derive a lower bound for the expected number of objects $\mathcal{A}$ can win. Let

$$\begin{aligned}
\epsilon &= \text{a positive infinitesimal amount;}\\
\beta &= \sum_{i=1}^{n} i^{k-1};\\
c_i &= \frac{i^{k-1}}{\beta};\\
E &= \{c_0, c_1, c_2, \ldots, c_n\};\\
D &= \{\epsilon, c_2+\epsilon, c_3+\epsilon, \ldots, c_n+\epsilon\}.
\end{aligned}$$

LEMMA 4.2. *$\mathcal{A}$ can win at least $\frac{\beta-1}{n^{k-1}}$ objects on average for any given initial bid sequence and probability distribution employed by the disadvantaged bidders.*

Proof. Given an initial bid sequence $b_1 \le b_2 \le \cdots \le b_n$ of the $k-1$ disadvantaged bidders, $\mathcal{A}$ chooses his initial bid sequence to be $b_1-(n-1)\epsilon, b_2+\epsilon, \ldots, b_n+\epsilon$. Since $\mathcal{A}$'s bids are different from $b_1, b_2, \ldots, b_n$, in light of Lemma 4.1, we may assume that the disadvantaged bidders permute their bids with the uniform probability distribution. Consequently, the expected number of objects won by $\mathcal{A}$ is as desired. □

We next prove a matching upper bound for the expected number of objects $\mathcal{A}$ can win.

LEMMA 4.3. *If the disadvantaged bidders employ $c_1, c_2, \ldots, c_n$ as their initial bid sequence and permute it with the uniform probability distribution, then $\mathcal{A}$ has an optimal initial bid sequence $a'_1, a'_2, \ldots, a'_n$ such that $a'_i \in D$ for all i.*

Proof. Given an optimal initial bid sequence $a_1, a_2, \ldots, a_n$ of $\mathcal{A}$, we show that this sequence can be transformed into a desired sequence $a'_1, a'_2, \ldots, a'_n$ without decreasing $W(\mathcal{A})$. Let m be the number of $\mathcal{A}$'s bids that are in E. There are three cases.

Case 1: $m = 0$. For each a_i, let $a'_i = c_j + \epsilon$ where j is the biggest index such that $c_j < a_i$. Then the expected number of objects won by $a'_1, a'_2, \ldots, a'_n$ is the same as that of $a_1, a_2, \ldots, a_n$, and the new sequence is as desired.

Case 2: $m = 1$. This case is impossible since $\mathcal{A}$ can increase $W(\mathcal{A})$ by decreasing one of his bids outside E by ϵ and increasing the one that is in E by ϵ.

Case 3: $m \ge 2$. Without loss of generality, let $a_1, a_2, \ldots, a_m$ be $\mathcal{A}$'s m bids in E in the increasing order. We first decrease a_1 by $(m-1)\epsilon$ and increase a_j by ϵ for $j = 2, \ldots, m$. As shown below, this adjustment never decreases $W(\mathcal{A})$. Then, since $\mathcal{A}$'s adjusted bids are not in E, his new initial bid sequence can be further transformed into a desired sequence as in Case 1. Let w_1 be the decreased amount of $W(\mathcal{A})$ resulted from decreasing a_1. Let w_j be the increased amount of $W(\mathcal{A})$ resulted from increasing a_j for $j = 2, \ldots, m$. We need to show that $-w_1 + w_2 + \cdots + w_m \ge 0$. It suffices to prove that $w_2 - w_1 \ge 0$. Let $\#_p$ denote the expected number of objects a_j wins if $a_j = c_p$. Then

$$\begin{aligned}
\#_p &= \sum_{i=0}^{k-1} \frac{1}{i+1} \cdot \text{Prob}\{a_j \text{ ties with } i \text{ disadvantaged bidders and beats the others}\}\\
&= \sum_{i=0}^{k-1} \frac{1}{i+1} \binom{k-1}{i} \left(\frac{1}{n}\right)^{i} \left(\frac{p-1}{n}\right)^{k-1-i}
\end{aligned}$$

$$= \sum_{i=0}^{k-1} \frac{1}{i+1} \binom{k-1}{i} \frac{(p-1)^{k-1-i}}{n^{k-1}}$$
$$= \left(\frac{p-1}{n}\right)^{k-1} \cdot \frac{1}{k} \cdot \left(\left(\frac{1}{p-1}\right)^{k} - 1\right).$$

Assume that $a_1 = c_q$ and $a_2 = c_r$. Then $w_1 = \#_q - (\frac{q-1}{n})^{k-1}$ and $w_2 = (\frac{r}{n})^{k-1} - \#_r$. Note that w_2 increases with r. Since $q \le r$, w_2 is minimized when $a_1 = a_2$ and thus $q = r$. Consequently,

$$\begin{aligned}
w_2 - w_1 &\ge \left(\frac{q}{n}\right)^{k-1} - \#_q - \#_q + \left(\frac{q-1}{n}\right)^{k-1} \\
&= \left(\frac{q}{n}\right)^{k-1} + \left(\frac{q-1}{n}\right)^{k-1} - 2 \cdot \sum_{i=0}^{k-1} \frac{1}{i+1} \binom{k-1}{i} \frac{(q-1)^{k-1-i}}{n^{k-1}} \\
&= \left(\frac{q}{n}\right)^{k-1} - \left(\frac{q-1}{n}\right)^{k-1} - 2 \cdot \sum_{i=1}^{k-1} \frac{1}{i+1} \binom{k-1}{i} \frac{(q-1)^{k-1-i}}{n^{k-1}} \\
&= \sum_{i=1}^{k-1} \binom{k-1}{i} \left(\frac{q-1}{n}\right)^{i} \left(\frac{1}{n}\right)^{k-1-i} - 2 \cdot \sum_{i=1}^{k-1} \frac{1}{i+1} \binom{k-1}{i} \frac{(q-1)^{k-1-i}}{n^{k-1}} \\
&= \sum_{i=1}^{k-1} \left(1 - \frac{2}{i+1}\right) \binom{k-1}{i} \frac{(q-1)^{k-1-i}}{n^{k-1}} \\
&\ge 0. \qquad \square
\end{aligned}$$

LEMMA 4.4. *If the $k-1$ disadvantaged bidders all employ $c_1, c_2, \ldots, c_n$ as their initial bid sequence and permute it with the uniform probability distribution, then $\mathcal{A}$ can win at most $\frac{\beta-1}{n^{k-1}}$ objects on average.*

Proof. From Lemma 4.3, $\mathcal{A}$ has an optimal initial bid sequence $a'_1, a'_2, \ldots, a'_n$, such that for all j, $a'_j \in D$. If $a'_j = \epsilon$, then it cannot win any object. If $a'_j = c_i + \epsilon$, then it can win $(\frac{i}{n})^{k-1}$ objects on average. The unit price $\mathcal{A}$ pays for these objects is strictly greater than

$$\frac{\frac{i^{k-1}}{\beta}}{(\frac{i}{n})^{k-1}} = \frac{n^{k-1}}{\beta}.$$

Since the expected number of objects won by such a'_j is an integral multiple of $\frac{1}{n^{k-1}}$, $W(\mathcal{A}) = m \cdot \frac{1}{n^{k-1}}$ for some integer m, and

$$m \cdot \frac{1}{n^{k-1}} \cdot \frac{n^{k-1}}{\beta} < 1.$$

Since m is an integer, $m \le \beta - 1$ and thus $W(\mathcal{A}) \le \frac{\beta-1}{n^{k-1}}$. $\square$

THEOREM 4.5. *If the disadvantaged bidders all employ $c_1, c_2, \ldots, c_n$ as their initial bid sequence and permute it with the uniform probability distribution, then each of them can win at least $1/k$ of $n - \frac{\beta-1}{n^{k-1}}$ objects on average, which is optimal.*

Proof. By Lemma 4.4, $\mathcal{A}$ wins at most $\frac{\beta-1}{n^{k-1}}$ objects on average. By Lemma 4.2, this upper bound is also the lower bound of the expected number of objects $\mathcal{A}$ can win. This theorem follows from the fact that our auction is a zero-sum game. $\square$

5. Extensions and open problems. This paper leaves several problems unsolved. Section 3 still lacks an optimal randomized bidding algorithm for the disadvantaged bidders when n is not a multiple of k. In section 4, if zero bids are allowed, the initial bid sequence $c_1, \ldots, c_n$ is no longer optimal for the disadvantaged bidders. In general, if disadvantaged bidders do not use identical bidding algorithms, it is not even clear what an optimal bidding algorithm should mean, especially for a more complicated information structure than discussed in this paper.

Our model can be extended to study sequential bidding. The bidders submit sealed bids for an object. Once that object is sold, the next object is auctioned the same way until all the objects are sold. For the case where n is a multiple of k, an optimal sequential bidding algorithm is described in the following lemma.

LEMMA 5.1. *If n is a multiple of k and the objects are auctioned sequentially, then a bidder can obtain n/k objects by bidding k/n on every object until his budget is exhausted.*

Proof. Assume that $\mathcal{B}_i$ employs this bidding algorithm. From his budget constraint, he wins at most n/k objects. This upper bound is also a lower bound. To prove this claim by contradiction, assume that $\mathcal{B}_i$ wins fewer than n/k objects and thus does not exhaust all his budget. Then, the total number of objects won by the other bidders exceeds $\frac{k-1}{k}\cdot n$. Because n is a multiple of k and $\mathcal{B}_i$ has not exhausted his budget, every object's winning bid must be at least k/n. Therefore, the total of the winning bids of the other bidders exceeds $k-1$. Since this contradicts the budget constraint, $\mathcal{B}_i$ can win at least n/k objects. □

Our model can also be extended to the case where the objects may have distinct values. In a general setting, the objects are divided into m groups. Let n_i denote the number of objects in the ith group, which may be any positive real number. The bidders are asked to submit bids for the m groups simultaneously. Whoever bids the highest for a group obtains all the objects in that group subject to the same tie-breaking rule. An m-group auction is equivalent to an auction of m objects with distinct values where n_i is the value of the ith group. As before, assume that an adversary bidder $\mathcal{A}$ knows the bidding algorithms of the other $k-1$ bidders and that all those disadvantaged bidders employ the same bidding algorithm.

LEMMA 5.2. *Assume that each disadvantaged bidder bids $n_i \cdot b_i$ for the ith group, where $b_1, b_2, \ldots, b_m$ are drawn from an m-dimensional probability distribution such that the marginal probability distribution of each b_i is F_k subject to $n_1 \cdot b_1 + \cdots + n_m \cdot b_m = 1$. Then the optimal expected number of objects won by $\mathcal{A}$ is n/k.*

Proof. Let $n_i \cdot b_{i,j}$ denote the bid on the ith object by the jth disadvantaged bidder. Let $n_i \cdot a_i$ be $\mathcal{A}$'s bid on the ith object. Because $b_1, b_2, \ldots, b_m \in [0, k/n]$, $\mathcal{A}$ has no incentive to set a_i greater than k/n. Thus, $a_i \le k/n$ and $F_k(a_i) = \left(\frac{n}{k}\cdot a_i\right)^{\frac{1}{k-1}}$. Since bids from different disadvantaged bidders are independent,

$$\begin{aligned} &\text{Prob}\{n_i \cdot a_i \text{ wins the } i\text{th object}\} \\ &= \text{Prob}\{b_{i,1} \le a_i\} \cdot \text{Prob}\{b_{i,2} \le a_i\} \cdots \text{Prob}\{b_{i,k-1} \le a_i\} \\ &= (F_k(a_i))^{k-1} \\ &= \frac{n}{k} \cdot a_i. \end{aligned}$$

$\mathcal{A}$ maximizes $W(\mathcal{A})$ as follows:

$$\max_{\substack{\sum n_i \cdot a_i = 1 \\ 1 \le a_i \le \frac{k}{n}}} W(\mathcal{A})$$

$$= \max_{\substack{\sum n_i \cdot a_i = 1 \\ 1 \le a_i \le \frac{k}{n}}} n_1 \cdot \left(\frac{n}{k} \cdot a_1\right) + n_2 \cdot \left(\frac{n}{k} \cdot a_2\right) + \cdots + n_m \cdot \left(\frac{n}{k} \cdot a_m\right)$$

$$= \frac{n}{k}. \qquad \square$$

CONJECTURE 5.3. *There exists an m-dimensional probability distribution for $(b_1, b_2, \ldots, b_m)$ subject to the constraint $n_1 \cdot b_1 + n_2 \cdot b_2 + \cdots + n_m \cdot b_m = 1$ such that the marginal probability distribution of each b_i is as described by* (3.1).

Remark. This conjecture can be reduced to the case $m = 2$ or $m = 3$.

We conclude the paper with two research directions. One is to consider general information structures as specified by arbitrary directed graphs; the other is to investigate more general budget constraints beyond the homogeneous one of this paper. It would be of significance to design bidding algorithms that can optimally or approximately achieve game-theoretic equilibria in meaningful combinations of these two directions.

Acknowledgments. We are indebted to Phil Long, Kasturi Varadarajan, and Professor Dennis Yang at the Economics Department of Duke University for very helpful comments. We also wish to thank the anonymous referees for contagious enthusiasm toward this work and unusually thoughtful comments and detailed suggestions.

THREE-PROCESSOR TASKS ARE UNDECIDABLE*

ELI GAFNI† AND ELIAS KOUTSOUPIAS†

Abstract. We show that no algorithm exists for deciding whether a finite task for three or more processors is wait-free solvable in the asynchronous read-write shared-memory model. This impossibility result implies that there is no constructive (recursive) characterization of wait-free solvable tasks. It also applies to other shared-memory models of distributed computing, such as the comparison-based model.

Key words. asynchronous distributed computation, task-solvability, wait-free computation, contractibility problem

1. Introduction.

A fundamental area in the theory of distributed computation is the study of asynchronous wait-free shared-memory distributed algorithms. Characterizing the class of distributed tasks that can be solved, no matter how "inefficiently," is an important step toward a complexity theory for distributed computation. A breakthrough was the demonstration by Fischer, Lynch, and Paterson [6] that certain simple tasks, such as *consensus*, are not solvable. Subsequently, Biran, Moran, and Zaks [1] gave a complete characterization of the tasks solvable by two processors and of tasks that can be solved when only one processor can fail. Recently, three teams [3, 9, 17] independently extended this result by providing powerful necessary conditions for task solvability, which enabled them to show that the *k-set agreement task* is not solvable for more than k processors. Finally, Herlihy and Shavit [10, 11] gave a simple condition that is necessary and sufficient for a given task to admit a wait-free protocol. This condition was extended by Borowsky and Gafni [2] to the more general model of asynchronous distributed computation of resiliency and set-consensus.

Here, we put the quest for complete characterization of solvable tasks to an abrupt end by showing that *there is no recursive characterization of wait-free tasks.* More precisely, we show that the problem of deciding whether a given finite task for three or more processors admits a wait-free protocol is undecidable. We also show that this holds for the comparison-based model (when processors can only compare their IDs). An immediate consequence of our result is that for any recursive function *f(s)* there are finite *solvable* tasks of size (number of input-output tuples) s that cannot be solved by any protocol in less than *f(s)* steps. Unfortunately, this may hamper the development of a "complexity theory" of asynchronous distributed computation.

Our proof exploits a surprising connection between distributed computation and topology. In particular, we give a reduction from the *contractibility problem* to the *task-solvability problem.* The contractibility problem asks whether a given loop of a

†Computer Science Department, UCLA, 3731 Boelter Hall, Los Angeles, CA 90095 (eli@cs.ucla.edu, elias@cs.ucla.edu).

simplicial complex is contractible, that is, whether it can be continuously transformed into a point.

The history of the contractibility problem goes back to Poincaré and Dehn at the beginning of the twentieth century (see [19]). Dehn [4] noticed that the contractibility problem is equivalent to the word problem of groups—given a word of a group as a product of its generators, decide whether it is equal to the identity. The relation between the contractibility of a loop and the word problem comes from the fact that a loop of a complex is contractible iff the corresponding word of the *fundamental group* of the complex is the identity. Dehn gave an algorithm (Dehn's algorithm) for the contractibility problem when the complex is a surface; for some recent interesting results for this special case see [5]. Attempts to extend Dehn's algorithm to higher dimensional manifolds made no substantial progress, however, for the very good reason that, as Novikov [15] showed in 1955, the word problem is undecidable.

The equivalence between the contractibility problem and the word problem of groups is based on the fact that every group with a finite representation (with generators and relations) is the fundamental group of a finite simplicial complex. Since the fundamental group depends only on the 2-skeleton of a complex (the collection of all simplices of dimension 2 or less), it follows that the contractibility problem is undecidable even for two-dimensional complexes. It is also known that every group with finite representation is the fundamental group of some four-dimensional manifold [13]. Thus, the contractibility problem is undecidable even for four-dimensional manifolds.

Our main result is a reduction from the contractibility problem to the task-solvability problem. We outline the ideas behind this reduction here. The Herlihy–Shavit condition [11] states that a task is solvable iff there is a chromatic subdivision of the input complex together with a simplicial map which is consistent with the input-output relation (carrier-preserving) and preserves colors. Here we consider a class of simple 3-processor tasks that is restricted to those whose input complex consists of a single triangle (2-simplex). In addition, these tasks have the property that whenever less than three processors participate, they must output a simplex of a fixed loop L of the output complex. The Herlihy–Shavit condition implies that if the task is solvable, then L is contractible. In fact, if we drop from the Herlihy–Shavit condition the restriction that the map must be color-preserving, the opposite would be true: L is contractible if the task is solvable. The difficult part of our reduction, then, is to extend this relation to the case of chromatic complexes and color-preserving simplicial maps. To do this, we proceed in stages. We first show that the contractibility problem remains undecidable for loops of length 3 of chromatic complexes. The final reduction is to take a chromatic complex with a loop of length 3 and transform it into a 3-processor task that is solvable iff the loop is contractible.

In section 2, we discuss the solvability problem, present the Herlihy–Shavit condition, and define the special class of tasks that we consider in this paper. In section 3, we discuss the contractibility problem and strengthen the result that the contractibility problem is undecidable for the special case of chromatic complexes and loops of length 3. We give a reduction from this stronger version of the contractibility problem to the task-solvability problem in section 4. The results from section 3 and the Herlihy–Shavit condition are then used to prove that the reduction works. We conclude by discussing some of the implications of our results.

2. The task-solvability problem. We will use standard terminology from algebraic topology (see [14]). All complexes considered here are *finite* and *pure*; that is,

all maximal simplices have the same dimension (usually two-dimensional).

In topology, a simplex is defined by a set of $n+1$ points, but in the theory of distributed computation a simplex represents a consistent set of views of $n+1$ processors. The natural ordering of processors (according to their IDs) imposes structure on the complexes in that their simplices are ordered. This order defines a natural *coloring* of the vertices of the complex, where colors represent the rank of the ID of a processor. More precisely, a coloring of an n-dimensional simplicial complex is an assignment of colors $\{0, 1, \ldots, n\}$ to its vertices such that each vertex receives exactly one color and vertices of each simplex receive distinct colors. A *chromatic* simplicial complex is a simplicial complex together with a coloring.

A distributed task is a natural generalization of the notion of a (computable) function for the model of distributed computation. The computation of functions by a distributed system imposes such tight coordination of processors that only trivial functions can be computed wait-free by asynchronous distributed systems. Mainly for this reason, the study of distributed computation is focused on computing relations, a natural generalization of functions which requires less tight coordination of processors. In general, a distributed task is an input-output relation. Because in a distributed system some processors may take no steps at all, the task input-output relation must be defined on partial inputs and outputs. This requirement is captured nicely by assuming that the inputs form a chromatic simplicial complex. The vertices of a simplex of this complex denote the inputs to a subset of processors, the *participating* processors [11]. Similarly, the possible outputs of a distributed task form a chromatic simplicial complex.

DEFINITION 1. *A distributed task for $n+1$ processors is a nonempty relation T between the simplices of two n-dimensional chromatic complexes I, O, $T \subset I \times O$, which preserves colors; that is, when $(A, B) \in T$, then A and B have the same colors (and therefore the same dimension).*

A distributed task is solvable when there is a distributed protocol such that the input to processor with ID k is a vertex of I with color k, its output is a vertex of O of color k, the set of the input vertices form a simplex $A \in I$, and the set of output vertices form a simplex $B \in O$ with $(A, B) \in T$. In other words, the participating processors get vertices of an input simplex and output vertices of a simplex of the output complex such that the input simplex and the output simplex form a pair of the task input-output relation. Each processor knows only its vertex, not the whole input simplex. Finding out the input simplex is usually impossible because that task is equivalent to the consensus problem, which is not solvable. Of course, the notion of solvability depends on the computational model. Here, we consider the standard computational model of wait-free protocols for shared read-write memory. In a wait-free protocol, a processor must produce a valid output even when all other processors fail.

A typical distributed task is shown in Figure 1. The input complex I contains only one triangle $\{a, b, c\}$, and the output complex O is a subdivided triangle. The numbers on the vertices are colors. The input-output relation $T \subset I \times O$ contains the tuples $(\{a, b, c\}\{x, y, z\})$ for all triangles $\{x, y, z\}$ of O (there are seven such triangles); it also contains all possible color-preserving tuples of simplices of the boundaries of I and O.

A problem central to the theory of distributed computation is the characterization of the set of solvable tasks. This problem has a trivial negative answer: whether a 1-processor task is solvable is equivalent to whether the task, that is, the input-

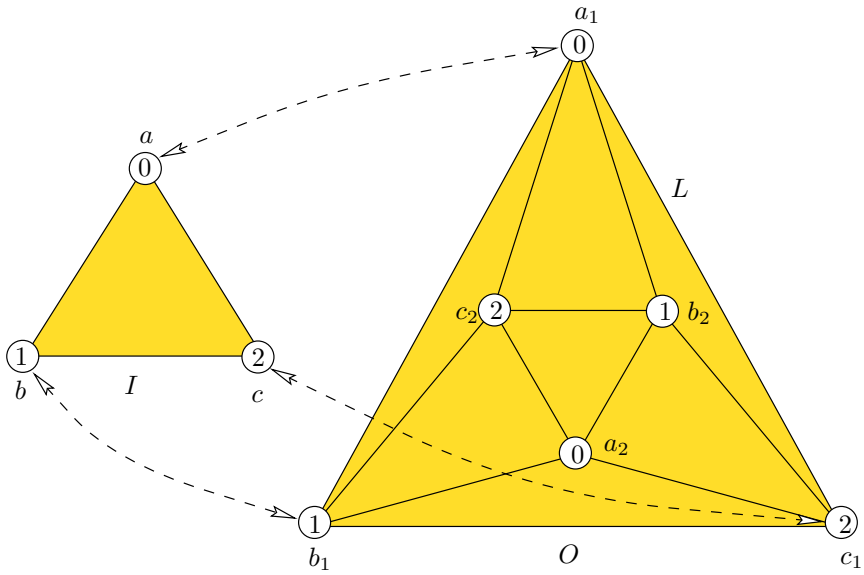

FIG. 1. *A standard inputless task.*

output relation, is recursive (computable); a similar observation was made in [12]. However, this is an unsatisfactory answer because it sheds no light on the difficulties inherent in distributed computation. Furthermore, many interesting distributed tasks are straightforward input-output relations. The interesting question, then, is whether a characterization of "simple" tasks exists. Here, we show that the answer for three or more processors remains negative, even for the simplest kind of tasks—finite tasks with a trivial input complex. For less than three processors, it is known that there exists a simple characterization for finite tasks of two processors that reduces the task-solvability problem to the connectivity properties of the output complex [1].

Our proof uses the Herlihy–Shavit condition for task solvability. Roughly speaking, this condition entails that a subcomplex of the output complex is "similar to" the input complex. To state the condition precisely, we need a few definitions: Consider a chromatic complex C and a subdivision C' of C (a subdivision of a complex is a refinement of it; see, for example, [14, p. 84]). For a simplex $A \in C'$, its carrier, $\text{carrier}(A)$, is the smallest simplex of C that contains A. The complex C' is a *chromatic subdivision* of C if it is chromatic and its coloring has the property that each vertex $u \in C'$ has the color of some vertex of $\text{carrier}(u)$.

PROPOSITION 1 (Herlihy–Shavit). *A task $T \subset I \times O$ is solvable wait-free iff there exists a subdivision I' of I and a color-preserving simplicial map $\mu : I' \mapsto O$ such that for each simplex $A \in I'$ there exists a simplex $B \in O$ with $\mu(A) \subset B$ and* $(\text{carrier}(A), B) \in T$.

A map μ that satisfies the above condition will be called *carrier-preserving* and *color-preserving*.

Proposition 1 provides a powerful tool for checking whether a particular task is solvable. For example, by applying the Herlihy–Shavit condition we can conclude immediately that the task of Figure 1 is wait-free solvable. To see this, notice that in this case we can take the subdivision I' to be the output complex and the map μ

to be the identity map.[1] If, however, we create a "hole" in the output complex by removing the triangle $\{a_2, b_2, c_2\}$, the resulting task is not solvable; intuitively, the map μ cannot create a "torn" image of I.

The main objective of our paper is to show that the condition of Proposition 1 is not constructive, namely, that there is no effective way to find I' from T; computing μ is easy, since one can try all possible simplicial maps from I' to O. We will restrict our attention to the simple case of tasks of three processors, $n = 2$. In this case, the simplices are triangles and the simplicial complexes are of dimension 2. For this dimension, our intuition about topological facts is usually correct; exactly the opposite is true for higher dimensions. We introduce one further simplification: we will deal only with tasks where the input complex consists of only one triangle. Furthermore, for each proper face of the input triangle there is exactly one possible output. In particular, there is a loop L of the output complex that has length 3 such that when less than three processors participate in the execution, the processors must output a simplex of L, and this simplex is unique because of the coloring requirements. When all three processors participate, the output can be any simplex of the output. We will call such a task a *standard inputless task* (O, L). The task of Figure 1 is an example of such a task. Since the input to each processor is fixed, we interpret a standard inputless task as follows: processors do not really get any input; rather, they simply execute a protocol in order to "agree on" some triangle of the output complex O. This could be trivially achieved (by agreeing on a triangle in advance), except for the difficulty that when some processors do not participate, the output simplex must belong to the loop L.

For a standard inputless task, the Herlihy–Shavit condition can be restated as "the task is solvable iff there is a chromatic subdivision I' of a triangle I and a color-preserving simplicial map μ that maps the boundary of I' to the loop L and that can be extended over I'." The coloring restrictions imply that the simplicial map μ maps the boundary of I' only once around L. Putting it differently, the requirement that μ is color-preserving guarantees that it is also carrier-preserving.

If we disregard colors for the moment, a standard inputless task is solvable iff there is a carrier-preserving simplicial map μ from the boundary of a subdivided triangle I' to the loop L which can be extended over the whole triangle. This condition shows the close connection between task solvability and the contractibility problem, because such I' and μ exist iff the loop L of the output complex O is contractible (we will elaborate on this connection in section 4). It is not, however, immediate that this observation holds for the special case of chromatic complexes and color-preserving simplicial maps. Here, we extend this connection to the chromatic case by a series of reductions.

3. The contractibility problem. Let X be a topological space. A *loop* L of X is a continuous map from the 1-sphere $S = \{x \in \mathbf{R}^2 : |x| = 1\}$ to X. Two loops L and L' are *homotopic* when L can be continuously deformed to L'. More precisely, L and L' are said to be homotopic if there exists a continuous map $F : S \times [0, 1] \mapsto X$, such that $F(x, 0) = L(x)$ and $F(x, 1) = L'(x)$ [14, p. 103]. A *nonsingular* loop is one without self-intersections (when the map is an injection). A loop L is *null-homotopic*, or *contractible*, when it is homotopic to a constant loop; the image of a constant loop is a point. Equivalently, loop L is null-homotopic when it can be continuously deformed to a point [18, p. 158]. For example, in Figure 2 the loop L_1 is null-homotopic while

[1] Strictly speaking, I' is combinatorially homeomorphic to O, and μ is this homeomorphism.

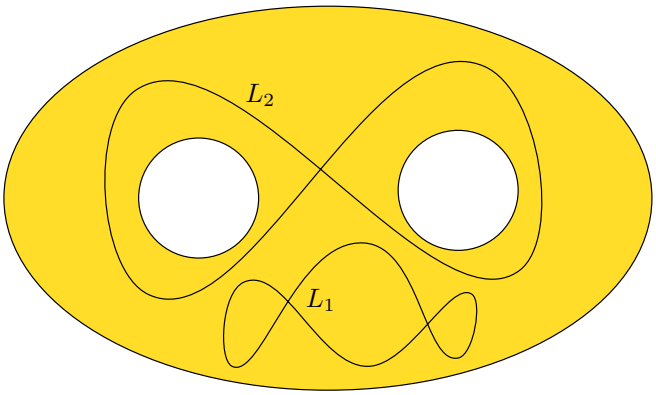

FIG. 2. *Contractible (L_1) and noncontractible (L_2) loops.*

the loop L_2 is not.

Let C be a simplicial complex, that is, a collection of simplices in the Euclidean space R^m. The polytope $|C|$ of C is the underlying Euclidean space consisting of the union of the simplices of C. A loop of a complex C is a simplicial loop of its polytope $|C|$. Thus, the image of a loop is a sequence of edges (v_1, v_2), $(v_2, v_3), \ldots, (v_{k-1}, v_k)$, (v_k, v_1) (the image of a null-homotopic loop is simply a vertex v). We usually do not distinguish between the loop of a complex and its image (as we have done many times so far); so, for example, we can refer to a simplex of the loop when we really mean a simplex of the image of it.

To show that task solvability is undecidable, we will use the standard technique of reducing a known undecidable problem to it. In our case, this problem is the contractibility problem [19].

DEFINITION 2. *The contractibility problem is defined as follows: given a simplicial complex C and a loop L of C, is L null-homotopic?*

For this definition to be complete, we need to fix the representation of C and L. Since we are interested only in whether the problem is decidable, the details of the representation are not important. For our purposes here, we assume that C and L are given explicitly by their simplices.

There is an important connection between the homotopic properties of loops and group theory, through the fundamental group of a complex. In particular, a loop is null-homotopic iff the corresponding word of the fundamental group is equal to the identity. This connection between contractibility and group theory results in the following proposition.

PROPOSITION 2. *The contractibility problem is undecidable for two-dimensional complexes.*

This folklore result is based on the fact that for every group G with a finite representation with generators and relations, there exists a finite simplicial complex with fundamental group G. This complex can be easily constructed from G (see, for example, [19, p. 129]). In fact, something stronger holds: each group G is the fundamental group of a four-dimensional simplicial manifold [13, pp. 143–144]. This means that the contractibility problem is undecidable for four-dimensional manifolds. In contrast, for two-dimensional manifolds (e.g., sphere, torus, projective plane) it is decidable [4]. Some recent work on this special case has led to a linear-time algorithm for almost all two-dimensional manifolds [5]. The contractibility problem for three-

dimensional manifolds is, to our knowledge, still unresolved; however, it is known that not every group with finite representation can be the fundamental group of a three-dimensional manifold.

Notice also that Proposition 2 refers to two-dimensional complexes. This is based on the fact that the fundamental group of a complex of any dimension is identical to the fundamental group of its 2-skeleton.

Since every group can be the fundamental group of a complex, the contractibility problem is equivalent to the word problem of groups. The word problem asks whether a word of a group (as a product of its generators) is equal to the identity [19, p. 46]. Novikov [15] showed that the word problem is undecidable: there exists a group G such that no algorithm can decide whether a word of this group is equal to the identity (for a textbook proof see [16, Chapter 12]). Notice that the group G need not be part of the input, although for our purposes the weaker version of the result when the group is part of the input will suffice.

We will make use of a stronger version of Proposition 2. We first observe that the contractibility problem is undecidable for *link-connected* two-dimensional complexes. A simplicial complex is link-connected when the link of every vertex is connected (the link of a vertex is the subcomplex induced by its adjacent vertices). To see that the contractibility problem remains undecidable for link-connected complexes, notice that it is undecidable for the 2-skeleton of 4-manifolds, and clearly these complexes are link-connected. Therefore we have the stronger proposition.

PROPOSITION 3. *The contractibility problem is undecidable for link-connected two-dimensional complexes.*

Link-connectivity must be preserved by all our reductions, but we will not use it until the last part (Lemma 3) of the proof of the main result.

The plan for reducing this undecidable problem to the task-solvability problem is as follows: First, we strengthen Proposition 3 to chromatic complexes and loops of length 3. A chromatic complex together with a loop of length 3 defines a standard inputless task. Using the Herlihy–Shavit condition, we then show that this task is solvable iff the loop is contractible.

We begin by showing that Proposition 3 holds for nonsingular loops (i.e., loops without self-intersections).

LEMMA 1. *The contractibility problem is undecidable for nonsingular loops of link-connected two-dimensional complexes.*

Proof. Given a link-connected two-dimensional simplicial complex C and a loop L of C, we create a new complex C' and a singular loop L' of C' such that L is null-homotopic iff L' is null-homotopic. The idea is that C' can be produced by attaching an annulus (ring) A to C: one boundary of A is identified with the loop L, and the other boundary is a nonsingular loop L' (see Figure 3). The annulus A is free of self-intersections except for points of L.

We claim that L is contractible in C iff L' is contractible in C'. But first we need a definition. A topological space Y is a *deformation retract* of a topological space X, $Y \subset X$, iff there is a continuous map $f : X \times [0,1] \mapsto X$ such that for all $x \in X$, $f(x,0) = x$ and $f(x,1) \in Y$, and for all $y \in Y$ and all t, $f(y,t) = y$.

If Y is a deformation retract of X, then Y and X have the same homotopy type [14, p. 108]. It is clear that $|C|$ is a deformation retract of $|C'|$: f gradually collapses the annulus $|A|$ to the loop $|L|$ keeping $|C|$ fixed. It follows that $|C|$ and $|C'|$ have the same homotopy and therefore that L is contractible in C iff it is also contractible in C'. The claim follows from the fact that L and L' are homotopic in C'.

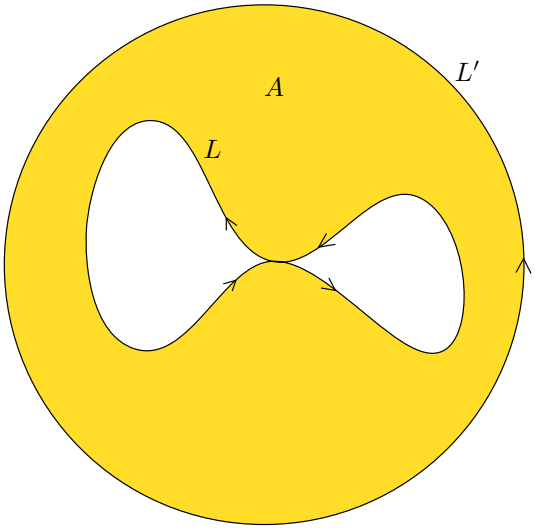

FIG. 3. *Reduction to nonsingular loop.*

A minor issue is that the annulus A must be constructed explicitly. We give here one such construction. Let $(x_0, x_1), (x_1, x_2), \ldots, (x_{k-1}, x_k), (x_k, x_0)$ be the edges of L (some of them may be identical when part of the loop retraces itself). The boundary of annulus A identified with L contains vertices $y_0, y_1, \ldots, y_k$ such that y_i will be identified with x_i. The other boundary, L', of annulus A contains distinct vertices $z_0, z_1, \ldots, z_k$. The triangles of annulus A are $\{y_i, y_{i+1}, z_i\}$ and $\{y_{i+1}, z_i, z_{i+1}\}$, for $i = 0, 1, \ldots, k$. We have to verify that these are indeed triangles (i.e., all vertices are distinct) and that annulus A is free of self-intersections except for points in L. Some of the vertices x_i of L may be identical, because the loop L may cross or even retrace itself. However, since (x_i, x_{i+1}) is an edge of L, it follows that y_i and y_{i+1} are distinct and therefore that the given triangulation of annulus A is valid. It is also easy to verify that annulus A has no self-intersections outside L.

Finally, we have to verify that the new complex C' is link-connected. It is clear that the links of vertices not in L are connected. Consider now the link $\mathrm{lk}(x_i)$ of a vertex $x_i \in L$. Since C is link-connected, every vertex of $C \cap \mathrm{lk}(x_i)$ is connected through $\mathrm{lk}(x_i)$ to x_{i-1} and to x_{i+1}. In particular, x_{i-1} and x_{i+1} are connected through $\mathrm{lk}(x_i)$ (or they are identical). Similarly, every vertex in $A \cap \mathrm{lk}(x_i)$ is connected to x_{i-1} or to x_{i+1}. Therefore, $\mathrm{lk}(x_i)$ is connected. □

This lemma allow us to consider only nonsingular loops. We may sometimes treat a nonsingular loop L of a complex C as the one-dimensional subcomplex of C consisting of the edges of L. We are now ready to strengthen Proposition 3 to chromatic complexes and loops of length 3.

THEOREM 1. *The contractibility problem is undecidable for loops of length* 3 *of link-connected two-dimensional chromatic complexes.*

Proof. Consider a link-connected two-dimensional simplicial complex C and a nonsingular loop L of it. We will show how to produce a chromatic complex C' and a loop $L' \subset C'$ of length 3.

Producing a chromatic complex is easy. Let bsd C denote the *barycentric subdivision* of the simplicial complex C [14, p. 85]. We can color the simplicial complex

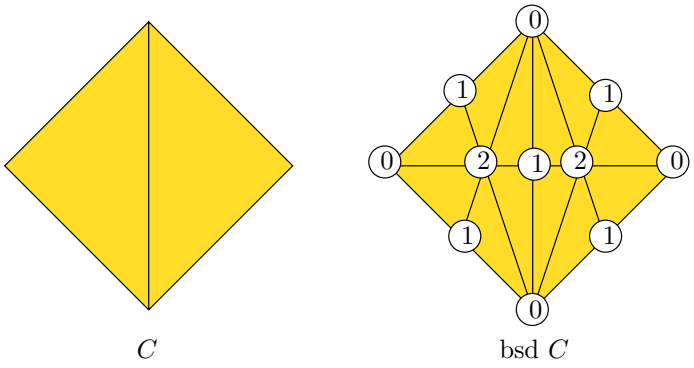

FIG. 4. *The chromatic barycentric subdivision.*

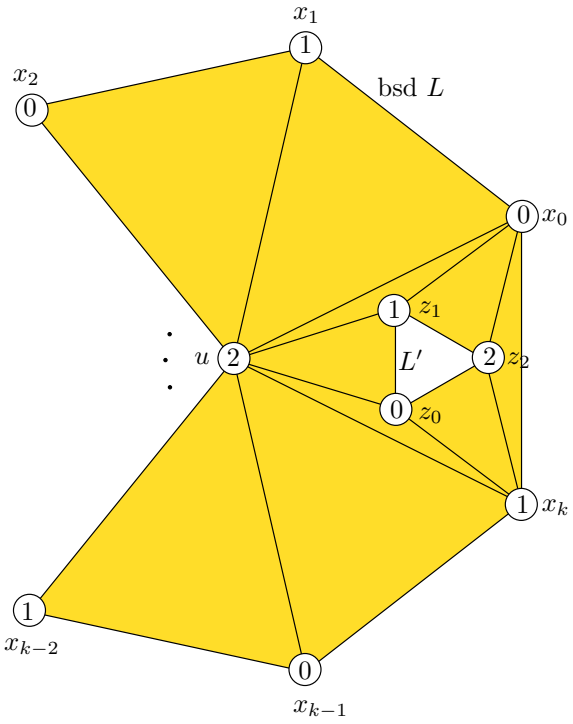

FIG. 5. *Reduction to loops of length* 3.

bsd C with three colors as shown in Figure 4. Original vertices of C are colored with 0, vertices on the edges—with carrier an edge—with 1, and the remaining vertices—with carrier a triangle—with color 2. With this coloring, bsd C becomes a chromatic complex. The nonsingular loop L of C corresponds to a nonsingular loop bsd L of the chromatic complex bsd C. Clearly, L is null-homotopic in C iff bsd L is null-homotopic in bsd C'. Notice also that the vertices of bsd L have colors 0 or 1.

Finally, to produce a complex C' and a loop L' of length 3, we employ the reduction of Lemma 1: C' is the result of attaching a chromatic annulus A to the nonsingular loop bsd L. Let (x_0, x_1), $(x_1, x_2), \ldots, (x_{k-1}, x_k)$, (x_k, x_0) be the edges

of bsd L. One boundary of the chromatic annulus A is identified with bsd L, while the other boundary L' contains three vertices, z_0, z_1, z_2, with colors 0, 1, and 2, respectively. There is also an internal vertex u of A with color 2. The chromatic annulus A is shown in Figure 5 (again, numbers on vertices indicate colors). We omit its precise description here since the reader can easily derive it from the figure. Remaining to be verified is that A is an annulus without self-intersections, and this follows directly from the fact that bsd L is nonsingular. Note that this is the only place where we need Lemma 1. We could actually use a simpler construction by letting L' be the loop (x_0, u, x_k), but the construction of Figure 5 is consistent with the proof of Lemma 1.

An argument identical with that of the proof of Lemma 1 establishes that the complex C' is link-connected and that L' is null-homotopic iff L is null-homotopic. The theorem follows from Lemma 1. □

The requirement that loop L has length 3 is a "technical" detail. We could prove our main result by simply considering loops L where, instead of an edge (z_i, z_{i+1}), there is a chromatic path between z_i and z_{i+1}. The restriction to loops of length 3 results in simpler constructions and proofs, however.

4. Reduction to task-solvability. To show that task-solvability for three processors is undecidable, we will reduce the stronger version of the contractibility problem of Theorem 1 to the task-solvability problem. The reduction is straightforward. Given a link-connected two-dimensional chromatic complex C and a loop L of length 3, the output is the standard inputless task $T = (C, L)$. We will show that the loop L is contractible in C iff the standard inputless task (C, L) is solvable.

The proof is based on the two following lemmas.

LEMMA 2. *Let $T = (C, L)$ be a standard inputless task. Loop L is contractible in C iff there is a subdivision I' of the input triangle I and a simplicial map $\psi : I' \mapsto C$ that is carrier-preserving.*

Proof. Notice first that we require neither that I' be a chromatic subdivision nor that μ be color-preserving. It follows directly from the definition of null-homotopic loops that loop L is contractible in C iff there is a *continuous map* ϕ from a disk B to $|C|$ that maps *homeomorphically* the boundary of the disk to $|L|$. Since the triangle I is homeomorphic to a disk, L is contractible in C iff there is a continuous map from I to $|C|$ that maps its boundary to the loop $|L|$ homeomorphically (and, therefore, simplicially). The problem with this definition is that ϕ is a continuous map, not a simplicial one. However, a fundamental result from algebraic topology, the simplicial approximation theorem [14, p. 89], allows us to replace the continuous map ϕ with a simplicial one. By the simplicial approximation theorem, there is a subdivision I' of the triangle I and a simplicial map $\psi : I' \mapsto C$ that *approximates* ϕ. It suffices, therefore, to verify that ψ is also carrier-preserving. By the definition of simplicial approximations, for each point x of I, $\psi(x)$ is a vertex of the smallest simplex of C that contains $\phi(x)$. Since ϕ maps simplicially the boundary of I to $|L|$, all points of an edge E of I are mapped to the same edge $\phi(E)$ of L. Thus, the vertices of I' with carrier E are mapped by ψ to vertices of $\phi(E)$, which shows that ψ is carrier-preserving. □

Lemma 2 shows the close connection between the contractibility of loops and the solvability of tasks. However, it requires only that the map ψ be carrier-preserving, while the Herlihy–Shavit condition requires the map to be chromatic too. The following lemma shows that this is not a problem.

LEMMA 3. *Let $T = (C, L)$ be a standard inputless task, where C is link-connected. If there exists a subdivision I' of the input triangle I and a carrier-preserving simplicial*

map $\psi : I' \mapsto C$, then there exists a chromatic subdivision A of I and a simplicial map $\mu : A \mapsto C$ that is both carrier-preserving and color-preserving.

Proof. The proof here is an adaptation of the proof of a similar result in [11, Lemma 5.21]. The basic idea is that the colors of C induce a coloring of I'. A vertex $u \in I'$ is assigned the color of its image $\psi(u) \in C$. We call such a coloring of I' ψ-induced. This coloring makes ψ a color-preserving map. However, such a coloring may not make I' a chromatic complex, because two adjacent vertices u_1 and u_2 of I' may receive the same color. Because ψ is a simplicial map, this happens only when these vertices are mapped to the same node, in which case we say that the edge $\{u_1, u_2\}$ is monochromatic. Similarly, we say that a triangle is monochromatic when all its vertices are mapped to the same vertex.

Let A be a subdivision of I such that there is a carrier-preserving simplicial map $\mu : A \mapsto C$ such that the number of monochromatic simplices of A with the μ-induced coloring is minimum. We claim that A has no monochromatic edges or triangles. Suppose that this is not the case. We will reach a contradiction by exhibiting a subdivision A' of A—and therefore of I—with one monochromatic simplex less than A.

Consider first the case when A with the μ-induced coloring has a monochromatic triangle $\{u_1, u_2, u_3\}$, and therefore $\mu(u_1) = \mu(u_2) = \mu(u_3)$. Let p be a vertex in the link of $\mu(u_1)$; such a vertex always exists because the complex C is pure. Consider now the subdivision A' of A where the triangle $\{u_1, u_2, u_3\}$ is subdivided into three triangles $\{u_1, u_2, c\}$, $\{u_1, c, u_3\}$, and $\{c, u_2, u_3\}$, where c is the barycenter of $\{u_1, u_2, u_3\}$. Consider also the map $\mu' : A' \mapsto C$ that agrees with μ on the vertices of A and $\mu'(c) = p$. But then A' with the μ'-induced coloring has one monochromatic simplex (the triangle $\{u_1, u_2, u_3\}$) less than A with the μ-induced coloring.

We now assume that no triangle of A is monochromatic but that there is a monochromatic edge $\{u_1, u_2\}$ on the boundary of A. Then, u_1 and u_2 belong to exactly one triangle of A. Let b be the third vertex of this triangle. We can construct a subdivision A' of A by subdividing the triangle $\{u_1, u_2, b\}$ into two triangles $\{u_1, c, b\}$ and $\{c, u_2, b\}$, where c is the barycenter of $\{u_1, u_2\}$. Consider the extension $\mu' : A' \mapsto C$ such that μ' agrees with μ on all vertices of A and $\{\mu'(c), \mu'(u_1)\}$ is an edge of the loop L. Because μ' is carrier-preserving, we have again reached a contradiction since A with the μ-induced coloring has one monochromatic simplex more than A' with the μ'-induced coloring.

The last, and more complicated, case to consider is when A has a monochromatic edge $\{u_1, u_2\}$ that is not in its boundary. This is the only place where we must require that complex C be link-connected. The edge $\{u_1, u_2\}$ belongs to exactly two triangles. Let a and b be the remaining vertices of these two triangles. Since μ is a simplicial map, $\mu(a)$ belongs to the link of $\mu(u_1)$ in C. Let p be a vertex in the link of $\mu(u_1)$ (not necessarily distinct for $\mu(a)$). But then the fact that C is link-connected implies that there is a path with edges (p_1, p_2), $(p_2, p_3), \ldots, (p_{k-1}, p_k)$ in the link of $\mu(u_1)$ that connects $\mu(a) = p_1$ and $p = p_k$. We can always choose a nonempty path, even when $p = a$, because C is pure. Similarly, there is a path with edges (q_1, q_2), $(q_2, q_3), \ldots, (q_{l-1}, q_l)$ which connects $\mu(b)$ and $p = q_l$. This suggests the following subdivision A' of A: The triangle $\{u_1, u_2, a\}$ is subdivided into triangles $\{\bar{p}_i, \bar{p}_{i+1}, u_1\}$ and $\{\bar{p}_i, \bar{p}_{i+1}, u_2\}$, $i = 1, 2, \ldots, k-1$. The vertices $\bar{p}_i$, $i = 2, 3, \ldots, k$, are new and distinct, and $\bar{p}_k$ is the barycenter of $\{u_1, u_2\}$. Similarly, the triangle $\{u_1, u_2, b\}$ is subdivided into triangles $\{\bar{q}_i, \bar{q}_{i+1}, u_1\}$ and $\{\bar{q}_i, \bar{q}_{i+1}, u_2\}$, $i = 1, 2, \ldots, l-1$, where $\bar{q}_l = \bar{p}_k$. Consider also the extension $\mu' : A' \mapsto C$ such that μ' agrees with μ on

A and $\mu'(\bar{p}_i) = p_i$, $i = 1, 2, \ldots, k$ and $\mu'(\bar{q}_i) = q_i$, $i = 1, 2, \ldots, l$. Using the fact that C is chromatic, it is easy to verify that B with the μ'-induced coloring has one monochromatic simplex less than A with the μ-induced coloring. □

An alternative proof of Lemma 3 can be obtained by employing the convergence algorithm of Borowsky and Gafni [2]. We outline this proof here. By the Herlihy–Shavit condition, it suffices to show that the task T is solvable. The protocol consists of two phases. In the first phase, processors "converge" on a simplex of I'. Let x_i be the vertex of I' where processor i converges. If the color of $\mu(x_i)$ is i, then the processor i stops and outputs $\mu(x_i)$. Obviously, at least one processor stops in this phase. Although the remaining processors do not know the output of the stopped processors, they know a simplex of C that contains the outputs of stopped processors. In the second phase, the remaining processors converge in C in the link of the output of all stopped processors; each of the remaining processors starts at a vertex of its color and, if possible, a vertex of the loop L. Since C is link-connected and chromatic, the remaining processors can indeed converge. Thus T is solvable.

We can now prove the main theorem of this paper.

THEOREM 2. *The task-solvability problem for three or more processors in the read-write wait-free model is undecidable.*

Proof. By Theorem 1, there is no algorithm to decide, given a standard inputless task $T = (C, L)$, whether the loop L is contractible in C when C is link-connected. However, by Lemmas 2 and 3 the loop L is contractible iff there is a chromatic subdivision I' of the input triangle I and a color-preserving and carrier-preserving simplicial map $\mu : I' \mapsto C$. This is precisely the Herlihy–Shavit condition for T to be solvable, and therefore L is contractible in C iff T is solvable. Hence, task solvability is undecidable for three processors.

This immediately implies that the solvability problem for more than three processors is also undecidable: Consider, for example, tasks where there is only one possible output of all but the first three processors; such a task is solvable iff the subtask for the first three processors is solvable. □

Biran, Moran, and Zaks [1] define a slightly different model of distributed computation in which the processors must produce a valid output only if all of them complete their protocol. For this model, the input-output relation contains only n-dimensional simplices. For each task $T \subset I \times O$, it is easy to construct an equivalent task T' in the model of [1]: The input for task T' to processor i may be a special value p_i that indicates that the processor does not "participate" in T. In that case, the processor must output a special value q_i. Otherwise, the input is a vertex of I and the output a vertex of O in such a way that the input-output relation of processors whose inputs are not special values is identical to T. It is easy to see that T is solvable iff T' is solvable in the model of [1]. This immediately implies the following.

COROLLARY 1. *The task-solvability problem for the model of Biran, Moran, and Zaks* [1] *is undecidable for three or more processors.*

Another interesting variant of the shared read-write memory model is the comparison-based model where processors cannot access directly their IDs but can only compare them [11]. A typical task for this model is the *renaming* task: the input (name) to each processor is a distinct member of a set S of size m, and the output must be a distinct member of a smaller set of size k. In the comparison-based model, the input to a processor is not a vertex of the input complex I but instead is some value associated with the vertex. Different vertices may have the same value. Similarly there are values associated with the vertices of the output complex. This generalization in

the definition of tasks is necessary for the comparison-based model to be different from the model we have considered so far; otherwise, when a processor gets as input a vertex of the input complex I, it can immediately determine its color and the rank of its ID. This suggests a trivial reduction from task-solvability to the comparison-based model task-solvability: Given a task $T \subset I \times O$, construct a comparison-based model task T' with the same input-output tuples where the value of each vertex is the vertex itself. Then all values are distinct, and a processor can infer its color from its input. It follows that T is solvable iff T' is solvable in the comparison-based model.

COROLLARY 2. *The task-solvability problem for three or more processors in the comparison-based model is undecidable.*

Recently, Herlihy and Rajsbaum [8] proposed an interesting extension of Theorem 2 to the models of resiliency and set-consensus. Using the contractibility problem, they showed that the task-solvability problem for these models is also undecidable in general.

5. Conclusion. Let us define the size of a task to be the number of its input-output tuples. Theorem 2 implies that for *any recursive function* $f(s)$, there are solvable tasks of size s whose protocols require at least $f(s)$ steps. This is indicative of the difficulty involved in developing a robust complexity theory for asynchronous distributed computation. The analogy for traditional complexity theory would be that the finite languages, a proper subset of regular languages, are nonrecursive! However, it may still be possible to develop a notion of complexity of distributed tasks that is independent of the task size. An intriguing open problem is finding a solvable "natural" task whose protocol requires, for example, exponential number of steps. Of course, one could use the reductions given in this paper to produce such a task, but that task could not be considered natural.

The Herlihy–Shavit condition (despite the title of [10]) is not constructive. Our results here cast some doubt on its applicability as a necessary and sufficient condition for task solvability. On the one hand, the best way to show that a task is solvable is to provide a distributed algorithm that solves the given task. On the other hand, showing that a task is not solvable often employs other weaker conditions that are easier to apply than the Herlihy–Shavit condition (e.g., Sperner's lemma or homology). However, our work does show how powerful the Herlihy–Shavit condition is, because no weaker condition would enable us to derive the results of this paper. Ironically, although our work exposes the inherent weakness of the Herlihy–Shavit condition, to our knowledge our work is the only work that makes full use of it.

Acknowledgments. The possibility that the Herlihy–Shavit condition might not be constructive was suggested by Shlomo Moran in a conversation with the first author in 1994. We would like to thank Geoffrey Mess of the UCLA Mathematics Department for providing useful pointers to the literature.

SIMPLE ALGORITHMS FOR ROUTING ON BUTTERFLY NETWORKS WITH BOUNDED QUEUES*

BRUCE M. MAGGS† AND RAMESH K. SITARAMAN‡

Abstract. This paper examines several simple algorithms for routing packets on butterfly networks with bounded queues. We show that for any greedy queuing protocol, a routing problem in which each of the N inputs sends a packet to a randomly chosen output requires $O(\log N)$ steps, with high probability, provided that the queue size is a sufficiently large, but fixed, constant. We also show that for any deterministic nonpredictive queuing protocol, there exists a permutation that requires $\Omega(N/q \log N)$ time to route, where q is the maximum queue size. We present a new algorithm for routing $\log N$ packets from each input to randomly chosen outputs on a butterfly with bounded-size queues in $O(\log N)$ steps, with high probability. The algorithm is simpler than the previous algorithms of Ranade and Pippenger because it does not use ghost messages, it does not compare the ranks or destinations of packets as they pass through switches, and it cannot deadlock. Finally, using Valiant's idea of random intermediate destinations, we generalize a result of Koch's by showing that if each wire can support q messages, then for any permutation, the expected number of messages that succeed in locking down paths from their origins to their destinations in back-to-back butterflies is $\Omega(N/(\log N)^{1/q})$. The analysis also applies to store-and-forward algorithms that drop packets if they attempt to enter full queues.

1. Introduction.

Many commercial and experimental parallel computers, including the NYU Ultracomputer [9], the IBM RP3 [19], the BBN Butterfly [5], and NEC's Cenju [18], use butterfly networks to route packets between processors. Several proposed designs for the switching fabric of scalable high-speed ATM networks use butterfly and other closely related multistage interconnection networks [26]. Although many routing algorithms with provably good performance have been devised for butterfly networks [2, 15, 20, 23, 24, 31, 32, 33, 34], simpler algorithms are often used in practice. Typically, packets are sent along shortest paths through the network, and simple queuing protocols such as first-in first-out (FIFO) are used to determine which packets to transmit at each step. In addition, the queues at the switches can usually hold only a small number of packets. The performance of these simple algorithms has proven surprisingly difficult to analyze. For example, the only previously known upper bound on the expected time required for each input of an N-input butterfly

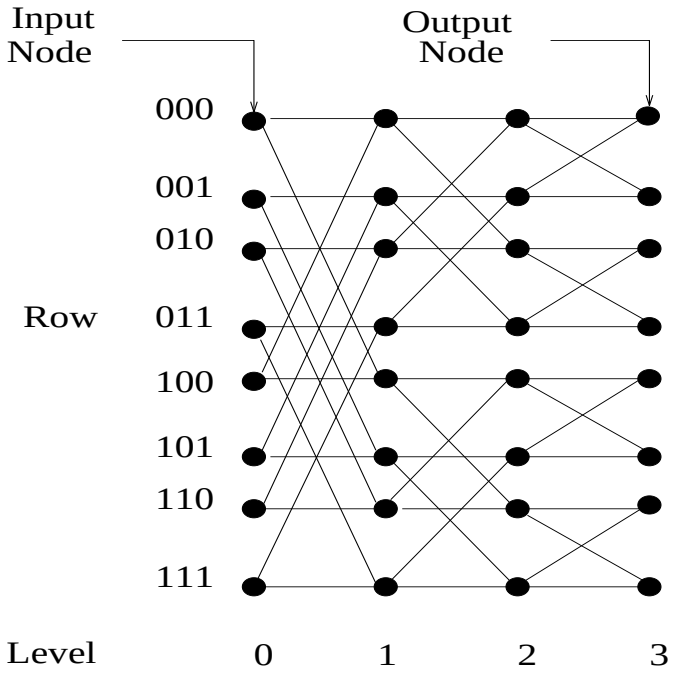

FIG. 1.1. *An 8-input butterfly network.*

network with constant-size FIFO queues to route a packet to a random destination was $O(N)$. In this paper, we show that the routing time is actually $O(\log N)$, with high probability. We also analyze the performance of several other simple algorithms for routing on butterflies with bounded queues.

1.1. Butterfly networks. An example of an N-input butterfly ($N = 8$) with depth $\log N$ ($\log N = 3$) is shown in Figure 1.1. *All logarithms in this paper are base* 2. The edges of the butterfly are directed from the node in the smaller numbered level to the node in the larger numbered level. The nodes in this directed graph represent switches, and the edges represent communication links. We use the terms node and switch interchangeably in the rest of the paper. Each node in a butterfly has a label $\langle l, c_0 \cdots c_{\log N-1}\rangle$, where the *level*, l, ranges from 0 to $\log N$, and the *row*, $c_0 \cdots c_{\log N-1}$, is a $\log N$-bit binary string. The switches on level 0 are called *inputs*, and those on level $\log N$ are called *outputs*. For $l < \log N$, node $\langle l, c_0 \cdots c_l \cdots c_{\log N-1}\rangle$ is connected to node $\langle l+1, c_0 \cdots c_l \cdots c_{\log N-1}\rangle$ by a *straight* edge, and to node $\langle l+1, c_0 \cdots \overline{c_l} \cdots c_{\log N-1}\rangle$ by a *cross* edge. (The notation $\overline{c_l}$ denotes the complement of bit c_l.) At each time step, each switch is permitted to transmit one packet along each of its outgoing edges.

In a butterfly network, packets are typically sent from the inputs on level 0 to the outputs on level $\log N$. One of the nice properties of the butterfly is that there is a unique path of length $\log N$ between any input and any output, and there is a simple rule for finding that path. In particular, when a packet with origin $\langle 0, a_0 \cdots a_{\log N-1}\rangle$ and destination $\langle \log N, d_0 \cdots d_{\log N-1}\rangle$ reaches level l, it passes through the node labeled $\langle l, d_0 \cdots d_{l-1} a_l \cdots a_{\log N-1}\rangle$. If $d_l = a_l$, then it takes the straight edge to $\langle l+1, d_0 \cdots d_l a_{l+1} \cdots a_{\log N-1}\rangle$. Otherwise, if $d_l \neq a_l$, then the packet takes the cross

edge from $\langle l, d_0 \cdots d_{l-1} a_l \cdots a_{\log N - 1} \rangle$ to $\langle l+1, d_0 \cdots d_{l-1} d_l \cdots a_{\log N - 1} \rangle$. This path selection algorithm is called *source oblivious* [6] because, at each node, the next edge taken by a packet depends only on its current location and its destination, and not on its source, or on the locations or paths taken by any of the other packets. All of the routing algorithms discussed in this paper are source oblivious.

1.2. Queuing protocols. This paper studies two broad classes of queuing protocols: greedy protocols and nonpredictive protocols. In a *greedy* queuing protocol, at each step, each switch with one or more packets in its queue selects a packet and then sends it to the next level, unless the queue that the packet wishes to enter is already full. A switch is not prohibited from sending more than one packet at each step, provided that they use different edges. Nonpredictive protocols are a subclass of greedy protocols. In a *nonpredictive* queuing protocol [13, section 3.4.4], [23], at each step, each switch selects one packet from its queue *without examining the destinations of any of the packets in its queue*, and sends the packet to the next level, unless the queue that it wishes to enter is full. If the queue is full, then the switch must select the same packet at the next step. The switch is not permitted to examine the destinations of any other packets until the selected packet has been successfully transmitted. Many easily implementable as well as conceptually simple queuing protocols like FIFO and fixed-priority scheduling are nonpredictive.

1.3. Previous work. A number of different routing problems have been studied on butterfly networks. If each input of an N-input butterfly sends a single packet, we say that the network is *lightly loaded*. A specific type of routing problem of interest is the *permutation routing problem*. In a permutation routing problem, each input of the butterfly sends exactly one packet to some output of the butterfly and each output receives exactly one packet from some input of the butterfly. If each input of an N-input butterfly sends $\log N$ packets, we say that the network is *fully loaded*.

The first important butterfly routing algorithm is due to Batcher [4], who showed that an N-input butterfly network can sort, and hence route, any permutation of N-packets in $O(\log^2 N)$ steps.

The next breakthrough came more than a decade later when Valiant [32] and Valiant and Brebner [34] observed that any permutation routing problem can be transformed into two random problems by routing the packets first to random intermediate destinations and then on to their true destinations. He also showed that an N-node hypercube (or N-input butterfly) can route N packets to random destinations (or from random origins) in $O(\log N)$ time using queues of size $O(\log N)$, with high probability. As a consequence, the hypercube or butterfly can route any permutation in $O(\log N)$ time, with high probability.

Valiant's result was improved in a succession of papers by Aleliunas [2], Upfal [31], Pippenger [20], Ranade [24], and Leighton et al. [14]. All of these papers use Valiant's idea of first routing to random intermediate destinations. Aleliunas and Upfal increased the number of packets that can be routed in $O(\log N)$ time. They developed the notion of a *delay path* and showed how to route N packets in any permutation on an N-node shuffle-exchange graph and $N \log N$ packets in any permutation on an N-input butterfly network, respectively, in $O(\log N)$ steps, using queues of size $O(\log N)$. Pippenger devised an ingenious algorithm for routing with bounded size queues. He showed how to route $N \log N$ packets in any permutation on a variant of the butterfly in $O(\log N)$ steps with queues of size $O(1)$. Finally, Ranade developed a simpler algorithm for routing with bounded queues that could also efficiently combine multiple packets with the same destination. As a consequence of Ranade's al-

gorithm, it is possible to simulate one step of an $N \log N$-processor CRCW PRAM on an N-input butterfly in $O(\log N)$ steps. Neither Pippenger's algorithm nor Ranade's algorithm are greedy.

Stamoulis and Tsitsiklis [27] consider the problem of dynamic routing in butterflies and hypercubes with unbounded queues. Unlike the static routing problems that we have seen so far, they assume that the packets with random destinations are generated at each input according to a Poisson process. They show that if the load factor on the network is less than one, then the network is stable in the steady state; the average delay is $O(\log N)$, and the average queue size is $O(1)$.

Recently, Broder, Frieze, and Upfal [7] have addressed the problem of dynamic routing in butterfly and other networks with constant-size queues. They develop a powerful method to reduce the steady state analysis of dynamic routing to the better understood problem of static routing analysis. They extend the results of section 2 to the dynamic setting, to provide a greedy algorithm that routes packets in expected $O(\log N)$ time on an N-node butterfly with constant-size buffers, assuming that packets with random destinations arrive at each input with expected interarrival time $\Omega(\log N)$. Further, they extend the results of section 4 to provide an algorithm that routes packets in expected $O(\log N)$ time on an N-node butterfly with constant-size buffers, assuming that packets with random destinations arrive at each input with expected interarrival time greater than some absolute constant.

Although the performance of greedy algorithms in butterflies with bounded queues has proven difficult to analyze, attempts have been made to approximately model [29, 17] or empirically determine [30] their performance.

Finally, there have been several papers that analyze algorithms that drop packets when there is contention. The BBN Butterfly algorithm has been studied by Kruskal and Snir [12] and Koch [11]. Koch showed that for a random problem the number of packets that succeed in locking down paths from their origins to their destinations in an N-input butterfly is $\Theta(N/\log^{\frac{1}{q}} N)$, with high probability, where q is the maximum number of packets that any wire can support.

The results presented for the BBN Butterfly algorithm also hold when packets are routed in a store-and-forward fashion, with each switch having a buffer of size q, and all packets attempting to enter a full buffer are dropped. Recently, there has been progress in extending these results to the dynamic case, where packets arrive at each input with a certain interarrival distribution. Rehrmann et al. [25] show that if one packet arrives at each input of an N-input butterfly at every time step, and each switch has a buffer of size 1 at each incoming edge, then the expected network throughput is $\Theta(N/\sqrt{\log N})$ packets per time step.

1.4. Our results. In section 2 we show that for any greedy queuing protocol, routing a random problem on a lightly loaded N-input butterfly requires $O(\log N)$ steps, with high probability, provided that the queue size is a sufficiently large fixed constant. Previously, only the trivial upper bound of $O(N)$ was known. An intriguing problem left open in this section is to bound the number of steps taken by a greedy queuing protocol when the butterfly is fully loaded.

In section 3 we show that for any deterministic nonpredictive queuing protocol, there exists a one-to-one routing problem (permutation) that requires $\Omega(N/q \log N)$ time to route, where q is the maximum queue size. Previously, no lower bound greater than $\Omega(\sqrt{N})$ was known. The $\Omega(\sqrt{N})$ bound is based on the congestion and is independent of the way the packets are scheduled. This section shows that greater delays can occur due to the way packets interact in the network.

Section 4 presents a simple, but nongreedy, algorithm for routing a random problem on a fully loaded N-input butterfly with bounded-size queues in $O(\log N)$ steps, with high probability. The algorithm is simpler than the previous algorithms of Ranade and Pippenger because it does not use ghost messages, it does not compare the ranks or destinations of packets as they pass through switches, and it cannot deadlock.

Finally, in section 5 we analyze routing algorithms that drop packets when there is contention. Examples of machines that drop packets are NEC's ATOM switch [28] and the BBN Butterfly [5]. The BBN Butterfly algorithm has been studied by Kruskal and Snir [12] and Koch [11]. Koch showed that for a random problem the number of packets that succeed in locking down paths from their origins to their destinations is $\Theta(N/\log^{\frac{1}{q}} N)$, with high probability, where q is the maximum number of packets that any wire can support. By routing the packets to randomly (but not independently) chosen intermediate destinations, we show that for *any fixed permutation* the expected number of packets that reach their destinations is $\Omega(N/\log^{\frac{1}{q}} N)$.

2. Greedy queuing protocols. In this section, we study the performance of greedy queuing protocols. In section 2.1, we analyze the average case behavior of any routing algorithm with a greedy queuing protocol. We show that if every input sends a packet to a randomly chosen output, then the time required for all of the packets to reach their destinations is $O(\log N)$, with high probability. In section 2.2, we show how any specific permutation routing problem on the butterfly can be routed in $O(\log N)$ steps using Valiant's idea of splitting a routing problem into two random routing problems.

2.1. Average case behavior. We first define a few terms. A *delay tree* is a rooted tree that is a subgraph of the butterfly. Its root is a level 0 node and the tree contains a (directed) path, which we call the *spine*, from the root to a node in level $\log N$ of the butterfly. The tree "grows out" from the spine so that there is a unique directed path in the tree from the root to each node in the tree. A *full node* is defined to be a node through which the paths of at least q packets pass, where q is the maximum size of the queue in each node. Note that in the course of the routing, a full node may never have a full queue since the packets could arrive at different times. However a nonfull node can never have a full queue. A *full delay tree* is a delay tree for which every node of the tree that is not on the spine is a full node. A *maximal full delay tree* is a full delay tree that is not properly contained in any other full delay tree. The number of *packets on a delay tree* is defined to be the sum over all nodes of the tree of the total number of packets passing through each node. Note that this number is different from the number of *distinct packets on a delay tree.* In the former, if a particular packet hits (i.e., passes through) many nodes of a tree it is counted many times in the sum. The significance of the above definitions becomes clear in Theorem 2.1 below.

THEOREM 2.1. *The maximum delay of any packet is less than or equal to the maximum number of packets on a full delay tree.*

Proof. Let the path of some packet p, from its source to destination, be denoted by P. Now consider the maximal full delay tree with the path P as its spine and the source of the packet p as its root. We will refer to this maximal full delay tree as the maximal full delay tree of packet p. We will bound the delay of p by the number of packets on its maximal full delay tree. Since the tree is maximal, every nontree node that is a neighbor of a tree node is not a full node. We will now show that at each time step t until packet p reaches its destination, some packet in its maximal full

delay tree moves. At every time step t there are three cases.

(a) The packet p moves.

(b) Some other packet queued at the same node as p moves.

(c) No packet queued at the same node as p moves.

In the first two cases, it is evident that some packet in the tree moves. Since the queuing protocol is greedy, case (c) necessarily means that the packet selected to be sent at time step t by the node that contains p could not move because the queue in the node n at the next level that it wanted to enter was full. Note that node n belongs to the maximal full delay tree since it has at least q packets passing through it. Now if some packet in node n moved at time step t we are done. If not we look at the packet selected by node n and repeat the argument again. Note that case (c) cannot apply at the leaves of a tree since it does not have any neighbors with full queues. So we must encounter either case (a) or (b) before we leave the tree. Therefore the delay of packet p is at most the number of packets on its maximal full delay tree. Thus the maximum delay of any packet is at most the maximum of the number of packets on a full delay tree. □

We will use the following property of the butterfly network in the proofs in this section.

OBSERVATION 2.2. *A packet can enter a delay tree contained in the butterfly at exactly one point, and once the packet leaves the tree it can never return to it.*

We state without proof a result due to Hoeffding [10] and a Chernoff-type bound [3] and [21, p. 56].

LEMMA 2.3 (Hoeffding). *Let X be the number of successes in r independent Bernoulli trials where the probability of success in the ith trial is p_i. Let S be the number of successes in r independent Bernoulli trials where the probability of success in each trial is $p = \frac{1}{r}\sum_{1\le i\le r} p_i$. Then $E(X) = E(S) = rp$, and for α such that $\alpha E(S) \ge E(S) + 1$,*

$$\Pr[X \ge \alpha E(X)] \le \Pr[S \ge \alpha E(S)].$$

LEMMA 2.4. *Let S be the number of successes in r independent Bernoulli trials where each trial has probability p. The $E(S) = rp$, and for $\alpha > 2e$,*

$$\Pr[S \ge \alpha E(S)] \le 2^{-\alpha E(S)}.$$

THEOREM 2.5. *Let constant q be the maximum queue size. Then the maximum delay of any packet is at most $\gamma \log N$ with probability at least $1 - \frac{1}{N}$ for sufficiently large but constant γ and q.*

Proof. We will show that if there is a packet with large delay, then there must be a delay tree with a large number of packets on it, which in turn we will show to be an unlikely event. Assume that some packet p has a delay of $\gamma \log N$ or more. Consider the maximal full delay tree of this packet. Let D denote the number of packets on the maximal full delay tree of p. By Theorem 2.1, we know that $D \ge \gamma \log N$. Also since every nonspine node of this delay tree is necessarily a full node, the maximum number of nodes of this maximal full delay tree is at most $\frac{D}{q} + \log N$. Let n be a node on any level l of the butterfly. The average number of packets passing through n is 1, because there are 2^l possible packets that can pass through n and each of these packets has a probability of 2^{-l} of passing through it. Therefore, the expected number of packets on the delay tree of p is at most $\frac{D}{q} + \log N$. The gist of the remainder of the proof is to show that the number of packets on a delay tree is clustered around its expected

value. Therefore, a delay tree is unlikely to have D packets on it for sufficiently large constants q and γ.

The number of *hits* made by a packet on a delay tree is the number of nodes of the tree through which the packet passes. Let us divide the hits on a delay tree into two types: b-hits (for big hits), which are hits made by packets that make at least c hits on the tree, and s-hits (for small hits), which are hits made by packets that make fewer than c hits on the tree, where c is some constant. It must be the case that either the total number of b-hits on some delay tree is greater than or equal to $\frac{D}{2}$ (call this event E_b) or the total number of s-hits on some delay tree is greater than or equal to $\frac{D}{2}$. The latter possibility also implies that there are at least $\frac{D}{2(c-1)}$ distinct packets hitting some delay tree (call this event E_s), since each packet making s-hits can make at most $c-1$ hits on the tree. Thus, the probability that some packet has delay d is at most $\Pr(E_b) + \Pr(E_s)$.

The intuitive reason as to why b-hits are unlikely is as follows. If you imagine packets running backward in time from destination to source, once a packet enters the tree, it can remain in the tree at the next step only if it takes the unique edge to its ancestor in the tree. So, at every step, it has approximately a probability of $\frac{1}{2}$ of making another hit. This exponentially decreasing probability for making more and more hits gives us the bound. Thus, this bound uses the tree structure in a crucial way. The bound we will prove for E_s, on the other hand, is valid for any set of $\frac{D}{q} + \log N$ nodes.

Bounding the big hits. Let us suppose that event E_b occurs; i.e., there exists a delay tree of size at most $\frac{D}{q} + \log N$ with a total of at least $\frac{D}{2}$ b-hits. To bound the probability of this event we will enumerate all the possible ways it can happen. The maximum value that D can take is $N \log N$, since each packet can contribute at most $\log N$ hits and there are a total of N packets. Therefore, the number of ways of choosing D is at most $N \log N$. The number of ways of choosing the root for the delay tree is N. A binary tree of size at most $\frac{D}{q} + \log N$ can be represented by indicating the number of children (no children, left son only, right son only, both sons) in breadth-first-search order. Thus the total number of ways of choosing the delay tree is at most $N 4^{\frac{D}{q} + \log N}$. The number of different packets causing these b-hits is at most $\frac{D}{c}$, since each packet causes at least c hits and there are a total of at most D hits on the tree. Let us assume that there is some arbitrary fixed ordering of the nodes in the tree, e.g., the breadth-first-search ordering of the tree. We will now pick a nondecreasing sequence (with respect to our ordering) of $\frac{D}{c}$ nodes in the tree, $n_1, n_2, \ldots, n_{\frac{D}{c}}$. Note that each node of the tree can occur more than once in this sequence. Node n_i is the last node on the tree through which the ith packet passed. The number of ways of choosing this sequence is at most

$$\left(\begin{array}{c} \frac{D}{q} + \log N + \frac{D}{c} \\ \frac{D}{c} \end{array} \right) = \left(\begin{array}{c} \frac{D}{q} + \log N + \frac{D}{c} \\ \frac{D}{q} + \log N \end{array} \right).$$

Let node n_i of the sequence be at level l_i of the butterfly. For every n_i, we now associate a nonnegative integer h_i denoting the number of hits made by a packet p_i before leaving node n_i. The number of ways of distributing at most D hits over $\frac{D}{c}$ elements of the sequence is at most

$$\left(\begin{array}{c} D + \frac{D}{c} \\ \frac{D}{c} \end{array} \right).$$

We can ignore any n_i with $h_i = 0$ in this. Since the packet p_i must have made exactly h_i hits before leaving the tree at n_i, the number of choices for p_i is $2^{l_i - h_i}$. Here we have used Observation 2.2. The total number of ways of choosing packets for all elements in the sequence is at most $\prod_i 2^{l_i - h_i}$. (We are overcounting a little since packets have to be distinct.) Now, we have chosen a particular tree, a sequence of nodes n_i, and the associated packets p_i. The probability that all the packets p_i pass through their corresponding nodes n_i is simply the product of the probabilities that each individual packet p_i passes through node n_i which equals $\prod_i 2^{-l_i}$. (We can multiply probabilities because each packet chooses its path independently.) Putting it all together, we have

$$\begin{aligned}
\Pr(E_b) &\le N \log N \cdot N 4^{\frac{D}{q} + \log N} \cdot \binom{\frac{D}{q} + \log N + \frac{D}{c}}{\frac{D}{q} + \log N} \\
&\quad \cdot \binom{D + \frac{D}{c}}{\frac{D}{c}} \cdot \prod_i 2^{l_i - h_i} \cdot \prod_i 2^{-l_i} \\
&\le N^5 2^{2\frac{D}{q}} \cdot \left(\frac{(\frac{D}{q} + \log N + \frac{D}{c})e}{\frac{D}{q} + \log N} \right)^{\frac{D}{q} + \log N} \cdot \left(\frac{(D + \frac{D}{c})e}{\frac{D}{c}} \right)^{\frac{D}{c}} \cdot 2^{-\sum_i h_i} \\
&\le 2^{5\frac{D}{\gamma}} \cdot 2^{2\frac{D}{q}} \cdot \left(\left(1 + \frac{q}{c}\right) e \right)^{\frac{D}{q} + \frac{D}{\gamma}} \cdot 2^{\log((c+1)e)\frac{D}{c}} \cdot 2^{-\frac{D}{2}} \qquad (2.1)
\end{aligned}$$

using the inequality $\binom{x}{y} \le x^y / y!$ to bound the combinatorial coefficients and using the fact that $D \ge \gamma \log N$ and $\sum_i h_i \ge \frac{D}{2}$. Note that the multiple of D in the exponent of the first four factors decreases with an increase in the values of c, q, and γ. So for some suitably large values for the constants c, q, and γ the expression in (2.1) is at most 2^{-kD} for some constant $k > 0$. We can use the fact that $D \ge \gamma \log N$ to bound the value of this expression (and hence $\Pr(E_b)$) to be at most

$$2^{-kD} \le 2^{-k\gamma \log N} = \frac{1}{N^{k\gamma}} \le \frac{1}{2N}$$

as long as the value of γ is chosen to be at least $2/k$.

Bounding the small hits. Let us suppose event E_s occurs; i.e., there is a tree of size at most $\frac{D}{q} + \log N$ with at least $\frac{D}{2(c-1)}$ different packets hitting the tree for some value of $D \ge \gamma \log N$. The number of ways of choosing a value for D is at most $N \log N$. The number of ways of choosing such a tree is at most $N 4^{\frac{D}{q} + \log N}$. Let X denote the total number of distinct packets hitting a tree of size at most $\frac{D}{q} + \log N$. X is a sum of N Boolean random variables, $X_i, 1 \le i \le N$. Each X_i is 1 if the packet originating at input i hits the tree and 0 otherwise. The expected number of distinct packets on the tree is at most the expected number of packets on the tree. Therefore, $E(X) \le \frac{D}{q} + \log N$. Using Lemmas 2.3 and 2.4 to derive the second inequality, we have

$$\begin{aligned}
\Pr(E_s) &\le N \log N \cdot N 4^{\frac{D}{q} + \log N} \cdot \Pr\left(X \ge \frac{D}{2(c-1)} \right) \\
&\le N \log N \cdot N 4^{\frac{D}{q} + \log N} \cdot 2^{-\frac{D}{2(c-1)}} \qquad (2.2)
\end{aligned}$$

as long as $\alpha = \frac{\frac{D}{2(c-1)}}{E(X)} > 2e$. Using the fact that $D \geq \gamma \log N$, we have

$$\alpha \geq \frac{\frac{D}{2(c-1)}}{\frac{D}{q} + \log N} \geq \frac{q\gamma}{2(c-1)(q+\gamma)}. \tag{2.3}$$

Let c_0, q_0, and γ_0 be values of c, q, and γ, respectively, for which $\Pr(E_b)$ was shown to be at most $\frac{1}{2N}$. We choose the values of c, q, and γ such that *both* $\Pr(E_b)$ and $\Pr(E_s)$ are at most $\frac{1}{2N}$ as follows. First we choose $c = c_0$. Next we choose constants q and γ such that $q = \gamma$. Let τ denote the value of q and γ. We choose τ such that $\tau \geq \max(q_0, \gamma_0)$. We make $\alpha > 2e$ by choosing τ large enough such that the right-hand side of (2.3) which equals $\tau/4(c-1)$ is greater than $2e$. Furthermore, τ is chosen large enough such that

$$4^{\frac{D}{q}} \cdot 2^{-\frac{D}{2(c-1)}} = 4^{\frac{D}{\tau}} \cdot 2^{-\frac{D}{2(c-1)}} \leq 2^{-j\frac{D}{c-1}}$$

for some constant $j > 0$. Since $D \geq \gamma \log N$,

$$2^{-j\frac{D}{c-1}} \leq 2^{-j\frac{\gamma \log N}{c-1}} = 2^{-j\frac{\tau \log N}{c-1}}.$$

Finally, the value of τ is made large enough such that

$$\Pr(E_s) \leq N \log N \cdot N 4^{\log N} \cdot 2^{-j\frac{\tau \log N}{c-1}} \leq \frac{1}{2N}.$$

Note that since $c = c_0$ and $q = \gamma = \tau \geq \max(q_0, \gamma_0)$, $\Pr(E_b)$ is at most $\frac{1}{2N}$ for the chosen values of c, q, and γ. It now follows that the probability that a packet has delay greater than $\gamma \log N$ is at most $\frac{1}{2N} + \frac{1}{2N}$, which equals $\frac{1}{N}$. □

2.2. Routing a fixed permutation. The results of section 2.1 deal with the routing delay of an average routing problem. What can we say about routing a fixed permutation? We can show that we can route any fixed permutation in $O(\log N)$ steps with high probability using Valiant's idea of routing in two phases. In Phase A, each packet is routed from its source in level 0 to a random intermediate destination in level $\log N$. For simplicity, we will assume that the butterfly network has wrap-around; i.e., each node in level $\log N$ is identified with the node in level 0 in its row. The packets are queued up at the end of Phase A, and in Phase B each packet is routed to its actual destination.

THEOREM 2.6. *Any fixed permutation can be routed such that the delay is* $O(\log N)$ *with probability* $\geq 1 - \frac{2}{N}$.

Proof. Phase A is precisely the same problem as that studied in section 2.1. In Phase B, each packet is routed from its intermediate destination to its final destination. For convenience, we will denote the level of its final destination as 0 and that of the intermediate destination as level $\log N$. This phase is different from the one we studied in section 2.1 in that the starting points are random while the destinations are fixed. But the same proofs for the delay will work with small modifications. It is perhaps best to imagine the packets running backward from level 0 (final destinations) to random nodes in level $\log N$ (intermediate destinations). In the proof for bounding the b-hits, the sequence n_i will now represent switches through which packets that hit the tree *entered* the tree (running backward in time). The number of ways of associating a packet with n_i in level l_i is 2^{l_i}. The probability that the packet makes h_i hits is now $2^{-(l_i+h_i)}$, since it must leave the tree at the unique ancestor of n_i in level $l_i - h_i + 1$. The rest of the calculation is the same as before. The proof for bounding the s-hits is identical. □

3. Difficult permutations. In this section, we prove that for any deterministic nonpredictive queuing protocol, there exists a permutation that requires $\Omega(N/q \log N)$ time to route on a butterfly network. Previously, the best lower bound for routing on a butterfly with queues of any size was $\Omega(\sqrt{N})$. The $\Omega(\sqrt{N})$ bound is proved by observing that certain permutations, such as the bit-reversal permutation, force $\Omega(\sqrt{N})$ packets to pass through a single switch [13, section 3.4.2]. (It is also not very difficult to prove that if the queue size is not bounded, then $O(\sqrt{N})$ is an upper bound on the time to route any permutation using any greedy protocol.) Because the $\Omega(\sqrt{N})$ bound is based on congestion only, it applies to any queuing protocol. The results in this section indicate that the manner in which packets are scheduled can potentially cause much greater delays. The proof involves a careful examination of the interaction of the packets as they route through the network.

To simplify the presentation in this section, we will assume that each switch has a single queue, and that at each step, its two neighbors at the previous level may each send a packet into the queue provided that, at the beginning of the step, the queue held at most q packets. We call q the *queue threshold* of the switch. Since a queue can receive 2 packets when it already has q, it may contain as many as $q+2$ packets but no more.

THEOREM 3.1. *For any deterministic nonpredictive queuing protocol, there exists a permutation π that requires $\Omega(N/q \log N)$ steps to route on a butterfly with queue threshold q.*

Proof. The proof is by induction. We will assume that there are two edges leading into each butterfly input, and we begin by computing the time, $t_d(r)$, required for a depth d butterfly to accept $r/2$ packets on each of the 2^{d+1} edges into its inputs. (For simplicity, we assume without loss of generality that r and q are even.) We will assume that at time step 1 and at each time step thereafter, 1 packet is available for transmission along each of these edges until $r/2$ packets have crossed the edge. Furthermore, we will assume that each output switch can transmit one packet at each step.

We begin by examining a 1-input butterfly, which consists of a single switch, s. Suppose that at the beginning of time step 1, the queue at switch s is empty. We would like to know how long it takes for s to receive $r/2$ packets from each of its incoming edges, where $r > q$. On time steps 1 through q, s receives one packet along each of its two incoming edges. During steps 2 through q, s transmits one packet at each step. Thus, after q steps, $2q$ packets have been received, $q-1$ have been transmitted, and the queue contains $q+1$ packets. Since the queue is full, s does not receive any packets on step $q+1$, but it does transmit one. Thereafter, s receives two packets on every other step and transmits one packet on every step, until a total of r packets have been received, which occurs on step $q + (r - 2q) = r - q$. Thus, $t_0(r) = r - q$.

Next, let us compute the time required for each input of a depth-d butterfly to receive $r/2$ packets along each of its incoming edges. In order for an input to receive r packets, it must transmit at least $r-(q+2)$ packets. Using the assumption that the queuing protocol is nonpredictive, we will choose the paths of these $r-(q+2)$ packets so as to maximize the delay. Since a switch cannot look at a packet's destination until it has been selected for transmission, we can wait until a packet has been selected and then decide if it should take a cross edge or a straight edge to the next level. The first $(r-(q+2))/2$ packets selected by each input switch $\langle 0, c_0 c_1 \cdots c_{d-1} \rangle$ will be sent to the switches labeled $\langle 1, 0 c_1 \cdots c_{d-1} \rangle$. These switches are the inputs of a depth-$(d-1)$

subbutterfly. The second $(r-(q+2))/2$ packets will be sent to the depth-$(d-1)$ subbutterfly whose inputs are labeled $\langle 1, 1c_1 \cdots c_{d-1} \rangle$.

The inputs of the first subbutterfly start accepting packets at step 2. By induction, the time required for each input to receive $r-(q+2)$ packets is $t_{d-1}(r-(q+2))$. Thus, the first subbutterfly receives packets during steps 2 through $t_{d-1}(r-(q+2))+1$. In the meantime, no packets are sent to the inputs of the second subbutterfly. The first packets arrive there on step $t_{d-1}(r-(q+2))+2$ and continue to arrive until step $2t_{d-1}(r-(q+2))+1$, at which point each input has received $r-(q+2)$ packets. Thus, $t_d(r) = 2t_{d-1}(r-(q+2))+1$. Solving this recurrence yields

$$\begin{aligned} t_d(r) &\geq 2^d t_0(r-(q+2)d) \\ &\geq 2^d(r-(q+2)(d+1)). \end{aligned}$$

The lower bound on $t_d(r)$ that we have just derived requires $r > (q+2)(d+1)$ packets to pass through each butterfly input. In a permutation routing problem, however, only one packet originates at each input. In order to use the bound, we will force r packets through each input of an N/r^2-input subbutterfly that spans levels $\log r$ through $\log N - \log r$. We call this subbutterfly the *busy subbutterfly*. It has depth $d = \log N - 2\log r$. Each input of this subbutterfly is the root of a depth-$\log r$ complete binary tree whose leaves are butterfly inputs on level 0. Call these trees the *input trees*. Each output is the root of a $\log r$-depth complete binary tree whose leaves lie on level $\log N$. Call these trees the *output trees*. All of these trees are completely disjoint. The r packets that originate at the leaves of an input tree will all be sent through the root of that tree. Each output of the busy subbutterfly receives exactly r packets. These packets are distributed among the r leaves of the corresponding output tree so that they each receive exactly one packet. Note that between levels $\log r$ and $\log N - \log r$, the only switches and edges used for routing are those in the busy subbutterfly.

All that remains is to choose appropriate values of r and d. From the construction of the busy subbutterfly, we know that $d = \log N - 2\log r$. In order for our lower bound on t_d to be greater than zero, we need $r > (q+2)(d+1)$. Choosing $r = 2(q+2)(\log N + 1)$ yields $t_d(r) \geq 2^d(q+2)(\log N+1) = (N/r^2)(q+2)(\log N+1) = N/(4(q+2)(\log N+1))$. Thus the delay is $\Omega(N/q\log N)$. □

Note that the maximum number of packets passing through any node (the congestion) for the worst-case permutation constructed in this section is only $O(q\log N)$. This implies that there are other more complex routing algorithms such as that of Ranade [24] which can route this permutation in $O(q\log N)$ steps!

4. A simple routing algorithm. In this section we present a simple, but nongreedy, algorithm for routing on butterfly networks. With high probability, the algorithm requires $O(k+\log N)$ time to route packets with random destinations, where k is the number of packets that originates at each input. The algorithm is simpler than the algorithms of Pippenger [20] and Ranade [24] because it does not use ghost messages, it does not compare the ranks or destinations of packets as they pass through a switch, and it cannot deadlock. Unlike the algorithm of Ranade, however, it does not combine packets with the same destination.

The routing algorithm begins by breaking the packets into *waves*. Each input contributes one packet to each wave. The waves of packets are separated by waves of *tokens*. Unlike the ghost messages in Ranade's algorithm, a token carries no informa-

tion other than its type, which requires $O(1)$ bits to represent.[1] Initially, there are k packets at each input and a token is placed between each pair of successive packets and after the last packet. For $0 \leq i \leq k-1$, the ith packet at each input is assigned to wave $2i$, and the ith token is assigned to wave $2i+1$. Thus, the packets belong to the even waves, and the tokens belong to the odd waves. Throughout the course of the routing, the algorithm maintains the following important invariant. For $i < j$, no packet or token in the jth wave leaves a switch before any packet or token in the ith wave. Furthermore, packets within the same wave pass through a switch in the increasing order of their row numbers of origin. (A row $c_0 \cdots c_{\log N-1}$ is viewed as a binary number where c_0 is the *lower* order bit.)

A switch labeled $\langle l, c_0 \cdots c_{\log N-1} \rangle$ has two edges into it, one from the switch labeled $\langle l-1, c_0 \cdots c_{l-2} 0 c_l \cdots c_{\log N-1} \rangle$, and the other from the switch labeled $\langle l-1, c_0 \cdots c_{l-2} 1 c_l \cdots c_{\log N-1} \rangle$. We call the first edge the 0-*edge*, and the other the 1-*edge*. At the end of each of these edges is a FIFO queue that can hold q packets or tokens. We call these queues the 0-queue and the 1-queue, respectively.

The behavior of each switch is governed by a simple set of rules. By "forward" a packet or token we mean send it to the appropriate queue in the next level. If that queue is full, the switch tries again in successive time steps until it succeeds. A switch can either be in 0-mode or in 1-mode and is initialized to be in 0-mode. In 0-mode, a switch forwards packets in the 0-queue in FIFO fashion, until a token is at the head of the 0-queue. It then changes to 1-mode. In 1-mode, a switch forwards packets in the 1-queue in FIFO fashion, until a token is at the head of the 1-queue as well. Now the switch waits until both the queues at its outgoing edges have room to receive a token and then simultaneously sends one token to each of them. After doing this, the switch changes back to 0-mode.

Note that at each step a switch is required to perform only $O(1)$ bit operations in order to determine which packet, if any, to send out. In the algorithms of Pippenger and Ranade, the switches must perform more complicated operations, such as comparing the destinations of two packets as they pass through a switch. In the succeeding sections, we show that our algorithm requires $O(k + \log N)$ steps, which is asymptotically optimal.

4.1. Delay sequences. The proof that the algorithm requires $O(k + \log N)$ time uses a delay sequence argument similar to those in [1, 14, 24]. A (w, f)-delay sequence consists of four components: a path P from an output to an input; a sequence $s_1, \ldots, s_w$ of w, not necessarily distinct switches which appear in order on the path; a sequence $h_1, \ldots, h_w$ of w distinct packets and tokens; and a nonincreasing sequence of wave numbers $r_1, \ldots, r_w$. The path P may trace any edge of the network in either direction. When the path traces an edge from some level l to level $l+1$, we call the edge a *forward* edge. The number of forward edges in the path is denoted by f. The length, L, of P is equal to the distance from an output to an input ($\log N$) plus two times the number of forward edges on P, $L = \log N + 2f$. We say that a delay sequence *occurs* if, for $1 \leq i \leq w$, packet or token h_i belongs to wave r_i and passes through switch s_i. The following lemma shows that if some packet is delayed, then a delay sequence must have occurred.

LEMMA 4.1. *If some packet arrives at its destination at step* $\log N + d$ *or later, then a* $(d + (q-2)f, f)$*-delay sequence must have occurred for some* $f \geq 0$. *Further-*

[1] Tokens are used in a similar fashion in a bit-serial algorithm for routing on the hypercube in [1]. It turns out, however, that tokens are not really needed in that algorithm. Ranade's proof of the equivalence of different queuing disciplines [23] implies that a FIFO queuing protocol will suffice.

more, no two tokens in the sequence belong to the same wave.

Proof. Before we begin the proof, we need some definitions. Let the *lag* of a switch s at time t on level l be $t-l$. Also, let the *rank* of a packet h be a 2-tuple consisting of h's wave number and the row number of the input in which it originated. Ranks are examined by first comparing wave numbers, and then, if there is a tie, comparing row numbers. A row $c_0 \ldots c_{\log N-1}$ is viewed as a binary number where c_0 is the low-order bit. Note that each packet has a distinct rank. Every token belonging to the same wave has the same rank. This rank is strictly less than all the packets in the wave above it but strictly greater than the packets in the wave below it. Note that ranks are used only as a tool for the analysis and not by the algorithm itself.

The algorithm maintains several important invariants. As mentioned before, the packets and tokens leave each switch in order of nondecreasing wave number. Furthermore, each edge transmits exactly one token from each odd wave. Finally, within an even wave, the packets that arrive at a switch via its 0-edge have smaller ranks than the packets that arrive via its 1-edge. As a consequence, each switch sends out packets and tokens in order of strictly increasing rank.

The delay sequence begins with the last packet to arrive at its destination. Suppose that some packet h_1 arrives at its destination, s_1, at step τ_1, where $\tau_1 \geq \log N + d$. Then s_1 has lag at least d at step τ_1. We will construct the delay sequence by spending lag points. We begin the sequence with h_1, s_1, and r_1, where r_1 is the wave number of h_1. Next, we follow h_1 back in time until the step at which it was last delayed.

In general, suppose that we have followed some packet or token h_i back in time from some switch s_i at time step τ_i until it was last delayed, at some switch s'_{i+1} at time step τ_{i+1}. As we follow h_i back in time, the nodes that h_i passes through are added to path P. Because h_i is delayed at s'_{i+1} at step τ_{i+1}, the lag at s'_{i+1} at step τ_{i+1} is one less than the lag of s_i at step τ_i. There are three possible reasons for the delay of h_i at switch s'_{i+1}.

First, if s_{i+1} selects another packet or token, h_{i+1}, to send instead of h_i, then h_{i+1} must have a strictly smaller rank than h_i. In this case, h_{i+1}, $s_{i+1} = s'_{i+1}$, and r_{i+1} are inserted into the sequence, where r_{i+1} is the wave number of h_{i+1}. We then follow h_{i+1} back in time until it was last delayed. We have spent one lag point and inserted one packet or token into the sequence.

Second, if s'_{i+1} doesn't send h_i because the queue at the end of one of its outgoing edges is full, then we extend the path, P, forward along that edge to the switch at its head, s''_{i+1}. The lag of switch s''_{i+1} at time τ_{i+1} is two less than the lag of s_i at step τ_i. However, the queue must contain a total of q packets and tokens, all of which have smaller rank than h_i. We insert these packets and tokens into the sequence. We then follow the packet or token at the head of the queue back in time until it was last delayed.

If neither of these cases is true, it must be the case that in switch s'_{i+1} at time τ_{i+1} either of the following occurs.

(a) h_i is a packet, it is at the head of the 1-queue, and the 0-queue is empty, or

(b) h_i is a token, it is at the head of one of the queues, and the other queue is empty.

In either case, we go back to the switch at the tail of the empty queue at the previous time step. Note that we do not lose any lag by this process. We continue to do this as long as we can find an empty queue at the current switch. Suppose we do it m times and we are at a switch s''_{i+1} at time $\tau_{i+1} - m$. Switch s''_{i+1} has packets or tokens at the heads of both of its queues but did not send anything through one of its edges

at time $\tau_{i+1} - m$. If one of the heads of its queues is a packet, we add it and switch s''_{i+1} to the delay sequence and continue to follow this packet back in time. Note that in case (a), this packet belongs to the same wave as h_i but has rank strictly less than h_i since the first edge we followed back from s'_{i+1} is a 0-edge. In case (b), the packet belongs to a wave earlier than that of token h_i and hence has a strictly smaller rank. In either case, we have added a packet of strictly smaller rank for the cost of one lag point. Now suppose that both the heads of queues are tokens. The only reason the tokens were not sent at time $\tau_{i+1} - m$ is that one of the outgoing edges of s''_{i+1} had a full queue. In this case we extend the path P forward to the switch at the head of the queue, insert all of the packets and tokens in that queue into the delay sequence, and follow the packet or token at the head of the queue back in time. Now we have added q packets and tokens for the cost of two lag points.

For each lag point spent, at least one new packet or token is inserted into the delay sequence. Furthermore, for each forward edge on the path P, an additional $q - 2$ packets and tokens are inserted. Let f be the number of forward edges on P. Since we had d lag points to spend, we must insert at least $d + (q-2)f$ packets and tokens. Since we are inserting packets or tokens in strictly decreasing order of rank, at most k of these can be tokens. The length of P is $\log N + 2f$. □

4.2. Bunched delay sequences. We have now established that if some packet is delayed, then a delay sequence occurs. To simplify the rest of the argument, we will restrict our attention to delay sequences in which the packets can be partitioned into *bunches* of size b such that all of the packets in each bunch pass through the same switch on the sequence and have the same wave number. We call such a delay sequence a *bunched* delay sequence. Note that a bunched delay sequence cannot contain tokens. The following lemma shows that if a delay sequence occurs, then a bunched subsequence also occurs.

LEMMA 4.2. *If a* $(d + (q-2)f, f)$ *delay sequence occurs, then a* (bg, f) *bunched delay sequence occurs, where*

$$g = \left\lceil \frac{d + (q-2b)f - bk - (b-1)\log N}{b} \right\rceil.$$

Proof. Suppose that a $(d + (q-2)f, f)$ delay sequence occurs. We will describe an algorithm for finding a bunched subsequence.

Starting at the first switch on the sequence, s_1, form a bunch of size b of packets with wave number $2(k-1)$. If successful, then form another bunch of packets with wave number $2(k-1)$. Otherwise, if there are fewer than b remaining packets with wave number $2(k-1)$, then there are two cases to consider. First, if there are other packets on the sequence that pass through s_1, then discard the remaining packets with wave number $2(k-1)$ and begin forming bunches out of packets with the next smaller even wave number. Since the wave number can decrease at most k times, this case can happen only k times. Each time, we may discard as many as $b-1$ packets from the original delay sequence. Second, if no other packets on the sequence pass through s_1, then move on to the second switch, s_2. This case can happen at most $\log N + 2f$ times, since the path has length $L = \log N + 2f$. As in the first case, we may discard $b-1$ packets from the original sequence.

Since the original sequence contains at least $d + (q-2)f - k$ packets, and we discard a total of at most $k(b-1) + (\log N + 2f)(b-1)$ packets, at least $d + (q - 2b)f - bk - (b-1)\log N$ packets are placed in bunches. Thus, there are at least $g = \lceil \frac{d+(q-2b)f-bk-(b-1)\log N}{b} \rceil$ bunches. □

4.3. The counting argument. We are now in a position to prove that, with high probability, every packet reaches its destination within $O(k + \log N)$ steps.

THEOREM 4.3. *For any c_2, there exist constants c_1 and $q > 0$ such that the probability that any packet is delayed for more than $d = c_1(k + \log N)$ steps is at most $1/N^{c_2}$, where k is the number of packets per input of the butterfly.*

Proof. Note that, by Lemma 4.1, if some packet suffers delay d, then a $(d + (q - 2)f, f)$-delay sequence must occur for some $f \geq 0$. Therefore, using Lemma 4.2, a (bg, f) bunched delay sequence must occur, where

$$g = \left\lceil \frac{d + (q - 2b)f - bk - (b - 1)\log N}{b} \right\rceil.$$

To prove this theorem we will enumerate all possible bunched delay sequences and show that it is unlikely that any of them occurs.

The number of different bunched delay sequences is at most

$$N \cdot 4^L \cdot \binom{L+g}{g} \cdot \binom{g+k}{g} \cdot \prod_{i=1}^{g} \binom{2^{d_i}}{b}, \tag{4.1}$$

where d_i is the level of the switch through which the ith bunch passes. The factors in this product are explained as follows. There are N choices for the output switch at which the path P in the delay sequence originates. At each of the L switches on the path, there are at most four choices for the next switch on the path. There are at most $\binom{L+g}{g}$ ways of choosing the g (not necessarily distinct switches) on the path that the g bunches pass through, and at most $\binom{g+k}{g}$ ways of choosing (not necessarily distinct) wave numbers for the g bunches. Finally, given a switch with level d_i and wave number w, there are $\binom{2^{d_i}}{b}$ ways of choosing b packets with wave number w that can pass through the switch.

Whether or not a particular delay sequence occurs depends entirely on the random destinations chosen by the packets in the delay sequence. It is important to note that every packet on the delay sequence is distinct. Therefore, the events regarding any two packets on the delay sequence are independent. Thus, the probability that all of the packets pass through their corresponding switches is $\prod_{i=1}^{g} \frac{1}{2^{bd_i}}$, since each of the b packets in the ith bunch has probability $1/2^{d_i}$ of passing through any particular switch on level d_i.

We can bound the probability that *any* delay sequence occurs by summing the probabilities of each individual delay sequence occurring, which is equivalent to multiplying (4.1) by $\prod_{i=1}^{g} \frac{1}{2^{bd_i}}$. Using the inequality $\binom{x}{y} \leq (ex/y)^y$ to bound $\binom{L+g}{g}$ and $\binom{g+k}{g}$, and using $\binom{x}{y} \leq x^y/y!$ to bound $\binom{2^{d_i}}{b}$, the product is at most

$$2^{3\log N + 4f} \cdot (e(L+g)/g)^g \cdot (e(g+k)/g)^g \cdot (1/b!)^g,$$

where $g = \lceil \frac{d+(q-2b)f-(b-1)k-(b-1)\log N}{b} \rceil$. First, we choose b such that $b! \geq 16e^2$. We can make g larger than $L = \log N + 2f$, k, and $3\log N + 4f$, by making q large compared with b (but still constant), and d large compared with $b(k + \log N)$ (but still $c_1(k + \log N)$, where c_1 is a constant).

In this case, the product is at most $(8e^2/b!)^g \leq 2^{-g}$. By making g large enough, we can make this product less than $1/N^{c_2}$ for any constant c_2. ∎

5. Algorithms that drop packets. In this section, we consider queuing protocols that resolve contention by dropping packets. Two examples of machines that use this kind of protocol are the BBN Butterfly [5] and the NEC ATOM switch [28].

The ATOM switch routes packets in a store-and-forward manner. At every time step, each switch examines the head of its input queue and forwards a packet to the appropriate output queue. If a queue receiving packets is already full, then it discards packets in excess of its maximum queue size. In the BBN Butterfly, each packet tries to lock down a path between its source and destination. We will assume that each edge of the butterfly can sustain up to q such paths. Therefore, if more than q packets want to use the same edge only q succeed, and the rest fail to lock down their paths. Packets that succeed in locking down paths are transmitted along these paths to their respective destinations. This method of routing is known as circuit-switching.

In both of these queuing protocols, a natural question to ask is how many of the packets reach their destinations. The ATOM switch has not been studied in this context before. Kruskal and Snir [12] and Koch [11] studied the average case performance of the BBN Butterfly algorithm. Koch showed that if each packet independently chooses a random destination, then the expected number of packets that get through is $\Theta(N/\log^{\frac{1}{q}} N)$. However, there are permutations that arise from natural problems in which only $O(\sqrt{N})$ packets get through. To combat this we show how to route any *fixed* permutation in either of the above-mentioned queuing protocols such that the expected number of packets that reach their destinations is $\Omega(N/\log^{\frac{1}{q}} N)$. As an aside, this section also provides an elementary proof of the fact that the expected number of packets that get through for a random routing problem on the butterfly is $\Omega(N/\log^{\frac{1}{q}} N)$. As mentioned earlier, this was first proved by Koch [11].

The idea for routing any fixed permutation is based on Valiant's idea of routing to random intermediate destinations. Consider two back-to-back butterflies, i.e., two butterflies whose level $\log N$ nodes are identified. The source of the packets is level 0 of one of the butterflies, and each packet has a destination in level 0 of the other butterfly. In the first stage, the packets route from level 0 to level $\log N$ of the first butterfly. In the second stage, the packets route from level $\log N$ to level 0 of the second butterfly. In the first stage we use a scheme for sending packets to random but not independent destinations. Ranade [22] was the first to use this scheme in order to reduce the amount of the randomness needed to send packets to intermediate destinations in a packet switching algorithm. The scheme is as follows. At time step i every level i switch receives two packets, one from each of its incoming butterfly edges. The switch selects a random outgoing edge for one of the packets and routes the other packet through the remaining outgoing edge. Therefore, in the first stage no packets are dropped. In the second stage, every packet is routed from this intermediate destination to its actual destination in level 0 of the second butterfly. In this stage, packets are dropped according to the rules of BBN Butterfly routing or that of the ATOM switch. We will assume that each packet picks a random rank from 1 to $r = \log^{\frac{1}{q}} N$. When packets must be dropped, packets with the least rank are dropped in favor of those with a higher rank. We will now show that the expected number of packets that reach their destinations is $\Omega(N/\log^{\frac{1}{q}} N)$.

Let n be a node at level l of the second butterfly. Consider any k packets whose final destinations are reachable from this node. We bound the probability that all k packets pass through this node.

LEMMA 5.1. *The probability that any k packets all pass through a node n in level l of the second butterfly is at most $\frac{1}{2^{lk}}$.*

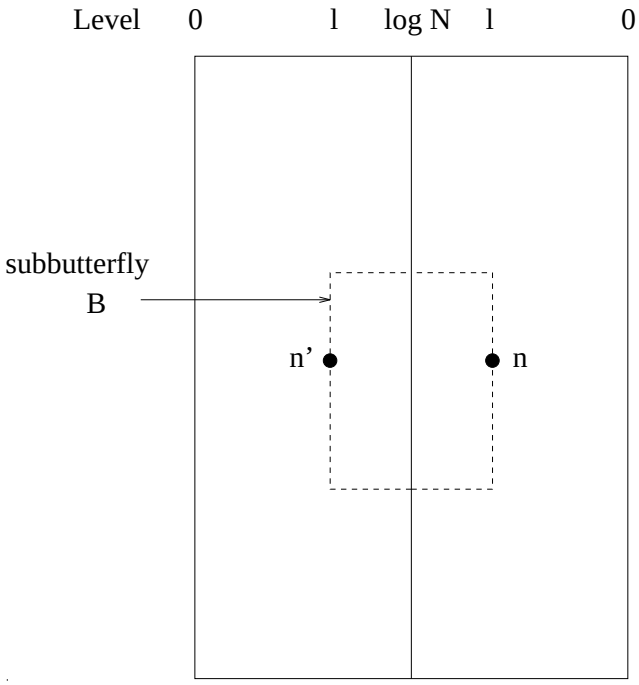

FIG. 5.1. *Subbutterfly B.*

Proof. Let the node in the first butterfly that corresponds to node n be n'. Let the subbutterfly from level l to $\log N$ of the first butterfly that contains n' be B (see Figure 5.1). Note that the k packets pass through the given node n if and only if all of these packets pass through some node of subbutterfly B. Consider the sources of the k packets in level 0 of the first butterfly and the unique shortest paths from each of the sources to subbutterfly B. If any two of them intersect before reaching the subbutterfly, these two packets cannot both hit subbutterfly B, since at the node of intersection only one packet can take the path to the subbutterfly. If no two paths intersect, then the probability of each packet hitting B is independent of the others and equals $\frac{1}{2^l}$. Thus in this case the probability of all of them hitting the subbutterfly is exactly $\frac{1}{2^{lk}}$. Therefore, given any k packets the probability of all k of them passing through the given node or equivalently hitting the subbutterfly is at most $\frac{1}{2^{lk}}$. □

THEOREM 5.2. *The expected number of packets that reach their destinations is* $\Omega(N/\log^{\frac{1}{q}} N)$.

Proof. Consider the path of a particular packet p in the second butterfly. We will now evaluate the probability that packet p reaches its destination. Note that with probability $\frac{1}{r}$ packet p will have the highest rank r. In this case, packet p can be dropped only if there is a node on its path with at least q packets going through it, all with rank r. We will now show a lower bound on the probability that there exist no such q packets. First let's bound E_q, the expected number of q-tuples of packets incident on a node at level l of the second butterfly,

$$E_q \leq \left(\begin{array}{c} 2^l \\ q \end{array} \right) \frac{1}{2^{ql}} \leq \frac{1}{q!},$$

since there are $\binom{2^l}{q}$ ways of choosing q packets that can pass through a node on level l, and by Lemma 5.1, the probability that these packets actually pass through the node is at most $1/2^{ql}$.

The expected total number of q-tuples incident on some node on the path of packet p is at most $\log N/q!$, since the path has length $\log N$. The expected number of such q-tuples with all packets having rank r is at most $\log N/(q!r^q)$ which equals $1/q!$, since $r = \log^{\frac{1}{q}} N$. Since $1/q! \leq 1$, the probability that no such q-tuple exists anywhere on the path of packet p is at least $1 - 1/q!$. (A slightly larger choice for r would make the arguments work for $q = 1$.) This implies that packet p reaches its destination with a probability of at least $(1 - 1/q!)(1/r)$, since the probability that packet p gets rank r is $1/r$. Therefore, the expected number of packets to reach their destinations is at least $(1 - 1/q!)(N/r)$ which is $\Omega(N/\log^{\frac{1}{q}} N)$. □

The proof that the expected number of packets that reach their destinations is $\Omega(N/\log^{\frac{1}{q}} N)$ also holds for a random routing problem in which each packet chooses independently a random destination. Lemma 5.1 is true because the probability that a packet passes through a node n in level l is $1/2^l$. Every packet chooses its path independently and hence the probability that all of them pass through the node exactly equals $1/2^{lk}$. The rest of the proof is the same as before. Koch [11] has observed that the expected number of packets that get through is not affected by the rule that is used to decide which messages to keep and which messages to drop, as long as the destinations of the packets are not used to make this decision. Therefore, for this problem, random ranks are necessary only as a tool for analysis and any other nonpredictive rule would exhibit the same average case behavior.

6. Open questions. The most vexing problem left open by this paper is to determine the average number of time steps required to route a random problem on a fully loaded N-input butterfly with constant-size FIFO queues. If fewer than $\Omega(\log N)$ packets may be queued at a node, then the only known upper bound on the time to route is $O(N \log N)$. This trivial upper bound is proven by showing that after $\log N$ steps, at least one packet arrives at the outputs at every time step until the routing is completed. Simulations show that the true time is closer to $O(\log N)$.

Another open question concerns the algorithm of section 4 for routing on a fully loaded butterfly with constant-size queues. We know from section 2 that a single wave of packets with random destinations can be routed using a greedy queuing protocol in $O(\log N)$ time, but when the waves are pipelined, as in section 4, the analysis requires us to use a simple, but not greedy, protocol to route each wave. It would be interesting to show that even if each individual wave was routed with a greedy protocol, the total time to route $\log N$ waves was $O(\log N)$.

Acknowledgments. The authors would like to thank Danny Krizanc, Christos Kaklamanis, Tom Leighton, Satish Rao, Nick Pippenger, Alan Frieze, and Thanasis Tsantilas for many helpful discussions.

FAST AND SIMPLE ALGORITHMS FOR RECOGNIZING CHORDAL COMPARABILITY GRAPHS AND INTERVAL GRAPHS*

WEN-LIAN HSU† AND TZE-HENG MA†

Abstract. In this paper, we present a linear-time algorithm for substitution decomposition on chordal graphs. Based on this result, we develop a linear-time algorithm for transitive orientation on chordal comparability graphs, which reduces the complexity of chordal comparability recognition from $O(n^2)$ to $O(n+m)$. We also devise a simple linear-time algorithm for interval graph recognition where no complicated data structure is involved.

Key words. chordal graph, triangulated graph, interval graph, analysis of algorithms, graph theory, substitution decomposition, modular decomposition, cycle-free poset, transitive orientation, graph partitioning, cardinality lexicographic ordering, graph recognition

1. Notation.

All graphs in this paper are simple and have no self-loops. We also assume all graphs are connected. (For the purposes of this paper, the components of a disconnected graph can always be processed independently.) Let $G = (V, E)$ be a graph. An undirected edge between vertices u and v is denoted by uv. A directed edge from u to v is written as (u, v). For undirected graphs, the neighborhood of a vertex v, $N(v)$, is $\{w \in V : vw \in E\}$. For a set S of vertices, $N(S)=\cup_{v\in S}N(v) \setminus S$. The *degree* of a vertex v, *d(v)*, is the cardinality of $N(v)$. The *closed neighborhood* of vertex v, $N[v]$, is $\{v\} \cup N(v)$. Let $m = |E|$, $n = |V|$.

A *chordal graph* is a graph with no induced subgraph isomorphic to a cycle C_k, $k \geq 4$. Chordal graphs have been studied extensively. They are also called *triangulated*, *rigid-circuit*, and *perfect elimination* graphs. There are several subclasses of chordal graphs which have gained a lot of attention, e.g., interval graphs, split graphs, strongly chordal graphs, and chordal comparability graphs. The latter are the comparability graphs of *cycle-free* partial orders.

A *module* in an undirected graph $G = (V, E)$ is a set of vertices $S \subseteq V$ such that for every vertex $v \in V \setminus S$, v is adjacent to all vertices in S or no vertex in S. A module is *nontrivial* if $1 < |S| < |V|$. A *substitution decomposition* of a graph is the process of substituting a nontrivial module in the graph with a marker vertex and doing the same recursively for the module and the substituted graph. It is also called a *modular decomposition*. The process of a substitution decomposition on a graph leads to a construction of a *decomposition tree*, where each subtree represents a nontrivial module marked by its root. An example of a substitution decomposition is shown in Fig. 1.1.

For general graphs, substitution decomposition takes $O(\min(n^2, m\alpha(m, n)))$ time [15], [21]. In this paper, we call a graph *prime* if it does not contain a nontrivial module.

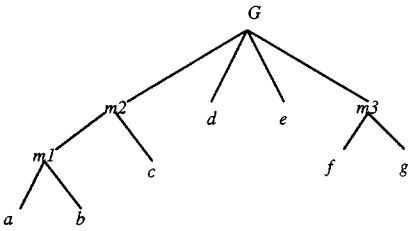
(a) A graph G.



(b) A substitution decompsition tree for G.
($m1$, $m2$, $m3$ are marker vertices.)

FIG. 1.1.

A directed graph $G = (V, E)$ is *transitive* if for all $u, v, w \in V$, $(u, v), (v, w) \in E \Rightarrow (u, w) \in E$. For a transitive graph G, since G has no self-loops, G must be acyclic. An undirected graph is a *comparability graph* if we can give each edge a direction such that the resultant directed graph is transitive. This process is called a *transitive orientation*. The complement of a comparability graph is called a *co-comparability graph*.

A *clique* is a set completely connected vertices. A clique is *maximal* if it is not an induced subgraph of any larger clique.

2. Introduction. A linear-time algorithm for the substitution decomposition on chordal graphs is given in this paper, which results in linear-time recognition algorithms for chordal comparability graphs and interval graphs. In the next section, we present an $O(n + m)$ algorithm for substitution decomposition on chordal graphs. Our algorithm uses a special ordering to force vertices in the same module to occur consecutively in this ordering. This algorithm decomposes chordal graphs into prime components. A prime graph has the following properties: (i) if it is a comparability graph, there is a unique transitive orientation [19] (up to the reversal of the directions of all edges); (ii) if it is an interval graph, there is a unique interval representation for the graph [13] (by which we mean there is a unique linear maximal clique arrangement up to the reversal of the interval model).

A *chordal comparability graph* is a graph which is both a chordal graph and a comparability graph. The fastest algorithm [20] for recognizing a comparability graph involves two stages. First, the input graph is transitively oriented, which can be done in $O(n^2)$ time. Then we test whether this directed graph is transitive. The fastest algorithm for the latter problem takes time proportional to that of multiplying two $n \times n$ Boolean matrices, which is currently $O(n^{2.376})$ [3]. Recently, an $O(n + m)$ algorithm has been developed to test whether a directed chordal graph is transitive

[16]. This brings the complexity of recognizing chordal comparability graphs down to $O(n^2)$. The new bottleneck is the transitive orientation of chordal graphs. In section 4, we present an algorithm which transitively orients a prime chordal comparability graph in $O(n + m)$ time. Combined with previous results, this yields an $O(n + m)$ algorithm for chordal comparability graph recognition.

A graph $G = (V, E)$ is called an *interval graph* if it is the intersection graph of a set F of closed intervals on the real line [14]. In other words, there is a one-to-one mapping between the vertices in G and the intervals in F such that two vertices are adjacent iff their corresponding intervals overlap. Interval graphs are exactly the chordal co-comparability graphs [10]. This class of graphs has a wide range of applications (cf. [11]).

Booth and Lueker [1] devised the first linear-time algorithm to recognize interval graphs using a complicated data structure called a PQ-tree. Korte and Möhring [11] simplified the operations on a PQ-tree by carrying out an incremental algorithm based on a lexicographic ordering. In section 5, we present a linear-time algorithm for recognizing prime interval graphs without using a PQ-tree. Combined with the decomposition algorithm, this yields a linear-time algorithm for interval graph recognition. We consider our algorithm to be much simpler than previous ones since there is no complicated data structure involved and the approach is intuitively appealing.

3. Substitution decomposition on chordal graphs. A vertex is *simplicial* if its neighbors form a clique. A necessary and sufficient condition for a graph to be chordal is that it admits a *perfect elimination scheme*, which is a linear ordering of the vertices such that, for each vertex v, the neighbors of v that are ordered after v form a clique. A perfect elimination scheme of a chordal graph can be obtained by taking the reverse of a *lexicographic ordering*, which can be carried out in linear time [18].

A lexicographic ordering can be considered a special kind of breadth-first ordering. Imagine there is a label of n digits, initially filled with zeros, associated with each vertex. After the ith vertex in the ordering is chosen, put a "1" into the ith digit of the labels of the neighbors of the vertex. The $(i + 1)$th vertex is then chosen among the unchosen vertices with the greatest label (with the first digit being the most significant digit). This ordering guarantees that if x is ordered before y and there is a vertex ordered before x which is a neighbor of one but not both of x, y, the first vertex added to the ordering with such property must be a neighbor of x. The linear-time algorithm is built upon a partitioning procedure. One implementation of a lexicographic ordering is shown in Fig. 3.1.

The output ordering π is the reverse of a *perfect elimination scheme* iff the input graph is chordal [18]. Perfect elimination schemes play a central role in most algorithms concerning chordal graphs.

A *cardinality lexicographic ordering* is just a lexicographic ordering with the vertices sorted by their degrees in descending order prior to the partitioning. This extra step ensures that when more than one vertex is eligible to be included to the ordering, the tie is broken by choosing a vertex with maximum degree. Since we can count the degrees and bucket sort the vertices of a graph in linear time, cardinality lexicographic ordering can also be done in linear time.

LEMMA 3.1. *Let S be a module in a chordal graph $G = (V, E)$. Either S is a clique or $N(S)$ is a clique.*

Proof. Suppose neither S nor $N(S)$ is a clique. There are $w, x \in S$, $y, z \in N(S)$, $wx, yz \notin E$. Since S is a module, both w and x are adjacent to y and z. Therefore, w, x, y, z form a C_4, which contradicts the assumption that G is chordal. □

```
procedure Lexicographic(G);
    create a list L of sets with V as the only set in L;
    /* each set in L is kept as a doubly linked list */
    for i := 1 to n do
        begin
            v := the first element of the first set in L;
            remove v;
            π(i) := v;
            split and replace each L_j ∈ L into N(v) ∩L_j and L_j \ N(v);
                /* put N(v) ∩L_j in front of L_j \ N(v) */
            discard empty sets;
        end;
end Lexicographic;
```

FIG. 3.1.

If module S is a clique, every vertex in S has the same closed neighborhood. Such a module is called a type I module. All type I modules can be located in $O(n+m)$ time by partitioning the vertices using the closed neighborhoods of all vertices. By Lemma 3.1, if there is a set with more than one vertex at the end of the partitioning process, it is a type I module.

LEMMA 3.2. *If $N[u] \subset N[v]$, then $\pi^{-1}(u) > \pi^{-1}(v)$ in every cardinality lexicographic ordering.*

Proof. Initially, v is ordered before u since v has greater degree than u. Since $N[u] \subset N[v]$, no partitioning can pull u in front of v. Therefore, v will be included in an ordering before u. □

We call a module type II if it is connected but not type I. After all type I modules are removed, a cardinality lexicographic ordering will put the vertices in a type II module consecutively and the neighborhood of the module will be ordered before the module.

LEMMA 3.3. *Let S be a connected module in a chordal graph G with no type* I *module. If π is a cardinality lexicographic ordering on G, then*

(i) $\pi^{-1}(v) < \pi^{-1}(u)$ $\forall v \in N(S)$, $u \in S$, *and*

(ii) *all vertices in S are ordered consecutively in π.*

Proof. (i) Since S is not type I, $N(S)$ is a clique. If $v \in N(S)$ and $u \in S$, then $N[v] \supseteq S \cup N(S) \supseteq N[u]$. $N[v] \neq N[u]$, otherwise u, v form a type I module. By Lemma 3.2, $\pi^{-1}(v) < \pi^{-1}(u)$.

(ii) Suppose there exists $\pi^{-1}(x) < \pi^{-1}(y) < \pi^{-1}(z), y \notin S, x, z \in S$, and $\pi^{-1}(x)$, $\pi^{-1}(y)$ are smallest possible. Since every vertex in $N(S)$ is ordered before x, and x must be the first element of S in π, when x is selected, it has a lexicographic value caused by $N(S)$. At the same moment, y, as well as all vertices in S, are in the first set in L. While we are adding vertices in S into the ordering, y is never placed into a set in front of a set containing a vertex in S since (by part (i)) $y \notin N(S)$. Since S is connected, we have a pair of adjacent vertices $x', z' \in S$, $\pi^{-1}(x') < \pi^{-1}(y) < \pi^{-1}(z')$. However, when x' is selected, z' will be placed into a set before y. Therefore, $\pi^{-1}(z') < \pi^{-1}(y)$, a contradiction. □

After getting the cardinality lexicographic ordering π, we scan the ordering from the last position. By Lemma 3.3, if there is a type II module, the vertices in the module must be in consecutive positions with all neighbors ordered before the module.

The algorithm to discover all type II modules in π tries to find the existence of such configurations. We use a "stack of stacks" to store scanned vertices. Each stack can be viewed as a candidate for a module. There are two conditions we have to enforce. First, no vertex in a stack has a neighbor in another previously created stack, since by Lemma 3.3, all neighbors of a type II module will be ordered before the module. Second, the neighborhoods of vertices in the stack should agree outside the stack. Each time a new vertex v is scanned, we try to start a new stack. If there is an edge extended from the top stack down to a lower stack, all boundaries between these two stacks must be broken. With each stack, we store the size of the stack, the common neighborhood of vertices in the stack, and the minimum $\pi^{-1}(w)$, where w is the neighbor of some but not all vertices in the stack. For a stack to be eligible to be a module, w must be included in the stack. After v is processed, if the size of the top stack is greater than 1 and the neighborhoods of vertices in the top stack agree on all the unscanned vertices, we conclude this stack forms a module.

Each time a module is reported, a minimal module is found. We then replace the top stack by a marker vertex, whose neighborhood is the CommonNeighbors of the stack. Afterwards, this marker vertex is treated the same as all other vertices. Hence, all modules will be reported in a recursive fashion. A pseudocode implementation of the algorithm is shown in Fig. 3.2. An example for the algorithm is shown in Fig. 3.3.

LEMMA 3.4. *ChordalSubstDecomp correctly finds all type* II *modules in a chordal graph in* $O(n+m)$ *time.*

Proof. Correctness: Suppose there is a type II module. By Lemma 3.3, all its vertices are in consecutive position in π; let v be the one with the greatest $\pi^{-1}(v)$ and u be the one with the smallest $\pi^{-1}(u)$ of the module. Since no vertex in this module has a neighbor after v in the ordering, after u is merged into the top stack v will still be the bottom vertex. After u is merged into this top stack, the MinDisagree of this stack is greater than or equal to $\pi^{-1}(u)$ since their neighborhoods agree on all vertices before u in π. This stack will be reported as a module.

Conversely, whenever a stack S is declared to be a module, no vertex is S has a neighbor beyond the bottom of S; otherwise, the stack would have been merged with that vertex. Moreover, since we check that the MinDisagree value is greater than or equal to the top of the stack, all vertices yet to be processed must agree on all elements of the stack. Hence the stack is in fact a module.

Time complexity: ChordalSubstDecomp steps through π and spends at constant on each vertex if we ignore the time for subroutine calls. (Since MergeTopTwoStacks can be called at most $O(n)$ times, the total cost of entering the while-loop is bounded by $O(n)$.) Each call of CreateStack(v) costs $O(|N(v)|)$ units of time. Overall, CreateStack takes $O(n+m)$ time. We assume the neighborhoods of each vertex are sorted by their indices in π (also the CommonNeighbors). The cost of MergeTopTwoStacks is proportional to the sizes of the CommonNeighbors of the top two stacks. Since the size of the CommonNeighbors of a stack is never larger than the degree of any member in the stack, we can charge this cost to the neighborhoods of the bottom vertex in the top stack and the top vertex in the second top stack. After a merge, the bottom of the top stack will never be a bottom and the top of the second top stack will never be a top. Therefore, the neighborhood of each vertex will never be charged more than twice. The total cost for MergeTopTwoStacks is then $O(n+m)$. Since all the costs are bounded by $O(n+m)$, the complexity of this algorithm is $O(n+m)$. □

```
ChordalSubstDecomp(G, π);
    i := 0; /* the number of stacks; an index */
    for j := n to 2 do
        begin
            v := π(j);
            CreateStack(v);
            while v has a neighbor in a lower stack do
                MergeTopTwoStacks;
            if the size of STACK(i) > 1 and STACK(i).MinDisagree ≥ j then
                report that vertices in STACK(i) form a module
        end;
end ChordalSubstDecomp;

CreateStack(v);
    i := i + 1;
    STACK(i).MinDisagree := n + 1;
        /* the value n + 1 indicates there is no disagreed neighbor */
    STACK(i).CommonNeighbors := N(v);
end CreateStack;

MergeTopTwoStacks;
    S := STACK(i).CommonNeighbors ∩ STACK(i − 1).CommonNeighbors;
    STACK(i − 1).MinDisagree := min( STACK(i).MinDisagree,
        STACK(i − 1).MinDisagree,
        (π^{-1}(v), v ∈ STACK(i).CommonNeighbors ∪
            STACK(i − 1).CommonNeighbors, v ∉ S) );
    STACK(i − 1).CommonNeighbors := S;
    i := i − 1
end MergeTopTwoStacks;
```

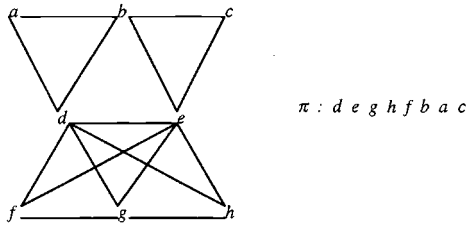
FIG. 3.2.

After we replace every type I and II module by a marker vertex, all remaining modules must be independent sets with the same neighborhoods. These modules, call them type III modules, can be found in linear time by partitioning the vertex set using their neighborhoods (as we did for finding type I modules). In conclusion, we have the following theorem.

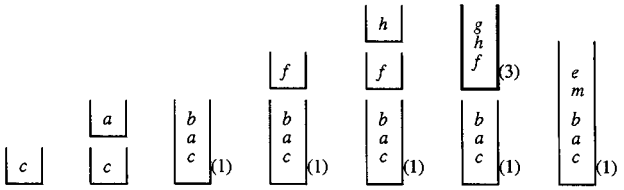
THEOREM 3.5. *The substitution decomposition on a chordal graph can be carried out in $O(n + m)$ time.*

Proof. We find type I, II, and III modules in stages. Each stage takes $O(n + m)$ time. We have to show only that at each stage, if a module of another type is generated, it will also be found.

During stage III, if a type I or II module is generated after we replace a type III module by a marker, then we must have had a connected module before the type III module is replaced by a marker. This module would have been detected in previous stages. After stage II, if a type I module S is generated, there must be some vertices in S which are markers of type II modules, otherwise S would have been detected in stage I. Suppose $v \in S$ is a marker of the last of these type II module. The module



(a) Input graph G and a cardinality lexicographic ordering.



(b) The changes of the stack configurations when π is being scanned backward. The number in the parenthesis for each nontrivial stack is its MinDisagree. Note that the stack for g,h,f is a module and is replaced by a marker vertex m.

FIG. 3.3. *An example for ChordalSubstDecomp.*

replaced by v together with $S \setminus \{v\}$ form a type II module. Therefore, by Lemma 3.4, S should be reported as a module at stage II. □

The decomposition tree can be easily constructed along with the decomposition process. Whenever a module S is reported, we replace S by a marker v with the same neighborhood as that of S. For the decomposition tree, create a tree rooted at v whose children are those vertices in S.

4. Transitive orientation on chordal graphs. In this section, we present a linear-time algorithm to transitively orient a prime chordal graph. Since a prime comparability graph admits a unique transitive orientation [19], the uniqueness provides us extra power to improve the efficiency. Together with the linear-time algorithms for substitution decomposition and transitive verification [16] on chordal graphs, we can thus recognize chordal comparability graphs in linear time.

We call $P = (X, R)$ a *partially ordered set (poset)* if X is a set and R is an irreflexive transitive binary relation on X. We say x *dominates* y if $(x, y) \in R$. If (u, v) or $(v, u) \in R$, we say that u, v are comparable. A poset $P = (X, R)$ can be viewed as a transitive graph $G = (V, E)$ by taking X as the vertex set V, R as the edge set E. Chordal comparability graphs, when transitively oriented, become a class of poset called *cycle-free* posets. For more about characteristics on cycle-free posets, see [5], [16].

A poset can be expressed by its Hasse diagram, which is an undirected graph with a minimum number of edges where there is an upward path from a to b iff a dominates b. A *chain* of a poset is a path on its diagram whose vertices are pairwise comparable. For brevity, all chains mentioned hereafter are assumed maximal unless

otherwise stated. The chains of a poset correspond to the maximal cliques of its comparability graph. Therefore, in a diagram, the vertices which appear in exactly one chain are simplicial in the poset's comparability graph.

To better understand the algorithm, the readers should keep in mind an imaginary diagram—call it the *target* diagram—which represents the poset resulting from the unique orientation of the input graph. Unlike the traditional transitive orientation algorithms, our algorithm initially does not actually orient the edges of the input graph. Instead, we explore the relative positions of vertices in the target diagram. In the end, each edge is then oriented according to the relative positions of its two endpoints.

We call a vertex w in a diagram *high* (resp., *low*) if it is dominated by (resp., dominates) a pair of incomparable vertices x, y. In a chordal comparability graph, a simplicial vertex is neither high nor low and a nonsimplicial vertex must be either high or low but not both, since if w is made high by u and v, and low by x and y, then $\{u, v, x, y\}$ induces a cycle of length 4. Thus, it can be observed that on a chain in the diagram of a cycle-free poset, the high (resp., low) vertices are above (resp., below) all simplicial and all low (resp., high) vertices. We say vertex x is higher (resp., lower) than y when there exists a chain containing both x and y where x is above (resp., below) y.

One of the most widely used characterizations of chordal graphs is that the maximal cliques of a chordal graph can be connected to form a tree T such that for each vertex v, the subgraph induced on T by the maximal cliques containing v is connected [2], [8]. (Call it the *connectivity property*.) Our algorithm applies a partitioning technique on the clique tree structure for the input chordal graph. At the end, all nonsimplicial vertices are marked either high or low and a topological sort for the target diagram is generated to provide the basis for a transitive orientation.

In our following discussion, we assume that all graphs under investigation are prime. Therefore, for any two vertices x and y, $N[x] \neq N[y]$ and $N(x) \neq N(y)$. The basic idea of our algorithm is to take a confirmed high (or low) vertex x in a certain chain and try to force the common vertices in a neighboring chain (i.e., another chain which has nonempty intersection with this one) to be low (or high). Formally, we claim the following.

LEMMA 4.1. *Let C_i and C_j be two chains with intersection S. If x is highest (resp., lowest) in C_i, $x \notin S$, then every vertex in S must be low (resp., high).*

Proof. Suppose v is the highest vertex in S. Since $x \notin C_j$, there exists $y \in C_j$, x, y are incomparable, y higher than v. Therefore, v is low and so is every vertex in S. □

To take advantage of the property of Lemma 4.1, we need to carry out our partitioning by the order where "extreme" vertices are considered first. This requirement can be easily met by the following observation.

LEMMA 4.2. *For two adjacent high (resp., low) vertices x, y, $N[x] \supset N[y]$ iff x is higher (resp., lower) than y.*

Proof. ($\Rightarrow$) Suppose $N[x] \supset N[y]$ but x is lower than y. (Note that since the graph is prime, $N[x] \neq N[y]$.) There must be a vertex z which is adjacent to x but not y. z must be higher than x since otherwise transitivity and the fact that y is higher than x would imply that y is higher than z, contradicting the fact that y and z are incomparable. y, z together with the two vertices u, v which make x high form a C_4, a contradiction.

```
procedure CliqueTree(G, π)
    create a clique C_1=π(1);
    for i := 2 to n do /* assuming the graph is connected */
        begin
            v := π(i);
            find u ∈ N(v) with maximum π^{-1} and π^{-1}(u) < i;
                /* since G is connected, u must exist. */
            let C_u be the clique generated or expanded when u is processed;
            if v and C_u form a clique, then expand C_u by adding v to it;
            else create a new clique C_j containing v and its neighbors with
                less π^{-1}, and link C_j to C_u;
        end
end CliqueTree;
```

FIG. 4.1.

($\Leftarrow$) If x is higher than y, but there exists a $z \in N[y]$ which is incomparable to x, z must be higher than y. Again, this implies the existence of a C_4. □

For an input graph G, a clique tree representation can be constructed by the algorithm CliqueTree (see Fig. 4.1). We assume that the input graph is connected. The algorithm goes through a lexicographic ordering starting from the first picked vertex. Each time a new vertex v (it must be simplicial in the subgraph induced by the previously processed vertices) is processed, we either add it to an existing clique or create a new clique for v and link the new clique to an existing one.

THEOREM 4.3. *CliqueTree creates a clique tree representation (i.e., links all maximal clique to form a tree T such that for each vertex v, the maximal cliques containing v induce a connected subtree) in $O(m+n)$ time.*

Proof. If we keep the record of the size of each clique, checking if v and C_u form a clique can be done in $|N(v)|$ time. Since each step can be done in $|N(v)|$ time as v is processed, CliqueTree can be done in $O(m+n)$ time.

For correctness, the following three conditions must be satisfied.

(i) All maximal cliques will be generated.

This can be proved by induction. The hypothesis is that the vertices $\pi(i)\pi(i-1)...\pi(1)$ processed by CliqueTree will generate all maximal cliques among them. This is trivially true when $i = 1$. When $\pi(i+1)$ is then processed, since it is simplicial, it can be in only one maximal clique. This clique is either created or expanded from an old one.

(ii) These maximal cliques are connected as a tree.

Since each new clique (except the first one) will link to exactly one existing clique, a tree structure of all existing maximal cliques is always kept.

(iii) The tree constructed has the connectivity property.

Again, we use induction. Suppose the tree constructed on $\pi(i)\pi(i-1)...\pi(1)$ is a legitimate clique tree. If $\pi(i+1)$ is added to an existing clique, there is no problem. Suppose a new clique C_p is created by $p = \pi(i+1)$, and C_p is linked to C_q which contains a neighbor q with maximum π^{-1} (which is smaller than $i+1$) and C_q is created or expanded when q is processed. Note that all the neighbors of q with smaller π^{-1} will appear in C_q. If there exists a vertex r which is in C_p and C_r but not in C_q, since $\pi^{-1}(r) < \pi^{-1}(q)$, and q and r must be adjacent (as they are both neighbors of the simplicial vertex p), r must in C_q. Therefore, the connectivity on the clique containing any vertex is kept after p is processed. □

```
procedure Orientation(G, T)
    v := a vertex of largest degree in G;
    Q := a queue containing only v;
    mark(v) := 1;
    /* a vertex u is high if it is marked 1, low if marked −1
        initially all vertices are marked 0 */
    while Q is not empty do
        begin
            remove the first vertex v from Q;
            for all tree edges e between an element of T_v and T \ T_v do
            begin
                    L := an empty list;
                    for all vertices w in e do
                        if mark(w) = 0 then
                            begin
                                mark(w) := -mark(v);
                                add w to L;
                            end;
                    sort L into order of decreasing degree;
                    append the elements of L, in order, to Q;
                    remove e from T;
            end;
        end;
end Orientation;
```

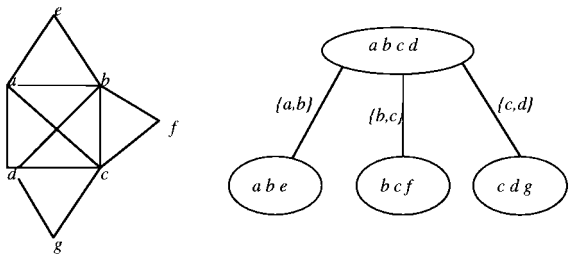
FIG. 4.2.

An example of the construction is included in Fig. 5.3. We also record the intersection of two adjacent maximal cliques on the edge connecting these maximal cliques. All these can be obtained in linear time. With this information, we are ready to perform a transitive orientation on a chordal comparability graph. The input is a chordal graph G with one of its clique tree T. Let T_v be the subtree induced by all maximal cliques containing v on T. We also assume each edge of T points to a set of vertices which are in both maximal cliques connected by that edge.

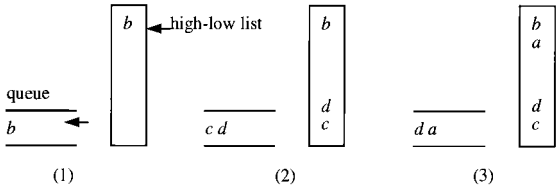
To avoid wasting time looking into an empty edge, we remove an edge on T when everything recorded in that edge is processed. This will not affect the correctness of the algorithm since our subsequent traversal is not going to pass beyond this edge anyway.

An ordering to be imposed on the vertices is constructed during our algorithm by filling in an array of length n from both ends. Whenever a vertex enters the queue, if it is marked high, it is inserted into the highest-indexed empty position in the array. Otherwise, it is inserted into the lowest-indexed empty position. Once procedure Orientation (see Fig. 4.2) has completed, we insert the remaining vertices, which are simplicial, arbitrarily into the remaining empty positions in the array. We can then orient an edge from the endpoint with a lower position to the endpoint with a higher position on the list. If the input graph is transitive, this orientation yields a partial order whose diagram is exactly characterized by the high-low relations generated by our algorithm. An example is shown in Fig. 4.3.

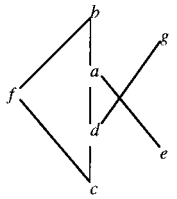
We are now ready to state the main theorem of this section.



(a) A chordal graph G and its clique tree representation. The intersections of adjacent cliques are shown in braces.



(b) The contents in the queue and the high-low list after: (1) b is selected as the initial extreme vertex and marked high; (2) b is processed (b is deleted from the braces $\{a,b\}$ and $\{b,c\}$); (3) c is processed.



(c) The target diagram constructed from the high-low list.

FIG. 4.3. *An example for the transitive orientation of a chordal graph.*

THEOREM 4.4. *A prime chordal graph, $G = (V, E)$, can be transitively oriented in $O(n + m)$ time.*

Proof. Throughout Orientation, we claim that our high-low assignments admit a feasible transitive orientation if the input graph is comparable; and the vertex x at the front of the queue must be maximal (i.e., no other vertex is higher (resp., lower) than x if x is high (resp., low)) among all unprocessed vertices. By Lemma 4.2, we know these conditions hold when we enter the while-loop. When a high vertex x is moved into the queue, all vertices higher than x are either already in the queue or they are entering the queue at the same time since, by Lemma 4.2, they exist on the same edge of the clique tree when x is detected. Since each vertex being processed is maximal among the unmarked vertices, by Lemma 4.1 and the sorting before putting vertices into the queue, we know these two conditions still hold after each operation.

The main point we need to prove is that if G is a comparability graph, every nonsimplicial vertex gets a high-low assignment when the algorithm ends. Suppose this is not true. Let x be a vertex which is high in the unique orientation after we fix the first vertex, but which is not marked high by the algorithm. Let S be the connected component containing x in the graph induced by $V \setminus M$, where M is the set of vertices marked by the algorithm. We claim that S contains more than one vertex.

Assume for a contradiction that S contains only one vertex. Then of the two vertices y, z which make x high, one (say, y) must be marked before z (y and z cannot be both simplicial, otherwise a module containing y and z can be found). There is a maximal clique containing x, y and another containing x, z, and they are connected by a path in the clique tree. When y is being processed, this path is traversed. There must be a time when y is not shared by two adjacent maximal cliques while x is. Therefore, x would have been marked opposite to y at that moment. This contradiction shows that S has at least two vertices. We claim S is a module. Suppose $u \in M$, which is not simplicial, is adjacent to v but not w, $v, w \in S$. (u must exist; otherwise $V \setminus M$ is a module.) We can find $v', w' \in S$ such that u is adjacent to v' but not w' and v', w' are adjacent. Again, there is a path in the clique tree connecting a maximal clique containing u, v' and another containing v', w'. Similar to what we have observed on x, y, z earlier, this implies that v' should have been marked opposite to u when u is used for partitioning. This contradicts $v' \in S$. Since G is prime, S cannot exist and every nonsimplicial vertex must be marked by the algorithm.

The $O(n + m)$ complexity comes from an amortized analysis [22]. The clique tree and the intersection of all pairs of adjacent maximal cliques can be obtained in linear time. When we traverse the clique tree, whenever an edge is passed, every vertex recorded in that edge will be processed (either ignored or moved to a list) in constant time and the edge of the clique tree is then deleted. Therefore, the cost of the traversal can be charged to the number of vertices stored in the edges, which is $O(n + m)$. When a set of vertices is put into the queue, we charge the cost of sorting to the edges in the clique induced by this set of vertices. Since there are quadratically many edges in a clique, we have plenty of time for sorting. After all nonsimplicial vertices are marked, the orientation can be performed in constant time per edge. The overall complexity is thus $O(n + m)$. □

COROLLARY 4.5. *Chordal comparability graphs can be transitively oriented in $O(n + m)$ time.*

Proof. We can incorporate the orientation algorithm with the substitution decomposition tree for a chordal graph. It is well known that the orientation within a module is independent to the orientation outside that module [9]. Formally, a graph is comparability iff each of its modules (including the prime graph represented at the root of a decomposition tree) can be transitively oriented. Since each module of a chordal graph is also chordal, our linear-time algorithm for prime chordal graph can be applied to each module when it is found. The overall time complexity is still linear since each edge is oriented once. □

Note that during the execution of our algorithm, we never check if an illegal orientation occurs. We only make sure that if the input graph is comparability, it will be transitively oriented correctly. With the linear-time algorithm for transitive verification for chordal graphs [16], we have the following result.

COROLLARY 4.6. *Chordal comparability graphs can be recognized in $O(m + n)$ time.*

5. Interval graph recognition. Interval graphs have been a very useful model for many applications. Interested readers are referred to [6], [9]. The fastest algorithm to recognize interval graphs relies on the following property.

THEOREM 5.1 (See [7]). *A graph G is an interval graph iff its maximal cliques can be linearly ordered such that, for each vertex v, the maximal cliques containing v occur consecutively.*

This linear ordering of the maximal cliques actually admits a clique tree which

is a path. Unfortunately, although we can generate a clique tree for a chordal graph in linear time, the clique tree constructed for an interval graph by the algorithm is not necessarily a path. Booth and Lueker [1] created a data structure called PQ-tree to capture the consecutive property of a set of intervals. Based on this data structure, a linear-time algorithm is devised to recognize interval graphs. However, their algorithm is quite involved. Korte and Möhring [11] devised a simpler algorithm to recognize interval graphs which also runs in linear time. They observed that if the input vertices follow a lexicographic ordering, the operations on the PQ-tree can be simplified.

Hsu [13] proved that an interval graph has a unique maximal clique arrangement if the graph is prime. In this section, we provide a linear-time algorithm to find the linear maximal clique arrangement of a prime interval graph. Together with the linear-time substitution decomposition algorithm, we have yet another linear-time algorithm for interval graph recognition. Our algorithm uses only basic techniques such as graph partitioning and lexicographic ordering; no special data structure such as PQ-tree is required. We consider it to be much simpler than the previous algorithms. However, we want to remind the readers that Booth and Lueker's algorithm is much more flexible in the sense that it can test the consecutive 1's property of a Boolean matrix and can operate in an "on-line" fashion. In contrast, our algorithm deals only with interval graphs and must operate in an "off-line" fashion. The readers are encouraged to make comparisons among these algorithms.

In order to better understand our algorithm, we ask the readers to keep in mind a geometric model which is the unique linear maximal clique arrangement for the input graph. Our algorithm is based on a graph partitioning idea. Initially, we obtain the clique tree representation of the input chordal graph as we did in the last section. Partition the maximal cliques into two sets such that there is a linear maximal clique arrangement (if G is an interval graph) where all the maximal cliques in one set are at the left of the maximal cliques in the other set. We then further refine our partition based on the following observation.

LEMMA 5.2. *Let A and B be two sets of maximal cliques where A is at the left of B in a linear arrangement. Suppose vertex v is shared by $C_A, C_B, C_A \in A, C_B \in B$. If X is a set of maximal cliques at the right of A, all maximal cliques in X containing v must be at the left of those not containing v. Symmetrically, if Y is a set of maximal cliques at the left of B, all maximal cliques in Y containing v must be at the right of those not containing v.*

The proof to this lemma, which is omitted here, can be observed from the geometric model of an interval graph. The refinement process is repeatedly picking a vertex which is in two maximal cliques in different sets of a partition. We can then further partition these sets by Lemma 5.2. To start the partitioning process, we need an initial partition which admits a feasible linear maximal clique arrangement if the input graph is interval. The following lemma provides an easy way to find such a configuration.

Before we prove Lemma 5.3, we investigate some basic behaviors on a lexicographic ordering. A lexicographic ordering is a breadth-first ordering. Therefore, the traversed vertices always form a connected component. Moreover, the traversal always adds vertices of a particular maximal clique until it is completely traversed. For a lexicographic ordering π on G, we say that maximal clique C_a is traversed before C_b if every vertex in C_a is included in π before the last ordered vertex in C_b.

If we focus on interval graphs with a particular geometric model, a lexicographic

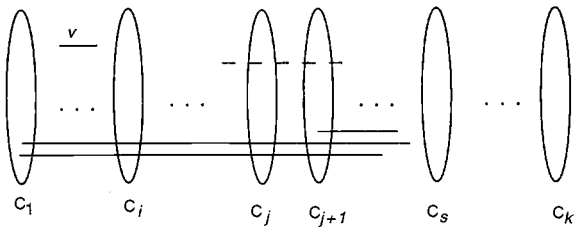


FIG. 5.1. *The scheme for proving Lemma* 5.3. *The dashed line represent an interval which cannot exist.*

ordering always picks a maximal clique to traverse first, then picks another which has the greatest lexicographic value defined by the traversed vertices, and so on. Intuitively, the traversal starts at a maximal clique and then expands toward both ends of a linear maximal clique arrangement. The maximal cliques might not be traversed consecutively as it is possible that there are more than one maximal clique with vertices which are tied in their lexicographic value.

LEMMA 5.3. *For any lexicographic ordering on a prime interval graph G, the maximal clique containing the last vertex (which is simplicial and thus contained by only one maximal clique) included in the ordering must be leftmost or rightmost on the linear maximal clique arrangement for G.*

Proof. Suppose G has k maximal cliques. Since G is prime, these maximal cliques have a unique ordering (up to reversal) $C_1, C_2, ..., C_k$, from left to right. (See Fig. 5.1.) Let C_s be the first traversed maximal clique. We claim that either C_1 or C_k will be the last traversed maximal clique. It suffices to prove that if $s > 1$, C_1 will be the last traversed maximal clique among $C_1, C_2, ..., C_s$. Suppose C_i, instead of C_1, is the last traversed maximal clique, $1 < i < s$. Keep in mind that during a lexicographic ordering, the lexicographic value of each vertex (as an interval in the linear maximal clique arrangement) is decided by its connection to the intervals that had been ordered. Let v be the first vertex which lies to the left of C_i being included in the ordering with lexicographic value α. It is clear that every unordered vertex in C_i also has the same lexicographic value. Let C_j be the maximal clique with greatest index value such that every unordered vertex in C_j also has a lexicographic value α. There is no interval connecting C_j and C_{j+1} except those that extend all the way to C_1. Otherwise, such a vertex will be ordered before v. Therefore, the set of vertices M whose interval representations end before C_{j+1} form a module. M is not trivial. Since C_1 has a simplicial vertex, and since C_i is maximal, there must be a vertex in C_i but not in C_1. This contradicts our assumption that G is prime. □

The clique tree structure provides enough information for us to partition a prime interval graph into a unique linear maximal clique arrangement. We now present a detailed description of the algorithm in Fig. 5.2. An example for this algorithm is presented in Fig. 5.3.

We now prove the main theorem of this section.

THEOREM 5.4. *Given a prime interval graph G, a linear maximal clique arrangement of G can be obtained in $O(m + n)$ time.*

Proof. Lemmas 5.2 and 5.3 assure that LinearMaxCliqueArrange never partitions the maximal cliques incorrectly. What we need to show is that when the execution is over, a linear maximal clique arrangement can be trivially derived from the partitioning. In other words, each set of maximal cliques contains exactly one

```
procedure LinearMaxCliqueArrangement(G)
    find a clique tree of G;
    create a initial partition P which consists all maximal cliques in G;
    partition the maximal clique containing the last vertex of a lexicographic
        ordering from the rest of the maximal cliques;
    move (and delete from the clique tree) the edges in the clique tree crossing
        these two sets of maximal cliques into CrossingEdge;
    while CrossingEdge ≠ ∅ do begin
        pick an edge C_iC_j from CrossingEdge and remove it from CrossingEdge;
        for each unprocessed v ∈ C_i ∩ C_j do
            begin
                for all sets S_i in P, partition S_i into maximal cliques containing
                    v, S_i', and maximal cliques not containing v, S_i'';
                if S_i' ≠ ∅ and S_i'' ≠ ∅ then do
                    begin
                        replace S_i by S_i', S_i'' according to Lemma 5.2;
                        for each edge e in the clique tree between a member of S_i'
                            and a maximal clique not in S_i', remove e from the
                            clique tree and add it to CrossingEdge;
                    end;
            end;
    end; {while}
end Partitioning;
```

FIG. 5.2.

maximal clique. If we suppose this is not the case, then we have more than one maximal cliques in the same set S after every edge in CrossingEdge has been processed. Let V_S denote the union of vertices in the maximal cliques in S. We claim that $M = \{x|N(x) \subset V_S, x \in V_S\}$ is a module. To show this, we show that, for any vertex $u \notin M$, on the interval model, u either meets all the maximal cliques in S or none of them. If this is not true, there must exist a vertex v, $v \in C_x, C_z; v \notin C_y; C_x, C_y \in S; C_z \notin S$. From the property of a clique tree, there is a path on the subtree induced by v connecting C_x and C_z. Traversing on the path from C_x, we can find an edge on the clique tree, $C'_xC'_z$, such that $C'_x \in S$, $C'_z \notin S$. When C'_x and C'_z were first partitioned into different sets, this edge must have been put into CrossingEdge and v would have been used to partition C_x, C_y into different sets before the algorithm ends. Thus M is a module. To see that it is nontrivial, note that S must contain two distinct maximal cliques C and C', so there must be a vertex $x \in C \setminus C'$ and a vertex $y \in C' \setminus C$. Since all vertices outside M meet all or none of S, x and y must be in M, so M is a nontrivial module, which contradicts the fact that G is prime. Therefore, no set contains more than one maximal clique when the partitioning is done.

A bipartite graph H connecting the vertex set and the maximal cliques can be constructed by scanning all the maximal cliques once, such that vertex v is connected to C iff $v \in C$. The size of this graph is in $O(n + m)$. To find a clique tree and the intersections of all adjacent maximal cliques on the tree can be done in $O(n + m)$ time. The partitioning caused by vertex v can be performed in $N_H(v)$ time since all we need to do is to mark the maximal cliques containing v and split a set into

FIG. 5.3. *An example for LinearMaxCliqueArrangement.*

two if necessary. To decide the left-right relation of two sets, we maintain a counter in each partitioned set recording the number of maximal cliques to the right of the set. Whenever a partition is caused by v, we examine whether v is connected to a left maximal clique (one with greater counter number) or to a right maximal clique. Since whenever an edge is moved into CrossingEdge, the edge is deleted from the clique tree, the total time needed for these movements is bounded by the number of edges in the graph. In our traversal on the maximal cliques of S'_i in order to find the crossing edges, the time we wasted on traversing noncrossing edges when a partition is caused by vertex v is bounded by $N_H(v)$. Therefore, the overall complexity is in $O(n+m)$. □

An interval model for the input graph G can be constructed from the linear maximal clique arrangement. It's easy to test in linear time whether this model is consistent with G. Therefore, we have a linear-time algorithm to recognize prime interval graphs. We can incorporate this algorithm with the substitution decomposition algorithm for chordal graphs to get a linear-time algorithm for recognizing interval graphs. Whenever a module S is identified, we test whether S is an interval graph. By Lemma 3.1, we can always replace the interval of a marker vertex v by the interval model of the module it represents and still have an interval model. If all the modules (including the last prime graph representing the input graph G) are interval graphs, G is an interval graph. We have thus proved the following corollary.

COROLLARY 5.5. *An interval graph can be recognized in linear time.*

Remark. After we submitted our paper [12], McConnell and Spinrad [17] have developed a linear-time algorithm to perform modular decomposition for general graphs. They also discussed the transitive orientation on a number of problems. Their time bound for recognizing chordal comparability graphs is $O(n + mlogn)$.

Yet another linear-time algorithm for recognizing interval graph without using PQ-tree is developed by Corneil, Olariu, and Stewart [4].

Acknowledgment. The authors thank the referees who made many helpful suggestions and a clearer presentation for procedure Orientation and the paper. We also want to thank Spinrad who pointed out an error on the clique tree construction in an earlier manuscript.

FAST CONNECTED COMPONENTS ALGORITHMS FOR THE EREW PRAM*

DAVID R. KARGER†, NOAM NISAN‡, AND MICHAL PARNAS‡

Abstract. We present fast and efficient parallel algorithms for finding the connected components of an undirected graph. These algorithms run on the exclusive-read, exclusive-write (EREW) PRAM. On a graph with n vertices and m edges, our randomized algorithm runs in $O(\log n)$ time using $(m + n^{1+\epsilon})/\log n$ EREW processors (for any fixed $\epsilon > 0$). A variant uses $(m + n)/\log n$ processors and runs in $O(\log n \log\log n)$ time. A deterministic version of the algorithm runs in $O(\log^{1.5} n)$ time using $m + n$ EREW processors.

1. Introduction.

Perhaps the most basic algorithmic problem involving an undirected graph is to find its connected components. In this problem, the input to the algorithm is an undirected graph $G = (V, E)$, with $|V| = n$ vertices and $|E| = m$ edges. The output is the connected components of the graph. There are various ways to represent the solution; the one we shall use is to label each vertex with the largest numbered vertex to which it is connected. Connected components can be found in linear sequential time by breadth-first search or depth-first search methods. However, these methods do not parallelize easily. Parallel algorithms for connected components have been known for quite some time ([HCS79], [CLC82], or see the survey in [KR90]). Until recently the best known algorithms required $O(\log n)$ time on CRCW PRAMs and $O(\log^2 n)$ time on CREW PRAMs (recall that CR (CW) PRAMs allow multiple processors to concurrently read (write) to the same memory location, while ER (EW) PRAMs allow only one processor to read (write) at a time). The number of processors used by the best of those algorithms is nearly optimal in the deterministic case [SV82, CV91, AS87] and completely optimal in the randomized case [Gaz91].

In their survey, Karp and Ramachandran [KR90] raised the question of the existence of $o(\log^2 n)$-time algorithms for connected components on exclusive-write PRAMs. Recently, Johnson and Metaxas [JM91] developed a CREW algorithm that runs in $O(\log^{1.5} n)$ time and uses $m+n$ processors. An $O(\log^{1.5} n)$-time algorithm for the EREW PRAM is described in [NSW92], but this algorithm uses a large polynomial number of processors.

In this paper we present improved EREW algorithms for connected components. One contribution is the first (randomized) algorithm that runs in $O(\log n)$ time. It is based on the parallelization of random walk techniques studied in [AKL*79], where it is shown that a relatively short random walk will visit all the vertices in a graph.

THEOREM 1.1. *The connected components of an undirected graph can be computed on a randomized EREW PRAM in $O(\log n)$ time with high probability*[1] *using $(m + n^{1+\epsilon})/\log n$ processors for any fixed $\epsilon > 0$.*

The running time of this algorithm is optimal, as the results of [CDR86] and [DKR94] imply a lower bound of $\Omega(\log n)$ time even on a randomized CREW PRAM. For graphs that are not too sparse, i.e., with $\Omega(n^{1+\epsilon})$ edges, the processor costs are optimal as well, because the total work remains linear in the input size. For sparse graphs, using a linear number of processors slightly increases the running time.

THEOREM 1.2. *The connected components of an undirected graph can be computed on a randomized EREW PRAM in $O(\log n \log\log n)$ time with high probability with $(m + n)/\log n$ processors.*

This is of course within an $O(\log\log n)$ factor of being work optimal. An important related open problem is to design a *deterministic* $O(\log n)$-time algorithm. We have made some progress in this direction.

THEOREM 1.3. *The connected components of an undirected graph can be computed on a deterministic EREW PRAM in $O(\log^{1.5} n)$ time using $m + n$ processors.*

The running time of this deterministic algorithm matches those of [JM91] and [NSW92]. It improves upon [JM91] by working in the more restricted EREW model instead of in the CREW model. It improves upon [NSW92] by requiring only a linear number of processors instead of a large polynomial number of processors. This last result was proved independently (using a different method) by [JM92].

After publication of the preliminary version of this paper [KNP92], several improvements were given. Chong and Lam [CL95] gave an $O(\log n \log\log n)$-time deterministic algorithm that uses $m + n$ processors. Halperin and Zwick improved our methods to yield first [HZ94] an optimal randomized algorithm for connected components that runs in $O(\log n)$ time with a linear number of processors, and subsequently [HZ6] an optimal randomized algorithm for finding a spanning forest of the graph (note that our algorithm does not find spanning forests).

In the following sections, we present the connectivity algorithm. To simplify the exposition, we first present a randomized algorithm that uses $m + n$ rather than $(m+n)/\log n$ processors. We give a general overview of the algorithm and then fill in the details and provide proofs of correctness. We then discuss the changes needed to make the algorithm deterministic. The modifications needed to reduce the processor cost by an additional factor of $\log n$ are somewhat complex and are left to a later section.

2. Overview of the algorithm. The algorithm is based on a simple and well-known idea: repeatedly find groups of connected vertices in the graph and contract (i.e., merge) each group into a single vertex, finishing when each connected component is contracted to a single vertex. The question lies in how to find these connected groups.

Suppose we are fortunate and the minimum degree of the graph is large. Let $N(i)$ be the set of vertices adjacent to i (including i). The following procedure can

[1] By "high probability" we mean that the probability of the event not happening can be made at most $n^{-\delta}$ for any fixed $\delta > 1$ without affecting the orders of run times.

be applied, using a processor for each vertex and a processor for each edge.

1. Each vertex looks at all vertices within distance two of itself, i.e., $N(N(i))$. If it finds a larger numbered vertex than itself, it makes this vertex its *parent*. Any vertex that fails to find a parent becomes a *leader*.
2. The selection of parents has created a group of trees with leaders at the roots (note that the tree edges need not be graph edges). Each tree is now contracted to a single vertex.

Assuming that the minimum degree is large, this process yields a much smaller graph, as the following lemma shows.

LEMMA 2.1 (neighborhoods). *If all neighborhoods $N(i)$ have size at least s, then at most n/s leaders can exist.*

Proof. The distance between two leaders must exceed 2. Thus the neighborhoods of two leaders are disjoint, and therefore at most n/s leaders remain. □

The contraction of the trees does not change the connected components, as can be seen from the following lemma.

LEMMA 2.2. *In the contracted graph, two leaders are connected iff they were connected in the old graph.*

Proof. Note that two leaders are adjacent iff each had a descendant such that the descendants were adjacent. The lemma then follows from the fact that all vertices are necessarily connected to their leaders. □

The running time of the algorithm will depend on the number of rounds needed to contract every connected component into a single vertex. Since the reduction is based on neighborhood size, this number of rounds depends on the minimum degree s of the graph. The problem is that the minimum degree of the graph may be small, and therefore the procedure described above may fail to reduce the size of the graph significantly. We will show how to solve this problem by "imagining" additional edges in the graph in order to make the neighborhoods large. As long as the imaginary edges connect vertices that are connected in the original graph, the two lemmas given above continue to hold. Similar ideas are explored in [BR91] and [NSW92]. The remainder of this paper is dedicated primarily to the question of how to construct quickly and in parallel a large neighborhood for each vertex in the graph.

Our approach to this question began with the following observation. It is known that an EREW PRAM with a polynomial number of processors can simulate any logspace algorithm in $O(\log n)$ time (see [KR90]). This extends to the fact that a randomized EREW PRAM can simulate randomized-logspace algorithms.[2] Since a randomized-logspace algorithm for connectivity is known [AKL*79], a randomized EREW algorithm follows.

Unfortunately, the parallelization of the random walk algorithm of [AKL*79] requires $\Omega(mn^2)$ processors. The reason so many processors are needed is that a random walk of length $\Omega(mn)$ must be taken to be sure of covering the entire graph. Thus the approach of [AKL*79] does not directly suggest an efficient algorithm. However, an important idea can be extracted from this approach, namely, that a random walk visits a large number of vertices relatively quickly. We thus explore the use of *short* walks on the graph.

Consider taking a walk of some length p from each vertex of the graph by traveling along edges of the graph. Using the vertices encountered along each walk as the

[2] In fact, the results in [Nis93] imply that any randomized-logspace algorithm with bounded two-sided error can be simulated with *zero error* by a randomized EREW PRAM in $O(\log n)$ time using a polynomial number of processors.

neighborhood of the walk's starting vertex, we will apply the contraction procedure described above to reduce the size of the graph by a significant factor. This procedure will be called a *walk phase of length p*. In the randomized algorithm, the walk is a random walk; in the deterministic algorithm, the walk is based on a deterministic traversal sequence. A walk phase takes $O(\log n)$ time to simulate in parallel, but since the walk phases construct large neighborhoods, a very small number of phases suffices to complete the algorithm. In more detail, consider the following procedure.

1. From each vertex $1 \leq i \leq n$, take a walk of length p. Let $W(i)$ be the *itinerary* of i, i.e., the set of vertices seen on the walk that starts at i.
2. Consider the edges defined by the walks, so that there is an edge $\{i, j\}$ if $j \in W(i)$ or $i \in W(j)$. These edges clearly connect vertices that are connected in G.
3. Use these "walk edges" to define the vertex neighborhoods. Each vertex examines its neighborhoods, as was described at the start of this section, to find a parent or become a leader.
4. To contract the resulting collection of trees, each vertex finds the leader in its tree of parents and transfers all its edges to the leader (i.e., replaces each edge $\{i, j\}$ in G by an edge from i's leader to j's leader).

When a walk phase is finished, we have a new graph G' whose vertices are the leaders in the old graph. Lemmas 2.1 and 2.2 tell us that G' is smaller than G and that G' embodies the same connectivity information.

The connectivity algorithm is to repeat the walk phases until the resulting graph has no edges. Each remaining vertex then represents the connected component containing that vertex. Every vertex that does not remain will have dropped out after selecting some vertex as its leader and giving that vertex its edges. The leader choices of the vertices form a forest—the root of each tree is one of the connected component representatives, and the vertices in each tree are a single connected component of the graph. Tree contraction can now be used to let each vertex identify its connected component representative.

To make the algorithm run quickly, we need to finish in a small number of walk phases. From this description, it can be seen that all we need in order to implement the algorithm are

- a walk that visits a large number of vertices, and
- a way to simulate a walk phase quickly in parallel.

We now show in detail how to achieve these two goals.

3. Implementing a walk phase. In the course of the following discussion of the implementation of the algorithm, assume that G is totally connected. The results we wish to prove then follow by independently considering the action of the algorithm on each connected component of the graph.

The key question that must be solved is how to construct a walk that visits a large number of vertices. Using randomization, the solution is straightforward. Knowing that a random walk expects to cover all n vertices of a graph in time $n^{O(1)}$, we will deduce that a random walk of length p visits $p^{\Omega(1)}$ vertices with high probability. This reduces the implementation of a walk phase to the problem of simulating a random walk from each vertex in parallel.

It is well known that CRCW can be simulated on an EREW machine with an $O(\log n)$ slowdown in running time and no increase in processor cost [KR90, pp. 894–895]. Since we wish the walk phase to have running time $O(\log n)$, we feel free to say that "processors concurrently read or write," so long as this occurs only a constant

number of times.

We now discuss the details of implementing a walk phase of length p using $m+pn$ processors.

3.1. Data structures and processor allocation. Each vertex i has a list L_i of edges leaving i. The edge connecting i and j appears as (i,j) in L_i and as (j,i) in L_j. The edge lists are stored contiguously in one array L of length $2m$, sorted by order of lists $L_1, L_2, \ldots, L_n$.

Each vertex i also has two variables, $first_i$ and $last_i$, which indicate the beginning and end of the list L_i in L. It is easy to determine the number of neighbors of i by computing $last_i - first_i + 1$.

The algorithm uses an $n \times p$ array $WALK$ to simulate random walks of length p. Two more arrays, MAX of dimensions $n \times p$ and $PARENT$ of length n, are used to find the leaders of the graph.

We use $O(\log n)$ time to redistribute the processors at the beginning of each walk phase.

- p processors are assigned to each vertex. Let $P_{i,1}, P_{i,2}, \ldots, P_{i,p}$ be the processors assigned to vertex i for $i = 1, \ldots, n$.
- One processor is assigned to every edge. These processors will be called *edge processors*. Let P_k, where $k = 1, \ldots, m$, be these processors assigned to edge k.

Therefore, the total number of processors is $m+pn$. Notice that after each walk phase the number of vertices of the graph reduces, and therefore in each walk phase we can allocate more processors per vertex. This will allow us to increase the length p of a walk phase and thus to contract the connected components even faster.

We now turn to the details involved in executing the four steps outlined in the overview of the algorithm.

3.2. Step 1: Simulating the random walk. We wish to simulate the process of taking a random walk of length p simultaneously from all vertices of G. For each vertex $1 \le i \le n$ and each $1 \le t \le p$, processor $P_{i,t}$ chooses a neighbor of vertex i uniformly at random and writes it into $WALK[i,t]$. Each processor does so using three concurrent reads of $first_i$, $last_i$, and L.

Consider the random variables u_t^i defined by

$$\begin{aligned} u_1^i &= i, \\ u_{t+1}^i &= WALK[u_t^i, t] \quad \text{for} \quad t = 1, \ldots, p. \end{aligned}$$

By the choice of the $WALK[i,t]$ values, the random variable u_t^i is a random walk starting at vertex i for each $1 \le i \le n$. The random walks with different sources are not independent, but this will not affect the analysis. As mentioned in the overview, let the itinerary $W(i)$ be the set of vertices encountered on the random walk from i. Figure 1 shows a filled $WALK$ array in which, for example, $W(8) = \{7, 8, 9\}$ (in the algorithm, each walk step moves from one vertex to a different vertex, but in our picture, for the sake of clarity, we have drawn some horizontal edges that imply walk steps that stand still). We will show later that all the $W(i)$ are large, i.e., of size exceeding $p^{\Omega(1)}$.

3.3. Step 2: Finding neighborhoods. As stated in step 2 of the outline, consider the *walk edges* defined by including (i,j) if $i \in W(j)$ or $j \in W(i)$. In step 3 each vertex looks for a parent among vertices up to two walk edges away. These

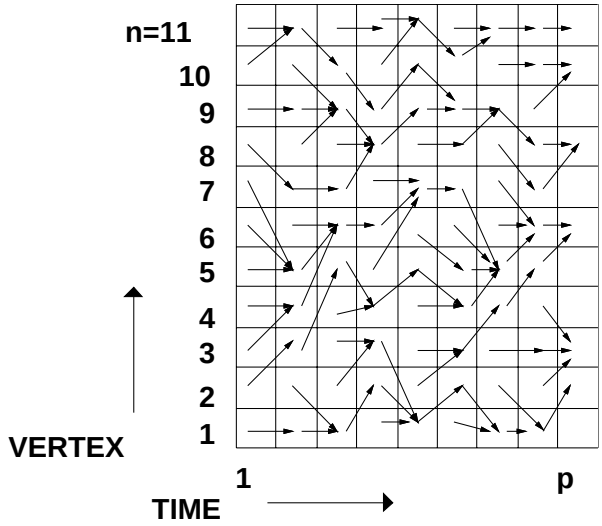

FIG. 1. *The WALK array.*

edges are not actually constructed; instead, each vertex deduces the information it needs directly from the *WALK* array. Furthermore, the edges considered are actually a superset of the walk edges, which will define larger neighborhoods $N(i) \supset W(i)$. But it will still be true that i is connected to all vertices in $N(i)$. Since larger neighborhoods cause a greater reduction in the size of the graph, this use of more edges can only help.

The values placed in the walk array in step 1 can be seen to define a collection of trees (the values provide parent pointers). We let the neighborhood of a vertex be the vertices to which it is connected by one of these trees. More formally, for each $i = 1, \ldots, n$, let $T_{i,t}$ be the set of array entries $[j, t']$ that are in the tree containing the entry $[i, t]$ and let $T_i = \bigcup_t T_{i,t}$. Define $N(i) = \{j \mid (\exists t)[j, t] \in T_i\}$ to be the neighborhood of vertex i. In other words, imagine an edge from i to j whenever i and j share a tree. Note that if the random walk from i encounters j then $[j, t] \in T_i$ for some t, so $W(i) \subset N(i)$. Also, since each tree edge corresponds to a step in a random walk, and thus to an edge in G, all members of $N(i)$ are necessarily connected to i.

Let H denote the graph with vertex set V but with edges defined by the neighborhoods $N(i)$. This is the graph that will be used to find connected sets of vertices to contract.

3.4. Step 3: Choosing leaders. We now implement the process of choosing a maximum parent of distance at most two in H, as described in the overview of section 2. This is achieved by calling twice the following procedure *Max-Neighbor*. The first call to this procedure chooses for each vertex i the maximum vertex in $N(i)$ (which corresponds to finding the maximum vertex of distance one from each vertex on the graph H). The second call finds the maximum vertex chosen by any vertex in $N(i)$ (which corresponds to finding the maximum vertex of distance two from each vertex on the graph H). Initialize the array $PARENT$ to $PARENT[i] = i$, and then call the following procedure twice.

Procedure *Max-Neighbor:*

1. For each $i = 1, \ldots, n$ and $t = 1, \ldots, p$, set $MAX[i, t] = \max_{[j,t'] \in T_{i,t}} PARENT[j]$.

2. For each $i = 1, \ldots, n$, set $PARENT[i] = \max_t MAX[i, t]$.

At the first iteration this process labels each vertex with its largest "neighbor," so the second iteration labels vertices with their largest neighbor at distance two. In other words, at the end of this process $PARENT[i]$ contains the parent of vertex i. Vertex i is a leader if $PARENT[i] = i$.

Implementing *Max-Neighbor* is straightforward. Step 2 is trivial. Step 1, maximizing over a tree, can be implemented using Euler tour techniques on the array *WALK* in time $O(\log n)$ using np processors (see [KR90, pp. 879–883]). The only nonstandard detail is that our filling up of the walk array has created trees with unidirectional edges, while the Euler tour method requires bidirectional edges. To build these edges, proceed as follows. Copy the *WALK* array, and then sort the edges $([i, t], [j, t+1])$ in the *WALK* array according to their second endpoints. We can do this in $O(\log np)$ time using np processors, either by applying Cole's sorting algorithm [Col88] or via a simple bucket sort using $(np)^2$ space. After the sort, all the edges that point to a particular position in the *WALK* array are grouped together for application of the Euler tour technique.

3.5. Step 4: Create the new graph G′. In this final step we must construct the new graph G' whose vertices are the leaders in the graph G. The selection of parents in procedure *Max-Neighbor* created a group of trees (not to be confused with the trees in the *WALK* array) with leaders at the roots. Each vertex now finds the leader at the root of its tree by using Euler tours as before [KR90]. We can now create the new smaller graph $G' = (V', E')$. The set of vertices V' is the set of leaders, i.e., $V' = \{leader(i) \mid i \in V\}$. The set of edges of G' is obtained by transforming each edge (i, j) of E to an edge $(leader(i), leader(j))$, i.e., $E' = \{(leader(i), leader(j)) \mid (i, j) \in E\}$.

To construct the set E', each edge processor P_k for $k = 1, \ldots, m$ concurrently reads the leaders of each of its endpoints and renames its edge appropriately. If P_k is handling edge (i, j), then P_k checks if $leader(i) = leader(j)$. If so, this edge has been contracted and is now useless, so P_k writes 0 at $L[k]$. If not, it writes the edge $(leader(i), leader(j))$ at $L[k]$.

Next sort L lexicographically by left and right endpoints in $O(\log n)$ time using Cole's sorting algorithm [Col88] or a bucket sort (for the bucket sort, a binary tree atop an array of size m can be used to let all items with a particular key merge into a list by walking up the tree). The renaming may yield multiple copies of some edges. These must be removed because otherwise the random walk becomes "biased" toward visiting vertices that are connected by many edges; our analysis requires that the random walk be unbiased. To remove these multiple edges, each edge processor P_k looks to its left at L. If $L[k] = L[k-1]$, then P_i writes a 0 at $L[k]$. Now compact the array L using standard parallel compaction [KR90, pp. 875–876].

Next it is necessary to update the $first_i$ and $last_i$ variables. To do so, first set $first_i = -1$ (using the processors $P_{i,1}$). Then each edge processor P_k looks to its left (right) at L, and if it is at the beginning (end) of the edge list of some processor i, it updates $first_i$ ($last_i$). Afterward, any vertex that still has $first_i = -1$ must have no incident edges. Such isolated vertices are marked as the representatives of connected components and removed. It should be noted that the new graph G' still has at most m edges.

Clearly, all the operations described above can be done in $O(\log n)$ time. Thus we have proved Lemma 3.1.

LEMMA 3.1. *A walk phase of length p can be implemented in $O(\log n + \log p)$*

time using $m + pn$ EREW processors.

4. Iterating the walk phase. Now that we have shown the required time and processor bounds, it remains to show that the new graph G' has significantly fewer vertices, and that as a consequence the algorithm terminates in a small number of walk phases. We require the following corollary to the known results regarding the cover time of random walks on graphs. This lemma was first observed by Linial [Lin]. For completeness we sketch the proof.

LEMMA 4.1. *Let G be an undirected graph. Let v be any vertex in G that is contained in a connected component of at least t vertices. Then the expected time needed for a random walk starting from v to see t vertices is $O(t^4)$.*

Proof. Define the random variable X_t to be the time it takes a random walk that starts at v to see t vertices. Assume that by time X_t we saw the set of vertices C_t. Let $w \notin C_t$ be a vertex that is adjacent to some vertex in C_t. Then the expected time to cover the graph $C_t \bigcup w$ (and thus see a new vertex) is $O(t^3)$ if we do not leave $C_t \bigcup w$. If we do leave it, then we shall see a new vertex even sooner. Hence $E(X_{t+1}) = E(X_t) + O(t^3) = O(t^4)$. □

It was shown by Barnes and Feige [BF93] that $O(t^3)$ expected time is sufficient to see t vertices. We can now obtain Lemma 4.2

LEMMA 4.2. *After a walk phase of length p, for every vertex $i = 1, \ldots, n$, the itineraries satisfy $|W(i)| = \Omega((\frac{p}{\log n})^\alpha)$ with high probability, where $\alpha = 1/4$.*

Proof. Consider the walk to be a composition of $\Omega(\log n)$ "subwalks" of equal length $\Omega(\frac{p}{\log n})$. Call each subwalk *good* if it visits $\Omega((\frac{p}{\log n})^\alpha)$ vertices. By the Markov inequality and Lemma 4.1, each subwalk has a constant probability of being good. This is true even if we condition on the outcomes of previous subwalks. Thus all the subwalks fail to be good with polynomially small probability. □

The result of [BF93] lets us take $\alpha = 1/3$, thus improving the constant factors in the following analysis.

COROLLARY 4.3. *A walk phase of length p reduces the number of vertices in a graph by a factor of $\Omega((\frac{p}{\log n})^\alpha)$ with high probability.*

Proof. Consider the above two lemmas and the fact that $W(i) \subset N(i)$. Now apply Lemma 2.1. □

We can now analyze the running time of our connected component algorithm.

LEMMA 4.4. *Using $m + pn$ processors, with high probability we can identify the connected components of the graph with $O(\log(\log n / \log p))$ walk phases.*

Proof. Assume for now that $p > \log^2 n$. The hypothesis gives us at least p processors per vertex. Running a walk phase of length p yields a graph of $O(n(\frac{\log^\alpha n}{p^\alpha}))$ vertices. On this graph redistribute the processors to get

$$\frac{np}{n \log^\alpha n / p^\alpha} = \frac{p^{1+\alpha}}{\log^\alpha n} > p^{9/8}$$

processors per vertex. Thus the number of processors per vertex after t walk phases is described with high probability by the recurrence

$$p_{t+1} > p_t^{9/8}$$

with solution

$$p_t > p^{(9/8)^t}.$$

Thus p_t exceeds pn within $O(\log(\log n/\log p))$ steps. Since this implies that all the processors are assigned to one vertex, the algorithm must be finished at this point. Therefore, this is the maximum expected number of walk phases needed.

There remains the detail of what to do if initially $p < \log^2 n$. To handle this case, note that even if $p = 1$, so that the random walks are in fact just inspections of a single neighbor, the neighborhoods still have size two. Thus the size of the graph is still reduced by a factor of two in each walk phase. Therefore, $O(\log(\log^2 n/p)) = O(\log(\log n/\log p))$ walk phases suffice to raise p to $\log^2 n$ and thus reduce to the previous case. □

Since each walk phase is simulated in $O(\log n)$ time, the overall running time of the algorithm is $O(\log n \log(\log n/\log p))$. Theorems 1.1 and 1.2 follow immediately, up to a factor of $\log n$ in the processor count that is removed in section 7.

5. Using fewer random bits. Randomness is used in our algorithm only to construct random walks. We show how to restrict this use of randomness to $O(n^\epsilon)$ bits for any $\epsilon > 0$. Note first that once we have n^ϵ processors per vertex and can simulate random walks of length n^ϵ, there is no need to reassign processors to vertices, since an additional $O(1/\epsilon)$ walk phases of length n^ϵ will finish the problem. Therefore, assume that random walks never exceed length n^ϵ. Now observe that a walk phase of length p needs only $p \log n$ random bits. Two entries in the *WALK* array need be independent only if it possible for a walk defined in the array to encounter both of them. Therefore, entries $WALK[i,t]$ and $WALK[i',t]$, $i \neq i'$, can use the same random seed in selecting edges, since a particular walk is only at one place at any particular time.

COROLLARY 5.1. *Connected components can be found in*

$$O(\log n \log(\log n/\log p) + (\log n)/\epsilon)$$

time using $m + pn$ processors and $O(n^\epsilon)$ random bits.

6. The deterministic version. Our techniques can also be used to obtain a deterministic algorithm for the EREW PRAM that runs in $O(\log^{1.5} n)$ time using $m + n$ processors. This improves on the deterministic $O(\log^{1.5} n)$-time algorithm of [NSW92] and matches an independent result of [JM92]. As in [NSW92], we use a universal sequence instead of a random walk. It will be convenient to consider a generalization of the universal sequences of [AKL*79] to allow walks on nonregular graphs.

DEFINITION 6.1. *A graph G with at most r vertices will be called* r-labeled *if the edges adjacent to each vertex are labeled with unique numbers from $\{1, 2, \ldots, r\}$.*

DEFINITION 6.2. *Given a string $\sigma \in \{1, 2, \ldots, r\}^*$ and an r-labeled graph G, a* walk according to σ *starting from a given vertex will follow an edge labeled i at step j if $\sigma_j = i$. If $\sigma_j = i$ and none of the edges leaving the current vertex are labeled i, the walk will remain in that vertex.*

DEFINITION 6.3. *A string $\sigma \in \{1, 2, \ldots, r\}^*$ is called an* r-universal sequence *if for every graph G with at most r vertices and any r-labeling of G a walk according to σ visits all the vertices of G regardless of the starting vertex.*

By following the proofs of [AKL*79], [BNS92], and [Nis92], it is not difficult to see that the construction of [Nis92] yields an r-universal sequence of length $r^{O(\log r)}$ in our general sense. We need only the following two properties.

THEOREM 6.4 (see [Nis92]). *An r-universal sequence of length $l = r^{O(\log r)}$ can be generated by an EREW PRAM in $O(\log l)$ time using $O(l \log l)$ processors.*

LEMMA 6.5. *For any undirected connected graph G with at least r vertices, and for any vertex v in G, a walk along an r-universal sequence σ starting from v visits at least r vertices of G.*

Proof. Label G so that each vertex of degree d is labeled with the numbers $\{1, 2, \ldots, d\}$. Assume the claim is false and σ visits fewer than r vertices.

Let C_r be the graph induced by all the vertices σ visits. Let $w \notin C_r$ be a vertex adjacent to some vertex $v' \in C_r$ such that the edge (v', w) is labeled with a number less than r (this is possible since v' has at most $r-2$ neighbors in C_r). Then the graph $C_r \cup w$ is an r-labeled graph with at most r vertices, and thus a walk according to σ should cover it and thus visit w, a contradiction. ∎

The deterministic algorithm proceeds as follows: instead of taking a random walk from each vertex, generate an r-universal sequence and then walk along this sequence. The parameter l is chosen such that the length of the resulting universal sequence is p (where p is the number of processors allotted to each vertex in the graph); thus $r = 2^{O(\sqrt{\log p})}$. We are thus assured by Lemma 2.1 that the number of vertices in the graph at the next round shrinks by a factor of at least r.

Letting p_i be the number of processors allotted to each vertex at iteration i, we argue as in the random walk case. We have the following recursion:

$$p_1 = 2,$$
$$p_{i+1} = p_i \cdot 2^{\sqrt{\log p_i}}.$$

LEMMA 6.6. *Let $p_1 = 2$ and $p_{i+1} = p_i \cdot 2^{\sqrt{\log p_i}}$. Then $p_j = n$ for some $j = O(\sqrt{\log n})$.*

Proof. Let $q_i = \log p_i$. Therefore, $q_1 = 1$ and $q_{i+1} = q_i + \sqrt{q_i}$. Then for every i, $q_{(i+\sqrt{q_i})} \geq 2q_i$. Thus the time to reach $q_j = \log n$ is at most $\sqrt{1} + \sqrt{2} + \sqrt{4} + \sqrt{8} + \cdots + \sqrt{\log n} = O(\sqrt{\log n})$. ∎

As a result of this lemma, we can conclude that after $O(\sqrt{\log n})$ walk phases the graph is contracted to a single vertex.

Theorem 1.3 follows immediately. Observe that starting with (polynomially many) more processors does not decrease the running time in this case.

COROLLARY 6.7. *If an n-universal sequence of polynomial length can be generated deterministically in $O(\log n)$ time, then connected components can be found in $O(\log n)$ time deterministically using $m + n^{1+\epsilon}$ processors for any fixed ϵ.*

7. Approaching optimal work. The algorithms described above perform work that exceeds the optimal by a factor of $O(\log n \log\log_p n)$. Here we reduce this factor to $O(\log\log_p n)$, showing how the $O(\log n \log\log_p n)$ running time can be achieved with $(m + pn)/\log n$ processors (this will be optimal for $p = n^\epsilon$). We begin with the assumption that $p > \log^2 n$ and later show how this assumption can be removed. Assume without loss of generality that $m \geq n/2$, since an initial step of the algorithm can use $n/\log n$ processors to remove any vertices with no edges.

7.1. Assuming $p > \log^2 n$. For now, assume that $p > \log^2 n$. Observe first that in this case the difference between using pn and $pn/\log n$ processors can be ignored, since for $p > \log^2 n$, $\log \frac{\log n}{\log p} = \Theta(\log \frac{\log n}{\log(p/\log n)})$. Thus the only need is to perform the m-processor steps with $m/\log n$ processors.

To do so, note that m processors are used for only one purpose: to update the edge list after leaders have been identified. There are three phases in this update process.

1. Replace the edge (i, j) by the edge $(\mathit{leader}(i), \mathit{leader}(j))$.
2. Detect and remove *dead* edges, namely, those that now have the form (i, i) because both endpoints chose the same leader.
3. Sort the remaining edges to remove duplicates and create edge lists for the contracted graph.

The real sticking point in this process is step 3. Since potentially nearly m edges may remain in the contracted graph, and since sorting them requires $\Omega(m \log m)$ work, it is unclear how step 3 can be performed.[3] Getting around this problem is the main topic of this section.

We begin by showing that steps 1 and 2 are easy to perform with $m/\log n$ processors. We allocate the processors according to the following scheme. Break the list of edges into sequential blocks of size $\log n$ and assign one processor to each block. Recall that the edge list is sorted by the first vertex in each edge. Therefore, the ith block contains first some of the edges of some first vertex f_i, then all the edges of some set of vertices V_i, and finally some of the edges of a last vertex l_i.

The advantage of this assignment is that it allows us to simulate, in $O(\log n)$ time, a single concurrent read by each edge (i, j) of some information from vertex i, and similarly, in $O(\log n)$ time, concurrent writes (with any conflict resolution scheme desired) by each edge (i, j) to vertex i. To simulate the read, proceed as follows. First use the standard concurrent read simulation to let processor i read from f_i and l_i into its local memory; these two reads take $O(\log n)$ time. Then each processor updates the $\log n$ edges it is responsible for—these updates now require only exclusive reads from its local copies of f_i and l_i or from the global values in the vertices V_i. The concurrent write simulation is similar.

Exploiting this simulation, we will freely use instructions of the form "each edge (i, j) reads from or writes to its vertex i," with the understanding that each such step actually takes $O(\log n)$ time.

One other small change is that it is necessary for each edge (i, j) to have a pointer to its *twin* edge (j, i) that is maintained as edges are moved around.

It is now easy to perform step 1 in $O(\log n)$ time—each edge (i, j) concurrently reads $\mathit{leader}(i)$ and replaces i by $\mathit{leader}(i)$ in (i, j) and in its twin (j, i). Step 2 can be performed easily by $m/\log n$ processors in $O(\log n)$ time with a standard array compaction algorithm.

It remains to deal with the difficulty of step 3. The approach we take is to ensure that the number of edges remaining after step 2 (counting duplications) is small, so that few processors are needed to perform step 3. We use the following lemma.

LEMMA 7.1. *If each edge of a graph is selected independently with probability q and connected components induced by the selected edges are contracted in the original graph, then with high probability the number of edges of the contracted graph is $O(n \ln n/q)$.*

In [KKT95], the number of remaining edges is shown to be $O(n/q)$ with high probability; this does not improve our application.

Proof. The number of edges in the contracted graph is just the number of edges crossing between the different connected components induced by the selected edges. The number of different arrangements of connected components is certainly no more than the number of ways to partition the set of n vertices into at most n groups, namely, n^n. For any given partition with k edges crossing between the components of the partition, the probability that no crossing edge is chosen is $(1 - q)^k \approx e^{-kq}$. The

[3] Possibly some form of bucket sort could be used to circumvent the sorting lower bound.

probability that k edges cross the partition resulting from the sampling construction is just the probability that for some partition with at least k crossing edges, no one of these k edges is chosen. This is at most $n^n e^{-kq} = e^{n \ln n - kq}$, which is negligible when $kq = \Omega(n \ln n)$. □

We therefore use the following approach: Given an m-edge graph, choose $m/\log n$ edges at random, and using $(m+pn)/\log n$ processors and the basic algorithm, compute connected components in this sampled graph in $O(\log n \log\log_p n)$ time. This labels all vertices in a given connected component of the sampled graph with a single vertex. If we treat the label of a vertex as its choice of a leader, then we can contract the original graph as if a walk phase has been performed. We use $m/\log n$ processors to relabel the edges and remove dead edges as was described at the beginning of this section. Lemma 7.1 shows that at this point $O(n \log^2 n)$ edges remain, so $O(n \log^2 n)$ processors suffice to perform step 3, sorting the edges and removing duplicates. We can finish the calculation by finding connected components in the resulting contracted graph; since the number of edges in the graph is $O(n \log^2 n)$, and since by assumption the number of processors is $pn > n \log^2 n$, this can be done in $O(\log n \log\log_p n)$ time with the available processors.

Thus when $p > \log^2 n$, connected components can be found in $O(\log n \log\log_p n)$ time using $O((m+pn)/\log n)$ processors.

7.2. Removing the assumption. We now handle the case $p < \log^2 n$. With such a value of p, the running time that we must achieve is $O(\log n \log\log n)$. Assume that in fact $p = 1$, since this merely restricts us further.

It suffices to find a procedure that, in $O(\log n)$ time and using $(m+n)/\log n$ processors, reduces the number of vertices by a constant factor. After $O(\log\log n)$ phases of this procedure, the graph will have $n' = O(n/\log^3 n)$ vertices. The algorithm of the previous section can be applied to solve this graph in $O(\log n \log\log n)$ time using $O(m/\log n + n' \log^2 n) = O((m+n)/\log n)$ processors.

We use the same allocation of processors to blocks of $\log n$ edges that was used previously, allowing the same simulation of concurrent reads and writes. The following procedure reduces the number of vertices in the graph by at least half in $O(\log n)$ time using $(m+n)/\log n$ processors.

1. For each vertex, compute the identity of its largest and smallest neighbors. To find the maximum, each edge (i,j) concurrently writes j to vertex i, letting multiple writes yield the maximum value written. Then do the same for the minimum value.
2. It is necessarily the case that either half the vertices have a larger neighbor or that half the vertices have a smaller neighbor. Which case we are in can be determined in $O(\log n)$ time using $n/\log n$ processors and the information from the previous step. Assume the first case; the other can be handled the same way.
3. Call vertices with no larger neighbors *leaders,* as before. The largest vertex j that is a neighbor of a nonleader vertex i becomes the *parent* of i as before. Mark the edge (i,j) in i's edge list, as well as its twin edge (j,i) in j's edge list.
4. Each vertex i can now identify its children: it examines its edges (i,j) and checks which ones were marked in the previous step.
5. Once each vertex has identified both parent and children, use the Euler tour technique to transform each tree of parent pointers into a list of the vertices in the tree and to identify the leader of each vertex.

6. Having identified leaders, relabel the edge list precisely as was done in section 7.1.
7. Since there is a linked list of vertices for each leader, and since each vertex has a contiguous list of its edges, we have an implicit linked list of all the edges that will be incident to a given leader after the graph is contracted. This allows us to use optimal list ranking to count the number of edges belonging to each leader in $O(\log n)$ time with $n/\log n$ processors and to rank them.
8. Take a length n array and write into the kth position the number of edges belonging to k if k is a leader, and 0 otherwise. Then, using array compaction, each leader can find the number of edges belonging to the leaders that precede it in the contracted graph.
9. The list ranking information just described suffices to determine the position each edge should be copied to in the edge array of the contracted graph, so the copying can be done in $O(\log n)$ time.

Note that duplicate edges do not affect this procedure, so we can ignore them until we reduce to the case of $p > \log^2 n$. Lemma 7.1, used to reduce to $m/\log n$ processors, holds even when duplicate edges exist. We do need to remove duplicates from the set of $m/\log n$ edges that we sample for the first application of the random walk algorithm, but the $m/\log n$ processors that we have are sufficient to do this by sorting.

8. Conclusion. Since the publication of the preliminary version of this paper [KNP92], Halperin and Zwick [HZ94] have used it to derive a work- and processor-optimal randomized EREW-connected components algorithm. The obvious remaining open problem is to find a deterministic $O(\log n)$-time EREW algorithm for connected components. One way to work toward this goal is to improve on the bounded space universal traversal sequence construction which is used in our deterministic algorithm, since any improvement in the space needed immediately yields a faster algorithm. There also remains an intriguing gap in the CRCW model, where the best-known algorithm has running time $O(\log n)$, but the best-known lower bound is $\Omega(\log n/\log\log n)$.

Acknowledgments. Thanks to Daphne Koller, who made our collaboration possible. Thanks also to Rajeev Motwani and Serge Plotkin for helpful discussions.

PRODUCTS AND HELP BITS IN DECISION TREES*

NOAM NISAN†, STEVEN RUDICH‡, AND MICHAEL SAKS§

Abstract. We investigate two problems concerning the complexity of evaluating a function f on k distinct inputs by k parallel decision-tree algorithms.

In the *product problem*, for some fixed depth bound d, we seek to maximize the fraction of input k-tuples for which all k decision trees are correct. Assume that for a single input to f, the best depth-d decision tree is correct on a fraction p of inputs. We prove that the maximum fraction of k-tuples on which k depth-d algorithms are all correct is at most p^k, which is the trivial lower bound. We show that if we replace the restriction to depth d by "expected depth d," then this result need not hold.

In the *help-bits problem*, before the decision-tree computations begin, up to $k-1$ *arbitrary* binary questions (help-bit queries) can be asked about the k-tuple of inputs. In the second stage, for each possible $(k-1)$-tuple of answers to the help-bit queries, there is a k-tuple of decision trees where the ith tree is supposed to correctly compute the value of the function on the ith input, for any input that is consistent with the help bits. The complexity here is the maximum depth of any of the trees in the algorithm. We show that for all k sufficiently large, this complexity is equal to $deg^s(f)$, which is the minimum degree of a multivariate polynomial whose sign is equal to f.

Key words. decision trees, help bits

1. Introduction.

Pick your favorite computation model and complexity measure, e.g., Boolean circuit size, communication complexity, decision-tree depth, interactive proof length, tensor rank, etc. Any attempt to understand such a model and complexity measure requires understanding the ways that an "unreasonable" computation can be more efficient than a "reasonable" one. Of course, what is reasonable changes as our understanding of the model improves.

Suppose we are given several unrelated instances of a problem to solve. The "reasonable" approach is to solve each instance separately; intuitively, any computation that is useful for solving one instance is irrelevant to any of the others. To what extent is this intuition valid in a given model? The following question is the most common way of formalizing this.

The direct-sum problem. Suppose that the complexity of computing some function f is c. Is it true that computing f twice, on two unrelated inputs, requires complexity $2c$? How about computing f on k unrelated inputs?

Versions of this question were first studied in the context of Boolean circuits [Ulig, Paul, GF]. Subsequent work has concerned bilinear circuits [JT, Bsh], Boolean circuits [FKN], communication complexity [KRW, KKN], and interactive proofs (see

the references contained in [Raz]). In this paper we consider two related problems of a similar flavor.

The product problem. Let f be a function, and suppose that for any allowable computation that has complexity bounded by c and attempts to compute f, the fraction of inputs on which it correctly computes f is at most p. Suppose that we have two independent computations, each taking as input the same ordered pair a, b of inputs to f, where the first computation is trying to compute $f(a)$ and the second is trying to compute $f(b)$. If each of the two computations has complexity at most c, can the fraction of input pairs a, b on which both are correct exceed p^2? What about the analogous question for k independent computations and k inputs?

If the first computation accesses only a and the second accesses only b, then the p^2 upper bound is trivial. Intuition suggests that there is no advantage in having each computation access the input of the other. A variant of this problem, in which we seek to compute f on the two inputs by a single computation, was studied recently in [IRW]. A version of this problem for interactive proofs, the well-known "parallel repetition problem," was recently solved by Raz [Raz].

The help-bit problem. Suppose that the complexity of exactly computing the Boolean function f is c. Suppose that we wish to compute f on two inputs a and b, and are allowed for free one "help bit," i.e., an arbitrary function of the two inputs. Is it possible to choose this help-bit function so that, given the help bit, $f(a)$ and $f(b)$ can each be evaluated by a computation of complexity less than c, and if so, how much can the complexity be reduced below c? How about computing f on k inputs with $k-1$ help bits?

The notion of help bits is essentially the same as that of bounded queries, which were studied in recursion theory [Be87]. The term "help bit" was introduced in the context of constant depth circuits in [Cai] and was also studied in the context of Boolean circuits in [ABG]. The point here is that if we have k inputs, then we can use k help bits to obtain the value of f on each of the inputs, and no further computation is necessary. With only $k-1$ help bits, we can for instance obtain the value of f at $k-1$ inputs, but then we still need complexity c to compute f on the last input. Is there a more effective use of the help bits?

In this paper we consider these problems in the context of Boolean decision-tree complexity—perhaps the simplest computational model. The cost of a computation (decision tree) is simply the number of input variables that are read (the depth of the decision tree); a more precise definition is given in section 2. While it is an easy exercise to see that "direct-sum" holds for decision-tree depth, the other two problems are more difficult. Our answer for the product problem is a qualified "Yes."

THEOREM 1.1. *Let f be a Boolean function and suppose that any depth-d decision tree computes f correctly on a fraction at most p of the inputs. Let $T_1, \ldots, T_k$ be decision trees that each access a set of nk variables corresponding to a k-tuple $\alpha^1, \ldots, \alpha^k$ of inputs to f. If each of the T_i has depth at most d, then the fraction of k-tuples $\alpha^1, \ldots, \alpha^k$ on which each T_i correctly outputs $f(\alpha^i)$ is at most p^k.*

The theorem seems completely obvious; however, readers might test their intuition on the following variation. Suppose that in the above theorem we change the complexity measure from "depth" to "average depth," i.e, the average over all inputs of the depth of the leaf reached by the input. This modified statement of the theorem seems similarly obvious but, as we will see, it is false.

The recent work of [IRW], which was done independently of ours, includes a (substantially different) proof of a weaker variant of this theorem, namely that a

single depth-d tree that tries to compute all k functions can be correct on at most a p^k fraction of the inputs. Our result shows that even if we use k parallel decision trees then we can't do better than this.

For the help-bit problem, the answer is more complicated. Linial [Lin] has shown that the complexity of computing f on two inputs with one help bit is at least $deg(f)$, the degree of the (unique) multilinear real polynomial that is equal to f. Since almost all Boolean functions on n variables have $deg(f) = n$, this says that for most functions one help bit does not help at all in evaluating two instances of the function (the case $k = 2$). It is natural to ask whether there are any functions for which one help bit helps.[1] Here, we show that for sufficiently large k, $k - 1$ help bits usually do help in computing a function on k different inputs. We manage to prove a lower bound that holds for all k, and is always tight when k, the number of instances to be solved, is sufficiently large. We need the following definitions. If f is an n-variate Boolean function, we say that the n variate real polynomial p *sign represents* f if for all inputs a, $f(a) = sgn(p(a))$, where $sgn(z) = 1$ if $z > 0$ and $sgn(z) = -1$ otherwise (here we are taking our Boolean set to be $\{-1, 1\}$). The *sign degree* of f, $deg^s(f)$, is the minimum degree of a polynomial that sign represents f. The sign degree of a function has been studied extensively in connection with threshold circuits and counting complexity classes. See the surveys [Sa93] and [Be93].

THEOREM 1.2. *Let f be an n-variate Boolean function. Then for all $k \geq 1$, any solution to the help-bit problem for f for k inputs and $k - 1$ help bits requires depth at least $deg^s(f)$. Furthermore, for all sufficiently large k, there is a decision-tree algorithm with $k - 1$ help bits whose depth is $deg^s(f)$.*

In the case that f is equal to the product of n variables (which corresponds to the parity function for $\{0, 1\}$-valued variables), $deg^s(f) = n$ and so the lower bound implies that help bits don't help in this case. Actually, this function and its negative are the only functions with $deg^s(f) = n$. Since the ordinary decision-tree complexity of most Boolean functions is n, this means that for large enough k, the complexity of k instances given $k - 1$ help bits is less than the ordinary decision-tree complexity for most functions. In particular, if f is the majority function, then $deg^s(f) = 1$, and the lower bound is trivial, while the upper bound says that for k sufficiently large, it is possible to ask $k - 1$ binary questions so that, given the answers, the value of the function on any one of the k inputs can be computed by probing just one variable. This remarkable savings is not typical; it has been observed by Anthony [Ant] and by N. Alon (personal communication) that almost all Boolean functions f satisfy $deg^s(f) \geq \lfloor n/2 \rfloor$.

In the next section, we review the decision-tree model. In section 3 we give a general formulation for the product problem in decision trees, and prove a generalization (Theorem 3.1) of Theorem 1.1. In section 4, we discuss the help-bit problem and prove Theorem 1.2.

2. Preliminaries. In this section we present some basic definitions and notation. Most of the notions discussed here are very familiar, but in some cases our notation is nonstandard.

2.1. Boolean functions. For the purposes of this paper it will be convenient to use $B = \{-1, 1\}$ as our Boolean set, instead of $\{0, 1\}$ (this choice of B is only significant in section 4). If X is a set, a *Boolean assignment* to X is a map α from X

[1] This question was recently answered in the negative by Beigel and Hirst [BH], who showed more generally that $\lfloor \log_2 k \rfloor$ help bits don't help for computing k functions.

to B. The set of Boolean assignments to X is denoted B^X. We refer to the elements of X as *variables*. We will consider probability distributions over the set of assignments. For a specified distribution D, a random assignment chosen according to D is denoted by placing a $\tilde{}$ above the identifier, e.g., $\tilde{\alpha}$. A *Boolean function* over the variable set X is a function with domain B^X. In this paper, the range of our functions will always be equal to B^k for some integer k.

2.2. Decision trees. All trees in this paper are rooted, ordered, binary trees. For such a tree T every internal node v has exactly two children, and the two children are distinguished as the (-1)-child and $(+1)$-child of v. The depth $d_T(v)$ of a node v is, as usual, the number of edges along the path from v to the root, and the depth d_T of T is the maximum depth of any node in T.

Formally, a *decision tree over* X is a triple (T, p, a), where T is a rooted, ordered, binary tree, p is a map that associates to each internal node v a variable $x = p_v$ in the set X, and a is a map that associates each leaf v with an element a_v of some set R. The label p_v is called the *query* associated with v, and node v is said to *probe* variable p_v. We will generally say that T is a decision tree, keeping the maps p and a implicit. The set of decision trees over X is denoted $\mathcal{T}(X)$, or simply $\mathcal{T}$.

Let T be a decision tree over X. If α is any assignment in B^X, the *computation* of T on α is the unique path $v^0, v^1, \ldots, v^s$ from the root of T to some leaf $v^s = l_T(\alpha)$ as follows: start from the root v^0 and inductively define v^{i+1} for $i \geq 0$ as the $\alpha(p_{v^i})$-child of v^i. The output of the computation is the label $a_{l_T(\alpha)}$. Thus T can be viewed as a Boolean function over X. Trivially, every function f over X is computed by some decision tree.

In the following definitions $\alpha \in B^X$, f is some function over X, T is a decision tree over X, $\mathcal{U}$ is a set of decision trees over X, d is a nonnegative integer, and D is a probability distribution over assignments to X.

- $C(T, \alpha)$, the *cost* of T on α, is the length (number of internal nodes) of the corresponding computation path.
- $C(T)$, the *complexity* or *depth* of T, is the maximum of $C(T, \beta)$ over all assignments β.
- $\mathcal{T}_d = \mathcal{T}_d(X)$ is the set of all decision trees over X of depth at most d.
- $C_D(T)$, the *distributional complexity* of T with respect to D, is the average of $C(T, \tilde{\alpha})$ with respect to D, i.e., $C_D(T) = \sum_{\alpha \in B^X} D(\alpha) C(T, \alpha)$.
- $q_D(f, T)$, the *agreement probability* of T with f relative to D, is the probability that $T(\tilde{\alpha}) = f(\tilde{\alpha})$, with respect to the random assignment $\tilde{\alpha}$ chosen according to D.
- The *decision tree approximation problem* for $(f, D, \mathcal{U})$ is to determine $q_D(f; \mathcal{U})$, which is defined to be the maximum agreement probability $q_D(f; T)$ over all $T \in \mathcal{U}$.
- T/β, the *contraction* of T by β where β is an assignment to some subset Y of X, is the decision tree on the variable set $X - Y$ that corresponds to executing T with the modification that whenever the current node v is labeled by $y \in Y$, follow the $\beta(y)$ branch without probing y. Formally, the tree T/β is obtained from T as follows: for each internal node v whose label p_v belongs to Y, replace the subtree rooted at v by the subtree rooted at the $\beta(p_v)$-child of v.
- A *decision forest* F over X is an ordered sequence $T_1, \ldots, T_k$, where T_i is a decision tree over X. F computes a Boolean function one short whose domain is B^X and whose range is $R = R_1 \times R_2 \times \cdots \times R_k$, where R_i is the range of

the function computed by T_i.

The following example illustrates some of the definitions.

Example 1. Consider the case of four variables, $X = \{x_1, x_2, x_3, x_4\}$, where $f(x_1, x_2, x_3, x_4) = (x_1 \wedge x_2) \vee (x_3 \wedge x_4)$. (Since our Boolean set is $\{-1, 1\}$ we treat -1 as the FALSE value here). Consider the distribution D on assignments in which the variables are assigned values independently, with x_1 and x_3 having probability p of being 1 and x_2 and x_4 having probability $1-p$ of being 1, where $p < 1/2$. Further, let $\mathcal{U}$ be the set $\mathcal{T}_2(X)$ of decision trees of depth at most 2. Let T be the following decision tree: First probe x_1. If $\alpha(x_1) = 1$, then probe x_2 and output $\alpha(x_2)$. Otherwise, if $\alpha(x_1) = -1$, probe x_3 and output $\alpha(x_3)$. Then this tree has depth 2, and it is easy to see that this algorithm will output $f(\alpha)$ unless $\alpha(x_1) = \alpha(x_3) = \alpha(x_4) = 1$ and $\alpha(x_2) = -1$, or $\alpha(x_1) = \alpha(x_4) = -1$ and $\alpha(x_3) = 1$. Thus the probability of agreement, $q_D(f; T)$, is $1-p^3(1-p)-p^2(1-p) = 1-p^2+p^4$. This turns out to be the largest agreement probability over all trees in $\mathcal{T}_2(X)$, so $q_D(f; \mathcal{T}_2(X)) = 1 - p^2 + p^4$.

3. The product problem. We now formalize the product problem stated in the introduction for the decision-tree model. Let $X_1, \ldots, X_k$ be pairwise-disjoint sets of variables, and let $D_1, \ldots, D_k$ be, respectively, distributions over assignments to $X_1, \ldots, X_k$. Let $X = X_1 \cup \cdots \cup X_k$. A Boolean assignment β for X will be viewed as a k-tuple $(\beta^1, \ldots, \beta^k)$, where β^i is an assignment for X_i. Let D denote the distribution over assignments to X given by $\mathrm{Prob}_D[\tilde{\alpha} = \beta] = \prod_{i=1}^{k} \mathrm{Prob}_{D_i}[\tilde{\alpha}^i = \beta^i]$, i.e., the product distribution $D_1 \times D_2 \times \cdots \times D_k$.

Now suppose that we have k decision-tree approximation problems $(f_1, D_1, \mathcal{U}_1), \ldots, (f_k, D_k, \mathcal{U}_k)$, where for each i, f_i is a function over X_i, and let $q_i = q_{D_i}(f_i; \mathcal{U}_i)$ be the optimal agreement probability for $\mathcal{U}_i$ with f_i relative to D_i. It will be convenient sometimes to view f_i as a function of the entire variable set X that does not depend on any variables except those in X_i. We consider the problem of *simultaneously approximating* $f_1, \ldots, f_k$ by a decision forest $F = (T_1, \ldots, T_k)$ where $T_i \in \mathcal{U}_i$. The *simultaneous agreement probability* $q_D(f_1, \ldots, f_k; T_1, \ldots, T_k)$ for $T_1, \ldots, T_k$ with $f_1, \ldots, f_k$ denotes the probability, for $\tilde{\alpha}$ chosen according to D, that $(T_1(\tilde{\alpha}) = f_1(\tilde{\alpha})) \wedge (T_2(\tilde{\alpha}) = f_2(\tilde{\alpha})) \wedge \cdots \wedge (T_k(\tilde{\alpha}) = f_k(\tilde{\alpha}))$. For $\mathcal{U}_1, \ldots, \mathcal{U}_k$ where $\mathcal{U}_i$ is a set of trees over X we define (see Example 2)

$$q_D(f_1, \ldots, f_k; \mathcal{U}_1, \ldots, \mathcal{U}_k) = \max\{q_D(f_1, \ldots, f_k; T_1, \ldots, T_k) : T_1 \in \mathcal{U}_1, \cdots, T_k \in \mathcal{U}_k\}.$$

Now, since f_i depends only on X_i, and since under D the assignments $\tilde{\alpha}^1, \ldots, \tilde{\alpha}^k$ to $X_1, \ldots, X_k$ are chosen independently, it would seem that $q_D(f_1, \ldots, f_k; T_1, \ldots, T_k)$ should just be the product of the probabilities $q_{D_i}(f_i; T_i)$. This is clearly the case if each tree T_i only queries variables in X_i. However (as shown by the examples below), if T_i is allowed to query variables outside of X_i, then this need not be the case. Intuitively, it would seem that variables outside of X_i could not help to approximate f_i and indeed this is trivially true, if we are only trying to approximate f_i. But when we seek to approximate all of the functions simultaneously, it is no longer true that such "cross-queries" are irrelevant.

Nevertheless, we might expect that for "reasonable" classes $\mathcal{U}_1, \ldots, \mathcal{U}_k$ of decision trees, the optimal simultaneous agreement probability is attained by a sequence of trees $T_1, \ldots, T_k$ with T_i querying variables only in X_i, and is thus equal to the product of the individual optimal agreement probabilities. The main result of this section is to prove this in the case that for each i, $\mathcal{U}_i$ is the set of trees of some fixed depth d_i.

THEOREM 3.1. *Let $f_1, \ldots, f_k$ and $D_1, \ldots, D_k, D$ be as above. Let $d_1, \ldots, d_k$ be nonnegative integers. Then*

$$q_D(f_1, \ldots, f_k; \mathcal{T}_{d_1}, \ldots, \mathcal{T}_{d_k}) = \prod_{i=1}^{k} q_{D_i}(f_i, \mathcal{T}_{d_i}).$$

Note that Theorem 1.1 is a special case of the above. Before giving the proof we present two examples to show that multiplicativity fails for some natural alternative choices of the classes $\mathcal{U}_1, \ldots, \mathcal{U}_k$.

Example 2. Theorem 3.1 fails if we replace the class $\mathcal{T}_{d_i}$ by the class $\mathcal{S}^i_{d_i}$ of trees that are restricted to query at most d_i variables from X_i along any path but can query any number of variables outside X_i. Consider the following trivial example. Let $k = 2$ and let $X_1 = \{x_1\}, X_2 = \{x_2\}$. The distribution D_1 assigns x_1 to 1 with probability $1/2$, and D_2 assigns x_2 to 1 with probability $1/2$, so $\tilde{\alpha}$ is uniformly distributed on B^2. The functions f_1 and f_2 are given by $f_1(x_1) = x_1, f_2(x_2) = x_2$. Now let $d_1 = d_2 = 0$. This means that we do not allow T_1 to look at any variables in X_1 and we do not allow T_2 to look at any variables in X_2. Clearly $q_{D_1}(f_1, \mathcal{S}^1_0) = q_{D_2}(f_2, \mathcal{S}^2_0) = 1/2$. However, we can achieve simultaneous agreement probability better than $1/4$. Let T_1 be the tree that queries x_2 and outputs $\tilde{\alpha}(x_2)$ and T_2 be the tree that queries x_1 and outputs $\tilde{\alpha}(x_1)$. Then, the probability that both T_1 and f_1 agree and T_2 and f_2 agree is just the probability that x_1 and x_2 are assigned the same value, which is $1/2$.

A somewhat more subtle example is the following.

Example 3. For a distribution D over B^X, let $\mathcal{T}^D_d$ be the class of trees whose expected depth with respect to D is d, i.e., $T \in \mathcal{T}^D_d$ if the average number of variables queried with respect to $\tilde{\alpha}$ chosen from D is at most d. Then the above theorem becomes false if we replace $\mathcal{T}_{d_i}$ with $\mathcal{T}^{D_i}_{d_i}$. To see this, let X be a set of four variables, and f be the product of the variables. Let U be the uniform distribution over assignments to X and let $d = 3$. First we show that the maximum agreement probability with f attained by a decision tree S of expected depth at most 3 is equal to $3/4$. Agreement probability $3/4$ is attained by the tree S that queries a particular variable x, and if it is -1, then it returns -1, and otherwise it queries the remaining three variables and returns their product. To see that this is the best possible, note that if T is any decision tree, then for each leaf l in T of depth less than 4, T will agree with f on exactly half of the inputs that reach l. Thus, if p_i is the probability that a random input $\tilde{\alpha}$ ends up at a leaf of depth i, then the agreement probability $q_D(f; T)$ can be bounded above by $p_4 + 1/2(1 - p_4)$; it suffices to show that $p_4 \leq 1/2$. Now p_1 either equals 0, $1/2$, or 1. If $p_1 > 0$ then $p_4 \leq 1/2$. If $p_1 = 0$, then the expected depth of the tree is at least $4p_4 + 2(1 - p_4) = 2 + 2p_4$, which means that $p_4 \leq 1/2$.

Now let X_1, f_1, D_1 and X_2, f_2, D_2 be copies of X, f, U on disjoint variable sets. We show that it is possible to choose decision trees T_1, T_2, each of expected depth at most 3, whose agreement probability exceeds $9/16 = (3/4)^2$. Let T_1 be the S described above and let x_1 denote the variable in X_1 probed first by T_1. Let T_2 be the following tree: first probe x_1 (in X_1). If it is -1, output -1. If it is $+1$, then probe all four variables in X_2 and output their product. The expected depth of this tree is 3, since half the paths have depth 1 and half the paths have depth 5. Now, let us consider the probability of the event A that both $T_1(\tilde{\alpha}) = f_1(\tilde{\alpha})$ and $T_2(\tilde{\alpha}) = T_2(\tilde{\alpha})$:

$$\text{Prob}_D[A] = \frac{1}{2}\text{Prob}_D[A \mid \tilde{\alpha}(x_1) = -1] + \frac{1}{2}\text{Prob}[A \mid \tilde{\alpha}(x_1) = 1].$$

The conditional probability of A given $\tilde{\alpha}(x_1) = -1$ is $1/4$ and the conditional probability of A given $\tilde{\alpha}(x_1) = 1$ is 1. Thus the probability of simultaneous agreement is $5/8$.

What happens in the above example is that the variable x_1 acts as a shared random coin that partially coordinates the two computations so that they are more likely to be simultaneously correct. On the face of it, it seems quite possible that a similar trick might also help for the class of trees covered by the theorem; but as we now show, no such trick can work in this case.

Proof of Theorem 3.1. Fix a sequence $T_1, \ldots, T_k$ of decision trees with T_i of depth at most d_i, and let $\tilde{\alpha} = (\tilde{\alpha}^1, \ldots, \tilde{\alpha}^k)$ be a random assignment to $X = X_1 \cup \cdots \cup X_k$ chosen according to the distribution D. For $I \subseteq [k] = \{1, \ldots, k\}$, let $C(I)$ denote the event $\bigwedge_{i \in I}(T_i(\alpha) = f_i(\alpha^i))$, i.e., the event that all of the trees indexed by I evaluate their respective functions correctly. We seek to prove that $\mathrm{Prob}[C([k])]$ is bounded above by $\prod_{i=1}^{k} q_{D_i}(f_i, \mathcal{T}_{d_i})$.

The proof is by induction on k, and for fixed k by induction on $d_1 + \cdots + d_k$. The result is trivial if $k = 1$.

So assume that $k \geq 2$. Consider first the case that $d_i = 0$ for some i. We may assume that $d_k = 0$. Thus, the kth computation must guess the value of $f_k(\tilde{\alpha}^k)$ without looking at any variables, so T_k consists of a single leaf labeled -1 or 1; i.e., $T_k(\alpha)$ is a constant $t \in B$. Now, by conditioning on the value of the vector $\tilde{\alpha}^k$, the probability, P^*, that $C([k])$ holds can be bounded above:

$$\begin{aligned}
P^* &\leq \sum_{\beta^k \in B^{X_k} \mid f_k(\beta^k) = t} \mathrm{Prob}[\tilde{\alpha}^k = \beta^k] \times \mathrm{Prob}[C([k-1]) \mid \tilde{\alpha}^k = \beta^k] \\
&\leq \max_{\beta^k \in B^{X_k}} \mathrm{Prob}[C([k-1]) \mid \tilde{\alpha}^k = \beta^k] \times \sum_{\beta^k \in B^{X_k} \mid f_k(\beta^k) = t} \mathrm{Prob}[\tilde{\alpha}^k = \beta^k] \\
&= \max_{\beta^k \in B^{X_k}} \mathrm{Prob}[C([k-1]) \mid \tilde{\alpha}^k = \beta^k] \times \mathrm{Prob}[T_k(\tilde{\alpha}^k) = f_k(\tilde{\alpha}^k)] \\
&\leq \max_{\beta^k \in B^{X_k}} \mathrm{Prob}[C([k-1]) \mid \tilde{\alpha}^k = \beta^k] \times q_{D_k}(f_k, \mathcal{T}_0).
\end{aligned}$$

Now let γ be the value of β^k that maximizes the probability in the last expression. For each i between 1 and $k-1$, define the tree U_i by contracting T_i using $\tilde{\alpha}^k = \gamma$. Then we may rewrite the last term as

$$\mathrm{Prob}[(U_1(\tilde{\alpha}) = f_1(\tilde{\alpha})) \wedge \cdots \wedge (U_{k-1}(\tilde{\alpha}) = f_{k-1}(\tilde{\alpha}))] \times q_{D_k}(f_k, \mathcal{T}_0).$$

Each tree U_i has depth at most d_i, and so we may bound the first factor by $q_D(f_1, \ldots, f_{k-1}; \mathcal{T}_{d_1}, \ldots, \mathcal{T}_{d_{k-1}})$, which is equal to $\prod_{i=1}^{k-1} q_{D_i}(f_i, \mathcal{T}_{d_i})$, by the induction hypothesis. Thus the desired result follows.

Now we assume that $d_i > 0$ for all i. Define a directed graph on $\{1, \ldots, k\}$ with an edge from i to j if the first variable probed by T_i is an input to f_j. Since this directed graph has out-degree one, it has a directed cycle, which may be a self-loop. Let $j \geq 1$ be the length of the cycle. Let us reindex the trees so that the vertices of the cycle in order are $1, \ldots, j$. Thus for each $i < j$, the first probe of T_i is a variable in X_{i+1} (which we will denote x_{i+1}) and the first probe of T_j is a variable, denoted x_1, in X_1. The case $j = 1$ does not have to be treated as a special case.

In the rest of the proof, we analyze the probability of simultaneous agreement of the trees with their corresponding functions by conditioning on the assignments to $x_1, \ldots, x_j$. This will enable us to apply the induction hypothesis and prove the theorem. For the case $j = 1$ this is easy; for $j > 1$ the underlying intuition is that it

is possible simultaneously to replace each of the trees T_i for $i \in [j]$, by trees T_i' of the same depth in which the first probe in T_i' is x_i, without decreasing the probability of simultaneous agreement.

For $b \in B$, let f_i^b denote the function obtained from f_i by fixing $x_i = b$. Also, let D_i^b be the distribution on the set $X_i - x_i$ obtained from D_i by conditioning on $x_i = b$.

Now, for $\mathbf{b} = (b_1, \ldots, b_j) \in B^j$, let $A(\mathbf{b})$ denote the event that $(\tilde{\alpha}(x_1) = b_1) \wedge \cdots \wedge (\tilde{\alpha}(x_j) = b_j)$. We can write the probability that all of the T_i compute correctly by conditioning on $\mathbf{b}$ as follows:

$$\sum_{\mathbf{b} \in B^{[j]}} \text{Prob}[A(\mathbf{b})]\text{Prob}[C([k]) \mid A(\mathbf{b})]. \tag{1}$$

We seek to upper-bound this expression by

$$\prod_{i=1}^{k} q_{D_i}(f_i, \mathcal{T}_{d_i}). \tag{2}$$

To do this we show the following.

Claim. For each $\mathbf{b} \in B^{[j]}$, the conditional probability of $C([k])$ given $A(\mathbf{b})$ is at most

$$\left(\prod_{i=1}^{j} q_{D_i^{b_i}}(f_i^{b_i}, \mathcal{T}_{d_i - 1})\right)\left(\prod_{i=j+1}^{k} q_{D_i}(f_i, \mathcal{T}_{d_i})\right).$$

Assuming the claim for the moment, we can then substitute into (1) to obtain the following bound on the probability that all of the trees are correct:

$$\left(\prod_{i=j+1}^{k} q_{D_i}(f_i, \mathcal{T}_{d_i})\right)\left(\sum_{\mathbf{b} \in B^j} \text{Prob}[A(\mathbf{b})] \prod_{i=1}^{j} q_{D_i^{b_i}}(f_i^{b_i}, \mathcal{T}_{d_i - 1})\right). \tag{3}$$

The sum can be rewritten as

$$\sum_{\mathbf{b} \in B^j} \prod_{i=1}^{j} \text{Prob}[\tilde{\alpha}(x_i) = b_i] q_{D_i^{b_i}}(f_i^{b_i}, \mathcal{T}_{d_i - 1}),$$

which is equal to

$$\prod_{i=1}^{j} \left(\text{Prob}[\tilde{\alpha}(x_i) = -1] q_{D_i^{-1}}(f_i^{-1}, \mathcal{T}_{d_i - 1}) \quad + \quad \text{Prob}[\tilde{\alpha}(x_i) = 1] q_{D_i^{1}}(f_i^{1}, \mathcal{T}_{d_i - 1})\right).$$

Now, the ith term in this product corresponds to the probability of correctly computing f_i if we first probe x_i and then, depending on the outcome, use the optimal depth $d_i - 1$ tree to evaluate the residual function. Thus, we can upper-bound this term by $q_{D_i}(f_i, \mathcal{T}_{d_i})$. But then (3) is upper-bounded by (2) as required.

So it suffices to prove the claim. Define $f_i^{A(\mathbf{b})}$ to be the function $f_i^{b_i}$ for $i \leq j$ and to be f_i otherwise. Similarly, the distribution $D_i^{A(\mathbf{b})}$ is equal to $D_i^{b_i}$ for $i \leq j$ and to D_i otherwise. Observe that by the mutual independence of $\tilde{\alpha}^1, \ldots, \tilde{\alpha}^k$, their joint distribution given $A(\mathbf{b})$ is the product distribution of $D_i^{A(\mathbf{b})}$ for i between 1 and k.

Let $T_i^{A(\mathbf{b})}$ be the tree obtained by contracting T_i under the assumption that $A(\mathbf{b})$ holds. Then the conditional probability given $A(\mathbf{b})$ that $T_i(\alpha) = f_i(\alpha^i)$ for all i, is equal to the probability (with respect to the product distribution on $D_i^{A(\mathbf{b})}$) that for all i, $T_i^{A(\mathbf{b})} = f_i^{A(\mathbf{b})}$. Now for each i the depth of $T_i^{A(\mathbf{b})}$ is at most $d_i - 1$ if $i \leq j$, and is at most d_i for $i > j$, so we may apply induction to say that the probability, with respect to the product distribution on $D_i^{A(\mathbf{b})}$, that $T_i^{A(\mathbf{b})} = f_i^{A(\mathbf{b})}$ for every i, is at most

$$\left(\prod_{i=1}^{j} q_{D_i^{A(\mathbf{b})}}(f_i^{A(\mathbf{b})}, \mathcal{T}_{d_i-1})\right)\left(\prod_{i=j+1}^{k} q_{D_i^{A(\mathbf{b})}}(f_i^{A(\mathbf{b})}, \mathcal{T}_{d_i})\right),$$

which is equal to the expression in the claim. This proves both the claim and the theorem. □

Remark 1. The proof of the theorem can be extended to a more general model of decision-tree computation. For this model, in the case of a single function we are given a function f on an arbitrary domain S, and want to compute $f(s)$ for an unknown input $s \in S$. We are further given a set Q of admissible queries, where each query $q \in Q$ is a partition of S into sets $(S_1^q, \ldots S_r^q)$. The response to query q is the index i such that $s \in S_i^q$. The nodes of a decision tree are labeled by queries, and the branches out of the node correspond to the answers to the query. For a set of functions f_i on disjoint domains S_i, the formulation of the product problem generalizes to this model. The statement and proof of the theorem now go through assuming that (1) each allowed query depends only on variables from one function and (2) the distributions D_i are independent.

4. Help bits. The help-bits model can be formulated with respect to any model of computation. Informally, we have a function g which we wish to compute using an algorithm from a given class of algorithms. Before we begin computing, we are allowed to ask a certain number of *arbitrary* binary questions about the input. Based on the answers to these questions we choose an algorithm and then do the computation on the input. The answers to the preliminary questions are referred to as "help bits." We say that g is computable by a class of algorithms using h help bits if there is such a procedure that uses at most h questions and correctly evaluates g on all inputs.

As was observed previously in specific computational contexts [Be87, CH], the problem of whether g can be computed with h help bits can be recast as a cover problem. Given g and a class of algorithms, we wish to choose a set of algorithms from the class that covers all inputs in the sense that for each input x, there is at least one algorithm in the chosen set that outputs $g(x)$. We refer to such a set of algorithms as a *cover* of g. Then g is computable by the class of algorithms using h help bits if and only if there is a cover of g of size 2^h. To see this, suppose that g is computable by the class using h help bits. Then each of the 2^h possible sets of answers to the questions specifies an algorithm in the class, and these algorithms together are a cover of g. Conversely, given a cover of size 2^h, index the algorithms in the cover by Boolean strings of length h, and for each input x choose a Boolean string b_x that indexes an algorithm $A(b_x)$ in the cover that correctly evaluates $g(x)$. Then we may take our help-bit queries to be, "What are the bits of b_x?"

Note that, provided that the class of algorithms includes all constant functions, any function g whose range has size at most 2^h is trivially computable using h help bits, so the problem is only interesting for functions whose range is "large enough."

In this paper we are interested in the special case of the help-bits problem where the function we are computing is a Cartesian product $\bar{f}$ of Boolean functions $f_1, \ldots, f_k$ over disjoint variable sets $X_1, \ldots, X_k$. The function $\bar{f}$ has variable set $X = X_1 \cup \cdots \cup X_k$, and its value on assigment $\alpha = (\alpha_1, \ldots, \alpha_k)$ is the k-tuple $f_1(\alpha^1), \ldots, f_k(\alpha^k)$. Given an unknown assignment α to X we want to evaluate $\bar{f}(\alpha) = (f_1(\alpha^1), \ldots, f_k(\alpha^k))$ by a decision forest. We are allowed to ask, "for free," an *arbitrary* set of h binary questions about the assignment α. The answer to these h questions is a vector $\mathbf{a} \in B^h$. For each such $\mathbf{a}$ we will have a decision forest $F^{\mathbf{a}} = (T_1^{\mathbf{a}}, \ldots, T_k^{\mathbf{a}})$, where we require that $F^{\mathbf{a}}(\alpha)$ agrees with $\bar{f}(\alpha)$ for every assignment α that is consistent with $\mathbf{a}$. Note that, unlike the product problem, we are now dealing with worst case complexity of exact computation.

An algorithm in this model is specified by l arbitrary Boolean functions $h_1, \ldots, h_l$ (the help-bit functions) on variable set X, together with 2^l decision forests, which are indexed by the possible outputs of $h_1, \ldots, h_l$. The depth of the algorithm is the maximum depth of any of the $2^l k$ decision trees in these forests. In general, the decision tree $T_i^{\mathbf{a}}$ that computes $f_i(\alpha^i)$ for α consistent with $\mathbf{a}$ is allowed to probe variables outside of X_i. This is conceivably useful, because together with the help bits, such probes could imply information about the variables in X_i. For instance, if one of the help-bit functions is $(f_i(\alpha^i) \times \alpha^j(x))$, where x is a variable in X_j, then by probing the variable x, we can deduce $f_i(\alpha^i)$. If $T_i^{\mathbf{a}}$ only probes variables in X_i we say that it is *pure*. If each of the $2^l k$ decision trees is pure, the algorithm is pure. We denote by $C_h(\bar{f})$ the minimum depth (complexity) of any algorithm that computes $\bar{f}$ using h help bits and by $C_h^{pure}(\bar{f})$ the minimum depth of a pure algorithm that computes $\bar{f}$.

Our main result applies to the case that, for some variable set X and Boolean function f over X, each of the X_i are copies of X and the functions f_i are copies of f, and in this case we denote the k-tuple $\bar{f}$ by $f^{[k]}$. It is not hard to generalize this and formulate similar results for the case that the f_i are arbitrary functions on arbitrary disjoint sets of variables. When convenient we state the lemmas below for this general case. The main result of this section (which is a slight refinement of Theorem 1.2), is the following theorem.

THEOREM 4.1. *For any Boolean function f on n variables and any positive integer k,*

$$C_{k-1}^{pure}(f^{[k]}) \geq C_{k-1}(f^{[k]}) \geq deg^s(f).$$

If k is sufficiently large, then

$$C_{k-1}^{pure}(f^{[k]}) = C_{k-1}(f^{[k]}) = deg^s(f).$$

Before proving the theorem, we mention an example. As noted in the introduction, if f is the majority function, then $deg^s(f) = 1$, and so for this function and any sufficiently large integer k, the theorem asserts that given $k-1$ help bits it is possible to compute $f^{[k]}$ with depth 1. M. Blum pointed out to us explicitly how to do this for the case $n = 3$. Enumerate the subsets of $\{1, \ldots, k\}$ having size at least $2k/3$. The number of these sets is 2^{ck} for some $c < 1$. Fix an encoding of these sets by ck bits. Now given k assignments to the variables of f imagine the assignments arranged in a $k \times 3$ array. In each row, at least two of the three entries agree with the majority value, so there is a column in which at least $2k/3$ of the entries agree with the function value on that row. For the help bits, we ask for the lowest index of such

a column (requiring two bits) and then for the set S of rows for which this column gives the function value (requiring ck bits). Armed with this information, the value of the function on the assignment indicated by row r is equal to the entry in that row and the designated column if $r \in S$, and is the negative of the entry otherwise. Thus the decision tree for evaluating f on the rth assignment need only probe that one variable.

To prove Theorem 4.1, it will be useful to "invert" our point of view and fix d and consider the minimum number of help bits required to compute a given function. Define $H_d(\bar{f})$ (resp. $H_d^{pure}(\bar{f})$) to be the minimum number of help bits needed to compute $\bar{f}$ using a depth-d algorithm (resp. pure depth-d algorithm).

We will prove the following theorem.

THEOREM 4.2. *Let f be a Boolean function on n variables.*

1. *If $d < deg^s(f)$, then for all k,*

$$H_d(f^{[k]}) = H_d^{pure}(f^{[k]}) = k.$$

2. *There exists a positive constant δ_f such that for $d = deg^s(f)$,*

$$H_d^{pure}(f^{[k]}) = (1 - \delta_f)k + o(k).$$

The first part of Theorem 4.2 easily implies the lower bound on $C_{k-1}(f^{[k]})$ (and hence on $C_{k-1}^{pure}(f^{[k]})$) in Theorem 4.1. Also, the second part of Theorem 4.2 implies that for sufficiently large k, $H_{deg^s(f)}^{pure}(f^{[k]}) \leq k - 1$, which implies $C_{k-1}^{pure}(f^{[k]}) \leq deg^s(f)$, which is the second part of Theorem 4.1.

Thus it suffices to prove Theorem 4.2. We can reinterpret $H_d(\bar{f})$ and $H_d^{pure}(\bar{f})$ in terms of the notion of cover given in the beginning of this section. Say that a set $\mathcal{F}$ of decision forests covers all assignments with respect to $\bar{f}$ if for each α there is an $F \in \mathcal{F}$ such that $F(\alpha) = \bar{f}(\alpha)$. Define $\tau_d(\bar{f})$ to be the minimum size of a cover that consists of forests of depth d. Then the remarks at the beginning of this section imply the following proposition.

PROPOSITION 4.1. *Let $\bar{f} = (f_1, \ldots, f_k)$ and d be a nonnegative integer. Then*

1. $H_d(\bar{f}) = \lceil \log \tau_d(\bar{f}) \rceil$,
2. $H_d^{pure}(\bar{f}) = \lceil \log \tau_d^{pure}(\bar{f}) \rceil$.

So we now concentrate on obtaining bounds on $\tau_d(f^{[k]})$ and $\tau_d^{pure}(f^{[k]})$. For this we need yet another definition. A *randomized decision tree over X* is a probability distribution Q on the set of decision trees over X. A randomized decision tree is said to *approximate f with probability p* if for each assignment α, if $\tilde{T}$ is chosen according to Q, the probability that $\tilde{T}(\alpha) = f(\alpha)$ is at least p. We define $p_d(f)$ to be the maximum p such that there is a distribution Q over the set of decision trees of depth at most d that approximates f with probability p. That this maximum exists follows by noting first that we may assume that Q assigns nonzero probability only to trees whose range is contained in the range of f. Let N be the number of such trees (which is finite). Then the set of all such distributions can be viewed as a subset of $\mathbf{R}^N$, and this subset is compact. For fixed f the probability that $\tilde{T}(\alpha) = f(\alpha)$ can be viewed as a continuous function of the "vector" Q. Thus we have a continuous function on a compact set, which must attain a maximum. It is easy to see that $p_d(f) \geq 1/2$ and that if d is equal to $C(f)$, the ordinary decision-tree complexity of f, then $p_d(f) = 1$. Intuitively, the quantity $p_d(f)$ represents the best agreement probability we can guarantee (with respect to worst case input) by choosing an appropriate randomized decision tree. A fundamental observation of Yao [Y2] (which was originally made in a slightly different

context) says that we can choose a probability distribution on inputs such that for any fixed decision tree (or randomized decision tree) the agreement probability with respect to that distribution does not exceed $p_d(f)$. This observation follows from the min-max theorem for two-person zero-sum games (matrix games), and variants of it hold in most nonuniform complexity models. To formalize this observation in our context, recall from the previous section that for a distribution D over assignments, a function f, and a class $\mathcal{T}$ of decision trees, we defined the agreement probability $q_D(f, \mathcal{T})$ to be the maximum over all trees $T \in \mathcal{T}$ of the probability that T and f agree on a random assignment chosen according to D.

LEMMA 4.1. *For any Boolean function f over X and integer $d \geq 0$, there exists a distribution $\hat{D}$ on assignments to X such that $q_{\hat{D}}(f, \mathcal{T}_d) = p_d(f)$.*

Proof. We need first to recall the min-max theorem for two-person zero-sum games. Let M be a $r \times s$ matrix with real entries. A stochastic vector is a nonnegative real-valued vector with entries summing to 1. If v is a vector, write $\max(v)$ for the maximum entry of v and $\min(v)$ for the minimum entry of v. In its simplest form the min-max theorem says that if v ranges over all stochastic vectors of length r then $\min(vM)$ attains a maximum V_1, and if w ranges over all stochastic vectors of length s then $\max(Mw)$ attains a minimum V_2, and $V_1 = V_2$.

To apply the min-max theorem in this case, let M be the matrix whose rows are indexed by the set $\mathcal{T}_d$ and whose columns are indexed by the set B^X of assignments, and whose entry in position (T, α) is 1 if $T(\alpha) = f(\alpha)$ and 0 otherwise. A stochastic vector v indexed by $\mathcal{T}_d$ corresponds to a randomized decision tree, and $\min(vM)$ represents the minimum over all assignments α of the probability that this randomized decision tree computes f correctly on all assignments. Taking the maximum of this over all such v, we get $V_1 = p_d(f)$. Similarly, a stochastic vector indexed by B^X corresponds to a probability distribution over all assignments, and thus V_2 is equal to the minimum over all such distributions D of $q_D(f, \mathcal{T}_d)$. Applying the min-max theorem we get that the distribution $\hat{D}$ that attains this minimum satisfies the conclusion of the lemma. □

Returning to the problem of bounding $\tau_d(f^{[k]})$, we now prove the following lemma.

LEMMA 4.2. *For any Boolean function f on n variables and $k, d \geq 0$, we have*

$$\frac{1}{p_d(f)^k} \leq \tau_d(f^{[k]}) \leq \tau_d^{pure}(f^{[k]}) \leq \left\lceil \frac{nk \ln 2}{p_d(f)^k} \right\rceil.$$

Proof. The middle inequality is trivial. For the last inequality, we use a standard probabilistic argument to show that there is a set of at most $\lceil \frac{nk \ln 2}{p_d(f)} \rceil$ pure forests of depth at most d that cover all of the assignments. Let Q be the distribution on decision trees over X of depth at most d that approximates f with probability $p_d(f)$. For $i \leq k$, let Q_i be the corresponding distribution over the set of decision trees over X. Then Q_i approximates f_i with probability $p_d(f)$. Consider the distribution $P = Q_1 \times \cdots \times Q_k$ over forests. Suppose we select t forests $\tilde{F}_1, \ldots, \tilde{F}_t$ according to P. For a given assignment α and $j \leq t$, the probability that $\tilde{F}_j$ covers α is at least $p_d(f)^k$. Thus the probability that none of the forests covers α is at most $(1 - p_d(f)^k)^t$, and the probability that there exists an assignment α that is covered by none of the forests is at most $2^{nk}(1 - p_d(f)^k)^t < 2^{nk} e^{-p_d(f)^k t}$. If $t = \lceil (nk \ln 2)/p_d(f)^k \rceil$, then this last expression is at most 1, so there is a positive probability that the forest covers all assignments, and so there must be a set of t forests of depth d that cover all assignments.

Now we turn to the lower bound on $\tau_d(f^{[k]})$. Let $\hat{D}$ be the distribution whose existence is asserted by Lemma 4.1. Suppose that $F_1, \ldots, F_t$ is a set of forests that cover all assignments α to X. Consider the distribution P over all assignments α which is the product $\hat{D}_1 \times \cdots \times \hat{D}_k$, where $\hat{D}_i$ is the copy of $\hat{D}$ on X_i. Then, by Theorem 3.1, for any forest F_i, the probability that it covers $\tilde{\alpha}$ is at most $p_d(f)^k$. Then the expected fraction of assignments covered by $F_1, \ldots, F_t$ is at most $tp_d(f)^k$. Since $F_1, \ldots, F_k$ covers all assignments, this expectation must be at least 1, so $t \geq 1/p_d(f)^k$. □

It is worth noting that the above lemma holds (with essentially the same proof) in the general setting described at the beginning of this section; we can replace $\mathcal{T}_d$ by any set of Boolean functions on variable set X and define analogues to $p_d(f)$ and $\tau_d(f)$.

As an immediate corollary of Lemma 4.2 and Proposition 4.1 we get the following bounds on the complexity of the help-bits problem.

COROLLARY 4.1. *For any Boolean function f on n variables and integers $k, l, d \geq 0$:*

$$k(-\log_2 p_d(f)) \leq H_d(f^{[k]}) \leq H_d^{pure}(f^{[k]}) \leq \lceil k(-\log_2 p_d(f)) + \log_2(nk) \rceil .$$

From this we have the following result.

COROLLARY 4.2. *For any Boolean function f on n variables and nonnegative integer d:*

1. *If $p_d(f) = 1/2$ then $H_d(f^{[k]}) = k$ for all k.*
2. *If $p_d(f) > 1/2$ then $H_d^{pure}(f^{[k]}) = k \log_2 \frac{1}{p_d(f)} + o(k)$.*

Next we need to connect the quantity $p_d(f)$ to the sign degree $deg^s(f)$. The following relationship has appeared elsewhere in slightly different form (see, e.g., [BS]).

PROPOSITION 4.2. *For any Boolean function f, $p_d(f) > 1/2$ if and only if $d \geq deg^s(f)$.*

Proof. Let $d \geq deg^s(f)$ and let the variable set X be $x_1, \ldots, x_n$. Then there is an n-variate polynomial $g(x_1, \ldots, x_n)$ of degree at most d such that $g(\alpha) > 0$ if and only if $f(\alpha) = 1$ for all assignments $\alpha = (\alpha_1, \ldots, \alpha_n)$. By adding a small constant to the polynomial we may assume that $g(\alpha)$ is never 0 and by an appropriate scaling we may assume without loss of generality that the sum of the absolute values of the coefficients of g is 1. Consider the following randomized decision tree: Choose a monomial of g uniformly at random, where the probability that a given monomial is chosen is the absolute value of its coefficient. Probe the variables of the monomial and output the product of the values. It is easily seen that for any assignment α, the probability of correctly evaluating $f(\alpha)$ minus the probability of incorrectly evaluating $f(\alpha)$ is equal to $|g(\alpha)|$, which is strictly positive (here we use that our domain is $\{-1, 1\}$). Thus for any α this algorithm correctly evaluates $f(\alpha)$ with probability exceeding 1/2.

Now suppose $p_d(f) > 1/2$. There must exist a randomized decision tree Q on depth-d trees that evaluates $f(\alpha)$ correctly with probability exceeding 1/2. It is well known and easy to see (by induction on d, looking at the two subtrees of the root) that if T is a decision tree of depth d on variables $\{x_1, \ldots, x_n\}$, then there is a polynomial g_T of degree d such that $g_T(\alpha) = T(\alpha)$ for all assignments α. Define the polynomial $g = -\frac{1}{2} + \sum_{T \in \mathcal{T}_d} Q(T) g_T$, where $Q(T)$ is the probability that T is selected under the distribution Q. Then $g(\alpha) = \text{Prob}_Q[\tilde{T}(\alpha) = 1] - 1/2$. By the choice of Q, this latter term is positive if and only if $f(\alpha) = 1$. □

Theorem 4.2 (and hence Theorem 4.1) now follows easily.

Proof of Theorem 4.2. By Proposition 4.2, $p_{deg^s(f)-1}(f) = 1/2$ and therefore, by Corollary 4.2, $H_{deg^s(f)-1}(f^{[k]}) = k$ for all k. Also by Proposition 4.2, $p_{deg^s(f)} > 1/2$, and so Corollary 4.2 implies that $H^{pure}_{deg^s(f)}(f^{[k]}) = \log_2 \frac{1}{p_{deg^s(f)}(f)} k + o(k)$. Taking $\delta_f = \log_2(2p_{deg^s(f)})$ yields the second part of Theorem 4.2. □

Remark 2. It is interesting to note that, for k large enough, it is possible to obtain an optimal algorithm in which all of the decision trees have a particularly simple form. The randomized algorithm in the proof of Proposition 4.2 uses only decision trees that correspond to computing monomials of g. Using this randomized algorithm in the proof of the upper bound of Lemma 4.2, the decision trees used in the help-bits algorithm are all of the same form.

Remark 3. In the proof of the lower bound in Lemma 4.2, we used Theorem 3.1 in order to deduce that for any forest F of depth at most d, the probability, with respect to a particular distribution P on assignments, that F is correct for all k functions is at most $p_d(f)^k$. In the special case $d = deg^s(f) - 1$, which is the relevant case for proving that $C_{k-1}(f^{[k]}) > deg^s(f) - 1$ in Theorem 4.1, there is an alternative argument which we now sketch. As noted above, for $d = deg^s(f) - 1$, we have $p_d(f) = 1/2$, and thus for $\tilde{\alpha}$ selected from $\hat{D}$ (the distribution of Lemma 4.1), any decision tree of depth d agrees with f with probability exactly $1/2$. In particular, this can be shown to imply that if we fix the values of any d variables, then either that partial assignment occurs with probability 0 under $\hat{D}$, or the value of f conditioned on this assignment is unbiased.

Now, define the random variable c_i to be 0 if $T_i(\tilde{\alpha}) = f_i(\tilde{\alpha})$ and 1 otherwise. We want to show that the probability that $c_i = 0$ for all i is at most $1/2^k$. In fact, the distribution on $(c_1, \ldots, c_k)$ is uniform on $\{0,1\}^k$. By the XOR lemma of [Vaz] (see also [CGHFRS]), a distribution over $\{0,1\}^k$ is uniform if for any subset J of $\{1, \ldots, k\}$, the random variable c_J defined to be the XOR of the c_i for $i \in J$ is unbiased. Let s_J be the probability that $c_J = 0$. The event $c_J = 0$ is the same as the event that $T_J(\tilde{\alpha})(= \prod_{i \in J} T_i(\tilde{\alpha}))$ is equal to $f_J(\tilde{\alpha})(= \prod_{i \in J} f_i(\tilde{\alpha}))$. Now by combining the decision trees $\{T_i | i \in J\}$ we get a single decision tree of depth at most $|J|d$ that computes T_J. We claim that such a decision tree must agree with f_J with probability exactly $1/2$, which is enough to finish the argument. We prove the claim by showing that for each leaf of the tree T_J that is reached with nonzero probability, $f_J(\tilde{\alpha})$ conditioned on $\tilde{\alpha}$ reaching the leaf is unbiased. For each such leaf of the tree, there is an $i \in J$ such that at most d variables of X_i appear on the path. Recall that the value of f_i is unbiased when conditioned on the values of these d variables. If we further condition the value of f_J by the values of all variables not in X_i, then f_i is still unbiased and therefore so is f_J.

Remark 4. One implication of Theorem 4.1 is that for every f, and k sufficiently large (depending on f), $C^{pure}_{k-1}(f^{[k]}) = C_{k-1}(f^{[k]})$, the best algorithm for computing $f^{[k]}$ using $k-1$ help bits uses pure trees. It is reasonable to speculate that this is the case for f for all k and l, and this is open. The first case of interest would be the case $k = 2$ and $l = 1$. In this case, it is not hard to show that $C^{pure}_1(f^{[2]}) = C(f)$, i.e., a pure algorithm computing $f^{[2]}$ with one help bit does no better then the ordinary decision tree complexity of f. (Very recent work of Beigel and Hirst [BH] extends this to general (not necessarily pure) algorithms.) To see this, note that the value of the help bit partitions the set of assignments of $X = X_1 \cup X_2$ into two groups A_1 and A_0. It is not hard to see that either the set of assignments on X_1 induced by A_1 is all of B^{X_1}, or the set of assignments on X_2 induced by A_0 must be all of B^{X_2}. Thus in the case that the help bit is 1, the decision tree used to evaluate (the copy of) f on the

variables X_1 must correctly evaluate f for all assignments to X_1 and thus has depth at least $C(f)$, and similarly in the case that the help bit is 0, the decision tree used to evaluate f on the variables X_2 must correctly evaluate f for all assignments to X_2 and thus has depth at least $C(f)$.

Acknowledgments. The authors have had many conversations with several people regarding this research. We would especially like to acknowledge the contributions of Richard Beigel, Nati Linial, Russell Impagliazzo, and Avi Wigderson. We also thank two anonymous referees for their extensive comments, which helped us to improve the exposition.

A TIME-SPACE TRADEOFF FOR UNDIRECTED GRAPH TRAVERSAL BY WALKING AUTOMATA*

PAUL BEAME†, ALLAN BORODIN‡, PRABHAKAR RAGHAVAN§, WALTER L. RUZZO†, AND MARTIN TOMPA†

Abstract. We prove a time-space tradeoff for traversing undirected graphs, using a structured model that is a nonjumping variant of Cook and Rackoff's "jumping automata for graphs."

Key words. graph connectivity, graph reachability, time-space tradeoff, walking automaton, jumping automaton, JAG

1. The complexity of graph traversal.

Graph traversal is a fundamental problem in computing, since it is the natural abstraction of many search processes. In computational complexity theory, graph traversal (or, more precisely, *st*-connectivity) is a fundamental problem for an additional reason: understanding the complexity of directed versus undirected graph traversal seems to be the key to understanding the relationships among deterministic, probabilistic, and nondeterministic space-bounded algorithms. For instance, although directed graphs can be traversed nondeterministically in polynomial time and logarithmic space simultaneously, it is not widely believed that they can be traversed deterministically in polynomial time and small space simultaneously. (See Tompa [32] and Edmonds and Poon [22] for lower bounds and Barnes et al. [5] for an upper bound.) In contrast, *undirected* graphs can be traversed in polynomial time and logarithmic space *probabilistically* by using a random walk (Aleliunas et al. [2], Borodin et al. [15]); this implies similar resource bounds on (nonuniform) deterministic algorithms (Aleliunas et al. [2]). More recent work presents uniform deterministic polynomial time algorithms for the undirected case using sublinear space (Barnes and Ruzzo [8]), and even $O(\log^2 n)$ space (Nisan [28]), as well as a deterministic algorithm using $O(\log^{1.5} n)$ space, but more than polynomial time (Nisan, Szemerédi, and Wigderson [29]).

In this paper we concentrate on the undirected case. The simultaneous time and space requirements of the best-known algorithms for undirected graph traversal are as follows. Depth-first or breadth-first search can traverse any n vertex, m edge undirected graph in $O(m+n)$ time, but requires $\Omega(n)$ space. Alternatively, a random walk can traverse an undirected graph using only $O(\log n)$ space, but requires $\Theta(mn)$ expected time (Aleliunas et al. [2]). In fact, Feige [23], based on earlier work

of Broder et al. [18] and Barnes and Feige [7], has shown that there is a spectrum of compromises between time and space for this problem: any graph can be traversed in space S and expected time T, where $ST \leq mn(\log n)^{O(1)}$. This raises the intriguing prospect of proving that logarithmic space and linear time are not simultaneously achievable or, more generally, proving a time-space tradeoff that closely matches these upper bounds.

Although it would be desirable to show a tradeoff for a general model of computation such as a random access machine, obtaining such a tradeoff is beyond the reach of current techniques. Thus it is natural to consider a "structured" model (Borodin [14]), that is, one whose basic move is based on the adjacencies of the graph, as opposed to one whose basic move is based on the bits in the graph's encoding. An appropriate structured model for proving such a tradeoff is some variant of the JAG ("jumping automaton for graphs") of Cook and Rackoff [20]. Such an automaton has a set of states, and a limited supply of pebbles that it can move from vertex to adjacent vertex ("walk") or directly to a vertex containing another pebble ("jump"). The purpose of its pebbles is to mark certain vertices temporarily, so that they are recognizable when some other pebble reaches them. The pebbles represent vertex names that a structured algorithm might record in its workspace. Walking represents replacing a vertex name by some adjacent vertex found in the input. Jumping represents copying a previously recorded vertex name.

Rabin (see [20]), Savitch [31], Blum and Sakoda [13], Blum and Kozen [12], Hemmerling [24], and others have considered similar models; see Hemmerling's monograph for an extensive bibliography (going back over a century) emphasizing results for "labyrinths": graphs embedded in two- or three-dimensional Euclidean space.

The JAG is a structured model, but not a weak one. In particular, it is general enough to encompass in a natural way most known algorithms for graph traversal. For instance, a JAG can execute a depth-first or breadth-first search, provided it has one pebble for each vertex, by leaving a pebble on each visited vertex in order to avoid revisiting it, and keeping the stack or queue of pebble names in its state. Furthermore, as Savitch [31] shows, a JAG with the additional power to move a pebble from vertex i to vertex $i+1$ can simulate an arbitrary Turing machine on directed graphs. Even without this extra feature, we have shown [10] that JAGs are as powerful as Turing machines for the purposes of solving undirected graph problems (our main focus).

Cook and Rackoff define the time T used by a JAG to be the number of pebble moves, and the space to be $S = P \log_2 n + \log_2 Q$, where P is the number of pebbles and Q the number of states of the automaton. (Keeping track of the location of each pebble requires $\log_2 n$ bits of memory, and keeping track of the state requires $\log_2 Q$.) It is well known that *st*-connectivity for directed graphs can be solved by a deterministic Turing machine in $O(\log^2 n)$ space, by applying Savitch's theorem [30] to the obvious $O(\log n)$ space nondeterministic algorithm for the problem. Cook and Rackoff show that the same $O(\log^2 n)$ space upper bound holds for deterministic JAGs by direct construction of an $O(\log n)$ pebble, $n^{O(1)}$ state deterministic JAG for directed *st*-connectivity. More interestingly, they also prove a lower bound of $\Omega(\log^2 n / \log\log n)$ on the space required by JAGs solving this problem, nearly matching the upper bound. Standard techniques (Adleman [1], Aleliunas et al. [2]) extend this result to any randomized JAG whose time bound is at most exponential in its space bound. Berman and Simon [11] extend this space lower bound to probabilistic JAGs with even larger time bounds, namely, exponential in $\log^{O(1)} n$.

In this paper we use a variant of the JAG to study the tradeoff between time and space for the problem of *undirected* graph traversal. The JAG variant we consider is

more restricted than the model introduced by Cook and Rackoff, because the pebbles are not permitted to jump. This nonjumping model is closer to the one studied by Blum and Sakoda [13], Blum and Kozen [12], and Hemmerling [24]. We will distinguish this nonjumping variant by referring to it as a WAG: "walking automaton for graphs."

Several authors have considered traversal of undirected regular graphs by a WAG with an unlimited number of states but only the minimum number (one) of pebbles, a model better known as a *universal traversal sequence* (Aleliunas et al. [2], Alon, Azar, and Ravid [3], Bar-Noy et al. [4], Borodin, Ruzzo, and Tompa [16], Bridgland [17], Buss and Tompa [19], Istrail [25], Karloff, Paturi, and Simon [26], Tompa [33]). A result of Borodin, Ruzzo, and Tompa [16] shows that such an automaton requires $\Omega(m^2)$ time (on regular graphs with $3n/2 \leq m \leq n^2/6-n$). Thus, for the particularly weak version of logarithmic space corresponding to the case $P = 1$, a quadratic lower bound on time is known.

The known algorithms and the lower bounds for universal traversal sequences suggest that the true time-space product for undirected graph traversal is approximately quadratic, perhaps $\Theta(mn)$. The result of this paper is a lower bound that provides progress toward proving this conjecture. More specifically, we prove lower bounds on time that are nonlinear in m for a wide range of values of P. In particular, for any WAG M solving st-connectivity in logarithmic space, there is a family of regular graphs on which M requires time $m^{1+\Omega(1)}$. Near the other extreme, if M uses a number of pebbles that is sublinear in m, there is a family of regular graphs on which M requires time superlinear in m. Although these give the desired quadratic lower bound only at the extreme of linear time, they each at least establish that logarithmic space and linear time are not simultaneously achievable on the nonjumping model when $m = \omega(n)$. (They do not settle the question of simultaneous achievability of logarithmic space and linear time when $m = O(n)$ since the families of regular graphs mentioned above have degree $d = \omega(1)$ and hence $m = \omega(n)$; see sections 3 and 4.)

We prove upper and lower bounds for undirected graph problems on other variants of the JAG in a companion paper [10]. Following the preliminary appearance of these results, Edmonds [21] proved a much stronger result for traversing undirected graphs, and Barnes and Edmonds [6] and Edmonds and Poon [22] proved even more dramatic tradeoffs for traversing directed graphs.

2. Walking automata for graphs. The problem we will be considering is "undirected st-connectivity": given an undirected graph G and two distinguished vertices s and t, determine if there is a path from s to t.

Consider the set of all n-vertex, edge-labeled, undirected graphs $G = (V, E)$ with maximum degree d. For this definition, edges are labeled as follows. For every edge $\{u, v\} \in E$ there are two labels $\lambda_{u,v}, \lambda_{v,u} \in \{0, 1, \ldots, d-1\}$ with the property that, for every pair of distinct edges $\{u, v\}$ and $\{u, w\}$, $\lambda_{u,v} \neq \lambda_{u,w}$. It will sometimes be convenient to treat an undirected edge as a pair of directed *half-edges*, each labeled by a single label. For example, the half-edge directed from u to v is labeled $\lambda_{u,v}$.

Following Cook and Rackoff [20], a WAG is an automaton with Q states and P distinguishable pebbles, where both P and Q may depend on n and d. For the st-connectivity problem, two vertices s and t of its input graph are distinguished. The P pebbles are initially placed on s. Each move of the WAG depends on the current state, which pebbles coincide on vertices, which pebbles are on t, and the edge labels emanating from the pebbled vertices. Based on this information, the automaton changes state and selects some pebble p and some $i \in \{0, 1, \ldots, d-1\}$.

The selected i must be an edge label emanating from the vertex currently pebbled by p, and p is moved to the other endpoint of the edge with label i. (The decision to make t "visible" to the WAG but s "invisible" was made simply to render one-pebble WAGs on regular graphs equivalent to universal traversal sequences.) A WAG that determines st-connectivity is required to enter an accepting state if and only if there is a path from s to t. Note that WAGs are nonuniform models.

We have defined WAGs running on arbitrary graphs, but our lower bounds apply even to WAGs that are only required to operate correctly on regular graphs. The restriction to regular graphs, in addition to strengthening the results, provides comparability to the known results about universal traversal sequences. A technicality that must be considered in the case of regular graphs is that they do not exist for all choices of degree d and number of vertices n, as is seen from the following proposition.

PROPOSITION 1. *d-regular, n-vertex graphs exist if and only if dn is even and $d \leq n-1$.*

(See [16, Proposition 1], for example, for a proof.) To allow use of Ω-notation in expressing our lower bounds, however, the "time" used by a WAG must be defined for *all* sufficiently large n. To this end, we consider the time used by a WAG on d-regular, n-vertex graphs where dn is odd to be the same as its running time on d-regular, $(n+1)$-vertex graphs.

3. The tradeoff. In this section we prove time lower bounds for WAGs with P pebbles. The proof generalizes an unpublished construction of Szemerédi (communicated to us by Sipser) that proved an $\Omega(n \log n)$ lower bound on the length of universal traversal sequences for 3-regular graphs.

THEOREM 2. *Let P and d be fixed functions of n with dn even, $P \geq 1$, $d \geq 6$, and $d^2 + Pd = o(n)$. Let $m = dn/2$, $\epsilon = 1/(3\ln(6e))$, and*

$$d_0 = (2P/e)^{3P/(3P+2)}\, n^{1/(3P+2)}.$$

Let M be any (deterministic) WAG with P pebbles that determines st-connectivity for all d-regular, n-vertex graphs. Then M requires time

(a) $\Omega\left(m(\log n)\frac{d/P}{\log(d/P)}\right)$, *if $P \leq \epsilon \ln(n/d^2)$ and $6P \leq d \leq d_0$,*

(b) $\Omega\left(mP\left(\frac{n}{d^2}\right)^{\frac{1}{3P}}\right)$, *if $P \leq \epsilon \ln(n/d^2)$ and $d_0 < d$, and*

(c) $\Omega\left(m \min\left(d, \log \frac{n}{(d^2+Pd)}\right)\right)$, *otherwise.*

Before proving the theorem, we will make a few observations about it. Perhaps the most noteworthy is that these bounds are nonlinear whenever either $d = \omega(1)$ or $d \geq 6P$.

It is obvious that the regions (i.e., the sets of (P, d) pairs) where the three cases apply are pairwise disjoint. It is also true that all three regions are nonempty for all sufficiently large n, although we will not justify this statement.

Although they have very different forms, the three bounds meet "smoothly," except along the line segment $d = 6P$, $1 \leq P \leq \epsilon \ln(n/d^2)$. Specifically, we will show that where any pair of the three bounds meet along the curve $P = \epsilon \ln(n/d^2)$, $d \geq 6P$, both are $\Theta(m \log(n/d^2))$, and where bounds (a) and (b) meet along the curve $d = d_0$, $1 \leq P \leq \epsilon \ln(n/d^2)$, both are $\Theta(md_0)$.

All three bounds are increasing functions of d (recall $m = dn/2$). The ratio of the lower bounds to m is also an interesting quantity. Note that the ratio of bound (a) to m is an increasing function of d, while that of bound (b) is decreasing. Since they are equal (within constant factors) at $d = d_0$, the two could be combined into the single expression $\Omega(m \min((\log n)(d/P)/\log(d/P),\ P(n/d^2)^{1/(3P)}))$, as was done in bound (c).

It seems likely that the decrease in bound (b) is an artifact of the proof technique rather than an intrinsic reduction in the complexity of the problem, since intuitively higher degree would seem to make the search more difficult. On the other hand, higher degree reduces the graph's maximum possible diameter, which perhaps helps. It is known that the length of universal traversal sequences is not monotonic in d, although it may be monotonic up to some large threshold, perhaps $d = \lfloor n/2 \rfloor - 1$. (See Borodin, Ruzzo, and Tompa [16] for a discussion.) Similarly, the complexity of st-connectivity is not monotone in d, since regular graphs of degree $d > \lfloor n/2 \rfloor - 1$ are necessarily connected, but it is plausibly monotone for d up to cn, for some constant $0 < c < 1/2$.

Two special cases of the theorem are of particular interest. Namely, the following two corollaries show that logarithmic space implies time $m^{1+\Omega(1)}$ and that sublinear space implies superlinear time.

COROLLARY 3. *Let M be a WAG with P pebbles that determines st-connectivity for all regular n-vertex graphs. If $P = O(1)$, then there is a family of regular graphs on which M requires time $\Omega(m^{1+1/(3P+3)})$.*

Proof. Consider the family of regular graphs with degree $d = d_0 = \Theta(n^{1/(3P+2)})$. Theorem 2 applies, specifically case (a). This gives a time lower bound of $\Omega(md) = \Omega(m^{1+1/(3P+3)})$. □

For $P = 1$ the $\Omega(m^{7/6})$ bound given above is not as strong as the $\Omega(m^2)$ bound given by Borodin, Ruzzo, and Tompa [16] but is included for comparative purposes. Also, the $\Omega(m^2)$ lower bound for universal traversal sequences holds for degree up to $n/3 - 2$, so the decrease in the ratio of bound (b) to m noted above certainly *is* an artifact of our proof when $P = 1$.

COROLLARY 4. *Let M be a WAG with P pebbles that determines st-connectivity for all regular n-vertex graphs. If $P = o(n)$, then there is a family of regular graphs on which M requires time $\Omega(m \log(n/P)) = \omega(m)$.*

Proof. Suppose $P \geq n^{1/3}$. Consider the family of regular graphs with degree $d = \sqrt{n/P} = \omega(1)$. Then $d^2 + Pd \leq 2\sqrt{Pn} = o(n)$, so Theorem 2 applies, specifically case (c). This gives a lower bound of $\Omega(m \log d) = \Omega(m \log(n/P))$ on time. When $P < n^{1/3}$, a similar analysis suffices, choosing $d = \log n$. □

Corollary 4 is tight: time $O(m)$ is possible with $O(n)$ pebbles [10, Theorem 15]. Note also that, when $P = \Theta(n)$, the time is still $\Omega(m \log(n/P))$ [10, Theorem 3].

Various constants in the theorem can be improved by slight modification to the construction and/or its analysis, but in the interest of clarity we will not present these refinements.

Proof of Theorem 2. The idea underlying the proof is to build a graph with many copies of some fixed gadgets, each with many "entry points." Since M does not have enough pebbles to mark all the gadgets it has explored, it must spend time reexploring each gadget from different entry points, or it risks the possibility that one of them might never be fully explored. The crux of the argument is to choose the right gadgets and to interconnect them so that we can be sure this happens. We use an "adversary" argument to show this. We begin by giving an overview of the argument, followed

by more detailed descriptions of the gadgets and adversary strategy, and finally the analysis.

Overview. Imagine the adversary "growing" the graph as follows. At a general point in the construction, the graph consists of some gadgets that are fully specified except for the interconnections among their "entry point" vertices. The adversary simulates M on this partial graph until M attempts to move some pebble p out of an entry point using a label for which no edge is yet defined. Our main freedom in the construction is the choice of the gadget at the other endpoint of this interconnecting edge f. The adversary will pick it so that M will spend a nonnegligible number of steps τ "exploring" the gadget reached through f. The adversary can achieve this for most of the $\Omega(m)$ interconnecting edges, yielding an $\Omega(m\tau)$ lower bound on time. The parameter τ will vary depending on n, P, and d, giving the three lower bounds quoted in the statement of the theorem.

The interconnecting edge f is chosen as follows. Note that no single labeled gadget γ will suffice to keep p "busy" for τ steps. For example, M's very next move of p, say by label a, might be an exit from γ. On the other hand, if the adversary can learn that M's next move of p will be on label a, it can choose some gadget in which label a moves from an entry point *into* the gadget, rather than exiting from it. Similarly, if it can learn the next τ moves by p (and/or other pebbles following p across f), the adversary can choose a gadget in which this whole sequence of moves avoids exiting from the gadget. A key point is that M can sense only very limited facts about the gadget that p enters when it crosses f. Suppose p has just crossed f, arriving at a vertex v. M can sense (i) the degree of v, (ii) whether v is the target vertex t, and (iii) whether there are other pebbles on v. Thus, in general M has several possible next moves for p, based on which of these conditions hold. The adversary avoids having to consider these alternative futures by assuming, respectively, (1) that the graph is d-regular, (2) that M does not reach t (within $\Omega(m\tau)$ steps), and (3) that f connects to a gadget that contains no other pebbles when p enters it, and that remains free of other pebbles (except perhaps ones that follow p across f) for τ moves. Given these assumptions, the adversary will be able to deterministically simulate the next several moves by M so that it can decide which labeled gadget can host those moves without allowing a pebble to exit. Of course, the adversary must also ensure that assumptions (1)–(3) are ultimately justified. Building a d-regular graph requires some care but is not too difficult. Assumption (2) will follow easily if each connecting edge accounts for τ moves. Assumption (3) is slightly trickier; we will return to it below.

We view the overall adversary strategy as a two-phase process. A *local* phase determines the internal ("local") structure required of a gadget hosting the next several moves of p so that no pebble will exit this gadget until at least τ moves have been charged to it, starting after p's entry. The basic idea is to use a "lazy, greedy" definition: lazy in that the adversary will not define a labeled half-edge in the gadget until just before M needs to move a pebble across it, and greedy in that when such a half-edge is defined, it will be defined to stay within the gadget. Of course, this cannot continue indefinitely, but it will be possible for at least the first τ moves within the gadget. Thus, pebble motion across half-edges exiting the gadget is deferred for at least this long.

The adversary's simulation of M is now "rolled back" to the point at which p crossed f. The *global* phase of the adversary's strategy is to choose a gadget already present in the graph and to connect f to it. Recall that our goal is to reuse each gadget many times, so that the total time spent in it asymptotically exceeds its number of

edges. (Occasionally, when all entry points of suitable gadgets have been used, a new copy of the needed gadget will be added. This process terminates when the number of vertices in the graph approaches n.) The gadget chosen for f must match the gadget determined by the local phase, must have an unused entry point to which to connect f, and (before f was connected to it) must have remained free of pebbles from the time when p crossed f until τ moves were charged to it. The "pebble-free" condition ensures assumption (3) above. Such a condition is necessary since, if it were violated, M might encounter "unexpected" pebbles in the chosen gadget, i.e., pebbles not encountered during the simulation in the local phase. This could cause M to deviate from the sequence of moves predicted by the local phase, and so possibly allow p or one of the pebbles that followed it across f to exit from the gadget in fewer than τ moves.

A point we slighted above is that the "τ steps" under discussion are not necessarily consecutive and are not necessarily all made by p or by pebbles that followed p across f. For example, p's moves after crossing f might be interleaved with moves by some other pebble p' after crossing another undefined edge f' and/or many previously defined connecting edges. In general, the adversary keeps track of these many interleaved activities by charging pebble moves to connecting edges, with the "local phase" for an undefined connecting edge f being the interval between its charge reaching 1 (at the first crossing of f by some pebble) and its charge reaching τ.

The final issue to address is that we want to avoid adding a new copy of a gadget until all entry points of most existing copies have been used. Specifically, we will have at most a fixed number ($P(\tau+2)+d$, to be precise) of "open" copies of each gadget at any time. As noted above, many steps may occur between the first and τth steps charged to f. During this interval, other pebbles might touch *all* open copies of the gadget needed for f, leaving no *pebble-free* open gadget to which to connect f. Our solution to this problem is found in the adversary's method of charging pebble moves to edges. Moves in f's gadget are always charged to f. In addition, certain moves touching other gadgets are charged to f also. With this scheme, we can bound both the number of moves that occur in f's gadget and the number of other gadgets that are touched by pebbles during f's local phase. Thus, no gadget is expected to absorb too many moves, and there will be at least one suitable pebble-free open copy of the needed gadget when f accumulates charge τ.

The construction will "waste" (i.e., not fully utilize the connecting edges of) up to $P(\tau+2)+d$ copies of each gadget. The main constraint that limits τ is that it must be small enough that this waste is small, i.e., $P(\tau+2)+d$ times the number of distinct types of labeled gadgets times the number of connecting edges per gadget is small compared to the total number of connecting edges.

We will now present the construction in more detail. We actually define a sequence of graphs $G_{i,j},\ 0 \le i \le \mu,\ 0 \le j$, representing successive phases of the construction. Like τ, the parameter μ varies slightly depending on n, p, and d, but will be $\Theta(m)$ in each case. (The maximum value of j is unimportant, but turns out to be about $P\tau$.) Each graph consists of the following:

1. A set of gadgets, each with the same size S and number L of entry vertices, and a fully defined internal structure and labeling. Each vertex that is not an entry vertex has degree d. There is a fixed $d' \ge 1$ such that each entry vertex has d' edges to neighbors in the same gadget, and up to $d-d'$ *connecting edges* joining it to the entry vertices of other gadgets or protogadgets (see below). We will show that $d-d' \ge d/2$ and that $L/S > 1/3$, ensuring at termination that the number of connecting edges is $\Theta(m)$.

2. A set of labeled *committed* connecting edges joining entry vertices of gadgets. $G_{i,j}$ will have exactly i committed connecting edges.

3. A set of up to P partially labeled *uncommitted* connecting edges, each joining an entry vertex u of some gadget to an entry vertex v of a protogadget (see below). The uncommitted half-edge from u to v is labeled, but the half-edge from v to u is unlabeled.

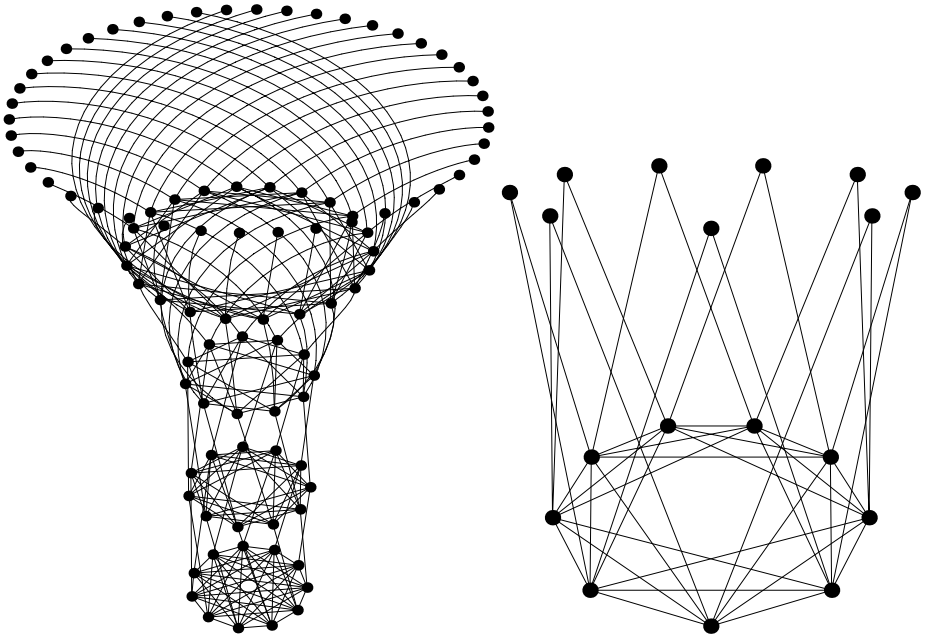
4. A set of up to P partially defined *protogadgets*. Like a gadget, a protogadget has S vertices, including L entry vertices, but unlike the gadgets, the internal structure of a protogadget is in general only partially defined; its vertices may have degree less than d, and its half-edges may not be labeled. In particular, only one entry vertex v of each protogadget will be incident to a connecting edge, say the uncommitted connecting edge $\{u, v\}$, and, as indicated above, the half-edge from v to u will be unlabeled. The protogadgets are the tools used in the local phases of the adversary's strategy.

In outline, the adversary's strategy is as follows. The initial graph $G_{0,0}$ consists of one arbitrarily chosen gadget. The start vertex s is an arbitrary vertex in this gadget. For any $G_{i,j}$, the *initial configuration* of M on $G_{i,j}$ consists of M in its start state and all P pebbles on $G_{i,j}$'s copy of s. Associate with each connecting edge of the graph $G_{i,j}$ an integer *charge*, initially zero. The adversary will charge each pebble motion to at most one connecting edge, according to a rule to be given later. It will simulate M starting from M's initial configuration on $G_{i,j}$ until one of the following two things happens. (It simulates M as if all vertices in $G_{i,j}$ were of degree d, even though some are of smaller degree.)

1. Suppose M attempts to move a pebble from a vertex u across a half-edge labeled a, where no such labeled half-edge exists. If u is an entry vertex in some gadget, add a new uncommitted half-edge from u labeled a to the entry point v of a new protogadget. More precisely, we define $G_{i,j+1}$ to be $G_{i,j}$ plus that half-edge and protogadget. If u is in some protogadget, choose some other vertex v in the *same* protogadget (according to a rule to be given later) and add a half-edge from u to v labeled a. More precisely, we define $G_{i,j+1}$ to be $G_{i,j}$ plus that half-edge (plus a few others, as we will see). The choice of v is not arbitrary; one point we must establish is that there will always be a suitable vertex v when needed. The thrust of this step in the adversary strategy is to keep pebbles "trapped" in protogadgets for as long as possible. This portion of the adversary's strategy is the "local" strategy introduced above, so-called because of its focus on the structure *within* a gadget.

2. Suppose an uncommitted edge f in $G_{i,j}$ accumulates a charge of τ. In this case, we will convert f into a committed edge. More precisely, we will form $G_{i+1,0}$ from $G_{i,j}$ by choosing an existing gadget "similar" to f's protogadget and committing f to enter the chosen gadget. (This is described more fully below.) Again, f cannot be committed arbitrarily; a second point that we must establish is that an appropriate gadget (usually) exists when needed, and that M's behaviors on $G_{i,j}$ and $G_{i+1,0}$ are similar. The thrust of this step is that the size of $G_{i+1,0}$ is growing slowly with i, since we are (usually) able to reuse existing gadgets, but the time M spends in $G_{i+1,0}$ is rising rapidly with i, since a lower bound on the total running time of M is τ times the number of committed edges (i, which is ultimately $\mu = \Theta(m)$). This portion of the adversary's strategy is the "global" strategy, so-called because of its focus on the interconnections among gadgets.

The adversary continues the simulation on $G_{i,j+1}$ or $G_{i+1,0}$ as appropriate, and repeats this process until $G_{\mu,0}$ is constructed.



(a)
$d = 10,\ k = 4,\ q = 2,\ r = 1$
For clarity, only half of the forward edges are shown.

(b)
$d = 8,\ k = 1,\ q = 2,\ r = 1$

FIG. 1. *Examples of the funnel gadgets.*

Gadgets. Before describing the adversary strategy in more detail, we will describe the gadgets and protogadgets. The gadgets are called "funnels." An example is shown in Fig. 1a. The entry vertices are those on the "rim" of the funnel. Intuitively, the adversary will try to "trap" pebbles in a funnel for a while by assigning edge labels so that the moves taken by pebbles in the gadget in the near future (i.e., the next τ moves in the gadget) either stay on the same layer or drop to the next deeper layer. The "cone" portion of the funnel (near the top of Fig. 1a) allows many entry vertices to share vertices in the narrower portion near the bottom of Fig. 1a. An example of a two-layer funnel is shown in Fig. 1b.

Four interrelated parameters k, q, g, and r, which in turn depend on n, P, and d, characterize the gadgets. All four are positive integers. Each gadget has $k+1$ *layers,* numbered 0 through k. Layer $l,\ 0 \le l \le k$, has

$$n_l = (d+1) \cdot \max(1, 2^{\lceil \log_2 k \rceil - l})$$

vertices, designated v_i^l, $0 \le i \le n_l - 1$. The entry vertices are those on layer 0. Hence, the number of entry vertices is

$$L = (d+1) \cdot 2^{\lceil \log_2 k \rceil},$$

and the total number of vertices per gadget is

$$S = (d+1)(2^{\lceil \log_2 k \rceil + 1} - 1 + k - \lceil \log_2 k \rceil).$$

Note that

$$\frac{L}{S} = \frac{(d+1)\cdot 2^{\lceil \log_2 k\rceil}}{(d+1)(2^{\lceil \log_2 k\rceil+1} - 1 + k - \lceil \log_2 k\rceil)} > \frac{2^{\lceil \log_2 k\rceil}}{2^{\lceil \log_2 k\rceil+1} + k} \geq \frac{1}{3}, \tag{1}$$

as promised, and that

$$S \leq (1+1/d)\, d\, (2\cdot 2^{\lceil \log_2 k\rceil} + k) \leq (7/6)\, d\, (5k) < 6dk. \tag{2}$$

The parameter q is an even integer, $2 \leq q$. The d edge labels $\{0, 1, \ldots, d-1\}$ are partitioned into $g = \lfloor d/q \rfloor$ "full" blocks, each of size q, plus perhaps one "partial" block of size $d \bmod q$ in case q does not evenly divide d. The same fixed partition is used for all gadgets and is arbitrary, except that for each $a \in \{0, 1, \ldots, d-1\}$, we place both a and its mate in the same block, where the *mate* of label a is $d-1-a$. Note that if d is odd, then $(d-1)/2$ is its own mate and will be in the partial block.

The remaining gadget parameter r is an integer satisfying $1 \leq r \leq g/3$. Note that the existence of such an r implies that $g \geq 3$, and hence

$$q \leq d/3. \tag{3}$$

Intuitively, r denotes an upper bound on the number of pebbles that we attempt to trap in a given gadget.

The edges within a gadget always connect vertices on the same or adjacent layers. A half-edge is called a "forward" half-edge if it goes from layer l to layer $l+1$, "backward" if it goes to layer $l-1$, and "cross" if it goes to layer l. For each layer l and each block B of labels, there is a $t \in \{\text{forward}, \text{backward}, \text{cross}\}$ such that all half-edges with labels in B leaving vertices on layer l will be of type t. Thus it is natural to refer to the labels and the blocks of labels at a layer as forward, backward, or cross, as well as the half-edges. For $i \in \mathbb{N}$, $a \in \{0, 1, \ldots, d-1\}$, and $0 \leq l \leq k$, define

$$\chi(i,a,l) = \begin{cases} (i+a+1) \bmod n_l & \text{if } a < (d-1)/2, \\ (i+n_l/2) \bmod n_l & \text{if } a = (d-1)/2, \\ (i-(d-1-a)-1) \bmod n_l & \text{if } a > (d-1)/2. \end{cases}$$

If $a \in \{0, 1, \ldots, d-1\}$ is a forward label at layer l, then for $0 \leq i \leq n_l - 1$, a will label the half-edge from vertex v_i^l to vertex $v_{\chi(i,a,l+1)}^{l+1}$. Similarly, if a is a cross label it will go to $v_{\chi(i,a,l)}^{l}$. Notice that a cross edge labeled a will be labeled by a's mate in the reverse direction. No parallel edges arise since $n_l \geq d+1$. As an example, if all edges are cross edges (a case that does not arise in our constructions) and if $n_l = d+1$, then layer l would be a $(d+1)$-clique. As another example, whenever label 0 is a cross label at layer l, the half-edges labeled 0 will form a Hamiltonian cycle through the layer l vertices, and those edges will be labeled $d-1$ (0's mate) in the other direction. Note that the backward labels are not constrained by χ.

The set of gadgets is defined as follows. For $0 \leq l \leq k$ let

$$b_l = \begin{cases} g - r & \text{if } l = 0, \\ r(n_{l-1}/n_l) & \text{otherwise,} \end{cases}$$

$$f_l = \begin{cases} 0 & \text{if } l = k, \\ r & \text{otherwise.} \end{cases}$$

See Table 1. If q does not evenly divide d, then the labels in the partial block will be cross labels at each layer $0 \leq l \leq k$. For each layer $0 \leq l \leq k$, choose f_l of

TABLE 1
Number of edge blocks of each type per layer.

Layer	0	1	$\cdots$	$\lceil \log_2 k \rceil$	$\lceil \log_2 k \rceil + 1$	$\cdots$	$k-1$	k
f_l	r	r	$\cdots$	r	r	$\cdots$	r	0
b_l	$g-r$	$2r$	$\cdots$	$2r$	r	$\cdots$	r	r
Cross	0	$g-3r$	$\cdots$	$g-3r$	$g-2r$	$\cdots$	$g-2r$	$g-r$

the remaining g blocks as forward labels and b_l as backward labels (connecting edge labels, if $l = 0$). All blocks not selected above will be cross labels. Note that the rules in the previous paragraph define the forward and cross half-edges, given their labels, but not the backward half-edges. The chosen backward labels are assigned to these half-edges in an arbitrary but fixed way. Note that there are just enough backward labels: each of the n_{l-1} vertices on level $0 \le l-1 < k$ has exactly qr forward labels, with destinations evenly distributed over the n_l vertices on layer l, so each vertex on layer l is incident to exactly $qr(n_{l-1}/nl) = q \cdot b_l$ edges from layer $l-1$.

For layer 0, the b_0 blocks selected above will label connecting edges. Thus, each entry vertex will be adjacent to exactly $d' = rq + (d \bmod q)$ other vertices in the same gadget, and to $d - d'$ connecting edges. Note, since $r \le g/3$ and $q \le d/3$ (from inequality (3)), that

$$d - d' = gq - rq \ge (2/3)gq = (2/3)\lfloor d/q \rfloor q \ge (2/3)((3/4)(d/q))q = d/2, \tag{4}$$

as claimed earlier. Also note that at most $3r$ blocks are chosen as forward and backward at each layer, and that this is always possible since $g \ge 3r$.

The number of distinct gadget types created by this process is

$$\begin{aligned}
&\binom{g}{r}^{k} \binom{g-r}{2r}^{\lceil \log_2 k \rceil} \binom{g-r}{r}^{k-\lceil \log_2 k \rceil - 1} \binom{g}{r}^{1} \\
&\qquad \le \binom{g}{r}^{2k-\lceil \log_2 k \rceil} \binom{g}{2r}^{\lceil \log_2 k \rceil} \\
&\qquad \le \left(\frac{eg}{r}\right)^{r(2k-\lceil \log_2 k \rceil)} \left(\frac{eg}{2r}\right)^{2r\lceil \log_2 k \rceil} \\
&\qquad \le \left(\frac{eg}{r}\right)^{r(2k+\lceil \log_2 k \rceil)}. \qquad (5)
\end{aligned}$$

Figure 1b fully shows a gadget with $d = 8,\ k = 1,\ q = 2,\ g = 4$, and $r = 1$, with forward edges labeled 0 and 7 from layer 0 and backward edges labeled 3 and 4 from layer 1. Figure 1a shows a gadget with $d = 10,\ k = 4,\ q = 2,\ g = 5$, and $r = 1$, with forward edges labeled 0 from layers 0 through 3. In the interest of clarity, the forward edges labeled 9 (0's mate) are not shown in the figure.

Protogadgets and local strategy. The protogadgets are built incrementally by the adversary. Initially, each consists of S vertices, denoted as in the gadgets, together with the cross edges defined by the partial block of labels (if any) at each level. As discussed previously, the adversary proceeds by simulating M from its initial configuration on $G_{i,j}$. Suppose during the tth step of this simulation that M attempts to move some pebble p along the half-edge labeled a from some vertex u but no such half-edge exists. As sketched earlier, if u is an entry vertex of some gadget, we create a new protogadget into which p will move. If u is a vertex v_i^l in some protogadget

π, the adversary decides whether to make the block of labels containing a all forward half-edges or all cross half-edges (see below). The graph $G_{i,j+1}$ is then defined to be the same as $G_{i,j}$, except that at layer l in π, a's block of half-edges is added. The adversary restarts the simulation of M, starting from M's initial configuration on $G_{i,j+1}$. It should be clear that during the first $t-1$ steps of the simulation, M will behave on $G_{i,j+1}$ exactly as it did on $G_{i,j}$, since $G_{i,j}$ is a subgraph of $G_{i,j+1}$. The tth step, of course, was impossible in $G_{i,j}$, but is possible in $G_{i,j+1}$. Note that p can exit from π only at an entry vertex but is no nearer to such a vertex in $G_{i,j+1}$ after the tth step than before. Thus we can view M as running on a dynamically growing graph, one being built by the adversary so as to trap pebbles in protogadgets for some number of moves. We will adopt this view when no confusion will arise and let $G_{i,*}$ denote the last $G_{i,j}$ built before $G_{i+1,0}$.

Let z be the number of free blocks at level l, i.e., blocks whose half-edges have not yet been defined. The adversary chooses a's block to label cross edges provided $z > b_l + f_l$ and forward edges provided $b_l < z \le b_l + f_l$. If $z \le b_l$, the adversary *fails* (but see Claim 1 below).

Let

$$\tau = \begin{cases} (k - \lceil \log_2 k \rceil)\, \lfloor g/3 \rfloor & \text{if } P \le r, \\ r & \text{if } P > r. \end{cases}$$

Note that $(k - \lceil \log_2 k \rceil)\, \lfloor g/3 \rfloor \ge r$ since $k \ge 1$ and $g/3 \ge r$, so in either case we have

$$(k - \lceil \log_2 k \rceil)\, \lfloor g/3 \rfloor \ge \tau. \tag{6}$$

We prove three claims about the protogadgets. We will see later that the global strategy prevents M from making more than τ moves in any protogadget, so Claim 1 below shows that the adversary will never fail.

CLAIM 1. *The adversary will never fail, provided M makes at most τ moves in any protogadget.*

Proof. First, clearly at most $\min(P, \tau)$ pebbles can enter a protogadget in τ steps, and for the particular definition of τ chosen above, $\min(P, \tau) \le r$. Now, suppose the claim is false. Suppose the adversary first fails during an attempted move at level l in some protogadget π. Then at least $g - b_l$ moves were previously made by pebbles at layer l. As noted, at most r pebbles can enter π in τ moves. It cannot be the case that $l < k$, since for all such layers $g - b_l \ge r = f_l$, so during the last r of the $g - b_l$ moves, all r pebbles moved past layer l, leaving none to cause failure there. Thus, the failure occurred in layer k. For a pebble to reach layer k, it must be that the maximum number of cross edges, plus at least one forward edge, have been previously defined at each layer less than k. Thus, the number of moves completed in this protogadget prior to failure is at least

$$\begin{aligned} &(g - b_k) + \sum_{l=0}^{k-1} (g - b_l - f_l + 1) \\ &= (g - r) + \lceil \log_2 k \rceil\, (g - 3r + 1) + (k - \lceil \log_2 k \rceil - 1)(g - 2r + 1) \\ &\ge (k - \lceil \log_2 k \rceil)(g - 2r + 1) \\ &> (k - \lceil \log_2 k \rceil)\, \lfloor g/3 \rfloor \\ &\ge \tau. \end{aligned}$$

The second inequality uses the assertion that $r \le g/3$, and the third uses inequality (6). ∎

CLAIM 2. *Each protogadget is a subgraph of some gadget.*

Proof. The adversary chooses at most f_l forward blocks and at most $g-(f_l+b_l)$ cross blocks at each layer. Thus there are enough unchosen blocks to select a total of exactly f_l forward and b_l backward blocks, which precisely defines a gadget. □

CLAIM 3. *All entry points of a protogadget are equivalent in the sense that if M makes at most τ moves in a protogadget entered through vertex v_h^0, then the resulting configuration will be exactly the same as if it had entered through vertex v_0^0, except that positions of all pebbles in it on layer l will be shifted by $h \bmod n_l$ for $0 \le l \le k$.*

Proof. Intuitively, this reflects the rotational symmetry of the funnel. To make this precise, we claim that for any $h \in \mathbb{N}$ and any protogadget π, the mapping $\phi_h(v_i^l) = v_{i'}^l$, where $i' = (i+h) \bmod n_l$, is an automorphism on π, i.e., a surjection on the vertices of π preserving labeled half-edges. Consider a forward edge labeled a at level l in π, say (v_i^l, v_j^{l+1}), where $j = \chi(i,a,l+1)$. Note that for each fixed a and l, there is a constant c (depending on a and l but independent of i) such that $\chi(i,a,l+1) = (i+c) \bmod n_{l+1}$. Now $\phi_h(v_i^l) = v_{i'}^l$, $\phi_h(v_j^{l+1}) = v_{j'}^{l+1}$, with $i' = (i+h) \bmod n_l$, and $j' = (j+h) \bmod n_{l+1}$, so since n_{l+1} divides n_l we have

$$\begin{aligned}
\chi(i',a,l+1) &= (i'+c) \bmod n_{l+1} \\
&= (((i+h) \bmod n_l) + c) \bmod n_{l+1} \\
&= (i+h+c) \bmod n_{l+1} \\
&= (((i+c) \bmod n_{l+1}) + h) \bmod n_{l+1} \\
&= (j+h) \bmod n_{l+1} \\
&= j'.
\end{aligned}$$

A similar argument applies to cross edges. □

The analog of Claim 3 also holds for gadgets, provided the τ moves use only forward and/or cross edges. The same may not be true if backward edge labels are used.

Global strategy. We have now described the gadgets and protogadgets and the adversary's strategy for building them. We turn to the remaining part of its strategy: charging and committing edges. Recall that the adversary associates a charge with each connecting edge, in which it counts moves in $G_{i,*}$. In addition, it associates with each connecting edge a second integer, called a *birthdate*, recording the time at which a pebble first crosses the edge.

The construction of $G_{i+1,0}$ from $G_{i,*}$ proceeds as follows. The adversary begins with M in its *initial* configuration in the current graph $G_{i,*}$. The adversary simulates successive moves of M on $G_{i,*}$ until some uncommitted connecting edge accumulates charge τ, where edge charges are determined by the following rules. During a move, suppose M moves pebble p along

1. an edge internal to a gadget or protogadget. Let f be the connecting edge most recently crossed by p. If f has charge less than τ, then charge the move to f; otherwise there is no charge.

2. a connecting edge f (committed or not). Charge the move to the oldest (i.e., least birthdate) connecting edge having charge less than τ. If this is the first step in which a pebble has crossed edge f in either direction, define the birthdate of f to be the current time.

As sketched in the overview, the second charging rule ensures that when an uncommitted connecting edge f, even one whose associated pebbles have moved infrequently, accumulates charge τ, only a few of the gadgets of the appropriate type can have been touched by pebbles since the birth of f.

When some uncommitted connecting edge $f = \{u, v\}$ with label $\lambda_{u,v} = a$ accumulates charge τ we stop the simulation and construct from $G_{i,*}$ a new graph $G_{i+1,0}$ defined as follows. Let π_v be the protogadget entered through f, with v in π_v. Note that by the charging rules above, each move in π_v has been charged to f, so there have been at most τ such moves. Thus by Claim 1 the adversary did not fail while building π_v. By Claim 2, the protogadget π_v is a subgraph of some gadget γ_v. We say an entry vertex of a gadget is *open* if it has degree less than d. If possible, choose an entry vertex x of a gadget in $G_{i,*}$ such that

(7)
- x is open,
- x's gadget is of the same type as γ_v,
- x and u are not adjacent, and
- x's gadget has remained pebble free since the birthdate of the uncommitted edge f.

$G_{i+1,0}$ is identical to $G_{i,*}$, except that the protogadget π_v is removed and the uncommitted edge $f = \{u, v\}$ is replaced by the committed edge $\{u, x\}$ with labels $\lambda_{u,x} = a$ and $\lambda_{x,u} = b$, where b is any label not already present on an outgoing half-edge at x. If there is no such x, or if using the only such x would result in $G_{i+1,0}$ having neither uncommitted edges nor open entry vertices, we instead add one additional gadget of type γ_v, choose as x any of the new gadget's entry vertices, then proceed as described above. The latter contingency avoids premature termination of the construction. The requirement that x and u be nonadjacent avoids construction of parallel edges.

The behavior of M on $G_{i+1,0}$ is similar to its behavior on $G_{i,*}$. Suppose in $G_{i,*}$ that the uncommitted edge f was first crossed during the simulation of the bth move of M (i.e., has birthdate b) and accumulates charge τ during move b'. When M is simulated on $G_{i+1,0}$, it will behave exactly as on $G_{i,j}$ for the first $b-1$ moves, since the portion of $G_{i+1,0}$ visited during that period is exactly the same as the portion visited in $G_{i,*}$. In particular, the charges and birthdates attached to edges will be the same. (Thus, one can view the adversary as rolling back the simulation to step b, committing f, and resuming.) Between steps b and b' those pebbles that crossed edge f in $G_{i,*}$ will be in x's gadget γ_x in $G_{i+1,0}$ instead of in the protogadget π_v entered through f as they were in $G_{i,*}$, but since γ_x contains π_v as a subgraph, their motions in $G_{i+1,0}$ will exactly reflect their motions in $G_{i,*}$. Note that by Claim 3 this is true regardless of which entry vertex x of γ_x was chosen. It is crucial that the chosen gadget γ_x was pebble free between steps b and b', so there is no possibility that these pebbles will meet pebbles in γ_x in $G_{i+1,0}$ that they did not meet in π_v in $G_{i,*}$. Again, the charges and birthdates attached to edges will be the same in $G_{i+1,0}$ as in $G_{i,*}$ through step b'. In particular, each of the $i+1$ committed edges in $G_{i+1,0}$ will have a charge of τ, and hence M will run for at least $(i+1)\tau$ steps on $G_{i+1,0}$.

Final Construction. After $G_{i+1,0}$ is built, we restart the simulation from the beginning on $G_{i+1,0}$ to build $G_{i+2,0}$, etc. Continue this process until $G_{\mu,0}$ is constructed. Finally, from $G_{\mu,0}$ we build a pair of similar graphs G and G', one connected and the other not, on which M will have identical behavior. In particular, if M runs for fewer than $\mu \cdot \tau$ steps, then M cannot be correct on both. The connected graph G is built by

1. committing all uncommitted edges, as described above;
2. joining the remaining open entry vertices with some number, Δ, of extra vertices so as to make G have n vertices and be d-regular; and
3. designating one of these extra vertices as t.

One way to accomplish the second step is the following. First, pick any two nonadjacent open vertices and connect them. Repeat this as often as possible. Let u be the number of "missing" half-edges, i.e., the total over all open vertices of d minus their degrees, and let i be the number of remaining open vertices. Since the pairing process could not be applied to reduce i further, it must be the case that the i open entry vertices form a clique. Recalling that each entry vertex is incident to at most $d - d'$ connecting edges, the number u of missing half-edges can be at most

$$i((d - d') - (i - 1)) \leq i(d - i) \leq d^2/4,$$

since $d' \geq 1$ and since $i(d-i)$ is maximized when $i = d/2$. Thus $u \leq d^2/4$. Furthermore, u will necessarily be even, since each entry vertex starts with $d-d'$ missing half edges; since from (4) $d - d'$ is a multiple of q, hence even; and since each committed edge replaces a pair of missing half-edges. Notice that this implies that $d(n - \Delta)$ is even, since the gadgets together contain $n - \Delta$ vertices and $d(n - \Delta) - u$ half-edges, which naturally occur in pairs. Complete the construction by adding a Δ-vertex, d-regular graph that contains a $u/2$-matching, removing the edges of this matching, and connecting each of the u missing half-edges to a distinct endpoint of the matching. Such a regular graph exists by Proposition 1, since dn, $d(n - \Delta)$, and hence $d\Delta$ are even; since, as shown below, $d < \Delta$ and $u \leq d^2/4 < \Delta$; and since the proof of Proposition 1 given in Borodin et al. [16] constructs a regular graph that is Hamiltonian and hence has a $u/2$-matching. (That construction is similar to the construction of cross edges in one layer of our gadgets, where the 0-labels form a Hamiltonian cycle.)

The nonconnected graph G' is built similarly, except that $d + 1$ of the Δ extra vertices, including t, are connected in a clique and hence are disconnected from the rest of the graph.

By an argument similar to the one above, M's behavior on both G and G' is essentially the same as on $G_{\mu,0}$. In particular, the edge charges will be the same, so M will run for at least $\mu \cdot \tau$ steps without reaching any of the Δ extra vertices, including t. One point to be shown in the analysis below is that $\Delta \geq d+1+\max(d+1, d^2/4) = d^2/4+d+1$, i.e., large enough to allow completion of the construction of G and G' as described above. Since $d \leq \sqrt{n} - 2$ (in fact, $d^2 + Pd = o(n)$), it suffices that $\Delta \geq n/4$.

Analysis. All that remains to show our $\Omega(m\tau)$ lower bound is to give values for the various parameters so as to satisfy the constraints listed above (and to maximize τ). For convenience, we summarize the relevant parameters and constraints here.

C1. Number of committed connecting edges: $\mu = \Omega(m)$.
C2. Number of vertices added in the final step of the construction: $\Delta \geq n/4$.
C3. Number of layers per gadget: $k \geq 1$.
C4. Size of full blocks in the label partition: $q \geq 2$, even.
C5. Number of full label blocks: $g = \lfloor d/q \rfloor$.
C6. Upper bound on the number of pebbles entering a protogadget: $1 \leq r \leq g/3$.
C7. Time per committed edge: τ; if $P \leq r$ then $\tau = (k - \lceil \log_2 k \rceil) \lfloor g/3 \rfloor$; else $\tau = r$.

To satisfy constraint C1, choose

$$\mu = \lfloor dLn/(8S) \rfloor . \tag{8}$$

Since we have seen in inequality (1) that $L/S = \Omega(1)$, we have $\mu = \Omega(m)$ as claimed above.

We now turn to constraint C2. We say a gadget is *closed* if each of its L entry vertices is connected to the maximum number $d-d'$ of committed half-edges; otherwise

the gadget is *open*. $G_{\mu,0}$ has exactly μ committed edges, or 2μ committed half-edges. From (4), each closed gadget contributes $(d-d')L \geq dL/2$ committed half-edges, so by (8) there can be no more than $2\mu/(dL/2) \leq n/(2S)$ closed gadgets in $G_{\mu,0}$, each of size S, and so closed gadgets contribute no more than $n/2$ vertices to G. Thus, to ensure constraint C2, i.e., that Δ is at least $n/4$, it suffices to ensure that the following additional constraint holds:

C8. Number of vertices in open gadgets: must be at most $n/4$.

When building $G_{i+1,0}$ from $G_{i,*}$, the adversary replaces a protogadget π by a copy of a fixed gadget γ. There might be many copies of the gadget γ with which π can be replaced. A key claim in establishing constraint C8 is that there are never more than $P(\tau+2)+d$ open copies of such a gadget.

CLAIM 4. *When $G_{i+1,0}$ is defined, if there are $P(\tau+2)+d$ open copies of the gadget γ_v, then at least one of them will have an entry vertex x satisfying the conditions* (7), *so a new (open) gadget will* not *be introduced into $G_{i+1,0}$.*

Proof. We show an upper bound on the number of open gadgets that are disqualified from containing x. It is easy to see that at most $d-d' \leq d-1$ entry vertices are adjacent to u in $G_{i,*}$. A more subtle problem is to bound the number of gadgets that can be touched by pebbles between the birth of π's uncommitted connecting edge f and the time at which f has accumulated charge τ. At most P gadgets contain pebbles at the time of f's birth. At most $P-1$ edges older than f can have charge less than τ, because, by Claim 1, for each such edge f' there is at least one pebble that does not leave its gadget or protogadget until f' has accumulated charge τ. Each gadget touched by some pebble after the birth of f necessitates the crossing of some connecting edge. Thus after at most $(P-1)\tau$ such crossings, f will be the oldest uncommitted edge, and after at most τ more crossings, f will have charge τ. Thus, at most $P(\tau+1)$ gadgets can be touched by pebbles during the relevant interval. Finally, at all times, at most P open gadgets are incident to uncommitted half-edges, hence at most P lack open entry vertices. Thus, the number of vertices x not disqualified is at least $P(\tau+2)+d-(d-1)-P(\tau+1)-P=1$, which establishes the claim. ∎

Inequality (5) bounds the number of distinct gadget types, Claim 4 bounds the number of open copies of each, and inequality (2) bounds the size of each copy. Thus, the total number of vertices in open gadgets is at most

$$\left(\frac{eg}{r}\right)^{r(2k+\lceil \log_2 k\rceil)} (P(\tau+2)+d)\, 6dk. \tag{9}$$

We divide the remainder of the analysis into two cases. The second applies when P is small. The first applies to either small or large P but gives a weaker bound than the second for small P.

Case 1. Let $\delta = 3\epsilon/2 = 1/(2\ln(6e))$, let

$$\beta = 72\left(d^2 + Pd\ln\frac{n}{d^2+Pd}\right),$$

and suppose n, P, and d are such that $d^2+Pd \leq n/e$ and $\beta \leq n/e^{6/\delta}$, both of which are true for all sufficiently large n, since $d^2+Pd = o(n)$. Then we claim that the following parameter values satisfy constraints C3–C8:

$$
\begin{aligned}
k &= 1, \\
q &= 2\left\lceil \frac{d-5}{\delta \ln(n/\beta)} \right\rceil, \\
g &= \lfloor d/q \rfloor, \\
r &= \lfloor g/3 \rfloor, \\
\tau &= r.
\end{aligned}
$$

Note that constraints C3 and C5 are immediately satisfied, as is constraint C7 since $k = 1$. It is also immediate that q is even and is positive, since $d \geq 6$, $\delta > 0$, and $n/\beta > 1$; hence constraint C4 is satisfied.

For constraint C6, it is immediate that $r \leq g/3$. To show $r \geq 1$ it suffices to show $q \leq d/3$:

$$
q = 2\left\lceil \frac{d-5}{\delta \ln(n/\beta)} \right\rceil \leq 2\left\lceil \frac{d-5}{6} \right\rceil = 2\left\lfloor \frac{d}{6} \right\rfloor \leq \frac{d}{3}.
$$

To satisfy constraint C8 above, we first note (making frequent use of the inequalities $x/2 \leq \lfloor x \rfloor$ and $\lceil x \rceil \leq 2x$, valid for all $x \geq 1$) that

$$
\begin{aligned}
g/r = g/\lfloor g/3 \rfloor &\leq g/(g/6) = 6, \\
r = \lfloor g/3 \rfloor &\leq g/3 = \lfloor d/q \rfloor /3 \leq d/(3q) \\
&= \frac{d}{6\left\lceil \frac{d-5}{\delta \ln(n/\beta)} \right\rceil} \leq \frac{1}{6}\frac{d}{d-5}\delta \ln(n/\beta) \leq \delta \ln(n/\beta), \\
r + 2 &\leq 3r, \\
d^2 + Pd &\leq d^2 + Pd \ln \frac{n}{d^2 + Pd} < \beta, \text{ and} \\
\delta &= 1/(2\ln(6e)) < 1.
\end{aligned}
$$

Returning to constraint C8, we must show that (9) is at most $n/4$:

$$
\begin{aligned}
\left(\frac{eg}{r}\right)^{r(2k+\lceil \log_2 k \rceil)} &(P(\tau+2)+d)\,6dk \\
&= 6\left(\frac{eg}{r}\right)^{2r}(d^2 + Pd(r+2)) \\
&\leq 18(6e)^{2r}(d^2 + Pdr) \\
&\leq 18(6e)^{2\delta \ln(n/\beta)}(d^2 + \delta Pd \ln(n/\beta)) \\
&= 18(n/\beta)(d^2 + \delta Pd \ln(n/\beta)) \\
&= \frac{18n(d^2 + \delta Pd \ln(n/\beta)}{72\left(d^2 + Pd \ln \frac{n}{d^2+Pd}\right)} \\
&< n/4,
\end{aligned}
$$

as desired.

To complete the analysis of Case 1, we show that τ is large enough to imply the bound in the statement of the theorem:

$$
\begin{aligned}
\tau = r = \lfloor g/3 \rfloor &\geq g/6 = \lfloor d/q \rfloor /6 \geq d/(12q) \\
&= \frac{d}{24\left\lceil \frac{d-5}{\delta \ln(n/\beta)} \right\rceil}.
\end{aligned}
$$

The latter quantity equals $d/24$, if $d \le \delta \ln(n/\beta) + 5$. If $d > \delta \ln(n/\beta) + 5$, then

$$\begin{aligned}
\frac{d}{24\left\lceil \frac{d-5}{\delta \ln(n/\beta)} \right\rceil} &\ge \frac{d}{48\left(\frac{d-5}{\delta \ln(n/\beta)}\right)} \\
&= \frac{1}{48}\frac{d}{d-5}\delta \ln(n/\beta) \\
&\ge \frac{\delta \ln(n/\beta)}{48} \\
&= \frac{\delta}{48} \ln \frac{n}{72\left(d^2 + Pd \ln \frac{n}{d^2+Pd}\right)} \\
&\ge \frac{\delta}{48} \ln \frac{n}{72\,(d^2 + Pd) \ln \frac{n}{d^2+Pd}} \\
&= \Omega\left(\ln \frac{n}{d^2 + Pd}\right).
\end{aligned}$$

The penultimate inequality holds since, by assumption, $\ln(n/(d^2+Pd)) \ge 1$. The final lower bound follows since $\ln(x/(72 \ln x)) = \Omega(\ln x)$. Thus, as claimed in the statement of the theorem, $\tau = \Omega(\min(d, \ln(n/(d^2 + Pd))))$.

Case 2. Recall $\epsilon = 1/(3\ln(6e))$ and suppose $6P \le d \le \sqrt{n}/6^9$ and $1 \le P \le \epsilon \ln(n/d^2)$. (Note that $d \le \sqrt{n}/6^9$ must be true for all sufficiently large n, since $d^2+Pd = o(n)$.) Then we claim that the following parameter values satisfy constraints C3–C8:

$$\begin{aligned}
\hat{q} &= \frac{ed}{P}\left(\frac{d^2}{n}\right)^{1/(3P)}, \\
q &= 2\left\lceil \hat{q}/2 \right\rceil, \\
g &= \lfloor d/q \rfloor, \\
r &= P, \\
k &= \left\lfloor \frac{\ln(n/d^2)}{3P \ln(ed/(qP))} \right\rfloor, \\
\tau &= (k - \lceil \log_2 k \rceil)\, \lfloor g/3 \rfloor = \Theta(gk).
\end{aligned}$$

Note that constraint C5 is immediately satisfied, as is constraint C7 since $r \ge P$. Since $\hat{q}$ is positive, it is also immediate that q is even and is positive, hence constraint C4 is satisfied.

Note for future use that

$$(n/d^2)^{1/(3P)} \ge (n/d^2)^{1/(3\epsilon \ln(n/d^2))} = e^{1/(3\epsilon)} = 6e. \tag{10}$$

For constraint C3, note that $q \ge \hat{q}$. Thus,

$$k = \left\lfloor \frac{\ln((n/d^2)^{1/(3P)})}{\ln(ed/(qP))} \right\rfloor \ge \left\lfloor \frac{\ln((n/d^2)^{1/(3P)})}{\ln(ed/(\hat{q}P))} \right\rfloor = \left\lfloor \frac{\ln((n/d^2)^{1/(3P)})}{\ln((n/d^2)^{1/(3P)})} \right\rfloor = 1.$$

Thus $k \ge 1$. Using a similar analysis, we note for future use that $k = 1$ whenever $q > 2$. This holds since $q > 2$ implies $\hat{q}/2 > 1$, which implies $q \le 2\hat{q}$. Thus,

$$k = \left\lfloor \frac{\ln((n/d^2)^{1/(3P)})}{\ln(ed/(qP))} \right\rfloor \le \left\lfloor \frac{\ln((n/d^2)^{1/(3P)})}{\ln(ed/(2\hat{q}P))} \right\rfloor = \left\lfloor \frac{\ln((n/d^2)^{1/(3P)})}{\ln((n/d^2)^{1/(3P)}/2)} \right\rfloor = 1. \tag{11}$$

The last equality follows from the fact that $1 < (\ln x)/(\ln(x/2)) < 2$ whenever $x > 4$, and from (10).

For constraint C6, it is immediate that $r = P \geq 1$. To show $r \leq g/3$ it suffices to show $3qP \leq d$. If $q = 2$, this holds, since by assumption $6P \leq d$. If $q > 2$, then $\hat{q}/2 > 1$, so

$$3qP = 6\lceil \hat{q}/2 \rceil P \leq 6\hat{q}P = 6(ed/P)(d^2/n)^{1/(3P)}P \leq 6ed/(6e) = d. \tag{12}$$

The last inequality follows from (10).

For constraint C8, we first note for integer $k \geq 1$ that

$$2k + \lceil \log_2 k \rceil \leq 8k/3.$$

(The bound is tight at $k = 3$.) Also,

$$\tau + 2 = (k - \lceil \log_2 k \rceil)\lfloor g/3 \rfloor + 2 \leq gk,$$

since $g \geq 3$. Using (9), we bound the number of vertices in open gadgets as follows.

$$\begin{aligned}
&\left(\frac{eg}{r}\right)^{r(2k+\lceil \log_2 k \rceil)} (P(\tau+2)+d)\, 6dk \\
&\qquad \leq 6\left(\frac{eg}{P}\right)^{8Pk/3} dk(Pgk + d) \\
&\qquad \leq 6\left(\frac{ed}{qP}\right)^{(8/3)P\left\lfloor \frac{\ln(n/d^2)}{3P\ln(ed/(qP))}\right\rfloor} dk(Pdk/q + d) \\
&\qquad \leq 6\left(\frac{n}{d^2}\right)^{8/9} d^2(Pk^2/q + k) \\
&\qquad \leq 6n^{8/9}d^{2/9}(Pk^2/q + k).
\end{aligned}$$

We break the rest of the derivation of constraint C8 into two subcases based on d. Note that, since $3qP \leq d$ from (12),

$$k = \left\lfloor \frac{\ln(n/d^2)}{3P\ln(ed/(qP))} \right\rfloor \leq \frac{\ln n}{3P\ln(3e)} \leq \ln n.$$

When $d < n^{1/4}$, since k and P are both $O(\log n)$, we have

$$6n^{8/9}d^{2/9}(Pk^2/q + k) = O(n^{8/9}(n^{1/4})^{2/9}\log^3 n) = O(n^{17/18}\log^3 n) = o(n).$$

When $d \geq n^{1/4}$, we will show that $q > 2P$ and $k = 1$, so we have

$$6n^{8/9}d^{2/9}(Pk^2/q + k) \leq 6n^{8/9}(n^{1/2}/6^9)^{2/9}(1/2 + 1) = n/4.$$

We show that $q > 2P$ as follows.

$$\frac{q}{P} \geq \frac{\hat{q}}{P} = \frac{ed}{P^2}\left(\frac{d^2}{n}\right)^{1/(3P)} \geq \frac{n^{1/4}}{P^2}\left(\frac{n^{2/4}}{n}\right)^{1/3} = \frac{n^{1/12}}{P^2} = \omega(1).$$

(Recall $P = O(\log n)$.) Since $q > 2P$ and $P \geq 1$, we have $q > 2$, so $k = 1$ by (11).

To complete the analysis of Case 2, we show that $\tau = (k - \lceil \log_2 k \rceil)\lfloor g/3 \rfloor$ is large enough to imply the bound in the statement of the theorem. Again we split the

analysis into two subcases based on d. We have $q > 2$ if and only if $\hat{q} > 2$, which holds exactly when

$$d > d_0 = (2P/e)^{3P/(3P+2)}\, n^{1/(3P+2)}.$$

In this case we have $k = 1$ by (11) and

$$\begin{aligned}\tau = \lfloor g/3 \rfloor &\geq g/6 \geq d/(12q) \geq d/(24\hat{q}) = \frac{d}{24\left(\frac{ed}{P}\left(\frac{d^2}{n}\right)^{1/(3P)}\right)} \\ &= \frac{P}{24e}\left(\frac{n}{d^2}\right)^{1/(3P)} \qquad (13) \\ &= \Omega\left(P\left(\frac{n}{d^2}\right)^{1/(3P)}\right),\end{aligned}$$

as claimed. We remark that, by (10), when P is maximal, (13) is $P/4 = \Theta(\log(n/d^2))$, so the transition to the bound given in Case 1 is "smooth."

In the second subcase we have $d \leq d_0$. First, note that

$$d_0 = (2P/e)^{3P/(3P+2)}\, n^{1/(3P+2)} \leq P n^{1/(3P+2)} \leq P n^{1/5} = o(n^{1/4}). \qquad (14)$$

Second, since $d \leq d_0$, we have $q = 2$ and $k \geq 1$. Also, note that $(k - \lceil \log_2 k \rceil)/k \geq 1/3$, (attaining the minimum at $k = 3$) and that $g \geq 3$. Hence $\tau = \Omega(gk)$ and

$$\begin{aligned} gk &= \left\lfloor \frac{d}{q} \right\rfloor \left\lfloor \frac{\ln(n/d^2)}{3P \ln(ed/(qP))} \right\rfloor \\ &\geq \frac{d \ln(n/d^2)}{24P \ln(ed/(2P))} \\ &= \frac{d \ln(n/o(n^{1/2}))}{24P \ln(ed/(2P))} \\ &= \Omega\left(\frac{d/P}{\ln(d/P)} \ln n\right), \end{aligned}$$

as claimed. We remark that when P is maximal and $d \geq 6P$, the estimate in (14) can be refined, allowing one to show $d = \Theta(P) = \Theta(\log n)$. Thus, τ again matches the bound in Case 1 (up to constant factors).

Finally, when $d = d_0$ we have $\hat{q}$ exactly equal to 2; similarly, when $d = d_0$, the expression of which k is the floor is precisely 1. Furthermore, both expressions vary slowly with d, so both are $\Theta(1)$ when d is near d_0. Thus, again $\tau = (k - \lceil \log_2 k \rceil)\, \lfloor \lfloor d/q \rfloor /3 \rfloor$ is "smooth" as d crosses d_0, the threshold between the lower bounds quoted in (a) and (b) in the statement of the theorem, and in fact both lower bounds are $\Theta(md_0)$ for d near d_0.

This completes the proof. □

It is interesting to note why the proof would fail if M were allowed to jump pebbles. In the local phase, the adversary was able to pick an existing gadget in which p must invest τ steps. In the presence of jumping, this fails, since p can always jump out of the new gadget. As a particular foil to the proof above, imagine an automaton that stations one pebble p on an entry vertex of some gadget, and successively moves a second pebble q to each neighbor, jumping q back to p to find the next neighbor. In time $\Theta(d)$, this has touched all $\Theta(d)$ connecting edges incident to that entry vertex, which was impossible in the construction above.

4. Open problem. The obvious important problem is to strengthen and generalize these lower bounds. Following an earlier version of this paper [9], Edmonds [21] proved a much stronger time-space tradeoff on general JAGs: for every $z \geq 2$, a JAG with at most $\frac{1}{28z}\frac{\log n}{\log\log n}$ pebbles and at most $2^{\log^z n}$ states requires time $n \cdot 2^{\Omega((\log n)/(\log\log n))}$ to traverse 3-regular graphs. The ultimate goal might be to prove that $ST = \Omega(mn)$ for JAGs or even for general models of computation.

Acknowledgment. We thank Michael Sipser for showing us the construction generalized in section 3.

ON THE APPROXIMABILITY OF NUMERICAL TAXONOMY (FITTING DISTANCES BY TREE METRICS)*

RICHA AGARWALA†, VINEET BAFNA‡, MARTIN FARACH§, MIKE PATERSON¶, AND MIKKEL THORUP‖

Abstract. We consider the problem of fitting an $n \times n$ distance matrix D by a tree metric T. Let ε be the distance to the closest tree metric under the L_∞ norm; that is, $\varepsilon = \min_T\{\| T-D \| \infty\}$. First we present an $O(n^2)$ algorithm for finding a tree metric T such that $\| T-D \| \infty \leq 3\varepsilon$. Second we show that it is $\mathcal{NP}$-hard to find a tree metric T such that $\| T-D \| \infty < \frac{9}{8}\varepsilon$. This paper presents the first algorithm for this problem with a performance guarantee.

1. Introduction. One of the most common methods for clustering numeric data involves fitting the data to a *tree metric*, which is defined by a weighted tree spanning the points of the metric, the distance between two points being the sum of the weights of the edges of the path between them. Not surprisingly, this problem, the so-called numerical taxonomy problem, has received a great deal of attention (see [2, 7, 8] for extensive surveys) with work dating as far back as the beginning of the century [1]. Fitting distances by trees is an important problem in many areas. For example, in statistics, the problem of clustering data into hierarchies is exactly the tree fitting problem. In "historical sciences" such as paleontology, historical linguistics, and evolutionary biology, tree metrics represent the branching processes which lead to some observed distribution of data. Thus, the numerical taxonomy problem has been, and continues to be, the subject of intense research.

In particular, consider the case of evolutionary biology. By comparing the DNA sequences of pairs of species, biologists get an estimate of the evolutionary time which has elapsed since the species separated by a speciation event. A table of pairwise distances is thus constructed. The problem is then to reconstruct the underlying evolutionary tree. Dozens of heuristics for this problem appear in the literature every year (see, e.g., [8]).

The numerical taxonomy problem is usually cast in the following terms. Let S

be the set of species under consideration.

The numerical taxonomy problem.
Input: $D : S^2 \to \Re_{\geq 0}$, a distance matrix.
Output: A *tree metric* T which spans S and *fits* D.

This definition leaves two points unanswered: first, what kind of tree metric, and, second, what does it mean for a metric to fit D? Typically we are talking about any tree metric, but sometimes we want to restrict ourselves to *ultrametrics* defined by rooted trees where the distance to the root is the same for all points in S. In order to distinguish specific types of tree metrics, such as ultrametrics, from the general case, we will refer to unrestricted tree metrics as *additive* metrics. There may be no tree metric coinciding exactly with D, so by "fitting" we mean approximating D under norms such as L_1, L_2, or L_∞. That is, for $k = 1, 2, \ldots, \infty$, we want to find a tree metric T minimizing $\| T - D \|_k$ ($\| T - D \|_k$ is formally defined in Definition 2.6).

History. The numerical taxonomy problem for additive metric fitting under L_k norms was explicitly stated in its current form in 1967 [4]. Since then it has collected an extensive literature. In 1977 [10], it was shown that if there is a tree metric T coinciding exactly with D, it is unique and constructible in linear, i.e., $O(|S|^2)$, time. Unfortunately there is typically no tree metric coinciding exactly with D, and in 1987 [5], it was shown that for L_1 and L_2, the numerical taxonomy problem is $\mathcal{NP}$-hard, both in the additive and in the ultrametric cases. Additional complexity results appear in [9].

The only positive fitting result is from 1995 [6] and shows that under the L_∞ norm an optimal ultrametric is polynomially computable, in fact, in linear time. However, while ultrametrics have interesting special case applications, the fundamental problem in the area of numerical taxonomy is that of fitting D by general tree metrics. Unfortunately no provably good algorithms existed for fitting distances by additive metrics, and in [6] the numerical taxonomy problem for general tree metrics under the L_∞ norm was posed as a major open problem.

Our results. We consider the numerical taxonomy problem for additive metrics under the L_∞ norm as suggested in [6]. Let ε be the distance to the closest additive metric under the L_∞ norm, that is, $\varepsilon = \min_T\{\| T - D \|_\infty\}$. First we present an $O(n^2)$ algorithm for finding an additive metric T such that $\| T - D \|_\infty \leq 3\varepsilon$. We complement this result not only by finding that an L_∞-optimal solution is $\mathcal{NP}$-hard, but we also rule out arbitrarily close approximations by showing that it is $\mathcal{NP}$-hard to find an additive metric T such that $\| T - D \|_\infty < \frac{9}{8}\varepsilon$.

Our algorithm is achieved by transforming the general tree metric problem to that of ultrametrics with a loss of a factor of 3 on the approximation ratio. Since the ultrametric problem is optimally solvable, our first result follows. We also generalize our transformation from the general tree metric to ultrametrics under any L_k norm with the same loss of a factor of 3.

The paper is organized as follows. After some preliminary definitions in section 2, we give our 3-approximation algorithm in section 3. We show in section 4 that our analysis is tight and that some natural "improved" heuristics do not help in the worst case. In section 5, we give our $\mathcal{NP}$-completeness and nonapproximability proofs. Finally, in section 6, we generalize our reduction from L_∞ to L_k norms with finite k.

2. Preliminaries. We present some basic definitions.

DEFINITION 2.1. *A* metric *on a set* $S = \{1, \ldots, n\}$ *is a function* $D : S^2 \to \Re_{\geq 0}$ *such that*

- $D[x, y] = 0 \iff x = y$,

- $D[x,y] = D[y,x]$,
- $D[x,y] \le D[x,z] + D[z,y]$ (*the triangle inequality*).

Likewise, $D : S^2 \to \Re_{\ge 0}$ is a *quasimetric* if it satisfies the first two conditions. For (quasi) metrics A and B, $A+B$ is the usual matrix addition, i.e., $(A+B)[i,j] = A[i,j] + B[i,j]$.

DEFINITION 2.2. *A (quasi) metric D is* (quasi) additive *if, for all points a,b,c,d,*

$$D[a,b] + D[c,d] \le \max\{D[a,c] + D[b,d], D[a,d] + D[b,c]\}.$$

This inequality is known as the 4-*point condition.*

THEOREM 2.3 (see [3]). *A metric is additive if and only if it is a tree metric.*

DEFINITION 2.4. *A metric D is an* ultrametric *if, for all points a,b,c,*

$$D[a,b] \le \max\{D[a,c], D[b,c]\}.$$

As noted above, an ultrametric is a type of tree metric.

DEFINITION 2.5. *A quasimetric D on n objects is a* centroid *quasimetric if $\exists l_1, \ldots, l_n$ such that $\forall i \ne j$, $D[i,j] = l_i + l_j$.*

A centroid quasimetric D is a *centroid metric* if $l_i \ge 0$ for all i. A centroid metric is a type of tree metric since it can be realized by a weighted tree with a star topology and edge weights l_i.

The k-norms are formally defined as follows.

DEFINITION 2.6. *For $n \times n$ real-valued matrices M and $k \ge 1$, define the k-norm, sometimes denoted L_k, by*

$$\| M \|_k = \left(\sum_{i<j} | M[i,j] |^k \right)^{\frac{1}{k}},$$

$$\| M \|_\infty = \max_{i<j} \{ | M[i,j] | \}.$$

3. Upper bound. Let $m_a = \max_i\{D[a,i]\}$. Let C^a be the centroid metric with $l_i = m_a - D[a,i]$, i.e., $C^a[i,j] = l_i + l_j = 2m_a - D[a,i] - D[a,j]$.

LEMMA 3.1 (see [2, Theorem 3.2]). *For any point a, D is quasiadditive if and only if $D + C^a$ is an ultrametric.*

LEMMA 3.2 (see [2, Corollary 3.3]). *Given an additive metric A and a centroid quasi-metric Q, $A+Q$ is additive if and only if $A+Q$ satisfies the triangle inequality.*

Let D be a distance matrix and let $\mathcal{X}$ be the set of all additive metrics. We define $\mathcal{A}(D)$ to be (one of) the additive metrics such that

$$\| D - \mathcal{A}(D) \|_\infty = \min_{A \in \mathcal{X}} \| D - A \|_\infty.$$

For point a, we say a metric M is *a-restricted* if $\forall i, M[a,i] = D[a,i]$. Let $\mathcal{X}^a$ be the set of a-restricted additive metrics. We define $\mathcal{A}^a(D)$ to be (one of) the a-restricted additive metrics such that $\| D - \mathcal{A}^a(D) \|_\infty = \min_{A \in \mathcal{X}^a} \| D - A \|_\infty$. In other words, $\mathcal{A}^a(D)$ is an optimal a-restricted additive metric for D. We will sometimes refer to such a metric as *a-optimal*. Similarly, we define $\mathcal{U}(D)$ to be an optimal ultrametric for D. Note that the functions $\mathcal{A}(), \mathcal{A}^a()$, and $\mathcal{U}()$ need not be uniquely valued. In

the following, we will let the output be an arbitrary optimal metric, unless otherwise noted. Recall that $\mathcal{U}()$ is computable in $O(n^2)$ time [6].

Lemma 3.1 suggests that we may be able to approximate the closest additive metric to D by approximating the closest ultrametric to $D + C^a$, i.e., by computing $\mathcal{U}(D + C^a) - C^a$ for some point a. Lemma 3.2 tells us that we need to guarantee the triangle inequality for the final metric to show that it is additive. Thus we need to modify our heuristic. Specifically, for any point a, we will show that $\| D - \mathcal{A}^a(D) \|_\infty \leq 3\| D - \mathcal{A}(D) \|_\infty$, and we will give a modification $\mathcal{U}^a()$ of $\mathcal{U}()$ such that $\mathcal{A}^a(D) = \mathcal{U}^a(D + C^a) - C^a$. We will use the following result implicit in [6].

THEOREM 3.3. *Consider two $n \times n$ distance matrices $L, M : S^2 \to \Re_{>0}$ and a real value h such that $L[i,j] \leq M[i,j] \leq h$ for all i, j. There is an $O(n^2)$ algorithm to compute an ultrametric U, if it exists, such that for all i, j, $L[i,j] \leq U[i,j] \leq h$, and $\| M - U \|_\infty$ is minimized.*

Proof. Our proof uses the construction of Theorem 5 in [6]. First we show how, given a distance matrix $A : S^2 \to \Re_{>0}$, we can construct in time $O(n^2)$ an ultrametric U, such that $U \leq A$ (i.e., $\forall i, j : U[i,j] \leq A[i,j]$) and such that for any ultrametric $U' \leq A$, $U' \leq U$.

Let T be a minimum spanning tree over the graph defined by A. The ultrametric U is now defined as follows. Let $e = (i,j)$ be the maximum weight edge of T, and let T_1 and T_2 be the subtrees of T obtained by deleting (i,j). Then U has root at height $A[i,j]/2$ and the subtrees of the root are the ultrametric trees U_1 and U_2 recursively defined on T_1 and T_2. Clearly, $U \leq A$.

CLAIM 3.3A. *For any ultrametric U', if $U' \leq A$ then $U' \leq U$.*

Proof. Let S_1 and S_2 be the partition of S defined by T_1 and T_2. By induction, for $k = 1, 2$, $U_k \geq U'|S_k^2$.

Let U_1' and U_2' be the two subtrees of U, and let S_1' and S_2' be the corresponding partitioning of S. Set $w = A[i,j]$ and $w' = \min_{(i,j) \in S_1' \times S_2'} A[i,j]$. Since w is the maximum weight in the minimum spanning tree T, $w' \leq w$. However, it is required that $U' \leq A$, so the height of the root of U' is $w'/2$, that is, the maximal distance in U' is w'. Thus for all $(i,j) \in S_1 \times S_2$, $U[i,j] = w \geq w' \geq U'[i,j]$. ∎

Consider an ultrametric U' as described in Theorem 3.3; i.e. for all i, j, $L[i,j] \leq U'[i,j] \leq h$, and $\varepsilon = \| M - U' \|_\infty$ is minimized. Set

$$\varepsilon^+ = \max_{i,j \in S}, (M[i,j] - U'[i,j]) \leq \varepsilon.$$

Suppose that we knew ε^+. Define A^{ε^+} such that $A^{\varepsilon^+}[i,j] = \min\{M[i,j] + \varepsilon^+, h\}$, and construct T^{ε^+} and $U^{\varepsilon^+} \leq A^{\varepsilon^+}$ as described above. Since $U' \leq A^{\varepsilon^+}$, $U^{\varepsilon^+}[i,j] \geq U'[i,j]$, so $L[i,j] \leq U^{\varepsilon^+}[i,j]$ and $\| M - U^{\varepsilon^+} \|_\infty \leq \| M - U' \|_\infty$.

Now observe that if T is a minimum spanning tree for M then T is also a minimum spanning tree for A^{ε^+}. Thus it follows that the topology of an optimal ultrametric U may be the same as the one we would construct from T and M. Given that T defines the right topology, we can construct the optimal ultrametric as follows.

Let $e = (i,j)$ be the maximum M-weight edge of T, and let T_1 and T_2 be the subtrees of T obtained by deleting (i,j). Let S_1 and S_2 be the partition of S defined by T_1 and T_2. Set

$$\mu = \frac{\max_{(i,j) \in S^2} M[i,j] + \min_{(i,j) \in S_1 \times S_2} M[i,j]}{2}.$$

Then U has root at height $\min\{h, \mu\}/2$ and the subtrees of the root are the ultrametric trees U_1 and U_2 recursively defined on T_1 and T_2. ∎

3.1. The L_∞ approximation. The *stem* of a leaf is the edge incident on it.

LEMMA 3.4. *For all points a,* $\| D - \mathcal{A}^a(D) \|_\infty \leq 3\| D - \mathcal{A}(D) \|_\infty$.

Proof. For all i, j, let $\varepsilon[i,j] = \mathcal{A}(D)[i,j] - D[i,j]$, and $\varepsilon = \max_{i,j}\{|\varepsilon[i,j]|\}$. Derive an a-restricted tree $T^{/a}$ from $\mathcal{A}(D)$ as follows. We will move all i either toward or away from a until each i is distance $D[a,i]$ from a. If $\mathcal{A}(D)[a,i] - D[a,i]$ is negative, we simply increase the length of its stem. Otherwise, i must be moved closer to a. Consider the (weighted) path from i to a. Let p be the point on this path which is distance $D[a,i]$ from a. We simply move i to this location. In either case, no point i is moved more than $|\varepsilon[a,i]|$, and so $|\mathcal{A}(D)[i,j] - T^{/a}[i,j]| \leq |\varepsilon[a,i]| + |\varepsilon[a,j]|$. Now, $T^{/a}$ is additive by construction, and for all i, $T^{/a}[a,i] = D[a,i]$. Further, for all i, j,

$$\begin{aligned} |D[i,j] - T^{/a}[i,j]| &\leq |\mathcal{A}(D)[i,j] - T^{/a}[i,j]| + |D[i,j] - \mathcal{A}(D)[i,j]| \\ &\leq (|\varepsilon[a,i]| + |\varepsilon[a,j]|) + |\varepsilon[i,j]| \\ &\leq 3\varepsilon. \end{aligned}$$

Finally, by the optimality of $\mathcal{A}^a(D)$,

$$\| D - \mathcal{A}^a(D) \|_\infty \leq \| D - T^{/a} \|_\infty \leq 3\varepsilon. \qquad \square$$

LEMMA 3.5. *For any point a,* $\mathcal{A}^a(D)$ *can be computed in polynomial time.*

Proof. We say an ultrametric U is a-restricted (with respect to D) if it satisfies the following constraints:

$$2m_a \geq U[i,j] \geq 2\max\{l_i, l_j\} \text{ for all } i, j, \tag{1}$$

$$U[a,i] = 2m_a \text{ for all } i \neq a. \tag{2}$$

For any distance matrix M, define $\mathcal{U}^a(M)$ to be an a-restricted ultrametric which minimizes $\| M - \mathcal{U}^a(M) \|_\infty$. Note that for all i, j, $\mathcal{U}^a(M)[i,j] \leq 2m_a$. We can therefore apply Theorem 3.3, and so $\| M - \mathcal{U}^a(M) \|_\infty$ can be computed in $O(n^2)$ time.

Let $T = \mathcal{U}^a(D + C^a) - C^a$. We now show that $T = \mathcal{A}^a(D)$.

CLAIM 3.5A. *T is an a-restricted additive metric.*

Proof. Let $D^a = D + C^a$. Constraint (2) implies that T is a-restricted, since $T[a,i] = \mathcal{U}^a(D + C^a)[a,i] - C^a[a,i] = 2m_a - (2m_a - D[a,i]) = D[a,i]$. By Lemma 3.2, we only need to show that T satisfies the triangle inequality, i.e.,

$$\begin{aligned} & T[i,j] \leq T[i,k] + T[k,j], \text{ for all distinct } i,j,k \\ \Leftrightarrow\ & \mathcal{U}^a(D^a)[i,j] - C^a[i,j] \leq \mathcal{U}^a(D^a)[i,k] - C^a[i,k] + \mathcal{U}^a(D^a)[k,j] - C^a[k,j] \\ \Leftrightarrow\ & \mathcal{U}^a(D^a)[i,j] \leq \mathcal{U}^a(D^a)[i,k] + \mathcal{U}^a(D^a)[k,j] - 2l_k \\ \Leftrightarrow\ & \mathcal{U}^a(D^a)[i,j] \leq \max\{\mathcal{U}^a(D^a)[i,k], \mathcal{U}^a(D^a)[k,j]\} \\ & \qquad + \min\{\mathcal{U}^a(D^a)[i,k], \mathcal{U}^a(D^a)[k,j]\} - 2l_k. \end{aligned}$$

Now, since $\mathcal{U}^a(D^a)$ is an ultrametric,

$$\mathcal{U}^a(D^a)[i,j] \leq \max\{\mathcal{U}^a(D^a)[i,k], \mathcal{U}^a(D^a)[k,j]\}.$$

Also, $\min\{\mathcal{U}^a(D^a)[i,k], \mathcal{U}^a(D^a)[k,j]\} \geq 2l_k$ by constraint (1). Hence, the claim is proved. $\square$

CLAIM 3.5B. *$\mathcal{A}^a(D) + C^a$ is an a-restricted ultrametric.*

Proof. From Lemma 3.1, $\mathcal{A}^a(D) + C^a$ is an ultrametric. To show that constraint (2) is satisfied, define $T' = \mathcal{A}^a(D) + C^a$ and note that

$$T'[a,i] = \mathcal{A}^a(D)[a,i] + C^a[a,i] = D[a,i] + l_i + l_a = 2m_a.$$

For constraint (1), we use the fact that $\mathcal{A}^a(D)$ is a metric, and therefore, for all $i, j \neq a$,

$$\begin{aligned} & \mathcal{A}^a(D)[a,j] \leq \mathcal{A}^a(D)[i,j] + \mathcal{A}^a(D)[a,i] \\ \Rightarrow \quad & T'[a,j] - C^a[a,j] \leq T'[i,j] - C^a[i,j] + T'[a,i] - C^a[a,i] \\ \Rightarrow \quad & T'[a,j] \leq T'[j,i] + T'[a,i] - 2l_i \\ \Rightarrow \quad & 2m_a \leq T'[j,i] + 2m_a - 2l_i \\ \Rightarrow \quad & T'[j,i] \geq 2l_i. \end{aligned}$$

By symmetry, $T'[j,i] \geq 2l_j$. Also,

$$\begin{aligned} T'[i,j] &= \mathcal{A}^a(D)[i,j] + l_i + l_j \\ &\leq \mathcal{A}^a(D)[a,i] + \mathcal{A}^a(D)[a,j] + l_i + l_j \\ &= 2m_a. \end{aligned}$$

Therefore, constraint (1) is also satisfied and Claim 3.5B is proved. □

Finally,

$$\begin{aligned} \| T - D \|_\infty &\geq \| \mathcal{A}^a(D) - D \|_\infty \text{ (by Claim 3.5A)} \\ &= \| (\mathcal{A}^a(D) + C^a) - (D + C^a) \|_\infty \\ &\geq \| \mathcal{U}^a(D + C^a) - (D + C^a) \|_\infty \text{ (by Claim 3.5B)} \\ &= \| T - D \|_\infty \text{ (by construction).} \end{aligned}$$

Therefore, $\| T - D \|_\infty = \| \mathcal{A}^a(D) - D \|_\infty$. This proves the lemma. □

Lemmas 3.4 and 3.5 imply the following theorem.

THEOREM 3.6. *Given an $n \times n$ distance matrix D, we can find a tree metric T in $O(n^2)$ time such that*

$$\| T - D \|_\infty \leq 3 \| \mathcal{A}(D) - D \|_\infty.$$

4. Tightness of analysis. In this section we show that the constant in Lemma 3.4 is tight, and that for some distance matrices it is not improved by trying different values of c.

THEOREM 4.1. *There is an $n \times n$ distance matrix D such that, for all points c,*

$$\frac{\| D - \mathcal{A}^c(D) \|_\infty}{\| D - \mathcal{A}(D) \|_\infty} = 3.$$

Proof. Consider the following distance matrix D for the points $q_0, \ldots, q_8$:

$$\begin{aligned} D[q_i, q_j] &= d - \varepsilon \quad \text{if } i = (j+1) \bmod 9 \text{ or } i = (j-1) \bmod 9 \\ &= 0 \qquad \text{if } i = j \bmod 3 \\ &= d + \varepsilon \quad \text{otherwise.} \end{aligned}$$

Note that for each $c = q_i$, there exists $a_1 = q_{(i+1) mod 9}$, $a_2 = q_{(i-1) mod 9}$, $b_1 = q_{(i+4) mod 9}$, and $b_2 = q_{(i-4) mod 9}$ such that

$$\begin{array}{ccccccc} D[c,a_1] & = & D[a_2,c] & = & D[b_2,b_1] & = & d-\varepsilon, \\ D[b_1,c] & = & D[c,b_2] & = & D[a_1,a_2] & = & d+\varepsilon, \text{ and} \\ D[a_1,b_1] & = & D[a_2,b_2] & = & 0. & & \end{array}$$

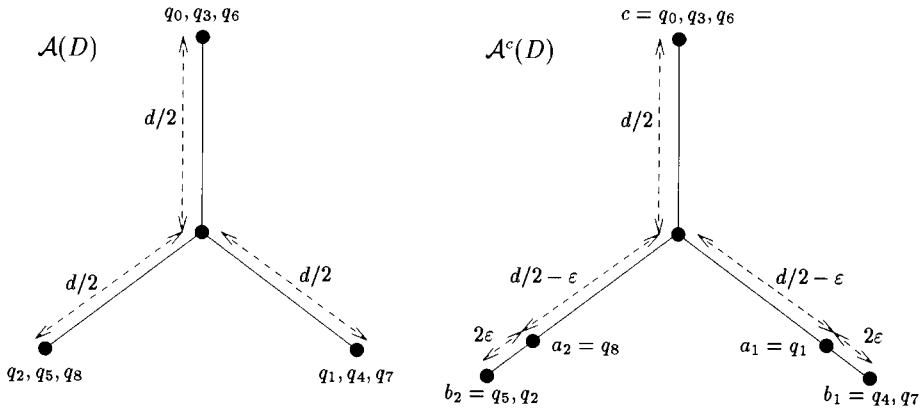

FIG. 4.1. *Trees approximating D.*

If we take d to be much larger than ε, it is easy to see that any reasonable approximation by a tree metric T uses a tree with a central vertex m from which three edges lead to subtrees containing c, $\{a_1, b_1\}$, and $\{a_2, b_2\}$ respectively.

Hence,

$$T[b_1, c] - T[c, a_1] + T[a_1, a_2] - T[a_2, c] + T[c, b_2] - T[b_2, b_1] = 0,$$

whereas

$$D[b_1, c] - D[c, a_1] + D[a_1, a_2] - D[a_2, c] + D[c, b_2] - D[b_2, b_1] = 6\varepsilon.$$

Therefore, any such approximation T satisfies $\| D - T \|_\infty \geq \varepsilon$.

For a c-restricted approximation T (where $T[u, c] = D[u, c]$ for all c), we find that

$$T[a_1, a_2] - D[a_1, a_2] - T[b_2, b_1] + D[b_2, b_1] = 6\varepsilon,$$

and so $\| D - T \|_\infty \geq 3\varepsilon$.

Figure 4.1 shows optimal solutions which establish that $\| D - \mathcal{A}(D) \|_\infty = \varepsilon$ and that $\| D - \mathcal{A}^c(D) \|_\infty = 3\varepsilon$. □

Some rather involved examples show that there are c-optimal trees for which changing the edge lengths cannot bring the error down below $3\varepsilon - o(1)$. Thus there is no significant worst-case advantage to the obvious heuristic of changing the edge lengths optimally using linear programming.

5. Lower bound. In this section, we show that the problem of finding a tree T such that $\| T - D \|_\infty < \frac{9}{8}\varepsilon$ is $\mathcal{NP}$-hard. First, we show that a decision version of the numerical taxonomy problem is $\mathcal{NP}$-complete.

The numerical taxonomy problem.
Input: A distance matrix $D : S^2 \to \Re_{\geq 0}$, and a threshold $\Delta \in \Re_{\geq 0}$.
Question: Is there a *tree metric* T which spans S and for which $\| T - D \|_\infty \leq \Delta$?

THEOREM 5.1. *The numerical taxonomy problem is $\mathcal{NP}$-complete.*

Proof. That the problem is in $\mathcal{NP}$ is immediate. We show $\mathcal{NP}$-completeness by reduction from 3SAT. For an instance of 3SAT with variables $x_1, \ldots, x_n$ and clauses $C_1, \ldots, C_k$, we will construct a distance matrix D such that the 3SAT expression is

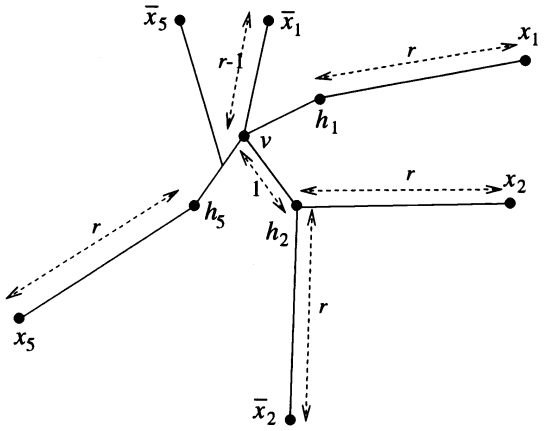

FIG. 5.1. *Portion of sample layout.*

satisfiable if and only if $\| D - \mathcal{A}(D) \|_\infty \leq \Delta = 2$. Let integer r represent some sufficiently large distance (such as 10). We construct a distance matrix D to approximate path lengths on a tree with leaves $x_i, \bar{x}_i, h_i$ for $1 \leq i \leq n$, and c_j, c'_j, c''_j for $1 \leq j \leq k$, and v.

To simplify the description of the construction we first present it in the form of a set of inequalities on the distances between the vertices of a tree T, which are expressed later in the required form. For example, we shall write "$T[x_i, \bar{x}_i] \geq 2r$" at first, and realize this constraint eventually by letting $D[x_i, \bar{x}_i] = 2r + \Delta$. We classify the inequalities as follows.

A. *Literal pairs.*

$$T[x_i, \bar{x}_i] \geq 2r, \quad T[x_i, h_i] \leq r, \quad T[\bar{x}_i, h_i] \leq r \quad \text{for all } i.$$

These inequalities force h_i to be the midpoint of the path between x_i and $\bar{x}_i$ for all i.

B. *Star-like tree.*

(1) $T[v, x_i] \leq r + 1, \quad T[v, \bar{x}_i] \leq r + 1 \quad \text{for all } i,$

(2) $T[h_i, h_j] \geq 2, \quad T[h_i, x_j] \geq r, \quad T[h_i, \bar{x}_j] \geq r \quad \text{for all } i, j \ (i \neq j).$

The inequalities B(1), together with those in A, imply $T[v, h_i] \leq 1$ for all i, and we can then use the first inequality of B(2) to deduce that $T[v, h_i] = 1$ for all i.

The vertex v must be at the center of a star with each h_i at distance 1 from it along separate edges. From each h_i, at least one of the two paths of length r to x_i and $\bar{x}_i$ proceeds away from v. An impression of a general feasible configuration is presented in Figure 5.1.

The essential feature of such configurations, which we shall use in our reduction, is that for each i, *at least one* of x_i and $\bar{x}_i$ is at distance $r + 1$ from v. The final inequalities will represent the satisfaction of clauses by literals. A satisfying literal will correspond to a vertex $\tilde{x}_i \in \{x_i, \bar{x}_i\}$ such that $T[v, \tilde{x}_i] = r - 1$. Clearly, x_i and $\bar{x}_i$ cannot both be satisfying literals.

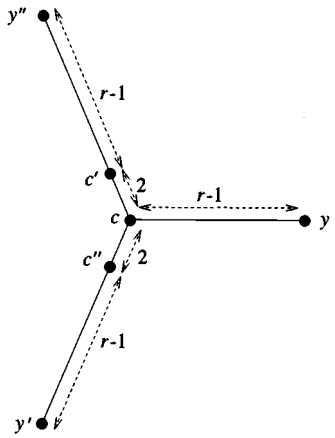

FIG. 5.2. *Layout of clause vertices.*

Now, we present the third set of inequalities that deal with the "clause" vertices c_j, c'_j, c''_j. Specifically, we will show that a clause is satisfied if and only if at least one of its literals is at a distance less than $r+1$ from v.

C. *Clause satisfaction.* For each clause $C_j = (y_j, y'_j, y''_j)$ where y_j, y'_j, y''_j are literals, we have three vertices c_j, c'_j, c''_j and the following inequalities (where we drop the subscript j for clarity):

$$T[c, y'] \leq r+1,\ T[c, y''] \leq r+1,$$

$$T[c', y''] \leq r+1,\ T[c', y] \leq r+1,$$

$$T[c'', y] \leq r+1,\ T[c'', y'] \leq r+1,$$

$$T[c, c'] \geq 2,\ T[c', c''] \geq 2,\ T[c'', c] \geq 2.$$

If $T[v, y_j]$, $T[v, y'_j]$, and $T[v, y''_j]$ are all $r+1$, then the first inequalities in C force each of c_j, c'_j, c''_j to coincide with v, contravening the last three inequalities. However, if at least one of these literals is at a distance $r-1$ of v then a configuration of the form illustrated in Figure 5.2 is feasible.

We claim that the complete set of inequalities is satisfiable if and only if the corresponding 3SAT formula is satisfiable. In one direction, suppose that there is a satisfying truth assignment to the logical variables. For each variable, lay out the corresponding tree vertices so that the vertex corresponding to the true literal is at distance $r-1$ from v (the "false" literal will be at distance $r+1$ from v). Each clause has a satisfying literal; therefore, for each j, at least one of y_j, y'_j, y''_j is at distance $r-1$ from v in the tree, thus allowing a legal placement of c_j, c'_j, c''_j. On the other hand, if there is a tree layout satisfying all the inequalities then at least one of y_j, y'_j, y''_j must be within distance $r-1$ of v for each j. Since at most one of x_i and $\bar{x}_i$ can be within $r-1$ of v, the layout yields a (partial) assignment which satisfies the logical formula.

To complete the proof, we construct a distance matrix D such that (1) if for some tree metric T, $\| T - D \|_\infty \leq \Delta$, then T satisfies all the inequalities from A, B, and

C, and (2) for the tree layout T described above, corresponding to a satisfiable 3SAT expression, we have $\| T - D \|_\infty \leq \Delta$.

Concerning (1), for all vertices a, b, and all $z \in \Re_{\geq 0}$, if an inequality is of the form $T[a,b] \geq z$, let $D[a,b] = z + \Delta$. Correspondingly, if the inequality is of the form $T[a,b] \leq z$, let $D[a,b] = z - \Delta$. Concerning (2), for $\tilde{x}_i \in \{x_i, \bar{x}_i\}$, $\tilde{x}_j \in \{x_j, \bar{x}_j\}$, $i \neq j$, in our intended configurations we have $2r - 2 \leq T[\tilde{x}_i, \tilde{x}_j] \leq 2r + 2$, with either extreme possible. Therefore, we take $D[\tilde{x}_i, \tilde{x}_j] = 2r$. Since $\Delta = 2$, this covers both extremes. Similarly, for each clause C we take $D[c, y] = D[c', y'] = D[c'', y''] = r + 1$. Suitable values for the remaining entries of D are easy to find. This completes the proof of Theorem 5.1. □

Next, we strengthen Theorem 5.1 to show a hardness-of-approximation result.

THEOREM 5.2. *Given a 3SAT instance S, a distance matrix D can be computed in polynomial time such that*

1. *if S is satisfiable, then $\| D - \mathcal{A}(D) \|_\infty \leq 2$;*
2. *if S is not satisfiable, then $\| D - \mathcal{A}(D) \|_\infty \geq 2 + \frac{1}{4}$.*

Proof. We extend the construction of Theorem 5.1 by relaxing some of the inequalities by a fixed amount δ and omitting others. The matrix D is the same as before.

A. *Literal pairs.*

$$T[x_i, \bar{x}_i] \geq 2r - \delta, \quad T[x_i, h_i] \leq r + \delta, \quad T[\bar{x}_i, h_i] \leq r + \delta \quad \text{for all } i.$$

B. *Star-like tree.*

$$T[v, x_i] \leq r + 1 + \delta, \quad T[v, \bar{x}_i] \leq r + 1 + \delta, \quad T[v, h_i] \leq 1 + \delta \quad \text{for all } i,$$

$$T[h_i, h_j] \geq 2 - \delta \quad \text{for all } i, j \ (i \neq j).$$

C. *Clause satisfaction.* For each clause $C = (y, y', y'')$ where y, y', y'' are literals, we have three vertices c, c', c'' and the following inequalities:

$$T[c, y'] \leq r + 1 + \delta,\ T[c, y''] \leq r + 1 + \delta,$$

$$T[c', y''] \leq r + 1 + \delta,\ T[c', y] \leq r + 1 + \delta,$$

$$T[c'', y] \leq r + 1 + \delta,\ T[c'', y'] \leq r + 1 + \delta,$$

$$T[c, c'] \geq 2 - \delta,\ T[c', c''] \geq 2 - \delta,\ T[c, c''] \geq 2 - \delta.$$

Note that the inequalities are a relaxation of the inequalities in the construction of Theorem 5.1. It follows that if S is satisfiable, then there is a tree T that satisfies these inequalities for all nonnegative δ. Consequently, if S is satisfiable, then $\| D - \mathcal{A}(D) \|_\infty \leq 2$.

In the remaining part, we consider an arbitrary tree T which satisfies inequalities A, B, and C. Our aim will be to show that if S is not satisfiable then $\delta \geq 1/4$, and so $\| D - T \|_\infty \geq 2 + 1/4$.

For any three distinct tree vertices u, v, w, let $\texttt{meet}(u, v, w)$ denote the intersection point of the paths between them. We interpret x_i as false if and only if

$T[h_i, \texttt{meet}(v, h_i, x_i)] \leq T[h_i, \texttt{meet}(v, h_i, \bar{x}_i)]$. Without loss of generality, we may *restrict our attention to a tree for which our interpretation sets all x_i to be false.*

For any variable x_i, let $\hat{h}_i$ denote $\texttt{meet}(h_i, x_i, \bar{x}_i)$ and $\hat{v}_i$ denote $\texttt{meet}(v, h_i, x_i)$. Note that x_i being false implies that $T[h_i, \hat{v}_i] \leq T[h_i, \hat{h}_i]$.

CLAIM 5.2A. *For all i,* (1) $T[h_i, \hat{v}_i] \leq T[h_i, \hat{h}_i] \leq 3\delta/2$, *and* (2) $T[x_i, \hat{h}_i] - T[h_i, \hat{h}_i] \geq r - 2\delta$.

Proof. For (1), $2T[h_i, \hat{h}_i] = T[x_i, h_i] + T[\bar{x}_i, h_i] - T[x_i, \bar{x}_i] \leq 2(r+\delta) - (2r-\delta) = 3\delta$. For (2), $T[x_i, \hat{h}_i] - T[h_i, \hat{h}_i] = T[x_i, \bar{x}_i] - T[\bar{x}_i, h_i] \geq 2r - \delta - (r + \delta) = r - 2\delta$. □

For each $j \neq i$, set $h_i^j = \texttt{meet}(h_j, h_i, x_i)$.

CLAIM 5.2B. *For all $\delta < \frac{2}{7}$ and for all $j \neq i$, $T[h_i, h_i^j] < T[h_i, \hat{v}_i]$.*

Proof. Suppose $T[h_i, h_i^j] \geq T[h_i, \hat{v}_i]$. Then there are simple paths from h_i to $\hat{v}_i$ to h_j and from v to $\hat{v}_i$ to h_j. Therefore,

$$\begin{aligned} 0 &= T[h_i, \hat{v}_i] + T[\hat{v}_i, h_j] - T[h_i, h_j] \\ &\leq T[h_i, \hat{v}_i] + T[v, h_j] - T[h_i, h_j] \\ &\leq 3\delta/2 + (1 + \delta) - (2 - \delta). \end{aligned}$$

Hence $\delta \geq \frac{2}{7}$. □

CLAIM 5.2C. *For all $\delta < \frac{2}{7}$ and for all $i \neq j$, $T[x_i, x_j] \geq 2r + 2 - 5\delta$.*

Proof. By Claims 5.2B and 5.2A(1), $T[h_i, h_i^j] \leq 3\delta/2$ and $T[h_j, h_j^i] \leq 3\delta/2$. Since $T[h_i, h_j] \geq 2 - \delta$ and $\delta \leq 1/2$, we may conclude that we have a simple path from h_i to h_i^j to h_j^i to h_j, and a simple path from x_i to $\hat{h}_i$ to h_i^j to h_j^i to $\hat{h}_j$ to x_j. Note, however, that $\hat{h}_i$ and h_i^j may coincide, and similarly for h_j^i and $\hat{h}_j$. In conclusion,

$$\begin{aligned} T[x_i, x_j] &= T[x_i, \hat{h}_i] + T[\hat{h}_i, h_i^j] + T[h_i^j, h_j^i] + T[h_j^i, \hat{h}_j] + T[\hat{h}_j, x_j] \\ &\geq T[x_i, \hat{h}_i] + T[h_i^j, h_j^i] + T[\hat{h}_j, x] \\ &= T[x_i, \hat{h}_i] + T[h_i, h_j] - T[h_i, \hat{h}_i] - T[h_j, \hat{h}_j] + T[\hat{h}_j, x_j] \\ &\geq 2(r - 2\delta) + 2 - \delta = 2r + 2 - 5\delta. \end{aligned}$$

For the last inequality, we used Claim 5.2A(2). □

Finally, we show that if S is not satisfiable then $\delta \geq 1/4$. If $\delta \geq 2/7$ then this is trivially true, so we may assume that the conclusions of Claims 5.2B and 5.2C apply.

Let vertices x, x', x'' in T correspond to the three false literals of a clause. Let $p = \texttt{meet}(x, x', x'')$. Without loss of generality, assume $T[x, p] \geq T[x', p] \geq T[x'', p]$. Let d be at the middle of the path from x to x''. By Claim 5.2C, $T[x, d] = T[x'', d] \geq r + 1 - 5\delta/2$. Hence the bounds of $r + 1 + \delta$ on $T[x, c']$ and $T[x'', c']$ from the inequalities in C imply that $T[d, c'] \leq 7\delta/2$.

Now d is situated on the path from x to p, and $T[p, x'] \geq T[p, x'']$, implying $T[d, x'] \geq T[d, x''] \geq r + 1 - 5\delta/2$. Hence, as above, the bounds of $r + 1 + \delta$ on $T[x, c'']$ and $T[x'', c'']$ imply that $T[d, c''] \leq 7\delta/2$. Consequently $T[c', c''] \leq T[c', d] + T[d, c''] \leq 7\delta$. However, from C we also have the inequality $T[c', c''] \geq 2 - \delta$. Thus $7\delta \geq 2 - \delta$ and so $\delta \geq 1/4$.

Since T was arbitrary, we have shown that if S is not satisfiable then there is no tree T such that $\| D - T \|_\infty < 2 + 1/4$, i.e., $\| D - \mathcal{A}(D) \|_\infty \geq 2 + 1/4$. □

Theorem 5.2 immediately implies a hardness-of-approximation result for the numerical taxonomy problem.

COROLLARY 5.3. *It is an $\mathcal{NP}$-hard problem, given a distance matrix D, to find*

an additive metric T such that

$$\frac{\| D - T \|_\infty}{\| D - \mathcal{A}(D) \|_\infty} < \frac{9}{8}.$$

Proof. For any such T, if $\| D - T \|_\infty \geq 2 + 1/4$ then $\| D - \mathcal{A}(D) \|_\infty > 2$ and S is unsatisfiable, and if otherwise then $\| D - \mathcal{A}(D) \|_\infty \leq \| D - T \|_\infty < 2 + 1/4$ and S is satisfiable. □

6. Generalization to other norms. First, we show that Lemma 3.4 can be generalized to other norms.

THEOREM 6.1. *Let D be a distance matrix and T be a tree such that $\| D - T \|_p \leq \varepsilon$. Then there exists a point a and an a-restricted tree $T^{/a}$ such that $\| D - T^{/a} \|_p \leq 3\varepsilon$.*

Proof. For any point a, the construction of Lemma 3.4 returns an a-restricted tree $T^{/a}$ such that

$$|T^{/a}[i,j] - D[i,j]| \leq |\varepsilon[i,j]| + |\varepsilon[a,i]| + |\varepsilon[a,j]| \text{ for all } i,j. \tag{3}$$

Also, by the convexity of the function $|x|^p$ for real x, we have

$$\sum_{i=1}^{k} \frac{|x_i|^p}{k} \geq \left| \frac{\sum_{i=1}^{k} x_i}{k} \right|^p. \tag{4}$$

We continue the proof by an averaging argument. Clearly,

$$\min_a \{(\| T^{/a} - D \|_p)^p\} \leq \frac{\sum_{a=1}^{n} (\| T^{/a} - D \|_p)^p}{n}.$$

We use inequalities (3) and (4) to bound the sum

$$\begin{aligned}
\sum_{a=1}^{n} (\| T^{/a} - D \|_p)^p &= \sum_{a=1}^{n} \sum_{i=1, i\neq a}^{n} \sum_{j=1, j\neq a}^{n} |\varepsilon[i,j] - \varepsilon[a,i] - \varepsilon[a,j]|^p \\
&\leq 3^{p-1} \sum_{a=1}^{n} \sum_{i=1, i\neq a}^{n} \sum_{j=1, j\neq a}^{n} |\varepsilon[i,j]|^p + |\varepsilon[a,i]|^p + |\varepsilon[a,j]|^p \\
&= 3^p n (\| T - D \|_p)^p.
\end{aligned}$$

The theorem follows. □

As in the case of L_∞, we can show that if T is an a-optimal tree for D under L_k, then $T + C^a$ is an optimal a-restricted ultrametric for $D + C^a$ under the same norm. We define the *Additive$_k$* problem as, given a matrix D, output an additive metric A minimizing $\| D - A \|_k$. Similarly, the *Ultrametric$_k$* problem is, given a matrix D, output an ultrametric U minimizing $\| D - U \|_k$.

We conclude with Theorem 6.2.

THEOREM 6.2. *If $A(D)$ is an algorithm which achieves an α-approximation for the a-restricted Ultrametric$_k$ problem and runs in time $T(n)$ on an $n \times n$ matrix, then there is an algorithm $F(D)$ which achieves a 3α-approximation for the Additive$_k$ problem and runs in $O(nT(n))$ time.*

COMPETITIVE ON-LINE ALGORITHMS FOR DISTRIBUTED DATA MANAGEMENT*

CARSTEN LUND†, NICK REINGOLD†, JEFFERY WESTBROOK†‡, AND DICKY YAN§

Abstract. Competitive on-line algorithms for data management in a network of processors are studied in this paper. A data object such as a file or a page of virtual memory is to be read and updated by various processors in the network. The goal is to minimize the communication costs incurred in serving a sequence of such requests. Distributed data management on important classes of networks—trees and bus-based networks—are studied. Optimal algorithms with constant competitive ratios and matching lower bounds are obtained. Our algorithms use different interesting techniques, such as work functions [Chrobak and Larmore, *Proc. DIMACS Workshop on On-Line Algorithms,* AMS, 1991, pp. 11–64] and "factoring."

Key words. on-line algorithms, competitive analysis, memory management, data management

1. Introduction.

The management of data in a distributed network is an important and much studied problem in management science, engineering, computer systems, and theory [3, 11]. Dowdy and Foster [11] give a comprehensive survey of research in this area, listing 18 different models and many papers. A data object, F, such as a file or a page of virtual memory, is to be read and updated by a network of processors. Each processor may store a copy of F in its local memory, so as to reduce the time required to read the data object. All copies must be kept consistent, however, so having multiple copies increases the time required to write to the object. As read and write requests occur at the processors, an on-line algorithm has to decide whether to replicate, move, or discard copies of F after serving each request while trying to minimize the total cost incurred in processing the requests. The on-line algorithm has no knowledge of future requests, and no assumptions are made about the pattern of requests. We apply competitive analysis [6] to such an algorithm.

Let σ denote a sequence of read and write requests. A deterministic on-line algorithm A is said to be *c-competitive* if for all σ, $C_A(\sigma) \leq c \cdot OPT(\sigma) + B$ holds, where $C_A(\sigma)$ and $OPT(\sigma)$ are the costs incurred by A and the optimal off-line solution, respectively, and c and B are functions which are independent of σ but which may depend upon the input network and file size. If A is a randomized algorithm, we replace $C_A(\sigma)$ by its *expected* cost and consider two types of adversaries: The *oblivious* adversary chooses σ in advance, and the more powerful *adaptive* on-line adversary builds σ on-line, choosing each request with knowledge of the random moves made

by A on the previous requests. The oblivious adversary is charged the optimal off-line cost, while the adaptive on-line adversary has to serve σ and be charged on-line. (See Ben-David et al. [6] for a full discussion of different types of adversaries.) An algorithm is *strongly* competitive if it achieves the best possible competitive ratio.

In this paper, we focus on two important classes of networks: trees and the uniform network. A tree is a connected acyclic graph on n nodes and $(n-1)$ edges; the uniform network is a complete graph on n nodes with unit edge weights. We obtain strongly competitive deterministic and randomized on-line algorithms for these classes.

Our algorithms use different interesting techniques, such as offset functions and "factoring." Competitive on-line algorithms based on offset functions have been found for the 3-server [9] and the migration problems [10]. An advantage of these algorithms is that they do not need to record the entire history of requests and the actions of the on-line algorithm since decisions are based on the current offset values which can be updated easily. Factoring is first observed in [7] and used in [10, 17]. The idea is to break down an on-line problem on a tree into single edge problems. Thus strongly competitive strategies for a single edge are generalized to a tree. Our algorithms are strongly competitive for specific applications and networks and also illustrate these two useful techniques. Our randomized algorithm for file allocation is *barely random* [20]; i.e., it uses a bounded number of random bits, independent of the number of requests. A random choice is made only at the initialization of the algorithm, after which it runs deterministically.

1.1. Problem description. We study three variants of distributed data management: *replication* [1, 7, 17], *migration* [7, 10, 22], and *file allocation* (FAP) [2, 5]. They can be described under the same framework. We are given an undirected graph $G = (V, E)$ with nonnegative edge weights and $|V| = n$, where each node represents a processor. Let F represent a data file or a page of memory to be stored in the processors. At any time, let $R \subseteq V$, the residence set, represent the set of nodes that contain a copy of F. We always require that $R \neq \emptyset$. Initially, only a single node v contains a copy of F and $R = \{v\}$.

A sequence of read and write requests occur at the processors. A *read at processor* p requests an examination of the contents of some data location in F; a *write at processor* p requests a change to the contents of some location in F. The location identifies a single word or record in F. A read can be satisfied by sending a message to any processor holding a copy of F; that processor then returns the information stored in the requested location. A write is satisfied by sending an update message to each processor holding a copy F, telling it how to modify the desired location. After a request is served, the on-line server can decide how to reallocate the multiple copies of F.

Let $D \in \mathcal{Z}^+$ be an integer constant, $D \geq 1$, which represents the number of records in F.[1] The costs for serving the requests and redistributing the files are as follows:

Service Cost. Suppose a request occurs at a node v. If it is a read request, it is served at a cost equal to the shortest path distance from v to a nearest node in R; if it is a write request, it is served at a cost equal to the size of the minimum Steiner tree[2] that contains all the nodes in $R \cup \{v\}$.

[1] $\mathcal{R}$, $\mathcal{Z}^+$, and $\mathcal{Z}_0^+$ represent the sets of reals, positive integers, and nonnegative integers, respectively.

[2] See section 2 for a definition.

Movement Cost. The algorithm can replicate a copy of F to a node v at a cost D times the shortest path distance between v and the nearest node with a copy of F; it can discard a copy of F at no cost.

A file reallocation consists of a sequence of zero or more replications and discards of copies of F. The replications and discards can be done in any order as long as the residence set has a size of at least 1. The movement cost incurred during a reallocation is equal to the total sum of all replication costs.

The replication and migration problems are special cases of file allocation. For migration, we require $|R| = 1$. For replication, all the requests are reads, and it can be assumed that all replicated copies of F are not discarded. The (off-line) optimization problem is to specify R after each new request is served so that the total cost incurred is minimized. For on-line replication, we consider only competitive algorithms that have $B = 0$ in the inequality above; otherwise a trivial 0-competitive algorithm exists [7].

Following previous papers on allocation and related problems, we adopt a "lookahead-0" model. In this model, once a request is revealed, the on-line algorithm must immediately pay the service cost before making any changes to the residence set. One may contrast lookahead-0 with a lookahead-1 model, in which the algorithm may change the residence set before paying the service cost. We discuss the lookahead issue further below, together with some implementation issues.

1.2. Previous and related results. Black and Sleator [7] were the first to use competitive analysis to study any of these problems, giving strongly 3-competitive deterministic algorithms for file migration on trees and uniform networks and strongly 2-competitive deterministic algorithms for replication on trees and uniform networks.

Replication. Imase and Waxman [14] showed that a greedy algorithm for building Steiner trees on-line is $\Theta(\log n)$-competitive, where n is the number of nodes, and that this ratio is optimal within constant factors for general networks. This algorithm is the basis of a solution for on-line replication in general networks. Koga [17] gave randomized algorithms that are 2-competitive and 4-competitive against an adaptive on-line adversary on trees and circles, respectively. He also obtained a randomized algorithm with a competitive ratio that depends only on D and approaches $(1+1/\sqrt{2})$ as D grows large, against an oblivious adversary on trees.

Migration. Westbrook [22] obtained a randomized algorithm for uniform networks with a competitive ratio that depends only on D and approaches $((5+\sqrt{17})/4)$ as D grows large, against an oblivious adversary. For general networks, Westbrook [22] obtained a strongly 3-competitive randomized algorithm against an adaptive on-line adversary. He also obtained an algorithm against an oblivious adversary with a competitive ratio that depends only on D and approaches $(1+\phi)$-competitive as D grows large, where $\phi \approx 1.62$ is the golden ratio. Chrobak et al. [10] studied migration on various classes of metric spaces, including trees, hypercubes, meshes, real vector spaces, and general products of trees. They gave strongly $(2+1/2D)$-competitive randomized algorithms for these spaces, $(2+1/2D)$-competitive deterministic algorithms for some of these spaces, and a general lower bound for deterministic algorithms of $(85/27)$. Recently, Bartal, Charikar, and Indyk [4] obtained a 4.086-competitive deterministic algorithm.

File Allocation. For general networks, Awerbuch, Bartel, and Fiat [2] and Bartal, Fiat, and Rabani [5] give $O(\log n)$-competitive deterministic and randomized algorithms against an adaptive on-line adversary, respectively. Westbrook and Yan [23] show that Bartal, Fiat, and Rabani's algorithm is $O(\log d(G))$-competitive on an un-

weighted graph with diameter *d(G)*, and there exists a $O(\log^2 d(G))$-competitive deterministic algorithm. Bartal, Fiat, and Rabani also find a $(3+O(1/D))$-competitive deterministic algorithm on a tree and strongly 3-competitive randomized algorithms against an adaptive on-line adversary on a tree and uniform network. Since replication is a special case of file allocation, these upper bounds are also valid for replication when the additive constant B is zero.

1.3. New results. This paper contributes the following results:

- For on-line file allocation on a tree, we give a strongly 3-competitive deterministic algorithm and a $(2+1/D)$-competitive randomized algorithm against an oblivious adversary and show that this is optimal even if G is an edge.
- For uniform networks, we show that the off-line file allocation problem can be solved in polynomial time. We give a strongly $(2 + 1/(2D))$-competitive randomized on-line algorithm for migration against an oblivious adversary on the uniform network.
- For the replication problem, we show that the off-line problem is NP-hard; this implies that the file allocation problem is also NP-hard. We obtain randomized algorithms that are $(e_D/(e_D - 1))$-competitive against an oblivious adversary on a tree and a uniform network; this is optimal even if G is an edge. (Albers and Koga [1] have independently obtained the same results for on-line replication using a different method.)
- We show that no randomized algorithm for replication on a single edge can be better than 2-competitive against an adaptive on-line adversary. Thus Koga's [17] algorithm for replication on a tree is strongly competitive.

Table 1.1 summarizes the competitive ratios of the best known deterministic and randomized algorithms against an oblivious adversary for replication, migration, and file allocation on trees and uniform networks. They are all optimal.

1.4. Lookahead and implementation issues. As stated above, we adopt the lookahead-0 model that has been used in all previous work on allocation and its variants. Studies of some other on-line problems, however, have used a lookahead-1 model, and in this subsection we comment briefly on the distinction.

In a lookahead-1 model of allocation, some request sequences could be served by an on-line algorithm at a lower cost than would be possible in the lookahead-0 model. For example, if a write request occurs, a lookahead-1 algorithm can drop all but one copies of F before servicing the request, thereby reducing the service cost. The lookahead-0 model is more appropriate for file allocation, however, because the service cost models both the message cost of satisfying a request, which includes the cost of transmitting an answer back to a read request or passing an update on to all copies, and the message cost of the control messages that must be transmitted in order for the algorithm to learn of new requests and to implement its replication and

drop decisions. Specifically, we assume that a new replication will not occur unless at least one member of the replication set has been told of a new request, and a processor will not discard a copy unless it has been told of a new write request.

We claim that for large values of D the optimal competitive ratio in a lookahead-1 model is not materially different from the optimal competitive ratio in a lookahead-0 model. In particular, if there is a c-competitive algorithm using lookahead-1, there is a $(c + 2/D)$-competitive algorithm using lookahead-0. The lookahead-0 algorithm simulates the lookahead-1 algorithm by keeping the same residence set. When the lookahead-1 algorithm saves service cost on a read, the amount saved can be no more than the distance it replicates files just prior to satisfying the request. Similarly, when the lookahead-1 algorithm saves service cost on a write, the amount saved can be no more than the weight of a minimum Steiner tree which connects the dropped copies to an undropped copy. But at some point in the past, at least one of the dropped copies must have been replicated over each edge in that Steiner tree. Hence for each unit of distance saved on reads by the lookahead-1 algorithm, one file was moved one unit of distance. The same holds for writes. The total cost saved by the lookahead-1 algorithm is $\frac{2}{D}$ times the total movement cost. Both algorithms incur the same movement cost, however.

One may ask whether our service cost is too optimistic: Could our algorithms actually be implemented using only the control messages accounted for in the service cost? Although we do not directly address this issue, our algorithms are essentially distributed in nature and can be implemented with only constant message overhead in the special case of uniform and tree networks.

2. Preliminaries. We use the technique of work functions and offset functions introduced by Chrobak and Larmore [9]. Let S be a set of states, one for each legal residence set. Thus S is isomorphic to $2^V \setminus \{\emptyset\}$. Let *R(s)* denote the residence set corresponding to state $s \in S$. We say the *file system is in state s* if the current residence set is $R(s), s \in S$. Let $Y = \{v^r, v^w | v \in V\}$ be the set of possible requests, where v^r and v^w represent read and write requests at node v, respectively. A request sequence $\sigma = (\sigma_1, \ldots, \sigma_p)$ is revealed to the on-line algorithm, with each $\sigma_i \in Y$. Suppose the network is in state s when σ_i arrives. The algorithm will be charged a service cost of $ser(s, \sigma_i)$, where $ser(s, \sigma_i) : S \times Y \longrightarrow \mathcal{R}$ is as described in section 1.1. After serving σ_i, the algorithm can move to a different state t at a cost *tran(s,t)*, where $tran : S \times S \longrightarrow \mathcal{R}$ is the minimum cost of moving between the two residence sets.

The work function $W_i(s)$ is the minimum cost of serving requests 1 to i, terminating in state s. Given σ, a minimum cost solution can be found by a dynamic programming algorithm with the following functional equation:

$$\forall\ s \in S,\ i \in \mathcal{Z}^+,\quad W_i(s) = \min_{t \in S}\{W_{i-1}(t) + ser(t, \sigma_i) + tran(t, s)\},$$

with suitable initializations. Let $opt_i = \min_{s \in S} W_i(s), i \geq 1$, be the optimal cost of serving the first i requests. We call $\omega_i(s) = W_i(s) - opt_i$ the *offset function* value at state s after request i has been revealed. Define $\Delta opt_i = opt_i - opt_{i-1}$; it is the increase in the optimal off-line cost due to σ_i.

Our on-line algorithms make decisions based on the current offset values, $\omega_i(s), s \in S$. Note that to compute the $\omega_i(s)$'s and Δopt_i's, it suffices to know only the $\omega_{i-1}(s)$'s. Since $OPT(\sigma) = \sum_{i=1}^{|\sigma|} \Delta opt_i$, to show that an algorithm A is c-competitive, we need only show that for each reachable combination of offset function, request, and file

system state, the inequality $\Delta C_A + \Delta\Phi \leq c \cdot \Delta opt_i$ holds, where ΔC_A is the cost incurred by A and $\Delta\Phi$ is the change in some defined potential function. If the total change in Φ is always bounded or nonnegative, summing up the above inequality over σ, we have $C_A(\sigma) \leq c \cdot OPT(\sigma) + B$, where B is some bounded value.

The Steiner tree problem. We shall refer to a network design problem called the Steiner tree problem (STP) [24], which can be stated as follows. An instance of STP is given by a weighted undirected graph $G = (V, E)$, a weight function on the edges $w : E \longrightarrow \mathcal{Z}_0^+$, a subset $Z \subseteq V$ of *regular nodes* or *terminals*, and a constant $B' \in \mathcal{Z}^+$. The decision problem is to ask if there exists a Steiner tree in G that includes all nodes in Z and has a total edge weight of no more than B'. STP is NP-complete even when G is restricted to bipartite graphs with unit edge weights or to planar graphs [12, 16]. Surveys on STP can be found in [13, 24]. On a tree network, the union of paths between all pairs of terminals gives the optimal Steiner tree.

3. Deterministic algorithms for FAP on a tree. We begin by introducing some concepts that will be used in building both deterministic and randomized algorithms for file allocation on trees.

We say a residence set is *connected* if it induces a connected subgraph in G. On a tree, if the residence set is always connected, each node without a copy of F can easily keep track of R, and hence the nearest copy of F, by using a pointer. In fact, when G is a tree we can limit our attention to algorithms that maintain a connected R at all times.

THEOREM 3.1. *On a tree, there exists an optimal algorithm that always maintains a connected residence set; i.e., given any (on-line or off-line) algorithm A, there exists an algorithm A' that maintains a connected R and $C_{A'}(\sigma) \leq C_A(\sigma)$ for all σ. If A is on-line, so is A'.*

Proof. Let $R(A)$ and (R') be the residence sets maintained by A and A', respectively. We simulate A on σ and let A' be such that at any time, $R')$ is the minimum connected set that satisfies $R(A) \subseteq R(A')$. Given $R(A)$ on a tree, $R(A')$ is defined and unique.

Since $R(A) \subseteq R(A')$, the reading cost incurred by A' cannot be greater than that by A. The same holds true for the writing cost issued at any node v, since $R(A') \cup \{v\}$ spans the unique minimum length Steiner tree for $R(A) \cup \{v\}$. So A' does not incur a greater read or write cost than A.

Algorithm A' does not need to carry out any replication unless A does, and only to nodes that are not already in $R(A')$. To maintain $R(A) \subseteq R(A')$, A' should leave a copy of F along any replication path; this can be done without incurring any extra cost. As $R(A) \subseteq R(A')$, A' never needs to traverse a replication path longer than that traversed by A for the same replication. Hence, A' cannot incur a greater replication cost. Since a reallocation is a sequence of replications and discards of F, A' maintains a connected set at all times and does not incur a greater cost than A in the reallocation. □

Henceforth we shall consider only algorithms that maintain a connected residence set R at all times. When we say that an algorithm replicates to node v, we shall mean it leaves a copy of F, at all nodes along the shortest path from the residence set to v. In a tree network we can make some additional simplifying assumptions. Suppose an algorithm A decides to move to residence set R' from set R. This reallocation involves some sequence of replications and drops.

LEMMA 3.2. *All replications can be performed before all drops without increasing the total cost of the reallocation.*

Proof. Dropping a copy can only increase the cost of following replications. □

Henceforth we assume that all algorithms comply with Lemma 3.2.

LEMMA 3.3. *Let $S = R' \setminus R$ be the nodes that gain a copy of F. Then F can be replicated to the nodes of S in any order at total cost $D \cdot |T(R') \setminus T(R)|$, where $T(R)$ is the subtree induced by node set R.*

Proof. A copy of F must be sent across each edge in $T(R') \setminus T(R)$ at least once. But in any order of replication, a copy cannot be sent across an edge more than once, because then both endpoints contain a copy of F. □

Henceforth we assume that all algorithms comply with Lemma 3.3.

A useful tool in handling on-line optimization on trees is *factoring* [7, 10]. It makes use of the fact that any sequence of requests σ and any tree algorithm can be "factored" into $(n-1)$ individual algorithms, one for each edge. The total cost in the tree algorithm is equal to the sum of the costs in each individual edge game. For edge (a, b) we construct an instance of two-processor file allocation as follows. The removal of edge (a, b) divides T into two subtrees T_a and T_b, containing a and b, respectively. A read or write request from a node in T_a is replaced by the same kind of request from a, and a request from a node in T_b is replaced by the same request from b. Let A be an algorithm with residence set $R(A)$. Algorithm A induces an algorithm on edge (a, b) as follows: if $R(A)$ falls entirely in T_a or T_b, then the edge algorithm is in state a or b, respectively; otherwise, the edge algorithm is in state ab. When the edge algorithm changes state, it does so in the minimum cost way (i.e., at most one replication). This factoring approach is used in our algorithms for file allocation on a tree. For the rest of this paper, given an edge (a, b), we use T_a and T_b to represent the subtrees described above, s to denote the state the edge is in, and let the offset functions triplet be $\omega_i = (\omega_i(a), \omega_i(b), \omega_i(ab))$, where $\omega_i(s)$ is the offset function value of state s after σ_i has arrived.

LEMMA 3.4. *For algorithm A and request sequence σ, let $A_{(a,b)}$ be the algorithm induced on edge (a, b) and σ_{ab} be the request sequence induced on edge (a, b). Then*

$$C_A(\sigma) = \sum_{(a,b)\in E} C_{A_{(a,b)}}(\sigma_{ab}).$$

Proof. We show that the cost incurred by any event contributes the same amount to both sides of the equation.

For a write request at a node v, $C_A(\sigma)$ increases by the weight of the unique Steiner tree, T', containing nodes in $R(A) \cup \{v\}$. In the induced problem of any edge e on T', the residence set and the request node are on opposite sides of e, and a write cost equal to e's weight is incurred. For other edges, v and the residence set lie on the same side of e, and no cost is incurred in their induced problems. So both sides of the equation increase by the same amount.

For a read request at a node v, the same argument as in the write case can be used, replacing T' by the unique path from v to the nearest node with a copy of F. Both sides of the equation increase by the same amount.

Suppose A moves from a residence set of R to R', and consider the sequence of replications and discards that make up the reallocation process. We show by induction on the length of this sequence that the movement cost to A is exactly equal to the sum of movement costs in the induced edge problems. Suppose that the first action in the sequence is to replicate F to node v. The cost to A is D times the sum of the lengths of the edges on the shortest path from R to v. Since R is connected, the edges on this path are exactly the edges that must replicate in their induced problems. Thus both

b^r	$\min(1,l)$	0	l	0
b^w	1	0	$\min(l+1,D)$	0

sides of the equation increase by the same amount. If the first action is a discard, then no costs are incurred by A or any of the induced edge algorithms. □

LEMMA 3.5. *Let $OPT(\sigma_{ab})$ be the cost incurred by an optimal edge algorithm for (a,b) on sequence σ_{ab}. Then $\sum_{(a,b)\in E} OPT(\sigma_{ab}) \leq OPT(\sigma)$.*

Proof. The lemma follows by letting A in Lemma 3.4 be the optimal off-line algorithm for FAP on a tree and noting $C_{A_{(a,b)}}(\sigma_{ab}) \geq OPT(\sigma_{ab})$ for any A and edge (a,b). □

It follows from Lemmas 3.4 and 3.5 that if A is an on-line algorithm such that on any σ, and for each edge (a,b), $C_{A_{(a,b)}}(\sigma_{ab}) \leq c \cdot OPT(\sigma_{ab})$ holds, then A is c-competitive.

To construct a deterministic algorithm for the tree, we first construct a suitable optimal algorithm for a single edge. We then design the tree algorithm so that it induces this optimal edge algorithm in each edge, thereby guaranteeing competitiveness.

3.1. An optimal deterministic edge algorithm. Let $G = (a,b)$ be an edge and let $S = \{a, b, ab\}$ be the set of states the file system can be in—only node a has a copy, only node b has a copy, and both a and b have a copy, respectively. We can assume G is of unit length; otherwise the offsets and cost functions can be scaled to obtain the same results. We write the offset functions as a triplet $\omega_i = (\omega_i(a), \omega_i(b), \omega_i(ab))$ and similarly for the work functions. Suppose the starting state is a. Then $W_0 = (0, D, D)$. The *ser* and *tran* functions are given in Table 3.1. By the definition of the offset functions, and since it is free to discard a copy of F, we always have $\omega_i(ab) \geq \omega_i(a), \omega_i(b)$, and at least one of $\omega_i(a)$ and $\omega_i(b)$ is zero. Without loss of generality, we assume a starting offset function vector of $\omega_i = (0, k, l)$, $0 \leq k \leq l \leq D$, after σ_i has arrived. Table 3.2 gives the changes in offsets for different combinations of requests and offsets in response to the new request σ_{i+1}.

Let s be the current state of R. Our algorithm specifies the new required residence

set, R, after σ_{i+1} has arrived and the offsets have been updated; it assumes state a is a zero-offset state.

ALGORITHM DETEDGE.

(1) **If** $s \neq ab$ and $\omega_{i+1}(s) = \omega_{i+1}(ab)$, replicate, i.e., set $s = ab$.

(2) **If** $s = ab$ and $\omega_{i+1}(b) = D$, drop at b, i.e., set $s = a$.

THEOREM 3.6. *Algorithm* **DetEdge** *is strongly* 3*-competitive.*

Proof. We first show that for each request σ_j, $\Delta C_{Edge} + \Delta\Phi \leq 3 \cdot \Delta opt_j$ $(*)$ holds for some function $\Phi(\cdot)$ defined below. Let a be a zero-offset state, and we have $\omega_i = (0, k, l)$. At any time, we define the potential function

$$\Phi(s,k) = \begin{cases} 2 \cdot D - 2 \cdot k & \text{if } s = a, \\ 2 \cdot D - k & \text{if } s = b, \\ D - k & \text{if } s = ab. \end{cases}$$

Initially, $\Phi = 0$, and we always have $\Phi \geq 0$. When $\omega_i = (0, 0, l)$ and $s \neq ab$, s can be considered to be in state a or b, and $\Phi(a, 0) = \Phi(b, 0) = 2D$. Note that $\omega_i = \omega_{i+1}$ and $\Delta\Phi = \Delta opt_i = 0$ hold in the following cases:

(i) $\omega_i = (0, D, D)$ and $\sigma_{i+1} = a^r$ or a^w;

(ii) $\omega_i = (0, l, l), l \geq 1$, and $\sigma_{i+1} = a^r$; and

(iii) $\omega_i = (0, 0, 0)$ and $\sigma_{i+1} = a^r$ or b^r.

Our algorithm ensures that $\Delta C_{Edge} = 0$ in these cases. Let us show that $(*)$ holds for all possible combinations of state, request, and offset. The offsets and state variables below are the ones *before* the new request σ_{i+1} arrives. We consider the $k \geq 1$ cases; the $k = 0$ cases are similar to that when $k \geq 1$ and $\sigma_{i+1} = a^r$ or a^w.

Case 1. $\sigma_{i+1} = a^r$.

We have $\Delta opt_{i+1} = 0$. If $s = a$ or ab, then the left-hand side (L.H.S.) of $(*) \leq 0$ and $(*)$ holds. If $s = b$, by the last execution of the algorithm, we must have $k < l$. Then $\Delta C_{Edge} = -\Delta\Phi = 1$, and $(*)$ holds.

Case 2. $\sigma_{i+1} = a^w$.

We have $\Delta opt_{i+1} = 0$. If $s = a$, then L.H.S $(*) \leq 0$ and $(*)$ holds. If $s = b$ or ab, we must have $k < D$. Then $\Delta C_{Edge} = -\Delta\Phi = 1$, and $(*)$ holds.

Case 3. $\sigma_{i+1} = b^r$ or b^w.

We have $\Delta opt_{i+1} = 1$. In this case $\Delta C_{Edge} \leq 1$, $\Delta\Phi \leq 2$, and L.H.S. $(*) \leq 3$ hold.

Inequality $(*)$ also holds when **DetEdge** changes state. When **DetEdge** moves from state ab to state a, $\omega_i = (0, D, D)$ and $\Delta\Phi = \Delta C_{Edge} = 0$; and when **DetEdge** moves to state ab, $\Delta\Phi = -\Delta C_{Edge} = -D$. Hence, $(*)$ holds for all possible combinations of offsets, requests, and residence sets.

We claim that no deterministic algorithm is better than 3-competitive for FAP on an edge. For migration, it is known that no deterministic algorithm can be better than 3-competitive on a single edge [7]. We show that given any on-line algorithm A for FAP there exists another on-line algorithm A' such that (i) $C_{A'}(\sigma) \leq C_A(\sigma)$ for any σ with only write requests; (ii) A' always keeps only one copy of F at a node in A's residence set; and (iii) whenever A has only one copy of F, A' has a copy at the same node. Since A' is a legal algorithm for any instance of the migration problem and since the optimal cost to process σ without using replications is no less than the optimal cost with replications, A is c-competitive on write-only sequences only if A' is a c-competitive migration algorithm. This implies the claim.

Algorithm A' is obtained from A as follows. Initially, both A and A' have a copy of F at the same node. The following rules are applied whenever A changes state:

(1) If A replicates, A' does not change state.
(2) If A migrates, A' follows.
(3) If A drops a page, A' follows to the same node.
It follows from the rules above that (ii) and (iii) hold, and A' cannot incur a write cost higher than that of A. Each movement of A' in (1) or (2) corresponds to a distinct migration or earlier replication by A, respectively. So A' cannot incur a higher movement cost than A. The claim follows. □

3.2. An optimal deterministic tree algorithm. Recall that for each edge $e = (a, b)$ on the tree, request sequence σ induces a sequence σ_{ab} on (a, b). The tree algorithm is based on factoring into individual edge subproblems and simulating **DetEdge** on each subproblem. After $r \in \sigma$ is served, for each edge $e = (a, b)$ the induced request r_{ab} is computed and the offset vector for the induced subproblem is updated. The following algorithm is then executed, updating the residence set, $R(Tree)$. Initially $R(Tree)$ consists of the single node containing F.

ALGORITHM DETTREE.

(1) Examine each edge (u, v) in any order, and simulate the first step of Algorithm **DetEdge** in the induced subproblem. If **DetEdge** replicates to one of the nodes, say v, in the induced subproblem, then add v to $R(Tree)$ and replicate to v.

(2) Simulate step 2 of **DetEdge** for all edges. For any node v, if the edge algorithm for an incident edge $e = (u, v)$ requires deleting node v from e's residence set in e's induced problem, mark v.

(3) Drop at all marked nodes.

To show that **DetTree** is 3-competitive, we will show that it chooses a connected residence set and, for each edge, it induces the state required by **DetEdge**. This is not immediately obvious because the requirements of **DetEdge** on one edge might conflict with those on another edge. For example, one edge might want to drop a copy that another edge has just replicated.

We begin by analyzing the structure of the offset functions in the induced edge problems. For the rest of this subsection, the offset values and functions for each edge (a, b) refer to results from the induced sequence σ_{ab}. The next lemma characterizes the offset distribution between two adjacent edges.

LEMMA 3.7. *The following properties hold:*

(A) *At any time, there exists a root node r such that $R = \{r\}$ corresponds to a zero-offset state in the induced problems of all edges.*

(B) *For any edge (x, y) on the tree, define $S_i(x, y) = \omega_i(xy) - \omega_i(x)$. Then for any adjacent edges (x, y) and (y, z), the inequality $S_i(x, y) \le S_i(y, z)$ holds $\forall$ i.*

Following from the earlier definitions (see the beginning of section 3.2), the claim (A) above states that there is a node r such that for any edge (a, b), where a is nearer to r than b, state a is a zero-offset state for the edge. Note that the location of the root node r may not be unique, and its location changes with requests. The lemma implies the following conditions.

COROLLARY 3.8.

(C) *Let (x, y) be an edge in T such that a root r is in T_x. Let $z \neq x$ be a neighbor of y, and edges (x, y) and (y, z) have offsets $(0, k_{xy}, l_{xy})$ and $(0, k_{yz}, l_{yz})$, respectively. Then*

(C.1) *$l_{xy} \le l_{yz}$;*
(C.2) *$l_{xy} - k_{xy} \ge l_{yz} - k_{yz}$;*
(C.3) *$k_{xy} \le k_{yz}$; and*
(C.4) *if $k_{yz} = 0$, then $k_{xy} = 0$ and $l_{xy} = l_{yz}$ hold.*

(D) *Let* (x, y) *and* (y, z) *be adjacent edges with a root* r *in the subtree that is rooted at* y *and formed from removing the two edges from* T*. Let the offsets in the edges be* $(k_{xy}, 0, l_{xy})$ *and* $(0, k_{yz}, l_{yz})$*, respectively. Then* $l_{xy} \geq (l_{yz} - k_{yz})$ *holds.*

Proof of Lemma 3.7. We use induction on the number of requests. Initially, let r be the node holding the single copy of F; all the edges have offset vectors $(0, D, D)$, and the lemma holds trivially. We assume the lemma holds for $t \in \mathcal{Z}_0^+$ revealed requests and show that it remains valid after σ_{t+1} has arrived at a node w. We first show how to locate a new root. Let P represent the path from r to w. Unless specified otherwise, the offsets referred to below are the ones *before* σ_{t+1} arrives. We choose the new root, r', using the following procedure.

PROCEDURE FINDROOT.

(1) **If** (i) $w = r$ or (ii) $w \neq r$ and all the edges along P have offsets of the form $(0, k, l)$, $k \geq 1$. **Then** $r' = r$.

(2) **Otherwise**, move along P from r toward w, and cross an edge if it has offset vector of the form $(0, 0, l)$ until we cannot go any further or when w is reached. Pick the node where we stop as r'.

Let us show that r' is a valid root for the new offsets. We picture P as a chain of edges starting from r, going from left to right, and ending in w. If the condition in step (1) of the algorithm is satisfied, σ_{t+1} corresponds to a request at the zero-offset state for all edges. By Table 3.2, r remains a valid root node. Suppose (2) above is executed. For any edge that is not on P, or is on P but is to the right of r', its zero-offset state remains the same. Node r' is a valid root node for these edges. By (C.4), edges along P with offsets of the form $(0, 0, l)$ must form a connected subpath of P, starting from r and ending in r'. They have the same value for the parameter l. By Table 3.2, their offsets change from $(0, 0, l)$ to $(1, 0, \min\{l + 1, D\})$ or $(\min(1, l), 0, l)$, and r' is a valid root node for them. Hence (A) holds for our choice of r' above.

To show that (B) holds, we consider any two adjacent edges (x, y) and (y, z) whose removal will divide T into three disjoint subtrees: T_x, T_y, and T_z, with roots x, y, and z, respectively. We show that for different possible positions of r and w, (B) remains valid after σ_{t+1} has arrived; i.e., $S_{t+1}(x, y) \leq S_{t+1}(y, z)$ holds when σ_{t+1} is a *write* or a *read*, when $r \in T_x, T_y$, or T_z, and when $w \in T_x, T_y$, or T_z. We assume **(B)** holds before σ_{t+1} arrives.

Suppose σ_{t+1} is a read request, $r \in T_x$, and $w \in T_x$. For edge (x, y), $\omega_t = (0, k_{xy}, l_{xy})$ and $\omega_{t+1} = (0, \min(k_{xy} + 1, l_{xy}), l_{xy})$. For edge (y, z), $\omega_t = (0, k_{yz}, l_{yz})$ and $\omega_{t+1} = (0, \min(k_{yz} + 1, l_{yz}), l_{yz})$. Inequality $S_{t+1}(x, y) \leq S_{t+1}(y, z)$ follows from $S_t(x, y) \leq S_t(y, z)$ or (C.1). Condition (B) can be shown to hold in other situations by a similar case analysis. Please refer to the appendix for the complete case analysis. Thus (B) holds for request $(t + 1)$, and the lemma follows. □

THEOREM 3.9. *Algorithm* **DetTree** *is strongly* 3*-competitive.*

Proof. We show that **DetTree** induces **DetEdge** on each tree edge. The theorem then follows from Lemmas 3.4 and 3.5 and Theorem 3.6.

We proceed by induction on the number of requests. Initially, $R(Tree)$ consists of a single node. Suppose $R(Tree)$ is connected after the first $t \in \mathcal{Z}_0^+$ requests, and for each edge (a, b), the state induced by $R(Tree)$ is equal to the state desired by **DetEdge** when run on σ_{ab}. Consider the processing of request $t + 1$.

Step (1): *Replication.* We do a subinduction on the number of replications done in Step (1) and show that no replication is in conflict with the state desired by any edge.

Suppose that processing edge (a, b) in Step (1) causes F to be replicated to a.

Then $r \in T_a$, $R(Tree)$ lies in T_b, inducing state $s = b$, and $\omega_{t+1} = (0, l, l)$. This follows from the definition of **DetEdge**, the definition of the induced subproblem, and the inductive hypothesis. Let Q be the path from b to the nearest node in $R(Tree)$. If $Q \neq \{b\}$, then, to avoid conflict, each edge along Q must also require replication across it. From (A) and (C.2) in Theorem 3.7, we see that each edge (x, y) in Q has an offset of the form $\omega_{t+1} = (0, l', l')$, where x is nearer to b than y and requires a replication. A similar argument holds for the case when $s = a$ and $\omega_{t+1} = (0, 0, 0)$.

Step (2): *Marking nodes to drop.* Again we perform a subinduction on the number of markings done in Step (2) and show that no marking is in conflict with the state desired by any edge and that a connected residence set results.

Suppose that processing edge (a, b) in Step (2) causes b to be marked. This occurs because (a, b) has $\omega_{t+1} = (0, D, D)$, $r \in T_a$, r a write, and $s = ab$.

Since $R(Tree)$ is connected by hypothesis, both a and b are in $R(Tree)$, and the nodes in T_b with a copy of F span a connected subtree of T_b, with b as its root. Let us call it T'_b. If $T'_b \neq \{b\}$, each edge (x, y) in T'_b is in state $s = xy$. By (A) and (C.3) in Theorem 3.7, (x, y) must have offset $\omega_{t+1} = (0, D, D)$, with x nearer to b than y is. Under **DetEdge**, (x, y) needs to drop the copy of F in node y. Hence all the nodes in T'_b are required to be removed from $R(Tree)$, the new $R(Tree)$ remains connected, and no edges are in conflict.

Thus $R(Tree)$ is connected, all induced edge algorithms match **DetEdge**, and **DetTree** is 3-competitive. □

4. Randomized algorithms for FAP on a tree. Our approach to building a randomized tree algorithm is the same as our approach in the deterministic case. We give a randomized algorithm for a two-point space, **RandEdge**, that is based on counter values assigned at the nodes. By factoring, we obtain from **RandEdge** a $(2+1/D)$-competitive algorithm, **RandTree**, for file allocation on a tree. **RandTree** requires the generation of only $O(\log D)$ random bits at the beginning of the algorithm, after which it runs completely deterministically. It is simpler than the tree algorithm in [19], which can require the generation of $\Omega(\log D)$ random bits after each request is served.

4.1. An optimal randomized edge algorithm, RandEdge. Let edge $e = (a, b)$. We maintain counters c_a and c_b on nodes a and b, respectively. They satisfy $0 \leq c_a, c_b \leq D$ and $(c_a + c_b) \geq D$. Our algorithm maintains a distribution of R dependent on the counter values. Initially, the node with a copy of F has counter value D, and the other node has counter value 0. The counter values change according to the following rules. On a read request at a, we increment c_a if $c_a < D$. On a write request at a, if $(c_a + c_b) > D$, we decrement c_b; if $(c_a + c_b) = D$ and $c_a < D$, we increment c_a. The counters change similarly for a request at b. There is no change in the counter values in other cases.

Algorithm **RandEdge** always maintains a distribution of R such that

$$p_e[a] = 1 - \frac{c_b}{D}, \tag{4.1a}$$

$$p_e[b] = 1 - \frac{c_a}{D}, \quad \text{and} \tag{4.1b}$$

$$p_e[ab] = \frac{c_a + c_b}{D} - 1. \tag{4.1c}$$

Observe that the probability of having a copy of F at node $v \in \{a, b\}$ is c_v/D.

In order to maintain this distribution, **RandEdge** simulates D deterministic algorithms, numbered from 1 to D. The moves of each deterministic algorithm are constructed (deterministically) on-line, according to rules given below. Before the first request, one of the D algorithms is picked at random. **RandEdge** then makes the same moves as the chosen deterministic algorithm. Thus $p_e[s]$, $s \in \{a, b, ab\}$, is the proportion of algorithms in state s, and the expected cost incurred by **RandEdge** is the average of the costs incurred by the D algorithms.

We define the D algorithms that achieve the probability distribution in (4.1). Suppose that initially only node a has a copy of F. Then initially the D algorithms are placed in state a. The following changes are made after a new request, σ_i, has arrived. Without loss of generality, we assume the request arises at node a. (The c_a and c_b values below refer to the counter values just *before* σ_i arrives.)

- There is no change in the algorithms if there is no change in the counter values.
- *Case* 1. If $\sigma_i = a^r$ and $c_a < D$, the lowest-numbered algorithm in state b moves to state ab.
- *Case* 2. If $\sigma_i = a^w$, $(c_a + c_b) > D$, the lowest-numbered algorithm in state ab moves to state a.
- *Case* 3. If $\sigma_i = a^w$, $(c_a + c_b) = D$, and $c_a < D$, the lowest-numbered algorithm in state b moves to state ab.

LEMMA 4.1. **RandEdge** *is feasible and maintains the probability distribution in* (4.1).

Proof. By feasible we mean that whenever a move must be made in Cases 1, 2, and 3, there is some algorithm available to make the move. The choice of lowest-numbered algorithm is only to emphasize that the choice must be independent of which algorithm **RandEdge** is actually emulating.

The lemma holds initially with $c_a = D$ and $c_b = 0$. We prove the lemma by induction on the requests and assume it holds before σ_i arrives. If there is no change in counter values after σ_i has arrived, the lemma holds trivially. By the induction hypothesis, in Case 1 above, since $c_a < D$ and $p_e[b] > 0$, at least one of the D algorithms is in state b; in Case 2, since $(c_a + c_b) > D$ and $p_e[ab] > 0$, there is an algorithm in state ab; in Case 3, since $c_a < D$, there is an algorithm in state b. Hence, **RandEdge** is feasible. It can be verified that the changes in the algorithms implement the probability distribution in (4.1) for the new counter values. ∎

THEOREM 4.2. **RandEdge** *is strongly* $(2 + 1/D)$*-competitive.*

Proof. For each node $v \in \{a, b\}$, we maintain the potential function

$$\phi_v = \begin{cases} \frac{D+1}{2} + \sum_{j=c_v}^{D-1} (2 - \frac{j}{D}), & \mathcal{OPT} \text{ has a copy of } F \text{ at } v, \\ \sum_{j=1}^{c_v} \frac{j}{D} & \text{otherwise,} \end{cases}$$

where $\mathcal{OPT}$ represents the adversary. Let the overall potential function $\Phi = \phi_a + \phi_b - (D + 1)/2$. Initially, $\Phi = 0$; at any time, $\Phi \geq 0$. We show that in response to each request and change of state,

$$\mathbf{E}(\Delta C_{\mathbf{RandEdge}}) + \mathbf{E}(\Delta M_i) + \Delta\Phi \leq (2 + 1/D) \cdot \Delta OPT \tag{4.2}$$

holds, where ΔOPT, $\mathbf{E}[\Delta C_{\mathbf{RandEdge}}]$, and $\mathbf{E}(\Delta M_i)$ are the cost incurred by the event on $\mathcal{OPT}$ and the service and movement costs incurred on **RandEdge**, respectively. The c_a and c_b values below are the counter values just before the new request σ_i arrives.

Case 1. Request $\sigma_i = a^r$.

If $c_a = D$, inequality (4.2) holds trivially. Suppose $c_a < D$. We have

$$\mathbf{E}(\Delta C_{\mathbf{RandEdge}}) = 1 - \frac{c_a}{D}, \quad \mathbf{E}(\Delta M_i) = 1,$$

$$\Delta\Phi = \begin{cases} -2 + \frac{c_a}{D}, & \mathcal{OPT} \text{ has a copy of } F \text{ at } a, \\ \frac{c_a+1}{D} & \text{otherwise.} \end{cases}$$

It follows that if $\mathcal{OPT}$ has a copy of F at a when σ_i arrives, L.H.S. (4.2) $= \Delta OPT = 0$; otherwise, L.H.S. (4.2) $= (2 + 1/D) = (2 + 1/D) \cdot \Delta OPT$. Inequality (4.2) holds.

Case 2. Request $\sigma_i = a^w$ and $(c_a + c_b) > D$.

We have

$$\mathbf{E}(\Delta C_{\mathbf{RandEdge}}) = \frac{c_b}{D}, \quad \mathbf{E}(\Delta M_i) = 0,$$

$$\Delta\Phi = \begin{cases} 2 - \frac{c_b-1}{D}, & \mathcal{OPT} \text{ has a copy of } F \text{ at } b, \\ \frac{-c_b}{D} & \text{otherwise, and} \end{cases}$$

$$\text{L.H.S. (4.2)} = \begin{cases} 2 + \frac{1}{D}, & \mathcal{OPT} \text{ has a copy of } F \text{ at } b, \\ 0 & \text{otherwise.} \end{cases}$$

Inequality (4.2) holds.

Case 3. Request $\sigma_i = a^w$ and $(c_a + c_b) = D$.

If $c_a = D$, L.H.S. (4.2) $= 0$ and (4.2) holds trivially. Suppose $c_a < D$. We have

$$\mathbf{E}(\Delta C_{\mathbf{RandEdge}}) = 1 - \frac{c_a}{D}, \quad \mathbf{E}(\Delta M_i) = 1,$$

$$\Delta\Phi = \begin{cases} -2 + \frac{c_a}{D}, & \mathcal{OPT} \text{ has a copy of } F \text{ at } a, \\ \frac{c_a+1}{D} & \text{otherwise, and} \end{cases}$$

$$\text{L.H.S. (4.2)} = \begin{cases} 0, & \mathcal{OPT} \text{ has a copy of } F \text{ at } a, \\ 2 + \frac{1}{D} & \text{otherwise.} \end{cases}$$

Hence, (4.2) holds.

Case 4. $\mathcal{OPT}$ changes state.

When $\mathcal{OPT}$ changes state, $\mathbf{E}(\Delta C_{\mathbf{RandEdge}}) = \mathbf{E}(\Delta M_i) = 0$. It can be checked from the definition of Φ that when $\mathcal{OPT}$ replicates, $\Delta OPT = D$ and $\Delta\Phi \leq (2D + 1)$ hold; when $\mathcal{OPT}$ discards a copy of F, $\Delta\Phi \leq 0$.

Since (4.2) holds for all possible events, by Theorem 4.6 **RandEdge** is strongly $(2 + 1/D)$-competitive. □

4.2. An optimal randomized tree algorithm—RandTree. We extend **RandEdge** to a randomized algorithm for FAP on a tree, T, by means of factoring. Our algorithm, **RandTree**, induces **RandEdge** on each edge for the induced request sequence for the edge.

Description of algorithm RandTree. RandTree internally simulates D deterministic algorithms. Each of them maintains a residence set that spans a subtree of T. Initially, the residence set for each of them is the single node that contains F. One of the D simulated algorithms is picked uniformly at random at the beginning, and **RandTree** behaves exactly the same as the particular algorithm chosen.

We maintain counters c_a and c_b for each edge (a, b) in the tree. Using the factoring approach (see section 3.2), we obtain an induced request sequence σ_{ab} for (a, b). The counter values change according to the same rules as described in the single edge case (section 4.1), using σ_{ab}. **RandTree** responds to each request and maintains an (induced) distribution as required by **RandEdge** in (4.1) for each of the edges.

Read request. Suppose the new request, σ_i, is a *read* request at a node g. Let T be rooted at g and $e = (a, b)$ be an edge with a nearer to g than b is. The c_a and c_b values described below are the counter values before σ_i arrives. The edges can be classified into three types:

- type 1: edges with $c_a = D$ and $c_b = 0$;
- type 2: edges with $c_a = D$ and $c_b > 0$; and
- type 3: edges with $c_a < D$.

RandEdge requires no change in probability values for the first two types of edges; for type 3 edges, it requires that $p_e[b]$ decreases by $1/D$ and $p_e[ab]$ goes up by $1/D$. For any node v, we use $T(v)$ to denote the subtree of T rooted at v. **RandTree** changes the subtree configurations maintained by the D algorithms by using the following procedure (Fig. 4.1).

(1) Let $\mathcal{F}$ be the forest of trees formed by all the type 3 edges.
(2) **While** there exists a tree $T' \in \mathcal{F}$ with at least one edge, **Do**
  (2.1) Let x be a leaf node in T' and P be the path from x to the root node of T'.
  (The root node of T' is the node in T' that is nearest to g.)
  (2.2) Pick any one of the D algorithms that maintains a subtree, Z, that includes node x and lies entirely in $T(x)$.
  Make that algorithm replicate along P, i.e., replace Z by $Z \cup P$.
  (2.3) Remove the edges in P from T' and update the forest $\mathcal{F}$.

FIG. 4.1. *Algorithm RandEdge (read requests).*

LEMMA 4.3. **RandTree** *implements the required changes for all the edges for a read request.*

Proof. We prove the lemma by induction on the requests. Suppose that **RandTree** induces **RandEdge** on all edges before σ_i arrives. Let y be the parent node of x. If **RandTree** is feasible, i.e., it can be executed, it implements the changes required by **RandEdge** as described above for all edges. We show that this is the case.

If x is a leaf node of T, since (x, y) is a type 3 edge, $p_{(x,y)}[x] > 0$ and one of the D algorithms must have the single node $\{x\}$ as its tree configuration.

Otherwise, suppose all the descending edges of x are of type 1. Let (x, w) be one of them. Then $p_{(x,w)}[xw] = p_{(x,w)}[w] = 0$; none of the algorithms maintain a subtree with any edge in $T(x)$. Since $p_{(x,y)}[x] > 0$, one of the algorithms must have $\{x\}$ as its subtree.

Otherwise, suppose x has descending type 2 edges. Let (x, w) be any one of them. Then $p_{(x,w)}[w] = 0$ and $p_{(x,w)}[xw] > 0$. Thus each of these edges is contained in the

subtree of at least one of the algorithms, and none of the algorithms has its subtree in $T(w)$. Since $p_{(x,y)}[x] > 0$, at least one of these subtrees must lie in $T(x)$ and contains node x.

Hence, our algorithm is feasible and the lemma holds. □

Write request. Suppose $\sigma_i = r^w$. We use the same notation as in the read request case. The edges can be classified into three types:

- type 1: edges with $(c_a + c_b) > D$;
- type 2: edges with $(c_a + c_b) = D$ and $c_a < D$; and
- type 3: edges with $(c_a + c_b) = D$ and $c_a = D$.

RandEdge requires no change in probability values for the type 3 edges; for type 1 edges, it requires that $p_e[ab]$ decreases by $1/D$ and $p_e[a]$ increases by the same amount; for type 2 edges, it requires that $p_e[b]$ decreases by $1/D$ and $p_e[ab]$ increases by the same amount. **RandTree** performs the following (Fig. 4.2).

(1) Let $\mathcal{F}$ be the forest of trees formed by all the type 1 edges.
(2) While there exists a tree $T' \in \mathcal{F}$ with at least one edge, **Do**
  (2.1) Let g' be the root node of T' and x be one of its children nodes in T'.
  (2.2) Pick an algorithm that has a subtree Z that includes edge (g', x).
  (2.3) If Z is contained in T', make the algorithm replace Z by the single-node subtree $\{g'\}$; otherwise, replace Z by the tree formed by edges in $(Z - T')$.
  (2.4) Replace T' in $\mathcal{F}$ by the subtrees formed by $T' - Z$.
(3) Let $\mathcal{F}$ be the forest of trees formed by all the type 2 edges.
(4) **While** there exists a tree $T' \in \mathcal{F}$ with at least one edge, **Do**
  (4.1) Let x be a leaf node of T' and P be the path from x to the root node of T'.
  (4.2) Pick any one of the D algorithms that maintains a subtree, Z, that includes node x and lies entirely in $T(x)$.
  Make that algorithm replicate along P, i.e., extends Z to $Z \cup P$.
  (4.3) Remove the edges in P from T' and update the forest $\mathcal{F}$.

FIG. 4.2. *Algorithm RandEdge (write requests).*

LEMMA 4.4. **RandTree** *implements the required changes for all the edges for a write request.*

Proof. We prove by induction and assume **RandEdge** is induced on all the edges before σ_i arrives. If **RandTree** is feasible, it implements the required changes for all the edges. We show that this is the case.

Consider the first loop of the algorithm (in step (2)). Since $p_{(g',x)}[g'x] > 0$, subtree Z must exist. **RandTree** removes edges from Z that are contained in T'. Note that the $p_e[ab]$ values for type 2 and 3 edges are zero; **RandTree** processes edges in T' in a top-down fashion, and configuration $(Z - T')$ is always a connected subtree. Thus the first loop can be executed.

Consider the second loop of the algorithm (in step (4)). Let y be a parent node of x. Then $p_{(x,y)}[xy] = 0$ and $p_{(x,y)}[x] > 0$ hold. If x is a leaf node in T, one of the D algorithms must have $\{x\}$ as its subtree. If x has a descending type 1 edge, by the first part of the algorithm, one of the D algorithms must have $\{x\}$ as its subtree after running the first loop of the algorithm. Suppose all the descending edges of x

are type 3 edges. Let (x, w) be a type 3 edge; then $p_{(x,w)}[w] = p_{(x,w)}[xw] = 0$ and $p_{(x,w)}[x] = 1$. Since $p_{(x,y)}[x] > 0$, one of the algorithms must have $\{x\}$ as its subtree.

Hence, the algorithm is feasible and the lemma follows. □

Lemmas 4.3 and 4.4 imply that **RandTree** induces **RandEdge** on all the edges. Theorem 4.5 follows from the above lemmas and Theorem 4.2.

THEOREM 4.5. *Algorithm* **RandTree** *is strongly* $(2 + 1/D)$*-competitive for FAP on a tree against an oblivious adversary.*

4.3. Lower bound. We show that the competitive ratio, $(2 + 1/D)$, obtained above is the best possible for file allocation against an oblivious adversary, even if G is a single edge.

THEOREM 4.6. *No on-line algorithm for the file allocation problem on two points* (a, b) *is* c*-competitive for any* $c < (2 + 1/D)$.

Proof. Let A be any randomized algorithm for the file allocation problem on two points. We define a potential function Ψ and give a strategy for generating adversary request sequences such that

(i) for any C there is a request sequence σ with optimum cost $\geq C$;

(ii) the cost to **RandEdge** on σ is at least $(2 + 1/D)OPT(\sigma) - B''$, for B'' bounded independent of σ;

(iii) Ψ is bounded; and

(iv) for each request generated by this adversary,

$$\Delta C_A + \Delta\Psi \;\geq\; \Delta C_{\mathbf{RandEdge}}. \tag{4.3}$$

If conditions (ii), (iii), and (iv) hold for an adversary sequence σ, then summing (4.3) over the sequence gives

$$C_A(\sigma) \geq (2 + 1/D) \cdot OPT(\sigma) - B,$$

where B is bounded. By condition (i), the adversary can make $OPT(\sigma)$ arbitrarily large, so there is no constant B' independent of σ such that $C_A(s) < (2 + 1/D) \cdot OPT(\sigma) + B'$. Hence A cannot be c-competitive for $c < 2 + 1/D$.

We now define the adversary's strategy. We assume that both the on-line and off-line algorithms start with a single copy of F at a. Our adversary will generate only requests that result in offset functions of the form $(0, i, i)$, where $0 \leq i \leq D$. A *zero-cost self-loop* is a request such that the offset function is unchanged and $\Delta opt = 0$. By a theorem of [18], there is always an optimal on-line algorithm that incurs zero expected cost on a zero-cost self-loop. We assume A has this property. This simplifies the adversary's strategy, although the result can still be proved without this assumption.

Suppose that the current offset function is $(0, i, i)$, and let p_i be probability that **RandEdge** is in state a. Suppose A is in state a with probability q. If $q < p_i$, the adversary requests a^w; otherwise the adversary requests b^r. When $i = D$ we will have $q = 1$ (a^w is a zero-cost self-loop if $i = D$), and so the adversary will request b^r. Similarly, when $i = 0$, $q = 0$ (a^r is a zero-cost self-loop) and the adversary requests a^w. Therefore the adversary can always generate a next request using the above rules, and the request sequence can be made arbitrarily long. Since there are only D offset functions that can be generated by this strategy, an arbitrarily long sequence of requests must cycle through the offset functions arbitrarily often. Notice, however, that the only cycles which cost $\mathcal{OPT}$ nothing are zero-cost self-loops. Since the adversary never uses these requests, all cycles have nonzero cost, so by continuing

long enough the adversary can generate request sequences of arbitrarily large optimum costs. Hence condition (i) holds.

Next we consider condition (ii). Recall c_a and c_b, the counter values maintained by **RandEdge**. We claim that if the offset function is $(0, i, i)$, then $c_a = D$ and $c_b = D - i$. This is true initially, when F is located only at a, and $i = D$. By inspection of **RandEdge** one can verify that whenever the adversary generates request b^r, c_b increases by 1, and that whenever the adversary generates a^w, c_b decreases by 1. Hence $p_i = i/D$ and the expected movement cost incurred by **RandEdge** is 1 on b^r and 0 on a^w. With reference to the proof of Theorem 4.2, note that the amortized cost to **RandEdge** is exactly $2 + 1/D$ times the cost to $\mathcal{OPT}$ on any request that the adversary might generate, assuming $\mathcal{OPT}$ does not move following the request. (The adversary never generates b^r if $c_b = D$ or a^w if $c_b = 0$.) The amortized cost incurred by **RandEdge** is therefore exactly $2 + 1/D$ times the cost incurred by an "optimum" algorithm that only ever has a copy of F at a. It is possible to show that this cost really is optimum for our sequences, but in any case it is certainly lower-bounded by the true optimum cost, and so (ii) holds.

Now define Ψ to be $D \cdot \max\{0, q - p_i\}$. This is trivially bounded by D, so (iii) holds. Finally, we must verify (4.3).

Case 1. The adversary requests a^w.

In this case the new offset function must be $(0, i + 1, i + 1)$. Suppose that after the request A has mass q' at a. Then $\Delta C_A = 1 - q + D \cdot \max\{0, q - q'\}$, $\Delta\Psi = D \cdot \max\{0, q' - p_{i+1}\} - D \cdot \max\{0, q - p_i\}$, and $\Delta C_{\mathbf{RandEdge}} = 1 - p_i$. Since $q < p_i < p_{i+1}$,

$$\begin{aligned}\Delta C_A + \Delta\Psi &= 1 - q + D \cdot \max\{0, q - q'\} + D \cdot \max\{0, q' - p_{i+1}\} - D \cdot \max\{0, q - p_i\} \\ &\geq 1 - q \\ &\geq 1 - p_i \\ &= \Delta C_{\mathbf{RandEdge}}.\end{aligned}$$

Case 2. The adversary requests b^r.

In this case the new offset function must be $(0, i - 1, i - 1)$. Suppose that after the request, A has mass q' at a. Then $\Delta C_A = q + D \cdot \max\{0, q - q'\}$, $\Delta\Psi = D \cdot \max\{0, q' - p_{i-1}\} - D \cdot \max\{0, q - p_i\}$, and $\Delta C_{\mathbf{RandEdge}} = p_i + 1$. Since $q \geq p_i > p_{i-1}$,

$$\begin{aligned}\Delta C_A + \Delta\Psi &= q + D \cdot \max\{0, q - q'\} + D \cdot \max\{0, q' - p_{i-1}\} - D \cdot \max\{0, q - p_i\} \\ &\geq q + D(q - p_{i-1}) - D \cdot \max\{0, q - p_i\} \\ &= q + D\,(p_i - p_{i-1}) \\ &= q + 1 \\ &\geq p_i + 1 \\ &= \Delta C_{\mathbf{RandEdge}}. \qquad \square\end{aligned}$$

5. Migration on a uniform network. We give a $(2+1/(2D))$-competitive randomized algorithm against an oblivious adversary for migration on a uniform network. This competitive ratio is optimal even for a single edge [10]. Let G be a complete graph on n nodes labeled 1 to n. Initially, only node 1 has a copy of F. Our algorithm is based on the offsets calculated on-line. Let $S = \{1, \ldots, n\}$ and the algorithm is in state s if the single copy of F is at node s. We have the cost functions

$$ser(t, \sigma_i) = \begin{cases} 0 & \text{if } t = \sigma_i, \\ 1 & \text{otherwise,} \end{cases} \qquad tran(t, s) = \begin{cases} 0 & \text{if } t = s, \\ D & \text{otherwise,} \end{cases}$$

and initially $W_0 = (0, D, \ldots, D)$.

Suppose the ith request is served and the new offset for each node, s, is calculated. Let $v_s = D - \omega_i(s)$, $k = \max\{j \in S | \sum_{m=1}^{j} v_m < 2D\}$, and $\delta = 2D - \sum_{m=1}^{k} v_m$.

ALGORITHM MIGRATE. The algorithm maintains the probability, $p[s]$, that a node, s, contains F as follows:

$$\text{If } k < n, \quad p[s] = \begin{cases} v_s/2D & \text{if } s \le k, \\ \delta/(2D) & \text{if } s = k+1, \\ 0 & \text{otherwise.} \end{cases}$$

$$\text{If } k = n, \quad p[s] = \begin{cases} v_s/2D & \text{if } s \le k \text{ and } v_s < D, \\ (v_s + \delta)/(2D) & \text{if } s \le k \text{ and } v_s = D, \\ 0 & \text{otherwise.} \end{cases}$$

After a new request has arrived, our algorithm moves to different states with transition probabilities that minimize the total expected movement cost while maintaining the new required distribution.

THEOREM 5.1. *Given any σ, the expected cost incurred by* **Migrate**, $\mathbf{E}[C_{mig}(\sigma)]$, *satisfies*

$$\mathbf{E}[C_{mig}(\sigma)] \le [2 + 1/(2D)] \cdot OPT(\sigma).$$

Proof. We show that after a request has arrived,

$$\mathbf{E}[\Delta C_{mig}] + \mathbf{E}[\Delta M] + \Delta\Phi \le \left(2 + \frac{1}{2D}\right) \cdot \Delta opt_i \tag{5.1}$$

holds, where $\mathbf{E}[\Delta C_{mig}]$ is the expected cost incurred by **Migrate**, $\mathbf{E}[\Delta M]$ is the expected movement cost, and $\Delta\Phi$ is the change in the potential function:

$$\Phi = \sum_{s=1}^{n} \sum_{j=1}^{v_s} \left(\frac{1}{2} + \frac{j}{2D}\right) - (3D+1)/4.$$

Initially, $\Phi = 0$. At any time, since at least one $v_s = D$, we have $\Phi \ge 0$.

An offset table similar to Table 3.2 for file allocation can be constructed. Since migration is equivalent to FAP with only write requests, it can be seen that if request σ_{i+1} is at a node s with $\omega_i(s) = 0$, we have $\omega_{i+1}(s) = 0$, the offsets for all other states will increase by one, subject to a maximum of D, and $\Delta opt_{i+1} = 0$. If σ_{i+1} is at a node s with $\omega_i(s) > 0$, the offset for state s will decrease by one, all other offsets remain the same, and $\Delta opt_{i+1} = 1$.

Case 1. A request at s such that $v_s < D$.

In this case, we have $\Delta opt_{i+1} = 1$, and v_s increases by one. If $s \le k$, then $\mathbf{E}[\Delta C_{mig}] \le [1 - v_s/(2D)]$. It can be verified that $\mathbf{E}[\Delta M] \le 1/2$, $\Delta\Phi \le 1/2 + (v_s + 1)/(2D)$, and L.H.S. (5.1)$\le 2 + 1/(2D)$ = right-hand side (R.H.S.) (5.1). If $s > k$, then the movement cost is zero. We also have $\mathbf{E}[\Delta C_{mig}] \le 1$, $\Delta\Phi = 1/2 + (v_s + 1)/(2D) \le 1 + 1/(2D)$; inequality (5.1) also holds.

Case 2. A request at s such that $v_s = D$.

We have $\Delta opt_{i+1} = 0$. For each $j \in S - \{s\}$ such that $v_j > 0$, v_j decreases by 1. Each such v_j contributes $-[1/2 + v_j/(2D)]$ to $\Delta\Phi$ and no more than $1/2$ to $\mathbf{E}[\Delta M]$. We have $\mathbf{E}[\Delta Cost] = (1 - p_s)$, where p_s is the probability mass at s, and

$$1 - p_s = \sum_{j \ne s} p_j \le \sum_{j \ne s, v_j > 0} \frac{v_j}{2D}.$$

Hence L.H.S. (5.1) ≤ 0. ∎

6. Replication. We give upper and lower bounds on the performance of randomized on-line algorithms for the replication problem.

6.1. Randomized on-line algorithms. Let $e_D = (1 + 1/D)^D$ and $\beta_D = e_D/(e_D - 1)$. So $\beta_D \longrightarrow e/(e-1) \approx 1.58$ as $D \longrightarrow \infty$. We describe randomized algorithms that are β_D-competitive against an oblivious adversary on the uniform network and trees. First, consider a single edge (r, b) of unit length. Initially, only r contains a copy of F. Suppose algorithm A is α-competitive, and it replicates F to node b with probability p_i after the ith request at b, where $\sum_i p_i = 1$. The p_i's and α must satisfy, for each $k \in \mathcal{Z}_0^+$,

$$\mathbf{E}[C_A(\sigma) \mid k] \leq \begin{cases} \alpha \cdot k, & k \leq D, \\ \alpha \cdot D, & k > D, \end{cases}$$

$$\text{where } \mathbf{E}[C_A(\sigma) \mid k] = \sum_{i=1}^{k} p_i \cdot (D + i) + \left(1 - \sum_{i=1}^{k} p_i\right) \cdot k$$

is the expected cost incurred by A when σ contains k requests at b. The optimal off-line strategy is to replicate a copy of F to b before the first request arrives if $k \geq D$ and does not replicate otherwise. Algorithm A incurs a cost of $(D + i)$ if it replicates right after serving the ith request, $i \leq k$; otherwise it incurs a cost of k. An optimal randomized algorithm is given by a set of p_i values that satisfy the above inequalities for all k such that α is minimized. We note that the conditions above are identical to those for the on-line block snoopy caching problem on two caches in [15]. Karlin et al. [15] showed that the optimal α value is β_D. This is achieved when $p_i = [(D+1)/D]^{i-1}/[D(e_D - 1)]$, $1 \leq i \leq D$, and other p_i's are zero. The above single edge algorithm can be applied to a uniform network by replicating F to each node v after the ith request at v, with a probability of p_i—another example of factoring.

THEOREM 6.1. *There exists a randomized algorithm that is strongly β_D-competitive against an oblivious adversary for replication on a uniform network.*

We can extend the single edge algorithm to a tree, T, rooted at r, the node that contains F initially. The algorithm responds only to requests at nodes not in the current residence set.

ALGORITHM TREE. Keep a counter c_i on each node $i \neq r$. Initially, all $c_i = 0$. Suppose a request arrives at a node x, and w is the node nearest to x that contains a copy of F. After serving the request, the counters for all the nodes along the path from w to x are increased by one. Let the nodes along the path be $w = i_0, i_1, \ldots, i_q = x$, $q \geq 1$. Perform the following procedure each time after a request has been served:

(1) Let $p_{c_{i_0}} = 1$.
(2) **For** $j = 1, \ldots, q$, **Do**
  (2.1) With probability $p_{c_{i_j}}/p_{c_{i_{j-1}}}$, replicate to node i_j from node i_{j-1}.
  (2.2) **If** F is not replicated to i_j, **STOP**.

THEOREM 6.2. *Algorithm* **Tree** *is strongly β_D-competitive against an oblivious adversary for replication on a tree network.*

Proof. Without loss of generality, we assume that a *connected* R is always maintained by any solution. Let $x \neq r$ be any node and y its parent. Before x obtains a copy of F, a cost equal to the weight of (x, y) is incurred on the edge for each request at a node in the subtree rooted at x. (This follows because R is connected and the unique path from x to r passes through (x, y).) By our single edge algorithm, the algorithm **Tree** is β_D-competitive if, for each node $x \neq r$, a copy of F is replicated to x after the ith request at the subtree rooted at x, with a probability p_i. It can be

shown by induction on the requests that before x acquires a copy of F, the counter on x records the number of requests that have arrived at the subtree rooted at x, and these counters form a nonincreasing sequence on any path moving away from r. Hence, the values $p_{c_{i_j}}/p_{c_{i_{j-1}}} = (1+1/D)^{c_{i_j}-c_{i_{j-1}}} \leq 1$, $j = 2, \ldots, q$, are defined probability values. It is simple to verify that each time a node at the subtree rooted at x receives a request, a copy of F is replicated to x with probability p_{c_x}, where c_x is x's new counter value. The theorem follows. ∎

6.2. Lower bound. We show that no randomized algorithm can be better than 2-competitive against an adaptive on-line adversary. We use n to denote the number of nodes in G.

THEOREM 6.3. *Let ϵ be any positive function of n and D, taking values between 0 and 1. No on-line algorithm is better than $(2-\epsilon(D,n))$-competitive for replication against an adaptive on-line adversary.*

Proof. Let node a have the initial copy of F, and let (a,b) be any edge in G. Let A be any on-line algorithm which replicates to b after the jth request at b with probability p_j, $j \in \mathcal{Z}^+$. The adversary issues requests at b until A replicates or until N_ε requests have been issued, whichever first happens. Algorithm A incurs an expected cost of

$$\mathbf{E}[C_A(\sigma)] = \sum_{j=1}^{N_\varepsilon} p_j \cdot (j+D) + \sum_{j=N_\varepsilon+1}^{\infty} p_j \cdot N_\varepsilon. \tag{6.1}$$

We choose different N_ε's for two different cases.

Suppose $\sum_{j=1}^{\infty} p_j \cdot j > D$. Let N_ε be the minimum positive integer that is greater than D and such that $\sum_{j=1}^{N_\varepsilon} p_j \cdot j \geq D$. Given D, parameter N_ε is a finite and unique constant. The adversary replicates to b before the first request arrives, incurring a cost of D. From (6.1), we have $\mathbf{E}[C_A(\sigma)] \geq D + \sum_{j=1}^{N_\varepsilon} p_j \cdot j \geq 2D$, giving a ratio of at least 2.

Suppose $\sum_{j=1}^{\infty} p_j \cdot j \leq D$. Let $\varepsilon = \epsilon(n,D)$. The adversary does not replicate and incurs an expected cost of

$$\sum_{j=1}^{N_\varepsilon} p_j \cdot j + \sum_{j=N_\varepsilon+1}^{\infty} p_j \cdot N_\varepsilon. \tag{6.2}$$

From (6.1), we have

$$\mathbf{E}[C_A(\sigma)] = \sum_{j=1}^{N_\varepsilon} p_j \cdot j + D \cdot \sum_{j=1}^{N_\varepsilon} p_j + \sum_{j=N_\varepsilon+1}^{\infty} p_j \cdot N_\varepsilon \tag{6.3a}$$

$$\geq \left(1 + \sum_{j=1}^{N_\varepsilon} p_j\right) \cdot \sum_{j=1}^{N_\varepsilon} p_j \cdot j + \sum_{j=N_\varepsilon+1}^{\infty} p_j \cdot N_\varepsilon. \tag{6.3b}$$

Given the p_j's, one can choose N_ε so that $\sum_{j=1}^{N_\varepsilon} p_j$ is arbitrarily close to 1. Since the series $\sum_{j=1}^{\infty} j \cdot p_j$ is bounded, one can also choose N_ε so that $\sum_{j=N_\varepsilon+1}^{\infty} p_j \cdot N_\varepsilon$ is arbitrarily close to zero. Thus, by comparing (6.2) and (6.3b), we see that given any ε, one can choose a finite N_ε so that the ratio is as close to $(2-\varepsilon)$ as desired. ∎

7. Off-line replication and file allocation. We show that the off-line replication problem is NP-hard, and the off-line file allocation problem on the uniform network can be solved in polynomial time.

7.1. The off-line replication problem. Awerbuch, Bartel, and Fiat find interesting relationships between the on-line Steiner tree problem [14, 23] and on-line FAP. We show that the (off-line) replication problem is NP-hard by using a straightforward reduction from the Steiner tree problem [12, 16] (see section 2 for the definition). The proof involves creating an instance for the replication problem in which $(D+1)$ requests are issued at each of the terminal nodes for the Steiner tree problem instance, forcing the optimal algorithm to replicate to these nodes.

THEOREM 7.1. *The replication problem is NP-hard, even if G is bipartite and unweighted or if G is planar.*

7.2. Off-line solution for file allocation on a uniform network. We show that the off-line file allocation problem on a uniform network can be solved in polynomial time by reducing it to a min-cost max-flow problem. A similar reduction was obtained by Chrobak et al. [8] for the k-server problem. We convert an instance of the FAP on a uniform network on nodes $1, \ldots, n$, to a min-cost max-flow problem on an acyclic layered network, N, with $O(n \cdot |\sigma|)$ nodes and $O(n^2|\sigma|)$ arcs. Initially node 1 has a copy of F. An integral maximum flow in N defines a dynamic allocation of F in the uniform network. The arc costs in N are chosen so that the min-cost max-flow in N incurs a cost that differs from the minimum cost for FAP on the uniform network by a constant. Network N is constructed as follows.

Nodes. Network N has $(|\sigma|+1)$ layers of nodes, $(2n-1)$ nodes in each layer, a source node s, and a sink node t. Layer k, $0 \le k \le |\sigma|$, has nodes $\{v_1^k, \ldots, v_n^k\}$ and $\{u_1^k, \ldots, u_{(n-1)}^k\}$. Each node allows a maximum flow of one unit into and out of it. The v_j^k nodes correspond to the nodes in the uniform network. Layer k of N corresponds to the state of the uniform network after σ_k has been served.

Arcs. There is an arc going from each layer k node to each layer $(k+1)$ node, $0 \le k \le (|\sigma|-1)$; there is an arc from each layer $|\sigma|$ node to t, arc (s, v_1^0), and arcs $(s, u_j^0), 1 \le j \le (n-1)$. All the arcs have unit capacity.

A flow. A maximum flow in N has a value of n. Given integer arc costs, there is a min-cost max-flow solution with only an integral flow of either 0 or 1 in each arc. A flow of 1 into v_j^k represents the presence of a copy of F at node j just before request k arrives. If the flow comes from $v_i^{(k-1)}$, it represents a copy of F being moved from node i to node j after serving the $(k-1)$st request; if the flow comes from $u_i^{(k-1)}$, it represents a replication to node j. A flow from $v_j^{(k-1)}$ to u_w^k represents that the copy of F at j is dropped after $\sigma_{(k-1)}$ is served. Thus an integral flow in N defines a strategy for relocating copies of F. Since there are $(n-1)$ u nodes in each layer, an integral max-flow must include a flow of 1 unit into at least one of the v nodes in each layer. This corresponds to the requirement that there is always at least a copy of F in the uniform network.

Edge costs. Edge costs are chosen so that the optimal flow has cost equal to the optimal off-line cost for FAP minus the number of read requests, J, in σ. Arcs with one end point at s or t have zero costs. Let (a, b) be any other arc, going between layer k and $(k+1)$. Its cost is equal to the sum of its associated *movement* and *service* costs. Suppose b is $v_i^{(k+1)}$. Then (a, b)'s associated movement cost is D unless a is v_i^k. If $\sigma_{(k+1)}$ is a write at some node other than node i, the service cost is 1; if $\sigma_{(k+1)}$ is a read at node i, the service cost is -1. The costs for all other cases are zero. The movement and service costs account for the cost for replication and serving requests, except a node is charged -1 when a read request arrives and it has a copy of F. If we add J to the cost of the optimal flow, thus charging each read request 1 in advance,

the sum is equal to the cost of an optimal dynamic allocation of F.

Using the algorithm in [21] for solving the min-cost max-flow problem on acyclic networks, FAP on a uniform network can be solved in polynomial time.

THEOREM 7.2. *An optimal (off-line) file allocation on a uniform network can be found in* $O(n^3 \cdot |\sigma| \cdot (1 + \log_n |\sigma|))$ *time.*

8. Open problems. Interesting open problems include finding a strongly competitive randomized algorithm for FAP on a uniform network. Awerbuch, Bartel, and Fiat [2] conjecture that if there exists a c_n-competitive algorithm for the on-line Steiner tree problem [14, 23], then there exists a $O(c_n)$-competitive deterministic algorithm for FAP. This conjecture is still open. For the migration problem, there is a gap between the best known bounds [4, 10].

Appendix: Complete proof for (B) in Lemma 3.7. The following is the complete proof for condition (B) in Lemma 3.7. It will be shown that

$$S_i(x, y) \le S_i(y, z) \tag{8.1}$$

holds for $i = (t + 1)$ after request $(t + 1)$ has arrived, by considering the change in offset values using Table 3.2 for all possible locations of the root node r, request node w, and offset vectors. In each case, the required inequality follows from the property that all offsets satisfy $0 \le k \le l$ and the assumption that (8.1) holds initially for $i = t$. We will be referring to the conditions (C.1) to (C.4) and (D) that are implied by (8.1) for $i = t$. We use L.H.S. and R.H.S. to denote the left- and right-hand sides of the inequality under consideration, respectively.

Suppose the request is a **READ** request:

Case 1: $r \in T_x$ and $w \in T_x$.
For (x, y): $\omega_t = (0, k_{xy}, l_{xy})$ and $\omega_{t+1} = (0, \min(k_{xy} + 1, l_{xy}), l_{xy})$.
For (y, z): $\omega_t = (0, k_{yz}, l_{yz})$ and $\omega_{t+1} = (0, \min(k_{yz} + 1, l_{yz}), l_{yz})$.
$S_{t+1}(x, y) \le S_{t+1}(y, z)$ follows from $S_t(x, y) \le S_t(y, z)$ or (C.1).

Case 2: $r \in T_y$ and $w \in T_y$.
For (x, y): $\omega_t = (k_{xy}, 0, l_{xy})$ and $\omega_{t+1} = (\min(k_{xy} + 1, l_{xy}), 0, l_{xy})$.
For (y, z): $\omega_t = (0, k_{yz}, l_{yz})$ and $\omega_{t+1} = (0, \min(k_{yz} + 1, l_{yz}), l_{yz})$.
$S_{t+1}(x, y) \le S_{t+1}(y, z) \Leftrightarrow l_{xy} - \min(k_{xy} + 1, l_{xy}) \le l_{yz}$ follows from (D).

Case 3: $r \in T_x$ and $w \in T_y$.
For (x, y): $\omega_t = (0, k_{xy}, l_{xy})$ and $\omega_{t+1} = \begin{cases} (0, k_{xy} - 1, l_{xy} - 1) & \text{if } k_{xy} \ge 1, \\ (\min(1, l_{xy}), 0, l_{xy}) & \text{if } k_{xy} = 0. \end{cases}$
For (y, z): $\omega_t = (0, k_{yz}, l_{yz})$ and $\omega_{t+1} = (0, \min(k_{yz} + 1, l_{yz}), l_{yz})$.
$k_{xy} \ge 1$: $S_{t+1}(x, y) \le S_{t+1}(y, z) \Leftrightarrow l_{xy} - 1 \le l_{yz}$ follows from (C.1).
$k_{xy} = 0$: $S_{t+1}(x, y) \le S_{t+1}(y, z) \Leftrightarrow l_{xy} - \min(1, l_{xy}) \le l_{yz}$ follows from (C.1).

Case 4: $r \in T_x$ and $w \in T_z$.
For (x, y): $\omega_t = (0, k_{xy}, l_{xy})$ and $\omega_{t+1} = \begin{cases} (0, k_{xy} - 1, l_{xy} - 1) & \text{if } k_{xy} \ge 1, \\ (\min(1, l_{xy}), 0, l_{xy}) & \text{if } k_{xy} = 0. \end{cases}$
For (z, y): $\omega_t = (0, k_{yz}, l_{yz})$ and $\omega_{t+1} = \begin{cases} (0, k_{yz} - 1, l_{yz} - 1) & \text{if } k_{yz} \ge 1, \\ (\min(1, l_{yz}), 0, l_{yz}) & \text{if } k_{yz} = 0. \end{cases}$
$k_{xy}, k_{yz} \ge 1$: $S_{t+1}(x, y) \le S_{t+1}(y, z) \Leftrightarrow l_{xy} \le l_{yz}$ follows from (C.1).
$k_{xy} = k_{yz} = 0$: By (C.4), $l_{xy} = l_{yz}$; hence $S_{t+1}(x, y) = S_{t+1}(y, z)$ holds in this case.
$k_{xy} \ge 1, k_{yz} = 0$: By (C.3), this case cannot happen.
$k_{xy} = 0, k_{yz} \ge 1$: $S_{t+1}(x, y) \le S_{t+1}(y, z) \Leftrightarrow l_{xy} - \min(1, l_{xy}) \le l_{yz}$ follows from (C.1).

Case 5: $r \in T_y$ and $w \in T_z$.
For (x, y): $\omega_t = (k_{xy}, 0, l_{xy})$ and $\omega_{t+1} = (\min(k_{xy} + 1, l_{xy}), 0, l_{xy})$.

For (z,y): $\omega_t = (0, k_{yz}, l_{yz})$ and $\omega_{t+1} = \begin{cases} (0, k_{yz}-1, l_{yz}-1) & \text{if } k_{yz} \geq 1, \\ (\min(1, l_{yz}), 0, l_{yz}) & \text{if } k_{yz} = 0. \end{cases}$

$k_{yz} \geq 1$: $S_{t+1}(x,y) \leq S_{t+1}(y,z) \Leftrightarrow l_{xy} - \min(k_{xy}+1, l_{xy}) \leq l_{yz}$ follows from (D).

$k_{yz} = 0$:

We need to show that $S_{t+1}(x,y) \leq S_{t+1}(y,z) \Leftrightarrow l_{xy} - \min(k_{xy}+1, l_{xy}) \leq l_{yz} - \min(1, l_{yz})$ holds, given $S_t(x,y) \leq S_t(y,z) \Leftrightarrow l_{xy} - k_{xy} \leq l_{yz}$ holds initially. The inequality holds because $l_{xy} - l_{xy} = 0 = l_{yz} - l_{yz} \leq$ R.H.S., and $l_{xy} - k_{xy} - 1 \leq l_{yz} - 1 \leq$ R.H.S.

Suppose the request is a **WRITE** request:

Case 1: $r \in T_x$ and $w \in T_z$.

For (x,y): $\omega_t = (0, k_{xy}, l_{xy})$ and $\omega_{t+1} = \begin{cases} (0, k_{xy}-1, l_{xy}) & \text{if } k_{xy} \geq 1, \\ (1, 0, \min(l_{xy}+1, D)) & \text{if } k_{xy} = 0. \end{cases}$

For (y,z): $\omega_t = (0, k_{yz}, l_{yz})$ and $\omega_{t+1} = \begin{cases} (0, k_{yz}-1, l_{yz}) & \text{if } k_{yz} \geq 1, \\ (1, 0, \min(l_{yz}+1, D)) & \text{if } k_{yz} = 0. \end{cases}$

$k_{xy}, k_{yz} \geq 1 : S_{t+1}(x,y) \leq S_{t+1}(y,z) \Leftrightarrow l_{xy} \leq l_{yz}$ follows from (C.1).

$k_{xy} \geq 1, k_{yz} = 0$: By (C.3), this case cannot happen.

$k_{xy} = k_{yz} = 0$: By (C.4), $l_{xy} = l_{yz}$; hence $S_{t+1}(x,y) = S_{t+1}(y,z)$ holds in this case.

$k_{xy} = 0, k_{yz} \geq 1$ $S_{t+1}(x,y) \leq S_{t+1}(y,z) \Leftrightarrow \min(l_{xy}+1, D) - 1 \leq l_{yz}$ follows from $S_t(x,y) \leq S_t(y,z) \Leftrightarrow l_{xy} \leq l_{yz}$.

Case 2: $r \in T_y$ and $w \in T_z$.

For (x,y): $\omega_t = (k_{xy}, 0, l_{xy})$ and $\omega_{t+1} = (\min(k_{xy}+1, D), 0, \min(l_{xy}+1, D))$.

For (y,z): $\omega_t = (0, k_{yz}, l_{yz})$ and $\omega_{t+1} = \begin{cases} (0, k_{yz}-1, l_{yz}) & \text{if } k_{yz} \geq 1, \\ (1, 0, \min(l_{yz}+1, D)) & \text{if } k_{yz} = 0. \end{cases}$

$k_{yz} \geq 1$: We need to show that

$$S_{t+1}(x,y) \leq S_{t+1}(y,z) \Leftrightarrow \min(l_{xy}+1, D) - \min(k_{xy}+1, D) \leq l_{yz} \text{ holds, given that} \tag{8.2}$$

$$S_t(x,y) \leq S_t(y,z) \Leftrightarrow l_{xy} - k_{xy} \leq l_{yz} \text{ holds initially.}$$

It can be proved as follows. If $k_{xy} = D$, then L.H.S. $= 0 \leq$ R.H.S.

If $k_{xy} < D$, then L.H.S. $\leq l_{xy} + 1 - (k_{xy}+1) \leq l_{yz} =$ R.H.S. Hence (8.2) holds.

$k_{yz} = 0$: We need to show that

$$S_{t+1}(x,y) \leq S_{t+1}(y,z) \Leftrightarrow \min(l_{xy}+1, D) - \min(k_{xy}+1, D) \leq \min(l_{yz}+1, D) - 1 \text{ holds, given that} \tag{8.3}$$

$$S_t(x,y) \leq S_t(y,z) \Leftrightarrow l_{xy} - k_{xy} \leq l_{yz} \text{ holds initially.}$$

If $l_{yz} < D$, (8.3) follows from (8.2). If $k_{xy} = D$, then L.H.S. $= 0 \leq$ R.H.S. Suppose $l_{yz} \leq (D-1)$ and $(k_{xy}+1) \leq D$. In this case L.H.S. $\leq l_{xy} - k_{xy} \leq l_{yz} =$ R.H.S. Hence (8.3) holds.

Case 3: $r \in T_y$ and $w \in T_y$.

For (x,y): $\omega_t = (k_{xy}, 0, l_{xy})$ and $\omega_{t+1} = (\min(k_{xy}+1, D), 0, \min(l_{xy}+1, D))$.

For (y,z): $\omega_t = (0, k_{yz}, l_{yz})$ and $\omega_{t+1} = (0, \min(k_{yz}+1, D), \min(l_{yz}+1, D))$.

We need to show that $S_{t+1}(x,y) \leq S_{t+1}(y,z)$

$\Leftrightarrow$ $\min(l_{xy}+1, D) - \min(k_{xy}+1, D) \leq \min(l_{yz}+1, D)$ holds,

given that $S_t(x,y) \le S_t(y,z) \Leftrightarrow l_{xy} - k_{xy} \le l_{yz}$ holds initially which follows from (8.3).

Case 4: $r \in T_x$ and $w \in T_y$.

For (x,y): $\omega_t = (0, k_{xy}, l_{xy})$ and $\omega_{t+1} = \begin{cases} (0, k_{xy}-1, l_{xy}) & \text{if } k_{xy} \ge 1, \\ (1, 0, \min(l_{xy}+1, D)) & \text{if } k_{xy} = 0. \end{cases}$

For (y,z): $\omega_t = (0, k_{yz}, l_{yz})$ and $\omega_{t+1} = (0, \min(k_{yz}+1, D), \min(l_{yz}+1, D))$.

$k_{xy} \ge 1$: $S_{t+1}(x,y) \le S_{t+1}(y,z) \Leftrightarrow l_{xy} \le \min(l_{yz}+1, D)$ follows from $S_t(x,y) \le S_t(y,z) \Leftrightarrow l_{xy} \le l_{yz}$.

$k_{xy} = 0$:

$S_{t+1}(x,y) \le S_{t+1}(y,z) \Leftrightarrow \min(l_{xy}+1, D)-1 \le \min(l_{yz}+1, D)$ follows from $S_t(x,y) \le S_t(y,z) \Leftrightarrow l_{xy} \le l_{yz}$.

Case 5: $r \in T_x$ and $w \in T_x$.

For (x,y): $\omega_t = (0, k_{xy}, l_{xy})$ and $\omega_{t+1} = (0, \min(k_{xy}+1, D), \min(l_{xy}+1, D))$.

For (y,z): $\omega_t = (0, k_{yz}, l_{yz})$ and $\omega_{t+1} = (0, \min(k_{yz}+1, D), \min(l_{yz}+1, D))$.

$S_{t+1}(x,y) \le S_{t+1}(y,z) \Leftrightarrow \min(l_{xy}+1, D) \le \min(l_{yz}+1, D)$ follows from $S_t(x,y) \le S_t(y,z) \Leftrightarrow l_{xy} \le l_{yz}$.

Thus we have shown that (B) holds after σ_{t+1} has arrived.

EFFICIENT DATABASE UPDATES WITH INDEPENDENT SCHEMES*

RICCARDO TORLONE† AND PAOLO ATZENI†

Abstract. The weak instance model is a framework for considering the relations in a database as a whole, regardless of the way attributes are grouped in the individual relations. Queries and updates can be performed for any set of attributes. The management of updates is based on a lattice structure on the set of legal states, and inconsistencies and ambiguities can arise.

In the general case, the test for consistency and determinism may involve the whole database. In this paper it is shown how, for the highly significant class of independent schemes, updates can be handled efficiently, considering only the relevant portion of the database.

Key words. relational database, weak instance model, lattice on database states, update operations, chase procedure, optimization

1. Introduction.

In a relational database, the universe of discourse is represented by means of a set of relations. The *weak instance approach* [6, 18, 22, 23, 24, 31] provides a framework to consider a database as a whole, regardless of the way attributes appear in the various relation schemes. The information content of a database state is considered to be embodied in the *representative instance*, a sort of relation with variables, obtained by extending all relations to the global set of attributes (called the *universe*) and then by *chasing* [21] their union. Query answering is performed by first computing the *total projection* [26] of the representative instance on the set of attributes involved in the query and then executing whatever further operations are needed. Any subset of the universe can in principle be queried.

EXAMPLE 1. *Consider a database scheme with relations* $R_1(EDP)$, $R_2(DMP)$ *and the functional dependencies* $E \to D$, $D \to M$ *as constraints. Figures* 1, 2, *and* 3, *show a consistent database state on this scheme, the corresponding representative instance, and a total projection, respectively.*

Following a new interest on the theory of database updates [1], we proposed a formal approach to updates in the weak instance model [9]; in the same way as for the management of queries, which allows the retrieval of tuples over any subset of the universe, insertions and deletions over any subset of the universe are allowed. Problems of consistency and determinism arise and have been completely characterized.

EXAMPLE 2. *If we want to insert in the state in Figure* 1 *a tuple defined on the attributes* EM, *with values* Jim *for* E *and* White *for* M, *we can consistently add the tuple* ⟨MS, White, C⟩ *to the second relation. Because of the dependency* $D \to M$, *the chase would combine the tuple* ⟨Jim, MS, C⟩ *already in* r_1, *with this tuple, generating a tuple in the representative instance with values* Jim *for* E *and* White *for* M. *Conversely, if we want to insert into the same state a tuple defined on* EPM,

with values Dan *for* E, C *for* P, *and* Moore *for* M, *we obtain a potential result only if we add one tuple to* r_1 *and one tuple to* r_2, *with the given values for* EPM *and with the same value for* D *whichever it is (provided that the constraints are not violated). In this case, some further piece of information has to be added, and there are several possible choices—this is a case of nondeterminism. Finally, an inconsistency arises if we try to insert a tuple on* EM *with* John *for* E *and* White *for* M, *since the functional dependencies imply that the only manager of* John *is* Smith.

In the general case, the characterizations for consistency and determinism of insertions require the construction of the representative instance of the state, by means of the application of the chase procedure to a set of data that involves the whole database [9]. However, updating a state often involves only a small part of the database. The case is therefore similar to that of query answering, where the crucial step is the computation of the representative instance, which has to be completely constructed in the general case. To solve this problem, various classes of schemes were introduced, beginning with *independent schemes* [17, 19, 25, 26], where queries can be answered by means of simple relational expressions, optimizable and independent of the actual database state [5, 19, 27, 28]. In this paper we show that a similar approach can be followed for updating as well: we study updates to relational databases through weak instances and show that they can be implemented efficiently.

The paper is organized as follows. In section 2 we briefly review the needed background. In section 3 we review definitions and characterizations of updates in the weak instance model. In section 4 we consider independent schemes and characterize consistency and determinism with this class of schemes. On the basis of these results, in section 5 we present practical and efficient algorithms for update operations, and in section 6 we show that some step of these algorithms can be simplified under certain

further assumptions. In section 7, we discuss modifications, another important class of database update operations, and finally, in section 8, we conclude by summarizing our contribution.

2. Background definitions and notation.

2.1. Relations, databases, and tableaux. The *universe* U is a finite set of symbols $\{A_1A_2 \dots A_m\}$, called *attributes*. As usual, we use the same notation A to indicate both the single attribute A and the singleton set $\{A\}$. Also, we indicate the union of attributes (or sets thereof) by means of the juxtaposition of their names. A *relation scheme* is an object $R(X)$, where R is the *name* of the relation scheme and X is a subset of U. A *database scheme* is a collection of relation schemes $\mathbf{R} = \{R_1(X_1), \dots, R_n(X_n)\}$, with distinct relation names (which therefore can be used to identify the relation schemes) and such that the union of the X_i's is the universe U.

The *domain* D is the disjoint union of two countably infinite sets, the set of *constants* and the set of *variables*. (For the sake of simplicity, we assume that all attributes have the same domain.) A *tuple* on a set of attributes X is a function t from X to D. If t is a tuple on X and if $Y \subseteq X$, then $t[Y]$ denotes the restriction of the mapping t to Y and is therefore a tuple on Y. A tuple t on a set of attribute X is *total* if it does not involve variables.

A *tableau* T is a set of tuples on the universe U. We say that a variable or a constant is *unique* in T if it appears only once. A *relation* of a relation scheme $R(X)$ is a finite set of total tuples on X. A (*database*) *state* of a database scheme $\mathbf{R}$ is a function $\mathbf{r}$ that maps each relation scheme $R_i(X_i) \in \mathbf{R}$ to a relation on $R_i(X_i)$. With a slight abuse of notation, given $\mathbf{R} = \{R_1, \dots, R_n\}$, we write $\mathbf{r} = \{r_1, \dots, r_n\}$.

Given a database state $\mathbf{r}$, the *state tableau* for $\mathbf{r}$ is a tableau (denoted by $T_{\mathbf{r}}$) formed by taking the union of all the relations in $\mathbf{r}$ extended to U by means of unique variables.

The *total projection* ($\pi^{\downarrow}$) is an operator on tableaux that produces relations, given a tableau T and a subset X of U, generating the set of total tuples on X that are restrictions of tuples in T: $\pi^{\downarrow}_X(T) = \{t[X] | t \in T \text{ and } t[X] \text{ is total}\}$. We will use two (orthogonal) generalizations of the total projection: (1) the *restricted total projection* of a tableau T on $X \subseteq U$ with respect to a set of constants C, denoted by $\pi^{\downarrow}_X[C](T)$, is the set of total tuples on X that do not contain constants in C: $\pi^{\downarrow}_X[C](T) = \{t[X] | t \in T, t[X] \text{ is total and, for each } A_i \in X, t[A_i] \notin C\}$; and (2) the *total projection of a tableau* T *on a database scheme* $\mathbf{R}$, denoted by $\pi^{\downarrow}_{\mathbf{R}}(T)$, is the state obtained by totally projecting T on the various relation schemes.

In this paper, we shall consider *relational expressions* whose only operators are select (σ), project (π), natural join ($\bowtie$), and union ($\cup$) and whose operands are relational schemes of a fixed database scheme. Given a database state $\mathbf{r}$ of a scheme $\mathbf{R}$ and a relational expression E with operands in $\mathbf{R}$, we denote by $E(\mathbf{r})$ the relation obtained by substituting $\mathbf{r}$ into the corresponding relation variables in E and evaluating E according to the usual definitions of relational operators [7, 20, 29]. The *target* of E is the set of attributes in U on which $E(\mathbf{r})$ is defined.

2.2. Constraints: Local satisfaction and global consistency. Usually associated with a database scheme is a set of *constraints*, that is, properties that are satisfied by the legal states. There are two notions of satisfaction: *local* satisfaction, defined on individual relations, and *global* satisfaction, or *consistency*, defined on the database state. We introduce the two concepts in turn. Various classes of constraints

have been defined in the literature [20, 29]; here, we limit our attention to functional dependencies.

Let $YZ \subseteq X \subseteq U$; a relation r on a scheme $R(X)$ *(locally) satisfies* the *functional dependency (FD)* $Y \rightarrow Z$ if, for every pair of tuples $t_1, t_2 \in r$ such that $t_1[Y] = t_2[Y]$, it is the case that $t_1[Z] = t_2[Z]$. Without loss of generality, in the following we will often assume that all FDs have the form $Y \rightarrow A$, where A is a single attribute.

Given a set of FDs, it usually happens that there are additional FDs implied by this set. The *closure* of a set of FDs F, denoted by F^+, is the set of dependencies that are logically implied by F, and the *closure* of a set of attributes X with respect to a set of FDs F, denoted by X_F^+ (or simply X^+ when F is understood from context), is the set of attributes $\{A \mid X \rightarrow A \in F^+\}$. A set of FDs F is said to be *nonredundant* if there is no $Y \rightarrow A \in F$ such that $(F - \{Y \rightarrow A\})^+ = F^+$. Let $R(X)$ be a relation scheme and F be a set of FDs defined on $R(X)$; a set of attributes $Y \subseteq X$ is a *superkey* of R if $Y \rightarrow X \in F^+$.

Let $\mathbf{R} = \{R_1(X_1), \ldots, R_n(X_n)\}$ be a database scheme; without loss of generality we associate with $\mathbf{R}$ a set of nonredundant FDs $F = \cup_{i=1}^n F_i$, where, for every $1 \leq i \leq n$, the FDs in F_i are defined on $R_i(X_i)$. Note that we assume the FDs to be embedded in relation schemes.

A state $\mathbf{r} = \{r_1, \ldots, \mathbf{r}_n\}$ *globally satisfies* [18] a set of FDs F if there is a relation w on the universe U (called a *weak instance* for $\mathbf{r}$ with respect to F) that (locally) satisfies F and contains the relations of $\mathbf{r}$ in its projections over the respective relation schemes: $\pi_{X_i}(w) \supseteq r_i$ for $1 \leq i \leq n$. A state that globally satisfies the set of dependencies associated with the database scheme is also said to be *(globally) consistent*.

2.3. The chase procedure. The chase [21] is a procedure that receives as input a tableau T and generates a tableau $CHASE_F(T)$ that, if possible, satisfies the given dependencies F. If only functional dependencies are considered, the process modifies values in the tableau, by equating variables and "promoting" variables to constants as follows. We use $\tau = \langle t_1, t_2, Y \rightarrow A \rangle$ to denote a *chase step*, with reference to a tableau T, where t_1 and t_2 are tuples in T and $Y \rightarrow A \in F$. We say that a chase step τ is *valid* if $t_1[Y] = t_2[Y]$ and that τ is *applied* to T, denoted $\tau(T)$, if it is valid and the A-value of t_1 and t_2 are modified as follows: if one of them is a constant and the other is a variable, then the variable is changed (is *promoted*) to the constant; otherwise the values are equated. If a chase step tries to identify two constants, then we say that the chase encounters a *contradiction*, and the process stops, generating a special tableau that we call the *inconsistent tableau* and denoted by T_∞. The tableau $CHASE_F(T)$ is obtained from T by applying all valid chase steps exhaustively to T. Lemma 1 states a property of the chase that will be used in the following discussion.

LEMMA 1 (see [5, Lemma 4.1]). *Let t be a tuple defined on U and $\mathbf{r} = \pi_{\mathbf{R}}^{\downarrow}(\{t\})$. Let $R_{i_0}(X_{i_0}) \in \mathbf{R}$ and t_{i_0} be the tuple in $CHASE_F(T_{\mathbf{r}})$ corresponding to $\pi_{X_{i_0}}(\{t\})$. Then $t_{i_0}[X_{i_0}^+] = t[X_{i_0}^+]$.*

2.4. Query answering in the weak instance model. The definition of global satisfaction is clearly not practical since, in general, there may be many weak instances (often infinitely many). However, the existence of a weak instance can be studied by means of the notion of representative instance, a tableau on the universe, U, of the attributes.

The *representative instance* for a state $\mathbf{r}$, denoted by $\mathrm{RI}_{\mathbf{r}}$, is the tableau obtained by chasing the state tableau $T_{\mathbf{r}}$ of $\mathbf{r}$ with respect to the dependencies associated with the database state.

The main property of the representative instance is that a database state is consistent if and only if the corresponding representative instance is not the inconsistent tableau [18]. Also, for every consistent state $\mathbf{r}$ and for every X, the X-total projection of the representative instance of $\mathbf{r}$ is equal to the set of tuples that appear in the projection on X of every weak instance of $\mathbf{r}$ [23].

The *weak instance approach* to query answering allows queries to be formulated on databases as if they were composed of just one relation over the universe U. For each query, being $X \subseteq U$ the set of attributes involved, the evaluation requires a first step that computes the relation over X implied by the current state: because of the result just mentioned on total projections [23], it follows that the X-total projection of the representative instance is the natural content of this relation.

We say that a tuple t over a set of attributes X *x-belongs* (in symbols, $t\widehat{\in}\mathbf{r}$) to a consistent state $\mathbf{r}$ of a database scheme $\mathbf{R}$ with a universe $U \supseteq X$ if t belongs to the X-total projection of the representative instance of $\mathbf{r}$.

Finally, the *completion* $\mathbf{r}^*$ of a consistent state $\mathbf{r}$ is the state obtained by projecting the representative instance of $\mathbf{r}$ on the scheme $\mathbf{R}$; that is, $\mathbf{r}^* = \pi^{\downarrow}_{\mathbf{R}}(\mathrm{RI}_{\mathbf{r}})$ [24]. A consistent state $\mathbf{r}$ is *complete* if it coincides with its completion; that is, if $\mathbf{r} = \pi^{\downarrow}_{\mathbf{R}}(\mathrm{RI}_{\mathbf{r}})$.

2.5. Tableau and relational expression containment. A *valuation function* v is a function from D to D that is the identity on constants. A valuation function v can be extended to tuples and tableaux as follows: (i) given a tuple t on a set of attributes X, $v(t)$ is a tuple on X such that $v(t)[A] = v(t[A])$ for every $A \in X$; (ii) given a tableau $T = \{t_1, \ldots, t_n\}$, $v(T) = \{v(t_1), \ldots, v(t_n)\}$.

Given two tableaux T_1, T_2, we say that T_1 is *contained* in T_2 (in symbols $T_1 \leq T_2$) if T_2 is the inconsistent tableau T_∞, or there is a valuation function ψ (called in this case *containment mapping*) defined on all the symbols appearing in T_1 such that $\psi(T_1) \subseteq T_2$.[1] If both $T_1 \leq T_2$ and $T_2 \leq T_1$, the two tableaux are *equivalent*. Note that, by definition, the inconsistent tableau properly contains every other tableau. We now recall some useful properties of tableaux and chase.

LEMMA 2 (see [9, Lemma 1]). *For every tableau T, T_1 and for every set F of FDs, the following statements hold:*

1. $T \leq \mathit{CHASE}_F(T)$;
2. *if* $T \leq T_1$, *then* $\mathit{CHASE}_F(T) \leq \mathit{CHASE}_F(T_1)$;
3. *if* $T \leq T_1$ *and* $T_1 = \mathit{CHASE}_F(T_1)$, *then* $\mathit{CHASE}_F(T) \leq T_1$.

2.6. Independent schemes. A scheme is *independent* [17, 25] if, for all its states, local satisfaction implies global satisfaction. Independent schemes are clearly important from the practical point of view because the global consistency of their states can be verified in a local manner, looking at the individual relations, without having to build and chase the state tableau. Graham and Yannakakis [17] derived an efficient test for independence (later improved in [19, 27]).

Independent schemes are also important in the weak instance approach to query answering, because they guarantee the efficient computation of total projection of the representative instance [5, 19]. Atzeni and Chan [5], Ito, Iwasaki, and Kasami [19], and Sagiv [28] showed that, for every independent scheme and for every subset X of its universe, there is a relational algebra expression E_X that computes the total projection of the representative instance for every state of the scheme. In the approach

[1] Note that tableau containment is defined in the opposite direction when it refers to containment of queries.

of Atzeni and Chan, E_X is a union of *simple chase join expressions* (scjes) [5, 4, 13], a restricted form of a project-join expression, that we recall next.

A preliminary concept is needed: a *derivation sequence* (*ds*) of some relation scheme $R_{i_0}(X_{i_0})$ is a finite sequence of FDs $\sigma = \langle Y_1 \to Z_1, \ldots, Y_m \to Z_m \rangle$ from F such that, for all $1 \leq j \leq m$: $Y_j \subseteq X_{i_0}Z_1 \cdots Z_{j-1}$ and $Z_j \cap X_{i_0}Z_1 \cdots Z_{j-1} = \emptyset$. We say that σ *covers* a set of attributes X if $X_{i_0}Z_1 \cdots Z_j \supseteq X$. Essentially, a ds of $R_{i_0}(X_{i_0})$ is a sequence of FDs used in computing (part of) the closure of X_{i_0}.

Given a ds $\sigma = \langle Y_1 \to Z_1, \ldots, Y_m \to Z_m \rangle$ covering a set of attributes X, the scjes *for* σ *over* X is the expression

$$\pi_X(R_{i_0} \bowtie \pi_{Y_1Z_1}(R_{i_1}) \bowtie \cdots \bowtie \pi_{Y_mZ_m}(R_{i_m})),$$

where $Y_j \to A_j$, for $1 \leq j \leq m$, is an FD in F_{i_j} and is therefore embedded in R_{i_j}. The subexpressions $R_{i_0}, \pi_{Y_1Z_1}(R_{i_1}), \ldots, \pi_{Y_mZ_m}(R_{i_m})$ are called the *components* of the scje.

Before closing this section, we mention an important property of independent schemes that will be often used in the sequel: each derived value in the chase of $T_{\mathbf{r}}$ is "uniquely" derived for an independent scheme.

LEMMA 3 (see [16, Lemma 4]). *Let* $\mathbf{R}$ *be an independent scheme. Then for any consistent state* $\mathbf{r}$*, for any* $R_j \in \mathbf{R}$*, and for any FD* $Y \to A \in F_j$*, it is the case that* $\pi^{\downarrow}_{YA}(CHASE_F(T_{\mathbf{r}})) = \pi_{YA}(r_j)$.

3. Updating in the weak instance model. In this section we briefly review our approach to updates in the weak instance model [9]. Similar to the approach to query answering, it allows updates to be formulated on every subset of the universe. As a preliminary tool, we introduce a partial order on states, which extends a known notion of equivalence of states [24]; then we discuss insertions, and finally deletions.

3.1. A lattice on states. A state $\mathbf{r}_1$ is *weaker* than a state $\mathbf{r}_2$ ($\mathbf{r}_1 \preceq \mathbf{r}_2$) if every weak instance of $\mathbf{r}_2$ is also a weak instance of $\mathbf{r}_1$. Two states $\mathbf{r}_1$, $\mathbf{r}_2$ are *equivalent* ($\mathbf{r}_1 \sim \mathbf{r}_2$) if both $\mathbf{r}_1 \preceq \mathbf{r}_2$ and $\mathbf{r}_2 \preceq \mathbf{r}_1$. The relation $\preceq$ is a partial order on the set of the complete states, since it is reflexive, antisymmetric, and transitive. Also, it is strongly related to (tableau) containment of representative instances, (set) containment of total projections, and relations, as stated in the next theorem.

THEOREM 1 (see [9, Theorem 1]). *Let* $\mathbf{r}_1 = \{r_{1,1}, \ldots, r_{1,n}\}$ *and* $\mathbf{r}_2 = \{r_{2,1}, \ldots, r_{2,n}\}$ *be two states. Properties* 1, 2, *and* 3 *below are equivalent; if the states are complete, then property* 4 *is also equivalent to the others.*

1. *The state* $\mathbf{r}_1$ *is weaker than the state* $\mathbf{r}_2$: $\mathbf{r}_1 \preceq \mathbf{r}_2$.
2. *The representative instance of* $\mathbf{r}_1$ *is contained in the representative instance of* $\mathbf{r}_2$: $\mathrm{RI}_{\mathbf{r}_1} \leq \mathrm{RI}_{\mathbf{r}_2}$.
3. *For every* $X \subseteq U$*, the* X*-total projection of* $\mathrm{RI}_{\mathbf{r}_1}$ *is a subset of the* X*-total projection of* $\mathrm{RI}_{\mathbf{r}_2}$: $\pi^{\downarrow}_X(\mathrm{RI}_{\mathbf{r}_1}) \subseteq \pi^{\downarrow}_X(\mathrm{RI}_{\mathbf{r}_2})$.
4. *The state* $\mathbf{r}_1$ *is a relationwise subset of the state* $\mathbf{r}_2$: *for every* $R_i \in \mathbf{R}$*, it is the case that* $r_{1,i} \subseteq r_{2,i}$.

By the equivalence of properties 1 and 3 of Theorem 1 above, it follows that two states are equivalent if and only if, for every X, their X-total projections are equal, that is if they have identical query answering behavior. Therefore, it makes sense to consider equivalence classes of states. To represent the various classes, we will use the set of complete states since it is known that each consistent state is equivalent to one and only one complete state [24, section 3].

In [9] we showed that the partial order $\preceq$ extended to the *complete inconsistent state* (a special state defined as the projection of the inconsistent tableau on the database scheme) induces a complete lattice [12] on the set of complete states, that is, every set of complete states has both a greatest lower bound (glb) and a least upper bound (lub).

3.2. Insertions. Let $\mathbf{R} = \{R_1(X_1), \ldots, R_n(X_n)\}$ be a database scheme, with $U = X_1X_2 \ldots X_n$. Given a state $\mathbf{r}$ of $\mathbf{R}$ and a tuple t over a set of attributes $X \subseteq U$, we consider the *insertion* of t into $\mathbf{r}$ defined through the following notion of result.

A state $\mathbf{r}_p$ is a *potential result* for the insertion of t into $\mathbf{r}$ if $\mathbf{r} \preceq \mathbf{r}_p$ and $t\widehat{\in}\mathbf{r}_p$. Various cases for an insertion of a tuple in a consistent state exist: the insertion of a tuple t over X in a state is *possible* if there is a consistent state $\mathbf{r}'$ such that $t\widehat{\in}\mathbf{r}'$, a possible insertion is *consistent* if it has a consistent potential result, and a possible and consistent insertion is *deterministic* if the glb of the potential results is a potential result. Note that the notion of determinism is defined only for possible and consistent insertions. When an insertion is deterministic, we consider the glb of the potential results as *the* result of the insertion. In other words, an insertion is possible if the dependencies allow us to generate t in the representative instance of a state $\mathbf{r}'$ possibly unrelated to the given state, it is consistent when the new tuple does not contradict the information content of the original state, and it is deterministic when the insertion can be univocally performed by adding only the information that is strictly needed.

In [9] we showed the following general characterizations for possibility, consistency, and determinism.

THEOREM 2 (see [9, Theorem 2]). *The insertion of t in a state is possible if and only if there is a relation scheme $R_i(X_i) \in \mathbf{R}$ such that F implies the FD $X_i \rightarrow X$.*

Let $\mathrm{RI}_{\mathbf{r}}$ be the representative instance of $\mathbf{r}$. The characterization of both consistency and determinism is based on the construction of a tableau obtained by adding to $\mathrm{RI}_{\mathbf{r}}$ a tuple t_e obtained by extending t to the universe U by means of unique variables. Let $T_{t,\mathbf{r}}$ be such a tableau.

THEOREM 3 (see [9, Theorem 3]). *Let the insertion of t in $\mathbf{r}$ be possible. It is consistent if and only if $CHASE_F(T_{t,\mathbf{r}}) \neq T_\infty$.*

DEFINITION 1 (state $\mathbf{r}_{+t}$). *The state $\mathbf{r}_{+t}$, or simply $\mathbf{r}_+$ when t is understood from context, is obtained from $\mathbf{r}$ and t by (totally) projecting $CHASE_F(T_{t,\mathbf{r}})$ on the database scheme: $\mathbf{r}_{+t} = \pi^{\downarrow}_{\mathbf{R}}(CHASE_F(T_{t,\mathbf{r}}))$.*

LEMMA 4 (see [9, Lemma 8]). *Let the insertion of t in $\mathbf{r}$ be possible and consistent. Then $\mathbf{r}_+$ is the glb of the potential results.*

THEOREM 4 (see [9, Theorem 4]). *Let the insertion of t in $\mathbf{r}$ be possible and consistent. It is deterministic if and only if $CHASE_F(T_{t,\mathbf{r}}) \equiv \mathrm{RI}_{\mathbf{r}_+}$.*

COROLLARY 1 (see [9, Corollary 1]). *Let the insertion of t in $\mathbf{r}$ be possible and consistent; it is deterministic if and only if $t\widehat{\in}\mathbf{r}_+$.*

Corollary 1 gives an effective characterization of determinism: given $\mathbf{r}$ and t, we can build $T_{t,\mathbf{r}}$, chase it with respect to the given constraints, then generate $\mathbf{r}_+$ and compute its representative instance $\mathrm{RI}_{\mathbf{r}_+}$, and finally check whether the total projection $\pi^{\downarrow}_X(\mathrm{RI}_{\mathbf{r}_+})$ contains t.

EXAMPLE 3. *Consider the first insertion in Example 2. The insertion is possible since for $R_1(X_1)$ we have $X_1 \rightarrow X \in F^+$. Then, following the definitions, we could build the tableau $T_{t,\mathbf{r}}$ and then chase it; the tableaux that we obtain are reported in Figure 4. It is possible to see that, if we project $CHASE_F(T_{t,\mathbf{r}})$ on the database scheme, we obtain the state we suggested as a result.*

FIG. 4. $T_{t,\mathbf{r}}$, $CHASE_F(T_{t,\mathbf{r}})$ *and* $\mathbf{r}_+$ *for Example* 3.

Note that the insertion of a tuple on a set of attributes $X \subseteq U$ allows a form of "side effect," since it may cause the addition of some extra information for the attributes not in X. For instance, in Example 3, we showed that the insertion of the tuple with values *Jim* for E and *White* for M produces the insertion of the tuple $\langle \text{MS}, \text{White}, \text{C} \rangle$ in r_2. This tuple states that *White* is the manager of the *MS* department and is involved in project C and that this information is not provided directly by the user. This fact, however, is just a consequence of the weak instance model framework in which the FDs allow us to derive, in the representative instance, further information from tuples of a database. Thus, the insertion of a new tuple (over a relation or any set of attributes) may induce new values for old tuples in the representative instance. However, with our approach, this side effect is always minimal because we have defined the result of an insertion as the glb of all the potential results; in this way the original state is always changed as little as possible. We will come back on this issue in section 6, where we will show that, under certain conditions, the side effect can also be kept "under control."

3.3. Deletions. The definitions of deletions are somewhat symmetric with respect to those concerning insertions.

A state $\mathbf{r}_p$ is a *potential result* for the deletion of a tuple t from a state $\mathbf{r}$ if $\mathbf{r}_p \preceq \mathbf{r}$ and $t \widehat{\notin} \mathbf{r}_p$. The empty state is a consistent potential result for every deletion, and so there is no need to define the notions of possible and consistent results for deletions. A deletion is *deterministic* if the lub of the potential results is a potential result. When a deletion is deterministic, we consider the lub of the potential results to be *the* result of the deletion.

Let $\mathbf{r}$ be a consistent state and t be a tuple on X that x-belongs to $\mathbf{r}$. We derived the following characterizations for deletions.

LEMMA 5 (see [9, Lemma 9]). *The deletion of t from $\mathbf{r}$ is deterministic only if there is a relation scheme $R_i(X_i)$ such that $X \subseteq X_i$.*

DEFINITION 2 (state $\mathbf{r}_{-t}$). *The state $\mathbf{r}_{-t}$, or simply $\mathbf{r}_-$ when t is understood from the context, is obtained from $\mathbf{r}$ and t by removing, from each relation r_i such that $X \subseteq X_i$, each tuple t' such that $t'[X] = t[X]$.*

THEOREM 5 (see [9, Theorem 5]). *The deletion of t from $\mathbf{r}$ is deterministic if and only if* (i) *there is a relation scheme $R_i(X_i)$ such that $X \subseteq X_i$ and* (ii) $t \widehat{\notin} \mathbf{r}_-$.

4. Insertions for independent schemes. In the same way as query answering can be efficiently performed for independent schemes, we want to show that, for this meaningful class of schemes, updates defined over any subset of the universe can be managed efficiently.

With respect to deletions, Theorem 5 already gives an efficient way to check for determinism and to perform the update. With respect to insertions, the problem is more complex in general. Regarding possibility, Theorem 2 gives a complete characterization at the scheme level, which can be efficiently verified by using the closure algorithm proposed by Bernstein [11], but with regard to consistency and determinism, the tests require the chase of $T_{t,\mathbf{r}}$ (Theorems 3 and 4), a tableau involving the whole database state. Since computing the chase of a tableau takes polynomial time in the number of the rows of the tableau [2], it follows that the tests for consistency and determinism of an insertion require time and size polynomial with respect to the size of the database state.

In the next section we show that it is possible to derive alternative methods for checking consistency and determinism of insertions to independent schemes that are easier to implement and optimize.

4.1. Consistency. Throughout this section we will consider a consistent state $\mathbf{r}$ on a scheme $\mathbf{R} = \{R_1(X_1), \ldots, R_n(X_n)\}$ and the insertion of a tuple t over $X \subseteq U$ in $\mathbf{r}$, assuming that it is possible.

Let $\bar{t}$ be the "extension" of t with respect to $\mathbf{r}$ generated by Algorithm 1 (shown in Figure 5). It turns out that $\bar{t}$ has interesting properties, which make it fundamental in the efficient check of both consistency and determinism.

Let us introduce a property to be used shortly.

CONDITION 1. *There is no $V \to A \in F_j$ for $j \in \{1, \ldots, n\}$ such that*

(i) *$VA \subseteq \overline{X}$, and*

(ii) *there exists $t' \in r_j$ such that $t'[V] = \bar{t}[V]$ and $t'[A] \neq \bar{t}[A]$.*

LEMMA 6. *If Condition 1 holds, then $\bar{t}$ is uniquely defined.*

Proof. Condition 1 implies that when there are two or more alternatives at any step, those not chosen remain valid after the transformation and therefore can be applied later. ∎

ALGORITHM 1.
Input : *a tuple* t *over* $X \subseteq U$ *and a database state* $\mathbf{r}$;
Output: *the "extension"* $\overline{t}$ *of* t *with respect to* $\mathbf{r}$ *and the set of attributes* $\overline{X}$;
begin
  $t_U[X] := t$; /* t_U *is a tuple of distinct variables over* U */
  $W := X$;
  while *there exists some* $V \to A \in F_j$, $1 \le j \le n$, *such that* $V \subseteq W, A \notin W$
    and *there exists* $t' \in r_j$ *such that* $t'[V] = t_U[V]$
  do begin
    $t_U[A] := t'[A]$;
    $W := W \cup A$
  end;
  return $t_U[W]$ *and* W
end.

FIG. 5. *Algorithm for the computation of the extension of a tuple.*

DEFINITION 3 (state $\tilde{\mathbf{r}}$). *Let* $\overline{t}$ *be the extension of* t *with respect to* $\mathbf{r}$ *and* $\tilde{t}$ *be a tuple over the universe* U *obtained by extending* $\overline{t}$ *to* U *by means of "new constants," that is, a unique constants not already appearing in* $\mathbf{r}$. *Then the state* $\tilde{\mathbf{r}}$ *is obtained from* $\mathbf{r}$ *and* $\tilde{t}$ *by adding the tuple* $\tilde{t}[X_j]$ *to each relation* $r_j \in \mathbf{r}$ *on* $R_j(X_j)$.

LEMMA 7. *If* $\mathbf{R}$ *is independent and Condition* 1 *holds, then* $\tilde{\mathbf{r}}$ *is a consistent potential result for the insertion of* t *in* $\mathbf{r}$.

Proof. We have to show that (1) $\tilde{\mathbf{r}}$ is consistent and (2) $\tilde{\mathbf{r}}$ is a potential result.

(1) $\tilde{\mathbf{r}}$ is consistent: Since $\mathbf{R}$ is independent, it is sufficient to show that $\tilde{\mathbf{r}}$ is locally consistent. By way of contradiction assume that it is not. Let $\tilde{r}_j$ be a relation that violates the respective FDs F_j. Since $\mathbf{r}$ is consistent, r_j satisfies F_j, and so the violation has to involve the new tuple $\tilde{t}[X_j]$ together with a tuple $t' \in r_j$; that is, there is an FD $V \to A \in F_j$ such that $t'[V] = \tilde{t}[V]$ and $t'[A] \neq \tilde{t}[A]$. Since the values of $\tilde{t}$ over attributes in $U - \overline{X}$ are all new constants, $\tilde{t}[V] = t'[V]$ implies $V \subseteq \overline{X}$ and so $\overline{t}[V] = t'[V]$. Then the computation of $\overline{t}$ would also add A to W and so to $\overline{X}$ because of $t' \in r_j$, and therefore $\tilde{t}[A] = \overline{t}[A]$. Then, we would have $t'[V] = \overline{t}[V]$ and $t'[A] \neq \overline{t}[A]$, for some $V \to A \in F_j$ with $VA \subseteq \overline{X}$, against Condition 1.

(2) $\tilde{\mathbf{r}}$ is a potential result: By construction $\mathbf{r} \preceq \tilde{\mathbf{r}}$. Also, since the insertion of t in $\mathbf{r}$ is possible, by Theorem 2, there is a relation scheme $R_i(X_i) \in \mathbf{R}$ such that F implies the FD $X_i \to X$ and so $X_i^+ \supseteq X$. Let t' be the tuple in $CHASE_F(T_{\tilde{\mathbf{r}}})$ originating from $\pi_{X_i}(\tilde{t})$. Then, by Lemma 1, $t'[X_i^+] = \tilde{t}[X_i^+]$, and since $X_i^+ \supseteq X$, by definition of $\tilde{t}$ we have $t'[X] = t$. It follows that $t \in \pi_X(\mathrm{RI}_{\tilde{\mathbf{r}}})$, and so $\tilde{\mathbf{r}}$ is a potential result. □

THEOREM 6. *The insertion of* t *in a state* $\mathbf{r}$ *of an independent scheme is consistent if and only if Condition* 1 *holds.*

Proof. Only if. The construction of $\overline{t}$ can be seen as an initial sequence in the chase of $T_{t,\mathbf{r}}$ with respect to F. Then, violation of Condition 1 implies that $CHASE_F(T_{t,\mathbf{r}}) = T_\infty$ and so, by Theorem 3, the claims follows.

If. This proof is made by Lemma 7. □

This theorem gives us an effective and efficient method to check for consistency of insertions in independent schemes: instead of performing the chase of $T_{t,\mathbf{r}}$ (as requested by Theorem 3), it is sufficient to apply Algorithm 1 and to check for violations of FDs involving $\overline{t}$.

EXAMPLE 4. *The scheme in Example* 1 *is clearly independent. Now consider the first insertions in Example* 2. *We have* $\overline{t} = \langle \text{Jim}, \text{MS}, \text{White} \rangle$, *so the insertion is consistent since such a tuple does not violate the FDs that involves. Conversely, if we want to insert the tuple* $\langle \text{John}, \text{White} \rangle$, *we would have an inconsistent insertion since* $\overline{t} = \langle \text{John}, \text{CS}, \text{White} \rangle$, *and Condition* 1 *does not hold for the FD* $D \rightarrow M$ *and, for instance, the tuple* $\langle \text{CS}, \text{Smith}, \text{A} \rangle$ *of* r_2.

4.2. Determinism. Throughout this section we will consider a consistent database state $\mathbf{r}$ of a scheme $\mathbf{R} = \{R_1(X_1), \ldots, R_n(X_n)\}$ and the insertion of a tuple t over $X \subseteq U$ in $\mathbf{r}$, assuming that it is possible and consistent.

As in section 4.1, let $\overline{t}$ be the extension of t with respect to $\mathbf{r}$ generated by Algorithm 1, let $\tilde{t}$ be the tuple obtained by extending $\overline{t}$ to the universe U by means of a set of new constants C_{new}, and let $\tilde{\mathbf{r}}$ be the state obtained by adding to the original state $\mathbf{r}$ the projections of $\tilde{t}$ over the various relation schemes.

DEFINITION 4 (state $\hat{\mathbf{r}}$). *Let* $\tilde{\mathbf{r}}^*$ *be the completion of* $\tilde{\mathbf{r}}$, *that is,* $\tilde{\mathbf{r}}^* = \pi^{\downarrow}_{\mathbf{R}}(\text{RI}_{\tilde{\mathbf{r}}})$. *Then,* $\hat{\mathbf{r}}$ *is the state obtained from* $\tilde{\mathbf{r}}^*$ *by removing all the tuples having some new constant:* $\hat{\mathbf{r}} = \pi^{\downarrow}_{\mathbf{R}}[C_{new}](\text{RI}_{\tilde{\mathbf{r}}})$.

We have the following result for the state $\hat{\mathbf{r}}$ (we recall that $\mathbf{r}_+ = \pi^{\downarrow}_{\mathbf{R}} CHASE_F(T_{t,\mathbf{r}})$, where $T_{t,\mathbf{r}} = \text{RI}_{\mathbf{r}} \cup \{t_e\}$ and t_e is the tuple obtained by extending t to the universe U by means of unique variables).

THEOREM 7. *The state* $\hat{\mathbf{r}}$ *coincides with the state* $\mathbf{r}_+$.

Proof. By Lemma 7, $\tilde{\mathbf{r}}$ is a potential result, and therefore—since by Lemma 4 the state $\mathbf{r}_+$ is the glb of the potential result—we have $\mathbf{r}_+ \preceq \tilde{\mathbf{r}}$ and thus $\mathbf{r}_+ \preceq \tilde{\mathbf{r}}^*$ as every state is equivalent to its completion. Since $\mathbf{r}_+$ is complete (being constructed as the projection of a chased tableau), by equivalence of parts 1 and 4 of Theorem 1, we have that $\mathbf{r}_+$ is a relationwise subset of $\tilde{\mathbf{r}}^*$, and thus of $\hat{\mathbf{r}}$, which is obtained from $\tilde{\mathbf{r}}^*$ by eliminating tuples that do not appear in $\mathbf{r}_+$. Thus, to complete the proof we need to show that for every $R_i \in \mathbf{R}$, it is also the case that $\hat{r}_i \subseteq r_{+_i}$, where $\hat{r}_i \in \hat{\mathbf{r}}$ and $r_{+_i} \in \mathbf{r}_+$. We will prove this part by showing that it is possible to build a tableau T, such that $T \leq CHASE_F(T_{t,\mathbf{r}})$ and $\hat{\mathbf{r}} = \pi^{\downarrow}_{\mathbf{R}}(T)$. Since $\mathbf{r}_+ = \pi^{\downarrow}_{\mathbf{R}}(CHASE_F(T_{t,\mathbf{r}}))$, the fact that $\hat{\mathbf{r}}$ is a relationwise subset of $\mathbf{r}_+$ would then follow directly from the definitions of containment mapping and total projection.

Let $T_1 = \text{RI}_{\mathbf{r}} \cup \{\overline{t}_e\}$, where $\overline{t}_e$ is obtained by extending $\overline{t}$ to the universe U by means of unique variables. Since $\overline{t}$ is built using chase steps that are valid in $T_{t,\mathbf{r}}$ and since the chase is independent of the order of the individual chase steps [21], it follows that T_1 can be seen as an intermediate result in chasing $T_{t,\mathbf{r}}$ and that $CHASE_F(T_1) = CHASE_F(T_{t,\mathbf{r}})$. Similarly, let $\mathbf{r}_{\tilde{t}}$ be the state obtained by projecting $\tilde{t}$ over the various relational schemes and let $T_2 = \text{RI}_{\mathbf{r}} \cup CHASE_F(T_{\mathbf{r}_{\tilde{t}}})$. By construction, $T_{\tilde{\mathbf{r}}} = T_{\mathbf{r}} \cup T_{\mathbf{r}_{\tilde{t}}}$, so T_2 can be considered as an intermediate result in chasing $T_{\tilde{\mathbf{r}}}$, and $CHASE_F(T_2) = CHASE_F(T_{\tilde{\mathbf{r}}}) = \text{RI}_{\tilde{\mathbf{r}}}$. The tableau T_2 contains all the tuples of $\text{RI}_{\mathbf{r}}$ and, by Lemma 1, n tuples t_i such that $t_i[X_i^+] = \tilde{t}[X_i^+]$ for $1 \leq i \leq n$. Then, let ϕ be a function from D to D that (i) maps the new constants in $\tilde{t}$ to unique variables in T_2 and (ii) is the identity on all the other elements in D, and consider the tableau $T_3 = \phi(T_2)$. This tableau is composed of the tuples of $\text{RI}_{\mathbf{r}}$ and n tuples t'_i such that $t'_i[A] = \overline{t}[A]$ if $A \in \overline{X}$, and $t'_i[A]$ is a variable otherwise. It easily follows that $T_3 \leq T_1$ because of a containment mapping that is the identity on $\text{RI}_{\mathbf{r}}$ and maps the n tuples t'_i to $\overline{t}_e$. Now, let us consider the chase of T_2 and let ψ be the function that maps each symbol appearing in T_2 to the symbols to which it is changed by the chase, that is, $\psi(T_2) = CHASE_F(T_2)$, and let $\psi' = \phi \circ \psi$. The function ψ' coincides with ψ except for the variables v that have been changed to new constants by chasing T_2, that is, $\psi'(v) =$

$\phi(\psi(v)) = v_j$ if $\psi(s)$ is a new constants c_j such that $\phi(c_j) = v_j$, and $\psi'(s) = \psi(s)$ for all the other symbols s in T_2. Since all the chase steps that can be applied to T_2 are also valid in the tableau T_3 if we replace the new constants with unique variables, it follows that $\psi'(T_2)$ coincides with the chase of T_3, that is, $\psi'(T_2) = CHASE_F(T_3)$. If we let $T_4 = \phi(\mathrm{RI}_{\tilde{\mathbf{r}}})$, we have $T_4 = \phi(\psi(T_2)) = \psi'(T_2) = CHASE_F(T_3)$, and therefore, since $T_3 \leq T_1$, by part 2 of Lemma 2, we have $CHASE_F(T_3) \leq CHASE_F(T_1)$, and so $T_4 \leq CHASE_F(T_1) = CHASE_F(T_{t,\mathbf{r}})$.

Now, since ϕ maps new constants to new variables and is the identity on the other elements of D, we have that $\pi^{\downarrow}_{\mathbf{R}}(T_4)$ exactly coincides with $\hat{\mathbf{r}}$. As argued above, it follows that $\hat{\mathbf{r}}$ is a relationwise subset of $\mathbf{r}_+ = \pi^{\downarrow}_{\mathbf{R}}(CHASE_F(T_{t,\mathbf{r}}))$. □

COROLLARY 2. *The insertion of a tuple t in a state $\mathbf{r}$ is deterministic if and only if $t \widehat{\in} \hat{\mathbf{r}}$.*

Proof. The proof follows by Corollary 1 and Theorem 7. □

Corollary 2 gives us an alternative method to check for determinism that does not requires the chase of the special tableau $T_{t,\mathbf{r}}$ over the whole database.

EXAMPLE 5. *Consider again the insertion of $t = \langle \mathrm{Jim}, \mathrm{White} \rangle$ over EM in the state in Figure 1. We have in this case $\bar{t} = \langle \mathrm{Jim}, \mathrm{MS}, \mathrm{White} \rangle$ over EDM and $\tilde{t} = \langle \mathrm{Jim}, \mathrm{MS}, \mathrm{c}_1, \mathrm{White} \rangle$ over U. Hence, $\tilde{\mathbf{r}}$ is obtained by adding $\langle \mathrm{Jim}, \mathrm{MS}, \mathrm{c}_1 \rangle$ to r_1 and $\langle \mathrm{MS}, \mathrm{White}, \mathrm{c}_1 \rangle$ to r_2. In computing the completion of $\tilde{\mathbf{r}}$, the tuple $\langle \mathrm{MS}, \mathrm{White}, \mathrm{C} \rangle$ is also added to the second relation and so, by deleting the tuples with the new constant c_1, we obtain again the state we suggest as the result.*

In the following section we will show how the new method can be efficiently implemented if the scheme is independent. For this purpose, we now mention some properties of $T_{t,\mathbf{r}}$ and $\hat{\mathbf{r}}$ for the class of independent schemes. We recall that, given a tuple t over a set of attributes $X \subseteq U$, the tuple t_e denotes its extension to U by means of unique variables.

LEMMA 8. *If $\mathbf{R}$ is independent, then for any $R_j \in \mathbf{R}$ and for any $Y \to A \in F_j$ it is the case that $\pi^{\downarrow}_{YA}(CHASE_F(T_{t,\mathbf{r}})) = \pi_{YA}(r_j) \cup \pi^{\downarrow}_{YA}(\{\bar{t}_e\})$.*

Proof. It is sufficient to prove that $\pi^{\downarrow}_{YA}(CHASE_F(T_{t,\mathbf{r}})) \subseteq \pi_{YA}(r_j) \cup \pi^{\downarrow}_{YA}(\{\bar{t}_e\})$ as the other containment, by construction, is trivial. Let us consider the state $\tilde{\mathbf{r}}$: Since, by Lemma 7, it is a consistent potential result, we have that $\mathbf{r} \preceq \tilde{\mathbf{r}}$ and $t \widehat{\in} \tilde{\mathbf{r}}$. Hence, $\mathrm{RI}_{\mathbf{r}} \leq \mathrm{RI}_{\tilde{\mathbf{r}}}$ and $t \in \pi^{\downarrow}_{X}(\mathrm{RI}_{\tilde{\mathbf{r}}})$ and therefore, since all the variables in t_e are unique, $T_{t,\mathbf{r}} = \mathrm{RI}_{\mathbf{r}} \cup \{t_e\} \leq \mathrm{RI}_{\tilde{\mathbf{r}}}$. Thus, by part 3 of Lemma 2, it follows that $CHASE_F(T_{t,\mathbf{r}}) \leq CHASE_F(T_{\tilde{\mathbf{r}}})$. Now let $t' \in \pi^{\downarrow}_{YA}(CHASE_F(T_{t,\mathbf{r}}))$. By equivalence of parts 2 and 3 of Lemma 1 we have $\pi^{\downarrow}_{YA}(CHASE_F(T_{t,\mathbf{r}})) \subseteq \pi^{\downarrow}_{YA}(CHASE_F(T_{\tilde{\mathbf{r}}}))$; hence, $t' \in \pi^{\downarrow}_{YA}(CHASE_F(T_{\tilde{\mathbf{r}}}))$. Since $\mathbf{R}$ is independent and, by Lemma 3, $\pi^{\downarrow}_{YA}(CHASE_F(T_{\tilde{\mathbf{r}}})) = \pi_{YA}(\tilde{r}_j)$, it follows that $t' \in \pi_{YA}(\tilde{r}_j)$. Now, by definition of $\tilde{\mathbf{r}}$, we have that $t' \in \pi_{YA}(r_j)$ or $t' = \tilde{t}[YA]$. In the first case, the proof is complete. In the second case, we have two subcases: (i) $YA \subseteq \overline{X}$ and so $\tilde{t}[YA] = \bar{t}[YA]$, which would again prove the claim; (ii) $YA \not\subseteq \overline{X}$ and therefore $\tilde{t}[YA]$ contains constants not appearing in $CHASE_F(T_{t,\mathbf{r}})$ and therefore $\tilde{t}[YA] \notin \pi^{\downarrow}_{YA}(CHASE_F(T_{t,\mathbf{r}}))$, which, however, contradicts $\tilde{t}[YA] = t' \in \pi^{\downarrow}_{YA}(CHASE_F(T_{t,\mathbf{r}}))$. □

LEMMA 9. *If $\mathbf{R}$ is independent and the insertion of t in $\mathbf{r}$ is deterministic, then for any $R_i(X_i)$ and for any $Y \to A \in F_i$, it is the case that $\pi_{YA}(\hat{r}_i) = \pi_{YA}(r_i) \cup \pi^{\downarrow}_{YA}(\{\bar{t}_e\})$.*

Proof. If the insertion is deterministic, then by Theorem 4, we have that $\mathrm{RI}_{\mathbf{r}_+} \equiv CHASE_F(T_{t,\mathbf{r}})$, and so by Theorem 7 and by equivalence of parts 1 and 2 of Theorem 1, $\mathrm{RI}_{\hat{\mathbf{r}}} \equiv CHASE_F(T_{t,\mathbf{r}})$. Also, since $\mathbf{R}$ is independent, by Lemma 3 we have that

ALGORITHM 2.

end.

FIG. 6. *Basic algorithm for update operations.*

for any $R_i(X_i) \in \mathbf{R}$ and for any FD $X \to A \in F_i$, it is the case that $\pi_{YA}(\hat{r}_i) = \pi^{\downarrow}_{YA}(\mathrm{RI}_{\hat{\mathbf{r}}})$. By equivalence of parts 2 and 3 of Theorem 1, it follows that $\pi_{YA}(\hat{r}_i) = \pi^{\downarrow}_{YA}(CHASE_F(T_{t,\mathbf{r}}))$, and so, by Lemma 8, $\pi_{YA}(\hat{r}_i) = \pi_{YA}(r_i) \cup \pi^{\downarrow}_{YA}(\{\bar{t}_e\})$. □

5. Algorithms for update operations. On the basis of the results of the previous sections, we present in this section efficient algorithms that can be used to update relational databases on independent schemes. Such algorithms exploit some known result on query answering for this class of schemes. In particular, we will use the results of Atzeni and Chan [5], who proved that, for independent schemes, the total projection of the representative instance can be obtained by means of a union of scjes and proposed an algorithm to compute and optimize this expression, which runs in polynomial time with respect to the size of the database scheme. In the following, we will denote by $E_X = \cup E_i$ the union of scjes for a set of attributes $X \subseteq U$ [5, Algorithm 5.8], and we will refer to E_X as the *AC-expression* for X.

5.1. Basic algorithm. In this subsection we provide an algorithm (shown in Figure 6) that will be used for several purposes in the rest of the paper, and whose aim is to test efficiently whether certain total tuple appears in the representative instance of a state defined on an independent scheme. More specifically, given a consistent state $\mathbf{s}$ of an independent scheme $\mathbf{R}$, a tuple t_Y over $Y \subseteq U$, a set of attributes $V \subseteq U$ such that $Y \subseteq V$, and a set of constants C, Algorithm 2 verifies whether there exists total tuples on V in $\mathrm{RI}_{\mathbf{s}}$, without constants in C, that coincide with t_Y on the attributes Y, that is, whether $\sigma_{Y=t_Y}(\pi^{\downarrow}_V[C](\mathrm{RI}_{\mathbf{s}}))$ is not empty. If $Y = V$ and $C = \emptyset$, the algorithm simply tests whether $t_Y \widehat{\in} \mathbf{s}$. The role of the set of attributes V and of the set of constants C will be clarified later.

The search is efficiently performed by joining t_Y with tuples of $\mathbf{s}$ on the basis of the scje in the AC-expression E_V for V, giving precedence to the components having some attribute in Y. This corresponds in performing selections on the values in t_Y as early as possible while computing $\sigma_{Y=t_Y}(E_V(\mathbf{r}))$.

In the inner loop of the algorithm the expression $\sigma_{Y=t_Y}(E_i(\mathbf{r}))$ for an scje $E_i \in E_V$ is evaluated. The loop halts as soon as the result turns out to be empty or when the scje has been completely computed. Then, the derived tuples having no constants in C are stored in the relation s_{out}. The algorithm stops as soon as s_{out} is not empty or when all the scjes in E_V have been examined. Thus, at termination, we have that s_{out} contains tuples of $\sigma_{Y=t_Y}(E_V(\mathbf{s}))$ without constants in C and that $s_{out} \neq \emptyset$ if and only if $\sigma_{Y=t_Y}(E_V(\mathbf{s}))$ contains at least one tuple without constants in C. Since in [5] it is proved that a tuple $t' \in \pi^{\downarrow}_V(\mathrm{RI}_{\mathbf{s}})$ if and only if $t' \in E_V(\mathbf{s})$, the following result easily follows.

LEMMA 10. *Assume that Algorithm* 2 *receives as input a tuple* t_Y *over* $Y \subseteq U$, *a consistent state* $\mathbf{s}$ *of a scheme* $\mathbf{R}$, *a set of attributes* $V \subseteq U$ *such that* $Y \subseteq V$ *and a set of constants* C. *Then, at termination,* (1) $s_{out} \subseteq \pi^{\downarrow}_V[C](\sigma_{Y=t_Y}(\mathrm{RI}_{\mathbf{s}}))$, *and* (2) $s_{out} \neq \emptyset$ *if and only if* $\pi^{\downarrow}_V[C](\sigma_{Y=t_Y}(\mathrm{RI}_{\mathbf{s}})) \neq \emptyset$.

COROLLARY 3. *Let* $Y = V$ *and* $C = \emptyset$, *then the output relation* s_{out} *of Algorithm* 2 *is not empty if and only if* $t_Y \widehat{\in} \mathbf{s}$.

Note that, for efficiency purposes, Algorithm 2 does not compute a complete total projection of the representative instance. Note also that if $\pi^{\downarrow}_V(\sigma_{Y=t_Y}(\mathrm{RI}_{\mathbf{s}}))$ is not empty, then s_{out} is not deterministic, since it depends on the order in which the scjes have been selected. However, this is not important since, as we will see, we just need a relation satisfying the above properties.

5.2. Performing insertions. Let $\mathbf{r}$ be a consistent state of a scheme $\mathbf{R}$, and consider the insertion of a tuple t over $X \subseteq U$ in $\mathbf{r}$, assuming that it is possible and consistent. In section 4 it has been shown that the property of determinism for insertions can be verified on the state $\hat{\mathbf{r}}$. The construction of this state requires the computation of the completion of the state $\tilde{\mathbf{r}}$. We will show now that we do not need to compute the full completion of $\tilde{\mathbf{r}}$, since, as suggested by Lemma 9, it is sufficient to find only those tuples without new constants of $\hat{\mathbf{r}}^*$ that coincide with $\bar{t}$ on the attributes involved in some FD.

More specifically, let us consider the following database state. Again, $\bar{t}$ denotes the extension of t with respect to $\mathbf{r}$, $\tilde{t}$ the tuple obtained by extending $\bar{t}$ to the universe U by means of new constants, $\tilde{\mathbf{r}}$ the state obtained by adding to the original state $\mathbf{r}$ the projections of $\tilde{t}$ over the various relation schemes, and $\tilde{\mathbf{r}}^*$ its completion.

DEFINITION 5 (state $\check{\mathbf{r}}$). *A state* $\check{\mathbf{r}}$ *is obtained from* $\mathbf{r}$ *and* $\tilde{\mathbf{r}}$ (1) *by adding the tuple* $\bar{t}[X_i]$ *to each relation* $r_i \in \mathbf{r}$ *on* $R_i(X_i)$ *such that* $\overline{X} \supseteq X_i$, *and* (2) *by adding at least one tuple without new constants* $t_j \in \tilde{r}^*_j$, *such that* $t_j[YA] = \bar{t}[YA]$ *and* $t_j \notin r_j$, *to each relation* $r_j \in \mathbf{r}$ *over* $R_j(X_j)$ *such that* $\overline{X} \not\supseteq X_j$ *and* $\overline{X} \supseteq YA$ *for some* $Y \to A \in F_j$,

An important point here is that, if the deterministic condition is satisfied, in case (2) above there must exist at least one tuple without new constants t_j in $\tilde{r}^*_j$ such that $t_j[YA] = \bar{t}[YA]$ and $t_j \notin r_j$. This follows from the fact that, by Lemma 9, $\pi_{YA}(\hat{r}_j) = \pi_{YA}(r_i) \cup \pi^{\downarrow}_{YA}(\{\bar{t}_e\})$ for each $Y \to A \in F_j$ and the fact that $\hat{r}_j$ is obtained from $\tilde{r}^*_j$ by just deleting tuples with new constants. Note also that, in general, several tuples may satisfy this property.

We have the following results for $\check{\mathbf{r}}$.

LEMMA 11. *If* $\mathbf{R}$ *is independent and the insertion of* t *in* $\mathbf{r}$ *is deterministic, then*

$\check{\mathbf{r}} \sim \hat{\mathbf{r}}$.

Proof. We have to show that for deterministic insertions (1) $\hat{\mathbf{r}} \preceq \check{\mathbf{r}}$ and (2) $\check{\mathbf{r}} \preceq \hat{\mathbf{r}}$.

(1) $\hat{\mathbf{r}} \preceq \check{\mathbf{r}}$. We prove this part by showing that, for every $R_i(X_i) \in \mathbf{R}$ and for every $t_i \in \hat{r}_i$, either (i) $t_i \in \check{r}_i$ or (ii) $t_i \in \pi^{\downarrow}_{X_i}(\mathrm{RI}_{\check{\mathbf{r}}})$. It would follow that every $t_i \in \hat{r}_i$ belongs to the relation $\check{r}_i^*$ in the completion $\check{\mathbf{r}}^*$ of $\check{\mathbf{r}}$. Since, by Theorem 7, $\hat{\mathbf{r}}$ coincides with a complete state and is therefore itself complete, the fact that $\hat{\mathbf{r}} \preceq \check{\mathbf{r}}$ then follows by the equivalence of parts 1 and 4 of Theorem 1.

Thus, let $t_i \in \hat{r}_i$ for some $R_i(X_i) \in \mathbf{R}$. By construction of $\hat{\mathbf{r}}$, we have three possible cases: (a) $t_i \in r_i$, where $r_i \in \mathbf{r}$—that is, t_i belongs to a relation of the original state; (b) $t_i \notin r_i$ and $\overline{X} \supseteq X_i$, and so $t_i = \bar{t}[X_i]$; and (c) $t_i \notin r_i$ and $\overline{X} \not\supseteq X_i$, and so t_i has been generated in chasing $T_{\check{\mathbf{r}}}$. In the first two cases we also have $t_i \in \check{r}_i$ by construction. With respect to the third case, we will show that t_i can be generated by chasing $T_{\check{\mathbf{r}}}$.

Thus, let t_i be a tuple of $\hat{r}_i$ on $R_i(X_i) \in \mathbf{R}$, such that $t_i \notin r_i$ and $\overline{X} \not\supseteq X_i$. Since, by Theorem 7, $\hat{\mathbf{r}} = \mathbf{r}_+$, we have that, by construction of $\mathbf{r}_+$, the tuple t_i is also generated by chasing $T_{t,\mathbf{r}}$. Moreover, since the insertion is deterministic, by Theorem 4, $\mathit{CHASE}_F(T_{t,\mathbf{r}})$ is equivalent to the representative instance of a database state. It follows that t_i originates in $\mathit{CHASE}_F(T_{t,\mathbf{r}})$ from a tuple t_0 of a relation $r_0 \in \mathbf{r}$ (indeed, t_0 can not originate from $\bar{t}$ since this would imply that $t_i = \bar{t}[X_i]$ and so $\overline{X} \supseteq X_i$). Let $\chi = \tau_1, \ldots, \tau_m$ be the sequence of chase steps that allows us to generate t_i from t_0 in the chase of $T_{t,\mathbf{r}}$. Since $\mathbf{R}$ is independent, by Lemma 8, each τ_k in χ promotes a variable to a constant in $\mathbf{r}$ or in t, because of a tuple t_j and an FD $Y \to A$, such that $t_j[YA] \in \pi_{YA}(r_j) \cup \pi^{\downarrow}_{YA}(\{\bar{t}_e\})$.

Now, for each $Y \to A \in F_j$ such that $\overline{X} \supseteq YA$, if $\overline{X} \supseteq X_j$, the tuple $\bar{t}[X_i]$ is in $\check{r}_j$ by construction. Moreover, if $\overline{X} \supseteq YA$ and $\overline{X} \not\supseteq X_j$, we have argued above that, for deterministic insertions, there must exist at least one tuple without new constants t'_j in $\tilde{r}_j^*$ such that $t'_j[YA] = \bar{t}[YA]$ and so, by construction, a tuple satisfying this property is also in $\check{r}_j$. It follows that the above sequence of chase step χ is also valid in $T_{\check{\mathbf{r}}}$; that is, it allows us to generate t_i from t_0 (which, by construction, belongs to $\check{\mathbf{r}}$), by chasing $T_{\check{\mathbf{r}}}$. As argued above, this concludes part (1) of the proof.

(2) $\check{\mathbf{r}} \preceq \hat{\mathbf{r}}$: the proof easily follows from their definitions. □

THEOREM 8. *For independent schemes the insertion of t in $\mathbf{r}$ is deterministic if and only if $t \widehat{\in} \check{\mathbf{r}}$.*

Proof. Only if. If the insertion is deterministic, then by Corollary 2, $t \widehat{\in} \hat{\mathbf{r}}$ and, by Lemma 11, $\check{\mathbf{r}} \sim \hat{\mathbf{r}}$. It follows that $t \widehat{\in} \check{\mathbf{r}}$.

If. Since, by construction, $\check{\mathbf{r}} \preceq \hat{\mathbf{r}}$, if $t \widehat{\in} \check{\mathbf{r}}$, then it is also the case that $t \widehat{\in} \hat{\mathbf{r}}$ and therefore, by Corollary 2, the insertion is deterministic. □

A state $\check{\mathbf{r}}$ can be efficiently derived from $\mathbf{r}$ and $\tilde{\mathbf{r}}$ by using Algorithm 3, shown in Figure 7. In this algorithm, C_{new} denotes the set of new constants used in the construction of $\tilde{t}$, and, for each $R_i(X_i) \in \mathbf{R}$, $Y^+_{F_i}$ denotes the *local closure* of a set of attributes $Y \subseteq X_i$ with respect to F_i. The following lemma confirms the correctness of the algorithm.

LEMMA 12. *Assume that Algorithm* 3 *receives as input a state $\mathbf{r}$ of an independent scheme $\mathbf{R}$, a tuple t over $X \subseteq U$, and its extensions $\bar{t}$ and $\tilde{t}$. Then, the output of the algorithm is a state $\check{\mathbf{r}}$.*

Proof. Since the tuples added to $\mathbf{r}_{out}$ in step (a) of Algorithm 3 belong to $\check{\mathbf{r}}$ by definition, it is sufficient to show that in step (b), only tuples satisfying condition (2) of the definition of $\check{\mathbf{r}}$, are added to $\mathbf{r}_{out}$, and nothing else. First, note that if there is a tuple $t_i \in \tilde{r}_i$ such that $t_i[YA] = \bar{t}[YA]$ for some $Y \to A$ in F_i, it easily

ALGORITHM 3.
Input : $\mathbf{r}$, t *over* $X \subseteq U$, $\bar{t}$ *over* $\overline{X}$, $\tilde{t}$ *over* U;
Output: *a state* $\check{\mathbf{r}}$;
begin
  $\mathbf{r}_{out} := \mathbf{r}$;
  for each $R_i(X_i) \in \mathbf{R}$
  do if $\overline{X} \supseteq X_i$
(a) **then** $r_{out_i} := r_{out_i} \cup \{\bar{t}[X_i]\}$
  else for each $Y \to A \in F_i$ *such that* $\overline{X} \supseteq YA$
    do if *does not exist* $t' \in r_{out_i}$ *such that* $t'[YA] = \bar{t}[YA]$
      then begin
        execute Algorithm 2 *over* $\tilde{\mathbf{r}}$, $\bar{t}[Y_{F_i}^+]$, X_i *and* C_{new};
(b) $r_{out_i} := r_{out_i} \cup s_{out}$
      end;
  return $\mathbf{r}_{out}$
end.

FIG. 7. *Algorithm for the generation of a state* $\check{\mathbf{r}}$.

follows that $\bar{t}$ is defined on $Y_{F_i}^+$ and $t_i[Y_{F_i}^+] = \bar{t}[Y_{F_i}^+]$. Then, by Lemma 10, in step (b) of Algorithm 3, we add to $\mathbf{r}_{out}$ at least one tuple (if any) without new constants in $\pi^{\downarrow}_{X_i}[C_{new}](\sigma_{Y_{F_i}^+ = \bar{t}[Y_{F_i}^+]}(\mathrm{RI}_{\tilde{\mathbf{r}}}))$. It follows that, for each relation $r_j \in \mathbf{r}$ over $R_j(X_j) \in \mathbf{R}$ such that $\overline{X} \not\supseteq X_j$ and $\overline{X} \supseteq YA$ for some $Y \to A \in F_j$, we add, in step (b) of Algorithm 3, at least one tuple $t_j \in \tilde{r}_j^*$ without new constants such that $t_j[YA] = \bar{t}[YA]$ and $t_j \notin r$, and nothing else. □

EXAMPLE 6. *Let* $\mathbf{r}$ *be the state in Figure* 1 *and* $t = \langle \mathrm{Jim}, \mathrm{White} \rangle$ *over* EM. *We have shown in Example* 4 *that* $\bar{t} = \langle \mathrm{Jim}, \mathrm{MS}, \mathrm{White} \rangle$ *over* $\overline{X} = EDM$. *Let* $\tilde{t} = \langle \mathrm{Jim}, \mathrm{MS}, \mathrm{c}_1, \mathrm{White} \rangle$ *and consider the execution of Algorithm* 3 *over these inputs. We have* $\overline{X} \not\supseteq X_1 = EDP$ *and* $\overline{X} \supseteq ED$, *where* $E \to D \in F_1$, *but* $\bar{t}[ED] \in \pi_{ED}(r_1)$ *and therefore* $r_{out_1} = r_1$. *We then have* $\overline{X} \not\supseteq X_2 = DMP$, $\overline{X} \supseteq DM$ *for the functional dependency* $D \to M \in F_2$, *and* $\bar{t}[DM] \notin \pi_{DM}(r_2)$. *Thus, in this case, Algorithm* 2 *needs to be executed with* $\tilde{\mathbf{r}}$, $\langle \mathrm{MS}, \mathrm{White} \rangle$, DMP, *and* $\{c_1\}$ *as inputs. We have* $E_{DMP} = R_2 \cup \pi_{DMP}(R_1 \bowtie \pi_{DM}(R_2))$. *For the first scje in* E_{DMP} *we obtain* $s_{out} = \emptyset$, *since* $\bar{t}[DM] \bowtie \tilde{r}_2 = \{\langle \mathrm{MS}, \mathrm{c}_1, \mathrm{White} \rangle\}$. *For the second scje we have* $\pi_{DMP}(\bar{t}[DM] \bowtie \tilde{r}_1 \bowtie \pi_{DM}(\tilde{r}_2)) = \{\langle \mathrm{MS}, \mathrm{C}, \mathrm{White} \rangle, \langle \mathrm{MS}, \mathrm{c}_1, \mathrm{White} \rangle\}$. *Hence, we obtain:* $r_{out_2} = r_2 \cup \{\langle \mathrm{MS}, \mathrm{C}, \mathrm{White} \rangle\}$. *Thus, in this case,* $\check{\mathbf{r}}$ *coincides with* $\hat{\mathbf{r}}$ (*see Example* 5) *and* $t \widehat{\in} \check{\mathbf{r}}$—*this confirms the determinism of the insertion of* t *in* $\mathbf{r}$.

We are now ready to present Algorithm 4 (shown in Figure 8), which summarizes all phases of insert operations to independent schemes.

Step (1) of Algorithm 4 checks for possibility (Theorem 2). This test requires the computation of closures of sets of attributes, an operation that can be performed in time $O(\|F\|)$, where $\|F\|$ is the size of the description of F, by using Bernstein's algorithm [10]. Since the closure has to be performed $|\mathbf{R}|$ times in the worst case, where $|\mathbf{R}|$ is the number of relation schemes in $\mathbf{R}$, it follows that testing for possibility is bounded by $O(|\mathbf{R}| \times \|F\|)$.

In step (2) the extension $\bar{t}$ of t with respect to the state $\mathbf{r}$ is computed by using Algorithm 1. This algorithm requires the computation of the closure of a set of attributes and, at each step of the computation, the selection of a tuple given a value

ALGORITHM 4.
Input : **r** *and* t *over* $X \subseteq U$*;*
Output: "not possible" | "not consistent" | "not deterministic" |
the result of the insertion of t *in* **r***;*
begin
(1) **if** *not exists* $R_i(X_i) \in \mathbf{R}$ *such that* $X_i^+ \supseteq X$
then return "not possible" **and stop***;*
(2) *compute* $\overline{t}$ *and* $\overline{X}$ *using Algorithm* 1;
(3) **if** *Condition* 1 *does not hold*
then return "not consistent" **and stop***;*
(4) *compute* $\check{\mathbf{r}}$ *using Algorithm* 3;
(5) *verify that* $t \widehat{\in} \check{\mathbf{r}}$ *using Algorithm* 2;
(6) **if** $s_{out} = \emptyset$
then return "not deterministic"
else return $\check{\mathbf{r}}$
end.

FIG. 8. *Algorithm for the execution of insert operations.*

on the left-hand side of an FD. The selection time depends on the cardinality of the relation, but it can be strongly reduced by defining indexes on the left-hand side of all the FDs in F. Let $k_{F,\mathbf{r}}$ be the maximum time needed to search for tuples in a database state **r**, given a value on the left-hand side of an FD in F. The cost of step (2) is then proportional to $\|F\| \times k_{F,\mathbf{r}}$. Under the same hypothesis, Condition 1 in step (3) (which, by Theorem 6, checks for possibility) can be tested in time $O(|F| \times k_{F,\mathbf{r}})$, where $|F|$ is the cardinality of the set of FDs F. This is because in an independent scheme each FD is embedded in at most one relational scheme [17].

In step (4) the state $\check{\mathbf{r}}$ is computed with Algorithm 3.

This algorithm requires, in the worst case, the execution of Algorithm 2 a number of times that, by the above property of independent schemes, is bounded by $|F|$. For any given X, there are at most as many scjes in E_X as relation schemes in **R** [5, 3]. It follows that the execution of Algorithm 2 corresponds to the execution of a number of relational algebra expressions bounded by $|F'| \times |\mathbf{R}|$, where F' denotes the FDs $Y' \rightarrow A'$ in F, such that there is no other FD $Y \rightarrow A$ in some $F_i \subseteq F$, for which $Y_{F_i}^+ \supseteq Y'A'$. The cost of each expression is bounded by $|r_{max}| \times k_{F,\mathbf{r}} \times |F|$, where $|r_{max}|$ is the size of the largest relation in **r**. In fact, the computation starts with a relation not larger than $|r_{max}|$ and then performs a number of joins, bounded by $|F|$, that simply require for each tuple in the intermediate relation the search for a tuple in a relation, given a value for its key (which is the left-hand side of an FD). This is because, at each step, the attributes of the intermediate relation include the left-hand side of the FD over which each component is projected. Note also that the size of the computed relation is always bounded by $|r_{max}|$. In sum, step (4) is bounded by $|r_{max}| \times |F|^2 \times |\mathbf{R}| \times k_{F,\mathbf{r}}$. On average however, it turns out that the cost of this operation is quite limited. This is because (i) updates often involve only a very small portion of FDs in F, (ii) relational expressions are optimized as described in [5] and selections are performed as early as possible, and (iii) the number of scjes for a set of attributes is small when the scheme enjoys the desirable property of "independent updatability" [16].

Finally, step (5) tests for determinism (Theorem 8 and Corollary 3) and requires

ALGORITHM 5.
Input : $\mathbf{r}$ *and* t *over* $X \subseteq U$*;*
Output: "not deterministic" | *the result of the deletion of* t *from* $\mathbf{r}$;
begin
(1) **if** *not exists* $R_i(X_i) \in \mathbf{R}$ *such that* $X_i \supseteq X$
    then return "not deterministic" **and stop**;
(2) **for each** $R_i(X_i) \in \mathbf{R}$ **do if** $X_i \supseteq X$
    then $r_{-_i} := r_i - \sigma_{X=t}(r_i)$;
(3) *verify that* $t \widehat{\in} \mathbf{r}_-$ *using Algorithm* 2;
(4) **if** verified
    then return "not deterministic" **and stop**
    else return $\mathbf{r}_-$
end.

FIG. 9. *Algorithm for the execution of delete operations.*

the execution of Algorithm 2 once more. Note that the state $\tilde{\mathbf{r}}$ as well as the state $\check{\mathbf{r}}$ do not need to be effectively constructed. So, Algorithms 2 and 3 could be slightly modified in order to work on the tuples in $\mathbf{r}$, $\tilde{\mathbf{r}}$, and $\check{\mathbf{r}}$, without actually adding tuples to $\mathbf{r}$.

From the discussion above, it turns out that Algorithm 4 provides a practical and efficient way to perform the insertion of a tuple t over any set of attributes $X \subseteq U$ in a state of an independent scheme.

EXAMPLE 7. *Examples* 4 *and* 6 *deal with the execution of all the steps of Algorithm* 4 *for the tuple* $t = \langle \text{Jim}, \text{White} \rangle$ *over* EM *and the state in Figure* 1.

5.3. Performing deletions. By the results of the previous sections it is also possible to give an efficient method for performing delete operations on a database state of an independent scheme. This algorithm is shown in Figure 9.

In step (1), the necessary condition for determinism of Lemma 5 is tested: it requires time proportional to $|\mathbf{R}|$. Then, in step (2), the state $\mathbf{r}_-$ is computed by executing a number of selections, again bounded by $|\mathbf{R}|$. Then, by Theorem 5 and Corollary 3, step (3) tests for determinism. This requires one execution of Algorithm 2, which is optimized as discussed in the previous subsection. Also in this case, the algorithm can be slightly modified in order to work on the tuples $\mathbf{r}$ and $\mathbf{r}_-$ without actually deleting tuples from $\mathbf{r}$.

Thus, again, given a state $\mathbf{r}$ of an independent scheme and a tuple t over any set of attributes $X \subseteq U$, Algorithm 5 provides a practical and efficient way to perform the deletion of t from $\mathbf{r}$.

EXAMPLE 8. *Assume that we want to delete the tuple* $t = \langle \text{Smith}, \text{B} \rangle$ *over* MP *from the state in Figure* 1. *The condition in step* (1) *of Algorithm* 5 *is verified for the scheme* $R_2(DMP)$. *Then, the state* $\mathbf{r}_-$ *is obtained in step* (2) *by deleting the tuple* $\langle \text{CS}, \text{Smith}, \text{B} \rangle$ *from* r_2. *However, it is easy to see that this tuple can be reconstructed from the tuple* $\langle \text{John}, \text{CS}, \text{B} \rangle$ *in* r_1 *and the tuple* $\langle \text{CS}, \text{Smith}, \text{A} \rangle$ *in* r_2. *It follows that in step* (3) *we obtain* $t \widehat{\in} \mathbf{r}_-$ *and therefore the insertion is not deterministic. Conversely, the deletion of* $t = \langle \text{White}, \text{B} \rangle$ *over the same attributes is deterministic since in this case we would have* $t \widehat{\notin} \mathbf{r}_-$.

6. Possible simplifications of the algorithms. In this section we show that, under certain further assumptions, update operations can be managed more easily.

6.1. Insertions. We recall that a database scheme $\mathbf{R}$ is *separable* if it is independent and every consistent state on $\mathbf{R}$ is complete [16]. (Chan and Mendelzon also provided an efficient test for separability.)

Now, let $\mathbf{r}$ be a state of a database scheme $\mathbf{R}$, t be a tuple over $X \subseteq U$, and $\bar{t}$ be the extension of t with respect to $\mathbf{r}$. Let us consider the following state.

DEFINITION 6 (state $\bar{\mathbf{r}}$). *The state $\bar{\mathbf{r}}$ is obtained from $\mathbf{r}$ and $\bar{t}$ by adding the tuple $\bar{t}[X_j]$ to each relation $r_j \in \mathbf{r}$ on $R_j(X_j) \in \mathbf{R}$ such that $X_j \subseteq \overline{X}$.*

THEOREM 9. *If $\mathbf{R}$ is separable, then $\bar{\mathbf{r}} = \mathbf{r}_+$.*

Proof. If $\mathbf{R}$ is separable, then the state $\tilde{\mathbf{r}}$ coincides with its completion $\tilde{\mathbf{r}}^*$, and therefore, by construction, $\hat{\mathbf{r}}$ can be obtained by eliminating from $\tilde{\mathbf{r}}$ the tuples with new constants. The state we obtain clearly coincides with $\bar{\mathbf{r}}$, and therefore, by Theorem 7, the claim follows. □

COROLLARY 4. *The insertion of a tuple t in a state $\mathbf{r}$ on a separable scheme is deterministic if and only if $t \widehat{\in} \bar{\mathbf{r}}$.*

Proof. The proof follows by Corollary 1 and Theorem 9. □

By this result, the test for determinism and the computation of the minimum result for insertions to separable schemes can be done more efficiently since in this case it is not required to compute the state $\check{\mathbf{r}}$ as it suffices to refer to the state $\bar{\mathbf{r}}$ which can be easily generated.

EXAMPLE 9. *The scheme of the state $\mathbf{r}$ in Figure 1 is independent but not separable since, for instance, the state obtained by deleting the tuple $\langle \mathrm{CS}, \mathrm{Smith}, \mathrm{B} \rangle$ from r_2 is not complete (see Example 8). Therefore, we have in general $\bar{\mathbf{r}} \neq \mathbf{r}_+$. In fact, for to the tuple $t = \langle \mathrm{Jim}, \mathrm{White} \rangle$ over EM, we have that $\bar{t} = \langle \mathrm{Jim}, \mathrm{MS}, \mathrm{White} \rangle$ and so $\bar{\mathbf{r}} = \mathbf{r}$, whereas we have shown that the insertion of t in $\mathbf{r}$ is deterministic. It is easy to show that, if the second relation would contain only the attributes D and P, the scheme would be separable. In this case the insertion above can be performed by adding to r_2 the tuple $\langle \mathrm{MS}, \mathrm{White} \rangle$, which is indeed embedded in $\bar{t}$.*

The state $\bar{\mathbf{r}}$ has an interesting property: it contains only the tuples that can be derived directly from t by extending this tuple with values from tuples of $\mathbf{r}$, using the FDs in F. Then, by simply computing the extension of t with Algorithm 1, we immediately know not only the tuples to insert in the original database, but also the side effect generated by the insertion. Therefore, when $\bar{\mathbf{r}}$ is the result of the insertion, we can keep the side effect under control. Unfortunately, as shown in Example 9, even for independent schemes, $\bar{\mathbf{r}}$ is not always the correct result, and insertion operations require, in the general case, a more involved computation, as described in section 5.

Interestingly however, it is possible to give for independent schemes "local" conditions at scheme level (which therefore can be efficiently tested) that allow us to refer to the state $\bar{\mathbf{r}}$ for insert operations even for schemes that are nonseparable. Let us consider the following property which refer to the insertion of a tuple t over $X \subseteq U$ in a state $\mathbf{r}$ of a scheme $\mathbf{R}$.

CONDITION 2. *For every relational scheme $R_i(X_i) \in \mathbf{R}$, at least one of the following holds:*

(i) $X_i \subseteq \overline{X}$,

(ii) $YA \not\subseteq \overline{X}$ *for any* $Y \rightarrow A \in F_i$,

(iii) F_i *contains an FD whose left-hand side is a superkey of* X_i.

THEOREM 10. *Let $\mathbf{R}$ be independent and assume that Condition 2 holds. Then, the insertion of t in $\mathbf{r}$ is deterministic if and only if $t \widehat{\in} \bar{\mathbf{r}}$.*

Proof. Only if. We prove this part by showing that if, for an independent scheme, Condition 2 holds and the insertion is deterministic, then for every $R_i(X_i) \in \mathbf{R}$

such that $X_i \not\subseteq \overline{X}$ it is the case that $\hat{r}_i = r_i$. The fact that $t \widehat{\in} \overline{\mathbf{r}}$ would then follow by Theorem 8 and the fact that in this case, by construction, $\check{\mathbf{r}} = \overline{\mathbf{r}}$. So, by way of contradiction, assume that $\mathbf{R}$ is independent, Condition 2 holds, and there is a scheme $R_i(X_i) \in \mathbf{R}$ such that $X_i \not\subseteq \overline{X}$ and $\hat{r}_i \neq r_i$. By definition of $\hat{\mathbf{r}}$, this implies that (i) $YA \subseteq \overline{X}$ for some $Y \rightarrow A \in F_i$, (ii) there is no tuple in r_i which coincides with $\overline{t}$ on YA, and (iii) there is a tuple $t' \in \tilde{r}_i^*$ without new constants such that $t'[YA] = \overline{t}[YA]$. But because of Condition 2, if $X_i \not\subseteq \overline{X}$ and $YA \subseteq \overline{X}$ for some $Y \rightarrow A \in F_i$, then there must exist an FD $Z \rightarrow B \in F_i$ such that Z is a superkey of X_i. Now, since the scheme is independent, by Lemma 3, $\pi^{\downarrow}_{ZB}(CHASE_F(T_{\check{\mathbf{r}}})) = \pi_{ZB}(\tilde{r}_i)$, and since Z is a superkey, this implies $\pi^{\downarrow}_{X_i}(CHASE_F(T_{\check{\mathbf{r}}})) = \tilde{r}_i$ and therefore $t' = \tilde{t}[X_i]$. This, in turn, implies that $t' = \overline{t}[X_i]$, since t' does not contain new constants, and therefore $X_i \subseteq \overline{X}$—a contradiction.

If. If $t \widehat{\in} \overline{\mathbf{r}}$, then it is also the case that $t \widehat{\in} \check{\mathbf{r}}$ since, by construction, $\overline{\mathbf{r}} \preceq \check{\mathbf{r}}$. Then, the claim follows by Theorem 8. □

EXAMPLE 10. *Consider again the insertion of the tuple* $t = \langle \text{Jim}, \text{White} \rangle$ *over* EM *in the state* $\mathbf{r}$ *in Figure* 1: *In this case Condition* 2 *is not verified since* $\overline{X} = EDM$. *For* $R_1(X_1)$ *we have* $X_1 \not\subseteq \overline{X}$, $E \rightarrow D \in F_1$ *and is embedded in* $\overline{X}$, *and the left-hand side of* $E \rightarrow D$ *does not contain a superkey of* X_1. *However, if we consider the insertion of* $t = \langle \text{Jim}, \text{D} \rangle$ *over* EP *in the same state, we obtain* $\overline{t} = \langle \text{Jim}, \text{MS}, \text{D} \rangle$, *and since in this case Condition* 2 *holds (*$X_1 \subseteq \overline{X}$ *and* $YA \not\subseteq \overline{X}$ *for any* $Y \rightarrow A \in F_2$*), the result of this insertion can be obtained by simply adding* $\overline{t}$ *to the first relation.*

Testing for Condition 2 on an independent scheme requires, in the worst case, time proportional to $|F| \times \|F\|$, since, as we have said before, each FD is embedded in at most one relational scheme. This test can be performed after step (3) of Algorithm 4, and if it succeeds, then steps (4)–(6) of Algorithm 4 can be replaced by just one step, verifying (by using Algorithm 2) that $t \widehat{\in} \overline{\mathbf{r}}$.

6.2. Deletions. With respect to deletions, we can test for determinism more efficiently if it is the case that every piece of information that is defined on some subset of a relation scheme is explicitly represented in the database. This is the property of the *embedded-complete* schemes [15]: a scheme $\mathbf{R}$ is *embedded-complete* if for any consistent state $\mathbf{r}$ of $\mathbf{R}$ and for any $X \subseteq U$ such that there exists $R_i(X_i) \in \mathbf{R}$ with $X_i \supseteq X$, it is the case that $\pi^{\downarrow}_X(\text{RI}_{\mathbf{r}}) = \bigcup_{X_j \supseteq X} \pi_X(r_j)$.

Let us consider the deletion of any tuple over a set of attributes $X \subseteq U$ from a state $\mathbf{r}$ of the scheme $\mathbf{R}$.

THEOREM 11. *The deletion of a tuple* t *from a state* $\mathbf{r}$ *on an embedded-complete scheme is deterministic if and only if there is a relational scheme* $R_i(X_i)$ *such that* $X_i \supseteq X$.

Proof. Only if. The proof follows by Lemma 5.

If. This part follows by Theorem 5 and the fact that if the database scheme is embedded-complete, then no tuple over a set of attributes which is contained in a relational scheme can be generated by the chase from other tuples, and so it is never the case that $t \widehat{\notin} \mathbf{r}_-$. □

Also in this case, it is possible to state local conditions at scheme level for independent schemes that allow us to test for determinism of a deletion of a tuple t over a set of attributes $X \subseteq U$ as follows.

CONDITION 3. *For every relation scheme* $R_i(X_i)$ *in* $\mathbf{R}$, *at least one of the following holds:*

(i) $X \not\subseteq X_i$,

(ii) *for every relation scheme* $R_j(X_j)$ *in* $\mathbf{R}$, $i \neq j$, $X \not\subseteq X_j^+$,

(iii) F_i *contains an FD whose left-hand side is a superkey of* X.

THEOREM 12. *Let* $\mathbf{R}$ *be independent and assume that Condition* 3 *holds. Then the deletion of* t *from* $\mathbf{r}$ *is deterministic if and only if there is a relational scheme* $R_i(X_i)$ *such that* $X \subseteq X_i$.

Proof. Only if. The proof is made by Lemma 5.

If. Assume by way of contradiction that, for an independent scheme $\mathbf{R}$, Condition 3 holds and that there is a relational scheme $R_i(X_i) \in \mathbf{R}$ such that $X \subseteq X_i$ but the deletion is not deterministic. By Theorem 5 it follows that $t \widehat{\in} \mathbf{r}_-$, and therefore there is a tuple t' in $\mathrm{RI}_{\mathbf{r}_-}$ such that $t'[X] = t$. Then let t_j be the tuple from which t' originates and assume that $t_j \in r_{-_j}$ over $R_j(X_j)$. Clearly, $X \not\subseteq X_j$ and so $i \neq j$. Moreover, since we have assumed that $t \widehat{\in} \mathbf{r}$, by Theorem 2, $X_j \rightarrow X \in F^+$, and so, $X \subseteq X_j^+$. This implies that there is an FD $Y \rightarrow A \in F_i$ such that Y is a superkey of X; otherwise Condition 3 would be false. Since $\mathbf{R}$ is independent, by Lemma 3, we have $\pi^{\downarrow}_{YA}(\mathrm{RI}_{\mathbf{r}_-}) = \pi_{YA}(r_{-_i})$, and since Y is a superkey of X, we have that $\pi^{\downarrow}_{X}(\mathrm{RI}_{\mathbf{r}_-}) = \pi_X(r_{-_i})$. But, by construction, $t \notin \pi_X(r_{-_i})$ and so it follows that $t \widehat{\notin} \mathbf{r}_-$—a contradiction. ∎

EXAMPLE 11. *Consider the deletion* $t = \langle \mathrm{CS}, \mathrm{Smith}, \mathrm{B} \rangle$ *over* $X = DMP$ *from the state* $\mathbf{r}$ *in Figure* 1. *Condition* 3 *does not hold since* $X \subseteq X_2 = DMP$, $X \subseteq X_1^+ = U$, *and the only FD* $D \rightarrow M$ *in* F_2 *has a left-hand side that is not a superkey of* X. *Therefore, for deletions defined on EDP we need to check whether* $t \notin \mathbf{r}_-$ *(it turns out that the deletion of* t *is not deterministic as shown in Example* 8*). Note that the scheme of* $\mathbf{r}$ *is not embedded-complete. Conversely, Condition* 3 *is verified for the tuple* $t' = \langle \mathrm{CS}, \mathrm{Smith} \rangle$ *over* DM *since we have* $DM \subseteq X_2$ *and* $DM \subseteq X_1^+$, *but in this case* D *is a superkey of* DM. *Hence, the deletion of* t' *from* $\mathbf{r}$ *is deterministic and the result of the deletion can be obtained by deleting the tuples* $\langle \mathrm{CS}, \mathrm{Smith}, \mathrm{A} \rangle$ *and* $\langle \mathrm{CS}, \mathrm{Smith}, \mathrm{B} \rangle$ *from* r_2.

Condition 3 can be tested for independent schemes in time bounded by $\|F\| \times (|\mathbf{R}|^2 + |F|)$ and can be performed after step (2) of Algorithm 5. If such a condition is verified, then the test for determinism in step (3) is no longer necessary, since in this case the state $\mathbf{r}_-$ is surely the maximum result.

7. Modification operations. The present paper studies insertions and deletions of tuples as basic database update operations. However, modifications form another important class of update operations, often used in practical situations. The goal of this section is to discuss briefly the modification of tuples: we show that they naturally fit in our framework and that, in general, insertion and deletion results can be used to characterize them.

A simple modification operation consists of changing the values of a single tuple. Therefore, we can represent a modification of a state $\mathbf{r}$ by means of a pair (t_{old}, t_{new}), where t_{old} and t_{new} are tuples defined over the same set of attributes $X \subseteq U$; the intended meaning of this operation is clearly to substitute t_{old} by t_{new} in $\mathbf{r}$.

According to the definition of insertions and deletions, this operation should be realized by altering the information content of the original state as little as possible. Thus, in the framework we have defined, a modification (t_{old}, t_{new}), defined over any set of attributes $X \subseteq U$, of a database state $\mathbf{r}$ for a scheme $\mathbf{R}$, can be defined through the following notion of result.

A state $\mathbf{r}_p$ is a *potential result* for the modification (t_{old}, t_{new}) to $\mathbf{r}$ if (1) $t_{old} \widehat{\notin} \mathbf{r}_p$, (2) $t_{new} \widehat{\in} \mathbf{r}_p$, and (3) for every state $\mathbf{r}' \preceq \mathbf{r}$ of $\mathbf{R}$ such that (a) $t_{old} \widehat{\notin} \mathbf{r}'$ and (b) the insertion of t_{new} in $\mathbf{r}'$ is consistent, $\mathbf{r}' \preceq \mathbf{r}_p$.

If we assume that $t_{old} \widehat{\in} \mathbf{r}$, a modification is always possible, but as with insertions, inconsistency and nondeterminism may arise. We then say that a modification is

consistent if it has a consistent potential result and is *deterministic* if the glb of the potential results is itself a potential result.

By the definition above, it turns out that a modification can be implemented, in most cases, through a deletion followed by an insertion. Specifically, we can easily show the following results

LEMMA 13. *Let* $\mathbf{r}$ *be a database state of a scheme* $\mathbf{R}$*, and* (t_{old}, t_{new}) *be a modification defined over a set of attributes* $X \subseteq U$*. Then the following properties hold:*

(i) *If the deletion of* t_{old} *from* $\mathbf{r}$ *is deterministic and the insertion of* t_{new} *to* $\mathbf{r}_{-t_{old}}$ *is consistent, then the modification* (t_{old}, t_{new}) *of* $\mathbf{r}$ *is consistent.*

(ii) *If the deletion of* t_{old} *from* $\mathbf{r}$ *is deterministic and the insertion of* t_{new} *to* $\mathbf{r}_{-t_{old}}$ *is deterministic, then the modification* (t_{old}, t_{new}) *of* $\mathbf{r}$ *is deterministic.*

(iii) *If the deletion of* t_{old} *from* $\mathbf{r}$ *is deterministic then* $(\mathbf{r}_{-t_{old}})_{+t_{new}}$ *is the glb of the potential results.*

We note that the converses of the above results do not hold in general. This is shown in the following example.

EXAMPLE 12. *Consider the database scheme* $\mathbf{R} = \{R_1(AB), R_2(BC)\}$*, with the FDs* $A \rightarrow B$ *and* $B \rightarrow C$ *defined for it, and the state of* $\mathbf{R}$*:*

$$\mathbf{r} = \{r_1 = \{\langle 1, 2\rangle\}, r_2 = \{\langle 2, 3\rangle\}\}.$$

Consider now the modification $(t_{old}, t_{new}) = (\langle 1, 2, 3\rangle, \langle 1, 2, 5\rangle)$ *defined over* ABC*. The deletion of* t_{old} *from* $\mathbf{r}$ *is not deterministic, since it can be realized either by deleting the tuple* $\langle 1, 2\rangle$ *from* r_1 *or the tuple* $\langle 2, 3\rangle$ *from* r_2*. However, we have that the modification is indeed deterministic. In fact, let* $\mathbf{r}'$ *and* $\mathbf{r}''$ *be the potential results for the deletion of* t_{old} *from* $\mathbf{r}$*. Then*

$$\mathbf{r}' = \{r'_1 = \emptyset, r'_2 = \{\langle 2, 3\rangle\}\} \text{ and } \mathbf{r}'' = \{r''_1 = \{\langle 1, 2\rangle\}, r''_2 = \emptyset\}.$$

Then, it is easy to see that the insertion of t_{new} *in* $\mathbf{r}'$ *is inconsistent, whereas the insertion of* t_{new} *in* $\mathbf{r}''$ *is consistent and deterministic. It follows that the glb of the potential results is indeed a potential result and can be obtained by substituting* $\langle 2, 5\rangle$ *for* $\langle 2, 3\rangle$ *in* r_2*.*

This example shows that in general, in order to implement a modification (t_{old}, t_{new}) of a state $\mathbf{r}$, we first have to find all the *maximal potential results* for the deletion of t_{old} from $\mathbf{r}$. We recall that a maximal potential result $\mathbf{r}_M$ for a deletion is a potential result for which there is no other potential result $\mathbf{r}_p$ such that $\mathbf{r}_M \preceq \mathbf{r}_p$ [9]. Then we have to select from among them the states for which the insertion of t_{new} is consistent and deterministic. Finally, the results for the insertion of t_{new} to the selected states have to be compared: if there is one that is weaker than each other, the modification is deterministic.

From the discussion above, it turns out that the algorithms derived for implementing insertions and deletions can be also used to implement modification operations.

8. Conclusions. In this paper we have shown that, similar to what has been done with respect to query answering, efficient algorithms for characterizing and performing update operations defined over any subset of the universe can be given for the highly significant class of independent schemes. In fact, the various characterizations, which require time and space polynomial with respect to the size of the database state [9], can be verified for this class of schemes efficiently, as in this case we can derive a restricted number of optimized relational expression that allow us to refer only to the relevant portion of the database.

In particular, with respect to insert operations, we have first shown that the property of consistency can be efficiently tested by considering only to the "extension" of the tuple to be inserted (which is obtained by adding to t further values derived from the original state and the constraints) and the involved FDs. With respect to the property of determinism, we have first provided an alternative method that does not require the construction of a special tableau over the whole database. This method refers to a state obtained from the original database by adding tuples that, for independent schemes, can be efficiently derived. If the insertion is deterministic, then this special state corresponds to the result of the insertion. We have then provided for both insertions and deletions practical algorithms implementing the various characterizations. We have finally shown that under some further conditions, update operations can be managed more easily.

Clearly, when nondeterministic updates arise, the system should not simply reject them but rather try to resolve these situations in some way. Indeed, this can be done in several ways since, in general, the problem is that some information for satisfying the request is missing and there are several possible choices for providing this extra information. For instance, potential ambiguities can be solved by means of a dialogue with the users, similar to the approach described in [8]. Therefore, the algorithms we have presented can be extended in several ways in order to try to resolve nondeterministic update operations.

New classes of database schemes, generalizing the class of independent schemes, have been introduced [14, 30]. Similar to the independent ones, these schemes enjoy the property that the consistency of a database state after a simple update to a base relation can be efficiently verified. Thus, it could be interesting to extend the results of this paper to these more general classes of schemes.

Acknowledgment. We would like to thank the anonymous referees for their very helpful comments and suggestions.

LEARNING DNF OVER THE UNIFORM DISTRIBUTION USING A QUANTUM EXAMPLE ORACLE*

NADER H. BSHOUTY† AND JEFFREY C. JACKSON‡

Abstract. We generalize the notion of probably approximately correct (PAC) learning from an example oracle to a notion of efficient learning on a quantum computer using a quantum example oracle. This quantum example oracle is a natural extension of the traditional PAC example oracle, and it immediately follows that all PAC-learnable function classes are learnable in the quantum model. Furthermore, we obtain positive quantum learning results for classes that are not known to be PAC learnable. Specifically, we show that disjunctive normal form (DNF) is efficiently learnable with respect to the uniform distribution by a quantum algorithm using a quantum example oracle. While it was already known that DNF is uniform-learnable using a membership oracle, we prove that a quantum example oracle with respect to uniform is less powerful than a membership oracle.

Key words. quantum example oracle, quantum computing, disjunctive normal form (DNF), machine learning, Fourier transform

1. Introduction.

Recently, there has been significant interest in the extent to which quantum physical effects can be used to solve problems that appear to be computationally difficult, using traditional methods [16, 8, 7, 6, 33, 31, 30]. In this paper, we apply quantum methods to questions in computational learning theory. In particular, we focus on the problem of learning—from examples alone—the class DNF of polynomial-size disjunctive normal form expressions.

The DNF learning problem has a long history. Valiant [32] introduced the problem and gave efficient algorithms for learning certain subclasses of DNF. Since then, learning algorithms have been developed for a number of other subclasses of DNF [25, 4, 2, 21, 3, 1, 11, 27, 13, 10] and recently for the unrestricted class of DNF expressions [22], but almost all of these results—in particular the results for the unrestricted class—use membership queries. (The learner is told the output value of the target function on learner-specified inputs.) While Angluin and Kharitonov [5] have shown that if DNF is PAC learnable in a distribution-independent sense (definitions are given in the next section) with membership queries, then it is learnable with respect to polynomial-time computable distributions without these queries, the question of the extent to which membership queries are necessary for distribution-dependent DNF learning is still open. In particular, Jackson's harmonic sieve [22] uses membership queries to learn DNF with respect to the uniform distribution. Can DNF be learned with respect to uniform from a weaker form of oracle?

We show that DNF is efficiently learnable with respect to the uniform distribution by a quantum algorithm that receives its information about the target function from a *quantum example oracle*. This oracle generalizes the traditional PAC example oracle

in a natural way. Specifically, the quantum oracle $QEX(f, D)$ is a traditional PAC example oracle $EX(f, D)$ except that $QEX(f, D)$ produces the example $\langle x, f(x)\rangle$ with amplitude $\sqrt{D(x)}$ rather than with probability $D(x)$. We also show that, with respect to the uniform distribution, a quantum example oracle can be simulated by a membership oracle but not vice versa.

To obtain our quantum DNF learning algorithm, we modify the harmonic sieve algorithm (HS) for learning DNF with respect to uniform using membership queries [22]. In fact, HS properly learns the larger class $\widehat{PT}_1$ of functions expressible as a threshold of a polynomial number of parity functions, and our algorithm properly learns this class as well. The harmonic sieve uses membership queries to locate parity functions that correlate well with the target function with respect to various near-uniform distributions. The heart of our result is showing that these parities can be located efficiently by a quantum algorithm, using only a quantum example oracle.

Our primary result, then, is to show that DNF is quantum-learnable, using an oracle that is strictly weaker than a membership oracle. Our algorithm also possesses a somewhat better asymptotic bound on running time than the harmonic sieve. We consider the potential significance of these results in more detail in the concluding section.

2. Definitions and notation.

2.1. Functions and function classes. We will be interested in the learnability of sets (*classes*) of Boolean functions over $\{0,1\}^n$ for fixed positive values of n. It will be convenient to use different definitions for "Boolean" in different contexts within this paper. In particular, at times we will think of a Boolean function as mapping to $\{0,1\}$ and at other times to $\{-1,+1\}$; the choice will either be indicated explicitly or clear from context. We call $\{0,1\}^n$ the *instance space* of a Boolean function f, an element x in the instance space an *instance*, and the pair $\langle x, f(x)\rangle$ an *example* of f. We denote by x_i the ith bit of instance x.

Intuitively, a learning algorithm should be allowed to run in time polynomial in the complexity of the function f to be learned; we will use the *size* of a function as a measure of its complexity. The size measure will depend on the function class to be learned. In particular, each function class $\mathcal{F}$ that we study implicitly defines a natural class $\mathcal{R}_{\mathcal{F}}$ of representations of the functions in $\mathcal{F}$. We define the *size of a function* $f \in \mathcal{F}$ as the minimum, over all $r \in \mathcal{R}_{\mathcal{F}}$ such that r represents f, of the size of r, and we define below the size measure for each representation class of interest.

A DNF expression is a disjunction of *terms*, where each term is a conjunction of *literals* and a literal is either a variable or its negation. The *size of a DNF expression* r is the number of terms in r. The *DNF function class* is the set of all functions that can be represented as a DNF expression of size polynomial in n.

Following Bruck [12], we use $\widehat{PT}_1$ to denote the class of functions on $\{0,1\}^n$ expressible as a depth-2 circuit with a majority gate at the root and polynomially many parity gates at the leaves. All gates have unbounded fanin and fanout 1. The *size of a* $\widehat{PT}_1$ *circuit* r is the number of parity gates in r.

2.2. Quantum turing machines. We now review the model of quantum computation defined by Bernstein and Vazirani [6]. First we define how the specification (program) of a *quantum Turing machine* (QTM) is written down. Then we describe how a QTM operates.

The specification of a QTM is almost exactly the same as the specification of a probabilistic TM (PTM). Recall that the transition table of a PTM specifies, for each state and input symbol, a set of moves—a move is a next state, new tape symbol, and head movement direction—along with associated probabilities that each move will be chosen. Of course, these probabilities must be nonnegative and sum to 1. In a QTM specification, the transition probabilities between PTM configurations are replaced with complex-valued numbers (*amplitudes*) that satisfy a certain *well-formedness* property. Loosely speaking, if the sum of the squares of the amplitudes for the transitions corresponding to each state/symbol pair is 1, then the QTM satisfies the well-formedness property. A somewhat peculiar aspect of amplitudes is that they may have negative real components, unlike the probabilities of the PTM model. Formally, we define well-formedness as follows. For a QTM M, let R_M be the (infinite-dimensional) matrix where each row and each column is labeled with a distinct machine configuration (c_r and c_c, respectively) and each entry in R_M is the amplitude assigned by M to the transition from configuration c_c to c_r. Then M satisfies the well-formedness property if R_M is unitary ($R_M^\dagger R_M = R_M R_M^\dagger = I$, where $R_M^\dagger$ is the transpose conjugate of R_M). A QTM specification also contains a set of states (including all of the final states) in which an *Obs* operation is performed; we define this operation below.

To describe the operation of a QTM, we use the notion of a *superposition* of configurations. For example, consider a probabilistic Turing machine M' that at step i flips a fair coin and chooses to transition to one of two configurations c_1 and c_2. While we would generally think of M' as being in exactly one of these configurations at step $i+1$, we can equivalently think of M' as being in *both* states, each with probability $1/2$. Continuing in this fashion, for each step until M' terminates we can think of M' as being in a superposition of states, each state with an associated probability. After M' takes its final step, each of its final states will have some associated probability (we assume without loss of generality that all computation paths in M' have the same length). If M' now "chooses" to be in one of these final states σ_f randomly according to the induced probability distribution on final states, then the probability of being in σ_f is exactly the same in this model as it is in the traditional PTM model.

In summary, we can view a PTM M' as being in a superposition of configurations at each step, where a superposition is represented by a vector of probabilities, one for each possible configuration of M'. Likewise, we view a QTM M as being in a superposition of configurations at each step, but now the superposition vector contains an amplitude for each possible configuration of M. The initial superposition vector in both cases is the all-zero vector except for a single 1 in the position corresponding to the initial configuration of the machine. Note that each step of a PTM M' can be accomplished by multiplying the current superposition vector by a matrix $R_{M'}$, which is defined analogously with R_M above. In the same way, each step of a QTM M is accomplished by multiplying its current superposition vector by R_M. The difference between the machines comes at the point(s) where M "chooses" to be in a single configuration rather than in a superposition of configurations. M does this (conceptually) by transitioning to a superposition of configurations all of which are in one of the *Obs* states mentioned above. The superposition vector is then changed so that a single configuration has amplitude 1 and all others are 0. This is exactly analogous to the PTM M' choosing its final state, except that the probability of choosing each configuration c_i is now the *square* of the magnitude of the amplitude associated with c_i in M's current superposition vector.

The notation

$$\sum_x a_x|x\rangle$$

denotes a superposition of configurations x, each having amplitude a_x. While in general this sum is over all possible configurations of the QTM, when we use this notation it will be the case (unless otherwise noted) that all of the configurations having nonzero amplitude are in the same state and have the tape head at the same position. In this case, the configurations x are distinguished only by their tape contents, so we will treat x as if it is merely the tape content and ignore the other configuration parameters. We will also assume that all tapes contain the same number of nonblank characters unless otherwise noted.

Given this notation, we now more formally define the *Obs* operation. Intuitively, an *Obs* will collapse a superposition S to one of two possible superpositions, S_0 or S_1, with the choice of superposition based on a probability that is a function of the value of the first bit of the tape (we are implicitly assuming that when an *Obs* is performed the configurations in a superposition differ only in terms of what is on the respective tapes, which will be sufficient for our purposes). Specifically, let $b \in \{0, 1\}$. Then

$$Obs\left(\sum_{bx} a_{bx}|bx\rangle\right)$$

$$= \begin{cases} \sum_x \frac{a_{0x}}{\sum_y |a_{0y}|^2}|0x\rangle & \text{with probability } \sum_x |a_{0x}|^2, \\ \sum_x \frac{a_{1x}}{\sum_y |a_{1y}|^2}|1x\rangle & \text{with probability } \sum_x |a_{1x}|^2. \end{cases}$$

Note that by permuting bits of the tape and performing successive *Obs* operations we can simulate the informal definition of *Obs* given earlier. We say that a language L is in BQP if there exists a QTM M such that, at the end of a number of steps by M polynomial in the length of the input to M, an *Obs* fixes the first tape cell to 1 with probability at least 2/3 if the input is in L and fixes it to 0 with probability at least 2/3 otherwise. We will also sometimes think of an *Obs* as simply computing the probability that the first cell will be fixed to 1.

Finally, we will at times want to introduce deterministic transitions into our QTMs while preserving the well-formedness property of the transition matrices. It can be shown [15] that as long as a deterministic computation is *reversible*, then the computation can be carried out on a QTM. Informally, a computation is reversible if given the result of the computation it is possible to determine the input to the computation. (See [6] for a formal definition and discussion of reversibility in the context of quantum computation.)

2.3. Standard learning models. We begin by defining the well-known PAC learning model and then generalize this to a quantum model of learning. First, we define several supporting concepts. Given a function f and probability distribution D on the instance space of f, we say that the Boolean function h having as its domain the instance space of f is an *ϵ-approximator for f with respect to D* if $\Pr_D[h = f] \geq 1 - \epsilon$. An *example oracle for f with respect to D* ($EX(f, D)$) is an oracle that on request draws an instance x at random according to probability distribution D and returns the example $\langle x, f(x)\rangle$. A *membership oracle for f* ($MEM(f)$) is an oracle that given

any instance x returns the value $f(x)$. Let $\mathcal{D}_n$ denote a nonempty set of probability distributions on $\{0,1\}^n$. Any set $\mathcal{D} = \cup_n \mathcal{D}_n$ is called a *distribution class*. We let $\mathcal{U}_n$ represent the uniform distribution on $\{0,1\}^n$ and call $\mathcal{U} = \cup_n \mathcal{U}_n$ simply the *uniform distribution.*

Now we formally define the probably approximately correct (PAC) model of learnability [32]. Let ϵ and δ be positive values (called the *accuracy* and *confidence* of the learning procedure, respectively). Then we say that the function class $\mathcal{F}$ is *(strongly) PAC learnable* if there is an algorithm $\mathcal{A}$ such that for any ϵ and δ, any $f \in \mathcal{F}$ (the *target function*), and any distribution D on the instance space of f (the *target distribution*), with probability at least $1 - \delta$ algorithm $\mathcal{A}(EX(f,D), \epsilon, \delta)$ produces an ϵ-approximation for f with respect to D in time polynomial in n, the size of f, $1/\epsilon$, and $1/\delta$. The probability that $\mathcal{A}$ succeeds is taken over the random choices made by EX and $\mathcal{A}$ (if any). We generally drop the "PAC" from "PAC learnable" when the model of learning is clear from context.

We will consider several variations on the basic learning models. Let $\mathcal{M}$ be any model of learning (e.g., PAC). If $\mathcal{F}$ is $\mathcal{M}$-learnable by an algorithm $\mathcal{A}$ that requires a membership oracle, then $\mathcal{F}$ is *$\mathcal{M}$-learnable, using membership queries*. If $\mathcal{F}$ is $\mathcal{M}$-learnable for $\epsilon = 1/2 - 1/p(n,s)$, where p is a fixed polynomial and s is the size of f, then $\mathcal{F}$ is *weakly $\mathcal{M}$-learnable*. We say that $\mathcal{F}$ *is $\mathcal{M}$-learnable by $\mathcal{H}$* if $\mathcal{F}$ is $\mathcal{M}$-learnable by an algorithm $\mathcal{A}$ that always outputs a function $h \in \mathcal{H}$. If $\mathcal{F}$ is $\mathcal{M}$-learnable by $\mathcal{F}$, then we say that $\mathcal{F}$ is *properly* $\mathcal{M}$-learnable. Finally, note that the PAC model places no restriction on the example distribution D; we sometimes refer to such learning models as *distribution-independent*. If $\mathcal{F}$ is $\mathcal{M}$-learnable for all distributions D in distribution class $\mathcal{D}$ then $\mathcal{F}$ is *$\mathcal{M}$-learnable with respect to $\mathcal{D}$*. Learning models which place a restriction on the distributions learned against we call *distribution-dependent* models.

2.4. The Fourier transform. We will make substantial use of the discrete Fourier transform in our analysis; this approach was introduced in machine learning by Linial, Mansour, and Nisan [28]. In this section we give some basic definitions and standard theorems.

For each bit vector $a \in \{0,1\}^n$ we define the function $\chi_a : \{0,1\}^n \to \{-1,+1\}$ as

$$\chi_a(x) = (-1)^{\sum_{i=1}^n a_i x_i} = 1 - 2\left(\sum_{i=1}^n a_i x_i \bmod 2\right).$$

That is, $\chi_a(x)$ is the Boolean function that is 1 when the parity of the bits in x indexed by a is even and is -1 otherwise. With inner product defined by[1] $\langle f, g\rangle = \mathbf{E}_x[f(x)\cdot g(x)] \equiv \mathbf{E}[fg]$ and norm defined by $\|f\| = \sqrt{\mathbf{E}[f^2]}$, $\{\chi_a \mid a \in \{0,1\}^n\}$ is an orthonormal basis for the vector space of real-valued functions on the Boolean cube $\mathbf{Z}_2^n$. That is, every function $f : \{0,1\}^n \to \mathbf{R}$ can be uniquely expressed as a linear combination of parity functions:

$$f = \sum_{a\in\{0,1\}^n} \hat{f}(a)\chi_a,$$

where $\hat{f}(a) = \mathbf{E}[f\chi_a]$. We call the vector of coefficients $\hat{f}$ the *Fourier transform* of f. Note that for f mapping to $\{-1,+1\}$, $\hat{f}(a)$ represents the correlation of f and χ_a

[1] Expectations and probabilities here and elsewhere are with respect to the uniform distribution over the instance space unless otherwise indicated.

with respect to the uniform distribution. Also, let 0^n represent the vector of n zeros. Then $\hat{f}(0^n) = \mathbf{E}[f\chi_{0^n}] = \mathbf{E}[f]$, since χ_{0^n} is the constant function $+1$.

By Parseval's identity, for every real-valued function f, $\mathbf{E}[f^2] = \sum_{a\in\{0,1\}^n} \hat{f}^2(a)$. For f mapping to $\{-1,+1\}$ it follows that $\sum_a \hat{f}^2(a) = 1$. More generally, it can be shown that for any real-valued functions f and g, $\mathbf{E}[fg] = \sum_a \hat{f}(a)\hat{g}(a)$.

3. The quantum example oracle. While it has been shown that DNF is learnable with respect to the uniform distribution if membership queries are available to the learning algorithm [22], it is desirable to have a DNF learning algorithm that can learn from examples alone. This seems to be a hard problem, using conventional computing paradigms. However, other problems—such as integer factorization—which had seemed to be hard have recently been shown to have efficient quantum solutions [30]. Thus it is natural to ask the following question: Is there a QTM M such that, given access to a traditional PAC example oracle $EX(f,D)$ for any function f in DNF, M efficiently learns an ϵ-approximation to f?

In this paper, we consider a related question that we hope may shed some light on the question posed above. Specifically, we consider the question of learning DNF from a *quantum example oracle*. This oracle, which we define below, generalizes the PAC example oracle to the quantum setting in a natural way. It should be noted that questions about the power of quantum computing relative to oracles has been investigated previously; for example, Berthiaume and Brassard [8, 7] consider the relative abilities of quantum and more traditional Turing machines to answer decision questions relative to a membership oracle.

We now define the quantum example oracle. Note that each call to the traditional PAC example oracle $EX(f,D)$ can be viewed as defining a superposition of 2^n configurations, each containing a distinct $\langle x, f(x)\rangle$ pair and having probability of occurrence $D(x)$. We generalize this to the quantum setting in a natural way. A *quantum example oracle for f with respect to D* ($QEX(f,D)$) is an oracle running coherently with a QTM M that changes M's tape $|y\rangle$ to

$$\sum_x \sqrt{D(x)}|y, x, f(x)\rangle.$$

That is, QEX defines a superposition of 2^n configurations much as EX does, but QEX assigns each configuration an amplitude $\sqrt{D(x)}$. As with the *Obs* operation, calls to QEX will be invoked by transitioning into designated states of M, and we will assume that any valid QTM program has the property that at each step either all of the states with nonzero amplitude in a superposition call QEX or none do. Note that for any f and D, a call to $QEX(f,D)$ followed by an appropriate *Obs* operation is equivalent to a call to $EX(f,D)$. We say that $\mathcal{F}$ is *quantum learnable* if $\mathcal{F}$ is PAC learnable by a QTM M using a quantum example oracle. Because every efficient TM computation can be simulated efficiently by a QTM [6] and because EX can be simulated by QEX, we have that every PAC-learnable function class is also quantum learnable.

For both standard and quantum example oracles, we use $EX(f)$ (respectively, $QEX(f)$) to represent learning with respect to the uniform distribution, that is, $EX(f,\mathcal{U}_\setminus)$ (respectively, $QEX(f,\mathcal{U}_\setminus)$).

4. Learning DNF from a membership oracle. In the next section we present our primary result, that DNF is quantum learnable with respect to the uniform distribution. Our result builds on the harmonic sieve (`HS`) algorithm for learning DNF with

respect to the uniform distribution using membership queries [22]. In this section we briefly review the harmonic sieve.

4.1. Overview of HS. The HS algorithm depends on a key fact about DNF expressions: for every DNF f and distribution D there is a parity χ_a that is a weak approximator to f with respect to D [22]. Also, for any function weakly approximable with respect to uniform by a parity function, a technique originally due to Goldreich and Levin [20] and first applied within a learning algorithm (KM) by Kushilevitz and Mansour [26] can be used to *find* such a parity (using membership queries). Combining these two facts gives that the KM algorithm weakly learns DNF with respect to uniform [9].

An obvious method to consider for turning this weak learner into a strong learner is some form of hypothesis boosting [29, 18, 17, 19]. In fact, HS is based on a particularly simple and efficient version of boosting discovered by Freund [18]. Each stage i of Freund's boosting algorithm explicitly defines a distribution D_i and calls on a weak learner to produce a weak approximator with respect to D_i. Distribution D_i is defined in terms of the performance of the weak hypotheses produced at the preceding boosting stages and in terms of the target distribution D. After a polynomial number of stages, a majority vote over the weak hypotheses gives a strong approximator with respect to D.

So in order to strongly learn DNF with respect to a distribution D, all that is needed is an efficient algorithm for weakly learning DNF with respect to the set of distributions $\{D_i\}$ defined by Freund's algorithm in the process of boosting with respect to D. While the question of whether or not such an algorithm exists for arbitrary D is an open problem, it is known that when boosting with respect to *uniform* a modified version of the KM algorithm can efficiently find a weakly approximating parity for any DNF f with respect to any of the distributions D_i defined by Freund's algorithm [22]. When learning with respect to such a distribution D_i, the modified KM algorithm must be given not only a membership oracle for f but also an oracle for the distribution D_i, that is, a function which given an instance x returns the weight that D_i places on x. Because Freund's booster explicitly defines the distribution D_i at each boosting stage i, an oracle for each D_i can be simulated and therefore the modified KM algorithm can be boosted by a modified version of Freund's algorithm that supplies D_i to the weak learner at each stage i. This then gives a strong learning algorithm that uses membership queries to learn DNF with respect to the uniform distribution.

4.2. Algorithmic details. The HS algorithm and its primary subroutine WDNF (the modified KM) are sketched in somewhat more detail in Figures 4.1 and 4.2. We will assume here and elsewhere that the number of terms s in the target function's representation as a DNF is known. This assumption can be relaxed by placing a standard guess-and-double loop around the body of the HS program (see, e.g., [24] for details); this increases the running time of the algorithm by at most a factor of $\log s$. The HS algorithm runs for $O(s^2 \log(1/\epsilon))$ stages. At each stage i, $r_i(x)$ (line 8) represents the number of weak hypotheses w_j among those hypotheses produced before stage i that are "right" on x. For uniform target distribution, the distributions D_i defined by Freund's booster are given by

$$D_i(x) = \frac{\alpha^i_{r_i(x)}}{\sum_y \alpha^i_{r_i(y)}}, \tag{4.1}$$

Invocation: $h \leftarrow \texttt{HS}(n, s, MEM(f), \epsilon, \delta)$
Input: n; s = size of DNF f; $MEM(f)$; $\epsilon > 0$; $\delta > 0$
Output: with probability at least $1-\delta$ (over random choices made by HS), HS returns h such that $\Pr[f = h] \geq 1 - \epsilon$

1. $\gamma \leftarrow 1/(8s+4)$
2. $k \leftarrow \frac{1}{2}\gamma^{-2}\ln(4/\epsilon)$
3. $w_0 \leftarrow \texttt{WDNF}(n, s, MEM(f), \mathcal{U}_n, \delta/2k)$
4. **for** $i \leftarrow 1, \ldots, k-1$ **do**
5. $\quad B(j; n, p) \equiv \binom{n}{j} p^j (1-p)^{n-j}$
6. $\quad \beta_r^i \equiv B(\lfloor k/2 \rfloor - r; k-i-1, 1/2+\gamma)$ if $i - k/2 < r \leq k/2$, $\beta_r^i \equiv 0$ otherwise
7. $\quad \alpha_r^i \equiv \beta_r^i / \max_{r=0,\ldots,i-1}\{\beta_r^i\}$.
8. $\quad r_i(x) \equiv |\{0 \leq j < i \mid w_j(x) = f(x)\}|$
9. $\quad \Theta \equiv c_2 \epsilon^3$
10. $\quad E_\alpha \leftarrow \textbf{Est}(\mathbf{E}_x[\alpha^i_{r_i(x)}], EX(f), \Theta/3, \delta/2k)$
11. $\quad$ **if** $E_\alpha \leq 2\Theta/3$ **then**
12. $\quad\quad k \leftarrow i$
13. $\quad\quad$ **break do**
14. $\quad$ **endif**
15. $\quad \tilde{D}_i(x) \equiv \alpha^i_{r_i(x)} / 2^n E_\alpha$
16. $\quad w_i \leftarrow \texttt{WDNF}(n, s, MEM(f), \tilde{D}_i(x), \delta/2k)$
17. **enddo**
18. $h(x) \equiv MAJ(w_0(x), w_1(x), \ldots, w_{k-1}(x))$
19. **return** h

FIG. 4.1. *Harmonic sieve* (HS) *algorithm for learning DNF from a membership oracle.* **Est**$(E, EX(f), \epsilon, \delta)$ *uses random sampling from* $EX(f)$ *to efficiently estimate the value of* E*, producing a value within an additive factor of* ϵ *of the true value with probability at least* $1-\delta$*.* c_2 *represents a fixed constant (*$1/57$ *is sufficient).*

Invocation: $w_i \leftarrow \texttt{WDNF}(n, s, MEM(f), cD, \delta)$
Input: n; s = size of DNF f; $MEM(f)$; cD, an oracle that given x returns $c \cdot D(x)$, where c is a constant in $[1/2, 3/2]$ and D is a probability distribution on $\{0,1\}^n$; $\delta > 0$
Output: with probability at least $1-\delta$ (over random choices made by WDNF), WDNF returns h such that $\Pr_D[f = h] \geq 1/2 + 1/(8s+4)$

1. $g(x) \equiv 2^n f(x) c D(x)$
2. find (using membership queries and with probability at least $1-\delta$) χ_a such that $|\mathbf{E}[g\chi_a]| \geq c/(4s+2)$
3. $h(x) \equiv \text{sign}(\mathbf{E}[g\chi_a]) \cdot \chi_a(x)$
4. **return** h

FIG. 4.2. WDNF *subroutine called by* HS.

where $\alpha_{r_i(x)}$ is defined in Figure 4.1. Note that while D_i is explicitly defined, it is not computationally feasible to compute D_i exactly because of the sum over an exponential number of terms in the denominator of (4.1). However, by a Chernoff bound argument this sum, and therefore D_i, can be closely approximated in time polynomial in the standard parameters. The function $\tilde{D}_i$ is HS's approximation to D_i. Note that because of the bound on the variable E_α and the accuracy with which E_α estimates $\mathbf{E}_x[\alpha^i_{r_i(x)}]$, with probability at least $1 - \delta/2k$, $\mathbf{E}_x[\alpha^i_{r_i(x)}] = c_3 E_\alpha$ for fixed $c_3 \in [1/2, 3/2]$. With the same probability, then, $\tilde{D}_i(x) = c_3 D_i(x)$ for all x.

Therefore, while we show WDNF in Figure 4.1 being called with an argument $\tilde{D}_i(x)$, the corresponding parameter in Figure 4.2 is cD, an oracle representing the product of a constant and a probability distribution. This oracle, along with the membership oracle for the target f, is used by WDNF to simulate an oracle g. We have omitted the details of line 2 of WDNF because this is the main point at which our quantum algorithm will differ from HS. Rather than using membership queries to locate the required parity χ_a, the new algorithm will use a quantum example oracle. Both algorithms depend on a key fact about DNF expressions [22]: for every DNF f with s terms and for every distribution D there exists a parity χ_a such that

$$|\mathbf{E}_D[f\chi_a]| \geq \frac{1}{2s+1}.$$

It follows from the definition of expectation that for either $h = \chi_a$ or $h = -\chi_a$

$$\mathbf{Pr}_D[f = h] \geq \frac{1}{2} + \frac{1}{4s+2}.$$

The WDNF algorithm can only guarantee to find a parity which is nearly optimally correlated with the target, which is why another factor of two is given up by the algorithm. Finally, WDNF also relies on the easily verified fact that for $g(x) = 2^n f(x)cD(x)$, $\mathbf{E}[g\chi_a] = c\mathbf{E}_D[f\chi_a]$. In essence, by combining the target f and distribution D we create a function g with the property that the large Fourier coefficients of g correspond to parities that are weak approximators to f with respect to D. This is why the hypothesis returned by WDNF is appropriate.

The version of WDNF modified to utilize a quantum example oracle is based on a similar idea of learning with respect to uniform in order to find a weak hypothesis with respect to a nonuniform distribution, but the implementation of the idea is quite different. We develop the modified algorithm in detail in the next section.

5. Learning DNF from a quantum example oracle. In this section we show how to modify the harmonic sieve in order to uniform-learn DNF using a quantum example oracle rather than a membership oracle. First, consider the call to WDNF at line 16 of HS for a fixed i, and for notational convenience let $D \equiv D_i$ and $\alpha(x) \equiv \alpha^i_{r_i(x)}$. Then, given the discussion concerning $\tilde{D}_i$ above and the definition of $\tilde{D}_i$ at line 15 in Figure 4.1, with high probability there is a $c_3 \in [1/2, 3/2]$ such that for all χ_a

$$\sum_x f(x)\chi_a(x)\tilde{D}_i(x) = c_3\mathbf{E}_D[f\chi_a] = \mathbf{E}[\alpha f\chi_a]/E_\alpha.$$

Also, again with high probability, the call to **Est** at line 10 is successful in estimating $\mathbf{E}[\alpha]$ to within the desired accuracy and therefore $E_\alpha \geq 2\Theta/3$. Applying this observation to the equation above and invoking the key DNF fact cited earlier gives that, with high probability, each time WDNF is called there exists some χ_a such that

$$|\mathbf{E}[\alpha f\chi_a]| \geq \frac{\Theta}{3(2s+1)} = \frac{c_2\epsilon^3}{3(2s+1)}, \tag{5.1}$$

and this χ_a (or its inverse) is a $(1/(4s+2))$-approximator to f. Our goal will be to find such a χ_a, or at least one that is nearly as good an approximator, using only a quantum example oracle for f.

Conceptually, to find such a χ_a we will repeatedly run a quantum subprogram that randomly selects one χ_a each time the subprogram runs. On any given run each

χ_a is selected with probability proportional to $\mathbf{E}^2[\alpha f \chi_a]$. The technique we use to perform this random sampling from the set of χ_a's is similar to a quantum algorithm of Bernstein and Vazirani that samples the χ_a's with probability $\hat{f}^2(a) = \mathbf{E}^2[f\chi_a]$. However, there are two difficulties with using their technique directly. First, their algorithm uses calls to the function f (membership queries), and we want an algorithm that uses only quantum example queries. Second, their technique works for Boolean ($\{-1,+1\}$-valued) functions, but the pairwise product αf, viewed as representing a single function, is clearly not Boolean in general. We address each of these difficulties in turn below.

5.1. Randomly selecting parities using a quantum example oracle. Our first step in modifying `WDNF` to learn from a quantum example oracle for Boolean f—$QEX(f)$—rather than from a membership oracle is to show that we can randomly select parity functions with probability proportional to $\hat{f}^2$, using only $QEX(f)$. The proof of the following lemma presents the required algorithm `QSAMP`.

LEMMA 1. *There is a quantum program* `QSAMP` *that, given any quantum example oracle $QEX(f)$ for $f : \{0,1\}^n \to \{-1,+1\}$, returns χ_a with probability $\hat{f}^2(a)/2$.*

Proof. `QSAMP` begins by calling $QEX(f)$ on a blank tape to get the superposition

$$\frac{1}{2^{n/2}} \sum_x |x, f(x)\rangle.$$

`QSAMP` next replaces $f(x)$ with $(1-f(x))/2$ (call this $f'(x)$); note that $(-1)^{f'(x)} = f(x)$. Then we will apply a Fourier operator F to the entire tape contents. We define F as

$$F(|a\rangle) \equiv \frac{1}{2^{n/2}} \sum_y (-1)^{a \cdot y} |y\rangle,$$

where $|a| = |y| = n$. This operation can be performed in n steps by a quantum Turing machine [6]. Also recall that $(-1)^{a \cdot y} \equiv \chi_a(y) \equiv \chi_y(a)$. Thus applying F gives us

$$\begin{aligned} F\left(\frac{1}{2^{n/2}} \sum_x |x, f'(x)\rangle\right) &= \frac{1}{2^{n/2}} \sum_x F(|x, f'(x)\rangle) \\ &= \frac{1}{2^{n+1/2}} \sum_{x,y,z} (-1)^{x \cdot y} (-1)^{f'(x)z} |y, z\rangle \\ &= \frac{1}{\sqrt{2}} \sum_y \mathbf{E}_x[\chi_y(x) f(x)] |y, 1\rangle \\ &\quad + \frac{1}{\sqrt{2}} \sum_y \mathbf{E}_x[\chi_y(x)] |y, 0\rangle \\ &= \frac{1}{\sqrt{2}} \sum_y \hat{f}(y) |y, 1\rangle + \frac{1}{\sqrt{2}} |\bar{0}, 0\rangle, \end{aligned}$$

where $|y| = |x| = n$ and $|z| = 1$ and the final line follows by orthonormality of the parity basis. An *Obs* operation at this point produces $|y, 1\rangle$ with probability $\hat{f}^2(y)/2$, as desired. ∎

5.2. Sampling parity according to coefficients of non-Boolean functions. While algorithm `QSAMP` is a good first step toward relaxing `HS`'s requirement for a

Invocation: $h \leftarrow$ HS'$(n, s, QEX(f), \epsilon, \delta)$
Input: n; s = size of DNF f; quantum example oracle $QEX(f)$; $\epsilon > 0$; $\delta > 0$
Output: with probability at least $1 - \delta$ (over random choices made by HS$'$), HS$'$ returns h such that $\Pr[f = h] \geq 1 - \epsilon$

1. γ, k, α_r^i, $r_i(x)$, Θ, $\tilde{D}_i(x)$ are defined as in HS
2. $w_0 \leftarrow$ WDNF'$(n, s, MEM(f), \mathcal{U}_n, \delta/2k)$
3. **for** $i \leftarrow 1, \ldots, k-1$ **do**
4. $\quad EX(f) \equiv Obs(QEX(f))$
5. $\quad E_\alpha \leftarrow \mathbf{Est}(\mathbf{E}_x[\alpha^i_{r_i(x)}], EX(f), \Theta/3, \delta/2k)$
6. $\quad$ **if** $E_\alpha \leq 2\Theta/3$ **then**
7. $\quad\quad k \leftarrow i$
8. $\quad\quad$ **break do**
9. $\quad$ **endif**
10. $\quad w_i \leftarrow$ WDNF'$(n, s, QEX(f), \tilde{D}_i(x), \delta/2k)$
11. **enddo**
12. $h(x) \equiv MAJ(w_0(x), w_1(x), \ldots, w_{k-1}(x))$
13. **return** h

FIG. 5.1. *Modified harmonic sieve* (HS$'$) *algorithm for learning DNF from a quantum example oracle* $QEX(f)$.

membership oracle, it is not enough. As noted above, we need to sample the parity functions according to the coefficients of the non-Boolean function αf. We will do this indirectly by sampling over individual bits of the function. First, note that we can limit the accuracy of α and still compute an adequate approximation to $\mathbf{E}[\alpha f \chi_a]$. Let T denote the quantity on the right-hand side of (5.1). Also let $d = \lceil \log(3/T) \rceil = O(\log(s/\epsilon^3))$. Then, since $0 \leq \alpha(x) \leq 1$ for all x, for $\theta(x) = \lfloor 2^d \alpha(x) \rfloor 2^{-d}$, we have

$$|\mathbf{E}[\theta f \chi_a]| \geq |\mathbf{E}[\alpha f \chi_a]| - \frac{T}{3}$$

for all χ_a. Furthermore, note that any value θ taken on by $\theta(x)$ can be written as

$$\theta = \theta_1 2^{-1} + \theta_2 2^{-2} + \cdots + \theta_d 2^{-d} + k 2^{-d},$$

where for each $j \in [1, d]$, $\theta_j \in \{-1, +1\}$ and $k \in \{-1, 0, 1\}$. Thus

$$|\mathbf{E}[\theta f \chi_a]| \leq \max_j |\mathbf{E}[\theta_j f \chi_a]| + \frac{T}{3}.$$

By (5.1), with high probability there exists χ_a such that $|\mathbf{E}[\alpha f \chi_a]| \geq T$. Therefore, for any such χ_a there is a fixed polynomial p_1 and an index j such that $|\mathbf{E}[\theta_j f \chi_a]| \geq 1/p_1(s, 1/\epsilon)$. Furthermore, for each j, the number of χ_a's such that $|\mathbf{E}[\theta_j f \chi_a]| \geq 1/p_1(s, 1/\epsilon)$ is at most $p_1^2(s, 1/\epsilon)$ by Parseval's identity. This suggests that to find a weak approximator to f with respect to D defined as in (4.1), we define θ as above and then apply quantum sampling using each of the d Boolean functions $\theta_j \cdot f$. We formalize this idea in the next section.

5.3. Modified HS algorithm. Combining the above observations, by modifying HS as shown in Figures 5.1 through 5.3, we obtain a quantum algorithm that uses a quantum example oracle to learn DNF with respect to the uniform distribution . The first difference between the new algorithm and the original is that **Est** will now be

Invocation: $w_i \leftarrow$ WDNF'$(n, s, QEX(f), \alpha, \delta)$
Input: n; $s =$ size of DNF f; $QEX(f)$; α, an oracle that given x returns $\alpha(x) \in [0,1]$; $\delta > 0$
Output: with probability at least $1-\delta$ (over random choices made by WDNF'), WDNF' returns h such that $\Pr_D[f = h] \geq 1/2 + 1/(8s+4)$

1. $T \equiv c_2\epsilon^3/(3(2s+1))$
2. $d \equiv \lceil \log(3/T) \rceil$
3. **for** $j \leftarrow 1, \ldots, n$ **do**
4. **for** $\ell \leftarrow 1, \ldots, 2^{2d+1}\ln(2n/\delta)$ **do**
5. $h =$ QSAMP'$(QEX(f), \theta_j)$
6. $EX(f) \equiv Obs(QEX(f))$
7. $E_c \leftarrow$ **Est-a**$(h, EX(f), \alpha, 1/(8s+4), \delta/(n2^{2d+2}\ln(2n/\delta)))$
8. **if** $|E_c| \geq 3/(8s+4)$ **then**
9. **return** $\mathrm{sign}(E_c) \cdot h$
10. **endif**
11. **enddo**
12. **enddo**
13. **return** 1

FIG. 5.2. WDNF' *subroutine called by* HS'. *Procedure* **Est-a**$(h, EX(f), \alpha, \epsilon, \delta)$, *described in the text, estimates* $\mathbf{E}_D[fh]$ *within accuracy* ϵ *with probability at least* $1-\delta$, *where* $D(x) = \alpha(x)/\sum_y \alpha(y)$. θ_j *represents the* j*th bit of* α.

Invocation: $h \leftarrow$ QSAMP'$(QEX(f), \theta_j)$
Input: Quantum example oracle $QEX(f)$; Boolean function $\theta_j(x)$.
Output: For $y \neq \bar{0}$, returns χ_y with probability $\hat{f}^2(y)/2$. Returns $\chi_{\bar{0}}$ with probability $1/2 + \hat{f}^2(\bar{0})/2$.

1. Call $QEX(f)$ on blank tape
2. In superposition, replace (reversibly) $f(x)$ with $(1 - f(x)\theta_j(x))/2$.
3. In superposition, apply Fourier operator F to the $n+1$ bits on the tape.
4. Perform an *Obs* operation.
5. Return χ_y, where y represents the first n bits on the tape.

FIG. 5.3. QSAMP' *subroutine called by* WDNF'.

given a simulated example oracle $EX(f)$—simulated using $QEX(f)$ as explained in section 3—in order to estimate expected values.

The second, more important, difference is that in order to find a weak approximator (line 2 of WDNF) we will use the quantum approach outlined above. That is, for each value of $j \in [1, d]$ we will sample the χ_a's in such a way that the probability of seeing each χ_a is exactly $\mathbf{E}^2[\theta_j f \chi_a]/2$. We do this by running a modified QSAMP that, after calling $QEX(f)$, replaces $f(x)$ with $\theta_j(x) \cdot f(x)$ expressed as a $\{0,1\}$-valued function. This is a reversible operation because x is still on the tape and $\theta_j^2(x) = 1$ for all x; therefore, this operation can be performed by a QTM. As shown in the preceding section, there exists some χ_a and some j such that χ_a is a weak approximator to f and $|\mathbf{E}[\theta_j f \chi_a]| \geq T/3 \geq 2^{-d}$. Therefore, if we run the modified QSAMP' $2^{2d+1}\ln(2n/\delta)$ times for each value of j, then—with probability at least $1 - \delta/2$—at least one of the χ_a's returned by the quantum sampler will be this weak approximator.

Finally, we will again simulate $EX(f)$—this time within WDNF′—in order to test whether or not a given h returned by QSAMP′ is a weak approximator. In order to perform this test, $\mathbf{E}_D[fh]$ is estimated (where D is the distribution defined by α as in (4.1)) by procedure **Est-a**. This procedure, given the uniform-distribution example oracle $EX(f)$ and the function $\alpha(x)$, simulates the example oracle $EX(f, D)$ using the same method as boost-by-filtering algorithms such as Freund's. Specifically, it queries $EX(f)$ and receives the pair $\langle x, f(x)\rangle$. It then flips a biased coin which produces heads with probability $\alpha(x)$. If the coin comes up heads, then the algorithm uses this pair in subsequent processing. Otherwise, it discards the pair, queries $EX(f)$ again, and repeats the coin-flip test. It can be shown that this process efficiently simulates $EX(f, D)$ for the α's produced by our algorithm (see, e.g., [18]). Finally, given $EX(f, D)$, by a standard Chernoff argument we can estimate $\mathbf{E}_D[fh]$ with the required accuracy and confidence with a number of samples polynomial in the appropriate parameters. Overall, WDNF′ allocates half of the confidence δ to estimating the $\mathbf{E}_D[fh]$'s. This gives us

THEOREM 2. *DNF is quantum learnable with respect to uniform.*

Also, $\widehat{PT}_1$, the class of functions expressible as a threshold of a polynomial number of parity functions, has the property that for every $f \in \widehat{PT}_1$ and every distribution D there exists a parity function χ_a that weakly approximates f with respect to D [22]. This was the only property of DNF that we used in the above arguments. Therefore, the following theorem holds.

THEOREM 3. *$\widehat{PT}_1$ is quantum learnable with respect to uniform.*

We now briefly examine the asymptotic time bound of this algorithm. First, Chernoff bounds tell us that to estimate the expected value of a Boolean variable to within an additive tolerance λ with confidence δ requires a sample (and time) $\tilde{O}(\lambda^2)$ (the notation $\tilde{O}(\cdot)$ is the same as standard big-O notation with log factors suppressed; in this case, δ contributes only a log factor and therefore does not appear in the bound). Using this fact and the earlier description of the algorithm, we can straightforwardly show that the algorithm as given has a time bound of $\tilde{O}(ns^6/\epsilon^{12})$. This compares with a bound on the harmonic sieve of $\tilde{O}(ns^8/\epsilon^{18})$. Furthermore, as noted in [24], the ϵ^3 factor that appears in the harmonic sieve can be brought arbitrarily close to ϵ^2; with this improvement the bounds improve to approximately $\tilde{O}(ns^6/\epsilon^8)$ and $(\tilde{O}(ns^8/\epsilon^{12})$, respectively. While neither bound is a "small" polynomial, the quantum algorithm is somewhat of an improvement. It is also reasonable to suspect that future improvements in the running time of the original algorithm would lead to similar improvements in the quantum algorithm as well.

6. Membership oracle versus quantum example oracle. In practice, it is not clear how a quantum example oracle could be constructed without using a membership oracle. Furthermore, because a QTM uses interference over an entire superposition to perform its computations, it might seem that perhaps there is some way to simulate a membership oracle given only a quantum example oracle by choosing a clever interference pattern. In this section we show that this is not the case.

DEFINITION 4. *We say that* membership queries can be quantum-example simulated for function class $\mathcal{F}$ *if there exists a BQP algorithm $\mathcal{A}$ and a distribution D such that for all $f \in \mathcal{F}$ and all x, running $\mathcal{A}$ on input x with quantum example oracle $QEX(f, D)$ produces $f(x)$.*

THEOREM 5. *Membership queries cannot be quantum-example simulated for DNF.*

Before proving this theorem, we develop some intuition. Consider two functions f_0 and f_1 that differ in exactly one input x. Then the superpositions returned by $QEX(f_0, D)$ and $QEX(f_1, D)$ are very similar for "almost all" D. In particular, if we think of superpositions as vectors in an inner product space of dimension 2^n, then there is in general an exponentially small angle between the superpositions generated by these two oracles. This angle will not be changed by unitary transformations. Thus, in general, an observation will be unable to detect a difference between the superpositions produced by $QEX(f_0, D)$ and $QEX(f_1, D)$. Therefore, a BQP algorithm with only a quantum example oracle $QEX(f_i, D)$, $i \in \{0, 1\}$, will be unable to correctly answer a membership query on x for both f_0 and f_1.

We now present two lemmas that will help us to formalize this intuition.

LEMMA 6. *Let $\mathcal{A}$ be a quantum algorithm that makes at most t calls to $QEX(f, D)$ for $f : \{0,1\}^n \to \{0,1\}$. Then there is an equivalent quantum program (modulo a slowdown polynomial in n and t) that makes all t calls at the beginning of the program.*

Proof. Let R_M be the unitary matrix representing the transitions of the QTM M. Let the configurations of M be encoded by bit strings in any reasonable way. Then suppose M is initially in a superposition

$$S_0 = \sum_y a_y |y\rangle,$$

where the sum is over all possible configurations y of M. After a single transition μ, M will be in the superposition

$$S_1 = \sum_{y,z} a_y R_M[z, y] |z\rangle.$$

Now assume that all of the configurations z with nonzero amplitude in S_1 cause $QEX(f, D)$ to be called. (Recall that by definition, either all of the configurations in a superposition cause this to happen or none of them do.) The resulting superposition will be

$$S_2 = \sum_{x,y,z} \sqrt{D(x)} a_y R_M[z, y] |z, x, f(x)\rangle$$

(by $z, x, f(x)$ we mean the configuration that results when $(x, f(x))$ is appended to the tape contents specified by the configuration z). But notice that there is a machine M' that, beginning with S_0, first calls $QEX(f, D)$, producing

$$S_1' = \sum_{x,y} \sqrt{D(x)} a_y |y, x, f(x)\rangle,$$

and then simulates the transition μ. A technical detail of this simulation is that a transition that corresponds to writing in a blank cell of y's tape necessitates shifting x and $f(x)$ to the right one cell first. Thus M' takes at most polynomially (in n) many steps and produces S_2 given S_0. A simple inductive argument completes the proof. ∎

Before presenting the next lemma, we need several definitions.

DEFINITION 7. *Define Obs over* any *linear combination of configurations (i.e., we no longer require that the sum of squared amplitudes be* 1*) as*

$$Obs\left(\sum_x u_x |x\rangle\right) = \sum_{x : x_1 = 1} |u_x|^2.$$

Define the length *of a linear combination of configurations* $S = \sum_x u_x|x\rangle$ *to be* $\|S\| = \sqrt{\sum_x |u_x|^2}$. *For any linear combination of configurations* S *we define for* $i \in \{0,1\}$

$$S^{(i)} = \sum_{x:x_1=i} u_x|x\rangle.$$

LEMMA 8. *Let* S_1 *and* S_2 *be superpositions and let* S *be any linear combination of configurations. Let* W *be any sequence of valid quantum operations. Then*

1. $Obs(S) \le \|S\|^2$;
2. $\|WS\| = \|S\|$;
3. $|\sqrt{Obs(S_1)} - \sqrt{Obs(S_2)}| \le \sqrt{Obs(S_1 - S_2)}$.

Proof. For part 1 we have

$$Obs(S) = \|S^{(1)}\|^2 \le \|S^{(0)}\|^2 + \|S^{(1)}\|^2 = \|S\|^2.$$

Part 2 follows from the fact that W is a unitary operation that preserves length.

To prove part 3 we have

$$\begin{aligned} |\sqrt{Obs(S_1)} - \sqrt{Obs(S_2)}| &= \left| \|S_1^{(1)}\| - \|S_2^{(1)}\| \right| \\ &\le \|S_1^{(1)} - S_2^{(1)}\| \\ &= \sqrt{Obs(S_1 - S_2)}. \end{aligned}$$ □

Proof of Theorem 5. By way of contradiction, assume that M is a QTM that can quantum-simulate membership queries for any DNF h, using calls to $QEX(h, D)$. By Lemma 6, we can assume without loss of generality that all of the calls to $QEX(h, D)$ occur at the beginning of M's program. Take $f(x) = 0$ and $g(x) = x_1^{c_1} \wedge \cdots \wedge x_n^{c_n}$, where $x^d = 1$ if and only if $x = d$. The second function is zero for all assignments to x except $c = (c_1, \ldots, c_n)$. We want to use the simulator M to find $h(c)$ for $h \in \{f, g\}$. The simulator will first make t calls to $QEX(h, D)$, giving

$$S_h = \sum_{z_1,\ldots,z_t} \sqrt{D(z_1)\cdots D(z_t)}|z_1, h(z_1), \ldots, z_t, h(z_t)\rangle.$$

After that, the computation for both f and g is the same in the sense that both computations consist of a series of applications of R_M to S_h. The superpositions S_f and S_g differ only in configurations

$$|z_1, h(z_1), \ldots, z_t, h(z_t)\rangle,$$

where one of the z_i is c.

Therefore,

$$S_f = S_g + E_{f,g},$$

where

$$\begin{aligned} E_{f,g} = &\sum_{(\exists i) z_i = c} \sqrt{D(z_1)\cdots D(z_t)}|z_1, f(z_1), \ldots, z_t, f(z_t)\rangle \\ &- \sum_{(\exists i) z_i = c} \sqrt{D(z_1)\cdots D(z_t)}|z_1, g(z_1), \ldots, z_t, g(z_t)\rangle. \end{aligned}$$

If W represents the sequence of transitions after the initial calls to $QEX(f, D)$, then at the end of the computation by M we observe $Obs(WS_f)$ and $Obs(WS_g)$ for f and g, respectively. By Lemma 8

$$\begin{aligned}
|\sqrt{Obs(WS_f)} - \sqrt{Obs(WS_g)}|^2 &\leq Obs(WE_{f,g}) \\
&\leq \|WE_{f,g}\|^2 \\
&= \|E_{f,g}\|^2 \\
&= 2 \sum_{(\exists i) z_i = c} \left(\sqrt{D(z_1) \cdots D(z_t)}\right)^2 \\
&= 2(1 - (1 - D(c))^t) \\
&\leq 2tD(c).
\end{aligned}$$

For any fixed D, any fixed polynomial p_1, and large enough n, almost all choices of c are such that $D(c) < 1/p_1(n)$. For all such c and appropriately chosen p_1 the observations $Obs(WS_f)$ and $Obs(WS_g)$ are indistinguishable. □

While it is not possible to simulate membership queries in polynomial time given only a quantum example oracle, it is a simple matter to simulate a uniform quantum example oracle with membership queries.

LEMMA 9. *For every Boolean function f, $QEX(f,\mathcal{U})$ can be simulated by a QTM making a single call to $MEM(f)$.*

Proof. $QEX(f,\mathcal{U})$ can be simulated by applying the Fourier transform F to the tape $|\bar{0}\rangle$ and then calling $MEM(f)$. □

Thus a membership oracle for f is strictly more powerful than a uniform quantum example oracle for f.

7. Concluding remarks. We have defined the notion of a quantum example oracle and argued that it is a natural quantum extension of the standard PAC example oracle. We then showed the learnability of DNF (and $\widehat{PT}_1$) with respect to uniform, given access to such an oracle. Such an oracle is also shown to be weaker (with respect to uniform) than a membership oracle.

While we believe that these results are interesting theoretically, like many oracle results in complexity theory the practical significance of our results is not clear. Our algorithm at the very least offers some potential speed-up over an implementation of the unmodified harmonic sieve for learning DNF from a membership oracle on a quantum computer. Also, while we do not currently see how to implement a quantum example oracle without recourse to a membership oracle, it is conceivable that there may be some way to build a quantum example oracle from something (much) less than a full membership oracle, which could add substantially to our algorithm's relevance to practical machine-learning problems. Finally, we hope that these results may provide stepping stones toward answering the larger question of whether DNF can be learned by a QTM from a standard PAC example oracle. A positive answer to this question has potentially great practical significance.

An earlier version of this paper [14] claimed that our quantum algorithm would learn DNF in a generalized persistent noise model. This propagated an erroneous claim by Jackson that the harmonic sieve was noise-tolerant [22]. While a modified version of the harmonic sieve has subsequently been shown to tolerate persistent classification noise [23], we do not consider the quantum extension of that algorithm in this paper, leaving this problem open for further study.

Acknowledgment. N. H. Bshouty thanks Richard Cleve for an enlightening seminar on quantum computation.

APPROXIMABILITY AND NONAPPROXIMABILITY RESULTS FOR MINIMIZING TOTAL FLOW TIME ON A SINGLE MACHINE*

HANS KELLERER†, THOMAS TAUTENHAHN‡, AND GERHARD J. WOEGINGER§

Dedicated to the memory of Gene Lawler

Abstract. We consider the problem of scheduling n jobs that are released over time on a single machine in order to minimize the total flow time. This problem is well known to be NP-complete, and the best polynomial-time approximation algorithms constructed so far had (more or less trivial) worst-case performance guarantees of $O(n)$.

In this paper, we present one positive and one negative result on polynomial-time approximations for the minimum total flow time problem: The positive result is the first approximation algorithm with a *sublinear* worst-case performance guarantee of $O(\sqrt{n})$. This algorithm is based on resolving the preemptions of the corresponding optimum preemptive schedule. The performance guarantee of our approximation algorithm is not far from best possible, as our second, negative result demonstrates: Unless $P = NP$, no polynomial-time approximation algorithm for minimum total flow time can have a worst-case performance guarantee of $O(n^{1/2-\varepsilon})$ for any $\varepsilon > 0$.

Key words. scheduling, approximation algorithm, worst-case analysis, total flow time, release time, single machine

1. Introduction.

Scheduling independent jobs on a single machine has been studied extensively under various objective functions. We consider one of the basic problems of this kind, which from a worst-case point of view also appeared to be among the most intractable ones: There are given n independent jobs $J_1, \ldots, J_n$ which have to be scheduled nonpreemptively on a single machine. Each job J_i has a processing time p_i and becomes available for execution at its release time r_i, where p_i and r_i are nonnegative real numbers. All job data are known in advance. Without loss of generality we assume that the smallest release time is equal to zero. In a certain schedule for these jobs, let C_i be the *completion time* of job J_i, let S_i be its *starting time* (i.e., $S_i + p_i = C_i$), and let $F_i = C_i - r_i$ denote its *flow time*, respectively. The objective is to determine a schedule that minimizes the total flow time $\sum F_i$. This problem is commonly denoted by $1|r_i|\sum F_i$.

In case all job release times are identical, the problem can be solved in $O(n \log n)$ time by applying the well-known *shortest processing time* (SPT) rule; see Smith [19]. For arbitrary release times, the problem becomes NP-complete (Lenstra, Rinnooy Kan, and Brucker [15]). Several authors (Chandra [4], Chu [6], Deogun [7], and

Dessouky and Deogun [8]) developed branch-and-bound algorithms for $1|r_i|\sum F_i$. Other papers (Bianco and Ricciardelli [3], Dyer and Wolsey [10], Hariri and Potts [13], and Posner [18]) gave branch-and-bound algorithms for $1|r_i|\sum w_iF_i$, the problem of minimizing the total *weighted* flow time. Gazmuri [12] designed asymptotically optimal algorithms for minimizing total flow time under very general probability distributions of the job data.

The preemptive version $1|\text{pmtn}, r_i|\sum F_i$ of the problem can be solved in polynomial time by the *shortest remaining processing time* (SRPT) rule (see, e.g., Baker [2]). The objective value of the optimum preemptive schedule clearly is a lower bound on the objective value of the nonpreemptive problem. Ahmadi and Bagchi [1] have shown that it dominates six other lower bounds for $1|r_i|\sum F_i$ that had been used in the scheduling literature.

Approximation algorithms. For an instance I of $1|r_i|\sum F_i$, let $F^H(I)$ denote the total flow time obtained when algorithm H is applied to I, and let $F^*(I)$ be the objective value of an optimum solution for I. We usually write F^H and F^* instead of $F^H(I)$ and $F^*(I)$, respectively, if the instance I is clear from the context. Now let $\rho : \mathbb{R}^+ \to \mathbb{R}^+$ and let H be an approximation algorithm. We say that algorithm H has *worst-case performance guarantee* ρ if

$$\sup\{F^H(I)/F^*(I) \mid I \text{ is an instance with } n \text{ jobs } \} \;\le\; \rho(n)$$

holds for all integers $n \ge 1$.

Chu [5] and Mao and Rifkin [17] investigated several "reasonable" algorithms for $1|r_i|\sum F_i$, but none of them yielded a sublinear worst-case performance guarantee. For instance, a straightforward procedure for $1|r_i|\sum F_i$ is the *earliest start time* (EST) algorithm: "Whenever the machine becomes free for assignment, take the shortest of the (at that time) available jobs and assign it to the machine." The following example shows that the total flow time in an EST schedule can be a factor of n away from the optimum: Let ε be a very small positive real number. Then choose $p_1 = 1$, $p_2 = \cdots = p_n = \varepsilon$, $r_1 = 0$, $r_2 = \cdots = r_n = \varepsilon$. The EST schedule processes the jobs in the ordering $(1, 2, \ldots, n)$ with total flow time $\Omega(n)$, whereas an optimum schedule processes the jobs in the ordering $(2, 3, \ldots, n-1, 1)$ with total flow time $O(1)$.

Another direct approach is the *earliest completion time* (ECT) rule. An ECT schedule is formed by scheduling jobs without any unnecessary idle time, where the next job to be scheduled is the one with the earliest possible completion time of all unscheduled jobs. Again, let ε be a very small positive real number. Then the job data $p_1 = 1 + 2\varepsilon$, $p_2 = \cdots = p_n = \varepsilon$ and $r_i = i - 1$ for all $i = 1, \ldots, n$ yields an ECT schedule of $(2, 3, \ldots, n-1, 1)$ with total flow time $\Omega(n)$, whereas the optimum schedule is $(1, 2, \ldots, n)$ with total flow time $O(1)$. Again, we get a worst-case ratio of n.

New results. The results of this paper are as follows. First we present a polynomial-time approximation algorithm with worst-case performance guarantee of $O(\sqrt{n})$. The algorithm starts from an optimum solution of the corresponding *preemptive* instance. Then the preemptive schedule is transformed step by step into a nonpreemptive one by successively resolving the preemptions. Our proof also demonstrates that for any instance the minimum total flow time of an optimum nonpreemptive schedule is at most a factor of $\sqrt{n}$ larger than the corresponding minimum total flow time of the optimum preemptive schedule.

In the second part of the paper, we prove that polynomial-time approximation algorithms for minimum total flow time on a single machine cannot have a worst-case performance guarantee of $O(n^{1/2-\varepsilon})$ for any $\varepsilon > 0$. This result is derived by an appropriate reduction from the NP-complete numerical three-dimensional matching problem.

Organization of the paper. Section 2 describes the approximation algorithm and proves the claimed worst-case performance guarantee of $O(\sqrt{n})$. Section 3 gives the nonapproximability result, and section 4 contains the discussion.

2. The approximation algorithm. In this section, we design a polynomial-time approximation algorithm for the minimum total flow time problem that has worst-case performance guarantee $O(\sqrt{n})$. The main idea is to start with an optimum solution of the corresponding problem, where preemption is allowed, and then to get rid of the preemptions while increasing the total flow time by only some "moderate" amount.

As already mentioned in the introduction, an optimum preemptive schedule can be obtained by applying the SRPT rule, which is defined as follows: The remaining processing time $P_i(t)$ of job J_i is the amount of processing time of J_i which has not been scheduled before time t. At any time t, the available job J_i with SRPT $P_i(t)$ is processed until it is either completed or until another job J_j with $p_j < P_i(r_j)$ becomes available. In the second case, J_i is preempted and J_j is processed.

We denote the total flow time in an optimum preemptive schedule by F^*_{pmtn}. With every job J_i we associate the interval $\mathcal{I}_i = [S_i, C_i]$ in the preemptive schedule. Note that due to possible preemptions, the length of $\mathcal{I}_i$ in general need not be equal to p_i. Let us observe some simple properties of the SRPT schedule: If a job J_i has a preemption at time t, then the processing of some job J_j with $p_j < P_i(t)$ starts at this time. Consequently, job J_i cannot return to the machine until job J_j is completed.

OBSERVATION 2.1. *In the SRPT schedule, for any two jobs J_i and J_j either the corresponding intervals $\mathcal{I}_i$ and $\mathcal{I}_j$ are disjoint or one of them contains the other one. Furthermore, there is no machine idle time during $\mathcal{I}_i$ and $\mathcal{I}_j$.* □

With the preemptive schedule we associate in the following way a directed ordered forest that describes the containment relations of the intervals $\mathcal{I}_i$. The jobs $J_1, \ldots, J_n$ form the vertices of the forest. We introduce a directed edge going from job J_i to J_j if and only if $\mathcal{I}_j \subseteq \mathcal{I}_i$ and there does not exist a job J_k with $\mathcal{I}_j \subseteq \mathcal{I}_k \subseteq \mathcal{I}_i$. For every vertex J_i, its sons are ordered from left to right according to the ordering of their corresponding intervals $\mathcal{I}_j$. This yields a collection of ordered directed out-trees. Out-trees that consist of a single vertex are called *trivial* out-trees. To complete the definition of the forest, we also order the roots of these out-trees from left to right according to the ordering of their corresponding intervals. By $T(i)$ we denote the maximal subtree of this forest rooted at J_i (hence, $T(i)$ exactly contains those jobs that are processed during $[S_i, C_i]$). A *leaf* is a job with out-degree zero. (Hence, it does not have any preemptions.)

Since our approximation algorithm transforms the preemptive schedule into a nonpreemptive one, the forest associated with the final schedule will be a collection of n trivial out-trees. In sections 2.1, 2.2, and 2.3, we describe three procedures for removing preemptions and simplifying the forest structure. Every procedure acts on a certain subtree $T(i)$ and removes all preemptions of the job J_i. Section 2.4 explains how the approximation algorithm applies and combines these three procedures.

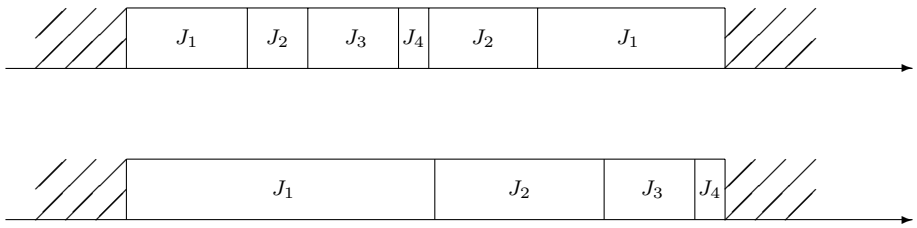

FIG. 1. *Illustration for Procedure SmallSubtree(i) with* $i = 1$.

2.1. How to handle small subtrees. A subtree $T(i)$ is called *small* if it contains at most $\sqrt{n}$ jobs. In this case we use the following procedure to resolve the preemptions of job J_i and of all jobs contained in $T(i)$.

PROCEDURE SmallSubtree(i).
Let $S_i = S_{i_0} < S_{i_1} < \cdots < S_{i_k}$ denote the starting times of the jobs in $T(i)$ in the current preemptive schedule. Remove all jobs and reinsert them without preemptions in the ordering $J_i, J_{i_1}, J_{i_2}, \ldots, J_{i_k}$.

For an illustration, see Figure 1. It is easy to see that SmallSubtree(i) does not decrease the starting time of any job. Hence, the resulting schedule still obeys all release times. Completion times of jobs outside of $T(i)$ are not changed, and the completion times of jobs in $T(i)$ are all increased by less than $C_i - r_i$. Since there are at most $\sqrt{n}$ jobs in $T(i)$,

$$\Delta_{small}(i) \;=\; \sqrt{n} F_i \tag{1}$$

is an upper bound on the increase of the objective function caused by SmallSubtree(i).

2.2. How to handle the last root. Now let J_i be the root of the rightmost nontrivial out-tree. (J_i is preempted, but all jobs that are processed after C_i are without preemptions.) Such a root J_i is called the *last root* and may be handled according to the following procedure.

PROCEDURE LastRoot(i).
Compute $\lceil \sqrt{n} \rceil + 1$ time points $t_0 = C_i, t_1, \ldots, t_{\lceil \sqrt{n} \rceil}$ such that there are exactly hp_i units of idle time between C_i and t_h in the current schedule for all $h \in \{0, \ldots, \sqrt{n}\}$. Determine $0 \le k \le \lceil \sqrt{n} \rceil - 1$ so as to minimize the value of $k + |\{j : \; t_k \le S_j \le t_{k+1}\}|$.
In case there is a job processed during $[t_k, t_k + p_i]$, shift it to the right until its processing is disjoint from $[t_k, t_k + p_i]$. If necessary shift also some later jobs to the right, but without changing their relative orderings and without introducing any unnecessary idle time. Then remove J_i and reschedule it in the interval $[t_k, t_k + p_i]$.

For an illustration, see Figure 2. Since the job starting times are not decreased, the resulting schedule is again feasible. Moreover, by definition of the numbers t_h, there are exactly p_i units of idle time between t_k and t_{k+1}. Hence, the shifting of jobs takes place only within the interval $[t_k, t_{k+1}]$, and no jobs outside of this interval are affected by LastRoot(i).

LEMMA 2.2. *The value of* k *determined by Procedure LastRoot(i) satisfies*

$$k + |\{j : \; t_k \le S_j \le t_{k+1}\}| \;\le\; \frac{3}{2}\sqrt{n}.$$

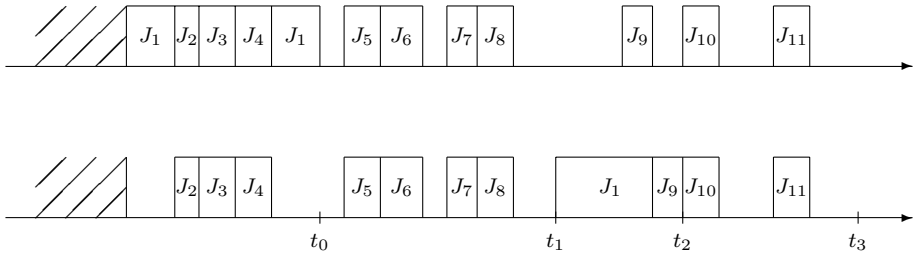

FIG. 2. *Illustration for Procedure LastRoot(i) with* $i = 1$.

Proof. Define $n_h = |\{j : \ t_h \le S_j \le t_{h+1}\}|$. Then

$$\sum_{h=0}^{\lceil\sqrt{n}\,\rceil-1} (h + n_h) \ \le \ \frac{1}{2}\lceil\sqrt{n}\,\rceil(\lceil\sqrt{n}\,\rceil - 1) + n \ \le \ \frac{3}{2}\sqrt{n}\lceil\sqrt{n}\,\rceil.$$

Since k was chosen to minimize $k + n_k$, the value $k + n_k$ is bounded from above by the average of these $\lceil\sqrt{n}\,\rceil$ numbers. □

Procedure LastRoot(i) increases the flow time of job J_i by at most $kp_i + \sum_{j=1}^{n} p_j$. Furthermore, the flow times of at most $n_k = |\{j : t_k \le S_j \le t_{k+1}\}|$ other jobs are increased by at most p_i. By applying Lemma 2.2 one gets that LastRoot(i) increases the value of the objective function by at most

$$\Delta_{last}(i) \ = \ kp_i + \sum_{j=1}^{n} p_j + n_k p_i \ \le \ \frac{3}{2}\sqrt{n}\, p_i + \sum_{j=1}^{n} p_j. \tag{2}$$

Finally, observe that in the new schedule J_i is processed entirely *after* its completion time in the old schedule.

2.3. How to handle fathers and sons. Procedure FatherSon(i, j) described below may be applied only if the jobs J_i and J_j fulfill the following four conditions:

(C1) J_j is a son of J_i.
(C2) All sons of J_i in $T(i)$ that lie to the right of J_j are leaves (i.e., jobs without preemption).
(C3) There are less than $\sqrt{n}$ jobs that lie to the right of J_j in $T(i)$.
(C4) Just before executing FatherSon(i, j), job J_i is removed and rescheduled entirely *after* its old completion time.

Condition (C4) may be fulfilled if J_i is rescheduled by LastRoot(i) or (as we will see) if it is rescheduled by FatherSon(k, i), where k was the father of i at that time. Condition (C4) has the following consequences: At the moment as SRPT decided to start processing J_j instead of J_i, it did so because the remaining processing time of J_i was larger than p_j. Hence, the total time that J_i is processed during $[C_j, C_i]$ is at least p_j, and *in case* J_i *is moved to some place after* C_i*, there is sufficient empty space in* $[C_j, C_i]$ *to schedule all of* J_j.

PROCEDURE FatherSon(i, j).

All jobs that are processed during $[C_j, C_j + p_j]$ are shifted to the right until their processing is disjoint from $[C_j, C_j + p_j]$. If necessary, also, some later jobs are shifted to the right but without changing

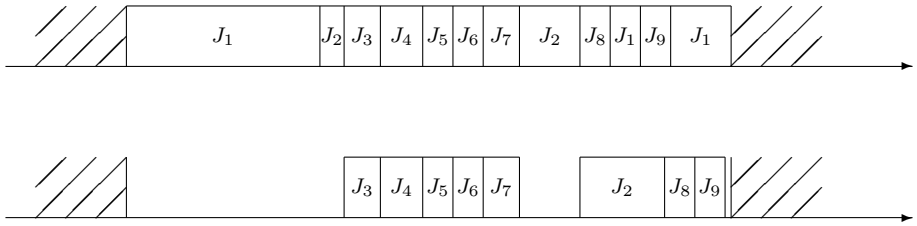

FIG. 3. *Illustration for Procedure FatherSon(i, j) with* $i = 1$ *and* $j = 2$.

their relative orderings and without introducing any unnecessary idle time.

Then remove J_j and reschedule it to the interval $[C_j, C_j + p_j]$.

For an illustration, see Figure 3. Note that in the new schedule J_j is processed entirely *after* its completion time in the old schedule. Furthermore note that Procedure FatherSon(i, j) transforms all sons of J_i in $T(i)$ that lie to the right of J_j into *trivial* out-trees.

Procedure FatherSon(i, j) produces another feasible schedule where job J_j no longer has preemption. Only jobs in the interval $[C_j, C_i]$ are shifted to the right, and no other jobs are affected. All the shifted jobs are contained in $T(i)$, they lie to the right of J_j, and, by condition (C3), their number is less than $\sqrt{n}$. The completion time of every moved job (including job J_j) increases by at most p_j. Hence, the total increase in the value of the objective function that FatherSon(i, j) produces can be bounded by

$$\Delta_{fson}(j) \;=\; \sqrt{n}\, p_j. \tag{3}$$

2.4. Putting everything together. Finally, we describe our approximation algorithm in detail. The algorithm starts with the optimum schedule for the preemptive problem and determines the corresponding directed ordered forest.

In the first phase, Procedure SmallSubtree(i) is applied to all jobs J_i for which $2 \le |T(i)| \le \sqrt{n}$ holds. Afterward, every subtree $T(i)$ either fulfills $|T(i)| = 1$ (and J_i has no preemption) or $|T(i)| > \sqrt{n}$ holds.

In the second phase, the algorithm goes through a number of steps and repeatedly modifies the rightmost nontrivial out-tree. Every such step increases the number of trivial out-trees by at least $\sqrt{n}$. Every step consists of one call to LastRoot, possibly followed by several calls to FatherSon. For a nonleaf vertex J_i in the forest, let RMNLS(i) denote the index of its *rightmost nonleaf son* and let LEAF(i) denote the number of sons of J_i lying to the right of RMNLS(i). (Obviously, all these LEAF(i) sons must be leaves.) Every step of the second phase is performed as follows. Let J_i be the root of the rightmost nontrivial out-tree.

LastRoot(i);
While RMNLS(i) exists and LEAF$(i) < \sqrt{n}$ do
    FatherSon$(i$,RMNLS$(i))$
    $i :=$RMNLS(i)
EndWhile

Let J_{i^*} denote the last job whose preemptions are resolved in such a step. Then either J_{i^*} has more than $\sqrt{n}$ sons (that all are leaves) to the right of RMNLS(i^*) or job

RMNLS(i^*) does not exist. In the latter case, all sons of J_i^* are leaves and, according to the result of the first phase, their number must be greater than $\sqrt{n}$. In either case, there are at least $\sqrt{n}$ leaves that formerly were preempting J_{i^*}, the father of J_{i^*}, its grandfather, and so on—the whole chain of ancestors to the formerly "last root." Since the execution of the step removes all preemptions from this chain of ancestors, it turns all these at least $\sqrt{n}$ leaves into trivial out-trees.

In the second phase of the algorithm the step described above is repeated over and over until all preemption have been removed. Since every step produces at least $\sqrt{n}$ new trivial out-trees, the second phase terminates after at most $\sqrt{n}$ steps. This completes the description of our approximation algorithm.

THEOREM 2.3. *The approximation algorithm described for the problem* $1|r_i|\sum F_i$ *has a worst-case performance guarantee of* $O(\sqrt{n})$*, and it can be implemented to run in* $O(n^{3/2})$ *time. Moreover, there exist instances for which the algorithm yields a schedule whose objective value is* $\Omega(\sqrt{n})$ *from the optimum.*

Proof. To analyze the worst-case behavior of the algorithm, we define job classes $\mathcal{S}$, $\mathcal{L}$, and $\mathcal{F}$. Class $\mathcal{S}$ contains the jobs J_i for which SmallSubtree(i) is executed, $\mathcal{L}$ the jobs J_i for which LastRoot(i) is executed, and $\mathcal{F}$ the jobs J_j for which FatherSon(i, j) is executed. Since every procedure removes all preemptions of the corresponding job, every job is contained in at most one of the classes $\mathcal{S}$, $\mathcal{L}$, and $\mathcal{F}$. Moreover, $|\mathcal{L}| \le \sqrt{n}$ holds, since LastRoot(i) is executed exactly once per step in the second phase, and there are at most $\sqrt{n}$ steps.

The constructed nonpreemptive schedule has an objective value F^H which satisfies

$$\begin{aligned} F^H &\le F^*_{pmtn} + \sum_{i\in\mathcal{S}} \Delta_{small}(i) + \sum_{i\in\mathcal{L}} \Delta_{last}(i) + \sum_{i\in\mathcal{F}} \Delta_{fson}(i) \\ &\le F^*_{pmtn} + \sum_{i\in\mathcal{S}} \sqrt{n} F_i + \sum_{i\in\mathcal{L}} \left(\frac{3}{2}\sqrt{n}\, p_i + \sum_{j=1}^{n} p_j \right) + \sum_{i\in\mathcal{F}} \sqrt{n}\, p_i. \end{aligned}$$

Here we used (1), (2), and (3). If we also apply the straightforward relations $p_i \le F_i$, for $1 \le i \le n$ and $\sum_{i=1}^{n} F_i = F^*_{pmtn}$, together with $|\mathcal{L}| \le \sqrt{n}$, then we determine that

$$F^H \;\le\; F^*_{pmtn} + \frac{3}{2}\sqrt{n} \sum_{i\in\mathcal{S}\cup\mathcal{L}\cup\mathcal{F}} F_i + |\mathcal{L}| \sum_{j=1}^{n} p_j \;\le\; \left(1 + \frac{5}{2}\sqrt{n}\right) F^*_{pmtn} \tag{4}$$

holds. Since $F^*_{pmtn} \le F^*$, this proves that the algorithm has a worst-case performance guarantee of $O(\sqrt{n})$.

What about the time complexity? The SRPT schedule can be computed in $O(n \log n)$ time. Procedure SmallSubtree needs to be run only on the vertices which have at most $\sqrt{n}$ descendants and whose father is either nonexistent or has more than $\sqrt{n}$ descendants. All these vertices can be located in a single $O(n)$ time traversal of the forest. Hence, procedures SmallSubtree and FatherSon are both executed only $O(n)$ times and always consider only $O(\sqrt{n})$ of the jobs. Procedure LastRoot may have to deal with up to $O(n)$ jobs, but it is executed only $O(\sqrt{n})$ times. Summarizing, this yields a time complexity of

$$|\mathcal{S}| \cdot O(\sqrt{n}) + |\mathcal{L}| \cdot O(n) + |\mathcal{F}| \cdot O(\sqrt{n}) \;\le\; O(n^{3/2}).$$

To see that the algorithm can be a factor of $\Omega(\sqrt{n})$ from the optimum, consider the instance of $n = x^2$ jobs: The jobs J_i with $1 \le i \le x - 1$ all have processing

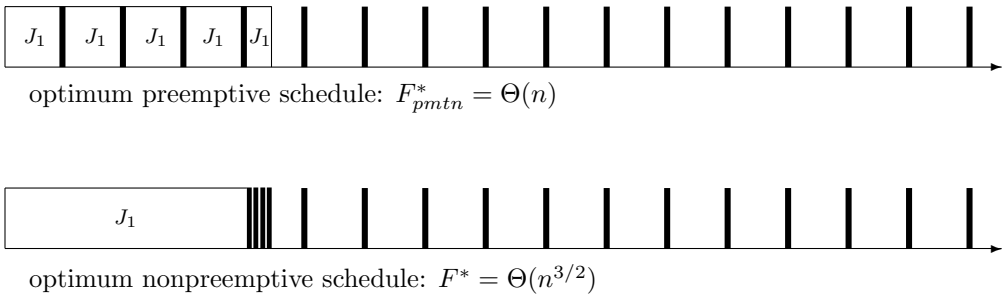

FIG. 4. *Illustration for the lower bound example in Corollary* 2.4.

time $1/(x-1)$ and release times $1+(i-1)/(x-1)$. Job J_x has processing time x^2 and release time 0. The remaining x^2-x jobs are dummy jobs, all with processing times 0 and release times 0. The forest corresponding to the optimum preemptive schedule has a single nontrivial tree with root J_x and $J_1, \ldots, J_{x-1}$ as leaves. Hence, our algorithm calls SmallSubtree(x) and produces a schedule with $F^H = x^3 - x + 2$, whereas $F^* = x^2 + 3$ holds. As x tends to infinity, the ratio F^H/F^* grows like $\Theta(x) = \Theta(\sqrt{n})$. □

COROLLARY 2.4. *For any instance of n jobs with release times on a single machine, the inequality $F^*/F^*_{pmtn} \le \frac{5}{2}\sqrt{n} + 1$ holds. Moreover, for every sufficiently large n, there exists an instance I_n such that $F^*(I_n)/F^*_{pmtn}(I_n) \approx \sqrt{n}$.*

Proof. The upper bound follows from (4) and $F^* \le F^H$. The lower bound follows from the instance with n jobs where $r_1 = 0$, $p_1 = n$, $r_i = (i-1)\sqrt{n}$, and $p_i = \varepsilon = 1/n$ for $i \ge 2$. Then $F^*_{pmtn} \approx n$ and $F^* \approx n^{3/2}$ holds. (See Figure 4.) □

3. The nonapproximability result. In this section, we will prove that no polynomial-time approximation algorithm for minimizing the total flow time may have worst-case performance guarantee $O(n^{1/2-\varepsilon})$ for any $\varepsilon > 0$. The proof is done by a reduction from the following version of the NP-complete numerical three-dimensional matching problem (see Garey and Johnson [11]).

Problem. Numerical three-dimensional matching (N3DM).

Instance. Positive integers a_i, b_i, and c_i, $1 \le i \le k$, with $\sum_{i=1}^{k}(a_i + b_i + c_i) = kD$.

Question. Do there exist permutations π, ψ such that $a_i + b_{\pi(i)} + c_{\psi(i)} = D$ holds for all i?

This problem remains NP-complete even if the numbers a_i, b_i, and c_i are encoded in unary and the total size of the input is $\Theta(kD)$. In the following discussion, we will make use of this unary encoding. Consider an arbitrary instance of N3DM and let $0 < \varepsilon < \frac{1}{2}$ be some real number. Define numbers

$$n = \lceil (20k)^{4/\varepsilon} D^{2/\varepsilon} \rceil, \qquad r = \lceil 2Dn^{(1-\varepsilon)/2} \rceil, \qquad g = 100rk^2.$$

Next we will construct from the N3DM instance and from the number ε a corresponding scheduling instance with n jobs. For every number a_i in the N3DM instance, we introduce a corresponding job with processing time $2r + a_i$, for every b_i we introduce a job with processing time $4r + b_i$, and for every c_i we introduce a job with processing time $8r + c_i$. These $3k$ jobs are called the *big* jobs and they are all released at time 0.

Moreover, there will be a number of so-called *tiny* jobs. Tiny jobs occur only in groups denoted by $G(t;\ell)$, where t and ℓ are positive integers. A group $G(t;\ell)$ consists

of ℓ tiny jobs with processing time $1/\ell$. They are released at the times $t + i/\ell$ for $i = 0, \ldots, \ell - 1$. Note that it is possible to process all jobs in $G(t; \ell)$ in a feasible way during the time interval $[t, t + 1]$ with a total flow time of 1. We introduce the following groups of tiny jobs.

(T1) For $1 \le i \le k$, we introduce the group $G((14r + D + 1)i - 1; rg)$.

(T2) For $1 \le i \le g$, we introduce the group $G((14r + D + 1)k + ri - 1; g)$.

In a pictorial setting, the groups of type (T1) occur at regular intervals from time $14r + D$ to time $(14r + D + 1)k$. They leave k holes, where each hole has length $14r + D$. Similarly, the groups of type (T2) occur in a regular pattern after time $(14r + D + 1)k$. They leave holes of size $r - 1$.

So far we have introduced $3k$ big jobs and $k + 100rk^2$ groups of tiny jobs, which amounts to an overall number of

$$3k + krg + 100rk^2 g = 3k + 100r^2k^3 + 10,000r^2k^4 < 11,000r^2k^4 < n$$

jobs. In order to simplify calculations, we introduce a number of artificial jobs all with processing time zero and release time zero such that the total number of jobs becomes equal to n. This completes the construction of the scheduling instance.

LEMMA 3.1. *If the N3DM instance has a solution, then for the constructed scheduling instance $F^* \le 200rk^2$ holds.*

Proof. Consider the following feasible schedule. All tiny jobs are processed immediately at their release times. Hence, their total flow time equals $k + 100rk^2$. For every triple $(a_i, b_{\pi(i)}, c_{\psi(i)})$ with sum D in the solution of the N3DM instance, we pack the corresponding three jobs together into one of the holes of length $14r + D$ that are left free by the groups of type (T1). The job corresponding to a_i is processed first, the job corresponding to $b_{\pi(i)}$ is processed second, and the job corresponding to $c_{\psi(i)}$ is processed last in this hole. It is easy to see that this yields a total flow time of

(5)
$$k + 100rk^2 + 3\sum_{i=1}^{k}(a_i + 2r) + 2\sum_{i=1}^{k}(b_i + 4r) + \sum_{i=1}^{k}(c_i + 8r) + \frac{3}{2}(14r + D + 1)k(k - 1).$$

Since $\sum_{i=1}^{k}(a_i + b_i + c_i) = kD$ and since $D \le r$, one easily gets an upper bound of

$$k + 100rk^2 + 25rk + 24rk(k - 1) \;<\; 200rk^2$$

for the expression in (5). □

LEMMA 3.2. *If the N3DM instance does not have a solution, then for the constructed scheduling instance $F^* \ge 100r^2k^2$ holds.*

Proof. Consider an optimum schedule S^* and suppose that its total flow time is strictly less than $100r^2k^2$. Our first claim then is that in S^* all tiny jobs in groups of type (T1) are processed as soon as they are released: Since all these tiny jobs have identical processing times, they are processed in S^* in order of increasing release times. It is easy to see that there is no use in splitting one of the groups of type (T1) by processing some larger jobs in between (since this would contradict the SPT rule). Since all big jobs have integer processing times and since the total processing time in every group is equal to 1, we may further assume that the starting time of every big job and of every group $G(t; \ell)$ in S^* is an integer. When the processing of some group $G(t; rg)$ starts at time $t + x$, for x an integer, the total flow time of the rg tiny jobs in $G(t; rg)$ is $rgx + 1 = 100r^2k^2x + 1$. This implies $x = 0$ and proves the claim.

Our second claim is that in S^* none of the big jobs are processed during the time interval that starts with release of the last group of type (T1) and ends with release of the last group of type (T2). Suppose otherwise. The groups of type (T2) are released at regular intervals of length r. Since big jobs all have processing times of at least $2r$, scheduling a big job somewhere between these groups would shift the jobs of at least one group by at least r time units away from their release time. This would yield a total flow time of at least $gr = 100r^2k^2$ and proves the second claim.

Our third claim is that in S^* one of the big jobs is processed after the last group of tiny jobs. Suppose otherwise. There are two types of holes that are left free by the tiny jobs for processing the big jobs: k holes of length $14r + D$ and $100rk^2$ holes of size $r - 1$. Since big jobs all have processing times of at least $2r$, they must be packed into the holes of size $14r + D \leq 15r$. Since two jobs corresponding to the numbers c_i and c_j have total processing time at least $16r$, every such hole must contain exactly one job corresponding to some c_i. By analogous arguments, we determine that every hole of size $14r+D$ must contain exactly one job corresponding to some a_i, b_j, and c_h, respectively. This implies that the corresponding three numbers fulfill $a_i+b_j+c_h \leq D$, which in turn yields $a_i + b_j + c_h = D$ (since the total sum of these $3k$ numbers is kD and the total size of the holes is kD). Hence, the N3DM instance would have a solution; this contradiction shows that our third claim holds true.

Finally, observe that the last group of tiny jobs is processed at time $t = (14r + D + 1)k + 100r^2k^2 - 1$. Hence, the big job that is processed after this last group has a completion time of at least $100r^2k^2$, and since its release time is zero, its flow time is at least $100r^2k^2$. This final contradiction completes the proof of the lemma. □

THEOREM 3.3. *For all $0 < \varepsilon < \frac{1}{2}$ and $0 < \alpha < 1$, there does not exist a polynomial-time approximation algorithm for the minimum total flow time problem with worst-case approximation guarantee $\alpha n^{1/2-\varepsilon}$ unless $P = NP$.*

Proof. Suppose such an approximation algorithm H would exist for some fixed $0 < \varepsilon < \frac{1}{2}$ and $0 < \alpha < 1$. Take an instance of N3DM that is encoded in unary, and perform the above construction. Since the instance is encoded in unary, the size of the resulting scheduling instance is polynomial in the size of the N3DM instance.

Then apply algorithm H to the scheduling instance. In case the N3DM instance has a solution, Lemma 3.1 and the worst-case performance guarantee of H imply that

$$F^H \leq \alpha n^{1/2-\varepsilon} \cdot F^* < \frac{r}{2} \cdot 200rk^2 = 100r^2k^2.$$

In case the N3DM instance does not have a solution, Lemma 3.2 implies that

$$F^H \geq F^* \geq 100r^2k^2$$

holds. Hence, with the help of algorithm H we could distinguish between these two possibilities in polynomial time, which would imply $P = NP$. □

4. Concluding remarks. In this paper we investigated the problem of minimizing total flow time on a single machine. For this NP-complete problem, only approximation algorithms with worst-case bounds of $\Omega(n)$ were known up to now. We presented the first approximation algorithm with sublinear worst-case performance guarantee. The algorithm has a tight worst-case of $O(\sqrt{n})$. It is based on a resolution of the interrupted jobs in the corresponding optimum preemptive schedule. Moreover, we derived a lower bound on the worst-case performance guarantee of polynomial-time approximation algorithms for this problem. We proved that no

polynomial-time approximation algorithm can have a worst-case performance guarantee of $O(n^{1/2-\varepsilon})$ with $\varepsilon > 0$. This also shows that our approximation algorithm is almost "best possible."

We finish the paper with some remarks and open problems.

(1) The open main problem concerns closing the gap between our upper bound and our lower bound. For example, there might exist an approximation algorithm with worst-case performance guarantee of $O(\sqrt{n}/\log n)$.

(2) Subsequent to and inspired by our work, Leonardi and Raz [16] investigated the problem $Pm|r_i|\sum F_i$ with parallel machines. Since the preemptive problem $Pm|\text{pmtn}, r_i|\sum F_i$ is NP-complete for $m \geq 2$ machines [9], Leonardi and Raz [16] do not have the optimum preemptive schedule as a starting point for their approximation algorithm. Instead, they start with an approximative solution for this relaxation and then resolve the preemptions.

(3) Another open problem consists in designing approximation algorithms for the total weighted flow time problem on a single machine. Also in this case, the corresponding preemptive problem $1|\text{pmtn}, r_i|\sum w_i F_i$ is NP-complete (Labetoulle et al. [14]).

(4) The *waiting* time W_i of some job J_i in a schedule is defined by $W_i = S_i - r_i$; i.e., it is the time that the job spends in the system while waiting for being processed. We are not aware of any positive results on approximating the total waiting time.

FAST ESTIMATION OF DIAMETER AND SHORTEST PATHS (WITHOUT MATRIX MULTIPLICATION)*

D. AINGWORTH†, C. CHEKURI†, P. INDYK†, AND R. MOTWANI†

Abstract. In the recent past, there has been considerable progress in devising algorithms for the all-pairs shortest paths (APSP) problem running in time significantly smaller than the obvious time bound of $O(n^3)$. Unfortunately, all the new algorithms are based on fast matrix multiplication algorithms that are notoriously impractical. Our work is motivated by the goal of devising purely combinatorial algorithms that match these improved running times. Our results come close to achieving this goal, in that we present algorithms with a small additive error in the length of the paths obtained. Our algorithms are easy to implement, have the desired property of being combinatorial in nature, and the hidden constants in the running time bound are fairly small.

Our main result is an algorithm which solves the APSP problem in unweighted, undirected graphs with an *additive* error of 2 in time $O(n^{2.5}\sqrt{\log n})$. This algorithm returns actual paths and not just the distances. In addition, we give more efficient algorithms with running time $O(n^{1.5}\sqrt{k \log n} + n^2 \log^2 n)$ for the case where we are only required to determine shortest paths between k *specified* pairs of vertices rather than all pairs of vertices. The starting point for all our results is an $O(m\sqrt{n \log n})$ algorithm for distinguishing between graphs of diameter 2 and 4, and this is later extended to obtaining a ratio 2/3 approximation to the diameter in time $O(m\sqrt{n \log n} + n^2 \log n)$. Unlike in the case of APSP, our results for approximate diameter computation can be extended to the case of *directed* graphs with *arbitrary* positive real weights on the edges.

1. Introduction.

Consider the problem of computing APSP in an unweighted, undirected graph G with n vertices and m edges. The recent work of Alon, Galil, and Margalit [2], Alon, Galil, Margalit, and Naor [3], and Seidel [16] has led to dramatic progress in devising fast algorithms for this problem. These algorithms are based on formulating the problem in terms of matrices with *small integer* entries and using fast matrix multiplications. They achieve a time bound of $\tilde{O}(n^\omega)$[1] where ω denotes the exponent in the running time of the matrix multiplication algorithm used. The current best matrix multiplication algorithm is due to Coppersmith and Winograd [9] and has $\omega = 2.376$. In contrast, the naive algorithm for APSP performs breadth-first searches (BFSs) from each vertex and requires time $\Theta(nm)$.

Given the fundamental nature of this problem, it is important to consider the desirability of implementing the algorithms in practice. Unfortunately, fast matrix multiplication algorithms are far from being practical and suffer from large hidden constants in the running time bound. Consequently, we adopt the view of treating

[1]The notation $\tilde{O}(f(n))$ denotes $O(f(n)\,\text{polylog}\,(n))$.

these results primarily as indicators of the existence of efficient algorithms and consider the question of devising a purely *combinatorial algorithm* for APSP that runs in time $O(n^{3-\epsilon})$. The (admittedly vague) term "combinatorial algorithm" is intended to contrast with the more algebraic flavor of algorithms based on fast matrix multiplication. To understand this distinction, the reader may find it instructive to try and interpret the "algebraic" algorithms in purely graph-theoretic terms even with the use of the simpler matrix multiplication algorithm of Strassen [17]. The best known combinatorial algorithm, due to Feder and Motwani [12], runs in $O(n^3/\log n)$ time, yielding only a marginal improvement over the naive algorithm.

We take a step in the direction of realizing the goals outlined above by presenting an algorithm which solves the APSP problem with an *additive* error of 2 in time $O(n^{2.5}\sqrt{\log n})$. This algorithm returns actual paths and not just the distances. Note that the running time is better than the $\tilde{O}(n^{2.81})$ time bound of the more practical matrix multiplication algorithm of Strassen [17]. Further, as explained below, we also give slightly more efficient algorithms (for *sparse* graphs) for approximating the diameter. Our algorithms are easy to implement, have the desired property of being combinatorial in nature, and the hidden constants in the running time bound are fairly small. Our additive approximations are presented only for the case of unweighted, undirected graphs, but they can be easily generalized to the case of undirected graphs with small integer edge weights. In addition, we give a more efficient algorithm with running time $O(n^{1.5}\sqrt{k \log n} + n^2 \log^2 n)$ for the case where we are only required to determine shortest paths between k specified pairs of vertices rather than all pairs of vertices.

A crucial step in the development of our result was the shift of focus to the problem of computing the diameter of a graph. This is the maximum over all pairs of vertices of the shortest path distance between the vertices. The diameter can be determined by computing APSP distances in the graph, and it appears that this is the only known way to solve the diameter problem. In fact, Fan Chung [6] had earlier posed the question of whether there is an $O(n^{3-\epsilon})$ algorithm for finding the diameter without resorting to fast matrix multiplication. The situation with regard to combinatorial algorithms for diameter is only marginally better than in the case of APSP. Basch, Khanna, and Motwani [4] presented a combinatorial algorithm that verifies whether a graph has diameter 2 in time $O\left(n^3/\log^2 n\right)$. A slight adaptation of this algorithm yields a Boolean matrix multiplication algorithm which runs in the same time bound, thereby allowing us to verify that the diameter of a graph is d, for any constant d, in $O\left(n^3/\log^2 n\right)$ time.

Consider the problem of devising a fast algorithm for *approximating* the diameter. It is easy to estimate the diameter within a ratio 1/2 in $O(m)$ time: perform a BFS from any vertex v and let d be the depth of the BFS tree obtained; clearly, the diameter of G lies between d and $2d$. No better approximation algorithm was known for this problem; in fact, it was not even known how to distinguish between graphs of diameter 2 and 4. Our first result is an $O(m\sqrt{n \log n})$ algorithm for distinguishing between graphs of diameter 2 and 4, and this is later extended to obtaining a ratio 2/3 approximation to the diameter in time $O(m\sqrt{n \log n} + n^2 \log n)$. It should be noted that, unlike in the case of APSP, our results for approximate diameter computation can be extended to the case of *directed* graphs with *arbitrary* positive real weights on the edges.

The problem of computing approximate shortest paths has been considered earlier in the literature but purely from the point of view of multiplicative errors in the

approximation. Awerbuch, Berger, Cowen, and Peleg [1] and Cohen [7] have presented efficient algorithms for computing t-stretch paths for $t \geq 4$, where a path is said to have stretch t if its length is at most t times the length of the shortest path between its endpoints. Cohen [8] gave an algorithm that approximates paths from s sources to all other nodes in a weighted graph in time $O((m + sn)n^{\epsilon})$ for any $\epsilon > 0$. This algorithm outputs paths of length $(1 + O(1/\operatorname{polylog} n))d(u, v) + O(w_{max} \operatorname{polylog} n)$, where $d(u, v)$ denotes the distance between vertices u and v, and w_{max} is the largest edge weight in the graph. Her algorithm may be specialized to the unweighted case to compute paths of length $(1 + \delta)d(u, v) + c$ for any $\delta > 0$ within the same time, where the constant c depends on ϵ and δ.

The rest of this paper is organized as follows. We begin in section 2 by presenting some definitions and an algorithm for a version of the dominating set problem that underlies all our algorithms. In section 3, we describe the algorithms for distinguishing between graphs of diameter 2 and 4, and the extension to obtaining a ratio 2/3 approximation to the diameter. As we remarked earlier, these results can be applied to directed, weighted graphs. Then, in section 4, we apply the ideas developed in estimating the diameter to obtain the promised algorithm for an additive-error approximation for APSP. These ideas are extended in section 5 to obtain a more efficient algorithm for additive-error approximations to the k-pairs shortest paths problem. Finally, in section 6 we present an empirical study of the performance of our algorithm for APSP.

2. Preliminaries and a basic algorithm. We present some notation and a result concerning dominating sets in graphs. Initially, all definitions are with respect to some undirected, unweighted, connected graph $G(V, E)$ with n vertices and m edges. Later, we will point out the extension to directed and weighted graphs.

DEFINITION 2.1. *The* distance*, $d(u, v)$, between two vertices u and v is the length of the shortest path between them.*

DEFINITION 2.2. *The* diameter*, Δ, of a graph G is defined to be* $\max_{u,v \in G} d(u, v)$.

DEFINITION 2.3. *The k-neighborhood, $N_k(v)$, of a vertex v is the set of all vertices other than v that are at distance at most k from v, i.e.,*

$$N_k(v) = \{u \in V \mid 0 < d(v, u) \leq k\}.$$

The degree *of a vertex v is denoted by $d_v = |N_1(v)|$. Finally, we will use the notation $N(v) = N_1(v) \cup \{v\}$ to denote the set of vertices at distance at most 1 from v.*

It is important to keep in mind that the set $N(v)$ contains not just the neighbors of v but also includes v itself.

DEFINITION 2.4. *For any vertex $v \in V$, we denote by* $\textsc{b}(v)$ *the depth of a BFS tree in G rooted at the vertex v.*

Throughout this paper, we will be working with a parameter s to be chosen later that will serve as the threshold for classifying vertices as being of *low* degree or *high* degree. This threshold is implicit in the following definition.

DEFINITION 2.5. *Let $L(V) = \{u \in V \mid d_u < s\}$ and $H(V) = V \setminus L(V) = \{u \in V \mid d_u \geq s\}$.*

The following is a generalization of the standard notion of a dominating set.

DEFINITION 2.6. *Given a set $A \subseteq V$, a set $D \subseteq V$ is a* dominating set for *A if and only if for each vertex $v \in A$, $N(v) \cap D \neq \emptyset$. That is, for each vertex in $A \setminus D$, one of its neighbors is in D.*

The following theorem underlies all our algorithms.

THEOREM 2.7. *There exists a dominating set for $H(V)$ of size $O(s^{-1}n\log n)$, and such a dominating set can be found in $O(m+ns)$ time.*

REMARK 2.8. *It is easy to see that choosing a set of $\Theta(s^{-1}n\log n)$ vertices uniformly at random gives the desired dominating set for $H(V)$ with high probability. This construction in the proof of this theorem is in effect a derandomization of this randomized algorithm.*

Proof. Suppose, to begin with, that $H(V) = V$; then we are interested in the standard dominating set for the graph G. The problem of computing a minimum dominating set for G can be reformulated as a set cover problem as follows: for every vertex v create a set $S_v = N(v)$. This gives an instance of the set cover problem $\mathcal{S} = \{S_v \mid v \in V\}$, where the goal is to find a minimum cardinality collection of sets whose union is V. Given any set cover solution $\mathcal{C} \subseteq \mathcal{S}$, the set of vertices corresponding to the subsets in $\mathcal{C}$ forms a dominating set for G of the same size as $\mathcal{C}$. This is because each vertex v occurs in one of the sets $S_w \in \mathcal{C}$ and thus is either in the dominating set itself or has a neighbor therein. Similarly, any dominating set for G corresponds to a set cover for $\mathcal{S}$ of the same cardinality.

The greedy set cover algorithm repeatedly chooses the set that covers the most uncovered elements, and it is known to provide a set cover of size within a factor $\log n$ of the *optimal fractional solution* [13, 15]. Since every vertex has degree at least s and therefore the corresponding set S_v has cardinality at least s, assigning a weight of $1/s$ to every set in $\mathcal{S}$ gives a fractional set cover of total weight (fractional size) equal to $s^{-1}n$. Thus, the optimal *fractional* set cover size is $O(n/s)$, and the greedy set cover algorithm must then deliver a solution of size $O(s^{-1}n\log n)$. This gives a dominating set for G of the same size. If we implement the greedy set cover algorithm by keeping the sets in buckets sorted by the number of uncovered vertices, the algorithm can be shown to run in time $O(m)$.

Consider now the case where $H(V) \neq V$. Construct a graph $G' = (V', E')$, adding a set of dummy vertices $X = \{x_i \mid 1 \leq i \leq s\}$, as follows: define $V' = V \cup X$ and $E' = E \cup \{(x_i, x_j) \mid 1 \leq i < j \leq s\} \cup \{(u, x_i) \mid u \in L(V)\}$. Every vertex in this new graph has degree s or higher, so by the preceding argument we can construct a dominating set for G' of size $O(s^{-1}(n+s)\log(n+s)) = O(s^{-1}n\log n)$. Since none of the new vertices in X are connected to the vertices in $H(V)$, the restriction of this dominating set to V will give a dominating set for $H(V)$ of size $O(s^{-1}n\log n)$. Finally, the running time is increased by the addition of the new vertices and edges, but since the total number of edges added is at most $ns + s^2 = O(ns)$, we get the desired time bound. ∎

2.1. Extension to directed graphs. We briefly indicate the extension of the preceding definitions, notation, and observations to directed graphs. Given a directed graph $G(V, E)$, we will denote by $\overleftarrow{G}$ the graph obtained from G by *reversing* the direction of all the edges of G.

We use $\rightarrow$ and $\leftarrow$ to overline quantities defined with respect to G and $\overleftarrow{G}$, respectively. We will use the term *degree* to refer to the *out-degree* of a vertex, and for $v \in V$ we will denote its degree by $\overrightarrow{d}_v$. The definitions of distance, diameter, neighborhoods, BFS tree, and dominating set given earlier extend naturally to directed graphs as described below. We give the definitions only for G, and definitions for $\overleftarrow{G}$ can be obtained similarly.

DEFINITION 2.9. *For any two vertices $u, v \in V$, we define $d(u, v)$ as the length of the shortest path from u to v. If no such path exists, we assume $d(u, v) = \infty$.*

Algorithm 2-vs-4

1. **if** $\vec{L}(V) \neq \emptyset$ **then**
   (a) **choose** $v \in \vec{L}(V)$
   (b) **compute** a $\overrightarrow{BFS}$ tree from v and a $\overleftarrow{BFS}$ tree from each of the vertices in $\vec{N}(v)$
2. **else**
   (a) **compute** an out-dominating set D for $\vec{H}(V) = V$
   (b) **compute** a $\overrightarrow{BFS}$ tree from each of the vertices in D
3. **endif**
4. **if** all BFS trees have depth 2 **then return** 2
   else return 4.

FIG. 3.1. *Algorithm* 2-*vs*-4.

Note that $d(u, v)$ is not symmetric in general.

DEFINITION 2.10. *The* diameter Δ *of a graph* G *is defined to be* $\max_{u,v \in G} d(u, v)$.

DEFINITION 2.11. *Let* $\vec{N}_k(v) = \{u \in V \mid 0 < d(v, u) \leq k\}$. *Further,* $\vec{N}(v) = \vec{N}_1(v) \cup \{v\}$ *denotes the set of vertices at distance at most* 1 *from* v.

DEFINITION 2.12. $\overrightarrow{BFS}$ *is a BFS tree in the directed graph* G. *For any vertex* $v \in V$, *we denote by* $\vec{\mathrm{B}}(v)$ *the depth of a* $\overrightarrow{BFS}$ *tree in* G *rooted at the vertex* v.

We define $\vec{H}(V)$, $\vec{L}(V)$, and dominating set for directed graphs with respect to out-going edges incident at the vertices.

DEFINITION 2.13. *For some* s, *let* $\vec{L}(V) = \{u \in V \mid \vec{d}_u < s\}$ *and* $\vec{H}(V) = V \setminus \vec{L}(V) = \{u \in V \mid \vec{d}_u \geq s\}$.

DEFINITION 2.14. *Given a set* $A \subseteq V$, *a set* $D \subseteq V$ *is an* out-dominating set for A *if and only if for each vertex* $v \in A$, $\vec{N}(v) \cap D \neq \emptyset$.

The following is an easy consequence of Theorem 2.7.

COROLLARY 2.15. *Given a directed graph* $G(V, E)$, *there exists an out-dominating set for* $\vec{H}(V)$ *of size* $O(s^{-1} \log n)$, *and such a dominating set can be found in* $O(m+ns)$ *time.*

3. Estimating the diameter. In this section we will develop an algorithm to find an estimate E such that $\frac{2}{3}\Delta \leq E \leq \Delta$. We first present an algorithm for distinguishing between graphs of diameter 2 and 4. It is then shown that this algorithm generalizes to the promised approximation algorithm.

3.1. Distinguishing diameter 2 from 4. The basic idea behind the algorithm is rooted in the following lemma whose proof is straightforward.

LEMMA 3.1. *Suppose that* G *has a pair of vertices* a *and* b *with* $d(a, b) \geq 4$. *Then, any* $\overrightarrow{BFS}$ *tree rooted at a vertex* $v \in \vec{N}(a)$ *and any* $\overleftarrow{BFS}$ *tree rooted at a vertex* $v \in \overleftarrow{N}(b)$ *will have depth at least* 3.

The algorithm shown in Figure 3.1, called Algorithm 2-vs-4, computes BFS trees from a small set of vertices that is guaranteed to contain such a vertex, and so one of these BFS trees will certify that the diameter is more than 2.

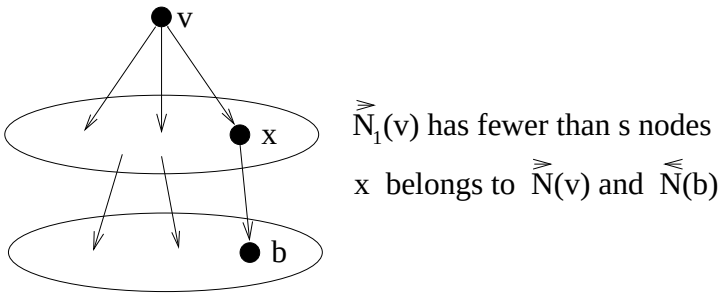

FIG. 3.2. *Case* 1 *in Algorithm* 2-*vs*-4.

We are assuming here that the sets $\overrightarrow{L}(V)$ and $D(V)$ are provided as a part of the input; otherwise, they can be computed in $O(m + ns)$ time.

THEOREM 3.2. *Algorithm* 2-*vs*-4 *distinguishes graphs of diameter* 2 *and* 4, *and it has running time* $O(ms^{-1}n \log n + ms)$.

Proof. It is clear that the algorithm outputs 2 for graphs of diameter 2 since in such graphs no BFS tree can have depth exceeding 2. Assume then that G has diameter 4 and fix any pair of vertices $a, b \in V$ such that $d(a, b) \geq 4$. We will show that the algorithm performs a properly directed BFS from a vertex $v \in \overrightarrow{N}(a) \cup \overleftarrow{N}(b)$. Since, by Lemma 3.1, the depth of the BFS tree rooted at v is at least 3, the algorithm will output 4.

We consider the two cases that can arise in the algorithm.

Case 1. $[\overrightarrow{L}(V) \neq \emptyset]$.

If b belongs to $\overrightarrow{N}(v)$, then there is nothing to prove. If $\overrightarrow{\mathrm{B}}(v) > 2$, then again we have nothing to prove. Note that if $\overrightarrow{\mathrm{B}}(v) = 1$, then $\overrightarrow{d}_v = n - 1$ and our choice of $s = o(n)$ would imply that $v \notin \overrightarrow{L}(V)$ which would be a contradiction. Therefore, the only case that remains is when $\overrightarrow{\mathrm{B}}(v) = 2$ and $d(v, b) = 2$ (see Figure 3.2). These assumptions imply that $\overrightarrow{N}(v) \cap \overleftarrow{N}(b) \neq \emptyset$, and Lemma 3.1 completes the proof. The size of $\overrightarrow{N}(v)$ is at most s; therefore, the time to compute the BFS trees is bounded by $O(ms)$.

Case 2. $[\overrightarrow{L}(V) = \emptyset]$.

Since D is an out-dominating set for V, it follows immediately that $D \cap \overrightarrow{N}(a) \neq \emptyset$, establishing the proof of correctness. From Theorem 2.7, we have $|D| = O(s^{-1}n \log n)$, and this implies a bound of $O(ms^{-1}n \log n)$ on the cost of computing the BFS trees in this case. □

Choosing $s = \sqrt{n \log n}$, we obtain the following corollary.

COROLLARY 3.3. *Graphs of diameter* 2 *and* 4 *can be distinguished in* $O(m\sqrt{n \log n})$ *time.*

3.2. Approximating the diameter. The ideas used in Algorithm 2-vs-4 can be generalized to estimate the diameter for all directed graphs: fix any two vertices a and b for which $d(a, b) = \Delta$, where Δ is the diameter of the graph. Suppose we can a find a vertex v in $\overrightarrow{N}_{\Delta/3}(a)$ or v' in $\overleftarrow{N}_{\Delta/3}(b)$; then it is clear that $\overrightarrow{\mathrm{B}}(v) \geq \frac{2}{3}\Delta$ or $\overleftarrow{\mathrm{B}}(v') \geq \frac{2}{3}\Delta$, and we can use $\overrightarrow{\mathrm{B}}(v)$ or $\overleftarrow{\mathrm{B}}(v')$ as our estimate. As before, we will find a small set of vertices which is guaranteed to have a vertex in $\overrightarrow{N}_{\Delta/3}(a) \cup \overleftarrow{N}_{\Delta/3}(b)$. Then

Algorithm Approx-Diameter

1. **compute** an s-partial-$\overrightarrow{BFS}$ tree from each vertex in V
2. **let** w be the vertex with the maximum depth ($\overrightarrow{\text{PB}}(w)$) partial-$\overrightarrow{BFS}$ tree
3. **compute** a $\overrightarrow{BFS}$ tree from w and a $\overleftarrow{BFS}$ tree from each vertex in $P\overrightarrow{BFS}_s(w)$
4. **compute** a new graph $\widehat{G}$ from G by adding all edges of the form (v, u) where $u \in P\overrightarrow{BFS}_s(v)$
5. **compute** an out-dominating set D in $\widehat{G}$
6. **compute** a $\overrightarrow{BFS}$ tree from each vertex in D
7. **return** estimate E equal to the maximum depth of all BFS trees from Steps 3 and 6.

FIG. 3.3. *Algorithm approx-diameter.*

we can compute the BFS tree from each of these vertices and use the maximum of the depths of these trees as our estimate E. The reason for choosing the fraction $1/3$ will become apparent in the analysis of the algorithm. In what follows, it will simplify notation to assume that $\Delta/3$ is an integer; in general, though, our analysis needs to be modified to use $\lfloor \Delta/3 \rfloor$. Also, we assume that $\Delta \geq 3$, and it is easy to see that the case $\Delta \leq 2$ can be handled separately.

A key tool in the rest of our algorithms will be the notion of a *partial-BFS* defined in terms of a parameter k.

DEFINITION 3.4. *A k-partial-BFS tree is obtained by performing a BFS up to the point where exactly k vertices (not including the root) have been visited.*

LEMMA 3.5. *A k-partial-BFS tree can be computed in time $O(k^2)$.*

Proof. The number of edges examined for each vertex visited is bounded by k since the k-partial-BFS process is terminated when k distinct vertices have been examined. This implies that the total number of edges examined is $O(k^2)$ and that dominates the running time. □

Note that a k-partial-BFS tree contains the k vertices closest to the root but that this set is not uniquely defined due to the need to break ties, which is done arbitrarily. Typically, k will be clear from the context and we will not specify it explicitly.

DEFINITION 3.6. *Let $P\overrightarrow{BFS}_k(v)$ be the set of vertices visited by a k-partial-$\overrightarrow{BFS}$ from v. Denote by $\overrightarrow{\text{PB}}(v)$ the depth of the tree constructed in this fashion. $P\overleftarrow{BFS}$ and $\overleftarrow{\text{PB}}(v)$ are defined similarly.*

Consider now the formal description of the approximation algorithm for diameter, algorithm approx-diameter, as shown in Figure 3.3.

The following lemmas constitute the analysis of this algorithm.

LEMMA 3.7. *The dominating set D found in step 5 is of size $O(s^{-1}n \log n)$.*

Proof. In $\widehat{G}$, each vertex $v \in V$ is adjacent to all vertices in $P\overrightarrow{BFS}_s(v)$ with respect to the graph G. Since $|P\overrightarrow{BFS}_s(v)| = s$ for every vertex v, the out-degree of each vertex in $\widehat{G}$ is at least s. From Theorem 2.7, it follows that we can find a dominating set of size $O(s^{-1}n \log n)$. □

LEMMA 3.8. *If $|\vec{N}_{\Delta/3}(v)| \geq s$ for all $v \in V$, then $D \cap (\vec{N}_{\Delta/3}(v) \cup \{v\}) \neq \emptyset$ for each vertex $v \in V$.*

Proof. Consider any particular vertex $v \in V$. If v is in D, then there is nothing
