OPTIMAL BIWEIGHTED BINARY TREES AND THE COMPLEXITY OF MAINTAINING PARTIAL SUMS*

HARIPRIYAN HAMPAPURAM† AND MICHAEL L. FREDMAN‡

Abstract. Let A be an array. The *partial sum problem* concerns the design of a data structure for implementing the following operations. The operation update(j, x) has the effect $A[j] \leftarrow A[j] + x$, and the query operation sum(j) returns the partial sum $\sum_{i=1}^{j} A[i]$. Our interest centers upon the optimal efficiency with which sequences of such operations can be performed, and we derive new upper and lower bounds in the semigroup model of computation. Our analysis relates the optimal complexity of the partial sum problem to optimal binary trees relative to a type of weighting scheme that defines the notion of *biweighted* binary tree.

Key words. data structures, partial sums, lower bounds

1. Introduction.

Let A be an array of length N. The *partial sum problem* concerns the design of a data structure for implementing the following operations. The operation update(j, x) has the effect $A[j] \leftarrow A[j] + x$ (where $1 \leq j \leq N$), and the query operation sum(j) returns the partial sum $\sum_{i=1}^{j} A[i]$. We refer to N as the *size* of the partial sum problem. Our interest centers upon the optimal efficiency with which sequences of such operations can be performed, and we derive new upper and lower bounds.

In this paper we investigate complexity relative to the *semigroup* model of computation: the array A can store values from an arbitrary commutative semigroup, and the implementations of the update and sum operations must perform correctly irrespective of the particular choice of the semigroup. In particular, the implementations are not permitted to utilize the subtraction operation. The model assumes the availability of memory registers $z_1, z_2, \ldots$ which store semigroup values and permits operations of the form $z_i \leftarrow z_j + z_k$. In this setting an $O(\log N)$ upper bound is readily established, and Yao [8] has shown that $\Omega(\log N / \log \log N)$ is an inherent lower bound for the amortized complexity of the operations (worst case). Here we consider average case complexity relative to a large class of probability distributions, and as a by-product of this approach, we are able to improve upon Yao's result, deriving an $\Omega(\log N)$ lower bound for the amortized complexity, even when the operations are performed off-line. We remark that with a slight change in the definition of the partial sum problem, namely, by redefining the operation update(j, x) to have the effect $A[j] \leftarrow x$, we find that matching $\theta(\log N)$ upper and lower bounds have been previously established for this problem [3]. This latter definition of the update operation is more readily exploited in a lower bound argument. In particular, in the semigroup

setting all structural quantities that depend on the old value of $A[j]$ are subsequently unusable after the current update is performed.

Our average case analysis concerns sequences of independently selected operations in which the operation update(j, x) is selected with probability p_j to be the next operation in the sequence, and the operation sum(j) is selected with probability q_j to be the next operation in the sequence, where $\sum_{j=1}^{N} p_j + \sum_{j=1}^{N} q_j = 1$. We are able to approximately characterize the optimal expected cost of implementing such sequences in terms of optimal binary trees relative to a type of weighting scheme, defining the notion of *biweighted* binary tree.

In the following section we define the notion of biweighted binary tree and demonstrate the connection between biweighted binary trees and data structures for the partial sum problem. We also present a heuristic for constructing approximately optimal biweighted binary trees. This heuristic serves to motivate the lower bound theorem presented in section 3.

In what remains of this section we describe a class of data structures which is natural with respect to the partial sum problem and which has provided a framework for some previous work. These structures also provide a starting point for the current analysis. Consider the obvious $O(\log N)$ data structure for the partial sum problem which consists of a balanced binary tree with N leaves labeled from 1 to N in order from left to right. The value in $A[i]$ is stored in leaf i, and stored in each internal node η is the sum of the values that are stored in the leaves of the subtree of η. The operation update(j, x) is performed by incrementing by x the values stored in the nodes along the path from leaf j to the root. The operation sum(j) is performed by summing the values in a minimal collection of nodes whose subtrees exactly cover the first j leaves. This data structure can be viewed as a particular instance of (and motivates) the following class of structures. Let $z_1, z_2, \ldots$ designate memory registers that store values from the space pertinent to the array A. A data structure belonging to our class consists of two sequences $U_1, \ldots, U_N$ and $R_1, \ldots, R_N$, where the U_i and the R_i are individual subsets of the memory registers $z_1, z_2, \ldots$. The task update(j, x) is performed by adding x to each register in the set U_j, and sum(j) is performed by summing the registers in the set R_j. The sizes of the U_j and R_j sets reflect the complexity of our operations, and it is readily demonstrated [4] that to correctly implement the partial sum problem, it is both necessary and sufficient that the following condition be satisfied:

$$|U_i \cap R_j| = \begin{cases} 1 & \text{if } i \leq j, \\ 0 & \text{otherwise.} \end{cases} \tag{1.1}$$

We refer to data structures for the partial sum problem that fall within this framework as *U-R systems*.

By imposing size restrictions on the U_i subsets (or the R_i subsets) it is possible to investigate update time versus query time tradeoffs within this class of data structures, as investigated in [1]. The investigation of such tradeoffs is motivated by circumstances in which, say, update operations are more frequently performed than query operations. In this paper we address directly those circumstances under which the operations are known to be requested with varying frequencies. Thus, if update(j, x) is performed with probability p_j and sum(j) is performed with probability q_j, then the expected cost of an operation is given by

$$C(\bar{p}, \bar{q}) = \sum_{j=1}^{N} (p_j |U_j| + q_j |R_j|), \tag{1.2}$$

where $\bar{p}$ and $\bar{q}$ represent the p_j and q_j probability sequences, respectively. We assume throughout this paper that all of the p_j and q_j probabilities are strictly positive; otherwise we can effectively reduce the size N of the array A. In the sequel we solve the problem of minimizing the quantity $C(\bar{p}, \bar{q})$ subject to the condition (1.1). Let $C_{min}(\bar{p}, \bar{q})$ denote this minimum value for $C(\bar{p}, \bar{q})$. It is shown in section 3 that $C_{min}(\bar{p}, \bar{q})$ approximates (to within a constant factor) the optimal cost of doing the operations in the general semigroup model of computation, extending beyond data structures that fall within the framework of U-R systems. Moreover, in terms of expected cost, this lower bound extends to off-line processing.

2. Biweighted trees. We proceed to define a family of valid data structures for the partial sum problem that fall within the U-R system framework. Let T be a binary tree with N nodes. We assume that the nodes of T have zero, one, or two children, and that T is ordered, so that each child of a given node is designated as a left child or right child. We also number the nodes of T from 1 to N in order from left to right. Now in terms of T we define a U-R system for the partial sum problem of size N as follows.

Let η be the jth node of T, and let $\eta_0 (= \eta), \eta_1, \ldots, \eta_h$, $h \geq 0$, be the nodes along the path from η to the root η_h of T. Then U_j consists of η and for $i > 0$ those η_i such that η_{i-1} is the left child of η_i; and R_j consists of η and for $i > 0$ those η_i such that η_{i-1} is the right child of η_i. Now let η_{ij} denote the lowest common ancestor of the ith and jth nodes of T. It is easily checked that

$$U_i \cap R_j = \begin{cases} \eta_{ij} & \text{if } i \leq j\,, \\ \phi & \text{otherwise.} \end{cases} \tag{2.1}$$

The condition (1.1) directly follows from (2.1) and therefore our construction yields a valid data structure for the partial sum problem. We let $\Delta(T)$ denote this data structure.

Next, we interpret the quantity $C(\bar{p}, \bar{q})$, the expected cost of an operation under the distribution $(\bar{p}, \bar{q})$, when implemented using $\Delta(T)$. Associate with the ith node of T the pair of probabilities (p_i, q_i), $1 \leq i \leq N$. Relative to these associated probabilities we then define the *biweighted* path length of T to be

$$W(T, \bar{p}, \bar{q}) = \sum_{i=1}^{N} (p_i \ell_i + q_i r_i)\,,$$

where ℓ_i is the number of left links on the path from the root of T to the ith node and r_i is the number of right links on this same path. Because $\ell_i = |U_i| - 1$ and $r_i = |R_i| - 1$ it follows immediately that

$$C(\bar{p}, \bar{q}) = W(T, \bar{p}, \bar{q}) + 1\,. \tag{2.2}$$

Note also that $W(T, \bar{p}, \bar{q})$ defines (one-half of) the usual weighted path length of T when $\bar{p} = \bar{q}$.

Equation (2.2) suggests the possibility that a good data structure for the partial sum problem, relative to the distribution $(\bar{p}, \bar{q})$, is given by $\Delta(T_{\bar{p},\bar{q}})$, where $T_{\bar{p},\bar{q}}$ is chosen to have minimum biweighted path length $W(T, \bar{p}, \bar{q})$. The following theorem addresses this possibility relative to U-R systems.

THEOREM 2.1. *Relative to the distribution $(\bar{p}, \bar{q})$ with strictly positive probabilities, an optimal U-R system for the partial sum problem is given by $\Delta(T_{\bar{p},\bar{q}})$. In other*

words,

$$C_{min}(\bar{p},\bar{q}) \;=\; W(T_{\bar{p},\bar{q}}\,,\,\bar{p}\,,\,\bar{q}) \;+\; 1\,.$$

Proof of Theorem 2.1. We relax the requirement that the weights $(\bar{p},\bar{q})$ sum to 1 and establish that

$$C_{min}(\bar{p},\bar{q}) \;=\; W(T_{\bar{p},\bar{q}}\,,\,\bar{p}\,,\,\bar{q}) \;+\; \sum_{j=1}^{N}(p_j+q_j)$$

from which Theorem 2.1 follows as an immediate consequence. (We use equation (1.2) to define $C(\bar{p},\bar{q})$ for arbitrary positive weights $(\bar{p},\bar{q})$.) The above equality is established once we show that we can construct, given an arbitrary U-R system, a tree T such that

$$C(\bar{p},\bar{q}) \;\geq\; W(T,\bar{p},\bar{q}) \;+\; \sum_{j=1}^{N}(p_j+q_j)\,. \tag{2.3}$$

Now given a U-R system $(\bar{U},\bar{R})$ consisting of sequences $\bar{U} \;=\; U_1\,,\ldots,\,U_N$ and $\bar{R} \;=\; R_1\,,\ldots,\,R_N$, for some integer $k\in[1,N]$ our construction below yields two U-R systems $(\bar{U}^\ell,\bar{R}^\ell)$ and $(\bar{U}^r,\bar{R}^r)$ for arrays of lengths $k-1$ and $N-k$, respectively, such that

$$|U_i^\ell| \;\leq\; |U_i|-1 \text{ and } |R_i^\ell| \;=\; |R_i| \tag{2.4}$$

for $1\leq i\leq k-1$; and

$$|U_i^r| \;=\; |U_{i+k}| \text{ and } |R_i^r| \;\leq\; |R_{i+k}|-1 \tag{2.5}$$

for $1\leq i\leq N-k$.

Assume for the moment that an integer k and U-R systems $(\bar{U}^\ell,\bar{R}^\ell)$ and $(\bar{U}^r,\bar{R}^r)$ satisfying (2.4) and (2.5) can be constructed. Let $(\bar{p}_\ell,\bar{q}_\ell)$ designate the first $k-1$ pairs (p_i,q_i) of the weights $(\bar{p},\bar{q})$ and let $(\bar{p}_r,\bar{q}_r)$ designate the last $N-k$ pairs of these weights. By assigning the weights $(\bar{p}_\ell,\bar{q}_\ell)$ to the system $(\bar{U}^\ell,\bar{R}^\ell)$, assigning the weights $(\bar{p}_r,\bar{q}_r)$ to the system $(\bar{U}^r,\bar{R}^r)$, and noting that $|U_k|,|R_k| \;\geq\; 1$, we conclude from (2.4) and (2.5) that

$$\begin{aligned} &C(\bar{p},\bar{q}) \\ &\quad\geq C(\bar{p}_\ell,\bar{q}_\ell)+C(\bar{p}_r,\bar{q}_r) \\ &\qquad+\sum_{j=1}^{k-1}p_j+\sum_{j=k+1}^{N}q_j \;+\; (p_k+q_k)\,. \end{aligned} \tag{2.6}$$

We construct the tree T satisfying (2.3) recursively as follows. The root of T is the kth node, where k defines the partition of $(\bar{U},\bar{R})$ as described above. The left subtree T_{left} of T is obtained recursively from $(\bar{U}^\ell,\bar{R}^\ell)$, and the right subtree T_{right} is obtained recursively from $(\bar{U}^r,\bar{R}^r)$. Upon assigning the weights $(\bar{p},\bar{q})$ to the nodes to T, so that $(\bar{p}_\ell,\bar{q}_\ell)$ designates the weights assigned to T_{left} and $(\bar{p}_r,\bar{q}_r)$ designates the weights assigned to T_{right}, we find that

$$\begin{aligned} W(T,\bar{p},\bar{q}) = W(T_\ell,\bar{p}_\ell,\bar{q}_\ell) \;+\; W(T_r,\bar{p}_r,\bar{q}_r) \\ +\sum_{j=1}^{k-1}p_j \;+\; \sum_{j=k+1}^{N}q_j\,. \end{aligned} \tag{2.7}$$

It follows by induction, using (2.7) and (2.6), that (2.3) is satisfied.

We complete the proof of Theorem 2.1 by giving the construction satisfying (2.4) and (2.5). Let

$$\Gamma = U_1 \cup \cdots \cup U_N \cup R_1 \cup \cdots \cup R_N .$$

For each element x in Γ, let

$$\text{u-extent}(x) = \max\{j | x \in U_j\} .$$

Observe that for any set R_j condition (1.1) implies that

$$\text{u-extent}(x) \leq j \text{ for each } x \text{ in } R_j . \tag{2.8}$$

For each set R_j let

$$\text{u-extent}(R_j) = \min\{\text{u-extent}(x) | x \in R_j\} .$$

Finally, let

$$k = \max\{\text{u-extent}(R_j) | 1 \leq j \leq N\} ,$$

and choose k' so that $k = \text{u-extent}(R_{k'})$. From (2.8) we have that $k \leq k'$. Also, for each $x \in R_{k'}$, $\text{u-extent}(x) \geq k$. Because $U_j \cap R_{k'} \neq \phi$ for $j < k'$, it follows that each set U_j with $j < k'$ contains an element x_j such that $\text{u-extent}(x_j) \geq k$. On the other hand (2.8) asserts that for each $j < k$ the set R_j contains no element x with $\text{u-extent}(x) \geq k$. Thus we can find in each set U_j with $j < k$ an element x_j (with $\text{u-extent}(x_j) \geq k$) not contained in any set R_h with $h < k$.

Accordingly, we construct the system $(\bar{U}^\ell, \bar{R}^\ell)$ by setting $U_j^\ell = U_j - \{x_j\}$, where x_j is some element in U_j with $\text{u-extent}(x_j) \geq k$, and setting $R_j^\ell = R_j$, $1 \leq j \leq k-1$. Certainly (2.4) is satisfied and moreover the system $(\bar{U}^\ell, \bar{R}^\ell)$ inherits condition (1.1) from the system $(\bar{U}, \bar{R})$ since the deleted elements x_j do not appear in any of the intersections $U_h \cap R_i$ when $h, i \leq k-1$.

Now every set R_j contains an element x_j with $\text{u-extent}(x_j) \leq k$. For $h > k$, none of these elements x_j appear within the sets U_h by definition of $\text{u-extent}(x)$. Thus, if we set $U_j^r = U_{j+k}$ and $R_j^r = R_{j+k} - \{x_j\}$, for $1 \leq j \leq N-k$, then the resulting system $(\bar{U}^r, \bar{R}^r)$ satisfies (2.5), and, as before, condition (1.1) is satisfied. □

Equation (2.7) suggests that the following balancing heuristic is reasonable to consider in constructing a tree T with near optimal biweighted path length: choose the root to be the kth node where k is chosen to equalize the sums $\sum_{j=1}^{k-1} p_j$ and $\sum_{j=k+1}^{N} q_j$ and construct the subtrees recursively. More precisely we define T_{BAL} so that its root is the kth node, where k is the least integer satisfying $\sum_{j=1}^{k-1} p_j \geq \sum_{j=k+1}^{N} q_j$, and whose subtrees are recursively constructed.

THEOREM 2.2. *Let T_{BAL} be defined as above. Then $W(T_{BAL}, \bar{p}, \bar{q}) \leq 2 \cdot W(T_{\bar{p},\bar{q}}, \bar{p}, \bar{q}) + 1$.*

Comment. Theorem 2.2 justifies using a balancing heuristic for constructing near optimal U-R systems. However, in view of Theorem 2.1 it is easy to construct truly optimal U-R systems by using dynamic programming to construct a tree having optimal biweighted path length. (The recurrence that forms the basis for the dynamic programming algorithm is obtained by selecting k in equation (2.7) to minimize the right-hand side.) But the true significance of Theorem 2.2 is revealed in the next

section when we consider the full class data structures within the semigroup model of computation. As a means for estimating complexity, T_{BAL} is a considerably more convenient object to reason about than the optimal tree, $T_{\bar{p},\bar{q}}$.

Proof of Theorem 2.2. Let η be any node in T_{BAL}, say, the jth node, let $T_{\eta,left}$ be the left subtree descending from η, and let $T_{\eta,right}$ be the right subtree descending from η. Let P_{sum} denote the sum of the p_i values associated with the nodes in $T_{\eta,left}$, and let Q_{sum} be the sum of the q_i values associated with the nodes in $T_{\eta,right}$. Now let γ be the lowest common ancestor in $T_{\bar{p},\bar{q}}$ of those nodes which comprise the subtree descending from η within T_{BAL}. Then either

(i) the left subtree $T_{\eta,left}$ descending from η lies to the left of γ in $T_{\bar{p},\bar{q}}$, or

(ii) the right subtree $T_{\eta,right}$ descending from η lies to the right of γ in $T_{\bar{p},\bar{q}}$.

For the purpose of estimating $W(T_{\bar{p},\bar{q}}, \bar{p}, \bar{q})$, in the case (i) we can charge the quantity P_{sum} to the left link of γ and in the case (ii) we can charge the quantity Q_{sum} to the right link of γ. We will demonstrate below that no p_i or q_i value gets charged to the same link of $T_{\bar{p},\bar{q}}$ twice. Assuming this, it follows that $W(T_{\bar{p},\bar{q}}, \bar{p}, \bar{q}) \geq$ the sum over all nodes in T_{BAL} of the quantities $\min(P_{sum}, Q_{sum}) = S_{BAL}$ (say). By definition of T_{BAL} we have that $P_{sum} \geq Q_{sum}$ and $Q_{sum} > P_{sum} - q_j - p_{j-1}$. It follows that

$$\min(P_{sum}, Q_{sum}) = Q_{sum} > \frac{1}{2}(P_{sum} + Q_{sum} - q_j - p_{j-1})\,. \tag{2.9}$$

Applying equation (2.7) to T_{BAL}, we note that $W(T_{BAL}, \bar{p}, \bar{q})$ equals the sum over all nodes in T_{BAL} of the quantities $P_{sum} + Q_{sum}$. Using the inquality (2.9) to compare the sums over the nodes of T_{BAL} that give, respectively, S_{BAL} and $W(T_{BAL}, \bar{p}, \bar{q})$, we conclude that $S_{BAL} \geq \frac{1}{2}W(T_{BAL}, \bar{p}, \bar{q}) - \frac{1}{2}$. Combining these inequalities for S_{BAL} yields the inequality in the statement of our theorem.

To complete the proof, we proceed to show that no p_i or q_i value gets charged to the same link of $T_{\bar{p},\bar{q}}$ twice. Suppose to the contrary that p_i (say) gets charged twice to the left link of γ, a node in $T_{\bar{p},\bar{q}}$. Now the first charge is through some node η_1 of T_{BAL} and the second charge is through some node η_2 of T_{BAL}. With respect to T_{BAL} both η_1 and η_2 are ancestors of the node τ with which p_i is associated and τ lies in the left subtrees of both η_1 and η_2. Therefore, the nearer ancestor η_1 (say) lies in the left subtree of η_2. Also in $T_{\bar{p},\bar{q}}$ we have that the nodes belonging (in T_{BAL}) to the left subtree of η_2 all lie to the left of γ. Consequently, the lowest common ancestor γ' (in $T_{\bar{p},\bar{q}}$) of the nodes in the subtree of η_1 (with respect to T_{BAL}) must lie to the left of γ. But the charge through η_1 must be assessed to a link of γ', contrary to the assumption. □

3. Unrestricted semigroup lower bound. In this section we generalize the lower bounds established in the preceding section for U-R systems to all computations that fall within the semigroup model of computation. Our bounds also apply to off-line computations. Our method of attack is to combine the biweighted tree perspective with the method of Wilber [7] used to analyze the off-line complexity of performing search tree operations intermixed with appropriately timed node rotations. Whereas the two problems, search tree operations versus partial sum operations, are very different, similar treatments succeed with both problems.

In the spirit of Wilber [7] we define a *lower bound tree* Υ that will be used to estimate the expected amount of work required to perform a random sequence of update and sum operations. For the partial sum problem of size N, with operations being requested randomly and independently in accordance with the distribution $(\bar{p}, \bar{q})$, we

choose Υ to be the tree T_{BAL} from the preceding section. Our argument proceeds in accordance with the following outline.

Part A. Given a specific sequence s of update and sum operations, we define the *score* of Υ with respect to the sequence s.

Part B. We show that the score defined in Part A provides a lower bound for the number of semigroup operations required to implement the sequence s off-line.

Part C. We estimate the expected value of the score defined in Part A for a random sequence s of operations.

Part A. Let η be the kth node in Υ, and let a and b be the smallest and largest nodes in the subtree descending from η. Now remove from the sequence s all update(j, x) and sum(j) operations with j outside of the interval $[a, b]$, remove all operations update(j, x) with $j > k$, and remove all operations sum(j) with $j < k$. Let s' be the resulting sequence. Then we define $\lambda(\eta, s)$ to be the number of pairs of consecutive terms in s' such that first term of the pair is an update operation and the second term is a sum operation. (Observe that $\lambda(\eta, s) = \lambda(\eta, s')$.) Finally, the score of Υ with respect to s is given by

$$\Lambda(\Upsilon, s) = \sum_{\eta \in \Upsilon} \lambda(\eta, s).$$

Part B. We choose as our semigroup the set of linear expressions over a set consisting of an infinite number of indeterminates. Assume that initially the quantity stored in $A[j]$ is given by x_j, where the x_j are distinct indeterminates. Also, assume that whenever an update(j, x) operation is performed, the quantity x is a newly introduced indeterminate. We associate with each indeterminate x the index j designating the array position $A[j]$ to which x contributes, and we refer to j as the *index of* x.

Our proof that $\Lambda(\Upsilon, s)$ provides a lower bound for the required number of semigroup operations proceeds by induction. Assume that the root η of Υ is the kth node in the tree. Consider an implementation σ of the sequence s of update and sum operations. If we eliminate from σ all semigroup operations involving indeterminates with index $\geq k$, then the remaining operations, σ_{left}, implement the subsequence s'' of update and sum operations in s whose array indices correspond to nodes in the left subtree Υ_{left} of Υ. Similarly, if we set to 0 all indeterminates with index $\leq k$ and then eliminate from σ any semigroup operations involving the addition of 0, then the remaining operations, σ_{right}, implement the subsequence s''' of update and sum operations whose array indices correspond to nodes in the right subtree Υ_{right} of Υ, treating the array A as though its index ranges over the interval $[k+1, N]$.

Now observe that

$$\begin{aligned} &\Lambda(\Upsilon, s) \\ &= \Lambda(\Upsilon_{left}, s'') + \Lambda(\Upsilon_{right}, s''') + \lambda(\eta, s'), \end{aligned} \tag{3.1}$$

where s' is defined in Part A. We easily see that the two sequences of semigroup operations σ_{left} and σ_{right} reflect disjoint semigroup operations in σ, and by the induction hypothesis, the number of operations in σ_{left} and σ_{right} dominate the first two terms on the right-hand side of equation (3.1). Part B is completed once we show that σ includes $\lambda(\eta, s')$ further semigroup operations.

Consider a pair of consecutive operations update(j', x), sum(j) in s'. The indeterminate x must be combined with x_j, the indeterminate originally stored in $A[j]$, by executing a semigroup operation. We may conclude, therefore, that there exists in

σ an operation $\alpha: z_p \leftarrow z_q + z_r$ contributing to the computation of sum(j), in which x gets combined with some indeterminate whose index is $\geq k$, and where x is not already found to be so combined among the operands on the right. This operation does not contribute to σ_{left} by definition. Likewise, it does not contribute to σ_{right} since the index j' of x does not exceed k (so that the operand in α containing x contains only indeterminates with index $\leq k$ and thus gets set to 0 in the process defining σ_{right}). Last, we may assume that the operation α excludes any indeterminate x' that follows x in s', since x must be produced in the sum(j) operation without the presence of x'. (In other words, if we remove from σ all semigroup operations that involve x', then the remaining operations would suffice to generate the required value for sum(j).) Thus, we can account for $\lambda(\eta, s')$ such operations α.

Part C. Let η be a node in $T_{BAL} = \Upsilon$, and assume that η is the kth node of Υ. We compute the expected value of $\lambda(\eta, s)$. Assume that the sequence s is of length m. Then the expected number of terms in s' is given by $m(P_{sum}+Q_{sum}+p_k+q_k) = mR$ (say). The conditional probability y_1 that a given term in s' is an update operation is given by $(P_{sum}+p_k)/R$, and the conditional probability y_2 that this term is a sum operation is given by $(Q_{sum}+q_k)/R$. By our definition of T_{BAL} we have $P_{sum} \geq Q_{sum}$ and $Q_{sum}+q_k > P_{sum}-p_{k-1}$. Therefore, $P_{sum}+p_k \geq \frac{1}{2}(R-q_k)$, and $Q_{sum}+q_k \geq \frac{1}{2}(R-p_{k-1}-p_k)$. We conclude that the expected number of pairs contributing to $\lambda(\eta, s)$ is given by $(mR-1)\cdot y_1 \cdot y_2 \geq \frac{mR}{4}(1-q_k/R)(1-(p_{k-1}+p_k)/R) - 1 \geq \frac{m}{4}(R-p_{k-1}-p_k-q_k) - 1$. Summing over all nodes η we conclude that $\Lambda(\Upsilon, s) = \Omega(m(W(T_{BAL}, \bar{p}, \bar{q}) - 1)) = \Omega(m(W(T_{\bar{p},\bar{q}}, \bar{p}, \bar{q}) - 1))$.

Summarizing the above discussion we have established the following theorem.

THEOREM 3.1. *For a random sequence s of* update(j, x) *and* sum(j) *operations, the optimal expected cost of executing the operations in s is given by $\theta(W(T_{\bar{p},\bar{q}}, \bar{p}, \bar{q}))$ per operation. In other words, U-R systems derived from optimal biweighted trees are near optimal within the semigroup model of computation. Moreover, the lower bound applies to off-line computations.*

Remark. Consider the special case $p_i = q_i = \frac{1}{2N}$ for $1 \leq i \leq N$. It is clear in this case that we may choose the optimal tree $T_{\bar{p},\bar{q}}$ to be the fully balanced tree with N nodes. Since $W(T_{\bar{p},\bar{q}}, \bar{p}, \bar{q}) = \Omega(\log N)$ in this instance, we conclude that the optimal off-line complexity of the partial sum problem is $\Omega(\log N)$ per operation. This improves upon the $\Omega(\log N/\log\log N)$ lower bound that was established for on-line computations [8].

4. Discussion. The problem of maintaining partial sums is perhaps the least complicated example of a nontrivial range or geometric query problem, and this problem is not yet fully understood. The partial sum problem is now well understood in the semigroup model of computation, but much remains to be resolved for less restrictive computational models. For example, in the group model of computation, wherein the space of array values is given by a group so that subtraction is available, a gap remains that separates the best upper and lower bounds for the worst-case amortized complexities. The best upper bound is $O(\log N)$ and the best lower bound is $\Omega(\log N/\log\log N)$ [5]. It seems reasonable to conjecture, however, that the truth will favor the upper bound. In particular, the notion of U-R systems generalizes for the group model; the sets U_i remain as before, and the sets R_i are replaced with linear expressions over the memory registers with integer coefficients. In this setting $\log N$ bounds are known [4] (both upper and lower), including even a determination of the constant factor. The biweighted tree treatment, however, does not seem to easily extend to cover the group case. In particular, lower bounds seem difficult.

Similarly, in the cell-probe model of computation with polylog(N) word size and with the space of array values given by Z_N, the integers mod N, the same gap exists between the best upper and lower bounds [5]. On the other hand, if the space of array values is given by Z_2, then matching upper and lower bounds of size $\theta(\log N/\log\log N)$ exist in the cell probe model [5] (see also [2]).

The nature of the possible tradeoffs between query versus update time in these less restrictive models is likewise not well understood. There is also an absence of off-line lower bounds in these other models.

As an object of independent interest, the biweighted trees pose some open questions. In particular, there seems to be no easy analogue to the entropy function, which is used to estimate the weighted path length of optimal trees in the usual setting. Complicating the situation is the fact that the function $C_{min}(\bar{p},\bar{q})$ highly depends on the ordering of the probabilities, even when the p_i and q_i values remain coupled. Simple examples exist which demonstrate the phenomenon that permuting the order of the probabilities can cause $C_{min}(\bar{p},\bar{q})$ to vary over the range from $O(1)$ and $O(\log N)$.

Finally, it is interesting to note that given any probability distribution with strictly positive probabilities, it is possible to explicitly exhibit arbitrarily large sequences of update and sum operations that have the corresponding proportions of the update and sum operations and satisfy the bounds of Theorem 3.1. The sequence is a generalization of the bit reversal sequence [7, 8]. The details of the construction can be found in [6].

Acknowledgment. The first author wishes to thank Vivek Gore for many helpful discussions.

DYNAMIC 2-CONNECTIVITY WITH BACKTRACKING*

JOHANNES A. LA POUTRÉ† AND JEFFERY WESTBROOK‡

Abstract. We give algorithms and data structures that maintain the 2-edge and 2-vertex-connected components of a graph under insertions and deletions of edges and vertices, where deletions occur in a backtracking fashion (i.e., deletions undo the insertions in the reverse order). Our algorithms run in $\Theta(\log n)$ worst-case time per operation and use $\Theta(n)$ space, where n is the number of vertices. Using our data structure we can answer queries, which ask whether vertices u and v belong to the same 2-connected component, in $\Theta(\log n)$ worst-case time.

1. Introduction.

Dynamic graph problems have been studied extensively in the last several years. Roughly speaking, the research has concentrated on two categories of dynamic graphs, viz., *partially dynamic* or *incremental* graphs, which are graphs that grow on line by the insertion of vertices and edges, and *fully dynamic* graphs, which are subject to arbitrary insertion and deletion of edges and vertices.

A number of different problems on incremental and fully dynamic graphs have been studied, including 2- and 3-edge connectivity, 2- and 3-vertex connectivity, spanning trees, and planarity testing [1], [5], [7], [8], [9], [10], [12], [13], [22], [18], [19], [20], [21], [26], [27], [30], [31], [33]. Deterministic algorithms for incremental 2-edge and 2-vertex connectivity running in $\Theta(\alpha(m,n))$ amortized time per operation, where m is the maximum number of edges and n the maximum number of vertices, are described in [18], [33]. Those algorithms require $\Theta(n)$ time per operation in the worst case. A fully dynamic deterministic algorithm for 2-edge connectivity running in $O(\sqrt{n})$ time is given by Eppstein et al. [7], and an $O(\sqrt{n}\log n)$ time algorithm for fully dynamic 2-vertex connectivity is given by Rauch [27]. (Again, m is the maximum number of edges and n the maximum number of vertices.)

Thus, there is a substantial gap in deterministic time complexity between the incremental and fully dynamic problems.[1] A tantalizing question is whether we can obtain much better time bounds than those for the fully dynamic problems by putting restrictions on the deletions of edges. A natural and useful restriction is to limit

[1]Recently randomization has been used to derive polylogarithmic time algorithms for several fully dynamic graph problems [17].

deletions to a backtracking *Undo*, which removes the most recently added edge not yet removed.

Dynamic backtracking problems appear to be an important research area for several reasons. The backtracking operation *Undo* is a common feature of interactive software systems. Also, backtracking search is a common search strategy in many logic and artificial intelligence applications. For example, maintaining 2-vertex-connected components (with backtracking) has been proposed as a way to improve search in Prolog [25]. Furthermore, dynamic graphs with backtracking suffice for many interactive system applications like, e.g., CAD/CAM systems and VLSI layout. Maintaining 2-vertex-connected components could potentially be used for problems in reliable network design, or for designing VLSI layouts.

Previous work on backtracking addressed the *Union-Find* problem, in which the standard disjoint set operations of *Union* and *Find* are augmented by the backtracking operation *Deunion*. (A *Deunion* undoes the most recent *Union* that has not been undone.) *Union-Find* with backtracking is a central problem in the implementation of unification and backtracking search in the logic programming language Prolog. Mannila and Ukkonen [23], [24] first formalized and studied this problem and proposed several algorithms which Westbrook and Tarjan [32] subsequently analyzed: each operation can be performed in $\Theta(\log n/\log\log n)$ amortized time. Blum [3] gave a data structure for *Union-Find* without backtracking that runs in $\Theta(\log n/\log\log n)$ worst-case time per operation. As observed in [32], Blum's data structure can be adapted to handle *Deunions* in the same time bound. Variants and extensions of this problem are studied in [11], [14].

In [30] it is observed that backtracking graph connectivity could be solved in $\Theta(\log n/\log\log n)$ time by a straightforward application of the backtracking *Union-Find* algorithm (as incremental graph connectivity can be solved by straightforwardly applying standard *Union-Find*). Tamassia [29] gave an algorithm for a hierarchical embedding problem related to VLSI design that is essentially an algorithm with *Undo* operations for maintaining an embedded planar *st*-orientable graph (such a graph is 2-connected if one edge (s,t) is added) under a restricted set of modifications; it thus gives a better time complexity than its fully dynamic counterpart for general, unrestricted embedded planar graphs [16] but only by a factor $\log n$.

In this paper, we consider maintaining the 2-edge and 2-vertex connectivity relations in dynamic graphs with backtracking, i.e., graphs subject to the modifications *Insert Vertex*(), which adds a new, isolated vertex to the graph; *Insert Edge*(u,v), which inserts a new edge between vertices u and v; and *Undo*, which undoes the effects of the most recent insertion not yet undone. We give algorithms and data structures that maintain a decomposition of a dynamic backtracking graph into its 2-edge and 2-vertex-connected components throughout any sequence of backtracking operations. Using our data structure we can answer *Test*(u,v) queries, which ask whether vertices u and v belong to the same 2-connected component, in $\Theta(\log n)$ worst-case time. Our algorithms run in worst-case time $\Theta(\log n)$ per operation and use $\Theta(n)$ space, where n is the current number of vertices ("existing") in the graph.

To our knowledge, the algorithms in this paper are the first nontrivial results for dynamic backtracking graph problems that yield a substantial improvement in time complexity over their fully dynamic counterparts. Our algorithms also solve the corresponding incremental problems in logarithmic worst-case time, improving the $\Theta(n)$ worst-case bounds on the algorithms given in [18], [33]. In fact, we present our results by first describing new incremental algorithms and then augmenting them to

support backtracking.

For comparison, we mention several alternate approaches to solving the backtracking problem. The simplest one is to push each edge on a stack as it is added, popping the stack for each *Undo*. A test query is answered by copying the edges on the stack, constructing the graph, and running a standard biconnectivity algorithm [4]. Updates require $\Theta(1)$ time in the worst case, queries take $\Theta(m)$ time, and the space required is $\Theta(m)$, where m is the maximum number of edges ever in the graph.

Another possibility is to use the techniques of *persistence* [6]. A normal data structure is *ephemeral* in the sense that after an update the old version is destroyed and replaced by the updated version. Using the techniques of Driscoll et al. [6], a pointer-based data structure in which all nodes have constant bounded in-degree and out-degree can be made *fully persistent*. In a fully persistent data structure all versions of the data structure can be accessed, and any old version can be updated to yield a new version. The amortized time per operation of the persistent data structure is equal to the worst-case time per operation of the underlying ephemeral data structure, and the space requirement of the persistent data structure is equal to the total number of pointer changes made in all versions of the ephemeral data structure. Applying persistence to a data structure for the incremental 2 connectivity problem gives a solution to the backtracking problem. The data structures of [19], [33] do not have constant bounded in-degree, and the worst-case time per operation is $\Theta(n)$. When we replace nodes with high in-degree with balanced binary trees, persistent versions of these data structures give a backtracking algorithm that runs in $\Theta(n \log n)$ amortized time per operation and requires $\Theta(Mn)$ space, where M is the total number of edge insertion operations. Applying persistence to the incremental data structures developed in this paper gives less dismal results: $\Theta(\log n)^2$ amortized time per operation and $\Theta(n + M \log n)$ space. (The additional factor of $\log n$ again arises from replacing nodes with high in-degree by balanced binary trees.) In contrast, our direct solution to the backtracking problem gives $\Theta(\log n)$ time in the worst-case and only $\Theta(n)$ space.

This paper is organized as follows. In section 3, we present a solution for 2-edge connectivity that runs in $\Theta(\log n)$ time per operation and $\Theta(n)$ space. Although obtaining these bounds for 2-edge connectivity is relatively simple, obtaining $O(\log n)$ bounds for 2-vertex connectivity requires rather more sophisticated data structuring and accounting. These are presented in section 4. There we first give an intermediate and simpler solution that runs in $\Theta(\log^2 n / \log \log n)$ time per operation and then present the $\Theta(\log n)$ solution.

2. Preliminaries.

2.1. Terminology. In this paper, we use the standard graph terminology in Harary [15].

Let $G = (V, E)$ be a graph. A *path* is a sequence of vertices $v_0, v_1, \ldots, v_k$ such that $\{v_i, v_{i+1}\} \in E, 0 \leq i < k$. Vertices v_0 and v_k are *endpoints* of the path; the remaining vertices are *internal*. Two vertices in V are *connected* if there exists a path between them. The connected components of G are the maximal subgraphs of mutually connected vertices.

Let $\{u, v\}$ be an edge of graph G whose removal disconnects the graph. Such an edge is called a *bridge*. The 2-*edge-connected components* of G are the connected components that remain after all bridges are removed. Two vertices are 2-*edge connected* if they belong to the same 2-edge-connected component. If u and v are 2-edge connected, then there are at least two edge disjoint paths between them.

Let u be a vertex whose removal disconnects G. Such a vertex is called a *cutpoint*. Two edges are called 2-*vertex connected* if they lie on a common simple cycle. Thus, 2-vertex connectivity is an equivalence relation on the edge set. The 2-*vertex-connected components* or *blocks* of G are the subgraphs of G induced by the edges in an equivalence class plus their end nodes. Two vertices are 2-*vertex connected* if they belong to the same 2-vertex-connected component. Thus, two vertices are 2-vertex connected if and only if there are at least two vertex-disjoint paths between them, and any two 2-vertex-connected components intersect at most at one cutpoint.

Recall from [33] that for the 2-edge and the 2-vertex connectivity relation, $\Theta(n)$ 2-connected components may be merged in case of an edge insertion, and, similarly, $\Theta(n)$ new components may arise in case of an *Undo* operation. Thus, it is possible to construct a sequence of operations in which each operation changes the number of 2-connected components by $\Theta(n)$. This is in contrast with connected components, where only two components may be joined or separated by an insertion or *Undo* operation.

2.2. Dynamic trees. In [28], Sleator and Tarjan presented their dynamic tree data structure. For later reference, we briefly describe the main features of this data structure.

The data structure maintains a rooted tree with costs on each edge or, alternatively, on each vertex. It performs the following operations (among others) in $\Theta(\log n)$ worst-case time:

find root(u), which returns the root of the tree in which node u is contained;

parent(u), which returns the parent of node u in the tree (if any);

find min(u), which returns the edge of minimum cost on the path from u to the root;

add cost(u, x), which adds value x to the cost of all edges on the path from u to the root;

cut(u), which creates two trees from one by cutting the edge from u to its parent;

link(u, v, x), which combines two trees into one by making u a child of v (it presumes that u is the root of a tree distinct from the tree containing v), where edge (u, v) has cost x;

and *evert*(u), which reroots the tree containing u at u.

If costs are associated with nodes, *add cost*(u, x) adds value x to the cost of all nodes on the path from u to the root, and *find min*(u) returns the node of minimal cost on the path from u to the root.

As observed in [30], maintaining the connectivity relation with backtracking can be performed in $\Theta(\log / \log \log n)$ time per operation and $\Theta(n)$ space by using a *Union-Find* structure with backtracking. We remark that the connectivity relation can also be maintained using dynamic trees in $\Theta(\log n)$ time per operation. For each component we maintain a spanning tree in the obvious way and test whether u and v are in the same component by *find root* operations for u and v. We will not make the maintenance of the connectivity relation explicit in our algorithms for 2-edge and 2-vertex connectivity.

3. 2-edge connectivity. In this section, we describe algorithms and data structures for maintaining the 2-edge connectivity relation in dynamic graphs with backtracking. We first describe a data structure that performs 2-edge connectivity queries and edge insertions in $\Theta(\log n)$ worst-case time, and we then extend this algorithm to handle backtracking.

Let T be a spanning tree of a graph G. An edge $e \in T$ is *covered* if it lies on the fundamental cycle (with respect to T) of some nontree edge $f \in G$.

LEMMA 3.1 (see [10]). *Two vertices are in the same 2-edge-connected component of G if and only if all edges on the path in T between u and v are covered.*

Using this lemma, it is easy to solve the incremental 2-edge connectivity problem in worst-case $\Theta(\log n)$ time per operation, using the variant of the dynamic tree data structure in which cost is attached to the tree edges. A spanning tree is maintained for each component of G and used for testing 2-edge connectivity. Each edge of G is classified as either a spanning tree edge, an *essential* nontree edge, or a *nonessential* nontree edge. The edge is a spanning tree edge if at the time of insertion it connected two previously unconnected components. The edge is an essential edge if at the time of insertion it reduced the number of 2-edge-connected components. Otherwise it is nonessential. At any time, let G' be the subgraph of G consisting of all vertices of G, all spanning tree edges, and all essential nontree edges. Thus, G and G' have the same 2-edge-connected components. The size of G' is $2(n-1)$ because each edge in G' is either a spanning tree edge or an edge that reduced the number of 2-edge-connected components by 1, which can happen at most $n-1$ times. The cost of a tree edge e will be the number of nonspanning tree edges in G' covering tree edge e. The operations on G defined in the introduction are implemented as follows.

Insert Vertex(): Create a new single-node tree and return a pointer to the new node.

Test(u, v): If u and v are in different components, return "no." Otherwise perform *evert*(v) followed by *find min*(u). If the minimum value is zero, return "no," otherwise "yes."

Insert Edge(u, v): If u and v are in different components, do *evert*(u) and perform *link*$(u, v, 0)$, creating a new tree edge e with cost 0. Otherwise, compute *Test*(u, v). If the result is "no," then *evert*(v) and *add cost*$(u, 1)$. Otherwise do nothing.

The correctness of these routines is easily seen by induction on the number of requests. The crucial observation is that the cost of an edge is exactly equal to the number of covering edges in the graph G', and that if there is an edge in G covering edge e, then there is an edge in G' covering e. Each operation runs in worst-case time $\Theta(\log n)$, since each performs a constant number of dynamic tree operations.

So far, we have a data structure for the incremental problem. To support *Undo*, we utilize a *backtrack stack*. If an *Insert Edge*(u, v) or *Insert Vertex*() operation changes the number of components or 2-edge-connected components, then it is essential and G' is augmented accordingly; a new record is pushed on the backtrack stack. The record contains the type of operation performed, the endpoints of the new edge in the case of an edge insertion, the name of the new vertex in the case of a vertex insertion, and a counter initialized to zero. This counter contains the number of nonessential, not yet undone insertions performed after the one described in the record (which is an essential one), and before the essential insertion described in the next record (if any). Thus, if an *Insert Edge*(u, v) operation adds an edge between two vertices that are already in the same 2-edge-connected component, the counter in the top stack-record is simply incremented.

To perform *Undo*, proceed as follows. Examine the counter in the top record on the stack. If it is greater than zero, decrement the counter and terminate. Otherwise pop the top record. If the operation stored in this record is an *Insert Vertex*(), then

delete the appropriate vertex. If the operation is *Insert Edge*(u, v), then do *evert*(v) and *add cost*$(u, -1)$. Perform *find min*(u). If it returns an edge e of cost -1 (meaning e is an edge that, when inserted, connected two previously unconnected components), then *cut*(u) is performed, while e is deleted. We obtain the following theorem.

THEOREM 3.2. *A sequence of* Test(u, v), Insert Vertex(), Insert Edge(u, v), *and* Undo *operations can be performed in* $\Theta(\log n)$ *worst-case time per operation and in* $\Theta(n)$ *space, where* n *is the current number of nodes.*

Proof. It is readily seen that the relation between G and G' is maintained. To show the correctness of the backtracking procedure, it suffices to confirm that an *Undo* performed immediately after an insertion restores the data structure to its condition prior to the insertion. The time bound follows from [28]. The space complexity follows since the size of the stack (i.e., the number of records in it) is bounded by the size of G'. □

4. 2-vertex connectivity. In this section, we describe algorithms and data structures for maintaining the 2-vertex connectivity relation in dynamic graphs with backtracking. As in the previous section, we begin by describing a data structure that performs only 2-vertex test queries and edge insertions in $O((\log n)^2/\log\log n)$ worst-case time. This then serves as a basis for a backtracking algorithm with this time complexity. Subsequently, we present data structures and algorithms to achieve $O(\log n)$ time per operation.

As in the case of 2-edge connectivity, our approach is to maintain a spanning tree of the graph and store information with the vertices and edges of the spanning tree that can be used efficiently to answer test queries. In the case of 2-vertex connectivity, however, there is no simple covering lemma, and our algorithms and data structures are consequently more complex. Our approach to 2-vertex connectivity is based on the following lemma.

LEMMA 4.1. *Let* T *be a spanning tree of graph* G. *Two nodes are in the same block of* G *if and only if all tree edges on the path* P *between* u *and* v *are in the same block.*

Proof. If all edges on P are in the same block, then u and v are in the same block, since if an edge is in block B so are its endpoints. Conversely, assume u and v are in the same block B. Any simple path between u and v (such as P) must be entirely contained inside B. Otherwise, it must pass out of B through some cutpoint, and by definition of a cutpoint it cannot return into B without going through the same cutpoint, contradicting the assumption that P is simple. □

To use the lemma we must find an efficient way to test 2-vertex connectivity along tree paths. We will use the dynamic tree data structure of Sleator and Tarjan with cost related to nodes as a basis. By itself, however, this data structure is insufficient for our needs. We augment the data structure to solve 2-vertex connectivity with backtracking.

4.1. The dynamic tree data structure of Sleator and Tarjan. The fundamental principle behind the data structure is a partitioning of tree edges into vertex-disjoint paths, called a *path decomposition*. An edge within a path is called *solid*, while a nonpath edge is called *dashed*. Dynamic tree operations are performed by manipulating the path partition so as to place relevant vertices in the same path. Each path p has two endnodes *head*(p) and *tail*(p), which are the nodes on p that are farthest from and nearest to the root, respectively.

Let T be a tree rooted at r. There is a unique path decomposition of T defined by its *heavy edges*. Denote by $s(v)$ the number of descendants of node v, and denote

by $p(v)$ the parent of v. Let $\langle u, v\rangle$ denote a tree edge with $v = p(u)$. Call edge $\langle u, v\rangle$ *heavy* if $2s(u) > s(v)$, otherwise *light*. Removal of light edges leaves a collection of disjoint paths. There are $O(\log n)$ light edges on any path to the root.

The solid path decomposition maintained by the Sleator–Tarjan dynamic tree data structure is exactly the heavy path decomposition, except possibly during the execution of one of the dynamic tree operations. At the conclusion of each operation, however, the correspondence between solid paths and the unique heavy path decomposition is restored.

The *costs* of nodes are examined and changed using only two functions: *find-min-on-path* and *add-cost-to-path*. The former operation finds the minimum cost node on a solid path, and the latter increases the cost of all nodes on a single solid path. To perform a *find min*(u) operation, for example, the path from u to the root r must be turned into a single solid path to which *find-min-on-path* is applied. After the minimum is found, the heavy path decomposition is restored. Each solid path p is stored in a binary search tree D_p, where the leaves of the tree correspond to the nodes on the path so that in order on the tree corresponds to path order from head to tail. Each internal node of D_p has a "partial" cost. The cost of the solid path node v stored at leaf l of D_p is the sum of all the partial costs stored with the internal nodes on the path from the root of D_p down to the leaf node l. Thus, the cost of all nodes on the solid path p can be changed by Δ by adding Δ to the partial cost of the root of D_p. By maintaining minima of subtrees in D_p, the minimum on path p can be found in time linear in the depth of D_p. Using the binary tree data structure, a path p can be split at node v to give three new paths, p_1, v, and p_2, with p_1 containing the former head of p and p_2 containing the former tail. After the split, the cost of v can be determined in $O(1)$ time. The inverse of splitting is a concatenation, which produces a single path p consisting of p_1, followed by v, followed by p_2.

The path decomposition is manipulated by means of three functions: *expose*, *conceal*, and *reverse* [28]. An *expose* creates a solid path starting at a specified node v and ending at the root. The new path may not necessarily contain only heavy edges. A *conceal* takes a solid path p containing the root and possibly some light edges and modifies the collection of solid paths so that every edge incident with a node of p is solid if and only if it is heavy. A *reverse* operation reverses the direction of tree edges in a solid path ending at the root. Thus, for example, an evert at v is implemented by an expose of v, a reverse of the resulting path, and a conceal of the path now rooted at v.

Let P be the path from node v to the root of T. The *expose*(v) operation turns all the dashed edges on P into solid edges and simultaneously turns all the solid edges incident to but not on P into dashed edges. Let $\langle x, y\rangle$ be a dashed edge on P ($y = p(x)$), and let $\langle z, y\rangle$ be the solid edge containing a sibling z of x. If y has no heavy child, there is no such edge. The process of making $\langle x, y\rangle$ into a solid edge and $\langle z, y\rangle$ into a dashed edge is called a *splice*, denoted *splice*(x). At the time of the *splice*, let p_x be the solid path containing x as its tail. A *splice* involves splitting the solid path p containing y into p_1, y, p_2 (both p_1 and p_2 may be empty) and concatenating p_x, y, p_2. While y is a singleton, its cost can be obtained or updated in $O(1)$ time. The expose operation performs the necessary *splices* in order from v to the root. The solid path initially containing v is split as necessary so that v has no descendant solid edge.

The *conceal* operation is the inverse of *expose*. Given a solid path P containing the root, with head v, a *conceal* turns all the light edges on P into dashed edges, and

all the heavy edges incident to but not on P into solid edges. It thus restores the heavy path decomposition. *Conceal* processes P from its tail down. Let $\langle x, y\rangle$ be a solid light edge on P and let $\langle z, y\rangle$ be the dashed heavy edge incident on y. If y has no heavy child z, there is no such edge. The process of making $\langle x, y\rangle$ into a dashed edge and $\langle z, y\rangle$ into a solid edge is called a *slice*, denoted *slice*(x). Obviously, *slice* is the inverse of *splice*. At the time of the *slice*, let p_z be the solid path containing z as its tail. A *slice* involves splitting the solid path P into p_1, y, p_2 (both p_1 and p_2 may be empty) and concatenating p_z, y, p_2. The *conceal* then continues down path p_1, which has tail x, unless p_1 is empty. The method by which *conceal* determines which edges are light is quite clever and intricate. It involves keeping track of the number of descendants of dashed edges in the data structure.

4.2. A dynamic tree data structure for 2-vertex connectivity. We use the Sleator–Tarjan data structure as a basis for our data structure.

Let T be a tree rooted at r. Given a path decomposition for T, we categorize the tree edges incident on a node v in three ways. Edge $\langle v, w\rangle$ is a *parent* edge if $w = p(v)$ with respect to the current tree root. (The parent edge may be either solid or dashed.) Edge $\langle u, v\rangle$ is a *solid child* edge if it belongs to a solid path and $v = p(u)$. All other edges are *dashed child* edges. A solid edge can change to a parent edge, and vice versa, via a reverse. A solid child edge can change to a dashed child edge, or vice versa, via an expose or conceal. No single operation, however, can change an edge incident on v from being a parent to being a dashed child.

With each node v we associate an integer *counter value* $c(v)$ that, roughly speaking, takes the place of the cost value maintained by the basic dynamic tree structure. The counter value differs from the cost value, however, in that it depends on both the current 2-connected components of G and the current path decomposition of the spanning tree T. The counter values satisfy the following:

(i) if v has both a solid child edge and a parent edge, then $c(v)$ is zero if these two edges are in different blocks of G, and positive (including ∞) otherwise;

(ii) if v has no solid child edge or no parent edge, then $c(v) = +\infty$.

The counter condition implies that two edges belonging to the same solid path are in the same block if and only if all intervening path vertices have value greater than zero. Solid paths are implemented in the same manner as in the standard Sleator–Tarjan data structure, and counter values can be examined or set using the *find-min-on-path* and *add-cost-to-path* functions. The symbol $+\infty$ indicates a positive number that cannot be changed by *add-cost-to-path*. (Below, we explain this further.)

The counter value of node v says nothing about the relationship between dashed edges incident on v nor between dashed edges and solid edges incident upon v. An additional data structure handles these relationships. For each vertex v we maintain a *block partition*, $\mathcal{B}_v$, of the edges $\{e_1, e_2, \ldots, e_k\}$ adjacent to v. Let $\mathcal{B}_v(e_i)$ denote the set of $\mathcal{B}_v$ containing edge e_i. Let y be the solid child edge, if any, of v, and let z be the parent edge, if any, of v. At all times, edges e_i and e_j belong to the same 2-vertex-connected component (block) of G if and only if at least one of the following holds:

1. $\mathcal{B}_v(e_i) = \mathcal{B}_v(e_j)$.
2. $\mathcal{B}_v(e_i) = \mathcal{B}_v(y)$, $\mathcal{B}_v(e_j) = \mathcal{B}_v(z)$, and $c(v) > 0$.
3. As in 2, but with e_i and e_j exchanged.

The block partition is subject to *Unions*, *Finds*, and eventually *Deunions*. For each tree edge $e = \langle u, v\rangle$ there is a record containing the names of its endpoints and pointers to two representatives, one for $\mathcal{B}_u$ and one for $\mathcal{B}_v$. We denote these

representatives by $e_{v,u}(u)$ and $e_{u,v}(v)$, respectively. The two representatives of e contain back pointers to the record for e. This edge data structure is created and initialized when a new tree edge connecting two previously unconnected components is added.

To implement edge insertions, we use the standard dynamic tree operations such as *evert* and *link*. Each of these operations is in turn implemented with $O(1)$ invocations of the primitives *reverse*, *expose*, and *conceal*. We will also call these primitives directly in our implementations. As these primitives are executed, the block partitions and counter values must be modified to preserve the needed invariants.

If the counter values and block partitions are valid prior to a *reverse* operation, they remain valid after a *reverse*. The other two primitives change the solid path decomposition, however, and hence may cause changes in our counter values and block partitions. The *expose* primitive uses the function *splice*, which makes a light dashed edge solid and a heavy solid edge dashed. The *conceal* primitive uses the function *slice*, which makes a light solid edge dashed and a heavy dashed edge solid. For our purposes, whether the edges are heavy or light does not matter. The block partition and counter values are modified as follows.

Let $y = \langle u, v\rangle$ be a solid child edge of v which must be made dashed. Let z be the parent edge, if any, of v. If $\mathcal{B}_v(y) \neq \mathcal{B}_v(z)$ and $c(v) > 0$, then unite $\mathcal{B}_v(y)$ and $\mathcal{B}_v(z)$. In any case, set $c(v) = +\infty$.

Let $y = \langle u, v\rangle$ be a dashed child edge of v which must be made solid (there is no solid child edge of v at this point). Let z be the parent edge, if any, of v. If $\mathcal{B}_v(y) \neq \mathcal{B}_v(z)$, then set $c(v) = 0$; otherwise set $c(v) = +\infty$.

It is straightforward to verify by case analysis that these algorithms correctly maintain the counter values and block partitions through any sequence of queries and edge insertions. To facilitate access to the representatives for edges y and z in the above algorithms, each tree node v is augmented with pointers to the representatives in $\mathcal{B}_v$ of the solid edges incident to v, or the dashed edge from v to its parent, as appropriate. These pointers can be updated as part of the extended splice and slice in $O(1)$ time.

4.3. Implementation of test and insertion operations. In this subsection we present the implementation of *Test*(u, v) and *Insert Edge*(u, v). (The implementation of *Insert Vertex*() is straightforward.)

Test(u, v):

1. If u and v are in different components, return "no" and terminate.
2. Save the tree root r.
3. Evert the tree at v, making v the root. (Expose v and reverse the path from v to r.)
4. Expose u.
5. Perform *find-min-on-path* on the resulting solid path. Return "no" if the minimum value is 0; otherwise return "yes."
6. Conceal u and evert the tree at r.

Insert Edge(u, v):

1. If u and v are in different components, and hence different trees, evert at u, and perform Link(u, v). Add two singleton sets to the block partitions $\mathcal{B}_u$ and $\mathcal{B}_v$, each representing edge {u,v}. Then terminate.
2. If u and v are in the same tree, compute *Test*(u, v).

3. If the result is "no," then evert at v; expose u; increment counters on the resultant path with *add-cost-to-path*; conceal u.

LEMMA 4.2. *The above implementations of* Test(u, v) *and* Insert Edge(u, v) *are correct.*

Proof. Each operation uses $O(1)$ calls to the primitives *add-cost-to-path*, *find-min-on-path*, *expose*, *conceal*, and *reverse*. By the discussion from the previous section, these operations are correct.

Consider the *Test*(u, v) operation. Step 1 is trivially correct. Steps 2–4 construct a new path decomposition in which u and v are in the same solid path and u is the root of the tree. The primitives *expose*, *conceal*, and *reverse* construct correct counter values and block partitions, as defined in the previous section, for the new path decomposition. The endpoints of the path to which *find-min-on-path* is applied always have counter value $+\infty$. Hence the *find-min-on-path* operation determines whether there is a zero on a node internal to the path, which in turn determines whether u and v are in the same 2-connected component. Step 6 restores the original path decomposition.

The correctness of *Insert Edge*(u, v) follows from a similar argument. Step 3 increases all counter values along the path, so there is no longer a node of zero cost separating u and v. The final *conceal* will possibly change the path partition but will correctly construct new counter values and block partitions. □

LEMMA 4.3. *The above implementations of* Test(u, v) *and* Insert Edge(u, v) *run in* $\Theta((\log n)^2/\log\log n)$ *worst-case time per operation.*

Proof. The implementations of *add-cost-to-path*, *find-min-on-path*, *expose*, *conceal*, and *reverse* given by Sleator and Tarjan run in $\Theta(\log n)$ time in the worst case. In addition, the number of splices and slices performed per expose or conceal is $\Theta(\log n)$ in the worst case. Node counter values can be obtained or set to a particular value in $O(1)$ time when paths are split and concatenated during splices and slices. (We defer explaining how to implement $+\infty$ for the moment.) There are $O(1)$ *Union* and *Find* operations on block partitions during a splice or slice. *Unions* and *Finds* can be done in $\Theta(\log n/\log\log n)$ worst-case time per operation using Blum's data structure [3]. □

Hence, an incremental algorithm that runs in $\Theta((\log n)^2/\log\log n)$ worst-case time per operation is the result of this section.

4.4. The *Undo* operation. The algorithms for 2-vertex connectivity are more complicated than those for 2-edge connectivity, and the *Undo* operation is correspondingly more complex. Correct backtracking can be guaranteed by logging every change to a pointer or data field done in the course of an operation. By unwinding the log, each change can be exactly undone and the exact previous state of the data structure restored. This approach is space intensive, however. Our goal is to store a minimal amount of backtracking information. This means that the *Undo* will not restore the exact state of the data structure prior to the operation being undone. In particular, an *Undo* will restore the exact previous path decomposition, block partitions, counter values, and backtracking stack, but it will not necessarily restore the previous states of the data structures used to implement the solid paths and block partitions. There is no conceptual problem, since several different data structure states may represent the same solid path or block partition.

To prove the correctness of our implementation of backtracking, it suffices to show that by using the information stored on the backtracking stack during an update

operation, the update operation can be immediately undone. That is, no matter what the states of the data structures implementing the solid paths and block partitions, the previous path decomposition, block partitions, counter values, and backtracking stack can be restored. The correctness of the whole algorithm then follows by induction on the number of operations, since the answers to biconnectivity queries are determined only by these attributes.

The implementation of *Test*(u, v) given in subsection 4.3 may change the block partition, since it executes *expose* and *conceal* operations. It is most convenient to undo these changes immediately after the test operation is completed. This can be done in a brute-force fashion by logging each change to any pointer or data field and by storing the location of the field and the previous value. The old values can be restored by going backward through the log. Since *Test*(u, v) runs in $O((\log n)^2/\log\log n)$ time in the worst-case, the total size of the log and the time to restore the previous values is $O((\log n)^2/\log\log n)$. A better approach is to observe that the implementation of *Test*(u, v) is almost the same as the implementation of *Insert Edge*(u, v). Hence we may use the *Undo* algorithm for *Insert Edge*(u, v) developed below with only minor modification.

Each time an essential edge is inserted, a record is pushed onto the backtracking stack. As in the algorithm for 2-edge connectivity, an edge is essential only if its insertion reduces the number of components or 2-vertex components. Each record contains a counter that indicates the number of not-yet-undone nonessential edge insertions performed after the essential one described in the record. Upon an insertion of a nonessential edge, the only change to the data structure is to increment the counter in the top record. Upon an *Undo*, the counter in the top record is examined. If greater than zero, it is simply decremented. This suffices to restore the state of the data structure prior to the most recent insertion.

If the insertion is essential, a new record with a zero counter is pushed on the stack. The record describes the operation performed and the effect: either a decrease in the number of components or a decrease in the number of blocks. The record also describes each of the $O(1)$ "suboperations," *expose*, *reverse*, *conceal*, and *add-cost-to-path*, that were done.

A *reverse* can be undone by another *reverse* on the same path. The effect of incrementing counters by *add-cost-to-path* can be undone by using *add-cost-to-path* to add -1 to the same path.

Undoing the effects of an *expose* or *conceal* is more complicated. For each such operation, the main backtracking record contains a substack of subrecords. This substack will record changes to the block partitions that occur during the operation.

Suppose we expose v and we want to immediately undo the *expose*. The heavy path decomposition that existed prior to the expose can be restored by an immediate *conceal*. Since the heavy path decomposition is unique, each *splice* occurring in the *expose* will be exactly undone by a *slice* in the *conceal*. The *conceal* algorithm processes each sliced edge in the reverse order that it was spliced by the *expose*. Similarly, a *conceal* operation, which travels down a solid path turning light edges on the path into dashed edges, can be immediately undone by an *expose* starting at the last vertex on the solid path traversed by the *conceal*. Each *slice* done by the *conceal* is exactly undone by a *splice* in the *expose*.

To restore the counter values and block partitions, it suffices to show how to modify *splice* to undo the effects of an immediately preceding *slice* and vice versa. The function *splice* makes a heavy solid child dashed, if there is one, and then makes

a light dashed child solid. The function *slice* makes a light solid child dashed, and then makes a heavy dashed child solid, if there is one. With respect to the counter and block partition, it does not matter whether the edges are heavy or light. Hence it suffices to show how to undo the effect of turning a dashed edge solid and how to undo the effect of turning a solid edge dashed.

The block partitions are managed by an algorithm for set *Union* with backtracking that supports the operations *Find*, *Union*, and *Deunion*. As described in section 1, these operations can be implemented in $\Theta(\log n / \log\log n)$ time, either worst case or amortized.

Let $y = \langle u, v\rangle$ be solid child edge of v which must be made dashed as part of a normal edge insertion. Let z be the parent edge, if any, of v. If $\mathcal{B}_v(y) \neq \mathcal{B}_v(z)$ and $c(v) > 0$, then unite $\mathcal{B}_v(y)$ and $\mathcal{B}_v(z)$; push a new subrecord on the substack, labeled with the name "v"; store the current value of $c(v)$ into the subrecord; and set $c(v) = +\infty$. In all other cases, simply set $c(v) = +\infty$. If x is being made dashed during an *Undo*, simply set $c(v) = +\infty$.

Let $y = \langle u, v\rangle$ be a dashed child edge of v which must be made solid. Let z be the parent edge, if any, of v. If $\mathcal{B}_v(y) \neq \mathcal{B}_v(z)$, then set $c(v) = 0$; otherwise set $c(v) = +\infty$. If y is being made dashed as part of an *Undo*, then examine the top subrecord on the substack. If it is labeled "v," then pop the subrecord, execute a *Deunion* in the block partition for v, and set $c(v)$ equal to the value stored in the subrecord.

By inspecting these routines, one may verify that after a normal solid-to-dashed operation, an immediate dashed-to-solid operation in *Undo* mode will correctly restore the previous block partition and counter value. Similarly, after a normal dashed-to-solid operation, an immediate solid-to-dashed operation in *Undo* mode correctly restores the previous state. Recall that to make a dashed child solid, v can have no other solid child, and hence $c(v) = +\infty$.

THEOREM 4.4. *A sequence of* m Test(u, v), Insert Vertex(), Insert Edge(u, v), *and* Undo *operations can be performed in* $\Theta((\log n)^2 / \log\log n)$ *worst-case time per operation and in* $\Theta(n)$ *space.*

Proof. As discussed above, the correctness of the *Undo* algorithm follows by induction, since sufficient information is stored on the backtrack stack to allow each function that changes the path decomposition or counter values to be immediately undone. The running time of an *Undo* is order of the running time of the operation being undone, which is $\Theta((\log n)^2 / \log\log n)$ in both cases.

Next we consider the space utilization. After $O(n)$ essential edge insertions, all edges are in the same 2-vertex component. Since $O(1)$ records are only pushed on the backtrack stack if components or blocks are joined, and $O(1)$ subrecords are only pushed on a substack if sets in the block partitions are united, the total space required on the backtrack stack is $O(n)$ main records plus $O(n)$ total subrecords. Obviously, $\Omega(n)$ space is required just to store the vertices. □

We use $+\infty$ to ease designing and analyzing the algorithm. It ensures that the endpoints of a path always have positive counter value and so cannot interfere with the operation *find-min-on-path*. If v is internal to a solid path, and both incident solid edges belong to the same set of the block partition, then $c(v)$ is also $+\infty$. This is an easy way to ensure that no amount of counter decrements performed during *Undo*s will accidentally reduce $c(v)$ to zero, thereby violating the counter condition. For theoretical purposes, there is no difficulty in assuming that the arithmetic operations of the target machine are augmented to handle $+\infty$. For actual implementations,

we can dispose of $+\infty$ as follows. Say that the value of $c(v)$ is *equivalent* to $+\infty$ if it is greater than the number of not-yet-undone counter increments that have been applied to v. Since this number is at least zero, a value equivalent to $+\infty$ is always positive. Modify the algorithms so that wherever a counter was previously set to $+\infty$ it is now set to one more than the current size of the backtrack stack. One may show the correctness of this modified algorithm by imagining that the original and modified algorithms are run side by side on the same input and verifying by induction that a counter in the modified algorithm is equivalent to $+\infty$ exactly when the corresponding counter in the original algorithm is equal to $+\infty$.

4.5. An $\Theta(\log n)$ algorithm for 2-vertex connectivity. We improve the worst-case running time to $\Theta(\log n)$ per operation by using *globally biased binary search trees* [2], [28] to implement the block partitions. In the Sleator–Tarjan data structure, the solid paths are already implemented by globally biased trees.

In a biased binary tree, A, each node has a specified *weight* $w(x)$. Let A_v be the subtree of A rooted at v; the *size* of a biased-tree node, $s(v)$, is defined as $s(v) = \sum_{u \in A_v} w(u)$. Define the *rank* of node v, $r(v)$, as $\log s(v)$. We use $r(A)$ to denote the rank of the root of biased binary tree A.

The biased binary tree data structure has the following properties.

1. The depth of node $v \in A$ is $O(r(A) - r(v))$.
2. For $v \in A$, the operation *split*(v) produces trees A_1, v, A_2 and requires time $O(r(A) - r(v))$.
3. The operation *concat*(A_1, A_2) concatenates two trees A_1 and A_2 in time

$$O(\max\{r(A_1), r(A_2)\} - \max\{r(\mathit{right}(A_1)), r(\mathit{left}(A_2))\}),$$

where *left*(A) and *right*(A) denote the leftmost and rightmost nodes, respectively, in tree A.

Note that concatenating trees A_1, v, and A_2 to give tree A requires time $O(r(A) - r(v))$. For this can be done by *concat*(*concat*$(A_1, v), A_2)$, requiring time $O(r(A_1) - r(v)) + O(\max(\max(r(A_1), r(v)) + 1, r(A_2)) - r(v))$ which is $O(r(A) - r(v))$.

Thus, splitting a tree A into A_1, v, A_2 by *split*(v) can be undone by concatenating A_1, v, and A_2 both within the same time bound $O(r(A) - r(v))$ and vice versa.

Recall that each tree edge $\langle u, v\rangle$ has two representatives, one each in the block partitions for u and v. Denote these by $e_{v,u}(u)$ and $e_{u,v}(v)$, respectively. If $\langle u, v\rangle$ is a dashed child edge of v, define $w(e_{u,v}(v))$ to be the number of descendants of u in the spanning tree T. If $\langle u, v\rangle$ is a parent or solid edge of v, define $w(e_{u,v}(v))$ to be zero. These weights are already explicitly maintained in the standard Sleator–Tarjan data structure and can be accessed in $O(1)$ time when needed by our modified algorithms.

Each block partition set $B \in \mathcal{B}_v$ is implemented by a header that contains pointers to one or two biased binary trees. The binary trees contain the dashed child edges of v, using the weights given above. Each tree root contains a back pointer to the set header. Set B may be stored in two trees if it contains both the parent and solid child edges of v, and it is stored in one tree otherwise. In case of two trees, one of them precedes the other as indicated by the pointers (distinguished as a left and a right pointer). We usually indicate this order by using indices with the trees, e.g., X_1,X_2. Furthermore, each parent or solid child edge e contains a pointer to the set header of $\mathcal{B}_v(e)$. Hence testing whether $\mathcal{B}_v(e_1) = \mathcal{B}_v(e_2)$ can be done by obtaining and comparing the corresponding set header for e_1 and e_2, either by using a direct pointer to a set header in case of a parent or solid child or by traversing the root path and using the pointer from the root to the set header in the case of a dashed child.

For biased binary tree A, we denote by $h(A)$ the node in A with maximum weight. In the case of a tie, the node with largest index is taken. (We assume that nodes have unique names $1, \ldots, n$). The following invariant is maintained.

> If $B \in \mathcal{B}_v$ contains neither a parent nor a solid edge, then the (single) biased tree A for set B satisfies $right(A) = h(A)$.

If the counter values and block partitions are valid prior to a *reverse* operation, they remain valid after the path reversal. This is because the block partition and counter values are modified only when a dashed child turns into a solid child. The primitives *expose* and *conceal*, however, may cause changes to counter values and block partitions via the functions *splice* and *slice*. Recall from sections 4.2 and 4.4 that it suffices to show how to turn a solid edge dashed, how to turn a dashed edge solid, and how to undo each of these actions.

We first examine how the block partition and counter values change when a solid edge $y = \langle u, v\rangle$ is made dashed. We assume that v is not the root, and that the parent edge of v is z. If v is the root, execute the following algorithm as if z exists but forms a singleton block, i.e., $\mathcal{B}_v(z) = \{z\}$. We will use x, y, and z to denote both edges incident on v and their representatives in the block partition trees of v.

1. If y is to be made dashed as part of a normal edge insertion, then test if $\mathcal{B}_v(y) \neq \mathcal{B}_v(z)$ and $c(v) > 0$. If so, then let Y be the tree of $\mathcal{B}_v(y)$ and Z the tree of $\mathcal{B}_v(z)$. Unite sets $\mathcal{B}_v(y)$ and $\mathcal{B}_v(z)$ by creating a new set header with two pointers to Y, Z, in that order. Push a new subrecord on the substack, labeled with the name "v," and copy $c(v)$ into the subrecord. Continue with the rest of this routine.

2. If $\mathcal{B}_v(y) = \mathcal{B}_v(z)$ then let Y_1, Y_2 be the two trees of set $\mathcal{B}_v(y)$. Concatenate (Y_1, y, Y_2).

3. If $\mathcal{B}_v(y) \neq \mathcal{B}_v(z)$ ($c(v) = 0$) then let Y be the tree for $\mathcal{B}_v(y)$. Let $Y' = concat(Y, y)$. Find $y' = h(Y')$. Perform $split(y')$, giving Y_1, y', Y_2, followed by concatenate (Y_2, Y_1, y'). The result is the new biased tree for $\mathcal{B}_v(y)$.

4. Set $c(v) = +\infty$.

We need to augment the biased tree data structure to allow us to search for the maximum weighted node $h(Y')$ in step 3. This can be done in a standard fashion, storing at each internal node of the biased tree the maximum weight/index pair of any descendant. Using this information, node $h(Y')$ can be found in time proportional to its depth, which is $O(r(Y') - r(h(Y')))$.

Next we examine how the block partition and counter values change when a dashed edge $x = \langle u, v\rangle$ is made solid. As before, if v is the root, execute the following algorithm as if z exists but forms a singleton block, i.e., $\mathcal{B}_v(z) = \{z\}$.

1. Let X be the biased tree of $\mathcal{B}_v(x)$. Perform $split(x)$, giving X_1, x, X_2. (Possibly $X_2 = \emptyset$.)

2. If $\mathcal{B}_v(x) \neq \mathcal{B}_v(z)$, then set $c(v) = 0$, execute $concat(X_2, X_1)$, and store a pointer to the result in the header for $\mathcal{B}_v(x)$.

3. If $\mathcal{B}_v(x) = \mathcal{B}_v(z)$, then set $c(v) = +\infty$ and store pointers to X_1, X_2 in that order.

4. If x is being made dashed as part of an *Undo*, then examine the top subrecord on the substack. If it is labeled "v," then pop the subrecord. Set $c(v)$ equal to the value stored in it. *Undo* the *Union* indicated by the subrecord creating two headers for $\mathcal{B}_v(x)$ and $\mathcal{B}_v(z)$, respectively. Make X_1 the tree for $\mathcal{B}_v(x)$ and X_2 the tree for $\mathcal{B}_v(z)$.

One may easily verify that these routines maintain valid counters and block partitions if no *Undo* operations are performed. We defer for the moment a discussion of

the *Undo* operation, and turn to an analysis of the running time.

LEMMA 4.5. *The functions* splice(u) *and* slice(u) *run in time* $O(1 + \log s(v) - \log s(u))$, *where* $v = p(u)$, $s(u)$, *and* $s(v)$ *are the number of descendants of* u *and* v, *respectively, given the current root of the spanning tree* T.

Proof. Consider the function that makes a solid child edge y dashed. Since the set headers for y and z can be accessed in $O(1)$ time, all set equivalence tests take $O(1)$ time. Step 1 requires $O(1)$ time. Step 2 requires time $O(r(Y') - r(y))$ for the concatenation, where Y' is the resulting tree. Step 3 requires time $O(r(Y') - r(y))$ for all the concatenation and split operations, since $r(y') \geq r(y)$ by definition, and in the final concatenation y is rightmost in Y_2.

Consider the function that makes a dashed child edge x solid. The split in step 1 takes time $O(r(X) - r(x))$. After the split, we have $O(1)$ time access to the set header for $\mathcal{B}_v(x)$. The concatenation in step 2 requires time $O(r(X) - r(h(X))) = O(r(X) - r(x))$. This follows because $h(X)$ was rightmost in X by the invariant and hence in X_2 (if $X_2 \neq \emptyset$), and $r(h(X)) \geq r(x)$, by definition. Steps 3 and 4 take time $O(1)$.

Splice and *slice* both perform one each of these operations. In both cases, the maximum rank of any tree in the block partition is $\log s(v)$. Hence the cost of a *splice* or *slice* is $O(1 + \log s(v) - r(x) - r(y))$.

In the case of a *splice*, $r(x) = \log s(u)$ by definition, and since y is a heavy child, $w(y) \geq s(v)/2$. It follows that a *splice* takes $O(1 + \log s(v) - \log s(u))$ time.

In the case of a *slice*, $r(y) = \log s(u)$ and $w(x) \geq s(v)/2$ for the analogous reason. This implies that *slice* takes $O(1 + \log s(v) - \log s(u))$ time. □

LEMMA 4.6. *Using globally biased trees, an* expose *or* conceal *operation requires time* $\Theta(\log n)$.

Proof. An *expose*(u) operation consists of a sequence of *splices* along the tree path from u to the root. Let $u_1, u_2, \ldots, u_k$ be the sequence of nodes at which a *splice* occurs, and let $v_i = p(u_i)$ for all i. By Lemma 4.5 the cost of the *expose* is $\sum_{i=1}^{k} O(1 + \log s(v_i) - \log s(u_i))$. Since $s(v_i) \leq s(u_{i+1})$ for $1 \leq i \leq k-1$, the sum telescopes to $O(k + \log n)$. The heavy path decomposition guarantees that $k = O(\log n)$, although $k = \Omega(\log n)$ in the worst case. A *conceal* operation is implemented by a sequence of *slices* going down the tree. Again the costs telescope for a total of $\Theta(\log n)$. □

Now consider the *Undo* operation. As in section 4.4, it suffices to verify that after a normal solid-to-dashed operation, an immediate dashed-to-solid operation in *Undo* mode will correctly restore the previous block partition and counter value. Similarly, after a normal dashed-to-solid operation, an immediate solid-to-dashed operation in *Undo* mode correctly restores the previous state.

Suppose a solid edge is made dashed. Either steps 2 and 4, steps 3 and 4, or steps 1, 2, and 4 of the solid-to-dashed routine are executed. Steps 2 and 4 of solid-to-dashed will be undone by steps 1 and 3 of dashed-to-solid. Steps 3 and 4 of solid-to-dashed will be undone by steps 1 and 2 of dashed-to-solid. Finally, steps 1, 2, and 4 of solid-to-dashed are undone by steps 1, 3, and 4 of dashed-to-solid.

Similarly, suppose a dashed edge is made solid. Either steps 1 and 2 or steps 1 and 3 of the dashed-to-solid routine are executed. Steps 1 and 2 of dashed-to-solid are undone by steps 3 and 4 of solid-to-dashed. Steps 1 and 3 of dashed-to-solid are undone by steps 2 and 4 of solid-to-dashed.

THEOREM 4.7. *A sequence of* m Test(u, v), Insert Vertex(), Insert Edge(u, v), *and* Undo *operations can be performed in* $\Theta(\log n)$ *worst-case time per operation and*

in $\Theta(n)$ *space.*

Proof. The running time follows from Lemma 4.6 and the previously established running time for the Sleator–Tarjan data structure. The space bound follows from the proof of Theorem 4.4. □

5. Remarks. The only lower bound known for backtracking problems is one of $\Omega(\log n / \log\log n)$ for a disjoint set union with backtracking [32]. This bound can be applied to any class of algorithms for backtracking graph problems that keep disjoint data structures for distinct components of the graph. Our algorithms fall into that class. Hence there remains a gap of $\Theta(\log\log n)$ between the known upper and lower bounds for 2-connectivity with backtracking. Note that in one operation, $\Omega(n)$ 2-connected components may be joined (or unjoined), which makes the problem apparently harder disjoint set union, where only two sets can be joined by a single step.

Other interesting open problems are backtracking algorithms for 3-connectivity and general planarity testing. The latter has as an application, e.g., VLSI design, amongst others. We anticipate that our algorithms herein provide a basis for efficient solutions of these problems.

Acknowledgments. We thank the anonymous referees for helpful comments.

ON THE STRUCTURE OF $\mathcal{NP}_{\mathbb{C}}$*

GREGORIO MALAJOVICH† AND KLAUS MEER‡

Abstract. This paper deals with complexity classes $\mathcal{P}_{\mathbb{C}}$ and $\mathcal{NP}_{\mathbb{C}}$ as they were introduced over the complex numbers by Blum, Shub, and Smale [*Bull. Amer. Math. Soc.*, 21 (1989), p. 1]. Under the assumption $\mathcal{P}_{\mathbb{C}} \neq \mathcal{NP}_{\mathbb{C}}$ the existence of noncomplete problems in $\mathcal{NP}_{\mathbb{C}}$ not belonging to $\mathcal{P}_{\mathbb{C}}$ is established.

Key words. complexity, NP-completeness, BSS machines over $\mathbb{C}$, Hilbert Nullstellensatz

1. Introduction.

In 1989 Blum, Shub, and Smale introduced a computational model over arbitrary ring structures [3]. It especially results in a complexity theory over the complex numbers $\mathbb{C}$ as well as a complex analogue "$\mathcal{P}_{\mathbb{C}} \neq \mathcal{NP}_{\mathbb{C}}$?" of the famous $\mathcal{P} \neq \mathcal{NP}$? problem over the integers. One of the main parts in [3] is devoted to asking for the existence of $\mathcal{NP}_{\mathbb{C}}$-complete problems. The main example is Hilbert's Nullstellensatz.

DEFINITION 1 (Hilbert's Nullstellensatz). *Let $\mathbb{K}$ be an algebraically closed field. The* Hilbert–Nullstellensatz *decision problem over $\mathbb{K}$, denoted by $HN_{\mathbb{K}}$, is defined as follows.*

Let $f_1, \ldots, f_s \in \mathbb{K}[x_1, \ldots, x_n]$ be given polynomials, $s, n \in \mathbb{N}$, $\deg f_i = 2$.

Decide if there is a common zero $x \in \mathbb{K}^n$ for all f_i.

For example, following the terminology of [3] the polynomial systems over $\mathbb{K}$ build the "input set" of decision problem $\mathrm{HN}_{\mathbb{K}}$, whereas the solvable ones build the "yes set.")

Assume that $\mathbb{K}$ is the field $\mathbb{C}$ of complex numbers or the algebraic closure $\overline{\mathbb{Q}}$ of the rationals over $\mathbb{C}$.

In the Blum, Shub, Smale (BSS) model over $\mathbb{K}$, the computational cost of every algebraic operation as well as the size of any element in $\mathbb{K}$ is supposed to be 1. Under those assumptions, it was proven in [3] that $\mathrm{HN}_{\mathbb{K}}$ is $\mathcal{NP}_{\mathbb{K}}$-complete.

Thus $\mathrm{HN}_{\mathbb{C}}$ represents the entire difficulty of class $\mathcal{NP}_{\mathbb{C}}$; it is solvable in polynomial time if and only if $\mathcal{P}_{\mathbb{C}} = \mathcal{NP}_{\mathbb{C}}$. In fact, most mathematicians assume $\mathcal{P}_{\mathbb{C}} \neq \mathcal{NP}_{\mathbb{C}}$, implying that $\mathrm{HN}_{\mathbb{C}}$ does not allow efficient (i.e., polynomial-time) algorithms. (For a more intensive treatment of related results we refer the interested reader to the forthcoming book [2] as well as the survey paper [10].)

However, except for the above-mentioned result only a few things are known about the intrinsic structure of $\mathcal{NP}_{\mathbb{C}}$ if $\mathcal{P}_{\mathbb{C}} \neq \mathcal{NP}_{\mathbb{C}}$ is assumed.

In the present paper we want to go a step in this direction and will show the following theorem.

MAIN THEOREM. *Assume $\mathcal{P}_{\mathbb{C}} \neq \mathcal{NP}_{\mathbb{C}}$. Then there is a decision problem in $\mathcal{NP}_{\mathbb{C}} \setminus \mathcal{P}_{\mathbb{C}}$ that is not $\mathcal{NP}_{\mathbb{C}}$-complete.*

The theorem is not surprising in stating that, once leaving the class of $\mathcal{NP}_{\mathbb{C}}$-complete problems, one will not directly jump into $\mathcal{P}_{\mathbb{C}}$.

The proof is constructive in the sense that we will describe exactly how to build a noncomplete decision problem in $\mathcal{NP}_{\mathbb{C}} \setminus \mathcal{P}_{\mathbb{C}}$. This problem is not a natural one. Finding more natural noncomplete problems may be an interesting task. We will discuss this question at the end of the paper.

Let us first briefly sketch the proof. The basic idea is to produce a noncomplete problem not in $\mathcal{P}_{\mathbb{C}}$, starting from a complete one. That idea was given by Ladner in [8]. There the Turing model analogue of the main theorem was established. Also see [12] for a more general approach to obtaining such results over the integers.

Given a complete problem one will switch stepwise to an easier one by changing the problem "dimensionwise." Here we will start with $\mathrm{HN}_{\mathbb{C}}$ and then carefully construct another problem. On some input dimensions it will still represent the $\mathrm{HN}_{\mathbb{C}}$ problem, whereas on the other dimensions it represents a trivial one.

However, Ladner's approach heavily relies on the fact that in the Turing setting the sets of $\mathcal{P}$- and $\mathcal{NP}$-machines are effectively countable. This is not at all the case for BSS machines over $\mathbb{C}$. We will circumvent the latter problem by using the following transfer principle given in [2, Chapter 6].

THEOREM 1 (Blum–Cucker–Shub–Smale). *Let (Y, Y_0) be a decision problem solved by a BSS machine M over $\mathbb{C}$. Moreover, let $(Y_{\overline{\mathbb{Q}}}, Y_{0\overline{\mathbb{Q}}})$ be its restriction to $\overline{\mathbb{Q}}$, i.e., $Y_{\overline{\mathbb{Q}}} := Y \cap \overline{\mathbb{Q}}^\infty$ and $Y_{0\overline{\mathbb{Q}}} := Y_0 \cap \overline{\mathbb{Q}}^\infty$.*

Then there exists a constant $c \in \mathbb{N}$ as well as a machine M' over $\overline{\mathbb{Q}}$ solving $(Y_{\overline{\mathbb{Q}}}, Y_{0\overline{\mathbb{Q}}})$ s.t. the running time $T_{M'}(y)$ of M' for all $y \in Y_{\overline{\mathbb{Q}}}$ is bounded by $T_M(y)^c$ (where $T_M(y)$ is the running time of M on y).

The transfer principle should be considered as follows. We first show the main theorem for the BSS-model over $\overline{\mathbb{Q}}$. This will be carried out in a similar way as Ladner's proof, but attention must be paid to several details such as the enumeration of all $\mathcal{P}_{\overline{\mathbb{Q}}}$-machines. To do this, symbolic computations for dealing with algebraic numbers will be necessary. In that way we built up two subproblems of $\mathrm{HN}_{\overline{\mathbb{Q}}}$ belonging to $\mathcal{NP}_{\overline{\mathbb{Q}}} \setminus \mathcal{P}_{\overline{\mathbb{Q}}}$. Then both subproblems are shown to be noncomplete. This part also differs from Ladner's approach in that we do not need effective countability of $\mathcal{NP}_{\overline{\mathbb{Q}}}$ machines.

We intend for this paper to be self-contained. Therefore, we will present the whole construction over $\overline{\mathbb{Q}}$, even though those readers that are aware of [8] would be able to fill in the remaining gaps by getting fewer details.

Finally, the above-mentioned subproblems are extended to decision problems over $\mathcal{NP}_{\mathbb{C}}$. The transfer principle guarantees that they do not to belong to $\mathcal{P}_{\mathbb{C}}$, too. Furthermore, its special structure will ensure that both of them will not be complete for $\mathcal{NP}_{\mathbb{C}}$.

2. Sketch of the proof for $\overline{\mathbb{Q}}$. In this section we are going to outline the proof of the main theorem where $\mathbb{C}$ is replaced by $\overline{\mathbb{Q}}$. The proof is given in section 3.

Note that according to [3] $\mathrm{HN}_{\overline{\mathbb{Q}}}$ is $\mathcal{NP}_{\overline{\mathbb{Q}}}$ - complete. We will need Theorem 2.

THEOREM 2. *There is a decision procedure for $\mathcal{NP}_{\overline{\mathbb{Q}}}$ working in time $s^{O(n)}$.*

For more details, see [6], [4], [5], or [11].

We chose dense representation for the system f that appears in the Hilbert Nullstellensatz. Therefore, its size S is greater than $sn \geq n \log_2(s)$. Hence, the Hilbert

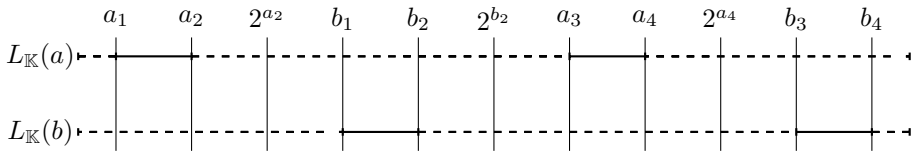

FIG. 1. *Problems $L_{\mathbb{K}}(a)$ and $L_{\mathbb{K}}(b)$.*

Nullstellensatz can be solved in exponential time $2^{O(S)}$ with respect to the input size.

The idea is to start with $\mathrm{HN}_{\overline{\mathbb{Q}}}$ and turn it into a sparser and sparser problem. This will be done by changing the problem to look like the empty set over $\overline{\mathbb{Q}}^n$ for certain "input dimensions" n.

Assume a fixed coding is given that represents an instance of $\mathrm{HN}_{\mathbb{C}}$, respectively, $\mathrm{HN}_{\overline{\mathbb{Q}}}$ as an element of some space $\mathbb{C}^n$ or $\overline{\mathbb{Q}}^n$ (where n only depends on the number of polynomials and the number of variables). The coding is assumed to be *dense*. This means that polynomials are represented by the coefficients of all possible monomials that may appear. For instance, the size of the representation of one quadratic polynomial in two variables should be at least 6, regardless of zero coefficients.

The following definitions will be crucial for understanding the structure of the decision problems we have to build.

DEFINITION 2. *Let $\mathbb{K} \in \{\overline{\mathbb{Q}}, \mathbb{C}\}$; for any strictly increasing sequence $a := (a_1, a_2, \ldots)$ of natural numbers let $L_{\mathbb{K}}(a)$ be the following decision problem over $\mathbb{K}$:*

for any input dimension $n \in \mathbb{N}$,

$$L_{\mathbb{K}}(a) \cap (\mathbb{K}^n, \mathbb{K}^n) := \begin{cases} HN_{\mathbb{K}} \cap (\mathbb{K}^n, \mathbb{K}^n) & \text{if } \exists i \in \mathbb{N} \text{ s.t. } a_{2i-1} \leq n < a_{2i}, \\ (\emptyset, \emptyset) & \text{otherwise.} \end{cases}$$

We call each of the subsets $\{a_j, \ldots, a_{j+1}\}$ a cluster *of the associated problem.*

DEFINITION 3. *Two sequences (a) and (b) are said to have an* exponential gap *if and only if they are strictly increasing and*

$$\begin{aligned} a_{2i+1} &> 2^{b_{2i}} \quad (i \geq 1), \\ b_{2i+1} &> 2^{a_{2i+2}} \quad (i \geq 0). \end{aligned}$$

Or, again,

$$a_1 < a_2 < 2^{a_2} < b_1 < b_2 < 2^{b_2} < a_3 < a_4 < 2^{a_4} < b_3 < \cdots.$$

Let's make the preceding definition a little bit more clear. Assume (a) and (b) have an exponential gap. Figure 1 shows the corresponding problems $L_{\mathbb{K}}(a)$ and $L_{\mathbb{K}}(b)$. A dotted line corresponds to those dimensions where a problem looks like the empty set, whereas a straight line represents those dimensions where it corresponds to the $\mathrm{HN}_{\mathbb{K}}$ problem.

LEMMA 1. *Let $\mathbb{K}$ be one of $\overline{\mathbb{Q}}$ or $\mathbb{C}$. Assume $\mathcal{P}_{\mathbb{K}} \neq \mathcal{NP}_{\mathbb{K}}$. Moreover let (a) and (b) be two sequences of natural numbers having an exponential gap. If both $L_{\mathbb{K}}(a)$ and $L_{\mathbb{K}}(b)$ belong to $\mathcal{NP}_{\mathbb{K}} \setminus \mathcal{P}_{\mathbb{K}}$, then both of them are not $\mathcal{NP}_{\mathbb{K}}$-complete.*

Proof. Assume, for example, that $L_{\mathbb{K}}(b)$ is $\mathcal{NP}_{\mathbb{K}}$-complete. Let M be a polynomial time machine performing a reduction from $L_{\mathbb{K}}(a)$ to $L_{\mathbb{K}}(b)$. Aside from the fact that (a) and (b) have an exponential gap, any instance y for problem $L_{\mathbb{K}}(a)$ of dimension n, $a^{2i+1} \leq n \leq a^{2i+2}$ for some $i \in \mathbb{N}$ big enough, must be mapped by M to an instance $M(y)$ of $L_{\mathbb{K}}(b)$ of dimension less than $b_{2i} \leq \log(n)$. This is due to the fact that between dimensions b_{2i} and b_{2i+1} the input- as well as the "yes"-set of $L_{\mathbb{K}}(b)$ by definition equal the empty set.

Applying a single exponential decision algorithm for $\mathrm{HN}_{\overline{\mathbb{Q}}}$ to $M(y)$ (cf. Theorem 2) will yield the right answer for $M(y)$ and hence for y in a polynomial number of steps with respect to $size(y)$. Thus it would follow that problem $L_{\mathbb{K}}(a)$ belongs to $\mathcal{P}_{\mathbb{K}}$, which contradicts the assumption. □

The rest of section 2 is devoted to explaining informally how to produce two sequences (v) and (w) such that the conditions listed below hold true:

(i) (v) and (w) have an exponential gap,
(ii) $L_{\overline{\mathbb{Q}}}(v)$ and $L_{\overline{\mathbb{Q}}}(w)$ both belong to class $\mathcal{NP}_{\overline{\mathbb{Q}}}$,
(iii) $L_{\overline{\mathbb{Q}}}(v)$ and $L_{\overline{\mathbb{Q}}}(w)$ both don't belong to $\mathcal{P}_{\overline{\mathbb{Q}}}$.

Clearly, if all three conditions are satisfied simultaneously, then according to Lemma 1 the main theorem over $\overline{\mathbb{Q}}$ will follow.

Let's explain more explicitely how to reach this goal.

The elements of sequences (v) and (w) are produced two at a time, through alternated steps. Each time a component v_{2j+2}, respectively, w_{2i} has been defined, condition (i) is enforced just by demanding the next component w_{2j+1}, respectively, v_{2i+1} to be at least exponentially far away. Of course this must be done by simultaneously respecting (ii) and (iii).

In order to guarantee (ii) and (iii) we take an effective enumeration $p_1, p_2, \ldots$ of all polynomial time machines over $\overline{\mathbb{Q}}$ together with one of $\overline{\mathbb{Q}}^{\infty}$. "Effective" here means that the enumeration can be produced by a BSS machine over $\overline{\mathbb{Q}}$. To do this we will use symbolic computations over $\overline{\mathbb{Q}}$ by representing algebraic numbers via minimal polynomials with rational coefficients. (In fact an ordinary Turing machine would suffice to perform this enumeration.)

The idea now is to define (v) and (w) such that for all $i \in \mathbb{N}$ machine p_i computes a false answer on at least one input of dimension n where $v_{2i-1} \leq n \leq v_{2i}$, respectively, $w_{2i-1} \leq n \leq w_{2i}$. Note that if v_{2i-1} or w_{2i-1} are already defined there will always exist a v_{2i}, respectively, w_{2i} with that property: on the clusters $\{v_{2i-1}, \ldots, v_{2i}\}$ and $\{w_{2i-1}, \ldots, w_{2i}\}$ the problems $L_{\overline{\mathbb{Q}}}(v)$ and $L_{\overline{\mathbb{Q}}}(w)$ look like $\mathrm{HN}_{\overline{\mathbb{Q}}}$. Thus if v_{2i} and w_{2i} are chosen large enough the polynomial time machine p_i will "believe" the above problems equal $\mathrm{HN}_{\overline{\mathbb{Q}}}$ except on a finite-dimensional space; consequently it must make a mistake.

The final task is to find the numbers v_{2i} and w_{2i} such that the resulting decision problems are members of $\mathcal{NP}_{\overline{\mathbb{Q}}}$. This can be gained in the following way: assume we already have defined $v_1, \ldots, v_{2i+1}$ as well as $w_1, \ldots, w_{2i}$ satisfying the following:

(∗) the machines $p_1, \ldots, p_i$ all fail on problems $L_{\overline{\mathbb{Q}}}(v)$ and $L_{\overline{\mathbb{Q}}}(w)$ for at least one input of dimension $\leq v_{2i+1}$.

In order to fool the next machine p_{i+1} on a cluster $\{v_{2i+1}, \ldots, v_{2i+2}\}$ choose v_{2i+2} large enough such that within v_{2i+2} many steps one can perform the following program:

- check condition (∗) to be true (this can be done inductively within v_{2i+1} steps);
- enumerate all possible inputs for $\mathrm{HN}_{\overline{\mathbb{Q}}}$ of dimension at least v_{2i+1};

- simulate p_{i+1} on these inputs;
- decide the solvability of the given system and compare with the result of p_{i+1};
- as soon as an input system is found on which p_{i+1} fails, the program stops.

Note that even though the decision procedure in between may use exponential time with respect to the size of the given systems, we circumvent this problem by enlarging the cluster until v_{2i+2} steps are sufficient to perform all the demanded operations. In a similar way the next cluster $\{w_{2i+1}, \ldots, w_{2i+2}\}$ is defined (ensuring $w_{2i+1} > 2^{v_{2i+2}}$).

This construction especially yields condition ii. The resulting $\mathcal{NP}_{\overline{\mathbb{Q}}}$ algorithms read as follows: given any polynomial system by a code in some $\overline{\mathbb{Q}}^n$, one has to check whether n belongs to one of the clusters. This can be done in polynomial time with respect to n. If "yes," the according $L_{\overline{\mathbb{Q}}}$-problem on $\overline{\mathbb{Q}}^n$ corresponds to $\mathrm{HN}_{\overline{\mathbb{Q}}}$, and a solution of the given system is guessed. If "no," reject the input.

Let's now present the formal construction of (v) and (w).

3. The main theorem over $\overline{\mathbb{Q}}$. The main result of this section is the following theorem.

THEOREM 3 (main theorem over $\overline{\mathbb{Q}}$). *Assume that $\mathcal{P}_{\overline{\mathbb{Q}}} \neq \mathcal{NP}_{\overline{\mathbb{Q}}}$. Then there are (we can construct) sequences (v) and (w) such that $L_{\overline{\mathbb{Q}}}(v)$ and $L_{\overline{\mathbb{Q}}}(w)$ are in $\mathcal{NP}_{\overline{\mathbb{Q}}} \backslash \mathcal{P}_{\overline{\mathbb{Q}}}$, and both of them are not $\mathcal{NP}_{\overline{\mathbb{Q}}}$-complete.*

3.1. Background: Computing over algebraic extensions. An algebraic extension of $\mathbb{Q}$ may be defined by a primitive element ζ or by the corresponding minimal polynomial

$$a(z) = z^d + a_{d-1}z^{d-1} + \cdots + a_0.$$

Elements of $\mathbb{Q}[\zeta]$ are equivalence classes of $\mathbb{Q}[z]$ modulo $a(z)$ and can be represented by a polynomial of degree $d-1$ with coefficients in $\mathbb{Q}$.

A general theory of computing over algebraic extensions can be found in the review paper by Loos [7].

Addition and subtraction can be performed as in $\mathbb{Q}[z]$. The product of elements represented by $b(z)$ and $c(z)$ is $b(z)c(z) \bmod a(z)$. It can be performed by multiplying $b(z)$ and $c(z)$ in the usual way and then performing the Euclidian algorithm.

The extended Euclidian algorithm can be used to compute division: if $b(z)c(z) + a(z)d(z) = 1$, then $c(\zeta) = d(\zeta)^{-1}$ in $\mathbb{Q}[\zeta]$.

Checking if $b(\zeta)$ is equal to zero (or not) is trivial.

Therefore, a machine over $\mathbb{Q}$, *without order*, can simulate a given machine p over an extension given by some $a(z)$. It is also possible to check that $a(z)$ is irreducible, for example, using the Lenstra–Lenstra–Lovász algorithm (cf. [9]).

In this paper, we will need to perform computations in $\mathbb{Q}[\zeta_1, \zeta_2]$. Given minimal polynomials of ζ_1 and ζ_2 over $\mathbb{Q}$, one may find (algorithmically) a primitive element and a minimal polynomial of $\mathbb{Q}[\zeta_1, \zeta_2]$. See [7, Theorem 6].

Computation with inputs in $\overline{\mathbb{Q}}$ can be simulated using the very same techniques.

3.2. Timing a machine. One important ingredient to prove Theorem 3 is the simulation of a machine for a given number of steps. Thus we have to deal with BSS machines which additionally are able to count the number of steps they perform. The construction of such timed machines is straightforward and can be performed as in the discrete setting. Therefore, without loss of generality we will assume machines to be timed whenever necessary.

3.3. Enumeration. Let $A = \{A_0, \ldots\}$ and $B = \{B_0, \ldots\}$ be countable sets. The triangular enumeration of $A \times B$ is

$$(A_0, B_0), (A_1, B_0), (A_1, B_1), (A_2, B_0) \ldots .$$

We will enumerate $\mathbb{Q}$, $\mathbb{Q}^2$, $\mathbb{Q}^3 = \mathbb{Q}^2 \times \mathbb{Q}$ this way. We may enumerate $\mathbb{Q}^\infty$ in the same way:

$$(0, \ldots ...), (q_1, 0, \ldots), (q_1, q_1, 0, \ldots), (q_2, 0 \ldots),$$

where $0, q_1, q_2, \ldots$ enumerates $\mathbb{Q}$.

The algebraic closure $\overline{\mathbb{Q}}$ of the rationals may be enumerated by enumerating all extensions of $\mathbb{Q}$ through the minimal polynomials, together with the elements of the extension. One has to pay attention to the fact that the polynomial defining an extension should be irreducible.

One can enumerate $\overline{\mathbb{Q}}^\infty$ in the same way. Finally, later on we need to enumerate BSS machines over $\overline{\mathbb{Q}}$ together with polynomial time bounds $n^k, k \in \mathbb{N}$. This will be done as indicated above by taking A to be the set of all BSS machines over $\overline{\mathbb{Q}}$ and $B := \mathbb{N}$.

3.4. A machine to fool a polynomial time machine. Under our general hypothesis $\mathcal{P}_{\overline{\mathbb{Q}}} \neq \mathcal{NP}_{\overline{\mathbb{Q}}}$, we will construct a machine M over $\overline{\mathbb{Q}}$ that will take as input

- an integer $m \in \mathbb{N}$,
- a list $p \in (\mathbb{Q}^{\deg a})^\infty$ representing (possibly) a machine $\tilde{p}$ over an extension $\mathbb{Q}[\zeta]$;
- an integer $r \in \mathbb{N}$ representing a polynomial time bound $\text{size}(x)^r$ for $\tilde{p}$;
- an integer $s \geq m$ representing a total running time bound for M.

Machine M is used for the construction of the two decision problems we are looking for. The purpose of this machine is the following.

Since $\text{HN}_{\overline{\mathbb{Q}}}$ is $\mathcal{NP}_{\overline{\mathbb{Q}}}$-complete, it remains complete when restricted to inputs exceeding the fixed dimension m. The list p is supposed to represent a machine that is a candidate for deciding this restricted $\text{HN}_{\overline{\mathbb{Q}}}$ in polynomial time bound $\text{size}(x)^r$, where x is an input of size $\geq m$.

Thus there must exist an input $\bar{x}, size(\bar{x}) \geq m$ such that $p(\bar{x})$ does not provide the right answer to the $\text{HN}_{\overline{\mathbb{Q}}}$ problem for input $\bar{x}$. Machine M will check whether both such $\bar{x}$ exists up to dimension s and can be found within s steps.

Let us explain more precisely the way M works: consider an input (m, p, r, s) and $s \geq m$. We assume M is timed. As soon as the procedure described below has performed more than s steps, machine M stops. In that case it returns the answer TIMEOUT indicating that up to dimension s no input $\bar{x}$ satisfying the above conditions exists.

As long as fewer than s steps have been executed M behaves as follows.

1. Enumerate all possible inputs belonging to $\overline{\mathbb{Q}}^\infty$ of size at least m; let x be the actually enumerated element.
2. Simulate machine p for at most $size(x)^r$ many steps on input x.
3. Simulate a decision procedure for $\text{HN}_{\overline{\mathbb{Q}}}$ on input x.
4. If 2 and 3 yield the same answer, goto 1 and take the next element of the enumeration; if 2 and 3 yield different answers, output c; here c denotes the maximum among $size(x)$ and the number of steps already performed by M.

Note that $M(m, p, r, s) =$TIMEOUT indicates that it is impossible to fool (p, r) in the above sense on $\text{HN}_{\overline{\mathbb{Q}}}$ for an input of size at least m and at most s. On the

other hand, if M returns $c \leq s$ there exists an $\bar{x} \in \overline{\mathbb{Q}}^c$ of size at least m such that $p(\bar{x})$ differs from the correct answer of $\mathrm{HN}_{\overline{\mathbb{Q}}}(\bar{x})$, and this difference can be shown by algorithm M in $\leq c$ steps.

We finally remark that in step 4 different answers comparing the simulation under 2 and 3 can be obtained either if the computation of $p(x)$ cannot be finished within $size(x)^r$ many steps or both simulations are completed but with different results.

Remark. Because of our assumption, $\mathcal{P}_{\overline{\mathbb{Q}}} \neq \mathcal{NP}_{\overline{\mathbb{Q}}}$ machine M will always end up with a suitable dimension $c \leq s$ if s is large enough.

3.5. A machine to produce (v) and (w) up to s. Next we will use machine M to construct another machine N that will produce sequences (v) and (w) in the following way.

Given an input $s \in \mathbb{N}$, all $v_j < s$ and $w_j < s$ will be computed. Sequences (v) and (w) do not depend on s. Furthermore, the following statements hold.

- Sequences (v) and (w) have an exponential gap.
- Machines $p_1, \ldots, p_i$ are fooled (in the sense of the previous section) for inputs of size in

$$\{v_1, \ldots, v_2\} \cup \{v_3, \ldots, v_4\} \cup \cdots \cup \{v_{2i-1}, \ldots, v_{2i}\}$$

  and also for inputs of size in

$$\{w_1, \ldots, w_2\} \cup \{w_3, \ldots, w_4\} \cup \cdots \cup \{w_{2i-1}, \ldots, w_{2i}\}.$$

- The running time of N is a polynomial in s.

Machine N is defined as explained now.

As an input it gets a natural number s; for the first cluster of sequence (v) we set $v_1 := 1$. As long as those values v_{2i} and w_{2i} already computed do not exceed s, the following algorithm is performed for $i = 0, 1, \ldots$.

1. Enumerate all BSS machines over $\overline{\mathbb{Q}}$ together with a natural number representing a polynomial time bound; let (p, r) be the actually enumerated element.
2. Let v_{2i+2} be the result of $M(v_{2i+1}, p, r, s)$.
3. If $v_{2i+2} = \mathrm{TIMEOUT}$ then algorithm N terminates.
4. Otherwise output v_{2i+2} as the next element of those clusters defining (v); compute the starting point w_{2i+1} of the next cluster for sequence (w) as $w_{2i+1} := 2^{v_{2i+2}} + 1$.
5. If $w_{2i+1} > s$ then algorithm N terminates.
6. Otherwise output w_{2i+1}; let w_{2i+2} be the result of $M(w_{2i+1}, p, r, s)$.
7. If $w_{2i+2} = \mathrm{TIMEOUT}$ then algorithm N terminates.
8. Otherwise output w_{2i+2} as the next element of those clusters defining (w); compute the starting point v_{2i+3} of the next cluster for sequence (v) as $v_{2i+3} := 2^{w_{2i+2}} + 1$.
9. If $v_{2i+3} > s$ then algorithm N terminates.
10. Otherwise output v_{2i+3}; increase i and goto 1.

The comparisons such as $v_{2i+3} > s$ can be performed without any order relation available, because it is assumed that the values involved are integers. The time bound for each comparison is $O(s)$.

Exponential gap and the fact that machines $p_1, \ldots, p_i$ are fooled follows from the construction of machine M.

The running time of each call to M is bounded by s, so the time bound $(O(s^2))$ follows.

3.6. Proof of Theorem 3. According to the previous subsections, given s one may compute in polynomial time (in s) the largest v_i and $w_i < s$. This implies the following lemma holds.

LEMMA 2. *$L_{\overline{\mathbb{Q}}}(v)$ (respectively, $L_{\overline{\mathbb{Q}}}(w)$) is in $\mathcal{NP}_{\overline{\mathbb{Q}}}$.*

Proof. Given input x, set $s = size(x)$. We may use machine N to compute the largest v_i (respectively, w_i) such that $v_i < s$ (respectively, $w_i < s$).

If i is even, $L_{\overline{\mathbb{Q}}}(v) \cap (\overline{\mathbb{Q}}^s, \overline{\mathbb{Q}}^s) = (\emptyset, \emptyset)$, so we may answer NO in polynomial time.

If i is odd, $L_{\overline{\mathbb{Q}}}(v) \cap (\overline{\mathbb{Q}}^s, \overline{\mathbb{Q}}^s) = \mathrm{HN}_{\overline{\mathbb{Q}}} \cap \overline{\mathbb{Q}}^{size(x)}$. This is known to be in $\mathcal{NP}_{\overline{\mathbb{Q}}}$. ∎

LEMMA 3. *$L_{\overline{\mathbb{Q}}}(v)$ (respectively, $L_{\overline{\mathbb{Q}}}(w)$) is not in $\mathcal{P}_{\overline{\mathbb{Q}}}$.*

Proof. This follows from the above construction: eventually, every machine p will appear in machine N, and it will be fooled at some time, inside a $\mathrm{HN}_{\overline{\mathbb{Q}}}$-cluster. Therefore, $L_{\overline{\mathbb{Q}}}(v)$ (respectively, $L_{\overline{\mathbb{Q}}}(w)$) cannot belong to $\mathcal{P}_{\overline{\mathbb{Q}}}$. ∎

According to Lemma 1 we proved that $L_{\overline{\mathbb{Q}}}(v)$ and $L_{\overline{\mathbb{Q}}}(w)$ both are not $\mathcal{NP}_{\overline{\mathbb{Q}}}$-complete. We also know that $L_{\overline{\mathbb{Q}}}(v) \in \mathcal{NP}_{\overline{\mathbb{Q}}} \backslash \mathcal{P}_{\overline{\mathbb{Q}}}$. Therefore, Theorem 3 is proved.

4. The main theorem over $\mathbb{C}$. We are now ready to prove our main theorem.

MAIN THEOREM. *Assume $\mathcal{P}_{\mathbb{C}} \neq \mathcal{NP}_{\mathbb{C}}$. Then there is a decision problem in $\mathcal{NP}_{\mathbb{C}} \setminus \mathcal{P}_{\mathbb{C}}$ that is not $\mathcal{NP}_{\mathbb{C}}$-complete.*

Proof. Let the sequences (v) and (w) be as in Theorem 3. We extend the corresponding problems $L_{\overline{\mathbb{Q}}}(v)$ and $L_{\overline{\mathbb{Q}}}(w)$ to the complex numbers. This will give $L_{\mathbb{C}}(v)$ and $L_{\mathbb{C}}(w)$, respectively. Note that both $L_{\mathbb{C}}(v)$ and $L_{\mathbb{C}}(w)$ are closely related to their $\overline{\mathbb{Q}}-$ counterparts: intersecting the input-, respectively, the "yes"-set of each of them with $\overline{\mathbb{Q}}^{\infty}$ will give exactly the input-, respectively, the "yes"-set of the corresponding $L_{\overline{\mathbb{Q}}}$-problem. Since this is obvious for the input sets, this follows for the "yes"-sets by Hilbert's Nullstellensatz; see [2, Chapter 6].

Now assume the class $\mathcal{NP}_{\mathbb{C}} \setminus \mathcal{P}_{\mathbb{C}}$ consists of $\mathcal{NP}_{\mathbb{C}}$-complete problems only. Both $L_{\mathbb{C}}(v)$ and $L_{\mathbb{C}}(w)$ belong to $\mathcal{NP}_{\mathbb{C}}$.

Given $x \in \mathbb{C}^n$, in order to check the cluster to which n belongs, the $\mathcal{P}_{\overline{\mathbb{Q}}}$ algorithm of section 3 can also be performed over $\mathbb{C}$. Moreover, $\mathrm{HN}_{\mathbb{C}}$ is in $\mathcal{NP}_{\mathbb{C}}$.

Furthermore, assume $L_{\mathbb{C}}(v)$ belongs to $\mathcal{P}_{\mathbb{C}}$. Then there is a polynomial time machine M deciding $L_{\mathbb{C}}(v)$. According to the transfer principle Theorem 1 there exists a BSS machine M' over $\overline{\mathbb{Q}}$ and a constant c s.t. M' solves $L_{\overline{\mathbb{Q}}}(v)$ in time $\leq T_M(y)^c \ \forall y \in \overline{\mathbb{Q}}^{\infty}$. This implies $L_{\overline{\mathbb{Q}}}(v) \in \mathcal{P}_{\overline{\mathbb{Q}}}$ in contradiction to Theorem 3.

Thus our second assumption is wrong and it follows $\mathcal{NP}_{\mathbb{C}}$-completeness of $L_{\mathbb{C}}(v)$; the same reasoning clearly holds true for $L_{\mathbb{C}}(w)$. But (v) and (w) have an exponential gap. Consequently according to Lemma 1 they are not $\mathcal{NP}_{\mathbb{C}}$-complete. Hence the introductory assumption was wrong, which finishes the proof. ∎

Let us conclude with some final remarks. The problems $L_{\mathbb{C}}(v)$ and $L_{\mathbb{C}}(w)$ used to establish the main theorem are quite artificial; the dimensions for which they coincide with $\mathrm{HN}_{\mathbb{C}}$ are chosen just in order to fool all polynomial time machines over $\overline{\mathbb{Q}}$ according to a given enumeration and not by a "natural" condition. We consider it an interesting task to figure out more natural problems neither belonging to $\mathcal{P}_{\mathbb{C}}$ nor being $\mathcal{NP}_{\mathbb{C}}$-complete. Here we just suggest one further problem which seems to be promising from that point of view.

Considering the $\mathcal{NP}_{\mathbb{C}}$-completeness proof of $\mathrm{HN}_{\mathbb{C}}$ in [3] it turns out to be sufficient if all polynomials of the given system depend on three variables only.

Let $2-\mathrm{HN}_{\mathbb{C}}$ be the problem of deciding solvability of such a system, if all involved polynomials just depend on at most two unknowns.

On the one hand, the completeness proof for $\mathrm{HN}_{\mathbb{C}}$ lets $2-\mathrm{HN}_{\mathbb{C}}$ seem unlikely to be $\mathcal{NP}_{\mathbb{C}}$-complete, too: reducing higher-degree systems to such a degree of two uses substitutions intrinsically including equations with three unknowns. We don't see any way to proof $\mathcal{NP}_{\mathbb{C}}$-completeness of $2-\mathrm{HN}_{\mathbb{C}}$. On the other hand it can be shown that problems like complex subset-sum (given $z_1,\ldots,z_n\in\mathbb{C}$, does there exist a subset $S\subset\{1,\ldots,n\}$ s.t. $\sum_{i\in S} z_i = 1$?) can be reduced to $2-\mathrm{HN}_{\mathbb{C}}$ in polynomial time. Note that the discrete version of subset-sum (rational inputs) is $\mathcal{NP}$-complete in the Turing model. Since there is no polynomial time algorithm known so far for complex subset-sum, this will give good reason to conjecture $2-\mathrm{HN}_{\mathbb{C}}\notin\mathcal{P}_{\mathbb{C}}$. Thus $2-\mathrm{HN}_{\mathbb{C}}$ seems to be a reasonable candidate of a noncomplete problem in $\mathcal{NP}_{\mathbb{C}}\setminus\mathcal{P}_{\mathbb{C}}$ (as well as complex subset-sum).

Finally consider the question treated in this paper for real BSS machines. The above proof fails: there is no transfer principle available in order to reduce the uncountable real case to a countable situation. However, over $\mathbb{R}$ one wouldn't have to pay attention to the computability of the sequences (v) and (w). The presence of the order relation allows us to code any such sequence in a single real number from which its components can be easily decoded (see [3]). Nevertheless, so far we see no way to build up sequences (v) and (w) such that the resulting problems $L_{\mathbb{R}}(v)$ and $L_{\mathbb{R}}(w)$ would force all (uncountable many) $\mathcal{P}_{\mathbb{R}}$-machines to fail.

The situation over the real numbers will be treated more intensively in the forthcoming paper [1].

Acknowledgment. Thanks are due to two unknown referees, whose comments helped to improve readability of an earlier version of this paper.

WEIGHTED NP OPTIMIZATION PROBLEMS: LOGICAL DEFINABILITY AND APPROXIMATION PROPERTIES*

MARIUS ZIMAND†

Abstract. Extending a well-known property of NP optimization problems in which the value of the optimum is guaranteed to be polynomially bounded in the length of the input, it is observed that, by attaching weights to tuples over the domain of the input, all NP optimization problems admit a logical characterization. It is shown that any NP optimization problem can be stated as a problem in which the constraint conditions can be expressed by a Π_2 first-order formula. The paper analyzes the weighted analogue of all syntactically defined classes of optimization problems that are known to have good approximation properties in the nonweighted case. Dramatic changes occur when negative weights are allowed.

Key words. NP optimization problems, logical definability, approximation properties, multiprover interactive systems.

1. Introduction.

Recent years have seen considerable progress in the understanding of the approximation properties of NP optimization problems. Two approaches have been the main cause for the new advancements: (a) the development of a robust model for optimization problems based on the logical definability of this type of problem, and (b) the characterization of NP in terms of multiprover interactive proof (MIP) or probabilistically checking proof (PCP) systems which allowed new reductions that preserve approximation properties between NP complete problems. The first approach was initiated by Papadimitriou and Yannakakis [PY91] who introduced the classes MAX SNP and MAX NP (later called MAX Σ_0 and MAX Σ_1 by Kolaitis and Thakur [KT94] in an attempt to uniformize notation). A maximization problem is in MAX SNP (MAX NP) if: (1) the input I is viewed as a finite structure, (2) the set of feasible solutions of an input I is given by the set of finite structures S having the same domain as I and satisfying a $\Sigma_0(\Sigma_1)$ first-order formula having a tuple of free variables, and (3) the objective function maps each feasible solution S to the cardinality of tuples over the domain of I satisfying ϕ when substituting the tuple of free variables and when the relation symbols in ϕ are interpreted as the relations of I and S. MAX SNP and MAX NP contain many natural problems, including MAX 3SAT, MAX CUT, and MAX SAT, and have the nice property that all the problems in these classes are approximable by polynomial-time algorithms with constant approximation ratio. Moreover, Khanna et al. [KMSV94] have shown that the class of NP optimization problems admitting polynomial-time constant ratio approximating algorithms coincides with the class of problems that are reducible to MAX SNP via a certain type of reduction that preserves approximation properties. It is proved in [ALM$^+$92],

via a reduction from a PCP, that no complete problem in MAX SNP can be approximated with arbitrarily small constant approximation ratio (i.e., have PTAS), unless NP = P. Many important minimization problems, like VERTEX COVER, DOMINATING SET, STEINER TREE, and TRAVELING SALESMAN with edge weights 1 and 2, and SHORTEST COMMON SUPERSTRING, are MAX SNP hard via reductions that preserve approximation properties (see Johnson [Joh92] for references and an excellent survey) and, thus, have the same approximation properties. Hence, the approximation capabilities of a large number of natural, important optimization problems have been fully understood by the joint contribution of the two approaches (a) and (b). However, MAX SNP and MAX NP are far from being the whole story. Panconesi and Ranjan [PR93] showed that MAX CLIQUE is not in MAX NP. This problem belongs to the class MAX Π_1 in which the feasible solutions are characterized by Π_1 formulae. By imposing a syntactical restriction on ϕ, Panconesi and Ranjan identified, inside MAX Π_1, the class RMAX(2) containing MAX CLIQUE and having the property that all problems in the class are self-improvable, i.e., the existence of approximation polynomial-time algorithms with a constant ratio of approximation implies the existence of PTAS. It has been shown, again by a reduction from a certain type of PCP, that there is no constant ratio, polynomial approximation algorithm for MAX CLIQUE, unless NP = P. Therefore, no complete problem in RMAX(2) has PTAS, unless NP = P. In a later development, Kolaitis and Thakur undertook in [KT94] a comprehensive investigation of the logical characterizations of NP optimization problems. Considering an arbitrary number of alternations of blocks of quantifiers, they introduced the classes MAX Π_n, MAX Σ_n, MIN Π_n, MIN Σ_n, $n \geq 0$. They showed that all NP optimization problems in which the value of the optimum is polynomially bounded in the length of the input are in MAX Π_2, in the case of maximization problems, and in MIN Π_1, in the case of minimization problems. Moreover, they proved that all polynomially bounded NP maximization and minimization problems can be placed in one of the levels of the following proper hierarchies: MAX $\Sigma_0 \subsetneqq$ MAX $\Sigma_1 \subsetneqq$ MAX Π_1 = MAX $\Sigma_2 \subsetneqq$ MAX Π_2, for maximization problems, and MIN Σ_0 = MIN $\Sigma_1 \subsetneqq$ MIN Π_1 = MIN Σ_2 = MIN Π_2, for minimization problems. Kolaitis and Thakur have also introduced and investigated in [KT94] and [KT95] the classes MAX FΣ_n, MAX FΠ_n, MIN FΣ_n, MIN FΠ_n, $n \geq 1$, which are closely related to the above classes and offer a more natural logical description for some NP polynomially bounded optimization problems. This time the formula characterizing the set of feasible solutions is closed (i.e., it has no free variables) and the objective function is defined to be the number of tuples satisfying a specified relation from the structure S over which we maximize or minimize. They identified two syntactically defined classes, MIN F$^+\Pi_1$ and MIN F$^+\Pi_2(1)$, containing many natural important problems and having good approximation properties. Thus, MIN F$^+\Pi_1$ contains VERTEX COVER and many minimization node and edge deletion problems. All the problems in this class have polynomial-time algorithms with constant approximation ratio. MIN F$^+\Pi_2(1)$ contains SET COVER, DOMINATING SET, HITTING SET, and other natural problems. All the problems in this class have polynomial-time approximation algorithms with the approximation ratio bounded by $\log n$, where n is the length of the input. A further step was taken by Behrendt, Compton, and Grädel [BCG92], who considered more powerful logics obtained by adding the least fixpoint operator to the first-order syntax. It is observed that MAX Σ_1^{FP}, which is just MAX Σ_1 extended with the least fixpoint operator, continues to be approximable within a constant factor. In [BCG92] and [GM93], limit laws are identified for many

of the above classes. These laws, similar to the 0-1 laws for various logics (see the survey paper [Com88]) constitute useful necessary criteria for the expressibility of a problem in the restricted syntax which define the respective classes.

In spite of the new techniques that have emerged in recent years, with one important exception, there has been no thorough investigation of arbitrary NP optimization problems, i.e., problems in which the optimum value is no longer polynomially bounded in the length of the input. Since these problems usually arise when numerical weights are added to the input data, we call them *weighted NP optimization problems*. There is no need to argue about the large percentage of problems of this type that appear in real applications. The exception paper alluded to above is again the work of Papadimitriou and Yannakakis [PY91]. They have considered the variants of MAX SNP and MAX NP in which positive weights are attached to the tuples over the domain of the input structure that can be substituted for the free variables $\vec{x}$ and showed that these more general classes continue to have polynomial-time algorithms with constant ratio.

In this work, we undertake a more comprehensive examination of weighted NP optimization problems. We consider the classes weight-MAX $\mathrm{F}\Sigma_n$, weight-MAX $\mathrm{F}\Pi_n$, weight-MIN $\mathrm{F}\Sigma_n$, weight-MIN $\mathrm{F}\Pi_n$, $n \geq 1$, which are just the weighted variants of the MAX $\mathrm{F}\Sigma_n$, MAX $\mathrm{F}\Pi_n$, MIN $\mathrm{F}\Sigma_n$, and MIN $\mathrm{F}\Pi_n$ classes from [KT94] and [KT95]. For example, a problem is in weight-MAX $\mathrm{F}\Pi_2$ if: (1) the set of feasible solutions for an input structure $I = (D_I, R_I)$ is given by the finite structures S having the same domain as I and the relation $S_1, S_2, \ldots, S_p$ and satisfying a formula of the form $\forall \vec{x}\ \exists \vec{y}\ \phi(\vec{x}, \vec{y}, R_I, S_1, \ldots, S_p)$ with ϕ closed and quantifier-free, (2) each m-tuple $(x_1, \ldots, x_m)$ over the domain of I has a real-valued weight, where m is the arity of S_1, and (3) the objective function is to maximize over all structures S as above the weight of tuples in S_1. If the weights are positive, then the problem is in weight(+)-MAX $\mathrm{F}\Pi_2$. We notice that all NP optimization problems, not just the polynomially bounded ones, admit a logical characterization. More precisely, all NP maximization (minimization) problems are in weight-MAX $\mathrm{F}\Pi_2$ (weight-MIN $\mathrm{F}\Pi_2$). It is easy to note that all problems in weight-MAX $\mathrm{F}\Sigma_1$ and weight(+)-MAX $\mathrm{F}\Sigma_1$ are solvable in polynomial time, and weight-MAX $\mathrm{F}\Sigma_2$ and weight(+)-MAX $\mathrm{F}\Sigma_2$ can be reduced in a way that preserves approximation properties to weight-MAX $\mathrm{F}\Pi_1$ and, respectively, to weight(+)-MAX $\mathrm{F}\Pi_1$. Similar properties hold for the analogue minimization classes and, consequently, these classes are less interesting from the point of view of approximation properties. From the syntactical point of view, the weight(+) classes satisfy the diagram in Figure 1, which is identical with the one satisfied by their non-weighted analogues. For the classes with arbitrary weights we only know the trivial relations represented in Figure 1. Making these relations more precise remains an open problem.

For all classes $\mathcal{C}$ earlier identified as having polynomial-time approximation algorithms with guaranteed low approximation ratio, we analyze the weight-$\mathcal{C}$ and weight(+)-$\mathcal{C}$ variants. We consider $\mathcal{C} \in \{\text{MAX SNP}, \text{MAX NP}, \text{MAX SNP}(\pi), \text{MAX } \mathrm{F}\Pi_1, \text{MAX } \mathrm{F}^{+}\Pi_2(1)\}$. (MAX SNP($\pi$) is a subclass of MAX SNP in which the structure S over which the maximum is searched is required to be a permutation of the domain of the input structure.)

In all cases, weight(+)-$\mathcal{C}$ continues to have the same approximation properties as $\mathcal{C}$, and weight-$\mathcal{C}$ fails to do likewise unless very unlikely hypotheses hold. Table 1 summarizes the approximation properties of the classes analyzed in this paper.

The notation is standard and most of it is explicitly introduced in the text. We

TABLE 1
Approximation properties of the classes with good approximation properties in the nonweighted case.

Syntax	Positive weights	Arbitrary weights
MAX SNP	const. approximable	not approx. with ratio $< n^{1/4}$ unless P = NP
MAX NP	const. approximable	not approx. with ratio $< n^{1/4}$ unless P = NP
MAX SNP(π)	const. approximable	not approx. with ratio $2^{\log^{\mu} n}$, for some $\mu > 0$, unless NP $\subseteq$ DTIME$[2^{\log^{O(1)} n}]$
MIN $F^+\Pi_1$	const. approximable	not approx. with ratio 2^{n^q}, any q, unless P = NP
MIN $F^+\Pi_2(1)$	log. approximable	not approx. with ratio 2^{n^q}, any q, unless P = NP

note here only that Σ^* is the set of finite binary strings and $\Sigma^{=n}$ is the set of binary strings of length n; if $x \in \Sigma^*$, then $|x|$ is the length of string x; if S is a set, then $|S|$ is the cardinality of S; and, finally, if y is a real number, then $|y|$ is the modulus of y. $\tilde{\text{P}}$ denotes DTIME$[2^{\log^{O(1)} n}]$ and $\log n$ is the integer part of $\log_2 n$.

2. Logical definability. The elements which define an optimization problem A are:

(1) a set $\mathcal{I}_A$ of input instances; we assume that this set can be recognized in polynomial time,
(2) for each $I \in \mathcal{I}_A$, a set $\mathcal{F}_A(I)$ of feasible solutions associated to each input instance; we assume that each element in $\mathcal{F}_A(I)$ has size polynomially bounded in the size of I, and
(3) an objective function f_A which maps to real numbers each pair (I, J) with $I \in \mathcal{I}_A$ and $J \in \mathcal{F}_A(I)$; we assume that this function is computable in polynomial time. There is also a default value for the cases when the set of feasible solutions is empty.

If the objective function takes only nonnegative values then A is called a positive optimization problem. Given an instance $I \in \mathcal{I}_A$, the goal is to find $\text{opt}_{J \in \mathcal{F}_A(I)} f_A(I, J)$ or output the default value in case $\mathcal{F}_A(I)$ is empty, where opt is max or min depending on what kind of an optimization we have. It is convenient to denote $\text{opt}_{J \in \mathcal{F}_A(I)}\ f_A(I, J)$ by $\text{opt}_A(I)$. A max (min) optimization problem A is an NP optimization problem if the following associated decision problem B is in NP.

Instance: An input instance $I \in \mathcal{I}_A$ and $k \in \mathbf{Z}$.
Question: Does there exist a feasible solution $J \in \mathcal{F}_A(I)$ such that $f_A(I, J) \geq k$ ($f_A(I, J) \leq k$, in the case of a min problem)?

Kolaitis and Thakur [KT94] have shown that each NP optimization problem in which the optimum is polynomially bounded in the size of an encoding of the input instance can be syntactically described as an optimization problem in which the goal is to find the max (or min) cardinality of a relation which together with some other relations satisfies a given first-order formula. Thus the objective function is the cardinality of tuples satisfying a relation of some specified arity and the set of feasible solutions is given by the structures satisfying a first-order formula. In order to make the above statements more precise we need some standard definitions from descriptive computational complexity that we introduce in a simplified manner which mixes together syntactical and semantical notions. For a rigorous treatment see [Fag74], [Gra84], [Imm89], [Lyn82].

DEFINITION 2.1. *A finite type is a finite sequence of nonnegative integers. Given a finite type $T = (n_1, n_2, \ldots, n_k)$, a finite T-structure is a $(k+1)$-tuple $F = (X, f_1, f_2, \ldots, f_k)$, where X is a nonempty finite set called the domain of the structure F and, for all i, f_i is a relation over X of arity n_i.*

Input instances of problems can naturally be viewed as finite structures of some finite type. For example, graphs are finite structures of the form (V, E), where V is the domain (the set of nodes) and E is a relation of arity 2 (the set of edges). Boolean formulae in CNF are finite structures of the form $(\{x_1, x_2, \ldots, x_n, c_1, \ldots, c_m\}, P, N)$, where $\{x_1, x_2, \ldots, x_n, c_1, \ldots, c_m\}$ is the set of variables and clauses and P and N are relations of arity 2 such that $P(x_i, c_j)(N(x_i, c_j))$ has the significance that variable x_i appears positively (negatively) in clause c_j. The following well-known theorem of Fagin [Fag74] characterizes the class of NP decision problems in logical terms.

THEOREM 2.2 (see [Fag74]). *Let T be a finite type. A set L of finite T-structures is in* NP *if and only if there exists a finite type $\mathcal{S}$ and a quantifier-free first-order closed formula ϕ such that for all input structures I:*

$$I \in L \leftrightarrow \exists S \quad \forall \vec{x} \quad \exists \vec{y}\ \phi(\vec{x}, \vec{y}, I, S),$$

where S is a finite structure of type $\mathcal{S}$ having the same domain as I and $\vec{x}$ and $\vec{y}$ are tuples of variables ranging over I's domain.

The reader should be aware that the notation in the above statement of Theorem 2.2 is highly abusive. While the "I" in the left-hand side denotes a whole finite structure, the "I" and both "S"'s in the right-hand side are a shorthand notation for the relations of the corresponding structures denoted by the same symbols. We have implicitly assumed (by notation) that ϕ is compatible with I and S; i.e., for each relation symbol occurring in ϕ there is a correspondent relation in I or S and there is agreement on arities. Also, in $\forall \vec{x}$ and $\exists \vec{y}$, the quantifier is applied to all the components in the tuple $\vec{x}$ and, respectively, $\vec{y}$. These conventions will be used

throughout the rest of the paper. As an example, if I is a finite structure describing a CNF boolean formula as above, then

$$I \in \text{SAT} \leftrightarrow \exists T \quad \forall c \quad \exists x \; [(P(x,c) \wedge T(x)) \vee (N(x,c) \wedge \neg T(x))].$$

As mentioned above, Kolaitis and Thakur [KT94] have shown a similar property for polynomially bounded NP optimization problems.

THEOREM 2.3 (see [KT94]). *Let A be a polynomially bounded* NP *optimization problem. There exists a finite type $\mathcal{S}$ and a closed first-order formula ϕ such that for each input structure I*

$$\text{opt}_A(I) = \text{opt}_S \; \{|S_1| \; : \; \phi(\vec{x}, I, S)\},$$

where S is a finite structure of type $\mathcal{S}$ with the same domain as I and relations $S_1, S_2, \ldots, S_k$, $\vec{x}$ is a tuple of variables ranging over I's domain, and opt *is* max *or* min. *Moreover, formula ϕ has the form $\forall \vec{x} \; \exists \vec{y} \; \psi(\vec{x}, \vec{y}, I, S)$ with ψ quantifier-free.*

Lautemann has observed in [Lau92] that this result can be improved to state that all the values in the range of the objective function, not just the optimal one, can be obtained through logical descriptions. Related to the above example, consider the NP optimization problem MAX SAT. Input structures I are boolean formulae in CNF and the goal is to find the maximum number of clauses that can be simultaneously satisfied by some truth assignment. This problem can be expressed as

$$\max{}_{Max\ Sat}(I) = \max_{C,T}\{|C| \; : \; \forall c \, \exists x [C(c) \rightarrow [(P(x,c) \wedge T(x)) \vee (N(x,c) \wedge \neg T(x))]]\}.$$

We generalize the above result to all NP optimization problems. The price for removing the polynomial bounding restriction is the introduction of weights for all n_1-tuples over the I's domain, where n_1 is the arity of S_1. Note that the domain of I, being finite, can be identified with a set of the form $\{1, 2, \ldots, n\}$.

DEFINITION 2.4.

(1) *Let $k \in \mathbf{N}$. A k-weight assignment is a sequence of recursive functions $\{w_i\}_{i \in \mathbf{N}}$, where each $w_i \; : \; \{1, 2, \ldots, i\}^k \rightarrow \mathbf{R}$. For each k-tuplet $\vec{x}$ and all i and j, if $w_i(\vec{x})$ and $w_j(\vec{x})$ are defined, then $w_i(\vec{x}) = w_j(\vec{x})$.*

(2) *A k-positive weight assignment is a sequence of recursive functions $\{w_i\}_{i \in \mathbf{N}}$, where each $w_i \; : \; \{1, 2, \ldots, i\}^k \rightarrow \mathbf{R}_+$. For each k-tuplet $\vec{x}$ and all i and j, if $w_i(\vec{x})$ and $w_j(\vec{x})$ are defined, then $w_i(\vec{x}) = w_j(\vec{x})$.*

(3) *If S is a relation of arity k over $\{1, 2, \ldots, i\}$ and w is a k-weight assignment, the weight of S is $w(S) = \sum_{\vec{x} \in S} w_i(\vec{x})$.*

THEOREM 2.5. *Let A be a (positive)* NP *optimization problem. There exists a finite type $\mathcal{S} = (n_1, n_2, \ldots, n_k)$, a closed first-order formula ϕ, and an n_1-weight (positive) assignment w such that for each input instance I whose set of feasible solutions is not empty,*

$$\text{opt}_A(I) = \text{opt}_S \; \{w(S_1) \; : \; \phi(\vec{x}, I, S)\}, \tag{2.1}$$

where S is a finite structure of type $\mathcal{S}$ with the same domain as I and relations $S_1, S_2, \ldots, S_k$, $\vec{x}$ is a tuple of variables ranging over I's domain, and opt *is* max *or* min. *Moreover, formula ϕ has the form $\forall \vec{x} \; \exists \vec{y} \; \psi(\vec{x}, \vec{y}, I, S)$ with ψ quantifier-free.*

Proof. Let A be an NP optimization problem. For simplicity we assume that the objective function f_A is integer-valued. Let I be an input structure with domain $\{1, 2, \ldots, n\}$. The structure I is encoded by a string whose length is bounded by

a polynomial in n. Since the objective function f_A is polynomial-time computable, there exists a constant d such that $|\text{opt}_A I| \leq 2^{n^d} - 1$, for all I, where n, as explained, is the size of I. We define inductively the following $(d+1)$-weight assignment w. Initially we order in the lexicographical order the $(d+1)$-tuples over $\{1,2\}$, and we assign to them, in this order, the weights $-2^{2^d-1}, \ldots, -2^0, 2^0, 2^1, \ldots, 2^{2^d-1}, 2^0, \ldots, 2^0$. At the end of stage n, we have assigned the values $-2^{n^d-1}, \ldots, -2^0, 2^0, 2^1, \ldots, 2^{n^d-1}$ to all $(d+1)$-tuples over $\{1, \ldots, n\}$. At stage $n+1$, we order lexicographically all $(d+1)$-tuples over $\{1, \ldots, n+1\}$ that contain $n+1$ and assign to them the values $-2^{(n+1)^d-1}, \ldots, -2^{n^d}, 2^{n^d}, \ldots, 2^{(n+1)^d-1}, 2^0, \ldots, 2^0$. There are $(n+1)^{d+1} - n^{d+1}$ such tuples and $2((n+1)^d - n^d)$ values of the form $\pm 2^k (k \neq 0)$ to assign, and thus, such an assignment is possible. The fact that we need is that for each integer m in the interval $[-(2^{n^d} - 1), 2^{n^d} - 1]$ there exists a set of $(d+1)$-tuples over $\{1, \ldots, n\}$ whose w weights sums to m. Let us suppose that A is a maximization problem (the case of a minimization problem is similar). We consider the following decision problem B.

Instance: A finite input structure $I \in \mathcal{I}_A$ with domain $\{1, 2, \ldots, n\}$, a relation U over $\{1, 2, \ldots, n\}$ of arity $(d+1)$, the $(d+1)$-weight assignment w defined above.
Question: Is there a feasible solution $J \in \mathcal{F}_A(I)$ such that $f_A(I, J) \geq w(U)$?

This is the decision problem associated to the NP optimization problem A and therefore is in NP. Consequently, by Fagin's Theorem 2.2, (I, U) is a YES instance to B if and only if there exists a quantifier-free first-order formula ψ and a finite structure R such that $\forall \vec{x}\ \exists \vec{y}\ \psi(\vec{x}, \vec{y}, I, U, R)$, where $\vec{x}, \vec{y}$, and R satisfy the conditions in Theorem 2.2. Now it is easy to see that if ϕ is the formula $\forall \vec{x}\ \exists \vec{y}\ \psi(\vec{x}, \vec{y}, I, U, R)$, then

$$\text{opt}_A(I) = \max_{U,R}\{w(U)\ :\ \phi(\vec{x}, \vec{y}, I, U, R)\}.$$

Indeed, let $m^* = \text{opt}_A(I)$. By a previous observation, there exists a relation U of arity $(d+1)$ such that $w(U) = m^*$. It follows that (I, U) is a YES instance to the decision problem B, and consequently, $\max_{U,R}\{w(U)\ :\ \phi(\vec{x}, \vec{y}, I, U, R)\} \geq m^*$. Conversely, let U, R be relations such that $\phi(\vec{x}, \vec{y}, I, U, R)$ holds and $w(U)$ is maximum. Then (I, U) is a YES instance to problem B. Therefore there exists a feasible solution $J \in \mathcal{F}_A(I)$ such that $f_A(J) \geq w(U)$ and, consequently, $m^* \geq \max_{U,R}\{w(U)\ :\ \phi(\vec{x}, \vec{y}, I, U, R)\}$. The proof for an arbitrary objective function (i.e., not necessarily integer-valued) is similar but more tedious. The key observation is that in polynomial time f_A can compute only rational values with a number of digits that is polynomial in n, and all these possible values can be covered by weights assigned to tuples of constant arity. The proof for positive NP optimization problems is absolutely similar. □

It should be remarked that, except for the arity, the weight assignment built in the proof of the above theorem is independent of the problem, and thus we have proved a stronger fact. More precisely, there exists a canonical family of weight assignments $\{w_1, \ldots, w_k, \ldots\}$ where, for each k, w_k is a k-assignment, such that for any NP optimization problem the weight assignment w in the expression (2.1) belongs to the family. Thus, the situation is completely similar to the polynomially bounded case from Theorem 2.3 (where the canonical weight assignment assigns value 1 to each tuplet).

We can now classify all NP optimization problems with respect to the quantifier structure of the formulae describing them.

DEFINITION 2.6. *For $n \geq 1$, a $\Sigma_n(\Pi_n)$ formula is a first-order closed formula in prenex normal form that has n alternations of quantifiers starting with a block of*

existential (*universal*) *quantifiers. A* Σ_0 *or* Π_0 *formula is a first-order quantifier-free closed formula.*

DEFINITION 2.7.

(1) *For each* $n \geq 1$, *weight*-MAX FΣ_n *is the set of optimization problems that can be expressed as*

$$\max_A(I) = \begin{cases} \max_S\{w(S_1) \ : \ \phi(\vec{x}, I, S)\}, & \text{if there is } S \text{ such that } \phi(\vec{x}, I, S), \\ default & \text{otherwise,} \end{cases}$$

where S, S_1, w *are as in Theorem* 2.5, *default is a real constant, and* ϕ *is a* Σ_n *formula compatible with* I *and* S.

(2) *For each* $n \geq 1$, *weight(+)*-MAX FΣ_n *is the subclass of weight*-MAX FΣ_n *in which* w *is a positive weight assignment.*

(3) *The classes weight*-MAX FΠ_n, *weight(+)*-MAX FΠ_n, *weight*-MIN FΣ_n, *weight(+)*-MIN FΣ_n, *weight*-MIN FΠ_n, *weight(+)*-MIN FΠ_n *are defined in the similar obvious way.*

It follows from Theorem 2.5 that all NP maximization (minimization) problems (we denote these two classes by weight-MAX NP and weight-MIN NP) are in weight-MAX FΠ_2 (weight-MIN FΠ_2). Also, all positive NP maximization (minimization) problems (denoted weight(+)-MAX NP and weight(+)-MIN NP) are in weight(+)-MAX FΠ_2 (weight(+)-MIN FΠ_2). From an algorithmic point of view, we observe first (by considering all polynomially many possible substitutions for the existentially quantified variables) that all problems in $\mathcal{C}$ FΣ_1, where $\mathcal{C} \in \{$weight(+)-MAX, weight(+)-MIN, weight-MAX, weight-MIN$\}$, can be solved in polynomial time and the problems in $\mathcal{C}$ FΣ_2 can be reduced to problems in $\mathcal{C}$ FΠ_1, with $\mathcal{C}$ as before. From the syntactical characterization point of view, we can prove the following relations.

THEOREM 2.8.

(1) *weight(+)*-MAX FΣ_1 $\subsetneq$ *weight(+)*-MAX FΠ_1 = *weight(+)*-MAX FΣ_2 $\subsetneq$ *weight(+)*-MAX FΠ_2 = *weight(+)*-MAX NP.

(2) *weight(+)*-MIN FΣ_1 *(weight(+)*-MIN FΠ_1*)* $\subsetneq$ *weight(+)*-MIN FΣ_2 $\subsetneq$ *weight(+)*-MIN FΠ_2 = *weight(+)*-MIN NP, *and weight(+)*-MIN FΣ_1 *and weight(+)*-MIN FΠ_1 *are incomparable.*

(3) *weight*-MAX FΣ_1 *(weight*-MAX FΠ_1*)* $\subseteq$ *weight*-MAX FΣ_2 $\subseteq$ *weight*-MAX FΠ_2 = *weight*-MAX NP, *and weight*-MAX FΣ_1 *and weight*-MAX FΠ_1 *are not equal.*

(4) *weight*-MIN FΣ_1 *(weight*-MIN FΠ_1*)* $\subseteq$ *weight*-MIN FΣ_2 $\subseteq$ *weight*-MIN FΠ_2 = *weight*-MIN NP, *and weight*-MIN FΣ_1 *and weight*-MIN FΠ_1 *are not equal.*

Proof. Most of the proof follows closely the arguments in the similar proofs in [KT95]. For convenience, we provide the appropriate pointers.

By Theorem 2.5, $\mathcal{C}$ FΠ_2 = $\mathcal{C}$ NP, where $\mathcal{C} \in \{$weight(+)-MAX, weight(+)-MIN, weight-MAX, weight-MIN$\}$, and thus, just from the syntactical characterization, ($\mathcal{C}$ FΣ_1, $\mathcal{C}$ FΠ_1) $\subseteq$ $\mathcal{C}$ FΣ_2 $\subseteq$ $\mathcal{C}$ FΠ_2.

As in [KT95, Theorem 6.2], MIN VERTEX COVER is in weight(+)-MIN FΠ_1 and in weight-MIN FΠ_1 but not in weight(+)-MAX FΣ_1 and not in weight-MIN FΣ_1.

By the arguments in [PR93], it can be shown that MAX CLIQUE is in weight(+)-MAX FΠ_1 and in weight-MAX FΠ_1 but not in weight(+)-MAX FΣ_1 and not in weight-MAX FΣ_1.

As in [KT95, Remark 2.1 and Theorem 2.1], weight(+)-MAX FΠ_1 = weight(+)-MAX Π_1 and weight(+)-MAX FΣ_i = weight(+)-MAX Σ_i, $i = 1, 2$ (where weight(+)-MAX Σ_i and weight(+)-MAX Π_i are the analogues of MAX Σ_i and MAX Π_i but

with positive weights on tuples). As in [KT94, Theorem 2], weight(+)-MAX Σ_2 = weight(+)-MAX Π_1. Thus, weight(+)-MAX FΣ_2 = weight(+)-MAX Σ_2 = weight(+)-MAX Π_1 = weight(+)-MAX FΠ_1.

As in [KT95, Proposition 2.1], weight(+)-MIN FΠ_1 = weight(+)-MIN Σ_1 and there exists a problem in weight(+)-MIN FΣ_1 which is not in weight(+)-MIN Σ_1 and, therefore, is not in weight(+)-MIN FΠ_1.

We have shown that weight(+)-MIN FΣ_1 and weight(+)-MIN FΠ_1 are incomparable, and thus, both classes are properly included in weight(+)-MIN FΣ_2.

As in [KT95, Theorem 6.2], MIN CYCLE (given a graph G, return the size of the shortest cycle in G) is in weight(+)-MIN FΠ_2 but not in weight(+)-MIN FΣ_2.

The only relation left unproven is weight(+)-MAX F$\Sigma_2 \subsetneqq$ weight(+)-MAX FΠ_2. Consider the following problem $\mathcal{P}$: given a graph $G = (V, E)$, find the length of the longest cycle in G or output 0 if no cycle exists. By Theorem 2.5, $\mathcal{P}$ is in weight(+)-MAX FΠ_2. Since weight(+)-MAX FΣ_2 = weight(+)-MAX FΠ_1, it is enough to show that $\mathcal{P}$ is not in weight(+)-MAX FΠ_1. So, suppose that

$$\max_{\mathcal{P}}(G) = \max_{S_1,\ldots,S_q}\{w(S_1) \ : \ \forall\vec{x}\phi(\vec{x}, G, S_1, \ldots, S_q)\}.$$

Let the arity of S_1 be k and consider the graph G consisting of a cycle $a_1, a_2, \ldots, a_n$, i.e., $(a_i, a_{i+1}) \in E$ and $(a_n, a_1) \in E$, and these are the only tuples in E. Take $n > k$. Let $S^* = (S_1^*, \ldots, S_q^*)$ be a relation that is optimal for G with respect to the above formula. Since $w(S_1^*) = n$, there must be a k-tuple $(a_{i_1}, \ldots, a_{i_k})$ such that $w(a_{i_1}, \ldots, a_{i_k}) > 0$. Let H be the subgraph of G obtained by restricting G to the vertices $a_{i_1}, \ldots, a_{i_k}$. Since Π_1 formulas are closed under taking substructures, $\forall\vec{x}\ \phi(\vec{x}, H, S_{1,H}^*, \ldots, S_{q,H}^*)$ holds true, where $S_H^* = (S_{1,H}^*, \ldots, S_{q,H}^*)$ is the restriction of S^* to $a_{i_1}, \ldots, a_{i_k}$. Therefore, $\max_{\mathcal{P}}(H) \geq w(S_q^*) > 0$. But H is not a cycle, and thus $\max_{\mathcal{P}}(H) = 0$. □

3. Approximation properties. As explained in the Introduction, the logical definability of optimization problems has in many important cases a direct impact on their approximation properties. The syntactical form of formulae describing the constraint conditions of a problem can imply the existence of polynomial-time algorithms achieving a specified ratio of approximation. Or, on the other hand, if a problem is hard under L- or A-reductions (these are some restricted variants of reductions that preserve approximation properties; they were introduced by Papadimitriou and Yannakakis in [PY91] and Panconesi and Ranjan in [PR93]), then the existence of good approximations algorithms is highly improbable. We investigate to what extent the known properties of polynomially bounded optimization problems remain valid when we pass to the positively weighted and arbitrarily weighted corresponding problems.

Definition 3.1.

(1) *Let A be an optimization problem. An approximation algorithm B for A is a function that maps input instances $I \in \mathcal{I}_A$ to feasible solutions in $\mathcal{F}_A(I)$. As a technical convenience, we require that $f_A(I, B(I))$ and* opt $A(I)$ *have strictly positive value for all I. The approximation algorithm B has approximation ratio $r_B \ : \ \mathbf{N} \to [1, +\infty)$ if for all input instances I:*

$$r_B(|I|) \geq \begin{cases} \frac{f_A(I,B(I))}{opt_A I} & \text{if } A \text{ is a minimization problem,} \\ \\ \frac{opt_A I}{f_A(I,B(I))} & \text{if } A \text{ is a maximization problem.} \end{cases}$$

(2) *An optimization problem A is constant* (log)*-approximable if there exists a polynomial-time approximation algorithm B for A such that $r_B(|I|) = O(1)$ ($r_B(|I|) = O(\log(|I|))$) for all input structures I of A.*
(3) *An optimization problem A is superpolylog approximable if there exists a* DTIME$[2^{\log^{O(1)} n}]$ *approximation algorithm B for A and a constant $\mu > 0$ such that $r_B(|I|) = 2^{\log^{\mu} |I|}$ for all input structures I of A.*

For the sake of simplicity, the above definition assumes that the approximation algorithm B outputs the result of the objective function applied to a feasible solution. However, all the following results hold in the more liberal setting in which B is allowed to compute just an approximation (from below or above) of the optimum.

DEFINITION 3.2. *The optimization problem Π L-reduces to the optimization problem Π' if there are two polynomial-time algorithms f and g and constants $\alpha, \beta > 0$ such that*

(1) *given any instance I of Π, f produces an instance I' of Π' such that* $\mathrm{opt}_{\Pi'} I' \leq \alpha\ \mathrm{opt}_{\Pi} I$,
(2) *given a feasible solution of I' of cost c', g produces a feasible solution of I of cost c such that $|c - \mathrm{opt}_{\Pi} I| \leq \beta |c' - \mathrm{opt}_{\Pi'} I'|$.*

We next take into review all syntactically defined classes of NP optimization problems that have been identified in earlier works to have good approximation properties.

MAX SNP and **MAX NP**. A polynomially bounded maximization problem A is in MAX NP if $\max_A(I) = \max_S\ |\{\vec{x}\ :\ \exists \vec{y}\ \phi(\vec{x}, \vec{y}, I, S)\}|$, where ϕ is a first-order quantifier-free formula. If $\max_A(I) = \max_S\ |\{\vec{x}\ :\ \phi(\vec{x}, I, S)\}|$, then A is in MAX SNP. It is known from [PY91] that if A is in MAX NP or MAX SNP, then A is constant approximable. The weighted variants of these classes are defined by considering m-weight assignments for the $\vec{x}$-tuples in the formulae above (m is the arity of $\vec{x}$) and proceeding as in the definition of the classes MAX FΣ_i or MAX FΠ_i. Papadimitriou and Yannakakis have shown in [PY91] that all problems in weight(+)-MAX NP and weight(+)-MAX SNP are constant approximable. This property does not extend to weight-MAX SNP (and to weight-MAX NP), unless NP $\subseteq$ P. In order to prove this we consider the following well-known problem.

weight-MAX 2SAT: An instance of this problem is a CNF formula with two literals per clause and with real-valued weights assigned to each clause. The goal is to maximize the total weight of the clauses that can be simultaneously satisfied by a truth assignment.

The problem is in weight-MAX SNP by the following logical description. An input structure consists of a pair $(Var, C_0, C_1, C_2, C_3)$, where the domain Var is the set of variables and C_i are relations of arity 4 such that $x_1, x_2, x_1, x_2 \in C_0$ means that there exists a clause $c = \overline{x}_1 \vee \overline{x}_2$, $x_1, x_2, x_2, x_1 \in C_1$ means that there exists a clause $c = x_1 \vee \overline{x}_2$, $x_1, x_2, x_1, x_1 \in C_2$ means that there exists a clause $c = \overline{x}_1 \vee x_2$, and $x_1, x_2, x_2, x_2 \in C_3$ means that there exists a clause $c = x_1 \vee x_2$ (we assume that all clauses have distinct variables). Assigning weights to any 4-tuple of variables in the obvious way, we can write $\max_{MAX\ 2SAT}(C) = \max_T\ w(\{(t,u,v,w)\ :\ (C_0(t,u,v,w) \rightarrow (\neg T(t) \vee \neg T(u))) \wedge (C_1(t,u,v,w)\ \rightarrow\ (T(t) \vee \neg T(u))) \wedge (C_2(t,u,v,w)\ \rightarrow\ (\neg T(t) \vee T(u))) \wedge (C_3(t,u,v,w) \rightarrow (T(t) \vee T(u)))\})$. The following lemma, whose proof is deferred until the end of this section, holds.

LEMMA 3.3. *If* NP $\neq$ P*, then weight-MAX 2SAT is not approximable within ratio n^c for any $c < 1/4$, and, if* NP $\neq$ coRP*, then weight-MAX 2SAT is not approximable within ratio n^c for any $c < 1/3$.*

Consequently we obtain the following theorem.

THEOREM 3.4. *If* NP $\neq$ P*, there are problems in weight-*MAX SNP *that are not approximable with approximation ratio* n^c *for any* $c < 1/4$*. If* NP $\neq$ coRP*, there are problems in weight-*MAX SNP *that are not approximable with approximation ratio* n^c *for any* $c < 1/3$.

We do not know if weight-MAX 2SAT is complete for weight-MAX SNP under L- (or A-) reductions. Nevertheless, this problem could be a good starting point for a chain of L-reductions showing that other natural problems do not possess the superpolylog approximation property under the same hypothesis. For example, the reduction from [PY91] shows that weight-MAX NOT-ALL-EQUAL-2 SAT falls into this category.

Papadimitriou and Yannakakis have considered in [PY91] a variant of MAX SNP, called MAX SNP(π), in which the structure over which we maximize is required to be a total linear ordering (i.e., a permutation) of the domain of the input structure. This class contains natural problems like MAX SUBDAG: given a directed graph $G = (V, E)$, find an acyclic subgraph $G' = (V, E')$ with E' as large as possible. The weighted version of this problem is obtained, of course, by assigning weights to edges. It was shown in [PY91] that MAX SUBDAG is L-complete for MAX SNP(π) and it is straightforward to extend this result to weight(+)-MAX SUBDAG. MAX SUBDAG and weight(+)-MAX SUBDAG can be approximated in polynomial time with ratio 2: take any permutation of the vertices and its reverse and choose the one that yields an orientation whose weight is larger. It follows that all problems in MAX SNP(π) and weight(+)-MAX SNP(π) are constant approximable. Clearly, weight-MAX SUBDAG continues to be constant approximable, because we can just disregard the edges with negative weights. We consider another important natural problem (see [GM84, p. 465 ff.]) in weight-MAX SNP(π), which is closely related to MAX SUBDAG.

weight-PRIORITY ORDERING: Given a set X and real-valued weights w to all pairs of distinct elements in X, find the maximum over all permutations π of $\sum_{\{(x,y):\pi(x)<\pi(y)\}} w(x, y)$.

In the hypothesis NP $\not\subseteq \tilde{\text{P}}$, we show in the next section that this problem is not superpolylog approximable. Thus we have established the following theorem.

THEOREM 3.5. *If* NP $\not\subseteq \tilde{\text{P}}$*, there are problems in weight-*MAX SNP(π) *that are not superpolylog approximable.*

MIN $\text{F}^+\mathbf{\Pi_1}$ and **MIN**$^+$ $\text{F}\mathbf{\Pi_2}(\mathbf{1})$. These are subclasses of MIN $\text{F}\Pi_1$ and, respectively, MIN $\text{F}\Pi_2$ and have been identified in [KT95] as having good approximation properties. A minimization problem A is in MIN $\text{F}^+\Pi_1$ if $\min_A(I) = \min_S\{|S| : \forall \vec{x}\ \phi(\vec{x}, I, S)\}$, where the structure S consists of a single relation and ϕ is a quantifier-free formula in CNF with variables $\vec{x}$ in which all occurrences of S are positive. The minimization problem A is in MIN $\text{F}^+\Pi_2(1)$ if $\min_A(I) = \min_S\{|S| : \forall \vec{x}\ \exists \vec{y}\ \phi(\vec{x}, \vec{y}, I, S)\}$, where the structure S consists of a single relation and ϕ is a quantifier-free formula in DNF with variables $\vec{x}, \vec{y}$ in which all occurrences of S are positive and S occurs at most once in each disjunct. The weighted versions of these classes are defined in the obvious way. These apparently obscure classes have as complete sets (under L-reductions) some very important optimization problems. Thus, it is shown in [KT94] that k-HYPERVERTEX COVER is complete for MIN $\text{F}^+\Pi_1(k)$ (a subclass of MIN $\text{F}^+\Pi_1$, in which S is restricted to appear at most k times in each clause of ϕ) and SET COVER, DOMINATING SET, and HITTING SET are complete for MIN $\text{F}^+\Pi_2(1)$ (see [KT95]). It is straightforward to extend these results for the weight and weight(+) versions of the problems and classes (e.g., weight

VERTEX COVER is L-complete for weight-MIN $\mathrm{F}^+\Pi_1(2)$, and so on). Since k-HYPERVERTEX COVER is constant approximable and SET COVER is log approximable (see [KT95]), it follows that all the problems in MIN $\mathrm{F}^+\Pi_1$ are constant approximable and all the problems in MIN $\mathrm{F}^+\Pi_2(1)$ are log approximable. It can be shown that weight(+)-k-HYPERVERTEX COVER continues to be constant approximable (the results in [BYE81] and [Hoc82] concerning weight(+) VERTEX COVER can be extended to weight(+)-k-HYPERVERTEX COVER). Chvàtal [Chv79] has proved that weight(+)-SET COVER also continues to be log approximable. From the L-completeness of these problems, we obtain the following theorem.

THEOREM 3.6.

(1) *All problems in weight(+)-*MIN $\mathrm{F}^+\Pi_1$ *are constant approximable.*

(2) *All problems in weight(+)-*MIN $\mathrm{F}^+\Pi_2(1)$ *are* log *approximable.*

We next pass to the general weighted version of these classes. Observe that weight-VERTEX COVER is in both weight-MIN $\mathrm{F}^+\Pi_1$ and weight-MIN $\mathrm{F}^+\Pi_2(1)$, since $\min_{VC}(G) = \min_S\{w(S) \ : \ \forall x\ \forall y\ (\neg E(x,y) \vee S(x) \vee S(y))\}$. The following lemma, whose proof is deferred until the end of this section, holds.

LEMMA 3.7. *If* $\mathrm{P} \neq \mathrm{NP}$*, then for every constant* q*, weight-VERTEX COVER is not approximable in polynomial time with ratio* 2^{n^q}.

Consequently, we obtain the following theorem.

THEOREM 3.8. *If* $\mathrm{NP} \not\subseteq \tilde{\mathrm{P}}$*, then, for every* q*, there are problems in weight-*MIN $\mathrm{F}^+\Pi_1$ *and weight-*MIN $\mathrm{F}\Pi_2(1)$ *that are not approximable in polynomial time with approximation ratio* 2^{n^q}.

It follows that the problems weight-SET COVER, weight-DOMINATING SET, and weight-HITTING SET, being L-complete for weight-MIN $\mathrm{F}^+\Pi_2(1)$, are not approximable in polynomial time within a 2^{n^q} ratio, unless NP = P.

In the rest of this section, we prove the hard-to-approximate properties of weight-MAX 2SAT and weight-VERTEX COVER.

Proof of Lemma 3.3. The proof consists of an L-reduction of INDEPENDENT SET to weight-MAX 2SAT which is obtained by slightly modifying the reduction of INDEPENDENT SET for graphs with bounded degree to MAX 2SAT from [PY91]. It can be easily shown that if δ is a lower bound on the approximation ratio of Π and π L-reduces to Π' with the constants α and β as in Definition 3.2, then $\delta/(\alpha\beta)$ is a lower bound on the approximation ratio of Π'. We will achieve $\alpha = \beta = 1$, and then we use the results of Bellare, Goldreich, and Sudan [BGS95] stating that if $\mathrm{P} \neq \mathrm{NP}$ ($\mathrm{NP} \neq \mathrm{coRP}$) then INDEPENDENT SET is not approximable in polynomial time with ratio n^c for any $c < 1/4$ (respectively, $c < 1/3$).

We only have to exhibit the L-reduction. Given $G = (V, E)$, an instance of INDEPENDENT SET, we build a formula ϕ in 2-CNF as follows: for each node i, we consider a clause x_i, and for each edge (i, j) we consider a clause $(\overline{x}_i \vee \overline{x}_j)$. All these clauses have weight 1. We consider a new variable y and two more clauses, y and $\overline{y}$, each with weight $-|E|$. It is easy to observe the following fact.

Fact. Given an assignment for ϕ with cost c, we can find in polynomial time an assignment with cost $c' \geq c$ such that all the clauses corresponding to edges are satisfied in the new assignment. Such an assignment is said to be in *normal form.*

Now, it is easy to see that the nodes corresponding to the clauses that are made true by a normal form assignment form an independent set. Taking into account that one of the clauses y, $\neg y$ is satisfied by any assignment, it follows that

$$\mathrm{opt}_{MAX2SAT}(\phi) = \mathrm{opt}_{IND.SET}(G) + |E| - |E| = \mathrm{opt}_{IND.SET}(G).$$

Also, given any assignment with cost c', we can build in polynomial time a normal form assignment with cost $c \geq c'$ which corresponds to an independent set of size c and, thus, $\text{opt}(G) - c \leq \text{opt}(\phi) - c'$. □

Proof of Lemma 3.7. The proof consists of a slight modification of the "classical" reduction of 3-SAT to VERTEX COVER in [GJ79]. Let ϕ be a formula in 3-CNF having variables $x_1, \ldots, x_n$ and clauses $C_1, \ldots, C_m$. We build the following undirected graph $G = (V, E)$. The nodes in V are $x_1, \overline{x}_1, \ldots, x_n, \overline{x}_n$, and for each clause $C_i = (\alpha \vee \beta \vee \gamma)$, there are the nodes $(\alpha, i), (\beta, i), (\gamma, i)$. The nodes described so far each have weight $W = 2^{n^q}$. There are two more special nodes, y and z, each of them having weight $1 - nW - 2mW$. For each variable x_i, there is the edge $(x_i, \overline{x}_i)$, and for each clause $C_i = (\alpha \vee \beta \vee \gamma)$, we introduce in E the edges $((\alpha, i), (\beta, i)), ((\beta, i), (\gamma, i))$, and $((\gamma, i), (\alpha, i))$ (forming a triangle). For all $(\alpha, i) \in V$, we introduce in E the edge $(\alpha, (\alpha, i))$ (the nodes labeled with over-lined variables correspond to negated variables). G also contains the edge (y, z).

Observe that in order to cover an edge of the form $(x_1, \overline{x}_i)$ corresponding to the variable x_i, we need to select at least one of x_i or $\overline{x}_i$ in the vertex cover, and in order to cover the three edges corresponding to a clause $C_i = (\alpha \vee \beta \vee \gamma)$, at least two of the nodes $(\alpha, i), (\beta, i), (\gamma, i)$ must be taken in the vertex cover. Also, one of y or z must also be chosen in the vertex cover. As in the classical reduction, it can be seen that if ϕ is satisfiable, there is a vertex cover of G having only the minimum number of nodes specified above and having weight $nW + 2mW + 1 - nW - 2mW = 1$. On the other hand, if ϕ is not satisfiable, at least one more node, other than y or z, must be taken in any vertex cover and, thus, in this case, $\min_{VC}(G) \geq 1 + W$. Consequently, if weight-VERTEX COVER would be approximable in polynomial time with ratio less than W, then we could solve 3-SAT in polynomial time. □

4. Reductions from MIP systems. The hard-to-approximate property of the problem PRIORITY ORDERING, which was introduced in the previous section, is established by a reduction from MIP systems running in one round. Such reductions have been extensively used in recent years to investigate and solve long-standing open problems regarding the approximation properties of many natural combinatorial optimization problems [ALM+92, Bel92, BS94, Con91, FGL+91, FL92, LY93a, LY93b, Zuc93, Zim93]. We now introduce the necessary terminology. Following [BGLR93], we denote by $\text{MIP}_1(r, p, a, q, \epsilon)$ a one-round MIP system in which the number of random bits is $r(n)$, the number of provers is $p(n)$, the size of each verifier's query is $q(n)$, the size of each prover's answer is $a(n)$, and the error probability is $\epsilon(n)$, where n is the size of the input (which, for conciseness, will be omitted). We describe the way such a system works. A $\text{MIP}_1(r, p, a, q, \epsilon)$ system involves $p + 1$ parties: one verifier V and p provers $P_1, P_2, \ldots, P_p$. All these parties share a common input x, and it is the joint goal of the provers to convince V to accept x. The interaction between $V, P_1, \ldots, P_p$ runs as follows. The verifier randomly selects a string R of length r and computes $\pi(x, R) = (q_1, q_2, \ldots, q_p)$, a p-tuplet of queries, all of length q, and sends, for all i, the query q_i to the prover P_i. The provers compute their answers $a_i = P_i(x, q_i)$, where P_i is the function defining the strategy of the prover P_i (note the overload in the notation P_i) and the length of all a_i's is a. After the verifier receives the answers $a_1, a_2, \ldots, a_p$, she computes $\rho(x, q_1, q_2, \ldots, q_p, a_1, a_2, \ldots, a_p)$, which tells her whether to accept x or not. We assume that π and ρ, which define the verifier strategy, are polynomial-time computable functions, but there is no restriction on the functions P_i (i.e., the provers are arbitrary powerful). Let $ACC_{V,(P_1,P_2,\ldots,P_p)}(x)$ denote the probability that $\rho(x, q_1, q_2, \ldots, q_p, a_1, a_2, \ldots, a_p) =$ "accept," when R is

chosen randomly of length r and the q_i's and a_i's are as above. The value of the verifier strategy V at x is the maximum of $ACC_{V,(P_1,P_2,\ldots,P_p)}(x)$ over all p-tuples $(P_1, P_2, \ldots, P_p)$ of prover strategies. We denote this value by $ACC_V(x)$. We say that V accepts a language L with error probability ϵ (where $\epsilon : \mathbf{N} \to \mathbf{R}$ and $L \subset \Sigma^*$) if:

(1) $x \in L$ implies $ACC_V(x) = 1$, and

(2) $x \notin L$ implies $ACC_V(x) < \epsilon(|x|)$.

We say that L is accepted by a $\mathrm{MIP}_1(r, p, a, q, \epsilon)$ if there is a verifier V running the above protocol that accepts L.

There has been a stream of important works, [BFL91], [ALM+92], [FGL+91], [FRS88], [FL92], [BGLR93], [FK94], [PS94], leading to multiprover interactive systems accepting the NP complete set SAT with increasingly better parameters r, p, a, q, ϵ. We use the following variant (see [BGLR93]).

THEOREM 4.1. *SAT is accepted by a* $\mathrm{MIP}_1(O(\log^3 n), 2, O(\log^3 n), O(\log^3 n), 1/n)$.

The general technique we use to prove that a maximization problem A is hard to approximate consists in reducing via a function Φ a $\mathrm{MIP}_1(r, p, a, q, \epsilon)$ verifier strategy V to A in such a way that valid provers' strategies $(P_1, P_2, \ldots, P_p)$ correspond to feasible solutions, $ACC_{V,(P_1,P_2,\ldots,P_p)}(x) = f_A(J)$, where $J \in \mathcal{F}_A(\Phi(x))$ and $\max_A \Phi(x) = 2^{r(|x|)} \cdot ACC_V(x)$.

DEFINITION 4.2. *We say that* $\mathrm{MIP}_1(r, p, a, q, \epsilon)$ *reduces to the maximization problem* A *if for any verifier strategy* V *running the* $\mathrm{MIP}_1(r, p, a, q, \epsilon)$ *protocol, there is a function* Φ_V *which maps a common input* x *for the verifier strategy into an instance* $\Phi_V(x) \in \mathcal{I}_A$ *of the optimization problem* A *and has the following properties:*

(1) *for all* $x \in \Sigma^*$, $\max_A \Phi_V(x) = 2^{r(|x|)} \cdot ACC_V(x)$, *and*

(2) $\Phi_V(x)$ *is computable in time* $2^{\log^c |x|}$ *for some constant* c.

The following lemma is an easy consequence of Theorem 4.1.

LEMMA 4.3. *Suppose that a* $\mathrm{MIP}_1(r, p, a, q, \epsilon)$ *of the type in Theorem* 4.1 *reduces to the maximization problem* A. *Then there is a constant* $\mu > 0$ *such that the existence of a* $\mathrm{DTIME}[2^{\log^\mu n}]$ *approximation algorithm* B *for* A *with* $r_B(|I|) < 2^{\log^\mu |I|}$ *implies* $\mathrm{NP} \subseteq \mathrm{DTIME}[2^{O(\log^{1/\mu} n)}]$.

Proof. Let ϕ be a boolean formula. There exists a verifier strategy V running a $\mathrm{MIP}_1(r, p, a, q, \epsilon)$ protocol of the type in Theorem 4.1 such that $\phi \in \mathrm{SAT} \to ACC_V(\phi) = 1$ and $\phi \notin \mathrm{SAT} \to ACC_V(\phi) \leq \epsilon(|\phi|) = 1/|\phi|$. There exists a constant c such that $|\Phi_V(\phi)| \leq 2^{\log^c |\phi|}$, where Φ_V is the reduction function. Note that

$$\phi \in \mathrm{SAT} \to ACC_V(\phi) = 1 \to \max A(\Phi_V(\phi)) = 2^{r(|\phi|)}$$

and

$$\phi \notin \mathrm{SAT} \to ACC_V(\phi) \leq \frac{1}{|\phi|} \to \max A(\Phi_V(\phi)) \leq \frac{1}{|\phi|} \cdot 2^{r(|\phi|)}.$$

Take $\mu = 1/c$ and suppose there is a $\mathrm{DTIME}[2^{\log^\mu n}]$ algorithm B for A with $r_B(|I|) < 2^{\log^\mu |I|}$, which means $r_B(|\Phi_V(\phi)|) < |\phi|$. In consequence:

$$\phi \in \mathrm{SAT} \to B(\Phi_V(\phi)) \geq \frac{1}{r_B(|\Phi_V(\phi)|)} \cdot \max A(\Phi_V(\phi)) > \frac{1}{|\phi|} \cdot 2^{r(|\phi|)}$$

and

$$\phi \notin \mathrm{SAT} \to B(\Phi_V(\phi)) \leq \max A(\Phi_V(\phi)) \leq \frac{1}{|\phi|} \cdot 2^{r(|\phi|)}.$$

Since $B(\Phi_V(\phi))$ can be computed in time $2^{O(\log^c |\phi|)}$, it follows that

$$\text{NP} \subseteq \text{DTIME}[2^{O(\log^{1/\mu} n)}]. \qquad \square$$

Taking into account Lemma 4.3, we need only to design the appropriate reduction from MIP systems with parameters as in Theorem 4.1 to PRIORITY ORDERING. This is the content of the next lemma.

LEMMA 4.4. $\text{MIP}_1(O(\log^3 n), 2, O(\log^3 n), O(\log^3 n), 1/n)$ *reduces to weight-PRIORITY ORDERING.*

Proof. Let V be a verifier executing a $\text{MIP}_1(d\log^3 n, 2, d\log^3 n, d\log^3 n, 1/n)$ protocol and let $n = |x|$, where x is the common input of the protocol. We build an instance for weight-PRIORITY ORDERING. Let $N = 2^{d\log^3 n}$. The set of elements to be ordered is

$$X = \{s_1, s_2, s_3, s_4\} \cup X_1 \cup X_2 \cup X_3,$$

where $X_1 = \{(u, v, a, 1) \ : \ u, v, a \in \Sigma^{=d\cdot\log^3 n}\}$, $X_2 = \{(u, v, b, 2) \ : \ u, v, b \in \Sigma^{=d\cdot\log^3 n}\}$, and $X_3 = \{(u, v, b, 3) \ : \ u, v, b \in \Sigma^{=d\cdot\log^3 n}\}$. We first overview the construction. Intuitively, u and v should be interpreted as queries to the first and, respectively, the second prover, and a and b, with or without subscripts, should be interpreted as answers provided by the first and, respectively, the second prover. By using large weights, we force any arrangement π that is a candidate for being the optimal one to achieve (i) $s_1 <_\pi s_2 <_\pi s_3 <_\pi s_4$, (ii) $s_2 <_\pi x <_\pi s_3$ for all $x \in X_2$, (iii) $x <_\pi s_4$ for all $x \in X_1$, and (iv) $s_1 <_\pi x$ for all $x \in X_3$. For all pairs $(u, v) \in (\Sigma^{=d\cdot\log^3 n})^2$ we order the set $X_{u,v,1} = \{(u, v, a, 1) \ : \ a \in \Sigma^{=d\cdot\log^3 n}\}$ in the lexicographical order $<_l$, obtaining $X_{u,v,1} = \{t_1 <_l t_2 <_l \cdots <_l t_N\}$. We assign weights such that ideally $s_3 <_\pi t_1 <_\pi t_2 <_\pi \cdots <_\pi t_N <_\pi s_1$. Since $s_1 <_\pi s_3$, this is not possible and therefore there exists j such that $t_{j+1} <_\pi t_{j+2} <_\pi \cdots <_\pi t_N <_\pi s_1 <_\pi s_3 <_\pi t_1 <_\pi \cdots <_\pi t_j$. Similarly, for all pairs $(u, v) \in (\Sigma^{=d\cdot\log^3 n})^2$ we order the set $X_{u,v,3} = \{(u, v, b, 3) \ : \ a \in \Sigma^{=d\cdot\log^3 n}\}$ in the lexicographical order $<_l$, obtaining $X_{u,v,3} = \{t_1 <_l t_2 <_l \cdots <_l t_N\}$, and we force the existence of $k \in \{1, \ldots, N\}$ with $t_{k+1} <_\pi t_{k+2} <_\pi \cdots <_\pi t_N <_\pi s_2 <_\pi s_4 <_\pi t_1 <_\pi \cdots <_\pi t_k$. Using some other combinations of weights involving the "stakes" s_1, s_2, s_3, s_4, we guarantee that for all $u \in \Sigma^{=d\cdot\log^3 n}$ there exists $j \in \{1, \ldots, N\}$ such that for all $v \in \Sigma^{=d\cdot\log^3 n}$, $(u, v, a_{j+1}, 1) <_\pi \cdots <_\pi (u, v, a_N, 1) <_\pi s_1 <_\pi s_3 <_\pi (u, v, a_1, 1) <_\pi \cdots <_\pi (u, v, a_j, 1)$ and for all $v \in \Sigma^{=d\cdot\log^3 n}$, there exists $k \in \{1, \ldots, N\}$ such that for all $u \in \Sigma^{=d\cdot\log^3 n}$, $(u, v, b_{k+1}, 3) <_\pi \cdots <_\pi (u, v, b_N, 3) <_\pi s_2 <_\pi s_4 <_\pi (u, v, b_1, 3) <_\pi \cdots <_\pi (u, v, b_k, 3)$. These unique values of j and k for each u and v define a pair of provers' strategies (P_1, P_2). Moreover, the weights are carefully defined in order to insure that $\max_\pi \sum_{\{(t,z) \ : \ \pi(t)<\pi(z)\}} w(t, z) = ACC_V(x)$.

Now we proceed with the complete and formal description of the reduction. We lexicographically order the sets of possible answers (i.e., the elements in $\Sigma^{=d\cdot\log^3 n}$) obtaining: $a_1 < a_2 \cdots < a_N$ and $b_1 < b_2 \cdots < b_N$ (of course, $a_i = b_i$, but keep in mind the above intuitive interpretation). Let $S = 3N^3 + 4$ denote the number of elements in X. We next define the weights, $w(\cdot, \cdot)$, for some pairs in $X \times X$. Given an ordering π of X and a subset $Y \subseteq X$, the contribution of Y is defined to be $C_\pi(Y) = \sum_{x,y\in Y,\pi(x)<\pi(y)} w(x, y)$. We call a permutation π *reasonable* if $C_\pi(X) \geq 0$. Since there exists an ordering σ (to be described below; it corresponds to a tuple of provers' strategies) such that $C_\sigma(X) \geq 0$, it follows that the optimal ordering π must be looked for among the reasonable ones.

For each 4-tuplet $(u, v, a, b) \in (\Sigma^{=d\cdot\log^3 n})^4$, we denote

$$val_{u,v,a,b} = \begin{cases} card\{R \in \Sigma^{=d\cdot\log^3 n} \ : \ \pi(x, R) = (u, v)\} & \text{if } \rho(x, u, v, a, b) = \text{ "accept,"} \\ 0 & \text{otherwise,} \end{cases}$$

and by solving a linear system, we fix for each u, v, a_i, b_h, a real value d_{u,v,a_i,b_h} such that for each $u, v \in \Sigma^{=d\cdot\log^3 n}$, and for each $j, k \in \{1, \ldots, N\}$, $\sum_{1\le i\le j} \sum_{1\le h\le k} d_{u,v,a_i,b_h} = val_{u,v,a_j,b_k}$. We now state the weights of pairs in X^2 in six stages (1)–(6) (all the pairs that are not mentioned below have weight 0).

(1) $w(s_2, s_1) = -M_1$, $w(s_3, s_2) = -M_1$, $w(s_4, s_3) = -M_1$,
$w(x, s_2) = -M_1$ and $w(s_3, x) = -M_1$ for all $x \in X_2$,
$w(s_4, x) = -M_1$ for all $x \in X_1$,
$w(x, s_1) = -M_1$ for all $x \in X_3$.
M_1 is defined as follows. Let k be the maximum weight for any pair defined in stages (2)–(6). Then $M_1 = \frac{S(S-1)}{2} \cdot k + 1$. The effect of these definitions is that if π is a reasonable ordering and $<_\pi$ denotes the order induced by π (i.e., $x <_\pi y$ if and only if $\pi(x) < \pi(y)$), then (i) $s_1 <_\pi s_2 <_\pi s_3 <_\pi s_4$, (ii) $s_2 <_\pi x <_\pi s_3$ for all $x \in X_2$, (iii) $x <_\pi s_4$ for all $x \in X_1$, and (iv) $s_1 <_\pi x$ for all $x \in X_3$. (See Figure 2.)

(2) For each pair $(u, a) \in (\Sigma^{=d\cdot\log^3 n})^2$, we fix a linear order $<_o$ on the set $Y_{u,a,1} = \{(u, v, a, 1) \ : \ v \in \Sigma^{=d\cdot\log^3 n}\}$, obtaining $Y_{u,a,1} = \{z_1 <_o z_2 <_o \cdots <_o z_N\}$. The order $<_o$ must have the following property: $\forall w \ \forall z$ [(w is the successor relative to $<_o$ of z) $\rightarrow$ (w is not the lexicographical successor of z) and (z is not the lexicographical successor of w)] and also z_1 and z_N are not the first and, respectively, last elements from $Y_{u,a,1}$ with respect to the lexicographical ordering. We define the weights:

$$\begin{array}{ll} w(s_3, z_1) = M_2, & w(z_1, s_3) = -M_2, \\ w(z_{i+1}, z_i) = -3M_2, & i = 1, \ldots, N-1, \\ w(z_N, s_1) = M_2, & w(s_1, z_N) = -M_2. \end{array}$$

M_2 is defined by $M_2 = \frac{S(S-1)}{2} \cdot k + 1$, where k is now the maximum weight defined in the future stages (3)–(6). The effect of these definitions is that for all $u, a \in \Sigma^{=d\cdot\log^3 n}$, if π is a reasonable ordering, then either all elements from $Y_{u,a,1}$ are smaller with respect to π than s_1 or all elements from $Y_{u,a,1}$ are larger with respect to π than s_3. (See Figure 2.)

(3) For each pair $(v, b) \in (\Sigma^{=d\cdot\log^3 n})^2$, we fix a linear order $<_o$ on the set $Y_{v,b,3} = \{(u, v, b, 3) \ : \ u \in \Sigma^{=d\cdot\log^3 n}\}$, obtaining $Y_{v,b,3} = \{z_1 <_o z_2 <_o \cdots <_o z_N\}$. The order $<_o$ is as in (2). We define the weights:

$$\begin{array}{ll} w(s_4, z_1) = M_3, & w(z_1, s_4) = -M_3, \\ w(z_{i+1}, z_i) = -3M_3, & i = 1, \ldots, N-1, \\ w(z_N, s_2) = M_3, & w(s_2, z_N) = -M_3. \end{array}$$

M_3 is defined by $M_3 = \frac{S(S-1)}{2} \cdot k + 1$, where k is the maximum weight defined in the future stages (4)–(6). The effect of these definitions is that for all $v, b \in \Sigma^{=d\cdot\log^3 n}$, if π is a reasonable ordering, then either all elements from $Y_{v,b,3}$ are smaller with respect to π than s_2 or all elements from $Y_{v,b,3}$ are larger with respect to π than s_4. (See Figure 2.)

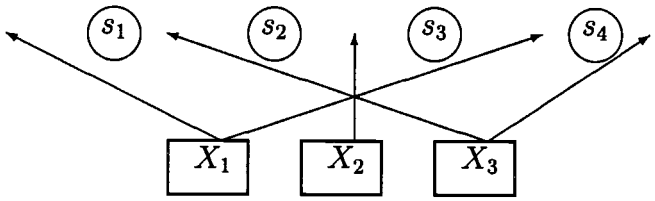

FIG. 2. *The effect of stages* (1), (2), *and* (3): *the elements of* X_1, X_2, *and* X_3 *must be positioned between the stakes* s_1, s_2, s_3, *and* s_4 *as in the figure.*

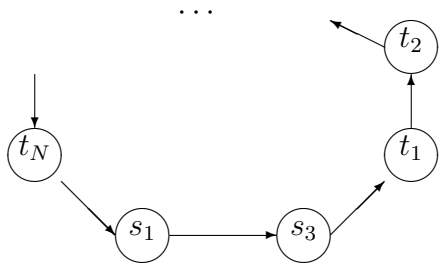

FIG. 3. *The effect of stage* (4): *only one of the edges* $(t_1, t_2), \ldots, (t_N, s_1)$ *should be "broken" by a reasonable* π.

(4) For all pairs $(u, v) \in (\Sigma^{=d\cdot\log^3 n})^2$ we order the set $X_{u,v,1} = \{(u, v, a, 1) : a \in \Sigma^{=d\cdot\log^3 n}\}$ in the lexicographical order $<_l$, obtaining $X_{u,v,1} = \{t_1 <_l t_2 <_l \cdots <_l t_N\}$. We define the weights:

$$\begin{array}{ll} w(s_3, t_1) = M_4, & w(t_1, s_1) = -M_4, \\ w(t_{i+1}, t_i) = -M_4, & i = 1, \ldots, N-1, \\ w(s_1, t_N) = -M_4, & \end{array}$$

with $M_4 = \frac{S(S-1)}{2} \cdot k + 1$, where k is now the maximum weight defined in the future stages (5)–(6). It can be seen that, by the precautions we took when selecting the order $<_o$, there is no conflict between the definitions in stages (2) and (4). It is important to note that, relative to an ordering π, $C_\pi(X_{u,v,1} \cup \{s_1, s_3\}) = 0$ if there exists $j \in \{1, \ldots, N\}$ such that

$$t_{j+1} <_\pi t_{j+2} <_\pi \cdots <_\pi t_N <_\pi s_1 <_\pi s_3 <_\pi t_1 <_\pi \cdots <_\pi t_j$$

or $C_\pi(X_{u,v,1} \cup \{s_1, s_3\})$ is less than $-M_4$ in all other situations. Hence, a reasonable ordering π must satisfy the above inequalities. (See Figure 3.)

(5) For all pairs $(u, v) \in (\Sigma^{=d\cdot\log^3 n})^2$ we order the set $X_{u,v,3} = \{(u, v, b, 3) : a \in \Sigma^{=d\cdot\log^3 n}\}$ in the lexicographical order $<_l$, obtaining $X_{u,v,3} = \{t_1 <_l t_2 <_l \cdots <_l t_N\}$. We define the weights:

$$\begin{array}{ll} w(s_4, t_1) = M_5, & w(t_1, s_4) = -M_5, \\ w(t_{i+1}, t_i) = -M_5, & i = 1, \ldots, N-1, \\ w(s_2, t_N) = -M_5, & \end{array}$$

with $M_5 = \frac{S(S-1)}{2} \cdot k + 1$, where k is now the maximum weight defined in stage (6). By the same arguments as in (4), a reasonable ordering π must

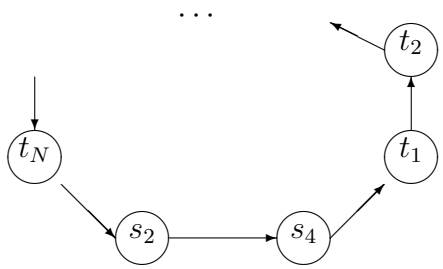

FIG. 4. *The effect of stage* (5): *only one of the edges* $(t_1, t_2), \ldots, (t_N, s_2)$ *should be "broken" by a reasonable* π.

satisfy

$$t_{k+1} <_\pi t_{k+2} <_\pi \cdots <_\pi t_N <_\pi s_2 <_\pi s_4 <_\pi t_1 <_\pi \cdots <_\pi t_k,$$

for some $k \in \{1, \ldots, N\}$. (See Figure 4.)

(6) For all 4-tuples $(u, v, a, b) \in (\Sigma^{=d\cdot\log^3 n})^4$,

$$w((u, v, b, 2), (u, v, a, 1)) = d_{u,v,a,b}, \quad w((u, v, b, 3), (u, v, a, 1)) = -d_{u,v,a,b}.$$

CLAIM 4.5. (i) *Let* $u \in \Sigma^{=d\cdot\log^3 n}$ *and let* π *be a reasonable ordering. There exists* $j \in \{1, \ldots, N\}$ *such that for all* $v \in \Sigma^{=d\cdot\log^3 n}$

$$(u, v, a_{j+1}, 1) <_\pi \cdots <_\pi (u, v, a_N, 1) <_\pi s_1 <_\pi s_3 <_\pi (u, v, a_1, 1) <_\pi \cdots <_\pi (u, v, a_j, 1).$$

(ii) *Let* $v \in \Sigma^{=d\cdot\log^3 n}$ *and let* π *be a reasonable ordering. There exists* $k \in \{1, \ldots, N\}$ *such that for all* $u \in \Sigma^{=d\cdot\log^3 n}$

$$(u, v, b_{k+1}, 3) <_\pi \cdots <_\pi (u, v, b_N, 3) <_\pi s_2 <_\pi s_4 <_\pi (u, v, b_1, 3) <_\pi \cdots <_\pi (u, v, b_k, 3).$$

Proof. We prove (i). From the definitions in stage (4), for each $v \in \Sigma^{=d\cdot\log^3 n}$ there exists a value $j(v)$ verifying the inequalities from (i). Suppose that for some pair $v \neq v'$, $j(v) < j(v')$. Then $(u, v, a_{j(v')}, 1) <_\pi s_1 <_\pi s_3 <_\pi (u, v', a_{j(v')}, 1)$, which means that two elements from $Y_{u,a_{j(v')},1}$ are on distinct "sides" of $s_1 <_\pi s_3$. But then π cannot be a reasonable ordering by the discussion following the definitions in stage (2). It follows that for all $v \in \Sigma^{=d\cdot\log^3 n}$, $j(v)$ represents the same value. The proof of (ii) is similar. □

If π is a reasonable ordering and (u, a_j) are as in Claim 4.5 (i) and (v, b_k) are as in Claim 4.5 (ii), then we say that π *forces* answer a_j to u and answer b_k to v.

CLAIM 4.6. *Let* π *be a reasonable ordering. We define the provers' strategies* (P_1, P_2) *by* $P_1(u) = a$ *if* π *forces answer* a *to* u, *and* $P_2(v) = b$ *if* π *forces answers* b *to* v. *Then* $C_\pi(X) = 2^{d\log^3 n} \cdot ACC_{V,(P_1,P_2)}(x)$.

Proof. Observe that the contribution of all pairs whose weight is defined in stages (1)–(5) is 0. It remains to consider only the pairs whose weight is defined in stage (6). For each u, let $j(u)$ be defined by $a_{j(u)} = P_1(u)$, and for each v, let $k(v)$ be defined by $a_{k(v)} = P_2(v)$. We can see that only pairs in which the first component is from X_2 and the second component is from X_1 or in which the first component is from X_3 and

the second component is from X_1 matter. From the way the elements of X_1, X_2, and X_3 are arranged between the "stakes" s_1, s_2, s_3, and s_4 in the stages (1), (2), and (3), the first type of pair occurs for (x, y) with $x \in X_2$ and $y \in X_1,\ y > s_3$, and the second type of pair occurs for (x, y) with $x \in X_3,\ s_1 < x < s_2$, and $y \in X_1,\ s_3 < y < s_4$. Keeping in mind the definitions of $j(u)$, $k(v)$, and the "complementary" way in which weights are defined in stage (6), we get:

$$\begin{aligned} C_\pi(X) &= \sum_u \sum_v \sum_{h=1}^{N} \sum_{i=1}^{j(u)} w((u, v, b_h, 2), (u, v, a_i, 1)) \\ &\quad + \sum_u \sum_v \sum_{h=k(v)+1}^{N} \sum_{i=1}^{j(u)} w((u, v, b_h, 3), (u, v, a_i, 1)) \\ &= \sum_u \sum_v \sum_{h=1}^{k(v)} \sum_{i=1}^{j(u)} d_{u,v,a_i,b_h} = \sum_u \sum_v val_{u,v,P_1(u),P_2(v)} \\ &= 2^{d \log^3 n} \cdot ACC_{V,(P_1,P_2)}(x). \end{aligned}$$

In the above sums, u and v range over $\Sigma^{=d \cdot \log^3 n}$. □

It follows from Claim 4.6 that $\max_\pi C_\pi(X) \leq 2^{d \log^3 n} \cdot ACC_V(x)$. On the other hand, from any pair of provers' strategies (P_1, P_2), one can easily build an ordering π such that $C_\pi(X) = 2^{d \log^3 n} \cdot ACC_{V,(P_1,P_2)}(x)$. It is sufficient that π satisfy the requirements from the discussions following stages (1), (2), and (3) and that it *force* to any queries u and v the real answers of the provers P_1 and P_2. In conclusion, $\max_\pi C_\pi(X) = 2^{d \log^3 n} \cdot ACC_V(x)$. It is not difficult to check that the whole construction can be made in DTIME$[2^{\log^c n}]$ for some constant c. □

5. Final remarks. It is known that many combinatorial problems become more difficult when we pass from positive parameters to arbitrary (i.e., both positive and negative) parameters. The most notorious example is probably the SHORTEST PATH problem (see [CLR90]). Our results offer an explicit expression to this paradigm: most classes of combinatorial problems known to be approximable when dealing with positive parameters lose this property when dealing with arbitrary parameters. This contrasts with the situation of numerical problems, where the additional algebraic structure provided by arbitrary parameters (i.e., the existence of inverses) may actually help. It would be interesting to detect a general, deep explanation for this dichotomy. There are also some other less obscure questions left open by this work. It would be interesting to find nontrivial syntactically defined classes which are well approximable even with arbitrary parameters. And, finally, another topic of interest is to investigate the real-valued weighted version of some other natural problems.

Acknowledgments. I thank Luca Trevisan for telling me the reductions in Lemmas 3.3 and 3.7, which strengthened and simplified the corresponding lemmas in an earlier version of this work. I thank Erich Grädel for valuable comments and useful pointers to the literature. I am grateful to Lane Hemaspaandra, Mitsunori Ogihara, Joel Seiferas, and the anonymous referees for helping improve the presentation of this paper.

THE COMPUTATIONAL STRUCTURE OF MONOTONE MONADIC SNP AND CONSTRAINT SATISFACTION: A STUDY THROUGH DATALOG AND GROUP THEORY*

TOMÁS FEDER† AND MOSHE Y. VARDI‡

Abstract. This paper starts with the project of finding a large subclass of NP which exhibits a dichotomy. The approach is to find this subclass via syntactic prescriptions. While the paper does not achieve this goal, it does isolate a class (of problems specified by) "monotone monadic SNP without inequality" which may exhibit this dichotomy. We justify the placing of all these restrictions by showing, essentially using Ladner's theorem, that classes obtained by using only two of the above three restrictions do not show this dichotomy. We then explore the structure of this class. We show that all problems in this class reduce to the seemingly simpler class CSP. We divide CSP into subclasses and try to unify the collection of all known polytime algorithms for CSP problems and extract properties that make CSP problems NP-hard. This is where the second part of the title, "a study through Datalog and group theory," comes in. We present conjectures about this class which would end in showing the dichotomy.

Key words. satisfiability, graph coloring, datalog, group theory, linear equations

1. Introduction.

We start with a basic overview of the framework explored in this paper; for an accompanying pictorial description, see Figure 1. A more detailed presentation of the work and its relationship to earlier work is given in the next section.

It is well known that if P≠NP, then NP contains problems that are neither solvable in polynomial time nor NP-complete. We explore the following question: what is the most general subclass of NP that we can define that may not contain such in-between problems? We investigate this question by means of syntactic restrictions. The logic class SNP is contained in NP and can be restricted with three further requirements: *monotonicity*, *monadicity*, and *no inequalities*. We show that if any two out of these three conditions are imposed on SNP, then the resulting subclasses of SNP are still general enough to contain a polynomially equivalent problem for every problem in NP, and in particular for the in-between problems in NP. We thus address the question by imposing all three restrictions simultaneously; the resulting subclass of SNP is called *MMSNP*.

We examine MMSNP and observe that it contains a family of interesting problems. A constraint-satisfaction problem is given by a pair I (the *instance*) and T (the *template*) of finite relational structures over the same vocabulary. The problem is satisfied if there is a homomorphism from I to T. It is well known that the constraint-satisfaction problem is NP-complete. In practice, however, one often encounters the situation where the template T is fixed and it is only the instance I that varies. We define *CSP* to be the class of constraint-satisfaction problems with

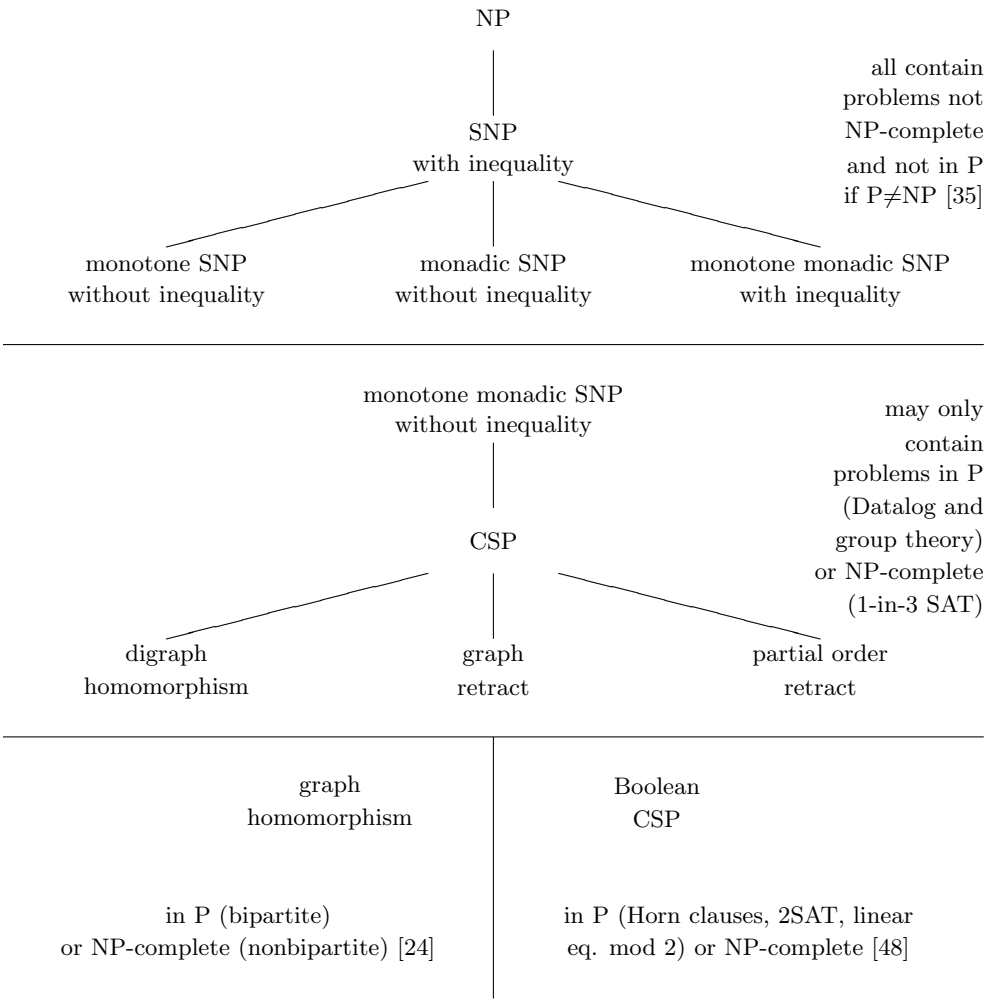

FIG. 1. *Summary.*

respect to fixed templates; that is, for every template T, the class CSP contains the problem P_T that asks for an instance I over the same vocabulary as T whether there is a homomorphism from I to T or not. The class CSP is contained in MMSNP. We show that CSP is in a sense the same as all of MMSNP: every problem in MMSNP has an equivalent problem in CSP under randomized polynomial time reductions.

The class CSP in turn has some interesting subclasses: the *graph-retract*, *digraph-homomorphism*, and *partial order-retract* problems. We show that in fact every problem in CSP has a polynomially equivalent problem in each of these three subclasses, so that all three of them are as general as CSP. Some special cases were previously investigated; for CSP with a Boolean template it was shown that there are three polynomially solvable problems, namely, Horn clauses, 2SAT, and linear equations modulo 2, while the remaining problems are NP-complete. For the graph-homomorphism problem, it was shown that bipartite graph templates are polynomially solvable and

nonbipartite graph templates are NP-complete. Could it then be that every problem in CSP is either polynomially solvable or NP-complete?

Some representative problems that were previously observed as belonging to CSP are k-satisfiability, k-colorability, and systems of linear equations modulo q; a polynomially solvable problem that can be less obviously seen to belong to CSP is labeled graph isomorphism. We notice here that at present, all known polynomially solvable problems in CSP can be explained by a combination of Datalog and group theory. More precisely, we define *bounded-width* problems as those that can be defined by Datalog programs, and *subgroup* problems as those whose relations correspond to subgroups or cosets of a given group; both subclasses are polynomially solvable. Two decidable subclasses of the bounded-width case are the *width* 1 and the *bounded strict width* problems; in fact, the three polynomially solvable cases with a Boolean template are width 1, strict width 2, and subgroup, respectively. The three main polynomial cases, namely, width 1, bounded strict width, and subgroup, are all characterized by algebraic closure properties, and so is convex programming, a polynomial constraint satisfaction problem over the reals.

We finally observe that the only way we know how to show that a problem is not bounded-width requires the problem to have a property that we call the *ability to count*. Once a problem has the ability to count, it seems that it must necessarily contain the general subgroup problem for an abelian group as a special case. When a new type of subset of a group, which we call *nearsubgroup*, is also allowed in a subgroup problem, the resulting problem reduces to subgroup problems, at least for solvable groups, and if an allowed nonsubgroup subset is not a nearsubgroup, then the subgroup problem becomes NP-complete. Does this sequence of observations lead to a classification of the problems in CSP as polynomially solvable or NP-complete?

2. Preliminaries. A large class of problems in artificial intelligence and other areas of computer science can be viewed as *constraint-satisfaction problems* [10, 34, 40, 41, 42, 43, 45]. This includes problems in machine vision, belief maintenance, scheduling, temporal reasoning, type reconstruction, graph theory, and satisfiability.

We start with some definitions. A *vocabulary* is a set $V = \{(R_1, k_1), \ldots, (R_t, k_t)\}$ of relation names and their arities. A *relational structure* over the vocabulary V is a set S together with relations R_i of arity k_i on the set S. An instance of constraint satisfaction is given by a pair I, T of finite relational structures over the same vocabulary. The instance is satisfied if there is a homomorphism from I to T; that is, there exists a mapping h such that for every tuple $(x_1, \ldots, x_k) \in R_i$ in I we have $(h(x_1), \ldots, h(x_k)) \in R_i$ in T. Intuitively, the elements of I should be thought of as variables and the elements of T should be thought of as possible values for the variables. The tuples in the relations of I and T should be viewed as constraints on the set of allowed assignments of values to variables. The set of allowed assignments is nonempty if and only if there exists a homomorphism from I to T. In what follows, we shall use the homomorphism and variable-value views interchangeably in defining constraint-satisfaction problems.

It is well known that the constraint-satisfaction problem is NP-complete. In practice, however, one often encounters the situation where the structure T (which we call the *template*) is fixed, and it is only the structure I (which we call the *instance*) that varies.

For example, the template of the 3SAT problem has domain $\{0, 1\}$ and four ternary relations C_0, C_1, C_2, C_3 that contain all triples except for $(0, 0, 0)$ in the case of C_0, except for $(1, 0, 0)$ in the case of C_1, except for $(1, 1, 0)$ in the case of C_2, and

except for $(1,1,1)$ in the case of C_3. The tuples in the instance describe the clauses of the problem. For example, a constraint $C_2(x,y,z)$ imposes a condition on the three variables x,y,z that is equivalent to the clause $\overline{x} \vee \overline{y} \vee z$.

As a second example, the template of the 3-coloring problem is the graph K_3; i.e., it has domain $\{r,b,g\}$ and a single binary relation E that holds for all pairs (x,y) from the domain with $x \neq y$. The tuples in the instance describe the edges of the graph. Thus, the variables $x_1, x_2, \ldots, x_n$ can be viewed as vertices to be colored with r,b,g, and the constraints $E(x_i,x_j)$ can be viewed as describing the edges whose endpoints must be colored differently. If we replace the template K_3 by an arbitrary graph H, we get the so-called *H-coloring* problem [24].

As a third example, given an integer $q \geq 2$, the template of the linear equations modulo q problem has domain $\{0,1,\ldots,q-1\}$, a monadic relation Z that holds only for the element 0, and a ternary relation C that holds for the triples (x,y,z) with $x+y+z=1 \pmod q$. It is easy to show that any other linear relations on variables modulo q can be expressed by introducing a few auxiliary variables and using only the Z and C relations.

In this paper we consider constraint-satisfaction problems with respect to fixed templates. We have defined *CSP* to be the class of such problems. It is easy to see that CSP is contained in NP. We know that NP contains polynomially solvable problems and NP-complete problems. We also know that if P≠NP, then there exist problems in NP that are neither in P nor NP-complete [35]. The existence of such "intermediate" problems is proved by a diagonalization argument. It seems, however, impossible to carry this argument in CSP. This motivates our main question, which follows.

Dichotomy question: *Is every problem in CSP either in P or NP-complete?*

Our question is supported by two previous investigations of constraint-satisfaction problems that demonstrated dichotomies. Schaefer [48] showed that there are essentially only three polynomially solvable constraint-satisfaction problems on the set $\{0,1\}$, namely, (1) 0-valid problems (problems where all-zeros is always a solution, and similarly 1-valid problems); (2) Horn clauses (problems where every relation in the template can be characterized by a conjunction of clauses with at most one positive literal per clause, and similarly anti-Horn clauses, with at most one negative literal per clause); (3) 2SAT (problems where every relation in the template can be characterized by a conjunction of clauses with two literals per clause); (4) linear equations modulo 2 (problems where every relation in the template is the solution set of a system of linear equations modulo 2). All constraint-satisfaction problems on $\{0,1\}$ that are not in one of these classes are NP-complete. The NP-complete cases include one-in-three SAT, where the template has a single relation containing precisely $(1,0,0)$, $(0,1,0)$, and $(0,0,1)$, and not-all-equal SAT, where the template has a single relation that contains all triples except $(0,0,0)$ and $(1,1,1)$.

Hell and Nešetřil [24] showed that the H-coloring problem is in P if H is bipartite and NP-complete for H nonbipartite. Bang-Jensen and Hell [8] conjecture that this result extends to the digraph case when every vertex in the template has at least one incoming and at least one outgoing edge: if the template is equivalent to a cycle then the problem is polynomially solvable, otherwise NP-complete.

The issue that we address first is the robustness of the class CSP. We investigate the dichotomy question in the context of the complexity class *SNP*, which is a subclass of NP that is defined by means of a logical syntax [32, 44] and which, in particular, includes CSP. We show that SNP is too general a class to address the

dichotomy question, because every problem in NP has an *equivalent* problem in SNP under polynomial time reductions. Here two problems are said to be equivalent under polynomial time reductions if there are polynomial time reductions from one to the other, in both directions. We then impose three syntactic restrictions on SNP, namely, *monotonicity*, *monadicity*, and *no inequalities*, since CSP is contained in SNP with these restrictions imposed. It turns out that if only two of these three restrictions are imposed, then the resulting subclass of SNP is still general enough to contain an equivalent problem for every problem in NP.

When all three restrictions are imposed, we obtain the class *MMSNP*: *monotone monadic* SNP *without inequality*. This class is still more general than CSP, because it strictly contains CSP. We prove, however, that every problem in MMSNP has an equivalent problem in CSP, this time under randomized polynomial time reductions (we believe that it may be possible to derandomize the reduction).

Thus, CSP is essentially the same as the seemingly more general class MMSNP. In the other direction, there are three special cases of CSP, namely, the *graph-retract*, the *digraph-homomorphism*, and the *partial-order-retract* problems, that turn out to be as hard as all of CSP, again under polynomial time reductions. The equivalence between CSP and classes both above and below it seems to indicate that CSP is a fairly robust class.

We then try to solve the dichotomy question by considering a more practical question.

Primary classification question: *Which problems in CSP are in P and which are NP-complete?*

In order to try to answer this question, we again consider Schaefer's results for constraint-satisfaction problems on the set $\{0, 1\}$ [48]. Schaefer showed that there are only three such polynomially solvable constraint-satisfaction problems. We introduce two subclasses of CSP, namely, *bounded-width* CSP and *subgroup* CSP, respectively, as generalizations of Schaefer's three cases. Bounded-width problems are problems that can be solved by considering only bounded sets of variables, which we formalize in terms of the language Datalog [50]. Both Horn clauses and 2SAT fall into this subclass; we show that linear equations modulo 2 do not. Subgroup problems are group-theoretic problems where the constraints are expressed as subgroup constraints. Linear equations modulo 2 fall into this subclass. Not only are these subclasses solvable in polynomial time, but, at present, *all* known polynomially solvable constraint-satisfaction problems can be explained in terms of these conditions.

Assuming that these conditions are indeed the only possible causes for polynomial solvability for problems in CSP, this poses a new classification problem.

Secondary classification question: *Which problems in CSP are bounded-width problems and which are subgroup problems?*

The main issue here is that it is not clear whether membership in these subclasses of CSP is decidable.

Our results provide some progress in understanding the bounded-width and subgroup subclasses. For example, for the bounded-width problems, our results provide a classification for the 1-width problems in CSP (these are the problems that can be solved by *monadic* Datalog programs). We also identify a property of problems, which we call *the ability to count*. We prove that this property implies that the problem cannot be solved by means of Datalog. Once a constraint-satisfaction problem has the ability to count, it is still possible in many cases to solve it by group-theoretic means.

While all known polynomially solvable problems in CSP can be reduced to the bounded-width and group-theoretic subclasses, not all such problems belong to those classes from the start. For example, we show that under some conditions nonsubgroup problems can be reduced to the subgroup subclass. These conditions are stated in terms of the new notion of *nearsubgroup*, and delineating the boundary between polynomially solvable and NP-complete group-theoretical problems seems to require certain progress in finite-group theory.

The remainder of the paper is organized as follows. Section 3 introduces the logic class MMSNP as the largest subclass, in some sense, of SNP, that is not computationally equivalent to all of NP. Section 4 introduces the class CSP as a subclass of MMSNP which is essentially equivalent to MMSNP. Section 5 studies three subclasses of CSP, the graph-retract, digraph-homomorphism, and partial order-retract problems, essentially equivalent to all of CSP. Section 6 considers classes of problems in CSP that are polynomially solvable. Section 6.1 considers the bounded-width problems, which are those that can be solved by means of Datalog, and their relationship to two-player games. Sections 6.1.1 and 6.1.2 examine two special subclasses of the bounded-width case for which membership is decidable, namely, the width 1 case with its connection to the notion of tree duality, and the strict width l case with its connection to the Helly property. Section 6.2 examines which problems are not of bounded width via a notion called the ability to count. Section 6.3 considers the group-theoretic case and introduces the notion of nearsubgroup in an attempt to understand the boundary between tractability and intractability. Section 7 explores further directions for a possible complete classification. An appendix explores the connection between constraint satisfaction and Etter's link systems.

3. Monotone monadic SNP without inequality. The class SNP [32, 44] (see also [14]) consists of all problems expressible by an existential second-order sentence with a universal first-order part, namely, by a sentence of the form $(\exists S')(\forall \mathbf{x})\Phi(\mathbf{x}, S, S')$, where Φ is a first-order quantifier-free formula. That is, Φ is a formula built from relations in S and S' applied to variables in $\mathbf{x}$, by means of conjunctions, disjunctions, and negation. Intuitively, the problem is to decide, for an input structure S, whether there exists a structure S' on the same domain such that for all values in this domain for the variables in $\mathbf{x}$ it is true that $\Phi(\mathbf{x}, S, S')$ holds. We will refer to the relations of S as *input relations*, while the relations of S' will be referred to as *existential relations*. The 3SAT problem is an example of an SNP problem: the input structure S consists of four ternary relations C_0, C_1, C_2, C_3 on the domain $\{0, 1\}$, where C_i corresponds to a clause on three variables with the first i of them negated. The existential structure S' is a single monadic relation T describing a truth assignment. The condition that must be satisfied states that for all x_1, x_2, x_3, if $C_0(x_1, x_2, x_3)$ then $T(x_1)$ or $T(x_2)$ or $T(x_3)$, and similarly for the remaining C_i by negating $T(x_j)$ if $j \leq i$. We are interested in the following question.

Which subclasses of NP have the same computational power as all of NP?

That is, which subclasses of NP are such that for every problem in NP there is a problem in the subclass equivalent to it under polynomial time reductions. More precisely, we say that two problems A and B are *equivalent* under polynomial time reductions if there is a polynomial time reduction from A to B, as well as a polynomial time reduction from B to A. It turns out that every problem in NP is equivalent to a problem in SNP under polynomial time reductions. This means that for every problem A in NP, there is a problem B in SNP such that there is a polynomial time reduction from A to B, as well as a polynomial time reduction from B to A.

In fact, we now show that this is the case even for restrictions of SNP. We start by assuming that the equality or inequality relations are not allowed in the first-order formula, only relations from the input structure S or the existential structure S'. For *monotone* SNP *without inequality*, we require that all occurrences of an input relation C_i in Φ have the same polarity. (The polarity of a relation is positive if it is contained in an even number of subformulas with a negation applied to it, and it is negative otherwise.) By convention, we assume that this polarity is negative, so that the C_i can be interpreted as constraints, in the sense that imposing C_i on more elements of the input structure can only make the instance "less satisfiable." Note that 3SAT as described above has this property. For *monadic* SNP *without inequality*, we require that the existential structure S' consist of monadic relations only. This is again the case for 3SAT described above. For *monotone monadic* SNP *with inequality*, we assume that the language also contains the equality relation, so both equalities and inequalities are allowed in Φ. (If we consider that equalities and inequalities appear with negative polarity, then only inequalities give more expressive power, since a statement of the form "if $x = y$ then $\Phi(x, y)$" can be replaced by "$\Phi(x, x)$.")

We have thus taken the class SNP, and we are considering three possible syntactic restrictions, namely, *monotonicity*, *monadicity*, and *no inequality*. We shall later be especially interested in SNP with all three syntactic restrictions imposed. However, for now, we are only considering the cases where only two of these three syntactic restrictions are simultaneously imposed.

THEOREM 1. *Every problem in NP has an equivalent (under polynomial time reductions) problem in monotone monadic SNP with inequality.*

Proof. Hillebrand et al. [30] showed that monadic Datalog with inequality (but without negation) can verify a polynomial time encoding of a Turing machine computation; the machine can be nondeterministic. A Datalog program is a formula Φ that consists of a conjunction of formulas of the form $R_0(\mathbf{x}_0) \leftarrow R_1(\mathbf{x}_1) \wedge \cdots \wedge R_k(\mathbf{x}_k)$, where the $\mathbf{x}_i$ may share variables. The relation R_0 cannot be an input relation, and monadicity here means that R_0, as a relation that is not an input relation, must be monadic or of arity zero; furthermore an R_i may be an inequality relation. There is a particular $\hat{R}_0$ of arity zero that must be derived by the program in order for the program to accept its input; this means that the input is rejected by the Datalog program if $(\exists \mathbf{R})(\forall \mathbf{x})(\Phi(\mathbf{R}, \mathbf{S}, \mathbf{x}) \wedge \neg \hat{R}_0)$. Notice that this formula Φ' is a monotone monadic SNP with inequality formula. Here $\mathbf{S}$ describes the computation of a nondeterministic Turing machine, including the input, the description of the movement of the head on the tape of the machine, and the states of the machine and cell values used during the computation. We would now like to assume that the computation of the machine is not known ahead of time. That is, only the input to the machine is given; the movement of the head and the cell values are not known and are quantified existentially. Unfortunately, the description of the movement of the head does not consist of monadic relations and may depend on the input to the machine. We avoid this difficulty by assuming that the Turing machine is *oblivious*; i.e., the head traverses the space initially occupied by the input back and forth from one end to the other, and accepts in exactly n^k steps for some k. We can then assume that the movement of the head is given as part of the input, since it must be independent of the input for such an oblivious machine. Thus only the states of the machine and cell values used during the computation must be quantified existentially, giving a monotone monadic SNP with inequality formula that expresses whether the machine accepts a given in-

put or not. A particular computation is thus described by a choice of states and cell values, which are described by monadic existential relations that are then used as inputs to the Datalog program. The condition that must be satisfied is that if a state is marked as being the (n^k)th state (this is determined by a deterministic component of the machine), then it must also be marked as being an accepting state (this depends on the nondeterministic choice of computation). The monotone monadic SNP with inequality formula will thus reject an instance if it does not describe an input followed by the correct movement of the head for the subsequent oblivious computation, accept the instance if the number of cells allowed for the computation is smaller than n^k, and otherwise accept precisely when the machine accepts. □

THEOREM 2. *Every problem in NP has an equivalent (under polynomial time reductions) problem in monadic SNP without inequality.*

Proof. Since the existence of an equivalent problem in monotone monadic SNP with inequality for every problem in NP was previously shown, it is sufficient to remove inequalities at the cost of monotonicity.

To remove inequalities at the cost of monotonicity, introduce a new binary input relation *eq*, augment the formula by a conjunct requiring *eq* to be an equivalence relation with the property that if an input or existential monadic relation holds on some elements, then it also holds when an element in an argument position is replaced by an element related to it under *eq*; finally, replace all occurrences of $x \neq y$ by $\neg eq(x, y)$. Thus the formula no longer contains inequalities, but it contains an input relation that appears with both positive and negative polarity; i.e., it is no longer monotone. The formula is therefore a monadic SNP without inequality formula. □

THEOREM 3. *Every problem in NP has an equivalent (under polynomial time reductions) problem in monotone SNP without inequality.*

Proof. Since the existence of an equivalent problem in monotone monadic SNP with inequality for every problem in NP was previously shown, it is sufficient to remove inequalities at the cost of monadicity.

To remove inequalities at the cost of monadicity, the intuition is that up to equivalence, certain *marked* elements form a *succ* path with *pred* as its transitive closure. Introduce a monadic input relation *special*, a binary input relation *succ*, a monadic existential relation *marked*, a binary existential relation *eq*, and a binary existential relation *pred*. Require now that every *special* element be *marked*, and every element related to a *marked* element under *succ* (in either direction) be *marked*. Require that *pred* be transitive but not relate any element to itself, that two elements related by *succ* be related by *pred* (in the same direction), that *eq* be an equivalence relation, that any two *special* elements be related by *eq*, that *pred* be preserved under the replacement of an element by an element related to it by *eq*, and that if two elements are related by *eq* and if each has a related element under *succ* (in the same direction), then these two other elements are also related by *eq*. Finally, restrict the original formula to *marked* elements, replace $x \neq y$ by $\neg eq(x, y)$, and consider that a relation holds on some elements if it is imposed on elements related to them by *eq*. Note that on elements that are forced to be *marked*, the relations *eq* and *pred* can be defined in at most one way, giving a *succ* path (up to *eq*, with *pred* as its transitive closure). □

From these three theorems, by Ladner's result [35] that if P≠NP then there exist problems in NP that are neither in P nor NP-complete, Theorem 4 follows.

THEOREM 4. *If* P $\neq$ NP*, then there are problems in each monotone monadic SNP with inequality, monadic SNP without inequality, and monotone SNP without inequality, that are neither in* P *nor* NP*-complete.*

We now consider the class *MMSNP*, which is *monotone monadic SNP, without inequality*. That is, in MMSNP we impose all three restrictions simultaneously (instead of just two at a time as in the three subclasses of SNP considered above). It seems impossible to carry out Ladner's diagonalization argument in MMSNP. Thus, the dichotomy question from the introduction also applies to this class.

4. Constraint satisfaction. Let S and T be two finite relational structures over the same vocabulary. A *homomorphism* from S to T is a mapping from the elements of S to elements of T such that all elements related by some relation C_i in S map to elements related by C_i in T. If T is the substructure of S obtained by considering only relations on a subset of the elements of S, and the homomorphism h from S to T is just the identity mapping when restricted to T, then h is called a *retraction*, and T is called a *retract* of S. If no proper restriction T of S is a retract of S, then S is a *core*; otherwise its core is a retract T that is a core. It is easy to show that the core of a structure S is unique up to isomorphism.

Here a *constraint-satisfaction problem* (or *structure-homomorphism problem*) will be a problem of the following form. Fix a finite relational structure T over some vocabulary; T is called the *template*. An *instance* is a finite relational structure S over the same vocabulary. The instance is satisfied if there is a homomorphism from S to T. Such a homomorphism is called a *solution*. We define *CSP* to be the class of constraint-satisfaction problems. We can assume that T is a core and include a copy of T in the input structure S, so that the structure-homomorphism problem is a structure-retract problem.

Remark. It is possible to define constraint satisfaction with respect to infinite templates. For example, digraph acyclicity can be viewed as the question of whether a given digraph can be homomorphically mapped to the transitive closure of an infinite directed path. We will not consider infinite templates in this paper. If we allow infinite structures T, then the constraint-satisfaction problems are just the problems whose complement is closed under homomorphisms, with the additional property that an instance with satisfiable connected components is satisfiable. Note that all problems in monotone SNP, without inequality, have a complement closed under homomorphisms.

We shall later show that CSP is strictly contained in MMSNP, and that every problem in MMSNP has an essentially equivalent problem in CSP, up to randomized polynomial time reductions. To obtain this result, we need a preliminary result that will often be used later in the paper as well.

We say that a structure S has *girth* greater that k if for any choice of at most k occurrences of relations R_i of arity r_i in S, the total number of elements mentioned by these k occurrences is at least $1 + \sum(r_i - 1)$. That is, k or fewer occurrences of relations never form a cycle.

THEOREM 5. *Fix two integers k, d. Then for every structure S on n elements there exists a structure S' on n^a elements (where a depends only on k and d) such that the girth of S' is greater than k, there is a homomorphism from S' to S, and for every structure T on at most d elements over the same vocabulary as S, there is a homomorphism from S' to T if and only if there is a homomorphism from S to T. In brief, every instance S of the constraint-satisfaction problem defined by T can be replaced by an instance S' of high girth. Furthermore, S' can be constructed from S in randomized polynomial time.*

Proof. The transformation that enforces large girth is an adaptation of a randomized construction of Erdős [11] of graphs with large girth and large chromatic number. Given a structure S on n elements, define S' by making $N = n^s$ copies of each element, where s is a large constant. If a relation R of arity r was initially imposed on some r elements, then it could a priori be imposed on N^r choices of copies. Impose R on each such choice with probability $N^{1-r+\epsilon}$, where ϵ is a small constant. We thus expect to impose R on $N^{1+\epsilon}$ copies. If R has arity $r = 1$, impose R on all copies of the element.

Finally, remove one relation from each cycle with at most k relations, i.e., minimal sets of relations R_i of arity r_i involving $t \leq \sum(r_i - 1)$ elements all together. Now, given such a cycle, it must correspond to a cycle that existed before the copies were made. The number of possible such short cycles is at most n^a for some constant a. Each such short cycle could occur in N^t choices of copies. For each such choice, the probability that it occurs is $\prod N^{1-r_i+\epsilon}$, so the expected number of occurrences is $n^a N^t \prod N^{1-r_i+\epsilon} \leq N^{a/s+k\epsilon} = N^{\epsilon'}$, and hence no more than twice this much with probability at least $1/2$ by Markov's inequality.

It is clear that if before making copies, there is a homomorphism from S to some T, then there is a homomorphism from S' to T as well: S' maps to S by a homomorphism. To obtain a converse, suppose that a homomorphism maps S' to T. If we consider the N copies of a particular element, then at least N/d of the copies agree on the image in T. If we select these copies, for each of the n elements, then the expected number of copies of a relation R of arity r is $(N/d)^r N^{1-r+\epsilon} = N^{1+\epsilon}/b$ for some constant b, and hence the probability that the number of copies is not even half this much is only $e^{-N^{1+\epsilon}/c}$ for some constant c by the Chernoff bound, since the occurrences of copies are independent. The total number of occurrences of relations R in the instance is n^r, and the number of possible choices of subsets of size N/d for the copies of the elements involved is at most 2^{rN}, and hence the probability that some choice of subsets will involve only $N^{1+\epsilon}/2b$ copies of some relation is at most $n^r 2^{rN} e^{-N^{1+\epsilon}/c}$, hence very small. Once $N^{1+\epsilon}/2b$ copies are present, the removal of $2N^{\epsilon'}$ of them is insignificant, provided s is large enough and ϵ is small enough. Therefore any choice of values in T for elements that appears on N/d of the copies will give a mapping from S to T. □

It remains open to derandomize this construction. The key question seems to be whether the construction of Erdős can be derandomized, i.e., whether given a fixed integer k, for integers n, there is a deterministic algorithm running in time polynomial in n that produces a graph of size polynomial in n, chromatic number at least n, and girth at least k. It may be possible to use quasi-random graphs for this purpose.

It is easy to see that CSP is contained in MMSNP. Let T be a template. Then there is a monadic monotone existential second-order sentence ϕ_T (without inequality) that expresses the constraint-satisfaction problem defined by T. For each element a in the domain of the template T, we introduce an existentially quantified monadic relation T_a; intuitively, $T_a(x)$ indicates that a variable x has been assigned value a by the homomorphism. The sentence ϕ_T says that the sets T_a are disjoint and that the tuples of S satisfy the constraints given by T.

It can be shown that CSP is strictly contained in MMSNP. Nevertheless, as the following two theorems show, in terms of the complexity of its problems, CSP is just as general as MMSNP.

We begin with a simple example of an MMSNP problem that is not a constraint-satisfaction problem: testing whether a graph is triangle-free. If it were a constraint-

satisfaction problem, there would have to exist a triangle-free graph to which one can map all triangle-free graphs by a homomorphism. This would require the existence of a triangle-free graph containing as induced subgraphs all triangle-free graphs such that all nonadjacent vertices are joined by both a path of length 2 and a path of length 3 (since a homomorphism can add edges or collapse two vertices); there are $2^{\Omega(n^2)}$ such graphs on n vertices, forcing T to grow exponentially in the size of S. On the other hand, this monotone monadic SNP problem can be solved in polynomial time, and is hence equivalent to a trivial constraint-satisfaction problem.

A more interesting example is the following: testing whether a graph can be colored with two colors with no monochromatic triangle (it can easily be related to the triangle-free problem to show that it is not a constraint-satisfaction problem). However, it can be viewed as a special case of not-all-equal 3SAT, where each clause is viewed as a triangle, and it is essentially equivalent to this NP-complete constraint-satisfaction problem.

THEOREM 6. *CSP is contained in MMSNP. Every problem in MMSNP is polynomially equivalent to a problem in CSP. The equivalence is by a randomized Turing reduction from the CSP problem to the MMSNP problem and by a deterministic Karp reduction from the MMSNP problem to the CSP problem.*

Proof. We just saw that CSP is contained in MMSNP; we prove the second statement. In fact, we can use a randomized Karp reduction if we only consider connected instances of the constraint-satisfaction problem; disconnected instances simply require a solution for each connected component.

Consider an MMSNP problem that asks, for an input structure S, whether there exists a monadic structure S' such that for all $\mathbf{x}$, $\Phi(\mathbf{x}, S, S')$. We write Φ in conjunctive normal form, or more precisely, as a conjunction of negated conjunctions. We can assume that each negated conjunction describes a biconnected component. For consider first the disconnected case, so that we have a conjunct of the form $\neg(A(\mathbf{x}) \wedge B(\mathbf{y}))$, where $\mathbf{x}$ and $\mathbf{y}$ are disjoint variable sets. We can then introduce an existential zero-adic relation p and write instead $(A(\mathbf{x}) \to p) \wedge (B(\mathbf{y}) \to \neg p)$. The case where A and B share a single variable z is treated similarly; we introduce an existential monadic relation q, and replace $\neg(A(\mathbf{x}, z) \wedge B(\mathbf{y}, z))$ by $(A(\mathbf{x}, z) \to q(z)) \wedge (B(\mathbf{y}, z) \to \neg q(z))$. If the conjunction cannot be decomposed into either two disconnected parts, or two parts that share a single articulation element z, we say that it describes a biconnected component. Before carrying out this transformation, we assume for each negated conjunction that every replacement of different variables by the same variable is also present as a negated conjunction. For instance, if $\neg A(x, y, z, t, u)$ is present, then so is $\neg A(x, x, z, z, u)$. This must be enforced beforehand, since biconnected components may no longer be biconnected when distinct variables are collapsed. We also assume that if an input relation R appears with all arguments equal, say, as $R(x, x, x)$, then it is the only input relation in the negated conjunction; otherwise, we can introduce an existential monadic p, replace such an occurrence of R by $p(x)$, and add a new condition $R(x, x, x) \to p(x)$; in other words, x is in this case an articulation element.

The next transformation is the main step; we enforce that each negated conjunction contains at most one input relation, and that the arguments of this input relation are different variables. For each negated conjunction, introduce a relation R whose arity is the number of distinct variables in the negated conjunction. Intuitively, this relation stands for the conjunction C of all input relations appearing in the negated conjunction. We replace the conjunction C by the single relation R; also, if the corresponding conjunction C' for some other negated conjunction is a subconjunction of C,

then we include the negated conjunction obtained by replacing C' with the possibly longer C, using new variables if necessary, and then replace C by R. Here we are not considering the case where it might be necessary to replace two arguments in R by the same argument; this will be justified because such instantiations were handled beforehand.

We must argue that the new MMSNP problem of the special form is equivalent to the original problem. Clearly, every instance of the original problem can be viewed as an instance of the new problem, simply by introducing a relation R on distinct input elements whenever the conjunction C that is represented by R is present on them in the input instance.

On the other hand, the converse is not immediately true. If we replace each occurrence of R by the appropriate conjunction C, then some additional occurrences of R may be implicitly present. Consider, for example, the case where triangles $E(x,y) \wedge E(y,z) \wedge E(z,x)$ have been replaced by a single ternary relation $R(x,y,z)$. Then an instance of the new problem containing $R(x_1,y_1,x_2)$, $R(x_2,y_2,x_3)$, and $R(x_3,y_3,x_1)$ also contains the triangle represented by $R(x_3,x_2,x_1)$, when each R is replaced by the conjunction that it stands for.

To avoid such hidden occurrences of relations, we show that every instance of the new problem involving the R relations can be transformed into an equivalent instance of large *girth*; the girth is the length of the shortest cycle. Fix an integer k larger than the number of conjuncts in any conjunction C that was replaced by an R. We shall ensure that for any choice of at most k occurrences of relations R_i of arity r_i in the instance, the total number of elements mentioned by these k occurrences is at least $1+\sum(r_i-1)$, so the girth is greater than k; this implies that such k occurrences define an acyclic substructure, so any biconnected R' implicitly present in the union of k such occurrences must be entirely contained in one of the R_i, and then the condition stated by R' was already stated for this R_i as well.

Large girth can be enforced by applying the previous theorem, provided the new problem can be viewed as a constraint-satisfaction problem. The new problem is very close to a constraint-satisfaction problem. In fact, it is a constraint-satisfaction problem if there are no zero-ary existential relations: construct the structure T by introducing one element for each combination of truth assignments for existential monadic relations on a single element, except for those combinations explicitly forbidden by the formula; impose a relation R on all choices of elements in T except for those combinations explicitly forbidden by the formula. To remove the assumption that there are no existential zero-ary relations, do a case analysis on the possible truth assignments for such relations, and make T the disjoint union of the T_i obtained in the different cases. The only difficulty here is that we must ensure that a disconnected instance still maps to a single T_i, so we introduce a new binary relation that holds on all pairs of elements from the same T_i, and consider only connected instances of the constraint-satisfaction problem. This concludes the proof. As mentioned before, solving disconnected instances is equivalent to solving all connected components of the constraint-satisfaction problem. □

The construction in the last theorem can also be used to show the following result, which will be proven useful later. The *containment* problem asks whether given two problems A and B over the same vocabulary, every instance accepted by A is also accepted by B.

THEOREM 7. *Containment is decidable for problems in MMSNP.*

Proof. (This problem becomes undecidable when the antecedent of the containment is generalized to monotone binary SNP without inequality, using Datalog to

encode Turing machines as before.) To decide whether A is contained in B for MMSNP problems, first assume that A and B are written in the canonical form involving biconnected components from the above proof. Also remove the existential quantifier in A (since it is in the antecedent of an implication), so that A is now a universal formula which is monotone except for monadic relations. Now, if B has an instance with no solution that satisfies A, then making copies of elements of the instance as before, we can assume that the only biconnected components that arise are those explicitly stated in the conditions for B, so go through the forbidden biconnected components stated in A and remove all negated conjunctions in B that mention them (since the stated condition will never arise on instances satisfying A). Here we must assume that B stated explicitly, for each element mentioned in a negated conjunction, which monadic relations are true or false. Now we can assume that A holds, and we are left to decide whether B is a tautology; this can be decided by considering the instance consisting of one element for each possible combination of truth and falsity of monadic input relations, and then imposing all other kinds of relations on all elements. □

5. Graphs, digraphs, partial orders. We have seen that CSP has the same computational power as all of MMSNP. We ask the following question.

Which subclasses of CSP have the same computational power as all of CSP?

The *graph-retract problem* is an example of a constraint-satisfaction problem. Fix a graph H, and for an input graph G containing H as a subgraph, ask whether H is a retract of G. (Note that when G and H are disjoint, we get the *graph-homomorphism* or H-coloring problem mentioned in the introduction [24].)

The *digraph-homomorphism problem* is another example of a constraint-satisfaction problem: this is the case where the template is a digraph. For an oriented cycle (cycle with all edges oriented in either direction), the *length* of the cycle is the absolute value of the difference between edges oriented in one direction and edges oriented in the opposite direction. A digraph is *balanced* if all its cycles have length zero; otherwise it is *unbalanced*. The vertices of balanced digraphs are divided into levels, defined by $level(v) = level(u) + 1$ if (u, v) is an edge of the digraph.

A *partial order* is a set with a reflexive antisymmetric transitive relation $\leq$ defined on it. If reflexive is replace by antireflexive, we have a *strict partial order*. We may also consider homomorphism and retract problems for partial orders.

THEOREM 8. *Every constraint-satisfaction problem is polynomially equivalent to a bipartite graph-retract problem.*

Proof. First ensure that the structure T defining the problem in CSP is a core. This ensures that each element in T is uniquely identifiable by looking at the structure T, up to isomorphisms of T; i.e., we can include a copy of T in an instance S and then assume that the elements of the copy of T in S must map to the corresponding elements of T. Next, assume that T can be partitioned into disjoint sets A_j so that for each relation C_i, the possible values for each argument come from a single A_j, and the possible values for different arguments come from different A_j; this can be ensured by making copies A_j of the set of elements of T and allowing an equality constraint between copies of the same element in different A_j. Now, the bipartite graph H consists of a single vertex for each A_j which is adjacent to vertices representing the elements of A_j; a single vertex for each relation C_i which is adjacent to vertices representing the tuples satisfying C_i; a bipartite graph joining the tuples coming from each C_i to the elements of the tuples from the A_j; and two additional adjacent vertices, one of them adjacent to all the elements of sets A_j, and the other one adjacent to all the tuples for conditions C_i.

To see that the resulting retract problem on graphs is equivalent to the given constraint-satisfaction problem, observe in one direction that an instance of the constraint-satisfaction problem can be transformed into an instance of the graph-retract problem, by requiring each element to range over the copy A_1 (just make it adjacent to the vertex for A_1 in H), and then to impose a constraint C_i of arity r on some elements, create a vertex adjacent to the vertex for C_i, and make this vertex adjacent to r vertices, each of which is adjacent to the vertex for the appropriate A_j (the r values for j are distinct); then make sure that the value chosen in A_j is the same as the value for the intended element in A_1, using an equality constraint. In the other direction, an instance of the graph-retract problem can be assumed to be bipartite, since H is bipartite; furthermore, each vertex can be assumed to be adjacent to either an A_j or C_i, since all other vertices can always be mapped to the two additional vertices that were added for H at the end of the construction. Then each vertex adjacent to vertex A_j can be viewed as an element ranging over A_j, and each vertex adjacent to vertex C_i can be viewed as the application of C_i on certain elements. □

Given a bipartite graph H, we say for two vertices x, y on the same side of H that x *dominates* y if every neighbor of y is a neighbor of x. We say that H is *domination-free* if it has no $x \neq y$ such that x dominates y. If R is a graph, we say that H is R-free if H contains no induced subgraph isomorphic to R. We are interested in the cases where R is either $K_{3,3}$, a complete bipartite graph with three vertices on each side, or $K_{3,3}$ minus a single edge. The following result will be used later in the study of the partial order-retract problem.

THEOREM 9. *Every constraint-satisfaction problem is polynomially equivalent to a domination-free, $K_{3,3}$-free, $K_{3,3}\backslash\{e\}$-free bipartite graph-retract problem.*

Proof. We first show that every constraint-satisfaction problem is equivalent to a $K_{3,3}$-free, $K_{3,3}\backslash\{e\}$-free bipartite graph-retract problem. We then show how domination-freedom can in addition also be achieved.

We know that every constraint-satisfaction problem can be encoded as a bipartite graph-retract problem. To achieve $K_{3,3}$-freedom and $K_{3,3}\backslash\{e\}$-freedom, we encode the bipartite graph-retract problem again as a bipartite graph-retract problem, by reusing essentially the same reduction.

So we are given a bipartite graph-retract problem with template $H = (S, T, E)$, which we shall show polynomially equivalent to another bipartite graph-retract problem with template $H' = (U, V, F)$. We introduce five new elements r, s, t, s', t', and define H' by $U = \{r\} \cup S \cup T$, $V = \{s, t, s', t'\} \cup E$, and $F = (\{r\} \times (\{s', t'\} \cup E)) \cup (S \times \{s, s'\}) \cup (T \times \{t, t'\}) \cup \{(u, e) : u \in S \cup T, e \in E, u \in e\}$.

Let $G = (S', T', E')$ be an instance for H. (We can assume that G is bipartite since it otherwise cannot map to H, and that we know that S' maps to S and T' maps to T because it is connected to the subgraph H; any other component of G can be mapped to a single edge of H.) We define an instance $G' = (U', V', F')$ for H' by letting $U' = \{r\} \cup S' \cup T'$, $V' = \{s, t, s', t'\} \cup E'$, and defining F' by letting r be adjacent to all of E', s adjacent to all of S', t adjacent to all of T', and each $e \in E'$ adjacent to the two vertices in $S' \cup T'$ it joins in G. It is immediate in the instance G' for H' that S' must map to S, T' to T, and E' to E with $e \in E'$ mapping to the element of E joining the images of the two vertices incident on e in G, so the retractions mapping G to H and those mapping G' to H' correspond to each other.

In the other direction, let $G' = (U', V', F')$ be an instance for H'. Since s', t' dominate s, t, respectively, no element need ever be mapped to s, t, other than s, t

themselves. So we can require that the neighbors of s, t map to elements of S, T, respectively, and then remove s, t from H' and G'. We can then assume that every element of U' that is not required to map to S or T maps to r, since r is adjacent to what remains of V. We can now remove r from H' and G'. Now if a vertex in V' is only adjacent to vertices that map to S we map it to s', if only to vertices that map to T, we map it to t', and if to both, it must map to E, thus defining a retract problem instance for H.

It only remains to show that H' is $K_{3,3}$-free and $K_{3,3}\backslash\{e\}$-free, and then to enforce dominance-freedom. Suppose that H' contains H_0, which is either a $K_{3,3}$ or a $K_{3,3}\backslash\{e\}$. Then every vertex v in the right side of H_0 must belong to the 3-side of a $K_{2,3}$. This immediately gives $v \neq s, t$ because any pair of neighbors of s is only adjacent to s, s', and similarly for t. So we can remove s, t in looking for H_0. Two vertices in S, T, respectively, share only one neighbor, so H_0 involves at most one of S, T, and we can remove one of them, say T. Two vertices in S have only s' as a common neighbor, so H_0 can have at most one vertex u in S. But this leaves only two vertices r, u in one side, so there is no H_0.

The last step enforces dominance-freedom. Suppose that x dominates y. Let H_1 be the graph consisting of an 8-cycle $C_8 = (1, 2, 3, 4, 5, 6, 7, 8)$, a 4-cycle $C_4 = (1', 2', 3', 4')$, and additional edges joining each i' to both i and $i + 4$. We join H_1 to H', with $y = 1'$ as common vertex in H_1 and H'. This does not introduce any new dominated vertices, and y is no longer dominated. Furthermore H_1 contains no $K_{3,2}$. So we only need to show that joining an H_1 at a vertex y gives an equivalent retract problem. If an instance for H' maps to H', it also maps to H' with H_1 joined; if it maps to H' with H_1 joined, since no vertices are forced to map to H_1 other than y, we can map all of H_1 to y and one of its neighbors in H', so the instance maps to H'. In the other direction, consider an instance for H' with H_1 joined. Certain vertices are required to map to specific vertices in C_8. If a vertex is adjacent to two vertices at distance 2 in C_8, then it must map to their unique common neighbor in C_8. So if a vertex v is adjacent to vertices in C_8, we may assume it is adjacent to either just one vertex in C_8 or two opposite vertices in C_8; in either case, we may assume that such a v maps to the unique vertex in C_4 having these adjacencies, and remove C_8 from the template. So the template is now H' with C_4 joined at a vertex $y = 1'$. Now for $3'$, we may insist that its neighbors map to $\{2', 4'\}$, and no other vertex maps to $3'$ since $1'$ now dominates $3'$, so we may remove $3'$ from the graph. Then if a vertex is labeled $2'$, $4'$, or $\{2', 4'\}$, its neighbors must map to $1'$, and we may remove $2'$ and $4'$ from the graph since every neighbor of $y = 1'$ in H' now dominates them. So we have reduced the instance for H' with H_1 joined to an instance for H' alone, as desired. □

THEOREM 10. *Every constraint-satisfaction problem is polynomially equivalent to a balanced digraph-homomorphism problem.*

Proof. We encode the graph-retract problem as a balanced digraph-homomorphism problem. Draw the bipartite graph with one vertex set on the left and the other on the right, and orient the edges from left to right. What remains is to distinguish the different vertices on each side. We describe the transformation for vertices in the right; a similar transformation is carried out for vertices in the left. In an oriented path, let 1 denote a forward edge and 0 a backward edge. If there are k vertices $0, 1, \ldots, k-1$ on the right, starting at the ith vertex, add an oriented path $(110)^i 1 (110)^{k-i-1} 11$. The intuition is that none of these paths maps to another one of them, and that if a digraph maps to two of them, then it maps to $(110)^k 11$, hence to all of them. Fur-

thermore, the question of whether a digraph maps to an oriented path is polynomially solvable; see sections 6.1.1 and 6.1.2. □

THEOREM 11. *Every constraint-satisfaction problem is polynomially equivalent to an unbalanced digraph-homomorphism problem.*

Proof. First assume that the given constraint-satisfaction problem consists of a single relation R of arity k; multiple relations can always be combined into a single relation by taking their product and adding their arities. Now, define a new constraint-satisfaction problem whose domain consists of k-tuples from the original domain; thus R is now a monadic relation. In order to be able to state an equality constraint among different components of different tuples, define a "shift" relation $S(t, t')$ on tuples $t = (x_1, x_2, \ldots, x_{k-1}, y)$ and $t' = (z, x_1, x_2, \ldots, x_{k-1})$; one can use such shifts to state that certain components of certain tuples coincide.

We have thus reduced the general constraint-satisfaction problem to a single monadic and a single binary relation. It is clear that any instance of the original problem can be represented using tuples on which the constraint R is imposed, and the relation S allows us to state that components of different tuples take the same value; similarly, the new problem only allows us to impose constraints from the original problem. We wish to have a single binary relation alone, i.e., a digraph. Define the following dag D. It has vertices corresponding to the tuples from the constraint-satisfaction problem just constructed. For each relation $S(t, t')$ that holds, introduce a new vertex joined by a path of length 1 to t and by a path of length 2 to t'. For each relation $R(t)$ that holds, introduce a new vertex joined by a path of length 3 to t. This completes the dag.

We show that the digraph homomorphism problem for D is equivalent to the original constraint-satisfaction problem. In one direction, given an instance of the original problem involving S and R, tag each element with a reverse path of length 2 followed by a path of length 1 followed by a reverse path of length 2. This ensures that the element can be mapped precisely to vertices in D representing elements of the domain; note here that we are using the fact that each t' is related to some t by S in the domain of the constraint-satisfaction problem. To state $S(t, t')$ and $R(t)$ on such elements, use incoming paths of lengths 1, 2, 3 as for D above. In the other direction, suppose that we have an instance of the digraph-homomorphism problem. We can assume that the instance is a dag, since D is a dag. We can also assume that if a vertex has both incoming and outgoing edges, then it has only a single incoming and a single outgoing edge, because this holds in D, so we could always collapse neighbors to enforce this. The input dag now looks like a bipartite graph (A, B, P), with disjoint (except at their endpoints) paths of different lengths joining vertices in A to vertices in B (all in the same direction). We can assume that the paths have length at most 3, since D has no path of length 4. We can also assume that a vertex at which a path of length 3 starts necessarily starts just this path, because this is the case in D. We can also assume that a vertex can start at most a single path of length 2, since this is the case in D. We also assume that a vertex starts at most a single path of length 1; the only way two different paths of length 1 could go in different directions would be if one of them mapped on the path of length 2 out of an out-degree-2 vertex v in D; but then, since the endpoint has no outgoing edges, all its neighbors would necessarily map to v, and so we could have mapped this endpoint to the other neighbor of v along the path of length 1. We can also assume that the only vertices that will map to an attached path of length 3 are vertices on a path of length 3; the reason is that if a directed graph containing no path of length 3 can be mapped to a reverse path of

length 3, then it can be mapped to a reverse path of length 2 followed by a path of length 1 followed by a reverse path of length 2, and this configuration can be found in D from a fixed endpoint of a path of length 3 without using this path (we used this same configuration before). We can now assume that vertices in A and B map to vertices in the two corresponding sides of the bipartite graph corresponding to D. For vertices in B, this is clear if they have incoming paths of length 3, or of length 2 since we have assumed that they do not map to a vertex inside a path of length 3, or of length 1 since we can assume that they do not map to a vertex inside a path of length 2; the same is then clear for vertices in A. But then the vertices in B can be viewed as elements of the original constraint-satisfaction problem, and the vertices in A can be viewed as imposing constraints on them. □

THEOREM 12. *Every constraint-satisfaction problem is polynomially equivalent to a bipartite graph-retract problem, but now only allowing three specific vertices of the template H to occur in the input G (but not just two vertices, which is polynomially solvable).*

Proof. We encode a digraph-homomorphism problem. The encoding introduces three special vertices r, b, g, which may occur in G, three additional vertices r', b', g' (which cannot appear in G), and a vertex a adjacent to r', b', g'; it replaces each vertex of the dag with a vertex adjacent to r and each edge in the dag with a path $0, 1, 2, 3, 4, 5, 6$ of length 6, where the intermediate vertices in positions 2 and 4 are adjacent to b and g, respectively, while those in positions $1, 3, 5$ are adjacent to a; and, finally, it links r', b', g' to all the vertices linked to r, b, g, respectively. The proof is here a straightforward encoding argument.

A bipartite graph with just two distinguished vertices can always be retracted to just a path joining the two vertices, namely, a shortest such path; this is then the core, which defines a polynomially solvable problem. □

THEOREM 13. *Every constraint-satisfaction problem is polynomially equivalent to a balanced digraph-homomorphism problem, but now for a balanced digraph with only five levels (but not just four levels, which is polynomially solvable).*

Proof. The digraph-homomorphism problem can be encoded as a balanced digraph-homomorphism problem with only five levels. Given an arbitrary digraph without self-loops, represent all vertices as vertices at level 1, and all edges as vertices at level 5. If vertex v has outgoing edge e, join their representations by an oriented path 111011. If vertex v has incoming edge e, join their representations by an oriented path 110111. If neither relation holds, join their representations by an oriented path 11011011. The key properties are that neither of the first two paths map to each other, and that a digraph maps to the third path if and only if it maps to the first two. Now given a digraph, we can decompose it into connected components by removing the vertices at levels 1 and 5. Each such component either maps to none of the three paths (in which case no homomorphism exists), or to all three of them (in which case it imposes no restriction on where the boundary vertices at levels 1 and 5 map), or to exactly one of the first two paths (in which case it indicates an outgoing or incoming edge in the original graph). Thus every instance of the new problem can be viewed as an instance of the original problem, given the fact that mapping digraphs to paths is polynomially solvable; see sections 6.1.1 and 6.1.2. □

Another case of interest is that of *reflexive graphs*, i.e., graphs with self-loops. The homomorphism problem is not interesting here, since all vertices may be mapped to a single self-loop. We consider the reflexive graph-retract problem, as well as two other related problems. The *reflexive graph-list* problem is the homomorphism

problem where in addition we may require that some vertex maps to a chosen subset of the vertices in the template. The *reflexive graph-connected list* problem allows only subsets that induce a connected subset of the vertices in the template. The following results are from Feder and Hell [18, 19].

THEOREM 14. *Every constraint-satisfaction problem is polynomially equivalent to a reflexive graph-retract problem. The reflexive graph-retract problem is NP-complete for graphs without triangles other than trees. The reflexive graph-list problem is polynomially solvable for interval graphs, and NP-complete otherwise. The reflexive graph-connected list problem is polynomially solvable for chordal graphs, and NP-complete otherwise. The graph-retract problem for connected graphs with some self-loops is NP-complete if the vertices with self-loops induce a disconnected subgraph.*

For partial orders and strict partial orders, the homomorphism problem is easy, since the core is either a single vertex, in the case of partial orders, or a total strict order, in the case of strict partial orders. We examine the corresponding retract problem. For strict partial orders, even if the strict partial order is bipartite, the problem is equivalent to the bipartite graph-retract problem and hence to all of CSP. For partial orders, there are applications to type reconstruction; see Mitchell [41], Lincoln and Mitchell [42], Wand and O'Keefe [43]. Pratt and Tiuryn [45] showed that the bipartite partial order-retract problem is polynomially solvable if the underlying graph is a tree (in fact, in NLOGSPACE), and NP-complete otherwise. We can give an alternative proof of this result here. If the underlying graph is a tree, we have a directed reflexive graph whose underlying graph is a tree. If we then associate a Boolean variable with each subtree, the problem is just a 2SAT problem, because if a set of subtrees pairwise intersect, then they jointly intersect. For the NP-completeness result, define an undirected reflexive graph on the same set as the bipartite partial order, making x, y adjacent if there exist s, t such that $s \leq x, y \leq t$; in this case, this means that $x \leq y$ or $y \leq x$. This gives a reflexive graph-retract problem on a graph without triangles and not a tree, which is NP-complete by the preceding theorem. We now examine the general case. Let the *depth* of a partial order be the number of elements in a total suborder.

THEOREM 15. *Every constraint-satisfaction problem is polynomially equivalent to a partial order-retract problem, even if only the top and bottom elements of the partial order can occur in an instance. The equivalence holds even for depth-3 partial order-retract problems.*

Proof. We prove the equivalence to the domination-free bipartite graph-retract problem, which was shown to be equivalent to all of CSP above. We shall assume that only the top and bottom elements of the partial order can be used in an instance; to extend the result to the case where all elements can be used, we can simply consider the core of the partial order. Let $H = (S, T, E)$ be a domination-free bipartite graph. Define the corresponding partial order $P = (Q, \leq)$ as follows. Let Q be the set of all bipartite cliques $A \times B \subseteq E$, with $A, B \neq \emptyset$. Let $A \times B \leq A' \times B'$ if $A \subseteq A'$ and $B' \subseteq B$. If $N(v)$ denotes the set of neighbors of v in H, then the bottom elements are $\{a\} \times N(a)$ for $a \in S$ and the top elements are $N(b) \times \{b\}$ for $b \in T$.

Given an instance G for H, we can assume that G is bipartite since H is bipartite, and that G and H share at least a vertex, since otherwise G can be mapped to a single edge in H, so that we know which side of G maps to S and which to T. Replace adjacency in G with $\leq$ from the side mapping to S to the side mapping to T, replace any occurrence of an H vertex in G by the corresponding bottom or top element in P, and ask whether this partial order maps to P. We can assume that top and bottom

elements map to top and bottom elements, respectively, and on these elements the $\leq$ relation in P corresponds to edges in H, so solving the problem on P solves the instance G for H.

In the other direction, given an instance R for P, where R and P only share top and bottom elements of P, we can assume that such elements are also top and bottom in R, since everything below a bottom element must map to that bottom element and everything above a top element must map to that top element. We can also assume that top and bottom elements in R map to top and bottom elements in P. To map such elements, determine the bipartite $\leq$ relation on them, and map them by solving the problem as a bipartite graph-retract problem for H, with the natural correspondence between bottom and top elements of P and vertices in the S, T sets of H. Clearly, if the bipartite graph-retract problem does not have a solution, neither does the partial order-retract problem. If the bipartite graph-retract problem has a solution, it only remains to map the middle vertices. If a middle element is between bottom and top elements that were mapped to subsets $A \subseteq S$ and $B \subseteq T$, map that middle element to $A \times B$ in P, completing the retraction.

In order to prove the depth-3 result, we first determine the core of the partial order. Clearly, the core must contain every $\{a\} \times N(a)$ for $a \in S$ and every $N(b) \times \{b\}$ for $b \in T$, because these elements can be used in an instance. As a result, it must also contain all maximal bipartite cliques $A \times B$, because such maximal bipartite cliques are the only bipartite cliques above the corresponding elements $\{a\} \times N(a)$ for $a \in A$ and below the corresponding elements $N(b) \times \{b\}$ for $b \in B$. Notice that the maximal bipartite cliques are precisely those bipartite cliques $A \times B$ with $A = N(B)$ and $B = N(A)$, where $N(C)$ denotes here the vertices adjacent to all of C. We now observe that the maximal bipartite cliques are indeed the entire core, because the mapping $f(A \times B) = N(N(A)) \times N(A)$ is an appropriate retraction.

Having identified the core of the partial order as the partial order on maximal bipartite cliques, we use the fact that the domination-free bipartite graph can also be assumed to be $K_{3,3}$-free and $K_{3,3}\backslash\{e\}$-free. Now, if $A_1 \times B_1 < A_2 \times B_2 < A_3 \times B_3 < A_4 \times B_4$ for maximal bipartite cliques, then the containments on the A_i and on the B_i must be strict, so $|A_i| \geq i$ and $|B_i| \geq 5 - i$. In particular, $A_2 \times B_2$ must contain a $K_{2,3}$ and $A_3 \times B_3$ must contain a $K_{3,2}$, and furthermore their union must contain a $K_{3,3}\backslash\{e\}$ by maximality of the bipartite cliques. This establishes the depth-3 claim. Notice also that $K_{3,3}$-freedom implies that a bipartite clique $A \times B$ must have $|A| \leq 2$ or $|B| \leq 2$, and since for maximal bipartite cliques, A and B uniquely determine each other, the partial order has size polynomial in the size of the bipartite graph. □

Therefore, the dichotomy question for MMSNP is equivalent to the dichotomy question for CSP, which in turn is equivalent to the dichotomy questions for graph-retract, digraph-homomorphism problems, and partial order-retract problems.

6. Special classes. Schaefer [48] showed that there are only three polynomially solvable constraint-satisfaction problems on the set $\{0, 1\}$, namely, Horn clauses, 2SAT, and linear equations modulo 2; all constraint-satisfaction problems on $\{0, 1\}$ that do not fit into one of these three categories are NP-complete. For general constraint-satisfaction problems, we introduce two classes, namely, *bounded-width* and *subgroup*, and examine two subclasses of the bounded-width class, namely, the *width* 1 and *bounded strict width* classes. These are generalizations of Schaefer's three cases, since Horn clauses have width 1, 2SAT has strict width 2, and linear equations modulo 2 is a subgroup problem. At present, all known polynomially solvable constraint satisfaction problems are simple combinations of the bounded-width case and the subgroup case.

Remark. A similar situation of only three polynomially solvable cases was observed for Boolean network stability problems by Mayr and Subramanian [39] and Feder [15]; the three cases there are monotone networks, linear networks, and nonexpansive networks, in close correspondence with Horn clauses, linear equations modulo 2, and 2SAT, respectively; it is the generalization of the nonexpansive case to metric networks that leads to characterizations along the lines of the bounded strict width case described below.

We describe the work on network stability in the context of constraint-satisfaction in more detail here. Say that a template is *functional* if all relations have some arity $k+l$ with $k, l \geq 0$ and are described by a function $f(x_1, x_2, \ldots, x_k) = (y_1, y_2, \ldots, y_l)$, called a *gate*, where the x_i are called *inputs* and the y_i are called *outputs*. A *network stability* problem is a constraint-satisfaction problem where the template is functional, and where the input structure has the property that every element participates in exactly two relation occurrences, one as an input and one as an output. The input structure is then called a *network*. The work in [39, 15] established the following. Let the *constant* gates be $f() = e$, and the *absorption* gate be $f(x) = ()$.

THEOREM 16. *Every network stability problem over a Boolean functional template containing the constant and absorption gates is NP-complete, with the exception of the following polynomially solvable cases:*

(1) *monotone functional templates, where every output y_j of every gate is a monotone function of the inputs x_i. For the general case with AND and OR gates, the problem is P-complete and determining whether there is a solution other than the zero-most and one-most solutions is NP-complete*;

(2) *linear functional templates, where every output y_i of every gate is a linear function of the inputs x_i modulo* 2;

(3) *adjacency-preserving functional templates, where every gate f has the property that changing the value of just one of the x_i inputs can affect at most one of the y_j outputs. Here the set of solutions can be described by a 2SAT instance because the median of three solutions, obtained by taking coordinate-wise majority, is also a solution.*

The case (3) *extends to a non-Boolean domain case by assuming that the template has an associated distance function on the elements satisfying the triangle inequality, such that for every gate f, if $f(x_1, x_2, \ldots, x_k) = (y_1, y_2, \ldots, y_l)$ and $f(x'_1, x'_2, \ldots, x'_k) = (y'_1, y'_2, \ldots, y'_l)$, then $\sum d(y_j, y'_j) \leq \sum d(x_i, x'_i)$. The functional template is then called nonexpansive and the associated network is metric*; *this case is also polynomially solvable. Here the structure of the set of solutions is a strict width* 2 *problem because the solutions form a* 2*-isometric subspace, where the corresponding* 2*-mapping property is obtained with the imprint function, yielding the* 2*-Helly property (see* [15] *for the definitions of* 2*-isometric subspace and imprint function).*

It is the structure presented in this theorem and its connection to Schaefer's work that initially led to the work presented here. In this paper, we are not considering special cases, such as network stability or planar graph coloring; here the template is fixed and the instance is not constrained.

6.1. Bounded-width problems. A problem is said to have *bounded width* if its complement (i.e., the question of nonexistence of a solution) can be expressed in Datalog. More precisely, it is said to have *width* (l, k) if the corresponding Datalog program has rules with at most l variables in the head and at most k variables per rule, and is said to have *width* l if it has width (l, k) for some k. For a related notion of width, see Afrati and Cosmadakis [4].

Datalog is the language of logic programs without function symbols [50]. The following Datalog program checks that an input graph is not 2-colorable:

$$\begin{array}{lcl} \mathit{oddpath}(X,Y) & :\!- & \mathit{edge}(X,Y) \\ \mathit{oddpath}(X,Y) & :\!- & \mathit{oddpath}(X,Z), \mathit{edge}(Z,T), \mathit{edge}(T,Y) \\ \mathit{not2colorable} & :\!- & \mathit{oddpath}(X,X). \end{array}$$

In this example, *edge* is an input binary relation, *oddpath* is a binary relation computed by the program, and *not2colorable* is a zero-ary relation computed by the program. The first rule says that a single edge forms an odd path; the second rule tells that adding two edges to an odd path forms an odd path; and the third rule says that the input graph is not 2-colorable if the graph contains an odd cycle. In Datalog programs for constraint-satisfaction instances we assume that there is a distinguished predicate p of arity zero (*not2colorable* in the above example) that must be derived when no solution exists for the instance. We say that such a program *solves* the problem.

The example above shows that 2-colorability has width $(2, 3)$, since it can be solved by a Datalog program with at most two variables in rule heads and at most three variables per rule. Also, 3SAT-Horn can be shown to have width 1. It is not hard to show that bounded-width problems are in monotone SNP without inequality. Furthermore, problems of width 1 are in MMSNP.

It is easy to see that all bounded-width problems are in P, since the rules can derive only a polynomial number of facts. Thus, we ask the following question.

Which problems in CSP have bounded width?

The predicates from the instance are called EDB predicates, and the new auxiliary predicates are called IDB predicates. Given a Datalog program with EDB predicates corresponding to the constraints of a constraint-satisfaction problem defined by a template T, we assign to each predicate in the program a relation on values from T. The EDB predicates already have an assigned relation in T. For IDB predicates, we initially assign to them the empty relation, then add tuples as follows. Given a rule, involving at most k variables, we consider the assignments of values from T to these k variables such that the constraints imposed on them by the current relations assigned to predicates in the body of the rule are satisfied. For these satisfying assignments for the body, we consider the induced assignments on the at most l variables in the head, and add all these tuples to the relation associated with the head of the rule. This process of adding tuples over values from T to the relations associated with IDB predicates must eventually terminate, mapping each IDB to a relation on values from T.

The relation associated with the distinguished p at the end of this process must be the empty relation. Otherwise, we could design an instance that has a solution yet for which p can be derived, simply by viewing the derivation tree that made p nonempty as an instance, contrary to the assumption that the Datalog program only accepts instances with no solution.

Even if we know that a constraint-satisfaction problem has width (l, k), there could be many Datalog programs that express the complement of the problem. Thus, it seems that to answer the question above we need to consider all possible (l, k)-programs. Surprisingly, it suffices to focus on very specific Datalog programs.

THEOREM 17. *For every constraint-satisfaction problem P there is a canonical Datalog (l, k)-program with the following property: if any Datalog (l, k)-program solves P, then the canonical one does.*

Proof. Intuitively, the canonical program of width (l, k) infers all possible constraints on l variables at a time by considering k variables at a time. This canonical program infers constraints on the possible values for the variables in the instance, both considered l at a time and k at a time, as follows. Initially, all constraints from the instance can be viewed as constraints on variables, k at a time. Now, a constraint on k variables can be projected down to a constraint on an l-subset of these k variables. In the other direction, a constraint on an l-subset can be extended up to a constraint on the k variables. This process can be iterated, and if a constraint on variables ever becomes the empty set, we can infer that the instance has no solution. This inference process can easily be described by a Datalog (l, k)-program, and in fact the inferences carried out by this canonical program contain all inferences performed by any Datalog (l, k)-program, with the interpretation of IDBs as relations on values from T defined above. □

Consider now the following two-player game on the structures S, the instance, and T, the template. Player I selects k variables and asks Player II to assign to them values from T. Then Player I keeps l out of these k assigned variables, extends this set of l to a new set of k, and asks Player II to assign values to the new $k-l$ variables, back to the earlier situation with k assigned variables. The game proceeds from there as before. Player I wins if at some point, some of the k assigned values violate a constraint from the instance.

THEOREM 18. *The canonical (l, k)-program for a constraint-satisfaction problem accepts an instance precisely when Player I has a winning strategy in the associated (l, k)-two-player game.*

Proof. Suppose the canonical program accepts an instance (such an instance necessarily fails to have a solution). Consider the corresponding derivation tree. Each node of the tree corresponds to a relation on at most k elements from S. This relation has an associated set of tuples from T as defined above. Player I traverses a path from the root to a leaf; at each step he holds a tuple that is not in the associated set. He starts at the root, where the relation has arity zero; there he holds the arity-zero tuple, which does not belong to the associated empty set. In general, at a given node v where Player I holds a tuple of arity at most l not in the associated set, Player I selects the rule corresponding to the node v and its children, and asks Player II to assign values to the remaining variables in the rule, up to a total of at most k. It cannot be that all the resulting assignments to at most l variables corresponding to the children of the node v are tuples in the sets associated with them, because then the original tuple would have been in the set associated with v. So Player I can select some child of v such that the assignment to its at most l variables is not in the associated set. When a leaf is reached, Player I holds an assignment violating a given constraint in the instance.

For the converse, suppose that Player I has a winning strategy. The playing of the game depending on the moves by Player II can then be viewed as a tree. For instance, at the root, after Player I has made its initial choice k elements, the children correspond to the possible choices of l elements out of these k that can be made by Player I, depending on the assignment of values to the k elements by Player II. At the next level, the extension of the l assigned values to a tuple of k variables chosen by Player I is again considered, until at the leafs we have assignments to at most l variables that violate a constraint. This tree is then precisely a derivation tree by which the canonical program can accept the instance. □

For related games, see Afrati, Cosmadakis, and Yannakakis [5], Kolaitis and Vardi

[33], and Lakshmanan and Mendelzon [36].

This notion of bounded width for constraint-satisfaction problems can also be extended to allow infinite Datalog programs (allowing infinitely many IDBs, infinitely many rules, and infinitely many conjuncts per rule); such programs have been studied before under the name L^ω. For constraint-satisfaction problems on a *finite* domain, infinite programs are no more powerful than finite programs; the reason here is that the canonical program has IDBs corresponding to constraint sets, but there are only finitely many possible constraint sets.

Remark. For constraint-satisfaction problems, it can be shown that Datalog is equivalent to Datalog($\neq, \neg$), finite or infinite. This equivalence holds more generally for problems closed under homomorphisms, finite and infinite cases being separate. For such problems, it turns out that monadic SNP with inequality is no more powerful than monotone monadic SNP without inequality, and the same holds for (binary) SNP with inequality compared with monotone (binary) SNP without inequality [16].

6.1.1. Width 1 and tree duality. Horn clauses have width $(1, k)$, where k is the maximum number of variables per Horn clause. To see this, express Horn clauses as implications with a conjunction of positive literals in the antecedent and at most one positive literal in the consequent. An instance has no solution if it implicitly contains a clause with an empty antecedent, which stands for "true" or 1, and an empty consequent, which stands for "false" or 0. This situation can be detected by Player I by selecting an appropriate clause with an empty consequent. Then Player II must assign value 0 to some variable in the antecedent, then Player I selects some appropriate clause with this variable as the consequent, and so on, until a clause with an empty antecedent is reached; then Player I wins.

Using Theorems 17 and 7, we can prove the following theorem.

THEOREM 19. *The question of whether a constraint-satisfaction problem has width* $(1, k)$ *or width* 1 *is decidable.*

Proof. The canonical program describes in that case a monotone monadic SNP problem, and we have seen that containment for such problems is decidable. In fact, we have also seen that it is never necessary to look at conditions for a monotone monadic SNP problem that do not define a biconnected component contained in biconnected components of the statement of the problem. However, these are only single relations in the case of constraint-satisfaction problems, so we can assume that the Datalog program looks only at single relations from the input. Thus k need not be larger than the largest arity, and hence width 1 is decidable. There is another way to see this. By Theorem 5, we may assume that an instance recognized by the monadic Datalog program has high girth—larger than the size of any rule. We may then assume that the body of the rule is a tree, and then the rule can be replaced by rules having only one EDB per rule, by introducing additional monadic IDB relations. So k is bounded by the largest arity. □

Let S be a connected structure. An element x is an *articulation element* if the structure S can be decomposed into two nonempty substructures that share only x. If we decompose a structure into substructures by identifying all its articulation elements, we say that the resulting substructures without articulation elements are *biconnected components.* A *tree* is a structure whose biconnected components consist of a single relation occurrence each. Following and generalizing the terminology of Hell, Nešetřil, and Zhu [25], we say that a constraint-satisfaction problem defined by a template T has *tree duality* if a structure S can be mapped to T if and only if every tree that can be mapped to S can be mapped to T.

THEOREM 20. *A constraint-satisfaction problem has tree duality if and only if it has width* 1.

Proof. Trees are precisely the objects generated by derivation trees of Datalog programs with at most one variable in the head and at most one EDB per rule. We observed in the proof of the previous theorem that if a problem has width 1, then it has a Datalog program of this form. Then an instance S does not map to T if and only if it is accepted by the Datalog program; i.e., some tree maps to S but does not map to T. Thus width 1 implies tree duality. Conversely, if tree duality holds, then width 1 follows by considering the Datalog program that generates all the trees that do not map to T; this is an infinite program, but we have observed before that infinite programs can be transformed into finite ones for constraint-satisfaction problems, e.g., the canonical program from Theorem 17. □

In fact, as observed in the proof of Theorem 7, width 1 can be decided as follows.

Tree duality decision procedure: Given a constraint-satisfaction problem with template T, let U be the structure defined as follows. The elements of U are the nonempty subsets A of the elements of T. For a relation R of arity k, impose $R(A_1, A_2, \ldots, A_k)$, the A_i not necessarily distinct, if for every $1 \leq i \leq k$ and every a_i in A_i there exist elements a_j in the remaining A_j such that $R(a_1, a_2, \ldots, a_k)$ is in T. Then tree duality holds if and only if U maps homomorphically to T.

For example, 2SAT will in particular enforce $x \vee y$ and $\overline{x} \vee \overline{y}$ on $x = y = \{0, 1\}$, hence no solution exists, showing that 2SAT does not have width 1. In general, the question of whether a constraint-satisfaction problem has bounded width (or width l, width (l, k), beyond the case $l = 1$) is not known to be decidable.

We give here an alternative proof of the correctness of the above decision procedure based on tree duality and its equivalence to the existence of a Datalog program for the problem with one EDB relation per rule and at most one variable in the head of each rule, which infers constraints on the possible values for elements of the structure.

THEOREM 21. *The above decision procedure correctly decides tree duality.*

Proof. Suppose that tree duality holds. Consider the structure U defined in the decision procedure whose elements are nonempty sets A. We show that U can be mapped to T. Every tree that maps to U has elements that are nonempty sets A. The tree can be mapped to T by choosing one element from the root of the tree, one consistent element from each of its children, and so on. Thus, by the definition of tree duality, U maps to T. Conversely, suppose that U maps to T, and let S be a structure such that every tree that maps to S maps to T. If we use the Datalog program on S, then every element of S will be assigned a nonempty set A by the program, otherwise the derivation tree would provide a tree that maps to S but not to T. This gives a mapping from S to U, and by composition from S to T. Therefore tree duality holds. □

Thus tree duality has a simple decision procedure. Consider the special case where the template T is an oriented path (a path each of whose edges may be oriented in either direction). This T was shown to have tree duality by Hell and Zhu [28]; in fact, they showed that it satisfies the stronger path duality property that S maps to T if and only if every oriented path that maps to S maps to T. We give a simple proof of tree duality via the above decision procedure. Suppose that the elements of the path T are numbered $1, 2, \ldots, r$ in order. For every nonempty subset A of $\{1, \ldots, r\}$, map A to the least numbered element of A. If there is an edge from A to B, then the least elements of A and B cannot be the same element a, since otherwise T would contain an edge from a to $a + 1$ and one from $a + 1$ to a. So either a is the least element of

A, $a+1$ is the least element of B, and T has an edge from a to $a+1$, or a is the least element of B, $a+1$ is the least element of A, and T has an edge from $a+1$ to a. Thus T has an edge from the image of A to the image of B, as required.

A more general case is the case of oriented trees, which defines both polynomial and NP-complete problems, as well as problems that have not yet been classified [26].

We say that a constraint-satisfaction problem defined by a template T with T a core has *extended tree duality* if a connected structure S with one element s preassigned a value t in T can be mapped to T, if and only if every tree that can be mapped to S can be mapped to T in such a way that the elements of the tree that map to s end up mapping to t. Just like tree duality could be decided by the existence of a mapping from a particular structure U to T, extended tree duality can be decided by the existence of a mapping from a particular structure U' to T, where U' is the substructure of U consisting of the union of the connected components containing the singletons $\{t\}$ for t in T. The proof of correctness is similar to the tree duality case. Since the extended tree duality property involves one special element s, and problems with tree duality have width 1, problems with extended tree duality have width 2. (The converse is false, e.g., 2SAT.)

THEOREM 22. *For a constraint-satisfaction problem with template T, tree duality is equivalent to the existence of a homomorphism from U to T. If T is a core, then extended tree duality is equivalent to the existence of a homomorphism from the substructure U' to T. Problems with extended tree duality have width* 2.

Say that two elements are *related* if they both belong to the same set A in the connected component U'. A special case of extended tree duality for digraphs is the case where there is a total ordering of the vertices of T such that if (a,b) and (c,d) are two edges of T with $a<b$ and $c<d$, with a,c related and b,d related, then (a,d) is also an edge of T. In this case we can map a nonempty set A in U' to the least element of A under the ordering. This case is essentially the same as the extended $\underline{\text{X}}$-property from [23, 25].

More generally, an (l,k)-*tree* is a structure given by a derivation tree of a Datalog program whose rules have at most l variables in the head and at most k variables per rule. Combinatorially, a structure S is an (l,k)-tree if there exists a tree t whose nodes are sets of elements of S of cardinality at most k, where a node and a child in t share at most l elements of S, the nodes in which an element of S participates form a subtree of t, and each relation occurrence in S involves elements contained in a single node of t. In the literature, when S is a graph and S is an (l,k)-tree, then it is said to have *tree-width* $k-1$ (see, e.g., [38, 47]).

Along the general lines of duality of graph homomorphisms (see Hell, Nešetřil, and Zhu [27]), a constraint-satisfaction problem defined by a template T has (l,k)-*tree duality* if a structure S can be mapped to T if and only if every (l,k)-tree that can be mapped to S can be mapped to T. The following is immediate from the definition of acceptance by a Datalog program.

THEOREM 23. *A constraint-satisfaction problem has (l,k)-tree duality if and only if it has width (l,k).*

Recall from section 3 the definition of the length of an oriented cycle and of balanced and unbalanced digraphs. Hell and Zhu [29] show that in the case where T is an unbalanced cycle, it is sufficient to test oriented paths, which are $(1,2)$-trees, and oriented cycles, which are $(2,3)$-trees; therefore unbalanced cycles define a problem of width $(2,3)$. The property that cycles of the instance S must satisfy is that their length is a multiple of the length of T. Therefore, in the special case where the length

is 1, cycles need not be tested, only oriented paths, and the problem has width $(1, 2)$. We show here that unbalanced cycles have extended tree duality, hence width 2, and that when their length is 1, they have tree duality, hence width 1. Suppose that a cycle has length $m \geq 1$. Enumerate the vertices $0, 1, \ldots, k$ in order around the cycle, where vertices 0 and k coincide, in such a way that there is a *level* function such that every edge (i, j) satisfies $level(j) = level(i) + 1$, with $level(0) = m$, $level(k) = 0$, and $level(i) \geq 1$ for $i \neq k$. Then define the total ordering mentioned above for extended tree duality to be the lexicographical ordering on pairs $(level(i), i)$. Notice that if two elements are related, their levels must differ by a multiple of m. In the case where $m = 1$, this imposes no restriction; i.e., we may use the structure U instead of U'. The same construction can be used to establish tree duality for balanced cycles such that if we denote by l an occurrence of a lowest level element and by h an occurrence of a highest level element, then the ordering $lhlh$ does not occur when the cycle is traversed once, so that the complete ordering of l and h is l^+h^+.

In general, for an arbitrary constraint-satisfaction problem, if we only consider instances that are (l, k)-trees with l, k fixed, then the problem is solved in polynomial time by the canonical Datalog (l, k)-program, since this program has as derivation trees precisely the (l, k)-trees that do not have a solution for the constraint-satisfaction problem.

THEOREM 24. *On (l, k)-tree instances, constraint-satisfaction problems are polynomially solvable, for l, k fixed.*

For more general results on polynomially solvable problems in the case of graphs of bounded tree-width, see, e.g., [1, 9].

6.1.2. Bounded strict width and the Helly property. The canonical algorithm for problems of width (l, k) involved inferring all possible constraints on l variables at a time by considering k variables at a time. We may in addition require that if this inference process does not reach a contradiction (the empty set), then it should be possible to obtain a solution by greedily assigning values to the variables one at a time while satisfying the inferred l-constraints. We say that a constraint-satisfaction problem that can be solved in this way has *strict width* (l, k), and we say that it has *strict width* l if it has strict width (l, k) for some k. It turns out that strict width l is equivalent to strict width (l, k), for all $k > l$, so we can assume $k = l + 1$.

This intuition behind strict width l can also be captured in two other ways. First, we can require that if we have an instance and that, after assigning specific values to some of the variables, we obtain an instance with no solution, then some l out of the specific value assignments chosen are sufficient to give an instance with no solution. We refer to this property as the l-Helly property. Second, we could require that there exists a function g that maps $l + 1$ elements from the domain of the structure T to another element, with the property that if all but at most one of the $l + 1$ arguments are equal to some value b then the value of g is also b, and, furthermore, for all constraints C_i in T, if we have $l + 1$ tuples satisfying C_i, then the tuple obtained by applying g componentwise also satisfies C_i. We call this property the l-mapping property.

THEOREM 25. *Strict width l, the l-Helly property, and the l-mapping property are equivalent. These properties are polynomially decidable (for a fixed l).*

Proof. The proof of the equivalence of the various formulations of bounded strict width shows first that the correctness of the greedy (l, k)-algorithm implies that the Helly property for l must hold. The reason is that the final step of finding a solution uses only the inferred constraints on l variables at a time, hence these constraints

must precisely characterize the solutions, showing that the Helly property for l holds. This in turn implies that the instance stating the existence of g must have a solution. The reason is that l out of the constant value assignments imposed on g can always be satisfied, because each of these constant value assignments has l out of the $l+1$ arguments equal for g; there must be an argument position that is not the one exceptional argument for any of the l constant value assignments being considered, so we can always return the value of this argument, satisfying all conditions. Since the constant value assignments considered l at a time are satisfiable, then altogether they must be satisfiable by the Helly property for l, and hence g exists.

Finally, the existence of g implies the correctness of the greedy $(l, l+1)$-algorithm; it implies in fact the correctness of a more restrictive algorithm that eliminates variables one by one in arbitrary order (by considering just the $l+1$-subsets containing a chosen variable to infer a constraint on the remaining l variables) and assigns values in reverse order. Consider the elimination of the first variable x_1. We claim that any solution x' of the resulting instance on the remaining variables $x_2, \ldots, x_n$ can be extended to a solution for x_1. We must show that there exists a value for x_1 satisfying all constraints involving x_1 in conjunction with x'. We first consider constraints involving only l of the variables in x'. If no value of x_1 satisfies the constraints involving x_1 and the chosen l variables, then this would result in the inference step in forbidding the value assignment on l variables induced by x', and x' would not have been a solution of the resulting instance. Therefore constraints involving only x_1 and l of the variables in x' can be satisfied (we are including here in the inference step constraints obtained as projections of constraints involving x_1 and variables possibly different from the chosen l). Consider now constraints involving only x_1 and k of the variables in x', for $k \geq l+1$, where we assume inductively that $k-1$ can be handled. Consider $l+1$ particular variables out of the chosen k from x'. For each choice of one variable (say, the ith one) out of these $l+1$, if we ignore it, then a value x_1^i for x_1 can be found by inductive assumption. But then, we can set $x_1 = g(x_1^1, x_1^2, \ldots, x_1^{l+1})$ and satisfy the constraints on x_1 and all k chosen variables. The reason is that any such constraint involves l variables including x_1. One of the $l-1$ variables other than x_1 may have been ignored in choosing x_1^i, but a value for it can be found since otherwise x_1^i would not have been considered consistent. Furthermore, a variable was ignored in choosing at most one x_1^i, so g applied to the $l+1$ values for this variable gives the correct majority value. Since the constraint is closed under g, the value x_1 obtained by applying g satisfies all the constraints, completing the induction. To handle the elimination of subsequent variables analogously, it is only important to observe that the constraints obtained by the inference step are also closed under g, since they are obtained by intersection and projection of constraints closed under g. This proves the correctness of the algorithm.

Note that the existence of g is itself an instance of the constraint-satisfaction problem, hence strict width l is decidable and in fact polynomially decidable, for fixed l. It is not known to be decidable when l is not fixed. □

2-colorability is an example of a constraint-satisfaction problem with strict width 2. If a graph is bipartite, but after having 2-colored some of the vertices there is no two-coloring consistent with this partial coloring, then either two vertices on different sides of the bipartite graph were given the same color or two vertices in the same side were given different colors. Also, 2SAT has strict width 2, and so does integer programming with two variables per inequality with variables ranging over a fixed range.

Feder [17] showed that digraph-homomorphism for oriented cycles is either polynomially solvable or NP-complete. The proof is a good illustration of some of the techniques we have been using up to this point; we give here a sketch of the proof.

THEOREM 26. *Every oriented cycle digraph-homomorphism problem is either polynomially solvable or NP-complete.*

Proof (sketch). The case where a template is an oriented path, which we saw in the previous section has width 1, also has strict width 2. To see this, number again the vertices $1, 2, \ldots, r$ and consider the mapping $g(x, y, z) = \text{median}(x, y, z)$. In the case where the template is a directed graph that maps to a cycle C, it is sufficient to consider only argument lists for g such that all arguments map to the same vertex in C. For unbalanced oriented cycles, which we saw have extended tree duality, we also have strict width 2; the argument considers the lexicographic ordering on pairs $(\mathit{level}(i), i)$ as before and uses the median(x, y, z) function on three arguments whose levels differ by a multiple of the length of the cycle. The same argument applies to the balanced cycles not containing the ordering $lhlh$ as mentioned before, so that the complete pattern of l and h is l^+h^+. There is a family of balanced cycles that does not have extended tree duality (it can encode 2SAT) yet has strict width 2: these are the balanced cycles with two l and two h elements that form the pattern $lhlh$ along the cycle. Consider the four paths $1 = l_1h_1$, $2 = l_2h_1$, $3 = l_2h_2$, $4 = l_1h_2$ on the cycle; given three paths $i - 1$, i, $i + 1$ out of these four (modulo 4), the *middle path* is i. The mapping $g(x, y, z)$, with the three arguments at the same level, is defined as follows. (1) If x, y, z belong to three different paths, return the one that belongs to the middle path. (2) If x, y, z belong to the same path, return the one in the middle position on the path. (3) If exactly two out of x, y, z belong to the same path, return the one of these two occurring earliest on the path. In each of the classes of the form $l^+h^+l^+h^+$, other than the polynomial class $lhlh$, there are both polynomial and NP-complete templates that are cores; the cases $(l^+h^+)^{\geq 3}$ are NP-complete for cores. It is shown in [17] that in the remaining case $l^+h^+l^+h^+$, all problems are either in P or NP-complete, completing the classification of oriented cycles. The proof uses the 2-Helly property for paths, which have strict width 2, and a generalization of Schaefer's classification of Boolean satisfiability to a k-partite version [17, 48]. □

Problems with bounded strict width are a special case of bounded-width CSP. For such problems we have a more efficient algorithm.

THEOREM 27. *A simplified version of the canonical algorithm runs in parallel $O^*(n)$ time using a polynomial number of processors (the O^* notation ignores polylogarithmic factors). In the case $l = 2$, this algorithm can be implemented in parallel $O^*(\sqrt{n})$ time, because variables can be eliminated in parallel.*

Proof. First, observe that the number of constraints that could be inferred is $O(n^2)$. Therefore the number of steps that infer at least $n^{1.5}$ constraints is only $O(\sqrt{n})$. Suppose that a step would infer only $n^{1.5}$ constraints, i.e., only these many pairs of values for pairs of variables are discarded. Suppose that we "charge" such a pair of values eliminated for two variables x_j, x_k to a variable x_i such that the inference on these three variables causes the pair of values to be eliminated. Since there are n variables, they are charged $n^{0.5}$ eliminations each in average, and thus at least half of them are charged at most $2n^{0.5}$ eliminations, involving at most $4n^{0.5}$ other variables. But then, it must be possible to choose a set of $n^{0.5}/8$ variables that are charged only $2n^{0.5}$ eliminations, each involving two other variables not in the set. But then these $n^{0.5}/8$ variables can be eliminated simultaneously, and hence this type of step need only be performed only $O(\sqrt{n})$ times as well. All inferences will thus be

obtained by the standard algorithm in $O(\sqrt{n})$ steps (consider eliminating a chosen pair last). To obtain a solution, either a value assignment for one variable restricts the values for $n^{0.5}$ others or there are $n^{0.5}$ pairwise unconstrained variables; alternatively, a maximal independent set computation works. □

6.2. Problems with the ability to count. Which problems in CSP do not have bounded width? Say that a constraint-satisfaction problem has *the ability to count* if the following two conditions hold: (1) The template T contains at least the values $0, 1$, as well as a ternary relation C that includes at least the triples $(1, 0, 0)$, $(0, 1, 0)$, and $(0, 0, 1)$, as well as a monadic relation Z that includes at least 0; (2) If an instance consists of only the constraints C and Z, with all constraints partitioned into two sets A and B such that A contains one more C constraint than B, and furthermore each variable appears in exactly two constraints, one from A and one from B, then the instance has no solution.

Intuitively, we can think of $C(x, y, z)$ as $x + y + z = 1$, and of $Z(x)$ as $x = 0$, with an obvious contradiction for instances of the special form, since adding the constraints from A and subtracting those from B yields $0 = 1$. Some problems of this form include linear equations over an abelian group (finite or infinite), where 0 is the identity of the group and 1 is any other element. In particular, this includes the problem for linear equations modulo 2. Another example of such a problem is linear programs over the nonnegative reals. For this last case, inexpressibility in Datalog($\neq$, *succ*) was shown by Afrati, Cosmadakis, and Yannakakis [5] using Razborov's monotone circuit lower bound for matching.

We shall first show that if a constraint-satisfaction problem has the ability to count, then it does not have polynomial size monotone circuits. We begin by citing Razborov's lower bound for matching [46]. In fact, Razborov's lower bound is not just for matching; it applies to any monotone problem such that certain particular instances are "yes" instances, certain other instances are "no" instances, and the remaining instances may be either "yes" or "no." Matching is just a specific application of the result. The exact statement of Razborov's result is the following.

THEOREM 28. *Consider a monotone problem on bipartite graphs such that* (1) *if the instance has a perfect matching, then the answer is "yes," and* (2) *if the instance contains a bipartite connected component with a different number of vertices in the two sides, then the answer is "no." Then monotone circuits for the problem have size* $m^{\Omega(\log m)}$.

The lower bound for matching is thus obtained by requiring a "yes" answer for the instances (1) and a "no" answer for all remaining instances, not just instances (2). The other extreme case is also interesting, namely, the problem that requires a "no" answer for the instances (2) and a "yes" answer for all remaining instances, not just instances (1). This gives a lower bound for systems of linear equations over the integers, the rationals, or the reals, as follows. View a complete bipartite graph with n vertices on each side as an instance with n^2 variables corresponding to the n^2 edges. View each vertex as stating the constraint that the sum of the variables corresponding to edges incident on the vertex is equal to 1. If the bipartite graph is not complete, then each missing edge is viewed as a constraint stating that the corresponding variable is equal to 0. Now if an instance contains a bipartite connected component with k vertices in the left side and k' vertices in the right side, and with $k \neq k'$, then the kk' variables corresponding to the possible edges joining the two sides must add to k according to the left side, and to k' according to the right side, so an instance (2) is indeed a "no" instance. On the other hand, if all connected components have $k = k'$, then we can

pair up the k and k' vertices in the two sides. For each such pair (u, v), there is an odd length path from u to v, so we can assign to the edges on the path the values 1 and -1 in alternation, so that the sum is 1 for edges incident on u, and on v, but 0 for edges incident on all other vertices; doing this for all chosen pairs (u, v) and adding up the values corresponding to the different paths gives a sum 1 for each of the k and k' vertices. So the answer is "yes" for every instance other than (2).

This gives the basic idea for getting a monotone circuit size lower bound on problems that have the ability to count, since both problems just considered have the ability to count. However, the theorem cannot be applied directly for other problems that have the ability to count, such as linear equations modulo 2. Nevertheless, a result just slightly stronger than Razborov's will yield what we need; we just weaken (2) a little bit.

THEOREM 29. *Consider a monotone problem on bipartite graphs such that* (1) *if the instance has a perfect matching, then the answer is "yes," and* (2) *if the instance contains a subgraph not connected to the rest of the graph with one more vertex on the left than on the right, then the answer is "no." Then monotone circuits for the problem have size* $m^{\Omega(\log m)}$.

Proof. Razborov's proof involves a choice of a random bipartite E_- on two vertex sets A and B with m elements each by selecting random subsets $A' \subseteq A$ and $B' \subseteq B$ and linking all vertices in A' to all vertices in B', as well as all vertices in $\overline{A'}$ to all vertices in $\overline{B'}$. The random E_- is used to bound probabilities for three events, namely (stating equations directly from [46]) $P(E_- \in [E]) \geq 2^{-s}$ (30), $P(E_- \in A(f_m)) \leq m^{-1/2}$ (31), and $P(E_- \in S) \leq h(t, r, s, m)$ (32). We replace E_- by an event E' chosen from a smaller space, conditioning on $|A'| = |B'| + 1$ as well as $|(|A'|) - (|\overline{A'}|)| > s$ (the latter for convenience only). Formula (30) measures the probability that a fixed matching of size s will be contained in E_-. To measure this for E', we can first choose $|A'|$ from the appropriate distribution, then assume that A' and B' are fixed while the s edges of the matching are chosen at random. From the assumptions on $|A'|$ and $|B'|$, it is clear that the first of these edges will fall in E' with probability at least $1/2$, and that if this has happened for the first $i-1$ edges, then it will happen for the ith edge with probability at least $1/2$ as well, as long as $i \leq s$. Hence (30) can only become stronger for E'. Formula (31) measures the probability that E_- has a perfect matching, but this probability is zero for E'. Only (32) becomes weaker; an E_- will satisfy the conditioning with probability $\Omega(1/\sqrt{m})$, so for E' the bound increases by a factor of $\sqrt{m}$; this factor carries over to the final $m^{\Omega(\log m)}$ lower bound on monotone circuit size (where it is insignificant). □

This result can now be applied to linear equations modulo q, with $q \geq 2$. Relate linear equations to bipartite graphs as before. If the bipartite graph has a perfect matching, then giving value 1 to the edges in the matching and value 0 to all other edges satisfies the linear equations. If the bipartite graph has a subgraph not connected to the rest of the graph with k vertices on the left and k' on the right, and $k = k' + 1$, then the kk' variables involved must add up to k and to k', yet now $k \neq k'$ holds even modulo q. We are now ready to apply the theorem to any problem with the ability to count.

THEOREM 30. *If a constraint-satisfaction problem has the ability to count, then monotone circuits for it have size* $m^{\Omega(\log m)}$.

Proof. We first represent the complete bipartite graph with n vertices on each side by a bipartite graph with vertices of degree 2 or 3, as follows. Replace every vertex of degree n with a path on $2n-1$ vertices $0, 1, 2, \ldots, 2n-2$, with the n incident edges

attached to the n vertices in even positions, thus achieving the degree constraint. Notice that in a perfect matching, the $n-1$ vertices in odd positions must be matched to $n-1$ out of the n vertices in even positions, leaving exactly 1 vertex in the even position left to be matched to a vertex not on that path. Thus perfect matchings for subgraphs of the complete bipartite graph and perfect matchings for subgraphs of the new graph obtained by removing edges other than those on the paths are in 1-to-1 correspondence. Similarly, subgraphs of the complete bipartite graph with one more vertex in the left side correspond to subgraphs of the new graph obtained by removing edges other than those on the paths, also with one more vertex in the left.

So we have reduced the previous theorem to the case of graphs that are subgraphs of a bipartite graph G with vertices of degree at most 3. Now view each edge as a variable, a vertex with three incident edges x, y, z as a constraint $C(x, y, z)$, and a vertex with two incident edges x, y as a constraint $C(x, y, z)$, where z is an auxiliary variable that is also constrained by $Z(z)$. Removing an edge x not on one of the paths corresponds to adding a constraint $Z(x)$. Clearly, if the graph has a perfect matching, then setting the variables in the matching to 1 and all other variables to 0 gives a solution for the problem with the ability to count. Similarly, if the graph has a subgraph with one more vertex in the left, this gives an instance of the problem with the ability to count that was required not to have a solution. The only technical point here is that removing an edge x incident to two vertices corresponds to having $C(x, y, z)$, $C(x, y', z')$, and $Z(x)$, so x participates in three constraints instead of just two as was required for problems with the ability to count with no solution. However, we can replace x with two variables x, x' constrained by $C(x, y, z)$, $C(x', y', z')$, $Z(x)$, and $Z(x')$, use the fact that the resulting instance has no solution by the definition of the ability to count, and then observe that identifying x and x' cannot make the constraint-satisfaction problem have a solution if it had no solution before identifying x and x'. □

Remark. The idea of obtaining monotone circuit lower bounds for problems that are strictly between the required "yes" and "no" instances was used previously by Tardos [49], who obtained a truly exponential monotone circuit lower bound for the Lovasz θ function, a polynomially computable function strictly between the NP-complete functions maximum clique and chromatic number.

Afrati, Cosmadakis, and Yannakakis [5] showed that if a problem does not have polynomial size monotone circuits, then it is not expressible in Datalog($\neq$, *succ*). Thus problems with the ability to count do not have bounded width. If we just want to show that a problem does not have bounded width, then it suffices to show that it does not have a Datalog (l, k)-program for any fixed l, k. This can be proved more easily via two-player games, by an argument similar again to an argument used by Afrati, Cosmadakis, and Yannakakis [5] for linear programs related to matching.

THEOREM 31. *If a constraint-satisfaction problem has the ability to count, then it does not have bounded width.*

Proof. An instance of the special form with no solution, as in the definition of the ability to count, can be viewed as a bipartite graph with no perfect matching, where the C constraints in A and B are viewed as two vertex sets, and the variables without a Z constraint imposed on them are viewed as edges joining the two vertices in A and B representing the constraints where they occur. Clearly, no perfect matching exists, since there is one more C constraint in A than in B. However, we can construct such an instance of size n such that if two players play the game with l, k about $\sqrt{n}$, where Player I selects edges and Player II indicates whether they are in the matching or

not, then Player II can ensure that if the two or three edges incident on a vertex are ever selected together, then exactly one of them is claimed to be in the matching, corresponding to satisfaction of C. First ignore the degree constraint and consider a complete $k+1$ by k bipartite graph. Then, intuitively, as long as fewer than k edges are currently in the matching, an unmatched vertex can always be matched by Player II. To bound the degree, we replace each vertex of degree d in this graph by a path on $2d-1$ vertices, with the d incident edges attached to alternating vertices in the graph; hence all vertices now have degree 2 or 3. (This last transformation is similar to the one given in the proof of the previous theorem.) Here $|A|$, $|B|$ and the number of variables (edges) are quadratic in k.

Hence rules with about $\sqrt{n}$ variables per rule will be needed to recognize certain instances with no solution on n variables. In the case of abelian groups, we can improve this lower bound to about n. The basic idea is that the complete bipartite graph considered above can be viewed as describing constraints $\sum_j x_{ij} = 1$ for all $1 \leq i \leq k+1$ and $\sum_i x_{ij} = 1$ for all $1 \leq j \leq k$, giving an obvious contradiction $\sum_i \sum_j x_{ij} = 1 + \sum_j \sum_i x_{ij}$. This equation is of the form $\sum_i y_i = 1 + \sum_i y_i$, where the y_i are added in different order on the left- and right-hand sides. If we consider the graph consisting of a path joining the y_i in the order from the left-hand side and another path joining the y_i in the order from the right-hand side, then in the case where the order of summation was exchanged, we essentially have a grid. For a square grid, a bipartition of the vertices into two sets of about equal size must have about $\sqrt{n}$ edges across the bipartition. On the other hand, an expander increases this quantity to about n, e.g., in the case where the order of y_i in the two sides is chosen independently at random. The game played by the two players consists of selecting vertices (variables y_i) and edges (variables representing partial sums); the removal of these may disconnect the graph, and Player II can always ensure that values are assigned so that the connected components with fewer than some constant fraction of the vertices have a solution consistent with the boundary constraints. A contradiction can only be reached by growing such components, but then the fact that the graph is an expander forces the number k of edges out of a sufficiently large component to be about n. We don't know whether such a bound can be obtained in the more general case via matchings. □

Thus, the polynomial solvability of linear equations modulo 2 cannot be explained in terms of Datalog.

It seems possible that the ability to count is the converse of having bounded width. The intuition for this is that the nonexistence of solutions can be attributed to the presence of the same variable in different constraints, something that cannot be remembered by Datalog if these occurrences in two different places are not ordered, and it seems that to keep track of equality of variables in different order one needs the ability to count.

Say that a core T *can simulate* a core T' if for every relation C_i in T' there is an instance S_i that defines on some variables in S_i a relation C_i' over the domain of T whose core is precisely C_i. (Here we can bound $|S_i| \leq |T|^{|C_i|}$.)

We are then saying that it may be that a constraint-satisfaction problem is not of bounded width if and only if it can simulate a problem that has the ability to count.

6.3. Subgroup problems. In this section we study subgroup problems, whose template has as elements the elements of a finite group G, and a relation of arity k in the template must be a subgroup or coset in the direct product G^k. We first show that if a problem gets the ability to count with the two relations $x = 0$ and

$x + y + z = 1$ modulo p, then it can simulate the general subgroup problem for $G = Z_p$. Furthermore, if a set that is not a subgroup or a coset in G^k is added to the general subgroup problem for an abelian G, the problem becomes NP-complete. The natural way to obtain more general problems is to allow nonabelian groups G. Here the subgroup problem with subgroups and cosets in G^k is polynomially solvable. Here again, if a subset is allowed whose projection into some abelian section of G^k is not a subgroup or a coset, the problem can simulate one-in-three SAT and is NP-complete. We call a subset containing the identity 1 whose projection into abelian sections forms subgroups a nearsubgroup. So non-nearsubgroups added to the general subgroup problem for G give NP-completeness. On the other hand, by a result of Aschbacher [3], the intersection of nearsubgroups is a nearsubgroup, so nearsubgroups alone cannot simulate one-in-three SAT and are thus unlikely to give NP-completeness. In fact, we identify a 2-element property, which Aschbacher shows holds for solvable groups, which implies polynomiality for nearsubgroups added to the subgroup problem. We finally identify a weaker nearsubgroup intersection property that also implies polynomiality for nearsubgroups added to the subgroup problem, and here Aschbacher has found no finite group counterexample.

The simplest example of a problem that has the ability to count is the constraint-satisfaction problem whose template is the integers modulo p for some prime p, with two of the relations in the template given by $x = 0$ and $x + y + z = 1$, modulo p. As far as we know, any problem with a finite template that has the ability to count can simulate this problem for some prime p. We wish to study the interaction between these relations on Z_p and other relations in the template. We begin with a simple observation.

THEOREM 32. *Suppose that a problem with template Z_p for p prime contains at least the two relations $x = 0$ and $x + y + z = 1$ modulo p, thus getting the ability to count. Then from these two relations, every relation that is a subgroup or a coset of a subgroup of some power Z_p^k can also be obtained.*

Proof. Every subgroup or coset of a subgroup of Z_p^k is an intersection of sets defined by linear equations $\sum_{i=1}^{k} a_i x_i = b$ modulo p. So it suffices to show that every such linear equation can be obtained. To obtain such a linear equation, it suffices to obtain all equations of the form $x = a$, $y = ax$, and $x + y = z$, modulo p, since every linear equation can be defined by combining these three basic types. In fact, we only need $x = 1$ and $x + y = z$, since $x = a$ is $x = 1 + 1 + \cdots + 1$ and $y = ax$ is $y = x + x + \cdots + x$, with a terms in the sums. To get $x = 1$, just set $x + y + z = 1$, $y = 0$, $z = 0$. To get $x + y = z$, just set $x + y + t = 1$, $z + u + t = 1$, $u = 0$. □

We shall later see that if in addition to all these subgroups and cosets for Z_p and its powers, the template also has a subset of Z_p^k that is not a subgroup or coset, then the constraint-satisfaction problem for that template is NP-complete. Thus if we wish to examine constraint-satisfaction problems that have at least the ability to count modulo p but are not NP-complete, it does not make sense to add new constraints in Z_p. It may still make sense, however, to examine templates where the p elements defining Z_p are only a subset of all the elements. Furthermore, the remaining elements should interact in a natural manner with the p elements defining Z_p, to avoid defining subsets of Z_p^k that are neither subgroups nor cosets. One way of achieving this is to encode Z_p as a problem such as digraph-homomorphism; the encoding adds extra elements to the template, but only defines linear equations modulo p on some p specific elements. This approach, however, does not create a template that is essentially different from Z_p itself, just an encoding of Z_p. There seems to be only one way of obtaining a

template with more than the p elements for Z_p without interfering with the structure of Z_p: simply view Z_p as a subgroup of a larger group, not necessarily abelian, and allow subgroup and coset relations on the larger group. Here we have the following.

Let the general subgroup problem for a finite group G be the constraint-satisfaction problem with template G whose relations are subgroups and cosets of subgroups of G^k. We shall need to bound k by some constant to obtain a finite template, but we will always allow k to be as large as needed for the argument at hand.

THEOREM 33. *The general subgroup problem for a finite group G is polynomially solvable.*

Proof. The result follows immediately from a known algorithm that finds generators for a group obtained by Babai [6] and Furst, Hopcroft, and Luks [21]; see also Theorem II.12 in Hoffmann [31].

The main observation is that, given a group H with known generators and a chain of subgroups $H = H_0 > H_1 > \cdots > H_r = \{1\}$, one can obtain distinct representatives from each coset of each H_i in H_{i-1} as follows. Select two elements x, x' among the generators of H_0 that belong to the same coset of H_1, say, $x' = xy$ with $y \in H_1$; then discard x' and add y to the list of generators. Iterate until there is only one generator in each coset of each H_i in H_{i-1}, and carry out the process for products xy of two current generators as well. The fact that only products of pairs are needed to obtain representatives for all cosets of each H_i in H_{i-1} requires proof; see Theorem II.8 in [31].

In our application, we have n elements that must be assigned values in G, so a solution is an element of $H = G^n$. Each relation in an instance defines a subgroup or more generally a coset a_iJ_i in H, for some subgroup J_i of H, with $1 \le i \le s$ if there are s relations in an instance. Let $H_i = J_1 \cap J_2 \cap \cdots \cap J_i$ for $1 \le i \le s$; then fix each of the n components to 1 successively until $H_r = H_{s+n} = \{1\}$ is obtained. Now obtain representatives for all cosets of each H_i in H_{i-1} using the algorithm above.

To solve the constraint-satisfaction problem, observe that the first relation a_1J_1 is a coset of $H_1 = J_1$ in H_0, so we may select a representative a for this coset from the above representation, and then look for a solution of the form ax with a fixed and x in H_1. Having fixed a, a condition $ax \in a_iJ_i$ now becomes $x \in a^{-1}a_iJ_i = b_iJ_i$. Now we proceed with b_2J_2 and H_2 as we did before for a_1J_1 and H_1. Here it might be that no coset representative b for H_2 in H_1 is in b_2J_2, in which case the problem has no solution. If such a representative b exists, we may again look for a solution of the form by with y in H_2, and proceed as before to $H_3, H_4, \ldots, H_s$. In the end, we just need to select an element of H_s, with no constraints, and we may just take 1.

This gives a polynomial time algorithm because n, r, $|G|$, and $|H_i|/|H_{i-1}|$ are polynomially bounded. □

Labeled graph isomorphism has polynomial time algorithms obtained by the authors mentioned above, and the algorithm described in the preceding theorem is essentially the same as the algorithm of Furst, Hopcroft, and Luks [21] as described in Hoffmann [31]. In labeled graph isomorphism, two graphs have been colored with each color occurring a bounded number of times, and we look for a color-preserving isomorphism. For simplicity, assume that each color occurs in k of the vertices of each of the two graphs. Let G be the group of permutations on $2k$ elements, corresponding to the $2k$ vertices of the same color in the two graphs. The constraint that vertices in one graph map to vertices in the other is a coset in G, while the constraint that adjacent vertices map to adjacent vertices is a subgroup of G for adjacent vertices of the same color, and a subgroup of G^2 for adjacent vertices of different colors.

Thus labeled graph isomorphism can be viewed as a subgroup constraint-satisfaction problem.

Let G be a finite group and consider the general subgroup problem for G. Suppose that we consider adding a nonsubgroup constraint, where we mean a subset of G^k that is neither a subgroup nor a coset. We have stated before that for Z_p, this makes the problem NP-complete. In fact, this is still true for any abelian group G. However, it turns out that for nonabelian groups, it is sometimes possible to include a nonsubgroup constraint and still have a polynomially solvable problem. The key notion turns out to be what we call a *nearsubgroup*; nearsubgroups coincide with subgroups in the abelian case, but not generally for an arbitrary nonabelian group.

Let G be a finite group, and let K be a subset of G such that $1 \in K$. We say that K is a *nearsubgroup* if for all $b \in G$ such that $1 \in bK$, for all subgroups M of G, and for all normal subgroups N of M such that $M^* = M/N$ is abelian, the set $bK^* = \{aN \subseteq M : bK \cap aN \neq \emptyset\}$ is a subgroup of M^*. In other words, the intersections of K with the abelian sections of G form subgroups.

An alternative definition is the following. Let G be a finite group and let K be a subset of G such that $1 \in K$ and if $x, y \in K$, then $xyx \in K$. We call this condition the *cycles condition* because, given that $1 \in K$, it is equivalent to stating that if $b, bx \in K$, then $bx^2 \in K$. Furthermore, this implies that $bx^i \in K$ for all i, thus obtaining a coset $b\langle x\rangle$ of a cyclic group such that $b\langle x\rangle \subseteq K$, where $\langle x\rangle$ denotes the subgroup generated by x. Suppose that K satisfies the cycles condition. If M is a subgroup of G, and N is a normal subgroup of M with M/N isomorphic to $E_4 = Z_2^2$, then there is no $b \in G$ such that $bK \cap M$ meets exactly three of the four cosets of N in M. In this case, K is a nearsubgroup.

It will be useful to consider nearsubgroups with the following stronger 2-*element property*. Here K satisfies the cycles condition, and if S is the set of 2-elements in G, and b is such that $1 \in bK$, then $S \cap \langle S \cap bK\rangle \subseteq bK$. That is, the 2-elements in bK generate a subgroup whose 2-elements are in bK.

Our interest in these notions comes from the following three theorems. A non-nearsubgroup is a bK with $1 \in K$ such that K is not a nearsubgroup.

THEOREM 34. *Let G be a finite group. Consider the general subgroup problem for G. Also include a single subset of G^k for some k that is a non-nearsubgroup. Then the subgroup problem with this additional non-nearsubgroup constraint can simulate one-in-three SAT and is therefore NP-complete.*

Proof. Let bK be the non-nearsubgroup in G^k. We can treat k-tuples as single elements, and so assume that bK is a non-nearsubgroup in G. We can simulate the constraint $x \in K$ by $y = bx$ and $y \in bK$, because $y = bx$ is a coset $(x, y) \in (1, b)H$ where $H = \{(z, z) : z \in G\}$. So K itself is a set in the problem, with $1 \in K$, and not a nearsubgroup.

Suppose that K does not satisfy the cycles condition. If for $y \in K$, we also have $y^{-1} \in K$, then the cycles condition can be restated as $x, y \in K$ implies $xy^{-1}x \in K$. Setting $a = y$ and $az = x$, we have $a, az \in K$ but $az^2 \notin K$; we also have this if $y^{-1} \notin K$ for some $y \in K$, letting $a = y$ and $az = 1$. Furthermore, we can use the set $K' = a^{-1}K$ as a constraint by $x = ay$ and $x \in K$. So we have a constraint set K with $1, z \in K$ but $z^2 \notin K$. We pass to $\langle z\rangle$, the group generated by z, which is Z_n for some n. We wish to obtain a set with just two elements $1, z$ in $Z_k = \langle z\rangle$ for some $k|n$, $k \geq 3$.

We start with K itself and gradually reduce the size of K or the integer n down to a smaller k. If $z^k, z^{k+1} \in K$ for some $k \neq 0$, then $K' = K \cap (z^{-k}K)$ still has

$1, z \in K'$ but with K' strictly contained in K, unless $x \in K$ if and only if $xz^k \in K$, in which case we may pass to the smaller Z_k which is isomorphic to $Z_n/\langle z^k \rangle$. So we may assume that $z^k, z^{k+1} \in K$ only for $k = 0, 1$. If K contains some z^k with $k \neq 0, 1$ relatively prime to n, then we set $K' = K \cap (z^k K^{-1})$, so that $1, z^k \in K'$ but $z \notin K'$, so K' is strictly smaller than K and we may rename z^k as z. Similarly, if K contains some z^k with $k \neq 0, 1$ and $k-1$ relatively prime to n, then we set $K' = K \cap (z^{k+1} K^{-1})$. Therefore $z, z^k \in K'$ but $1 \notin K'$, so K' is strictly smaller than K and we may rename z^k as 1 by a simple transformation. Now, if K contains some z^k with $k \neq 0, 1$ with $k-1$, and k not relatively prime to n, then arguing in the smaller groups generated by z^{k-1} and z^k we may assume that K contains z^{2k} and z^{2k-1}; but this is only possible if $2k - 1 = n$, contrary to the assumption that k is not relatively prime to n.

So we may indeed assume that K contains precisely $1, z$ in $Z_n = \langle z \rangle$ with $n \geq 3$. Now consider $x, y, t \in K \cap Z_n$ with the coset constraint $xyt = z$. Then one of x, y, t is z and the other two are 1, thus defining one-in-three SAT and giving NP-completeness.

For the other case, suppose that K meets exactly three of the four cosets of N in M. We may then pass to $E_4 = M/N = \{1, a, b, ab\}$ and assume $K = \{1, a, b\}$. Then consider $x, y, z \in \{1, a\}$ with $xyz = a$, which are all subgroup and coset constraints; furthermore, add $t \in \{1, b\}$ with $(x, t) \in \{(1, 1), (a, b)\}$, which are still subgroup constraints. Finally, $yt = u$ with $u \in K$. Then one of x, y, z is a and the other two are 1, again defining one-in-three SAT and giving NP-completeness. □

THEOREM 35. *Let G be a finite group. Consider the general subgroup problem for G. Include also any number of subsets bK of G^k, where the sets K are nearsubgroups. Then the subgroup problem with these additional nearsubgroup constraints cannot simulate one-in-three SAT (and is thus unlikely to be NP-complete).*

Proof. Since the intersection of nearsubgroups is a nearsubgroup by a result of Aschbacher [3], it suffices to show that a single one-nearsubgroup K of G^3 cannot represent the one-in-three SAT relation via some cK. Suppose that it does, so that cK contains three elements (a, b, b), (b, a, b), (b, b, a) with $a \neq b$. We may assume $b = 1$, and then multiply by $(a^-1, 1, 1)$, so the three triples are $(1, 1, 1)$, $(a^-1, a, 1)$, and $(a^{-1}, 1, a)$ in K. But the product (a^-2, a, a) of the last two is also in K since the last two also commute, so we have a triple (a^{-1}, a, a) together with $(a, 1, 1)$, $(1, a, 1)$, $(1, 1, a)$. That is, the core will still contain some (x, a, a) for $x = 1$ or $x = a$, which does not define one-in-three SAT. □

Consider now a problem whose constraints are subsets of G^k containing the identity element 1; the only constraints that do not contain 1 are single-element subsets $\{a\} \in G$. If every such a is of odd order, we call this the *odd problem* for G. If every such a is of order a power of 2, we call this the 2-*element problem* for G.

THEOREM 36. *Consider a problem on a finite group G with arbitrary constraints. This problem reduces to the odd problem and the 2-element problem together, with constraints aR corresponding to the constraints R in the original problem. Furthermore,* (1) *the odd problem reduces to the subgroup problem for G if all constraints satisfy the cycles condition*; (2) *the 2-element problem reduces to the subgroup problem for G if all constraints K satisfy $S \cap \langle S \cap K \rangle \subseteq K$, where S is the set of two elements, and also $\langle x \rangle \in K$ for $x \in K$. Therefore, the problem for G with nearsubgroup satisfying the 2-element property reduces to the subgroup problem for G and is thus polynomially solvable.*

Proof. The first step takes arbitrary constraints on G and reduces them to odd problems and 2-element problems. The basic idea is that if we have r constraints,

and s of them already contain the identity element 1, then we shall force one more of these constraints to contain 1. Repeating this step eventually forces all constraints to contain 1, and then 1 is a solution. Let K be the chosen set not containing 1, and ignore the remaining $r-s-1$ constraints. For $K \subseteq G^k$ itself, we may just try each of the possible values for k variables involved. Suppose we just consider them one at a time. We have thus reduced the problem to a problem where all constraints contain 1 except for a single constraint that assigns a value to a single variable. If this constant is of odd order or of order a power of two, we have an odd problem or a 2-element problem, respectively. If this constant is of order rs, with r odd and s a power of 2, then it can be written as (a, b) in $Z_r \times Z_s$, where a generates Z_r and b generates Z_s. We initially replace b with a variable constrained to Z_s, so we only have the odd order constant a, and hence an odd problem. After solving the odd problem, we obtain a solution s, and we may look for a solution of the form sx. This means that in $Z_r \times Z_s$ we want the element $(1, s_i^{-1}b)$, and this is now a 2-element problem.

It remains to reduce the odd problem and the 2-element problem to the subgroup problem in the cases mentioned in the theorem. We first consider the odd problem, where the constraints are subsets K of G^k containing 1 and satisfying the cycles condition. Additional constraints just assign a single odd order value to a variable. We replace each variable with two variables. If K is a subset of G^k, we replace it with the subgroup H of G^{2k} generated by the pairs (x, x^{-1}) in K. If a is a single odd order constant, we replace it by the pair $(a^{\frac{1}{2}}, a^{-\frac{1}{2}})$, where $a^{\frac{1}{2}}$ denotes $a^{\frac{r+1}{2}}$, r being the order of a. After a solution is found for the resulting subgroup problem, we replace each pair (x, y^{-1}) in the solution by the product xy to obtain a solution for the original problem. If the original problem had a solution, we could choose s a power of 2 such that $x^s = x$ for odd order elements x and x^s has odd order for all x. Raising the solution to the power s gives an odd order solution t, and we may use the pair $(t^{\frac{1}{2}}, t^{-\frac{1}{2}})$ as a solution to the new problem. Conversely, if the new problem has a solution, then the odd constant pairs $(a^{\frac{1}{2}}, a^{-\frac{1}{2}})$ give the right product value a. Furthermore, a pair (x, y^{-1}) in H can be written as $(x_1 x_2 \cdots x_k, x_1^{-1} x_2^{-1} \cdots x_k^{-1})$ with the x_i in K, and then $xy = x_1 x_2 \cdots x_k x_k \cdots x_2 x_1$ is in K by the cycles condition, as desired.

For the 2-element problem, the constraints are subsets K of G^k containing 1 and satisfying the condition $S \cap \langle S \cap K \rangle \subseteq K$. Additional constraints just assign a single 2-element value to a variable. The main point is that the set K and the subgroup $\langle S \cap K \rangle$ are indistinguishable as far as their 2-elements are concerned, i.e., $S \cap \langle S \cap K \rangle = S \cap K$. So we replace the set K with the subgroup $\langle S \cap K \rangle$ and insist for either problem that the solution consist of 2-elements. As before, we can choose r odd such that $x^r = x$ for 2-elements x and x^r is a 2-element for all x; raising a solution to either problem to the power r guarantees that the solution is a 2-element, as desired. □

Summarizing, non-nearsubgroups give NP-completeness, nearsubgroups give non-NP-completeness unless the reduction is not a simulation of one-in-three SAT, and nearsubgroups with the 2-element property give polynomiality by a reduction to the subgroup case.

We first showed that nearsubgroups are the same as subgroups in the abelian case. We moved on to the nonabelian case, and still showed that nearsubgroups are the same as subgroups for 2-groups. This led us to consider the case of odd order groups, where we encountered a nearsubgroup that is not a subgroup: the elements are triples from Z_p with product operation $(i, j, k)(i', j', k') = (i + i' + jk', j + j', k + k')$

and the nearsubgroup K consists of the elements of the form $(\frac{1}{2}jk, j, k)$. For odd order groups, nearsubgroups immediately satisfy the 2-element property. From this we inferred that for groups that are the product of a 2-group and an odd order group, in particular for nilpotent groups, nearsubgroups satisfy the 2-element property, and so the constraint-satisfaction problem for nearsubgroups is polynomially solvable.

We then asked whether it might always be the case that nearsubgroups satisfy the 2-element property, so that the constraint-satisfaction problem for nearsubgroups is polynomially solvable. Aschbacher found a counterexample, where $K = I$ is the set of involutions (elements of order 2) plus the identity element 1, in a rank-1 simple Lie group of even characteristic with at least one element of order 4.

Because of this example, we considered the case of groups with no element of order 4 and showed for such groups that when the 2-Sylow subgroups have at most four elements, then nearsubgroups satisfy the 2-element property; Aschbacher [3] proved a general theorem that implies that nearsubgroups satisfy the 2-element property for all groups with no element of order 4. Since all groups where we had previously shown that nearsubgroups satisfy the 2-element property are solvable, and Aschbacher's counterexample is not a solvable group, we asked whether there might be any counterexample for solvable groups. Here we could understand the case of a dihedral group, $\langle a, b\rangle$, with $a^2 = b^n = 1$ and $ab = b^{-1}a$; then the only nearsubgroups that are not necessarily subgroups are given for r, s dividing n by the elements of the form b^{ir} and ab^{js}, provided that the same power of 2 divides r and s. Aschbacher showed that nearsubgroups satisfy the 2-element property for solvable groups. Finally, since it is not possible to simulate one-in-three SAT and obtain NP-completeness with nearsubgroups alone, we asked whether nearsubgroups could give a non-nearsubgroup by intersection. Aschbacher showed that this is not possible—the intersection of nearsubgroups is a nearsubgroup.

Summarizing our findings and those of Aschbacher [3], we state the following theorem.

THEOREM 37. *Let G be a finite group.*

(1) *If G is abelian, or a 2-group, then its nearsubgroups are subgroups.*

(2) *Let I be the involutions plus 1. If G has two involutions whose product has order 4, then I is not a nearsubgroup. Otherwise, I is a nearsubgroup. If in addition I generates no element of order 4, then I satisfies the 2-element property; otherwise it does not. There exist groups G that meet this condition for I being a nearsubgroup but not satisfying the 2-element property.*

(3) *If G has no element of order 4, or if it is solvable, then its nearsubgroups satisfy the 2-element property.*

(4) *The intersection of nearsubgroups is a nearsubgroup.*

The fact that there are finite groups G with nearsubgroups that do not satisfy the 2-element property, such as the ones in (2) above, creates an interesting situation. Consider the nearsubgroup problem for G. We know that this problem cannot simulate one-in-three SAT, and is thus unlikely to be NP-complete. On the other hand, only nearsubgroups with the 2-element property seem to be transformable into subgroups so as to obtain a subgroup problem, so the problem might not be polynomially solvable. This is our best candidate for a constraint-satisfaction problem that might be neither polynomially solvable nor NP-complete.

On the other hand, we have identified a property, the *nearsubgroup intersection property*, that would imply that the problem with nearsubgroups is polynomially solvable. We know of no counterexamples to the nearsubgroup intersection property,

and it is implied by the 2-element property. The nearsubgroup intersection property is as follows. Let G be a finite group with a subgroup H of index 2. Then there exists an element g in $G \setminus H$ such that g belongs to every nearsubgroup K of G such that the 2-elements in the intersection of K^* and $G^* \setminus H^*$ generate G^*. Here $G^* = G/N$, where N is some normal subgroup of G (dependent on K) such that H contains N, kN is contained in K for every k in K, and H^*, K^* are the corresponding induced subsets of G^* obtained from H, K. The *weak nearsubgroup intersection property* considers only nearsubgroups K with $N = 1$. That is, for a finite group G with a subgroup H of index 2, there exists an element g in $G \setminus H$ such that g belongs to every nearsubgroup K of G such that the 2-elements in the intersection of K and $G \setminus H$ generate G. The following theorem can be proved using the weak nearsubgroup intersection property; we have chosen to use the stronger definition because it leads to a simpler proof and algorithm.

THEOREM 38. *Suppose that the nearsubgroup intersection property holds. Then the 2-element problem is polynomially solvable for nearsubgroups, and therefore the problem for nearsubgroups is polynomially solvable.*

Proof. We have already shown that to solve the problem with nearsubgroup constraints, it is sufficient to solve the 2-element problem. In the 2-element problem, we have a space which is the direct product of groups $G_1, G_2, \ldots, G_n$, where $G_1 = \langle r \rangle$ is a group generated by a 2-element r (we would like to obtain this element r in a solution), and all constraints are nearsubgroups of the direct product of a bounded number of G_i. Call G the product of all the G_i, and let H be the subgroup of index 2 obtained by replacing G_1 with $G_1' = \langle r^2 \rangle$. If we can obtain a solution g in $G \setminus H$, this solution will have r^{2i+1} in G_1, and then a solution having r itself can be easily obtained since $r = (r^{2i+1})^j$ for some j. So suppose we are looking for a solution g in $G \setminus H$. Consider the first nearsubgroup constraint K, which constrains, say, the direct product of the first k groups G_i. Call N the product of the remaining G_i. By taking the factor group defined by N, we move to G^* and obtain H^* and K^*. It is then sufficient to look for a solution in the group generated by the 2-elements in the intersection of K^* and $G^* \setminus H^*$. This gives a subgroup of G, and we may obtain generators for this subgroup. By carrying out this process of further restricting G by considering each nearsubgroup constraint K in turn, we obtain a decreasing chain of subgroups (we may need to look at the same nearsubgroup more than once; this process is similar to how the subgroup problem was solved). If at the end of this process, the subgroup H still has index 2 in G, then the nearsubgroup intersection property guarantees the existence of a solution with all nearsubgroup constraints. To actually find such a solution, we may successively fix the values in $G_2, G_3, \ldots, G_n$ and test that H still has index 2, until we find a complete solution. □

7. Conclusions and further directions. Every known polynomially solvable problem in CSP can be explained by a combination of Datalog and group theory. In fact, only three specific cases combine to give all known polynomially solvable problems. The three cases are width 1, bounded strict width, and subgroup problems.

These three cases have something in common, which is best illustrated by the following characterizations, where we also include a fourth case where the template is over the reals.

(1) A problem has width 1 if and only if there is a function f that maps nonempty subsets of the template to elements of the template, such that for every relation R in the template, of arity k, the following holds. Let $S_1, S_2, \ldots, S_k$ be subsets with the property that for every x_i in S_i, there exist x_j in S_j for $j \neq i$ such that $(x_1, x_2, \ldots, x_k)$

is in R. Then $(f(S_1), f(S_2), \ldots, f(S_k))$ is in R. The case of extended width 1 is slightly more general, because it only considers a fraction of the subsets of the template. The existence of solutions can also be described in terms of tree duality.

(2) A problem has strict width l if and only if there is a function g that maps $(l+1)$-tuples from the template to elements of the template, such that for every relation R in the template, of arity k, the following holds. First, if all but at most one of some $l+1$ elements x_i are equal to some specific element x, then $g(x_1, x_2, \ldots, x_{l+1}) = x$. Second, let x_{ij} be elements with $(x_{1j}, x_{2j}, \ldots, x_{kj})$ in R for every j. Then $(g(x_{11}, x_{12}, \ldots, x_{1(l+1)}), g(x_{21}, x_{22}, \ldots, x_{2(l+1)}), \ldots, g(x_{k1}, x_{k2}, \ldots, x_{k(l+1)}))$ is in R. The existence of solutions can also be described in terms of the Helly property.

(3) A problem is a subgroup problem if and only if we can define a group operation on the elements of the template such that for every relation R in the template, of arity k, the following holds. If the three tuples $(b_1, b_2, \ldots, b_k)$, $(b_1x_1, b_2x_2, \ldots, b_kx_k)$, $(b_1y_1, b_2y_2, \ldots, b_ky_k)$ are in R, then the tuple $(b_1x_1y_1, b_2x_2y_2, \ldots, b_kx_ky_k)$ is also in R. This means that R is a coset of a subgroup of G^k. The case of nearsubgroups can be viewed as mapping b, bx, by into $bxyz$, rather than into bxy, where z is an element of the commutator group of the subgroup generated by x and y. The algorithm that finds solutions depends on the fact that when G acts on itself every subgroup defines a partition into cosets; we do not know whether a partition theory can also be developed for nearsubgroups.

(4) Convex programming, a constraint satisfaction problem over the reals solvable in polynomial time with the ellipsoid method, has the property that if $(x_1, \ldots, x_k)$ and $(y_1, \ldots, y_k)$ are both in some convex set, then so is $(h_\alpha(x_1, y_1), \ldots, h_\alpha(x_k, y_k))$, where $h_\alpha(x, y) = \alpha x + (1 - \alpha)y$ and $0 \leq \alpha \leq 1$. Here convex programming duality is of interest in the study of solutions.

These four characterizations are all *closure properties*; i.e., there exists a function (f, g, group operation, or h_α) such that every relation R in the template is closed under componentwise application of the function. Furthermore, there is always an associated structure theory for the study of the existence of solutions (tree duality, Helly property, coset partition, convex programming duality, respectively). Schaefer [48] used such closure properties when he classified the polynomially solvable and NP-complete problems in Boolean CSP. He was thus in a sense showing that Horn clauses, 2SAT, and linear equations modulo 2, the three polynomially solvable cases, are width 1, strict width 2, and subgroup, respectively. We do not know whether polynomial solvability for CSP is always necessarily tied to a closure property.

The algorithmic significance of these closure properties is an interesting question. For problems of width 1, the f mapping is not needed to solve the problem in polynomial time, but can be used to obtain a solution directly once the Datalog program has found nonempty sets associated with each variable. For problems of strict width l, once the Datalog program has found nonempty sets associated with l-tuples of variables satisfying the Helly property, the g mapping can be used to obtain a solution efficiently in parallel. There are, however, problems where the f and g mappings help find fast algorithms without running the Datalog program. Here the following results from Feder and Hell [18] are good examples. The connected list problem for reflexive graphs is polynomially solvable for chordal graphs, and NP-complete otherwise. For chordal graphs, this problem has width 1. By using the perfect elimination ordering for perfect graphs, a fast parallel algorithm can be found for this problem, and here the f mapping is based on the existence of a perfect elimination ordering. Similarly, the arbitrary list problem for reflexive graphs is polynomially solvable for

interval graphs, and NP-complete otherwise. For interval graphs, this problem has strict width 2. By using the interval representation for interval graphs, a reduction to 2SAT can be found for this problem, giving again a fast parallel algorithm. Here the g mapping is based on the existence of an interval representation. Thus the f and g mappings can help understand the structure of a problem and lead to fast parallel algorithms. For subgroup problems, the situation is more drastic: we do not know of any algorithm that does not involve finding generators, and here the group operation is used directly.

This raises an important question. For subgroup problems, the set of solutions has a polynomial number of generators. This means that there exists a polynomial number of solutions such that if we take the closure under the mapping that maps s, sx, sy to sxy, then we obtain all solutions. Now we may ask whether there exist a polynomial number of generators for the width 1 and bounded strict width cases, when closure under f and g mappings is considered. We first study the bounded strict width case. Here there does exist a polynomial number of generators; namely, if a problem has strict width l, then for each choice of l variables $x_1, x_2, \ldots, x_l$, determine the assignments of values to these variables for which a solution exists, and choose one solution for each assignment. This produces at most n^l generators. To see that these are generators, suppose that we have a solution and consider the values it assigns to $l+1$ variables $x_1, \ldots, x_{l+1}$. For each choice of a variable x_i, there exists a generator that assigns the correct value to the remaining x_j, but not necessarily to x_i. Find $l+1$ such generators, one for each i, and then applying the g mapping to them will assign the correct value to the $l+1$ variables. Inductively, we can then obtain the correct assignment for all variables. Now consider the width 1 case. Here we write $f(S) = t$ for a set of solutions S and a solution t if for each variable x_i, letting S_i be the set of values taken by x_i in S, and letting t_i be the value of x_i in t, we have $f(S_i) = t_i$. In general, the number of generators needed for this f mapping is exponential. For Horn clauses, with $f(\{0\}) = 0$, $f(\{1\}) = 1$, and $f(\{0,1\}) = 0$, the mapping $f(S) = t$ corresponds to set intersection. Even for independent set, a special case of Horn clauses, the set of generators with the f mapping must contain at least the maximal number of independent sets, and there can be an exponential number of them. Independent set, on the other hand, is also a special case of 2SAT, and the number of generators with the g mapping is polynomial. For linear programming, the generators with the h_α mappings are the vertices of the polytope, and there can be an exponential number of them. Notice now that Horn clauses and linear programming are in general P-complete, while neither bounded strict width problems nor subgroup problems seem to be P-complete; it might be that P-completeness is tied to the nonexistence of a closure property that allows for a small (polynomial or at least nonexponential) set of generators.

Our attempt to classify the problems in CSP and establish a dichotomy is based on the following two conjectures.

CONJECTURE 1. *A constraint-satisfaction problem is not in Datalog if and only if the associated core T can simulate a core T' consisting of two relations C, Z that give the ability to count. This is equivalent to simulating either Z_p or one-in-three SAT.*

CONJECTURE 2. *A constraint-satisfaction problem is NP-complete if and only if the associated core T can simulate a core T' consisting of the single relation C defining one-in-three SAT.*

The first conjecture indicates a sharp line out of Datalog and into group theory:

since one-in-three SAT can simulate Z_2, and, when the two linear equations $x = 0$, $x + y + z = 1$ modulo p give the ability to count, then every linear equation modulo p can be simulated, it follows that the conjecture basically says that a problem not in Datalog is at least as powerful as the general subgroup problem for Z_p.

So we assume that a template not in Datalog contains at least the general subgroup problem for Z_p. We then move on to the second conjecture, which indicates a sharp line into NP-completeness. We thus try to determine what can make a problem that can simulate Z_p able to simulate one-in-three SAT, and thus NP-complete. We first observe that on the p elements that simulate Z_p, any relation that is not a subgroup or a coset in a power of Z_p makes it possible to simulate one-in-three SAT. It is thus not possible to interfere with Z_p itself and avoid NP-completeness. This suggests that the only way to enlarge the Z_p problem and still obtain a problem that cannot simulate one-in-three SAT may be to view Z_p as a subgroup of a larger, not necessarily abelian, group. It seems that any other approach to extending Z_p would simply combine Z_p with other problems without interfering with Z_p itself, either by taking the product of Z_p with another problem or by encoding Z_p in a special class such as digraph-homomorphism.

Suppose then that we have the general subgroup problem for a finite group, which is still polynomially solvable. It is no longer true that adding a nonsubgroup makes it possible to simulate one-in-three SAT. We can show that adding a non-nearsubgroup makes it possible to simulate one-in-three SAT. So we only allow nearsubgroups. The intersection of nearsubgroups gives nearsubgroups. So nearsubgroups do not make it possible to simulate one-in-three SAT, which by the second conjecture would mean that adding nearsubgroups to a subgroup problem cannot make the problem NP-complete. We can show that if we restrict our attention further to nearsubgroups with the 2-element property, then nearsubgroups can be replaced with related subgroups, and the resulting problem reduces to subgroup problems and is thus polynomially solvable.

But then nearsubgroups have the 2-element property for many groups, including solvable groups and groups with no element of order 4, by results of Aschbacher [3]. It may then be that a subgroup problem always remains polynomially solvable when we add nearsubgroups. However, Aschbacher identifies a group with a nearsubgroup that does not have the 2-element property. It does not seem possible to represent this nearsubgroup as a subgroup, so the problem does not immediately reduce to a subgroup problem, although it still contains the general subgroup problem for the chosen group; this may mean that the problem is not polynomially solvable. On the other hand, the fact that nearsubgroups cannot simulate one-in-three SAT may mean that the problem is not NP-complete.

We thus have our best candidate for a problem in CSP that may be neither polynomially solvable nor NP-complete, which is the following. Consider the general subgroup problem for a finite group and focus on the set of involutions, including the identity, which we wish to add as a new constraint. If some element of order 4 is the product of two involutions, then involutions are not a nearsubgroup and the problem is NP-complete. Otherwise, the involutions are a nearsubgroup. If no element of order 4 is generated by involutions, then the involutions have the 2-element property, and the problem is polynomially solvable. Otherwise, the involutions do not have the 2-element property. Aschbacher observed that there are such finite groups, where the involutions form a nearsubgroup without the 2-element property. Could it be that for such groups the involutions define a problem that is neither polynomially solvable

nor NP-complete? On the other hand, the following may hold.

CONJECTURE 3. *The nearsubgroup intersection property holds for all finite groups. Therefore, the constraint-satisfaction problem with nearsubgroup constraints is polynomially solvable.*

This is the current state of the attempt to classify the problems in CSP and obtain a dichotomy. Considering the three main conjectures, it may be that there is a direct approach towards proving the first one, concerning the ability to count. One might start by showing that if a subgroup problem does not have the ability to count, then it can be solved with Datalog, beginning with abelian groups. Similarly, one could consider linear programming, a constraint-satisfaction problem over the reals that gets the ability to count by representing bipartite matching or linear equations, and show that if a linear programming template does not have the ability to count, then it can be solved with Datalog.

The second conjecture cannot be approached directly, as we cannot show non-NP-completeness without showing P≠NP. It might still be possible to show that if a CSP problem cannot simulate one-in-three SAT, then it belongs to a class that is unlikely to contain NP-complete problems, such as co-NP; this would establish a dichotomy, namely, NP-complete versus in NP∩co-NP. An approach along these lines was successful in showing that graph isomorphism is not NP-complete unless the polynomial hierarchy collapses. The approach there was via interactive proofs for graph nonisomorphism; interactive proofs have already been shown to be relevant in the study of constraint satisfaction problems; see [20, 7].

It might be possible to answer the third conjecture with the theory of nearsubgroups as studied by Aschbacher [3].

A basic question remains open. Find a deterministic construction of small graphs of high chromatic number and high girth, in particular with the size of the graph polynomial in the chromatic number, with the girth lower-bounded by a constant. This would help derandomize the reduction between equivalent MMSNP and CSP problems.

The class NP consists of all problems expressible by an existential second-order sentence with an arbitrary first-order part (see [14]; the first-order part need not be universal, as for SNP). What is the complexity of problems in *MMNP*, the class *monotone monadic NP without equality or inequality*?

Appendix: Constraint satisfaction and link systems. In his paper "Process, system, causality, and quantum mechanics" [12], Etter proposes link systems as a unifying framework for i-o systems, Markov processes, and quantum mechanics; he also suggests that link systems provide an interpretation for relativity and for relational databases. In this paper, we have proposed constraint satisfaction as a unifying framework for problems that can be solved with Datalog, such as Horn clauses and 2-satisfiability; for NP-complete problems, such as 3-coloring and one-in-three-satisfiability; for problems from group theory, such as systems of linear equations and labeled graph isomorphism; for linear programming, graph matching, and a family of matroid parity problems; and for network stability and stable matching.

In this Appendix we intend to expose a direct connection between constraint satisfaction and link systems, so that this work and the work of Etter may benefit from each other.

A *link system* is a stochastic process on a set of random variables $x_1, x_2, \ldots, x_n$, together with a set of *links*. A link is a condition of the form $x = y$ on two variables x and y of a stochastic process, thereby creating a new process in which the uncondi-

tional probability $p(E)$ of any event E is $p(E|x = y)$ in the old process. The duplicate variable y is then dropped.

A *proper link system* is a link system in which all links are between different independent parts of the stochastic process, and no two links involve the same variable. Etter is primarily interested in proper link systems.

A *white variable* is a random variable with a uniform distribution. An *i-o system* is a link system where every link is of the form $x = w$ and where w is a white variable, with x and w independent. Notice that when the process is conditioned on $x = w$, so that x and w are linked and w is dropped, the distribution of x in the resulting stochastic process is the same as in the original process, because w is white.

Suppose that x and y are independent random variables. Then the probability that x and y will both have some value k is the product of the probabilities that they will have value k separately, i.e., $p(x = y = k) = p(x = k)p(y = k)$. Let's call $p(x = k)$ and $p(y = k)$ the *unlinked* probabilities of x being k and of y being k. Now suppose we impose the link condition $x = y$. The *linked* probability is then the probability, conditioned by $x = y$, that both $x = k$ and $y = k$. The probability that x is k, as a function of k, is proportional to $p(x = k)p(y = k)$.

In short, linked probabilities are always quadratic in unlinked probabilities. If the distributions of x and y are identical, which is the quantum situation, then linked probabilities are the squares of unlinked probabilities. That is, quantum amplitudes are simply unlinked probabilities, which explains the square root law. The main additional element that appears in quantum mechanics is that probability theory must be extended by allowing cases to count negatively. Much of the trouble that we have when looking for an interpretation of quantum mechanics is that we are looking for an i-o system, where one of the two linked variables is white, when instead it is the case that the two variables are identically distributed.

This is in essence a summary of some of the basic ideas in Etter's paper. He also shows that the velocity law of relativity, which adds velocities as $(v + v')/(1 + vv')$, where the speed of light is 1, can be viewed as linking two variables x and x' corresponding to coin tosses, where the velocity is the probability of heads minus the probability of tails.

In a second paper, "Quantum mechanics as a branch of mereology" [13] Etter proposes an approach to link systems from relational databases instead of probability theory. The word *mereology* means the mathematical theory of parts and wholes. The idea is to use the record count for database tables instead of probabilities. Linking is then defined in the usual sense for combining tables in relational databases. For example, let A be a two-field table with record count $A(x, y)$ and let B be another two-field table with record count $B(y, z)$. When A and B are linked at y to obtain a three-field table, the record counts multiply, giving record count $A(x, y)B(y, z)$ for the entry given by the triple x, y, z. When we hide the linked field y, we obtain a two-field table C, adding the record counts over y, so the record count is $C(x, z) = \sum_y A(x, y)B(y, z)$. In short, when A, B, C are viewed as matrices, we have $C = AB$. That is, linking is intimately tied to matrix multiplication. Etter uses this connection to examine the two core laws of quantum mechanics, the Born probability rule and the unitary dynamical law (whose best-known form is Schrödinger's equation), formulated by von Neumann in the language of Hilbert space in terms of matrices as $\text{prob}(P) = \text{trace}(PS)$ and $S'T = TS$, respectively. Etter observes that the algebraic forms of these two core laws occur as completely general theorems about links.

We now turn to the connection with constraint satisfaction. Given an instance

I of constraint satisfaction, suppose we create an auxiliary instance I' where every variable in I has been replaced by many variables, so that every variable occurs in precisely one constraint. The instance I' always has a solution, namely, satisfying each constraint separately. Now view I' as a stochastic process, by requiring for each constraint $(x_1, \ldots, x_k) \in R$ that the variables x_i be distributed so as to give a uniform distribution over the satisfying assignments for R. Now I can be viewed as the system obtained from I' by linking the many variables that came from the same variable. The resulting distribution is then the uniform distribution over the set of satisfying assignments to the instance I.

This is in essence the connection between constraint satisfaction and link systems. We may then ask what part of the framework of Etter makes sense in the context of constraint satisfaction. A first observation is that the use of Datalog allows for rules such as $C(x, z)$:–$A(x, y), B(y, z)$. When conjunctions and disjunctions are replaced by multiplication and addition, respectively, the rule becomes $C(x, z) = \sum_y A(x, y)B(y, z)$, which we saw arises in link systems.

Consider next the network stability problem. Here the constraints are gates; i.e., they involve $k+l$ variables via a functional constraint $f(x_1, x_2, \ldots, x_k) = (y_1, y_2, \ldots, y_l)$. In the instance I', prior to the linking, the x_i variables are independently and uniformly distributed. All the links are of the form $y = x$, matching an output y to an input x, where the input x is uniformly distributed, and hence a white variable. Therefore, network stability is just an i-o system, in Etter's terminology. Stable matching is known to be the special case of network stability where all variables are Boolean and all gates are the X gate $X(x_1, x_2) = (x_1\overline{x_2}, x_2\overline{x_1})$, in addition to the constant generating gates with $k = 0$ and $l = 1$, as well as the absorption gate with $k = 1$ and $l = 0$. For every network there is an underlying digraph, namely, the digraph with a vertex for every constraint C, and a directed edge from C to C' if an output of C is an input to C'. This digraph need not be acyclic in general and, for example, stable matching problems give digraphs that are usually not acyclic. Then the network stability may not have any solutions or more than one solution. When the digraph is acyclic, the network is called a circuit, and there is then a unique solution obtained by evaluating the gates in the order in which they appear in the digraph.

Notice that in the case of network stability, variables occur in disjoint linked pairs, as in Etter's proper linked systems. In general, we have not made the assumption that every variable occurs in precisely two constraints in this paper. Without this assumption, we have conjectured that the constraint-satisfaction problems are either solved with Datalog or have the ability to count; in the latter case, we either have linear equations or one-in-three satisfiability. Suppose we make the same conjecture in the case where every variable occurs in precisely two constraints; then one-in-three satisfibility becomes a polynomially solvable problem, namely, graph matching.

In fact, graph matching generalizes to a family of matroid parity problems as a constraint-satisfaction problem with the property that every variable occurs in only two constraints. To see this assume that each relation in the template is a matroid. Then all relations occurring in an instance form a single matroid that decomposes into a collection of small matroids—one for each relation. The constraints that pair up the variables define a matroid parity problem. Notice that the bases exchange property acts once again as a closure property. By limiting the number of relations involving a single variable, we are in essence limiting fanout. In the case of network stability, every variable occurs in one relation as an input and in one relation as an output. This limits fanout unless we have a copy gate $f(x) = (x, x)$ that creates fanout. Mayr

and Subramanian [39] observed that in the Boolean case, forbidding such a copy gate gives rise precisely to the adjacency-preserving case. In the case where the relations are arbitrary, not necessarily gates, the constraint that each variable appear in only two constraints limits fanout unless we have a copy relation $R(x, x, x)$ that creates fanout. Here we observe that in the Boolean case, if we consider only relations where all tuples have the same number of zeros and the same number of ones, then forbidding such a copy relation gives rise precisely to the matroid parity problems just described. It is also interesting whether limiting fanout has relevance in the quantum context, as suggested by applications in quantum cryptography.

Now let us look at the definition of the ability to count in detail. This definition involves a system I' consisting of two disjoint parts A and B that do not share any variables; and the links that produce I involve a pair of variables, one from A and one from B, with each variable participating in exactly one pair. This is precisely the main case of interest for Etter, where removing the links disconnects the system into two independent parts A and B.

Finally, when we looked at group-theoretic problems, specifically in the odd order problem, we saw that to turn the nearsubgroup problem into a subgroup problem, each variable x had to be replaced by a pair $(x^{1/2}, x^{-1/2})$. That is, just as in quantum mechanics, we have a square root law. It would be interesting to see whether the fact that a square root law arises in group theory is not a coincidence, since group theory has central importance in quantum mechanics. In fact, could it be that nearsubgroups have some interpretation in quantum physics?

Etter has observed that, given that constraint satisfaction is the problem of mapping a structure S to a fixed template T, it makes sense to exchange the roles of S and T and to look for a homomorphism from T to S. He has observed that this duality has something in quantum mehanics that seems related to this strange reversal, which is the Foch-space representation of the wave-particle duality that reverses the role of vector and tensor components in Hilbert space. He suspects that duality will turn out to be a key concept for unifying quantum mechanics with relativity. In the context of constraint satisfaction, the simplest example of this form of duality is the case where the template is a clique K_r on r vertices. Mapping S to K_r is the problem of coloring a graph with r colors, while mapping K_r to S is the problem of whether a graph has a clique of size r.

Acknowledgments. We benefitted greatly from early discussions with Yatin Saraiya and with Peter Winkler. Christos Papadimitriou suggested the connection between constraint satisfaction and two problems with a fixed structure that were previously studied, graph-homomorphism and the Boolean domain case. Milena Mihail suggested that quasi-random graphs may derandomize the representation of monotone monadic SNP in CSP. Tom McFarlane showed us the paper of Tom Etter on link systems. We also had very valuable conversations with Miki Ajtai, Michael Aschbacher, Yossi Azar, Laszlo Babai, Ron Fagin, Jim Hafner, Pavol Hell, Rajeev Motwani, and Moni Naor. The comments of two anonymous referees were very helpful in the final writing of this paper.

ASYMPTOTICALLY TIGHT BOUNDS FOR PERFORMING BMMC PERMUTATIONS ON PARALLEL DISK SYSTEMS*

THOMAS H. CORMEN†, THOMAS SUNDQUIST‡, AND LEONARD F. WISNIEWSKI§

Abstract. This paper presents asymptotically equal lower and upper bounds for the number of parallel I/O operations required to perform bit-matrix-multiply/complement (BMMC) permutations on the Parallel Disk Model proposed by Vitter and Shriver. A BMMC permutation maps a source index to a target index by an affine transformation over $GF(2)$, where the source and target indices are treated as bit vectors. The class of BMMC permutations includes many common permutations, such as matrix transposition (when dimensions are powers of 2), bit-reversal permutations, vector-reversal permutations, hypercube permutations, matrix reblocking, Gray-code permutations, and inverse Gray-code permutations. The upper bound improves upon the asymptotic bound in the previous best known BMMC algorithm and upon the constant factor in the previous best known bit-permute/complement (BPC) permutation algorithm. The algorithm achieving the upper bound uses basic linear-algebra techniques to factor the characteristic matrix for the BMMC permutation into a product of factors, each of which characterizes a permutation that can be performed in one pass over the data.

The factoring uses new subclasses of BMMC permutations: memoryload-dispersal (MLD) permutations and their inverses. These subclasses extend the catalog of one-pass permutations.

Although many BMMC permutations of practical interest fall into subclasses that might be explicitly invoked within the source code, this paper shows how to quickly detect whether a given vector of target addresses specifies a BMMC permutation. Thus, one can determine efficiently at run time whether a permutation to be performed is BMMC and then avoid the general-permutation algorithm and save parallel I/Os by using the BMMC permutation algorithm herein.

Key words. bit-defined permutations, BMMC permutations, matrix factoring, parallel disk systems, parallel I/O, potential functions, universal lower bounds

1. Introduction.

From both the theoretical and practical points of view, permuting is an interesting and important problem when the data reside on disk. As one of the most basic data-movement operations, permuting is central to the theory of I/O complexity. The problems that we attack with supercomputers are ever-increasing in size, and in several applications matrices and vectors exceed the memory provided by even the largest supercomputers. (Such applications include seismic problems, compu-

tational fluid dynamics, and processing large images. For a list of "grand challenge" applications with huge I/O requirements, see the list compiled by del Rosario and Choudhary [14].) One solution is to store large matrices and vectors on parallel disk systems. The high latency of disk accesses makes it essential to minimize the number of disk I/O operations. Permuting the elements of a matrix or vector is a common operation, particularly in the data-parallel style of computing, and good permutation algorithms can provide significant savings in disk-access costs over poor ones when the data reside on parallel disk systems.

This paper examines the class of bit-matrix-multiply/complement (BMMC) permutations for parallel disk systems and derives four important results:

1. a universal lower bound for BMMC permutations,
2. an algorithm for performing BMMC permutations whose I/O complexity asymptotically matches the lower bound, thus making it asymptotically optimal,
3. an efficient method for determining at run time whether a given permutation is BMMC, thus allowing us to use the BMMC algorithm if it is, and
4. two new subclasses of BMMC permutations, memoryload-dispersal (MLD) permutations and their inverses, which we show how to perform in one pass.

Depending on the exact BMMC permutation, our asymptotically optimal bound may be significantly lower than the asymptotically optimal bound proven for general permutations. Moreover, the low constant factor in our algorithm makes it very practical.

Model and previous results. We use the Parallel Disk Model first proposed by Vitter and Shriver [24], who also gave asymptotically optimal algorithms for several problems including sorting and general permutations. In the Parallel Disk Model, N *records* are stored on D *disks* $\mathcal{D}_0, \mathcal{D}_1, \ldots, \mathcal{D}_{D-1}$, with N/D records stored on each disk. The records on each disk are partitioned into *blocks* of B records each. When a disk is read from or written to, an entire block of records is transferred. Disk I/O transfers records between the disks and a *random-access memory* (which we shall refer to simply as "memory") capable of holding M records. Each *parallel I/O operation* transfers up to D blocks between the disks and memory, with at most one block transferred per disk, for a total of up to BD records transferred. We assume *independent I/O*, in which the blocks accessed in a single parallel I/O may be at any locations on their respective disks, as opposed to *striped I/O*, which has the restriction that the blocks accessed in a given operation must be at the same location on each disk.

We measure an algorithm's efficiency by the number of parallel I/O operations it requires. Although this cost model does not account for the variation in disk access times caused by head movement and rotational latency, programmers often have no control over these factors. The number of disk accesses, however, can be minimized by carefully designed algorithms. Optimal algorithms have appeared in the literature for fundamental problems such as sorting [3, 6, 21, 22, 24], general permutations [24], and structured permutations [9, 10, 26], as well as higher-level domains such as fast Fourier transform (FFT) [24], matrix-matrix multiplication [24], LUP decomposition [27], computational geometry problems [5, 18], graph algorithms [8], and boolean function manipulation [4].

For convenience, we use the following notation extensively:

$$b = \lg B\ , \quad d = \lg D\ , \quad m = \lg M\ , \quad n = \lg N\ .$$

We shall assume that b, d, m, and n are nonnegative integers, which implies that B, D, M, and N are exact powers of 2. In order for the memory to accomodate

FIG. 1. *The layout of $N = 64$ records in a parallel disk system with $B = 2$ and $D = 8$. Each box represents one block. The number of stripes is $N/BD = 4$. Numbers indicate record indices.*

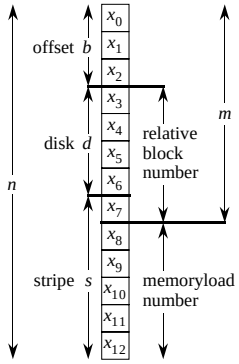

FIG. 2. *Parsing the address $x = (x_0, x_1, \ldots, x_{n-1})$ of a record on a parallel disk system. Here, $n = 13$, $b = 3$, $d = 4$, $m = 8$, and $s = 6$. The least significant b bits contain the offset of a record within its block, the next d bits contain the disk number, and the most significant s bits contain the stripe number. The most significant $n - m$ bits form the record's memoryload number, and bits $b, b+1, \ldots, m-1$ form the relative block number, used in section 4.*

the records transferred in a parallel I/O operation to all D disks, we require that $BD \leq M$. Also, we assume that $M < N$, since otherwise we can just perform all operations in memory. These two requirements imply that $b + d \leq m < n$.

The Parallel Disk Model lays out data on a parallel disk system as shown in Fig. 1. A *stripe* consists of the D blocks at the same location on all D disks. We indicate the *address*, or *index*, of a record as an n-bit vector x with the least significant bit first: $x = (x_0, x_1, \ldots, x_{n-1})$. Record indices vary most rapidly within a block, then among disks, and finally among stripes. As Fig. 2 shows, the offset within the block is given by the least significant b bits $x_0, x_1, \ldots, x_{b-1}$, the disk number by the next d bits $x_b, x_{b+1}, \ldots, x_{b+d-1}$, and the stripe number by the $s = n-(b+d)$ most significant bits $x_{b+d}, x_{b+d+1}, \ldots, x_{n-1}$.

Since each parallel I/O operation accesses at most BD records, any algorithm that must access all N records requires $\Omega(N/BD)$ parallel I/Os, and so $O(N/BD)$ parallel I/Os is the analogue of linear time in sequential computing. Vitter and Shriver showed an upper bound of $\Theta(\min(\frac{N}{D}, \frac{N}{BD}\frac{\lg(N/B)}{\lg(M/B)}))$ parallel I/Os for general permutations, that is, for arbitrary mappings $\pi : \{0, 1, \ldots, N-1\} \overset{1\text{-}1}{\rightarrow} \{0, 1, \ldots, N-1\}$. The first term comes into play when the block size B is small, and the second term is the sorting bound $\Theta(\frac{N}{BD}\frac{\lg(N/B)}{\lg(M/B)})$, which was shown by Vitter and Shriver for randomized sorting and subsequently by Nodine and Vitter [22] and others [3, 6, 21] for deterministic sorting. These bounds are asymptotically tight, because they match the lower bounds proven earlier by Aggarwal and Vitter [2] using a model with one disk and D independent read/write heads, which is at least as powerful as the Parallel Disk Model.

TABLE 1

Classes of permutations, their characteristic matrices, and upper bounds shown in [10] *on the number of passes needed to perform them. A pass consists of reading and writing each record exactly once and therefore uses exactly* $2N/BD$ *parallel I/Os. For MRC permutations, submatrix dimensions are shown on matrix borders. For BMMC permutations,* r *is the rank of the leading* $\lg M \times \lg M$ *submatrix of* A*, and the function* $H(N, M, B)$ *is given by equation* (1)*. For BPC permutations, the function* $\rho(A)$ *is defined in equation* (3)*.*

Permutation	Characteristic matrix	Number of passes
BMMC (bit-matrix-multiply/ complement)	Nonsingular matrix A	$2\left\lceil \frac{\lg M - r}{\lg(M/B)} \right\rceil + H(N, M, B)$
BPC (bit-permute/ complement)	Permutation matrix A	$2\left\lceil \frac{\rho(A)}{\lg(M/B)} \right\rceil + 1$
MRC (memory-rearrangement/ complement)	$\begin{array}{c} \begin{array}{cc} m & n-m \end{array} \\ \left[\begin{array}{c|c} \text{nonsingular} & \text{arbitrary} \\ \hline 0 & \text{nonsingular} \end{array}\right] \begin{array}{l} m \\ n-m \end{array} \end{array}$	1

Specific classes of permutations sometimes require fewer parallel I/Os than general permutations. Vitter and Shriver showed how to transpose an $R \times S$ matrix ($N = RS$) with only $\Theta(\frac{N}{BD}(1 + \frac{\lg \min(B,R,S,N/B)}{\lg(M/B)}))$ parallel I/Os. Subsequently, Cormen [10] studied several classes of bit-defined permutations that include matrix transposition as a special case. Table 1 shows some of the classes of permutations examined and the corresponding upper bounds derived in [10].

BMMC permutations. The most general class considered in [10] is that of BMMC permutations.[1] A BMMC permutation is specified by an $n \times n$ *characteristic matrix* $A = (a_{ij})$ whose entries are drawn from $\{0, 1\}$ and is nonsingular (i.e., invertible) over $GF(2)$.[2] The specification also includes a *complement vector* $c = (c_0, c_1, \ldots, c_{n-1})$ of length n. Treating a *source address* x as an n-bit vector, we perform matrix-vector multiplication over $GF(2)$ and then form the corresponding n-bit *target address* y by complementing some subset of the resulting bits: $y = A\,x \oplus c$, or

$$\begin{bmatrix} y_0 \\ y_1 \\ y_2 \\ \vdots \\ y_{n-1} \end{bmatrix} = \begin{bmatrix} a_{00} & a_{01} & a_{02} & \cdots & a_{0,n-1} \\ a_{10} & a_{11} & a_{12} & \cdots & a_{1,n-1} \\ a_{20} & a_{21} & a_{22} & \cdots & a_{2,n-1} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ a_{n-1,0} & a_{n-1,1} & a_{n-1,2} & \cdots & a_{n-1,n-1} \end{bmatrix} \begin{bmatrix} x_0 \\ x_1 \\ x_2 \\ \vdots \\ x_{n-1} \end{bmatrix} \oplus \begin{bmatrix} c_0 \\ c_1 \\ c_2 \\ \vdots \\ c_{n-1} \end{bmatrix}.$$

Because we require the characteristic matrix A to be nonsingular, the mapping of source addresses to target addresses is one-to-one. (This property is a consequence of Lemma 3 in section 2.)

We shall generally focus on the matrix multiplication portion of BMMC permutations rather than on the complement vector. The permutation π_A characterized by

[1] Edelman, Heller, and Johnsson [15] call BMMC permutations *affine transformations* or, if there is no complementing, *linear transformations*.

[2] Matrix multiplication over $GF(2)$ is like standard matrix multiplication over the reals but with all arithmetic performed modulo 2. Equivalently, multiplication is replaced by logical-and, and addition is replaced by exclusive-or.

a matrix A is the permutation for which $\pi_A(x) = A\,x$ for all source addresses x.

The following lemma shows the equivalence of multiplying characteristic matrices and composing permutations when the complement vectors are zero. For permutations π_Y and π_Z, the *composition* $\pi_Z \circ \pi_Y$ is defined by $(\pi_Z \circ \pi_Y)(x) = \pi_Z(\pi_Y(x))$ for all x in the domain of π_Y.

LEMMA 1. *Let Z and Y be nonsingular $n \times n$ matrices and let π_Z and π_Y be the permutations characterized by Z and Y, respectively. Then the matrix product $Z\,Y$ characterizes the composition $\pi_Z \circ \pi_Y$.*

Proof. For any source address x, we have

$$\begin{aligned}(\pi_Z \circ \pi_Y)(x) &= \pi_Z(\pi_Y(x)) \\ &= \pi_Z(Y\,x) \\ &= Z(Y\,x) \\ &= (Z\,Y)x\ ,\end{aligned}$$

and so the matrix product $Z\,Y$ characterizes the composition $\pi_Z \circ \pi_Y$. ∎

When we factor a characteristic matrix A into the product of several nonsingular matrices, each factor characterizes a BMMC permutation. The following corollary describes the order in which we perform these permutations to effect the permutation characterized by A.

COROLLARY 2. *Let the $n \times n$ characteristic matrix A be factored as $A = A^{(k)}\,A^{(k-1)}\,A^{(k-2)} \cdots A^{(1)}$, where each factor $A^{(i)}$ is a nonsingular $n \times n$ matrix. Then we can perform the BMMC permutation characterized by A by performing, in order, the BMMC permutations characterized by $A^{(1)}, A^{(2)}, \ldots, A^{(k)}$. That is, we perform the permutations characterized by the factors of a matrix from right to left.*

Proof. The proof is a simple induction, using Lemma 1. ∎

The BMMC algorithm in [10] exploits Corollary 2 to factor a characteristic matrix into a product of other characteristic matrices, performing the permutations given by the factors right to left. It uses

$$\frac{2N}{BD}\left(2\left\lceil\frac{\lg M - r}{\lg(M/B)}\right\rceil + H(N,M,B)\right)$$

parallel I/Os, where r is the rank of the leading $\lg M \times \lg M$ submatrix of the characteristic matrix and

$$H(N,M,B) = \begin{cases} 4\left\lceil\dfrac{\lg B}{\lg(M/B)}\right\rceil + 9 & \text{if } M \le \sqrt{N}\ , \\ 4\left\lceil\dfrac{\lg(N/B)}{\lg(M/B)}\right\rceil + 1 & \text{if } \sqrt{N} < M < \sqrt{NB}\ , \\ 5 & \text{if } \sqrt{NB} \le M\ . \end{cases} \tag{1}$$

One can adapt the lower bound proven in this paper to show that $\Omega\left(\frac{N}{BD}\frac{\lg M - r}{\lg(M/B)}\right)$ parallel I/Os are necessary (see section 2.8 of [9]), but so far it has been unknown whether the $\Theta\left(\frac{N}{BD}\,H(N,M,B)\right)$ term is necessary in all cases. This paper shows that it is not.

BPC permutations. By restricting the characteristic matrix A of a BMMC permutation to be a permutation matrix—having exactly one 1 in each row and each

column—we obtain the class of *bit-permute/complement*, or *BPC*, permutations.[3] One can think of a BPC permutation as forming each target address by applying a fixed permutation to the source-address bits and then complementing a subset of the resulting bits. The class of BPC permutations includes many common permutations such as matrix transposition (when dimensions are powers of 2), bit-reversal permutations (used in performing FFTs), vector-reversal permutations, hypercube permutations, and matrix reblocking.

Previous work [10] expressed the I/O complexity of BPC permutations in terms of cross-ranks. For any $n \times n$ permutation matrix A and for any $k = 0, 1, \ldots, n-1$, the *k-cross-rank* of A is

$$\rho_k(A) = \operatorname{rank} A_{k..n-1,0..k-1} = \operatorname{rank} A_{0..k-1,k..n-1} \ , \tag{2}$$

where, for example, $A_{k..n-1,0..k-1}$ denotes the submatrix of A consisting of the intersection of rows $k, k+1, \ldots, n-1$ and columns $0, 1, \ldots, k-1$. The *cross-rank* of A is the maximum of the b- and m-cross-ranks:

$$\rho(A) = \max(\rho_b(A), \rho_m(A)) \ . \tag{3}$$

The BPC algorithm in [10] uses at most

$$\frac{2N}{BD}\left(2\left\lceil\frac{\rho(A)}{\lg(M/B)}\right\rceil + 1\right)$$

parallel I/Os. One can adapt the lower bound we prove in section 3 for BMMC permutations to show that this BPC algorithm is asymptotically optimal. The BMMC algorithm in section 6, however, is asymptotically optimal for all BMMC permutations—including those that are BPC—and it reduces the innermost factor of 2 in the above bound to a factor of 1. Not only is the BPC algorithm in [10] improved upon by the results in this paper, but the notion of cross-rank appears to be obviated as well.

MRC permutations. *Memory-rearrangement/complement*, or *MRC*, permutations are BMMC permutations with the additional restrictions shown in Table 1: both the leading $m \times m$ and trailing $(n-m) \times (n-m)$ submatrices of the characteristic matrix are nonsingular, the upper right $m \times (n-m)$ submatrix can contain any 0-1 values at all, and the lower left $(n-m) \times m$ submatrix is all 0. Cormen [10] shows that any MRC permutation requires only one pass of N/BD parallel reads and N/BD parallel writes. If we partition the N records into N/M consecutive sets of M records each, we call each set a *memoryload*. Each memoryload consists of M/BD consecutive stripes in which all addresses have the same value in the most significant $n-m$ bits, as Fig. 2 shows. Any MRC permutation can be performed by reading in a memoryload, permuting its records in memory, and writing them out to a (possibly different) memoryload number. Because a memoryload may be read and written with striped I/Os, any MRC permutation may be performed with striped reads and striped writes. The class of MRC permutations includes those characterized by unit upper-triangular matrices. As [10] shows, both the standard binary-reflected Gray code and its inverse have characteristic matrices of this form, and so they are MRC permutations.

[3] Johnsson and Ho [19] call BPC permutations *dimension permutations*, and Aggarwal, Chandra, and Snir [1] call BPC permutations without complementing *rational permutations*.

MLD permutations. We define here a new BMMC permutation subclass, which we shall use in our asymptotically optimal BMMC algorithm. To define this subclass, we first need the standard linear-algebraic notion of a kernel. The *kernel* of any $p \times q$ matrix A is the set of q-vectors that map to 0 when multiplied by A. That is,

$$\ker A = \{x : Ax = 0\} .$$

An MLD permutation has a characteristic matrix that is nonsingular and of the following form:

$$\begin{array}{c} \begin{array}{cc} \multicolumn{1}{c}{m} & \multicolumn{1}{c}{n-m} \end{array} \\ \left[\begin{array}{c|c} \text{arbitrary} & \\ \hline \lambda & \text{arbitrary} \\ \hline \mu & \end{array}\right] \end{array} \begin{array}{l} b \\ m-b \\ n-m \end{array} ,$$

subject to the *kernel condition*

$$\ker \lambda \subseteq \ker \mu; \tag{4}$$

or, equivalently, $\lambda x = 0$ implies $\mu x = 0$.

As we shall see in section 4, the kernel condition implies that we can perform any MLD permutation in one pass by reading in each source memoryload, permuting its records in memory, and writing these records out to M/BD blocks on each disk. Although the blocks read from each memoryload must come from M/BD consecutive stripes, the blocks written may go to any locations at all, as long as M/BD blocks are written to each disk. That is, MLD permutations use striped reads and independent writes. We shall also see in section 4 that we can perform the inverse of an MLD permutation in one pass with independent reads and striped writes.

Outline. The remainder of this paper is organized as follows. Section 2 reviews some fundamental linear-algebraic notions and proves some properties that we shall use in later sections. Section 3 states and proves the lower bound for BMMC permutations. Section 4 shows how to perform any MLD permutation in one pass and gives some additional properties of MLD permutations and their inverses. Section 5 previews several of the matrix forms used in section 6, which presents an algorithm for BMMC permutations whose I/O complexity asymptotically matches the lower bound. Section 7 shows how to detect at run time whether a vector of target addresses describes a BMMC permutation, thus enabling us to determine whether the BMMC algorithm is applicable; this section also presents an easy method for determining whether a nonsingular matrix satisfies the kernel condition (4) and therefore characterizes an MLD permutation. Finally, section 8 contains some concluding remarks.

The algorithms for MLD and BMMC permutations in sections 4 and 6 take little computation time and space. (They do, however, require permutations to be performed in memory, and various architectures may differ in how efficiently they do so.) The data structures are vectors of length $\lg N$ or matrices of size at most $\lg N \times \lg N$. Even sequential algorithms for the harder computations (e.g., finding a maximal set of linearly independent columns of a bit matrix) take time polynomial in $\lg N$, in fact, $O(\lg^3 N)$.

We shall not concern ourselves with memory issues when manipulating characteristic matrices. That is, we assume throughout this paper that $\lg^2 N \ll M$, since as a practical matter, the size of any characteristic matrix is much smaller than memory.

Consider, for example, a problem with $N = 2^{60}$ records, or about one quintillion. (This problem is much larger than any problem that one is likely to see for a long time. If each record were only one byte long, such a data set would occupy one billion gigabytes.) A 60×60 characteristic matrix for a problem this large would require 3600 bits, or 120 words of 32 bits if each column is packed into two words. This amount is insignificant compared to memory sizes of even modest computer systems. Consequently, we shall think of the M-record memory as holding only records and not the characteristic matrix or complement vector.

We shall use several notational conventions in this paper, as in equation (2). Matrix row and column numbers are indexed from 0 starting from the upper left. Vectors are indexed from 0, too. We index rows and columns by sets to indicate submatrices, using ".." notation to indicate sets of contiguous numbers. When a matrix is indexed by just one set rather than two, the set indexes column numbers; the submatrix consists of entire columns. When a submatrix index is a singleton set, we shall often omit the enclosing braces. We denote an identity matrix by I and a matrix whose entries are all 0s by 0; the dimensions of such matrices will be clear from their contexts. All matrix and vector elements are drawn from $\{0, 1\}$, and all matrix and vector arithmetic is over $GF(2)$. When convenient, we interpret bit vectors as the integers they represent in binary. Vectors are treated as 1-column matrices in context.

Some readers familiar with linear algebra may notice that a few of the lemmas in this paper are special cases of standard linear-algebra properties restricted to $GF(2)$. We include the proofs here for completeness.

2. Linear-algebraic fundamentals. This section reviews some standard linear-algebraic terms and proves a few simple properties that we shall use later on. It also shows how to find a maximal set of linearly independent columns of a bit matrix.

Ranges and preimages. For a $p \times q$ matrix A with 0-1 entries, we define the *range* of A by

$$\mathcal{R}(A) = \{y : y = Ax \text{ for some } x \in \{0, 1, \ldots, 2^q - 1\}\} ;$$

that is, $\mathcal{R}(A)$ is the set of p-vectors that can be produced by multiplying all q-vectors with 0-1 entries (interpreted as integers in $\{0, 1, \ldots, 2^q - 1\}$) by A over $GF(2)$. We also adopt the notation

$$\mathcal{R}(A) \oplus c = \{z : z = y \oplus c \text{ for some } y \in \mathcal{R}(A)\} ;$$

that is, $\mathcal{R}(A) \oplus c$ is the exclusive-or of the range of A and a fixed vector c.

LEMMA 3. *Let A be a $p \times q$ matrix whose entries are drawn from $\{0, 1\}$, let c be any p-vector whose entries are drawn from $\{0, 1\}$, and let $r = \operatorname{rank} A$. Then $|\mathcal{R}(A) \oplus c| = 2^r$.*

Proof. Let S index a maximal set of linearly independent columns of A, so that $S \subseteq \{0, 1, \ldots, q - 1\}$, $|S| = r$, the columns of the submatrix A_S are linearly independent, and for any column number $j \notin S$, the column A_j is linearly dependent on the columns of A_S. We claim that $\mathcal{R}(A) = \mathcal{R}(A_S)$. Clearly, $\mathcal{R}(A_S) \subseteq \mathcal{R}(A)$, since $\mathcal{R}(A)$ includes the sum (over $GF(2)$) of each subset of columns of A. To see that $\mathcal{R}(A) \subseteq \mathcal{R}(A_S)$, consider any q-vector $y \in \mathcal{R}(A)$. There is some set T of column indices such that $y = \bigoplus_{j \in T} A_j$. For each column index $j \in T - S$, let $S_j \subseteq S$ index

the columns of A_S that A_j depends on: $A_j = \bigoplus_{k \in S_j} A_k$. Then we have

$$\begin{aligned} y &= \bigoplus_{j \in T} A_j \\ &= \left(\bigoplus_{j \in T \cap S} A_j \right) \oplus \left(\bigoplus_{j \in T - S} A_j \right) \\ &= \left(\bigoplus_{j \in T \cap S} A_j \right) \oplus \left(\bigoplus_{j \in T - S} \left(\bigoplus_{k \in S_j} A_k \right) \right) , \end{aligned}$$

and so y is a linear combination of columns of A_S. Thus, $y \in \mathcal{R}(A_S)$, which in turn proves that $\mathcal{R}(A) \subseteq \mathcal{R}(A_S)$, and consequently $\mathcal{R}(A) = \mathcal{R}(A_S)$.

We have $|\mathcal{R}(A_S)| = 2^{|S|} = 2^r$, since each vector in $\mathcal{R}(A_S)$ is the sum of a unique subset of the columns of S and each column index in S may or may not be included in a sum of the columns. Thus, $|\mathcal{R}(A)| = 2^r$. Exclusive-oring the result of the matrix multiplication by a constant p-vector does not change the cardinality of the range. Therefore, $|\mathcal{R}(A) \oplus c| = |\mathcal{R}(A)| = 2^r$. □

For a $p \times q$ matrix A and a p-vector $y \in \mathcal{R}(A)$, we define the *preimage* of y under A by

$$\mathrm{Pre}(A, y) = \{x : Ax = y\} .$$

That is, $\mathrm{Pre}(A, y)$ is the set of q-vectors x that map to y when multiplied by A.

LEMMA 4. *Let A be a $p \times q$ matrix whose entries are drawn from $\{0, 1\}$, let y be any p-vector in $\mathcal{R}(A)$, and let $r = \operatorname{rank} A$. Then $|\mathrm{Pre}(A, y)| = 2^{q-r}$.*

Proof. Let S index a maximal set of linearly independent columns of A, so that $S \subseteq \{0, 1, \ldots, q-1\}$, $|S| = r$, the columns of the submatrix A_S are linearly independent, and for any column number $j \notin S$, the column A_j is linearly dependent on the columns of A_S. Let $S' = \{0, 1, \ldots, q-1\} - S$.

We claim that for any value $i \in \{0, 1, \ldots, 2^{q-r} - 1\}$, there is a unique q-vector $x^{(i)}$ for which $x^{(i)}_{S'}$ is the binary representation of i and $y = A\,x^{(i)}$. Why? We have $y = A_S\, x^{(i)}_S \oplus A_{S'}\, x^{(i)}_{S'}$ or, equivalently,

$$y \oplus A_{S'} x^{(i)}_{S'} = A_S\, x^{(i)}_S \ . \tag{5}$$

The columns of A_S span $\mathcal{R}(A)$, which implies that for all $z \in \mathcal{R}(A)$, there is a unique r-vector w such that $z = A_S\, w$. Letting $z = y \oplus A_{S'}\, x^{(i)}_{S'}$, we see that there is a unique r-vector $x^{(i)}_S$ that satisfies equation (5), which proves the claim.

Thus, we have shown that $|\mathrm{Pre}(A, y)| \geq 2^{q-r}$. If we had $|\mathrm{Pre}(A, y)| > 2^{q-r}$, then because y is arbitrarily chosen from $\mathcal{R}(A)$, we would have that $\sum_{y' \in \mathcal{R}(A)} |\mathrm{Pre}(A, y')| > 2^q$. But this inequality contradicts there being only 2^q possible preimage vectors. We conclude that $|\mathrm{Pre}(A, y)| = 2^{q-r}$. □

Row spaces. The *row space* of a matrix A, written $\operatorname{row} A$, is the span of the rows of A. We prove the following lemma about the relationship between kernels and row spaces, which we shall use later to prove properties resulting from the kernel condition of MLD permutations and to check that the kernel condition holds.

LEMMA 5. *Let K and L be q-column matrices. Then $\ker K \subseteq \ker L$ if and only if $\operatorname{row} L \subseteq \operatorname{row} K$.*

Proof. For any vector space X, the *orthogonal space* of X, written $X^\perp$, is the set of vectors Y such that for all $x \in X$ and all $y \in Y$, the inner product $x \cdot y$ is 0. We use the following well-known facts from linear algebra (see Strang [23, pp. 138–139], for example).

1. The row space and the kernel are orthogonal spaces of each other. Thus, $(\operatorname{row} K)^\perp = \ker K$ and $(\operatorname{row} L)^\perp = \ker L$.
2. For any vector spaces X and Y, $X \subseteq Y$ implies $Y^\perp \subseteq X^\perp$.
3. For any vector space X, $(X^\perp)^\perp = X$.[4]

The latter two properties imply that if $Y^\perp \subseteq X^\perp$, then $X \subseteq Y$. Thus we have

$$\begin{aligned} \ker K \subseteq \ker L \ &\text{iff}\ (\operatorname{row} K)^\perp \subseteq (\operatorname{row} L)^\perp \\ &\text{iff}\ \operatorname{row} L \subseteq \operatorname{row} K\ , \end{aligned}$$

which proves the lemma. □

Finding a maximal set of linearly independent columns. We conclude this section with a simple sequential algorithm to find a maximal set S of linearly independent columns of a $p \times q$ matrix K. We shall use this technique several times in this paper.

We use the following pseudocode:

```
1  S ← ∅
2  for each row index i ← 0 to p − 1 do
3     if there exists some column index j for which K_ij = 1
4        then for each column index j′ such that K_ij′ = 1 do
5                 add column j to column j′
6                 S ← S ∪ {j}
```

At the completion of this algorithm, the set S contains the indices for a maximal set of linearly independent columns of K. Lines 4–5 zero out any column in the set. Each iteration of the outer loop zeros out the next row. By the end of the algorithm, every column gets zeroed out as a column in S or by the addition of some subset of columns in S.

This algorithm takes $O(p^2 q)$ time on a sequential machine. In our applications of this algorithm, p and q are at most $\lg N$, and so the sequential time will always be $O(\lg^3 N)$.

3. A universal lower bound for BMMC permutations. In this section, we state and prove the lower bound for BMMC permutations. After stating the lower bound, we briefly discuss its significance before presenting the full proof. The lower bound is given by the following theorem.

THEOREM 6. *Any algorithm that performs a nonidentity BMMC permutation with characteristic matrix A requires*

$$\Omega\left(\frac{N}{BD}\left(1 + \frac{\operatorname{rank}\gamma}{\lg(M/B)}\right)\right)$$

parallel I/Os, where γ is the submatrix $A_{b..n-1,0..b-1}$ of size $\lg(N/B) \times \lg B$. □

This lower bound is *universal* in the sense that it applies to all inputs other than the identity permutation, which of course requires no data movement at all. In

[4] The proof that this property holds over $GF(2)$ is not as straightforward as the conventional proof that it holds over $\mathbb{R}^n$. Lang [20, p. 131] contains a proof for $GF(2)$.

contrast, lower bounds such as the standard $\Omega(N \lg N)$ lower bound for sorting N items on a sequential machine are *existential*: they apply to worst-case inputs, but for some inputs an algorithm may be able to do better.

Section 6 presents an algorithm that achieves the bound given by Theorem 6, and so this algorithm is asymptotically optimal.

Technique. To prove Theorem 6, we rely heavily on the technique used by Aggarwal and Vitter [2] to prove a lower bound on I/Os for matrix transposition; their proof is based in turn on a method by Floyd [16]. We prove the lower bound for the case in which $D = 1$; the general case follows by dividing by D. We consider only I/Os that are *simple*. An input is simple if each record read is removed from the disk and moved into an empty location in memory. An output is simple if the records are removed from the memory and written to empty locations on the disk. When all I/Os are simple, exactly one copy of each record exists at any time during the execution of an algorithm. The following lemma, proven by Aggarwal and Vitter, allows us to consider only simple I/Os when proving lower bounds.

LEMMA 7. *For each computation that implements a permutation of records, there is a corresponding computation strategy involving only simple I/Os such that the total number of I/Os is no greater.* □

The basic scheme of the proof of Theorem 6 uses a potential-function argument. *Time* q is the time interval starting when the qth I/O completes and ending just before the $(q+1)$st I/O starts. We define a potential function Φ so that $\Phi(q)$ is the *potential* at time q. This potential measures how close the current record ordering is to the desired permutation order. Higher potentials indicate that the current ordering is closer to the desired permutation. We compute the initial and final potentials and bound the amount that the potential can increase in each I/O operation. The lower bound then follows.

To be more precise, we start with some definitions. For $i = 0, 1, \ldots, N/B - 1$, we define the ith *target group* to be the set of records that belong in block i according to the given BMMC permutation. We denote by $g_{\text{block}}(i, k, q)$ the number of records in the ith target group that are in block k on disk at time q, and $g_{\text{mem}}(i, q)$ denotes the number of records in the ith target group that are in memory at time q. We define the continuous function

$$f(x) = \begin{cases} x \lg x & \text{if } x > 0 \ , \\ 0 & \text{if } x = 0 \ , \end{cases}$$

and we define *togetherness functions*

$$G_{\text{block}}(k, q) = \sum_{i=0}^{N/B-1} f(g_{\text{block}}(i, k, q))$$

for each block k at time q and

$$G_{\text{mem}}(q) = \sum_{i=0}^{N/B-1} f(g_{\text{mem}}(i, q))$$

for memory at time q. Finally, we define the *potential* at time q, denoted $\Phi(q)$, as the sum of the togetherness functions:

$$\Phi(q) = G_{\text{mem}}(q) + \sum_{k=0}^{N/B-1} G_{\text{block}}(k, q) \ .$$

Aggarwal and Vitter embed the following lemmas in their lower-bound argument. The first lemma is based on the observation that the number of parallel I/Os needed is at least the total increase in potential over all parallel I/Os divided by the maximum increase in potential (denoted $\Delta\Phi_{\max}$) in any single parallel I/O.

LEMMA 8. *Let $D = 1$, and consider any algorithm that uses t parallel I/Os to perform a permutation. Then $t = \Omega\left(\frac{\Phi(t)-\Phi(0)}{\Delta\Phi_{\max}}\right)$.* □

LEMMA 9. *Let $D = 1$, and consider any permutation that can be performed with t parallel I/Os. Then $\Phi(t) = N \lg B$ and $\Delta\Phi_{\max} = O(B \lg(M/B))$. Therefore, any algorithm that performs a permutation uses $\Omega\left(\frac{N \lg B - \Phi(0)}{B \lg(M/B)}\right)$ parallel I/Os.* □

Observe that these lemmas imply lower bounds that are universal. No matter what permutation is being performed, the initial potential is $\Phi(0)$, the final potential is $\Phi(t)$, the increase in potential per parallel I/O is at most $\Delta\Phi_{\max}$, and so $\Omega\left(\frac{\Phi(t)-\Phi(0)}{\Delta\Phi_{\max}}\right)$ parallel I/Os are required.

We can now show a trivial lower bound for all nonidentity BMMC permutations.

LEMMA 10. *If $D = 1$, any algorithm that performs a nonidentity BMMC permutation requires $\Omega(N/B)$ parallel I/Os.*

Proof. Consider a BMMC permutation with characteristic matrix A and complement vector c. It is the identity permutation if and only if $A = I$ and $c = 0$, so we shall assume that either $A \neq I$ or $c \neq 0$.

A *fixed point* of the BMMC permutation is a source address x for which

$$A\,x \oplus c = x \ . \tag{6}$$

If a record's source address is not a fixed point, its source block must be read and its target block must be written. We shall show that for any nonidentity BMMC permutation, at least $N/2$ addresses are not fixed points. Even if these records are clustered into as few source blocks as possible, then at least half the source blocks, or $N/2B$, must be read. The lemma then follows.

To show that at least $N/2$ addresses are not fixed points, we shall show that at most $N/2$ addresses are. Rewriting equation (6) as $(A \oplus I)x = c$, we see that we wish to bound the size of $\mathrm{Pre}(A \oplus I, c)$. If $c \notin \mathcal{R}(A \oplus I)$, then this size is 0. Otherwise, by Lemma 4, this size is $2^{n-\mathrm{rank}(A \oplus I)}$. If $A \neq I$, then $\mathrm{rank}(A \oplus I) \geq 1$, which implies that $|\mathrm{Pre}(A \oplus I, c)| \leq 2^{n-1} = N/2$. If $A = I$, then $A \oplus I$ is the 0 matrix, and the only vector in its range is 0. But $A = I$ and $c = 0$ yields the identity permutation, which we specifically disallow. □

Proof of Theorem 6. Recall that we shall prove Theorem 6 by proving the lower bound for the case in which $D = 1$; the general case follows by dividing by D. We work with characteristic matrix A and complement vector c. We assume that all I/Os are simple and transfer exactly B records, some possibly empty. Since all records start on disk and I/Os are simple, memory is initially empty.

We need to compute the initial potential in order to apply Lemma 9. The initial potential depends on the number of records that start in the same source block and are in the same target group. A record with source address $x = (x_0, x_1, \ldots, x_{n-1})$ is in source block k if and only if

$$k = x_{b..n-1} \ , \tag{7}$$

interpreting k as an $(n-b)$-bit binary number with the least signficant bit first. This

record maps to target block i if and only if

$$\begin{aligned} i &= A_{b..n-1,0..n-1}\, x_{0..n-1} \oplus c_{b..n-1} \\ &= A_{b..n-1,0..b-1}\, x_{0..b-1} \oplus A_{b..n-1,b..n-1}\, x_{b..n-1} \oplus c_{b..n-1} \ , \end{aligned} \tag{8}$$

also interpreting i as an $(n-b)$-bit binary number. The following lemma gives the exact number of records that start in each source block and are in the same target group.

LEMMA 11. *Let $r = \operatorname{rank} A_{b..n-1,0..b-1}$, and consider any source block k. There are exactly 2^r distinct target blocks that some record in source block k maps to, and for each such target block, exactly $B/2^r$ records in source block k map to it.*

Proof. For a given source block k, all source addresses fulfill condition (7), and so they map to target block numbers given by condition (8) but with $x_{b..n-1}$ fixed at k. The range of target block numbers is thus $\mathcal{R}(A_{b..n-1,0..b-1}) \oplus (A_{b..n-1,b..n-1}\, k \oplus c_{b..n-1})$ which, by Lemma 3, has cardinality 2^r.

Now we determine the set of source addresses in source block k that map to a particular target block i in $\mathcal{R}(A_{b..n-1,0..b-1}) \oplus (A_{b..n-1,b..n-1}\, k \oplus c_{b..n-1})$. Again fixing $x_{b..n-1} = k$ in condition (8) and exclusive-oring both sides by $A_{b..n-1,b..n-1}\, k \oplus c_{b..n-1}$, we see that this set is precisely $\operatorname{Pre}(A_{b..n-1,0..b-1}, i \oplus A_{b..n-1,b..n-1}\, k \oplus c_{b..n-1})$. By Lemma 4, this set has cardinality exactly 2^{b-r}, which equals $B/2^r$. ∎

We can interpret Lemma 11 as follows. Let $r = \operatorname{rank} A_{b..n-1,0..b-1}$, and consider a particular source block k. Then there are exactly 2^r target blocks i for which $g_{\text{block}}(i,k,0)$ is nonzero, and for each such nonzero target block, we have $g_{\text{block}}(i,k,0) = B/2^r$.

Now we can compute $\Phi(0)$. Since memory is initially empty, $g_{\text{mem}}(i,0) = 0$ for all blocks i, which implies that $G_{\text{mem}}(0) = 0$. We have

$$\begin{aligned} \Phi(0) &= G_{\text{mem}}(0) + \sum_{k=0}^{N/B-1} G_{\text{block}}(k,0) \\ &= 0 + \sum_{k=0}^{N/B-1} \sum_{i=0}^{N/B-1} f(g_{\text{block}}(i,k,0)) \\ &= \sum_{k=0}^{N/B-1} 2^r \frac{B}{2^r} \lg \frac{B}{2^r} \qquad \text{(by Lemma 11)} \\ &= \frac{N}{B} B \lg \frac{B}{2^r} \\ &= N(\lg B - r) \ . \end{aligned} \tag{9}$$

Combining Lemmas 9 and 10 with equation (9), we get a lower bound of

$$\Omega\left(\frac{N}{B} + \frac{N \lg B - N(\lg B - r)}{B \lg(M/B)}\right) = \Omega\left(\frac{N}{B}\left(1 + \frac{\operatorname{rank} A_{b..n-1,0..b-1}}{\lg(M/B)}\right)\right)$$

parallel I/Os. Dividing through by D yields a lower bound of

$$\Omega\left(\frac{N}{BD}\left(1 + \frac{\operatorname{rank} A_{b..n-1,0..b-1}}{\lg(M/B)}\right)\right) \ ,$$

which completes the proof of Theorem 6.

4. MLD permutations. In this section, we describe how to perform any MLD permutation in only one pass. This section also discusses additional properties of MLD and MRC permutations and concludes with a discussion of MLD^{-1} permutations, which are permutations whose inverses are MLD permutations. Section 7 shows how to determine whether a given matrix characterizes an MLD permutation.

How the kernel condition implies a one-pass permutation. We shall show in three steps that the kernel condition implies that, for a given source memoryload, the source records are permuted into full target blocks spread evenly across the disks. To do so, we first need to define the notion of relative block number, as shown in Fig. 2. For a given n-bit record address $x_{0..n-1}$, the *relative block number* of x is the $m-b$ bits $x_{b..m-1}$. The relative block number ranges from 0 to $M/B-1$ and determines the number of a block within its memoryload. Recall that the memoryload number is the $n-m$ bits $x_{m..n-1}$. We shall prove that *for a given source memoryload*, the following properties hold.

1. Its records map to all M/B relative block numbers, and each relative block number has exactly B records mapping to it.
2. Records that map to the same relative block number map to the same target memoryload number as well.

The first two properties imply that the records of each source memoryload map to exactly M/B target blocks and that each such target block is full.

3. These M/B target blocks are distributed evenly among the disks, with M/BD mapping to each disk.

Given these properties, we can perform an MLD permutation in one pass. Like the other one-pass permutations described in [10], we allow the permutation to map records from one set of N/BD stripes (the "source portion" of the parallel disk system) to a different set of N/BD stripes (the "target portion"). One can think of addresses as relative to the beginning of the appropriate portion. In this way, we need not be concerned with overwriting source records before we get a chance to read them. Note that when we chain passes together, as in the BMMC algorithm of section 6 and the BPC algorithm of [10], we can avoid allocating a new target portion in each pass by reversing the roles of the source and target portions between passes, and so the total disk space used is $2N$ records.

We perform an MLD permutation by processing source memoryload numbers from 0 to $N/M-1$. For each source memoryload, we first read into memory its M/BD consecutive stripes from the source portion. We then permute its records in memory, clustering them into M/B full target blocks that are distributed evenly among the disks. We then write out these target blocks using M/BD independent writes to the target portion. After processing all N/M source memoryloads, we have read each record from the source portion and written it to where it belongs in the target portion. Thus, we have performed the MLD permutation in one pass.

The following lemma gives an important consequence of the kernel condition.

LEMMA 12. *If the matrix A characterizes an MLD permutation, then the submatrix λ has rank $m-b$.*

Proof. We shall prove that all rows of the leading $m \times m$ submatrix of A are linearly independent. The lemma then follows because λ is a subset of these rows.

Because A is nonsingular, the rank of its leftmost m columns (i.e., the submatrix $A_{0..n-1,0..m-1}$) is m. The row rank of any matrix equals the column rank, and so there are m linearly independent rows in $A_{0..n-1,0..m-1}$.

Since $\ker \lambda \subseteq \ker \mu$, Lemma 5 implies that $\operatorname{row} \mu \subseteq \operatorname{row} \lambda$. Thus, every row of μ is linearly dependent on some rows of λ and hence on some rows of the leading $m \times m$ submatrix of A. Since there are m linearly independent rows in $A_{0..n-1,0..m-1}$, all rows of the leading $m \times m$ submatrix must be linearly independent. □

We now prove property 1.

LEMMA 13. *The records of each source memoryload in an MLD permutation map to exactly M/B relative block numbers. Moreover, for a given source memoryload, each relative block number has exactly B records mapping to it.*

Proof. Let A characterize an MLD permutation with complement vector c. By Lemma 12, $\operatorname{rank} A_{b..m-1,0..m-1} = m - b$. The target relative block number $y_{b..m-1}$ corresponding to a source address x is given by the equation

$$y_{b..m-1} = A_{b..m-1,0..m-1}\, x_{0..m-1} \oplus A_{b..m-1,m..n-1}\, x_{m..n-1} \oplus c_{b..m-1} \ . \tag{10}$$

The value of $x_{m..n-1}$ is fixed for a given source memoryload, and so the $(m-b)$-vector $A_{b..m-1,m..n-1}\, x_{m..n-1} \oplus c_{b..m-1}$ has the same value for all records. By Lemma 3, $y_{b..m-1}$ takes on $2^{\operatorname{rank} A_{b..m-1,0..m-1}} = 2^{m-b} = M/B$ different values for the M different values of $x_{0..m-1}$. That is, the records of each source memoryload map to exactly M/B different relative block numbers.

Now consider some relative block number $y_{b..m-1}$ that some source address in a memoryload maps to. Using equation (10), the number of source addresses $x_{0..m-1}$ within that memoryload that map to $y_{b..m-1}$ is equal to $|\mathrm{Pre}(A_{b..m-1,0..m-1}, y_{b..m-1} \oplus A_{b..m-1,m..n-1}\, x_{m..n-1} \oplus c_{b..m-1})|$. By Lemma 4, this number is equal to

$$2^{m - \operatorname{rank} A_{b..m-1,0..m-1}} = 2^{m-(m-b)} = B \ . \qquad \square$$

Property 2 follows directly from the kernel condition. Although we use kernel notation for its simplicity of expression, the following lemma shows that the kernel condition is equivalent to requiring that, for a given source memoryload, every record destined for a particular relative block number must also be destined for the same target memoryload.

LEMMA 14. *Let K and L be matrices with q columns. Then $\ker K \subseteq \ker L$ if and only if for all q-vectors x and y, $Kx = Ky$ implies $Lx = Ly$.*

Proof. Suppose that $\ker K \subseteq \ker L$ and $Kx = Ky$. Then $K(x \oplus y) = 0$, which implies that $L(x \oplus y) = 0$, which in turn implies $Lx = Ly$.

Conversely, suppose that $Kx = Ky$ implies $Lx = Ly$ for all q-vectors x and y, and consider any q-vector $z \in \ker K$. We have $Kz = 0 = K \cdot 0$, which implies $Lz = L \cdot 0 = 0$. Thus, $z \in \ker L$. □

For an MLD permutation, since $\ker \lambda \subseteq \ker \mu$, we apply Lemma 14 with $K = \lambda$ and $L = \mu$. Thus, any two source records x and y from the same source memoryload that are mapped to relative block number $\lambda\, x_{0..m-1}$ are also mapped to the same target memoryload $\mu\, x_{0..m-1}$.

Property 3 follows from property 1. Each source memoryload maps to relative block numbers $0, 1, \ldots, M/B-1$. As Fig. 2 shows, the number of the disk that a block resides on is encoded in the least significant d bits of its relative block number. The M/B relative block numbers, therefore, are evenly distributed among the D disks, with M/BD residing on each disk.

Thus, we have the following theorem.

THEOREM 15. *Any MLD permutation can be performed in one pass with striped reads and independent writes.*

Proof. The above argument demonstrates that we can perform any MLD permutation in one pass with independent writes. Because a memoryload can be read with M/BD striped reads and the above method for performing MLD permutations reads full memoryloads, it uses striped reads. ∎

Additional properties of MLD and MRC permutations. We now examine some additional properties of MLD permutations. We shall use these properties primarily to combine matrix factors in the BMMC algorithm, thus reducing the number of passes. The first property bounds the rank of the submatrix μ as another consequence of the kernel condition.

LEMMA 16. *In the characteristic matrix for an MLD permutation, the submatrix μ has rank at most $m - b$.*

Proof. By Lemma 5 and the kernel condition, $\operatorname{row}\mu \subseteq \operatorname{row}\lambda$, which in turn implies that $\dim(\operatorname{row}\mu) \le \dim(\operatorname{row}\lambda)$, where the dimension of a vector space is the size of any basis for it. Applying Lemma 12, we have that $\operatorname{rank}\mu \le \operatorname{rank}\lambda = m - b$. ∎

Thus, if the lower left $(n-m) \times m$ submatrix of a characteristic matrix has rank more than $m - b$, the matrix cannot characterize an MLD permutation.

THEOREM 17. *Let the matrix Y characterize an MLD permutation, and let the matrix X characterize an MRC permutation. Then the matrix product YX characterizes an MLD permutation.*

Proof. Write the nonsingular matrix Y as

$$Y = \begin{array}{c} \begin{matrix} m & n-m \end{matrix} \\ \left[\begin{array}{c|c} \alpha & \beta \\ \hline \gamma & \delta \end{array}\right] \begin{matrix} m \\ n-m \end{matrix} \end{array},$$

where

$$\ker \alpha_{b..m-1,0..m-1} \subseteq \ker \gamma \ . \tag{11}$$

Write the nonsingular matrix X as

$$X = \begin{array}{c} \begin{matrix} m & n-m \end{matrix} \\ \left[\begin{array}{c|c} \phi & \sigma \\ \hline 0 & \nu \end{array}\right] \begin{matrix} m \\ n-m \end{matrix} \end{array},$$

where ϕ and ν are nonsingular. We now show that the product

$$YX = \begin{array}{c} \begin{matrix} m & n-m \end{matrix} \\ \left[\begin{array}{c|c} \alpha\phi & \alpha\sigma \oplus \beta\nu \\ \hline \gamma\phi & \gamma\sigma \oplus \delta\nu \end{array}\right] \begin{matrix} m \\ n-m \end{matrix} \end{array}$$

characterizes an MLD permutation. Observe that the product YX is nonsingular because Y and X are each nonsingular.

We must also prove that the kernel condition (4) holds for the product, i.e., that $\ker(\alpha\phi)_{b..m-1,0..m-1} \subseteq \ker(\gamma\phi)$. For an $m \times m$ matrix τ, note that $\tau_{b..m-1,0..m-1} = I_{b..m-1,0..m-1}\,\tau$, where I is the usual $m \times m$ identity matrix. We have that $x \in \ker(\alpha\phi)_{b..m-1,0..m-1}$ implies $(I_{b..m-1,0..m-1}\alpha\phi)x = 0$ (taking $\alpha\phi$ as τ), which in turn implies that $\phi x \in \ker(I_{b..m-1,0..m-1}\alpha) = \ker \alpha_{b..m-1,0..m-1} \subseteq \ker\gamma$, by property (11). Thus, $\gamma\phi x = 0$, and so $x \in \ker(\gamma\phi)$. We conclude that $\ker(\alpha\phi)_{b..m-1,0..m-1} \subseteq \ker(\gamma\phi)$, which completes the proof. ∎

Theorem 17 shows that the composition of an MLD permutation with an MRC permutation is an MLD permutation. Since we have seen how to perform MLD permutations, we can gain an intuitive understanding of why Theorem 17 holds. An MRC permutation permutes memoryload numbers, with records that start together within a source memoryload remaining together in a target memoryload. We perform an MLD permutation by reading in entire memoryloads. Thus, to perform the composition as an MLD permutation, we only have to remap the source memoryload numbers and adjust the in-memory permutations accordingly. Furthermore, as the following lemma shows, the composition of two MRC permutations is merely the composition of their memoryload mappings with the in-memory permutations adjusted accordingly.

THEOREM 18. *The class of MRC permutations is closed under composition and inversion. That is, if a matrix A characterizes an MRC permutation, then so does the matrix A^{-1}, and if $A^{(1)}$ and $A^{(2)}$ characterize MRC permutations, then so does the product $A^{(1)}\,A^{(2)}$.*

Proof. We first show that MRC permutations are closed under inverse. Let the matrix

$$A = \left[\begin{array}{c|c} \overset{m}{\alpha} & \overset{n-m}{\beta} \\ \hline 0 & \delta \end{array}\right] \begin{matrix} m \\ n-m \end{matrix}$$

characterize an MRC permutation, so that the leading submatrix α and trailing submatrix δ are nonsingular. The inverse of this matrix is

$$A^{-1} = \left[\begin{array}{c|c} \overset{m}{\alpha^{-1}} & \overset{n-m}{\alpha^{-1}\beta\delta^{-1}} \\ \hline 0 & \delta^{-1} \end{array}\right] \begin{matrix} m \\ n-m \end{matrix},$$

where the leading $m \times m$ submatrix α^{-1} and trailing $(n-m) \times (n-m)$ submatrix δ^{-1} are nonsingular. Thus, the matrix A^{-1} characterizes an MRC permutation.

We now show that MRC permutations are closed under composition. Consider MRC characteristic matrices

$$A^{(1)} = \left[\begin{array}{c|c} \overset{m}{\alpha^{(1)}} & \overset{n-m}{\beta^{(1)}} \\ \hline 0 & \delta^{(1)} \end{array}\right] \begin{matrix} m \\ n-m \end{matrix},$$

$$A^{(2)} = \left[\begin{array}{c|c} \overset{m}{\alpha^{(2)}} & \overset{n-m}{\beta^{(2)}} \\ \hline 0 & \delta^{(2)} \end{array}\right] \begin{matrix} m \\ n-m \end{matrix},$$

where the submatrices $\alpha^{(1)}$, $\alpha^{(2)}$, $\delta^{(1)}$, and $\delta^{(2)}$ are nonsingular. Then their product is

$$A^{(1)}\,A^{(2)} = \left[\begin{array}{c|c} \overset{m}{\alpha^{(1)}\,\alpha^{(2)}} & \overset{n-m}{\alpha^{(1)}\,\beta^{(2)} \oplus \beta^{(1)}\,\delta^{(2)}} \\ \hline 0 & \delta^{(1)}\,\delta^{(2)} \end{array}\right] \begin{matrix} m \\ n-m \end{matrix}.$$

Because $\alpha^{(1)}$ and $\alpha^{(2)}$ are nonsingular, so is their product $\alpha^{(1)}\,\alpha^{(2)}$. Similarly, the product $\delta^{(1)}\,\delta^{(2)}$ is nonsingular. The product $A^{(1)}\,A^{(2)}$, therefore, characterizes an MRC permutation. □

On the other hand, the composition of two MLD permutations is not necessarily an MLD permutation. We can see this fact in two ways. First, since we perform an MLD permutation by reading in entire memoryloads but writing blocks independently, it may not be possible to remap the source memoryload numbers. Second, consider the product of two matrices, each of which characterizes an MLD permutation. Although the rank of the lower left $(n-m) \times m$ submatrix of each factor is at most $m-b$, it may be the case that the rank of the lower left $(n-m) \times m$ submatrix of the product exceeds $m-b$. If so, then by Lemma 16, the product cannot characterize an MLD permutation.

Moreover, the composition of an MRC permutation with an MLD permutation (that is, reversing the order of the factors in Theorem 17) is not necessarily an MLD permutation. A simple example is the product

$$\begin{array}{ccc} \begin{array}{c} \scriptstyle b \quad m-b \quad n-m \\ \left[\begin{array}{c|c|c} 0 & I & 0 \\ \hline I & 0 & 0 \\ \hline 0 & 0 & I \end{array}\right] \end{array} & \begin{array}{c} \scriptstyle b \quad m-b \quad n-m \\ \left[\begin{array}{c|c|c} I & 0 & 0 \\ \hline 0 & I & 0 \\ \hline 0 & I & I \end{array}\right] \end{array} & = \begin{array}{c} \scriptstyle b \quad m-b \quad n-m \\ \left[\begin{array}{c|c|c} 0 & I & 0 \\ \hline I & 0 & 0 \\ \hline 0 & I & I \end{array}\right] \end{array} \begin{array}{l} \scriptstyle b \\ \scriptstyle m-b \\ \scriptstyle n-m \end{array} , \\ \text{MRC} & \text{MLD} & \text{not MLD} \end{array}$$

with $b = m - b = n - m$. This product is not MLD since an m-vector with 0s in the first b positions and 1s in the last $m-b$ positions is a vector in $\ker \lambda$, but it is not a vector in $\ker \mu$.

Finally, we note that any MRC permutation is an MLD permutation. Observe that the lower left $(n-m) \times m$ submatrix of an MRC permutation must be 0, which implies that its kernel is the set of all m-vectors. No matter what $\ker \lambda$ is, it is a subset of this set.

Inverses of MLD permutations. The first BMMC algorithm we shall see works by factoring the BMMC characteristic matrix into matrices that characterize MRC and MLD permutations. In some settings, it may be easier to perform a permutation whose inverse is MLD (we call this class MLD^{-1}) than to perform an MLD permutation. We shall see an alternative way to factor BMMC characteristic matrices—into MRC and MLD^{-1} characteristic matrices—so that the resulting algorithm takes the same number of parallel I/Os as the original factorization into MRC and MLD permutations. In the remainder of this section, we examine the properties of MLD^{-1} permutations that enable this alternative factorization.

Striped writes may be valuable when redundant data is maintained on a parallel disk system to reduce the chance of data loss due to a failed device. Many common parallel-disk organizations fall under the heading of RAID (redundant array of inexpensive disks) [7, 17], which is organized into "levels" of redundancy. In RAID levels 3 and 4, an additional disk is added to the disk array to store redundancy. Each block of this *parity disk* contains the bitwise exclusive-or of the contents of the corresponding blocks of the other D data disks. If any one data disk fails, its contents are easily reconstructed from the contents of the $D-1$ remaining data disks and the parity disk. If an entire stripe is written to the disk array, it is easy to compute the corresponding parity information at the same time and write it to the parity disk in parallel with the data being written to the data disks. On the other hand, when less than a full stripe of data is being written to a given stripe of the disk array, updating the parity disk is harder. For each partial stripe being written, the old data and parity information must be read and the new data and parity information must be written. If k different

stripes are being written, accessing the parity disk may become a severe bottleneck since k different blocks of the parity disk must be read and rewritten. Because an independent write may update individual blocks in several different stripes, in a RAID 3 or 4 organization, algorithms that use striped writes are preferable to those that use independent writes.

With this motivation, we begin our investigation of MLD^{-1} permutations with a property that pertains to all one-pass permutations.

LEMMA 19. *If a permutation Π is a one-pass permutation, then its inverse permutation Π^{-1} is also a one-pass permutation. Moreover, if we perform Π using striped reads (respectively, writes), then we can perform Π^{-1} using striped writes (respectively, reads).*

Proof. Consider a one-pass algorithm to perform the permutation Π. It repeatedly reads a set of blocks, permutes their records in memory, and writes the records as full blocks. The one-pass algorithm reads and writes each record once. To perform the inverse permutation Π^{-1}, we invert each read-permute-write step in the algorithm for Π. In each step, we read the blocks that were written in the corresponding step for Π, we perform the inverse in-memory permutation, and we write the blocks that were read in the corresponding step for Π. Each record is still read and written once, and thus Π^{-1} is also a one-pass permutation. Note that if a read (respectively, write) for Π is striped, then the corresponding write (respectively, read) for Π^{-1} is also striped. □

The following corollary follows directly from Theorem 15 and Lemma 19.

COROLLARY 20. *Any MLD^{-1} permutation can be performed in one pass with independent reads and striped writes.* □

Our final property of MLD^{-1} permutations is analogous to Theorem 17.

LEMMA 21. *Let the matrix X characterize an MRC permutation, and let the matrix Y characterize an MLD^{-1} permutation. Then the matrix product XY characterizes an MLD^{-1} permutation.*

Proof. Let $Z = XY$, so that $Z^{-1} = Y^{-1}X^{-1}$. Since the matrix Y characterizes an MLD^{-1} permutation, the matrix Y^{-1} characterizes an MLD permutation. By Theorem 18, the matrix X^{-1} characterizes an MRC permutation. By Theorem 17, therefore, the matrix Z^{-1} characterizes an MLD permutation. We conclude that the matrix Z characterizes an MLD^{-1} permutation. □

5. Matrix-column operations. In this section, we classify forms of matrices which, as factors, have the effect of adding columns of other matrices to yield a product. We shall use matrices of this form in section 6 to transform the characteristic matrix for any BMMC permutation into a characteristic matrix for an MRC permutation. This section shows the structure and useful properties of specific characteristic matrix forms we shall use.

Column additions. We define a *column-addition* matrix as a matrix Q such that the product $A' = AQ$ is a modified form of A in which specified columns of A have been added into others. Denoting the kth column of A by A_k, we define the matrix $Q = (q_{ij})$ by

$$q_{ij} = \begin{cases} 1 & \text{if } i = j\ , \\ 1 & \text{if column } A_i \text{ is added into column } A_j\ , \\ 0 & \text{otherwise}\ . \end{cases}$$

For example,

$$\underbrace{\begin{bmatrix} 1 & 0 & 1 & 1 \\ 0 & 1 & 1 & 0 \\ 1 & 1 & 0 & 0 \\ 0 & 1 & 0 & 1 \end{bmatrix}}_{A} \quad \underbrace{\begin{bmatrix} 1 & 1 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 \end{bmatrix}}_{Q} = \left[\begin{array}{c|c|c|c} A_0 & A_0 \oplus A_1 \oplus A_3 & A_0 \oplus A_2 & A_3 \end{array}\right]$$

$$= \underbrace{\begin{bmatrix} 1 & 0 & 0 & 1 \\ 0 & 1 & 1 & 0 \\ 1 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}}_{A'} .$$

Column-addition matrices are also subject to a *dependency restriction* that if column i is added into column j, then column j cannot be added into any other column. That is, if $q_{ij} = 1$, then $q_{jk} = 0$ for all $k \neq j$. The following lemma shows that any column-addition matrix is the product of two nonsingular matrices, and so any column-addition matrix is also nonsingular.

LEMMA 22. *Any column-addition matrix is nonsingular.*

Proof. We shall prove by induction on the matrix size n that any column-addition matrix Q is the product of two nonsingular matrices L and U. Thus, the matrix Q is also nonsingular.

For the basis, when $n = 2$, the only column-addition matrices are $\left[\begin{smallmatrix} 1 & 0 \\ 1 & 1 \end{smallmatrix}\right]$, $\left[\begin{smallmatrix} 1 & 1 \\ 0 & 1 \end{smallmatrix}\right]$, and $\left[\begin{smallmatrix} 1 & 0 \\ 0 & 1 \end{smallmatrix}\right]$. Since each of these matrices is nonsingular, each of them is the product of itself and the identity matrix.

For the inductive step, we assume that every $(n-1) \times (n-1)$ column-addition matrix is the product of two nonsingular matrices. We partition an arbitrary $n \times n$ column-addition matrix Q as

$$Q = \begin{array}{c} \begin{array}{cc} 1 & n-1 \end{array} \\ \left[\begin{array}{c|c} 1 & \psi \\ \hline \theta & \chi \end{array}\right] \begin{array}{c} 1 \\ n-1 \end{array} \end{array} .$$

The trailing $(n-1) \times (n-1)$ submatrix χ is a column-addition matrix because all of its diagonal elements are 1s and, as a submatrix of Q, it obeys the dependency restriction. By our inductive hypothesis, therefore, the submatrix χ is the product of two $(n-1) \times (n-1)$ nonsingular matrices, say ν and η. By the dependency restriction, if there are any 1s in θ, then there cannot be any 1s in ψ. Therefore, either ψ or θ is a zero submatrix, and consequently we can factor Q as

$$Q = \underbrace{\begin{array}{c} \begin{array}{cc} 1 & n-1 \end{array} \\ \left[\begin{array}{c|c} 1 & 0 \\ \hline \theta & \nu \end{array}\right] \end{array}}_{L} \quad \underbrace{\begin{array}{c} \begin{array}{cc} 1 & n-1 \end{array} \\ \left[\begin{array}{c|c} 1 & \psi \\ \hline 0 & \eta \end{array}\right] \begin{array}{c} 1 \\ n-1 \end{array} \end{array}}_{U} .$$

The rightmost $n-1$ columns of L are linearly independent since the submatrix ν is nonsingular and the upper right $1 \times (n-1)$ submatrix is 0. The leftmost column is linearly independent of the rightmost $n-1$ columns since its top entry is 1 and the top entry of each of the rightmost $n-1$ columns is 0. Thus, L is nonsingular. Similarly,

because the submatrix η is nonsingular and the lower left $(n-1) \times 1$ submatrix of U is 0, the matrix U is nonsingular. Thus, any column-addition matrix is the product of two nonsingular matrices, and therefore is also nonsingular. □

In fact, the factors L and U in the proof of Lemma 22 are unit lower-triangular and unit upper-triangular matrices, respectively. Thus, we can factor the example above as

$$Q = \begin{bmatrix} 1 & 1 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 \end{bmatrix} = \begin{bmatrix} 1 & 1 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 \end{bmatrix} = L\,U\ .$$

Partitioning the matrix. In section 6, we shall factor nonsingular matrices into column-addition matrices and matrices that characterize MRC permutations. These matrices will be of various block forms, and to classify these forms, we use the following block representation. We partition a matrix into three sections: left, middle, and right. The *left section* includes the leftmost b columns, the *middle section* includes the middle $m-b$ columns, and the *right section* includes the rightmost $n-m$ columns. When the form of a particular submatrix is known, we label that block accordingly. Otherwise, we place an asterisk (*) in blocks whose contents are not of any particular form.

For column-addition operations, the characteristic matrix has the following form. Every entry on the diagonal is 1. We place an asterisk in each submatrix that contains any nondiagonal 1s as defined by the operation. Returning to the example above, if $b = 1$ and $m = 2$, the form of Q is

$$Q = \begin{array}{c} \begin{array}{ccc} b=1 & m-b=1 & n-m=2 \end{array} \\ \left[\begin{array}{c|c|c} I & * & * \\ \hline 0 & I & 0 \\ \hline 0 & * & I \end{array}\right] \end{array} \begin{array}{l} b=1 \\ m-b=1 \\ n-m=2 \end{array} .$$

We define several column-addition operations and MRC permutations by the form of their characteristic matrices. Each of these forms is nonsingular and characterizes a one-pass permutation. We shall show that the inverse of each of these one-pass permutations falls into a specific class of one-pass permutations.

Trailer matrix form. In section 6, we shall need to transform a nonsingular matrix into one that has a nonsingular trailing $(n-m) \times (n-m)$ submatrix. We shall create the nonsingular trailing submatrix by adding some columns from the left and middle sections to the right section. We define a *trailer matrix* as a column-addition matrix that adds some columns from the left and middle sections into the columns of the right section. The matrix T for this operation is of the form

$$T = \begin{array}{c} \begin{array}{ccc} b & m-b & n-m \end{array} \\ \left[\begin{array}{c|c|c} I & 0 & * \\ \hline 0 & I & * \\ \hline 0 & 0 & I \end{array}\right] \end{array} \begin{array}{l} b \\ m-b \\ n-m \end{array} .$$

The trailer matrix form characterizes an MRC permutation.

Reducer matrix form. Once we have a matrix with a nonsingular trailing submatrix, we need an operation that puts the matrix into "reduced form." (We shall define reduced form precisely in section 6.) We convert a matrix into reduced form by adding columns from the left and middle sections into other columns in the left and middle sections while respecting the dependency restriction. Thus, a *reducer matrix* R is a column-addition matrix of the form

$$R = \begin{array}{c} \begin{array}{ccc} b & m-b & n-m \end{array} \\ \left[\begin{array}{c|c|c} * & * & 0 \\ \hline * & * & 0 \\ \hline 0 & 0 & I \end{array}\right] \end{array} \begin{array}{l} b \\ m-b \\ n-m \end{array} .$$

Since the dependency restriction is obeyed, the leading $m \times m$ submatrix of R is nonsingular. Thus, the matrix R characterizes an MRC permutation.

We can multiply the forms T and R to create another matrix form that also characterizes a one-pass permutation. The product $T\,R$ results in a matrix of the form

$$P = \begin{array}{c} \begin{array}{ccc} b & m-b & n-m \end{array} \\ \left[\begin{array}{c|c|c} * & * & * \\ \hline * & * & * \\ \hline 0 & 0 & I \end{array}\right] \end{array} \begin{array}{l} b \\ m-b \\ n-m \end{array} .$$

Since both of the matrix forms T and R characterize MRC permutations, by Theorem 18, so does the matrix form P and its inverse.

Swapper matrix form. We shall also need to transform the columns in the lower left and lower middle submatrices into columns of zeros. To do so, we must move the nonzero columns in the lower left submatrix into the lower middle submatrix positions by swapping at most $m - b$ columns at a time from the left section with those in the middle section. Thus, the swap operation is a permutation of the leftmost m columns. A *swapper matrix* is of the form

$$S = \begin{array}{c} \begin{array}{cc} m & n-m \end{array} \\ \left[\begin{array}{c|c} \text{permutation} & 0 \\ \hline 0 & I \end{array}\right] \end{array} \begin{array}{l} m \\ n-m \end{array} ,$$

so that the leading $m \times m$ submatrix is a permutation matrix, which dictates the permutation of the leftmost m columns. The matrix form S characterizes an MRC permutation and, by Theorem 18, so does its inverse.

Erasure matrix form. The last operation used in section 6 is an erasure operation to zero out columns in the lower middle submatrix. To perform this operation, we add columns from the right section into columns in the middle section. Thus, an *erasure* matrix form is defined as

$$E = \begin{array}{c} \begin{array}{ccc} b & m-b & n-m \end{array} \\ \left[\begin{array}{c|c|c} I & 0 & 0 \\ \hline 0 & I & 0 \\ \hline 0 & * & I \end{array}\right] \end{array} \begin{array}{l} b \\ m-b \\ n-m \end{array} .$$

This matrix form characterizes an MLD permutation because $E_{b..m-1,0..m-1}$'s kernel includes only those m-vectors x with $x_{b..m-1} = 0$, and each such vector is also

in the kernel of $E_{m..n-1,0..m-1}$. Moreover, observe that any matrix of this form is its own inverse. Consequently, the inverse of such a matrix characterizes an MLD permutation.

6. An asymptotically optimal BMMC algorithm. In this section, we present an algorithm to perform any BMMC permutation by factoring its characteristic matrix into matrices which characterize one-pass permutations. We assume that the BMMC permutation is given by an $n \times n$ characteristic matrix A and a complement vector c of length n. We show that the number of parallel I/Os to perform any BMMC permutation is at most $\frac{2N}{BD}(\lceil \frac{\operatorname{rank}\gamma}{\lg(M/B)} \rceil + 2)$ parallel I/Os, where γ is the submatrix $A_{b..n-1,0..b-1}$, which appears in the lower bound given by Theorem 6.

Our strategy is to factor the matrix A into a product of matrices, each of which characterizes an MRC or MLD permutation. For now, we ignore the complement vector c. According to Corollary 2, we read the factors right to left to determine the order in which to perform the permutations.

To obtain the factorization for A, we multiply A by matrices of the forms described in Section 5. By applying these matrix-column operations, we transform the matrix A into a matrix F that characterizes an MRC permutation. Multiplying F by the inverse of each of the matrix-column factors yields the factorization.

Creating a nonsingular trailing submatrix. We start to transform the characteristic matrix A by creating a nonsingular matrix $A^{(1)}$ which has a nonsingular trailing $(n-m) \times (n-m)$ submatrix. We represent the matrix A as

$$A = \begin{array}{c} \begin{array}{cc} m & n-m \end{array} \\ \left[\begin{array}{c|c} \alpha & \beta \\ \hline \phi & \delta \end{array}\right] \begin{array}{c} m \\ n-m \end{array} \end{array} .$$

Our algorithm depends on the structure of ϕ rather than γ. The following lemma allows us to consider $\operatorname{rank}\phi$ instead of $\operatorname{rank}\gamma$ with only a minor difference.

LEMMA 23. *For any matrix A,*

$$\operatorname{rank} A_{b..n-1,0..b-1} - \lg(M/B) \le \operatorname{rank} A_{m..n-1,0..m-1} \le \operatorname{rank} A_{b..n-1,0..b-1} + \lg(M/B) .$$

Proof. Because the rank of a submatrix is the maximum number of linearly independent rows or columns, we have

$$\begin{aligned} \operatorname{rank} A_{m..n-1,0..b-1} &\le \operatorname{rank} A_{b..n-1,0..b-1} \\ &\le \operatorname{rank} A_{m..n-1,0..b-1} + \lg(M/B) , \end{aligned} \tag{12}$$

$$\begin{aligned} \operatorname{rank} A_{m..n-1,0..b-1} &\le \operatorname{rank} A_{m..n-1,0..m-1} \\ &\le \operatorname{rank} A_{m..n-1,0..b-1} + \lg(M/B) . \end{aligned} \tag{13}$$

Subtracting $\lg(M/B)$ from the right-hand inequality of (12) and combining the result with the left-hand inequality of (13) yields

$$\begin{aligned} \operatorname{rank} A_{b..n-1,0..b-1} - \lg(M/B) &\le \operatorname{rank} A_{m..n-1,0..b-1} \\ &\le \operatorname{rank} A_{m..n-1,0..m-1} . \end{aligned} \tag{14}$$

Adding $\lg(M/B)$ to the left-hand inequality of (12) and combining the result with the right-hand inequality of (13) yields

$$\begin{aligned} \operatorname{rank} A_{m..n-1,0..m-1} &\le \operatorname{rank} A_{m..n-1,0..b-1} + \lg(M/B) \\ &\le \operatorname{rank} A_{b..n-1,0..b-1} + \lg(M/B) . \end{aligned} \tag{15}$$

Combining inequalities (14) and (15) proves the lemma. □

By Lemma 23, therefore,

$$\operatorname{rank}\phi \le \operatorname{rank}\gamma + \lg(M/B)\ . \tag{16}$$

We shall use this fact later in the analysis of the algorithm to express the bound in terms of $\operatorname{rank}\gamma$.

We make the trailing $(n-m)\times(n-m)$ submatrix nonsingular by adding columns in ϕ into those in δ. Consider δ as a set of $n-m$ columns and ϕ as a set of m columns. Because A is nonsingular, the submatrix of A consisting of the bottom $n-m$ rows (i.e., submatrices ϕ and δ) has rank $n-m$. Hence, there exists a set of $n-m$ linearly independent columns in the bottom $n-m$ rows of A. We use the method described in section 2 to determine a maximal set V of $\operatorname{rank}\delta$ linearly independent columns in δ and a set W of $n-m-\operatorname{rank}\delta$ columns in ϕ that, along with V, comprise a set of $n-m$ linearly independent columns. Denoting by $\overline{V}$ the $n-m-\operatorname{rank}\delta$ columns of δ not in V, we make the trailing submatrix of A nonsingular by pairing up columns of W with columns of $\overline{V}$ and adding each column in W into its corresponding column in $\overline{V}$. Because V is a maximal set of linearly independent columns in δ, the columns of $\overline{V}$ depend only on columns of V and not on columns of W. Adding a column of W into a column of $\overline{V}$ must produce a column that is linearly independent of those in V. Because each column of $\overline{V}$ has a different column of W added in, the resulting columns are linearly independent of each other, too.

We must express the above transformation as a column-addition operation. Although we focused above on adding columns of ϕ to columns of δ, column-addition operations add entire columns, and so we must also add the corresponding columns of α to the corresponding columns of β. Since we add columns from the leftmost m columns of A to the rightmost $n-m$ columns, the characteristic matrix of this operation has the trailer matrix form T described in section 5. The matrix product is now

$$A^{(1)} \;=\; AT \;=\; \begin{array}{c} \begin{array}{cc} m & n-m \end{array} \\ \left[\begin{array}{c|c} \alpha & \widehat{\beta} \\ \hline \phi & \widehat{\delta} \end{array}\right] \end{array} \begin{array}{l} m \\ n-m \end{array},$$

where $\widehat{\delta}$ is nonsingular. Since the matrices A and T are nonsingular, the matrix $A^{(1)}$ is nonsingular.

Transforming the matrix into reduced form. The next step is to transform the matrix $A^{(1)}$ into reduced form. For our purposes, a matrix is in *reduced form* when there are $\operatorname{rank}\phi$ linearly independent columns and $m-\operatorname{rank}\phi$ columns of zeros in the lower left $(n-m)\times m$ submatrix, and the trailing $(n-m)\times(n-m)$ submatrix is nonsingular. Once again, we use the method of section 2 to determine a set U that indexes $\operatorname{rank}\phi$ linearly independent columns of ϕ. To perform the reduction, we determine for each linearly dependent column ϕ_j a set of column indices $U_j \subseteq U$ such that $\phi_j = \oplus_{k\in U_j}\phi_k$. Adding the set of columns of ϕ indexed by U_j into ϕ_j zeros it out. We add linearly independent columns from the left and middle sections into the linearly dependent columns of these sections. Since we never add a linearly dependent column into any other column and there are no column additions into the linearly independent columns, we respect the dependency restriction. The matrix R that reduces the matrix $A^{(1)}$ has the reducer matrix form described in section 5.

Thus, the matrix product $T\,R$ is of the form P also described in section 5, and it characterizes an MRC permutation. We now have the product

$$A^{(2)} \;=\; A^{(1)}\,R \;=\; A\,T\,R \;=\; A\,P \;=\; \begin{array}{c} \begin{array}{cc} m & n-m \end{array} \\ \left[\begin{array}{c|c} \widehat{\alpha} & \widehat{\beta} \\ \hline \widehat{\phi} & \widehat{\delta} \end{array}\right] \begin{array}{c} m \\ n-m \end{array} \end{array},$$

with a nonsingular trailing submatrix $\widehat{\delta}$ and a lower left submatrix $\widehat{\phi}$ in reduced form. Since A and P are nonsingular, the matrix $A^{(2)}$ is also nonsingular.

Zeroing out the lower left submatrix. Our eventual goal is to transform the original matrix A into a matrix F that characterizes an MRC permutation. At this point, the matrix A has been transformed into the nonsingular matrix $A^{(2)}$. Thus, our final task is to multiply $A^{(2)}$ by a series of matrices that transform the rank ϕ nonzero columns in the lower left $(n-m) \times m$ submatrix $\widehat{\phi}$ into columns of zeros. We do so by multiplying $A^{(2)}$ by matrices of the swapper and erasure matrix forms described in section 5. Let us further partition the leftmost m columns of $A^{(2)}$ into the leftmost b columns and the middle $m-b$ columns:

$$A^{(2)} \;=\; \begin{array}{c} \begin{array}{ccc} b & m-b & n-m \end{array} \\ \left[\begin{array}{c|c|c} \widehat{\alpha}' & \widehat{\alpha}'' & \widehat{\beta} \\ \hline \widehat{\phi}' & \widehat{\phi}'' & \widehat{\delta} \end{array}\right] \begin{array}{c} m \\ n-m \end{array} \end{array}.$$

Our strategy is to repeatedly use swapper matrix forms to move at most $m-b$ columns from the left section into the middle section and then zero out those columns using erasure matrix forms.

We begin by swapping $m - b - \operatorname{rank}\widehat{\phi}''$ columns from $\widehat{\phi}'$ with the zero columns of $\widehat{\phi}''$. Multiplying the matrix $A^{(2)}$ by a nonsingular matrix S_1 of the swapper matrix form described in section 5, we swap at most $m-b$ columns from the left section with the appropriate columns in the middle section. After performing the swap operation on the matrix $A^{(2)}$, the lower left submatrix has $m - b - \operatorname{rank}\widehat{\phi}''$ additional zero columns and the lower middle submatrix has full rank. The above discussion assumes that $\operatorname{rank}\widehat{\phi}' \geq m - b - \operatorname{rank}\widehat{\phi}''$; if the opposite holds, we swap $\operatorname{rank}\widehat{\phi}'$ columns and the lower left submatrix becomes all zeros.

Our next step is to transform the $m - b$ columns in the lower middle submatrix into columns of zeros. Since the nonsingular trailing $(n-m) \times (n-m)$ submatrix $\widehat{\delta}$ forms a basis for the columns of the lower $n - m$ rows of matrix $A^{(2)}$, we zero out each nonzero column in the lower middle submatrix by adding columns of $\widehat{\delta}$. Since we add columns from the rightmost $n - m$ columns into the middle $m - b$ columns, we perform the matrix-column operation characterized by a nonsingular matrix E_1 of the erasure matrix form described in section 5. After multiplying by the erasure matrix E_1, the original matrix is transformed into a nonsingular matrix

$$A^{(3)} = A\,P\,S_1\,E_1\ ,$$

which has zero columns in the lower middle $(n-m) \times (m-b)$ submatrix and possibly some more nonzero columns in the lower left $(n-m) \times b$ submatrix.

If there are still nonzero columns in the lower left $(n-m) \times b$ submatrix of the matrix $A^{(3)}$, then those columns must also be swapped into the lower middle $(n-m) \times (m-b)$ submatrix by a swapper matrix and transformed into zero columns by an erasure matrix. We repeatedly swap in up to $m - b$ nonzero columns of the

lower left submatrix into the lower middle submatrix. Each time we perform a swap operation, we multiply the current product by a matrix S_i of the swapper matrix form. Note that we swap entire columns here, not just the portions in the lower submatrices. After we perform each matrix-column operation S_i, we zero out the lower middle submatrix by multiplying the current product by a matrix E_i of the erasure matrix form.

After repeatedly swapping and erasing each of the nonzero columns in the lower left $(n-m) \times m$ submatrix, the lower left submatrix will contain only zero columns. This matrix is the matrix F mentioned at the beginning of this section. Since the matrix $A^{(2)}$ is in reduced form, there are at most $\operatorname{rank} \phi$ columns in the submatrix $\widehat{\phi}$ that need to be transformed into zero columns. Thus, at most

$$g = \left\lceil \frac{\operatorname{rank} \phi}{m-b} \right\rceil \tag{17}$$

pairs of swap and erasure operations transform all the columns in the lower left $(n-m) \times m$ submatrix into zero columns. Since each matrix-column operation that we performed on the original matrix A to transform it into F is nonsingular, the resulting matrix product

$$F = A\,P\,S_1\,E_1\,S_2\,E_2\,\cdots S_g\,E_g$$

is a nonsingular matrix that characterizes an MRC permutation. Multiplying both sides by the inverses of the factors yields the desired factorization of A:

$$A = F\,E_g^{-1}\,S_g^{-1}\,E_{g-1}^{-1}\,S_{g-1}^{-1}\,\cdots\,E_1^{-1}\,S_1^{-1}P^{-1}\ . \tag{18}$$

Analysis. We now apply several properties that we have gathered to complete the analysis of our BMMC permutation factoring method.

THEOREM 24. *We can perform any BMMC permutation with characteristic matrix A and complement vector c in at most*

$$\frac{2N}{BD}\left(\left\lceil \frac{\operatorname{rank} \gamma}{\lg(M/B)} \right\rceil + 2\right)$$

parallel I/Os, where $\gamma = A_{b..n-1,0..b-1}$, using striped reads, independent writes, and $2N$ records of disk space.

Proof. Ignore the complement vector c for the moment. In the factorization (18) of A, both factors S_1^{-1} and P^{-1} characterize MRC permutations. By Theorem 18, therefore, so does the product $S_1^{-1}\,P^{-1}$. As we saw in section 5, each factor E_i^{-1} characterizes an MLD permutation. Applying Theorem 17, each grouping of factors $E_1^{-1}\,S_1^{-1}\,P^{-1}$ and $E_i^{-1}\,S_i^{-1}$, for $i = 2, 3, \ldots, g$, characterizes an MLD permutation. By Theorem 15, and adding in one more pass for the MRC permutation characterized by F, we can perform A with $g+1$ passes.

If the complement vector c is nonzero, we include it as part of the MRC permutation characterized by the leftmost factor F. See [10] for details.

Regardless of the complement vector, therefore, we can perform the BMMC permutation with $g+1$ passes. Combining equation (17) and inequality (16), we obtain a bound of

$$g + 1 = \left\lceil \frac{\operatorname{rank} \phi}{\lg(M/B)} \right\rceil + 1$$

$$\leq \left\lceil \frac{\operatorname{rank}\gamma + \lg(M/B)}{\lg(M/B)} \right\rceil + 1$$
$$= \left\lceil \frac{\operatorname{rank}\gamma}{\lg(M/B)} \right\rceil + 2$$

passes for a total of at most

$$\frac{2N}{BD}\left(\left\lceil \frac{\operatorname{rank}\gamma}{\lg(M/B)} \right\rceil + 2\right)$$

parallel I/Os.

Because each factor characterizes either an MRC permutation (performed with striped reads and writes) or an MLD permutation (performed with striped reads and independent writes), and striped I/O is a special case of independent I/O, the method as a whole uses striped reads and independent writes. The method uses $2N$ records of disk space by reversing the roles of the source and target portions between passes. That is, the target portion written to in one pass becomes the source portion read from in the next pass. □

Performing BMMC permutations with striped writes. Here we describe another way to compose the factors from the product of equation (18) into $g + 1$ factors, such that each factor characterizes either an MRC or MLD^{-1} permutation. Both MRC and MLD^{-1} permutations can be performed with striped writes. As mentioned in section 4, striped writes may have advantages in parallel disk systems organized as RAID levels 3 or 4.

In our alternative factorization, we start by noting that because any erasure matrix is its own inverse, not only does each factor E_i^{-1} in the factorization (18) characterize an MLD permutation, it also characterizes an MLD^{-1} permutation. Instead of grouping the factors $E_1^{-1} S_1^{-1} P^{-1}$ and $E_i^{-1} S_i^{-1}$ for $i = 2, 3, \ldots, g$, here we group by $F E_g^{-1}$ and $S_i^{-1} E_{i-1}^{-1}$, for $i = 2, 3, \ldots, g$. By Lemma 21, each such grouping of factors characterizes an MLD^{-1} permutation. Thus, the resulting factorization of A has g MLD^{-1} factors and the MRC product $S_1^{-1} P^{-1}$. This alternative factorization of A has the same number of one-pass factors as our previous grouping, but it uses only MRC and MLD^{-1} permutations as its factors. Thus, we have proven the following.

THEOREM 25. *We can perform any BMMC permutation with characteristic matrix A and complement vector c in at most*

$$\frac{2N}{BD}\left(\left\lceil \frac{\operatorname{rank}\gamma}{\lg(M/B)} \right\rceil + 2\right)$$

parallel I/Os, where $\gamma = A_{b..n-1,0..b-1}$, using independent reads, striped writes, and $2N$ records of disk space. □

7. Detecting BMMC permutations at run time. In practice, we wish to run the BMMC algorithm of section 6 whenever possible to reap the savings over having run the more costly algorithm for general permutations. For that matter, we wish to run even faster algorithms for any of the special cases of BMMC permutations (MRC, MLD, MLD^{-1}, or block BMMC [10]) whenever possible as well. We must know the characteristic matrix A and complement vector c, however, to run any of these algorithms. If A and c are specified in the source code, before running the algorithm we only need to check that A is of the correct form, e.g., that it is nonsingular for a BMMC permutation, of the MLD or MRC form, etc. Later in this section, we show

how to check the kernel condition for MLD permutations. If instead the permutation is given by a vector of N target addresses, we can detect at run time whether it is a BMMC permutation by the following procedure.

1. Check that N is a power of 2.

2. Form a candidate characteristic matrix A and complement vector c such that if the permutation is BMMC, then A and c must be the correct characterizations. This section shows how to do so with only $\lceil \frac{\lg(N/B)+1}{D} \rceil$ parallel reads.

3. Check that the characteristic matrix is of the correct form. That is, check that it is nonsingular, which is easily done by the method of section 2. If further structure is desired, e.g., MRC or MLD forms, check further for the desired form.

4. Verify that all N target addresses are described by the candidate characteristic matrix and complement vector. If for any source address x and its corresponding target address y we have $y \neq A\,x \oplus c$, the permutation is not BMMC and we can terminate verification. If $y = A\,x \oplus c$ for all N source-target pairs, the permutation is BMMC. Verification uses at most N/BD parallel reads, since we need to read each target address at most once. Source addresses are generated implicitly, and so they do not entail any I/O cost.

The total number of parallel I/Os is at most

$$\frac{N}{BD} + \left\lceil \frac{\lg(N/B)+1}{D} \right\rceil ,$$

all of which are reads, and it is usually far fewer when the permutation turns out not to be BMMC.

One benefit of run-time BMMC detection is that the programmer might not realize that the desired permutation is BMMC. For example, as noted in section 1, the standard binary reflected Gray code and its inverse are both MRC permutations. Yet the programmer might not know to call a special MRC or BMMC routine. Even if the system provides an entry point to perform the standard Gray code permutation and this routine invokes the MRC algorithm, variations on the standard Gray code may foil this approach. For example, a standard Gray code with all bits permuted the same (i.e., a characteristic matrix of $\Pi\,G$, where Π is a permutation matrix and G is the MRC matrix that characterizes the standard Gray code) is BMMC but not necessarily MRC. It might not be obvious enough that the permutation characterized by $\Pi\,G$ is BMMC for the programmer to invoke the BMMC algorithm explicitly.

Forming the candidate characteristic matrix and complement vector. The method for forming the candidate characteristic matrix A and candidate complement vector c is based on two observations. First, if the permutation is BMMC, then the complement vector c must be the target address corresponding to source address 0. This relationship holds because $x = 0$ and $y = A\,x \oplus c$ imply that $y = c$.

The second observation is as follows. Consider a source address $x = (x_0, x_1, \ldots, x_{n-1})$, and suppose that bit position k holds a 1, i.e., $x_k = 1$. Let us denote the jth column for matrix A by A_j. Also, let S_k denote the set of bit positions in x other than k that hold a 1: $S_k = \{j : j \neq k \text{ and } x_j = 1\}$. If $y = A\,x \oplus c$, then we have

$$y = \left(\bigoplus_{j \in S_k} A_j \right) \oplus A_k \oplus c \ , \tag{19}$$

since only the bit positions j for which $x_j = 1$ contribute a column of A to the sum of columns that forms the matrix-vector product. If we know the target address y, the

complement vector c, and the columns A_j for all $j \neq k$, we can rewrite equation (19) to yield the kth column of A:

$$A_k = y \oplus \left(\bigoplus_{j \in S_k} A_j \right) \oplus c \ . \tag{20}$$

We shall compute the complement vector c first and then the columns of the characteristic matrix A one at a time, from A_0 up to A_{n-1}. When computing A_k, we will have already computed $A_0, A_1, \ldots, A_{k-1}$, and these will be the only columns we need in order to apply equation (20). In other words, $S_k \subseteq \{0, 1, \ldots, k-1\}$. Recall that as Fig. 2 shows, the lower b bits of a record's address give the record's offset within its block, the middle d bits give the disk number, and the upper $s = n-(b+d)$ bits give the stripe number.

From equation (20), it would be easy to compute A_k if S_k were empty. The set S_k is empty if the source address is a unit vector, with its only 1 in position k. If we look at these addresses, however, we find that the target addresses for a disproportionate number—all but d of them—reside on disk $\mathcal{D}_0$. The block whose disk and stripe fields are all zero contains b such addresses, so they can be fetched in one disk read. A problem arises for the s source addresses with one 1 in the stripe field: their target addresses all reside on different blocks of disk $\mathcal{D}_0$. If we use this method, each of these blocks must be fetched in a separate read. The total number of parallel reads to fetch all the target addresses corresponding to all unit-vector source addresses is $s + 1 = \lg(N/BD) + 1$.

To achieve only $\lceil \frac{\lg(N/B)+1}{D} \rceil$ parallel reads, each read fetches one block from each of the D disks. The first parallel read determines the complement vector, the first $b + d$ columns, and the next $D - d - 1$ columns. Each subsequent read determines another D columns, until all n columns have been determined.

In the first parallel read, we do the same as above for the first $b + d$ bits. That is, we fetch blocks containing target addresses whose corresponding source addresses are unit vectors with one 1 in the first $b + d$ positions. As before, b of them are in the same block on disk $\mathcal{D}_0$. This block also contains address 0, which we need to compute the complement vector. The remaining d are in stripe number 0 of disks $\mathcal{D}_1, \mathcal{D}_2, \mathcal{D}_4, \mathcal{D}_8, \ldots, \mathcal{D}_{D/2}$. Having fetched the corresponding target addresses, we have all the information we need to compute the complement vector c and columns $A_0, A_1, \ldots, A_{b+d-1}$.

The columns we have yet to compute correspond to bit positions in the stripe field. If we were to compute these columns in the same fashion as the first $b + d$, we would again encounter the problem that all the blocks we need to read are on disk $\mathcal{D}_0$. In the first parallel read, the only unused disks remaining are those whose numbers are not a power of 2 ($\mathcal{D}_3, \mathcal{D}_5, \mathcal{D}_6, \mathcal{D}_7, \mathcal{D}_9, \ldots$). The key observation is that we have already computed all d columns corresponding to the disk field, and we can thus apply equation (20). For example, let us compute column A_{b+d}, which corresponds to the first bit of the stripe number. We read stripe 1 on disk $\mathcal{D}_3$ and find the first target address y in this block. Disk number 3 corresponds to the first two disk-number columns, A_b and A_{b+1}. Applying equation (20) with $S_{b+d} = \{b, b+1\}$, we compute $A_{b+d} = y \oplus A_b \oplus A_{b+1} \oplus c$. The next column we compute is A_{b+d+1}. Reading the block at stripe 2 on disk $\mathcal{D}_5$, we fetch a target address y and then compute $A_{b+d+1} = y \oplus A_b \oplus A_{b+2} \oplus c$. Continuing on in this fashion, we compute a total of $D - d - 1$ stripe-bit columns from the first parallel read.

The remaining parallel reads compute the remaining stripe-bit columns. We follow the stripe-bit pattern of the first read, but we use all disks, not just those whose disk numbers are not powers of 2. Each block read fetches a target address y, which we exclusive-or with a set of columns from the disk field and with the complement vector to compute a new column from the stripe field. The first parallel read computes $b + D - 1$ columns, and all subsequent parallel reads compute D columns. The total number of parallel reads is thus

$$\begin{aligned} 1 + \left\lceil \frac{n - (b + D - 1)}{D} \right\rceil &= 1 + \left\lceil \frac{\lg(N/B) - D + 1}{D} \right\rceil \\ &= \left\lceil \frac{\lg(N/B) + 1}{D} \right\rceil . \end{aligned}$$

Checking the kernel condition for MLD permutations. In practice, we would like a simple procedure to verify that a given matrix characterizes an MLD permutation. By the method of section 2, it is easy to verify that a candidate matrix A is nonsingular. It may not be obvious how to verify that $\ker \lambda \subseteq \ker \mu$ when the matrix is blocked into λ and μ. Instead of determining directly whether $\ker \lambda \subseteq \ker \mu$, we check whether $\operatorname{row} \mu \subseteq \operatorname{row} \lambda$. By Lemma 5, these conditions are equivalent.

Checking whether $\operatorname{row} \mu \subseteq \operatorname{row} \lambda$ is easy. Note that the rows of the submatrix $A_{b..n-1,0..m-1}$ consist of the union of the rows of λ and μ, and observe that $\operatorname{row} \mu \subseteq \operatorname{row} \lambda$ if and only if $\operatorname{row} \lambda = \operatorname{row} A_{b..n-1,0..m-1}$. That is, if including the rows of μ adds no new vectors to the row space of λ, then the row space of μ must be a subset of the row space of λ. The condition $\operatorname{row} \lambda = \operatorname{row} A_{b..n-1,0..m-1}$ is equivalent to $\dim \operatorname{row} \lambda = \dim \operatorname{row} A_{b..n-1,0..m-1}$, which is in turn equivalent to $\operatorname{rank} \lambda = \operatorname{rank} A_{b..n-1,0..m-1}$. We can check this last condition easily by using the method of section 2.

8. Conclusions. This paper has shown an asymptotically tight bound on the number of parallel I/Os required to perform BMMC permutations on parallel disk systems. It is particularly satisfying that the tight bound was achieved not by raising the lower bound proven here and in [9], but by decreasing the upper bound in [10]. (After all, we would rather perform BMMC permutations with fewer parallel I/Os.) The multiplicative and additive constants in the I/O complexity of our algorithm are small, which is especially fortunate in light of the expense of disk accesses. Our algorithm has been implemented on a DEC 2100 server with eight disk drives [13]. This implementation uses asynchronous independent reads and asynchronous striped writes, so that when performing each MRC or MLD^{-1} permutation, it overlaps prefetching the next memoryload, writing the previous memoryload, and permuting in memory the current memoryload. A later implementation that runs on either the DEC 2100 server or a network of workstations [11] uses asynchronous striped reads and asynchronous independent writes; it is a key subroutine in an efficient out-of-core FFT implementation [12].

One can adapt the proof by Aggarwal and Vitter [2] of Lemma 9 to bound $\Delta\Phi_{\max}$ precisely, rather than just asymptotically. In particular, it is a straightforward exercise to derive the bound

$$\Delta\Phi_{\max} \leq B \left(\frac{2}{e \ln 2} + \lg(M/B) \right) .$$

Moreover, the potential change is at most zero for write operations, and so the potential increases only during read operations. If all I/Os are simple, then the total

number of blocks read equals the total number of blocks written. Therefore, we can modify the lower bound of Lemma 8 to $2\,\frac{\Phi(t)-\Phi(0)}{\Delta\Phi_{\max}}$, with which we can derive a lower bound of

$$\frac{2N}{BD}\,\frac{\operatorname{rank}\gamma}{\frac{2}{e\ln 2}+\lg(M/B)}$$

parallel I/Os for any BMMC permutation. Since the quantity $2/(e\ln 2)$ is approximately 1.06, this lower bound is quite close to the exact upper bound given by Theorem 24.

We have also shown how to detect BMMC permutations at run time, given a vector of target addresses. Detection is inexpensive and, when successful, permits the execution of our BMMC algorithm or possibly a faster algorithm for a more restricted permutation class.

Wisniewski [25] uses the linear-algebraic technique of performing column additions and row additions to derive BMMC-permutation algorithms on distributed-memory models and main-memory/cache models. On what other memory models can we use this technique to efficiently perform BMMC permutations?

What other permutations can be performed quickly? Several $O(1)$-pass permutation classes appear in [9], and this paper has added two more (MLD and MLD^{-1} permutations in section 4). We have shown that the inverse of any one-pass permutation is a one-pass permutation. One can also show that the composition of an MLD permutation with an MLD^{-1} permutation is a one-pass permutation. What other useful permutation classes can we show to be BMMC?

Finally, is the lower bound of $\Omega(\frac{\Phi(t)-\Phi(0)}{\Delta\Phi_{\max}})$ parallel I/Os universally tight for all permutations, not just those that are BMMC? One possible approach is to design an algorithm that explicitly manages the potential. If each pass increases the potential by $\Theta\left(\frac{N}{BD}(\Delta\Phi_{\max})\right)$, the algorithm's I/O count would match the lower bound.

Acknowledgments. Thanks to C. Esther Jeserum, Michael Klugerman, and the anonymous referees for their helpful suggestions.

L-PRINTABLE SETS*

LANCE FORTNOW†, JUDY GOLDSMITH‡, MATTHEW A. LEVY‡, AND STEPHEN MAHANEY§

Abstract. A language is L-printable if there is a logspace algorithm which, on input 1^n, prints all members in the language of length n. Following the work of Allender and Rubinstein [*SIAM J. Comput.*, 17 (1988), pp. 1193–1202] on P-printable sets, we present some simple properties of the L-printable sets. This definition of "L-printable" is robust and allows us to give alternate characterizations of the L-printable sets in terms of tally sets and Kolmogorov complexity. In addition, we show that a regular or context-free language is L-printable if and only if it is sparse, and we investigate the relationship between L-printable sets, L-rankable sets (i.e., sets A having a logspace algorithm that, on input x, outputs the number of elements of A that precede x in the standard lexicographic ordering of strings), and the sparse sets in L. We prove that under reasonable complexity-theoretic assumptions, these three classes of sets are all different. We also show that the class of sets of small generalized Kolmogorov space complexity is exactly the class of sets that are L-isomorphic to tally languages.

Key words. sparse sets, logspace, L-isomorphisms, Kolmogorov complexity, computational complexity, ranking, regular languages, context-free languages

1. Introduction.

What is an easy set? Typically, complexity theorists view easy sets as those with easy membership tests. An even stronger requirement might be that there is an easy algorithm to print all the elements of a given length. These "printable" sets are easy enough that we can efficiently retrieve all of the information we might need about them.

Hartmanis and Yesha first defined P-printable sets in 1984 [HY84]. A set A is P-printable if there is a polynomial-time algorithm that on input 1^n outputs all of the elements of A of length n. Any P-printable set must lie in P and be sparse; i.e., the number of strings of each length is bounded by a fixed polynomial of that length. Allender and Rubinstein [AR88] give an in-depth analysis of the complexity of the P-printable sets.

Once P-printability has been defined, it is natural to consider the analogous notion of logspace-printability. Since it is not known whether or not L = P, an obvious question to ask is: do the L-printable sets behave differently than the P-printable sets? In this paper, we are able to answer this question in the affirmative, at least under plausible complexity-theoretic assumptions. Jenner and Kirsig [JK89] define L-printability as the logspace computable version of P-printability. Because L-printability implies P-printability, every L-printable set must be sparse and lie in L. In this paper we give

the first in-depth analysis of the complexity of L-printable sets. (Jenner and Kirsig focused only one chapter on printability, and most of their printability results concern NL-printable sets.)

Whenever a new class of sets is analyzed, it is natural to wonder about the structure of those sets. Hence, we examine the regular and context-free L-printable sets. Using characterizations of the sparse regular and context-free languages, we show in section 4 that every sparse regular or context-free language is L-printable. (Although the regular sets are a special case of the context-free sets, we include the results for the regular languages because our characterization of the sparse regular languages is simple and intuitive.)

We might expect many of the properties of P-printable sets to have logspace analogues, and, in fact, this is the case. In section 5 we show that L-printable sets (like their polynomial-time counterparts) are closely related to tally sets in L and to sets in L with low generalized *space-bounded* Kolmogorov complexity.

A set is said to have *small generalized Kolmogorov complexity* if all of its strings are highly compressible and easily restorable. Generalized time-bounded Kolmogorov complexity and generalized space-bounded Kolmogorov complexity are introduced in [Har83] and [Sip83]. Several researchers [Rub86, BB86, HH88] show that P-printable sets are exactly the sets in P with small generalized time-bounded Kolmogorov complexity. [AR88] show that a set has small generalized time-bounded Kolmogorov complexity if and only if it is P-isomorphic to a tally set. Using similar techniques, we show in section 5 that the L-printable sets are exactly the sets in L with small generalized space-bounded Kolmogorov complexity. We also prove that a set has small generalized space-bounded Kolmogorov complexity if and only if it is L-isomorphic to a tally set.

In section 6, we note that sets that can be ranked in logspace (i.e., given a string x, a logspace algorithm can determine the number of elements in the set $\leq x$) seem different from the L-printable sets. For sparse sets, P-rankability is equivalent to P-printability. We show a somewhat surprising result in section 6, namely, that the sparse L-rankable sets and the L-printable sets are the same if and only if there are no tally sets in $\mathrm{P} - \mathrm{L}$ if and only if LinearSPACE = E.

Are all sparse sets in L either L-printable or L-rankable? Allender and Rubinstein [AR88] show that every sparse set in P is P-printable if and only if there are no sparse sets in $\mathrm{FewP} - \mathrm{P}$. In section 6, we similarly show a stronger collapse: every sparse set in L is L-printable if and only if every sparse set in L is L-rankable if and only if there are no sparse sets in $\mathrm{FewP} - \mathrm{L}$ if and only if LinearSPACE = FewE.

Unlike L-printable sets, L-rankable sets may have exponential density. Blum (see [GS91]) shows that every set in P is P-rankable if and only if every #P function is computable in polynomial time. In section 6, we also show that every set in L is L-rankable if and only if every #P function is computable in logarithmic space.

2. Definitions. We assume a basic familiarity with Turing machines and Turing machine complexity. For more information on complexity theory, we suggest either [BDG88] or [Pap94]. We also assume a familiarity with regular languages and expressions and context-free languages as found in [Mar91]. We denote the characteristic function of A by χ_A. We use the standard lexicographic ordering on strings and let $|w|$ be the length of the string w. (Recall that $w \leq_{lex} v$ iff $|w| < |v|$ or $|w| = |v|$ and, if i is the position of the leftmost bit where w and v differ, $w_i < v_i$.) The alphabet $\Sigma = \{0, 1\}$, and all strings are elements of Σ^*. We denote the complement of A by $\overline{A}$.

The class P is deterministic polynomial time, and L is deterministic logarithmic space; remember that in calculating space complexity, the machine is assumed to have separate tapes for input, computation, and output. The space restriction applies only to the work tape. It is known that $\mathrm{L} \subseteq \mathrm{P}$, but it is not known whether the two classes are equal. The class E is deterministic time $2^{O(n)}$, and LinearSPACE is deterministic space $O(n)$.

DEFINITION 2.1. *A set A is in the class* PP *if there is a polynomial-time nondeterministic Turing machine that, on input x, accepts with more than half its computations if and only if $x \in A$. A function f is in #P if there is a polynomial-time nondeterministic Turing machine M such that for all x, $f(x)$ is the number of accepting computations of $M(x)$.*

Allender[All86] defined the class FewP. FewE is defined analogously.

DEFINITION 2.2 (see [All86]). *A set A is in the class* FewP *if there is a polynomial-time nondeterministic Turing machine M and a polynomial p such that on all inputs x, M accepts x on at most $p(|x|)$ paths. A set A is in the class* FewE *if there is an exponential-time nondeterministic Turing machine M and a constant c such that on all inputs x, M accepts x on at most 2^{cn} paths. (Note that this is small compared to the double exponential number of paths of an exponential-time nondeterministic Turing machine.)*

DEFINITION 2.3. *A set S is* sparse *if there is some polynomial $p(n)$ such that for all n, the number of strings in S of length n is bounded by $p(n)$ (i.e., $|S^{=n}| \leq p(n)$).*

A set T over alphabet Σ is a tally *set if $T \subseteq \{\sigma\}^*$, for some character $\sigma \in \Sigma$.*

The work here describes certain enumeration properties of sparse sets in L. There are two notions of enumeration that are considered: rankability and printability.

DEFINITION 2.4. *If $\mathcal{C}$ is a complexity class, then a set A is* $\mathcal{C}$-printable *if and only if there is a function computable in $\mathcal{C}$ that, on any input of length n, outputs all the strings of length n in A.*

Note that P-printable sets are necessarily in P and are sparse, since all of the strings of length n must be printed in time polynomial in n. Since every logspace computable function is also computable in polynomial time, L-printable sets are also P-printable, and thus are also sparse.

DEFINITION 2.5. *If $\mathcal{C}$ is a complexity class, then a set, A, is* $\mathcal{C}$-rankable *if and only if there is a function r_A computable in $\mathcal{C}$ such that $r_A(x) = |\{y \leq_{lex} x : y \in A\}|$. (In other words, $r_A(x)$ gives the lexicographic rank of x in A.) The function r_A is called the* ranking function *for A.*

Note that P-rankable sets are necessarily in P but are not necessarily sparse. Furthermore, a set is P-rankable if and only if its complement is P-rankable. Finally, note that any P-printable set is P-rankable.

DEFINITION 2.6. *If $\mathcal{C}$ is a complexity class, then two sets, A and B, are* $\mathcal{C}$-isomorphic *($A \cong_{\mathcal{C}} B$) if there are total functions f and g computable in $\mathcal{C}$ that are both one–one and onto, such that $f(g(x)) = x$ and $g(f(y)) = y$, f is a reduction from A to B, and g is a reduction from B to A.*

In order for two sets to be P-isomorphic, their density functions must be close to each other: if one set is sparse and the other is not, then any one–one reduction from the sparse set to the dense set must have superpolynomial growth rate. By the same argument, if one has a superpolynomial gap, the other must have a similar gap.

A lexicographic (or order-preserving) isomorphism from A to B is, informally, a bijection that maps the ith element of A to the ith element of B and maps the ith element of $\overline{A}$ to the ith element of $\overline{B}$. Note that in the definition of similar densities,

the isomorphisms need not be computable in any particular complexity class. This merely provides the necessary condition on densities in order for the two sets to be P-isomorphic or L-isomorphic.

DEFINITION 2.7. *Two sets, A and B, have* similar densities *if the lexicographic isomorphisms from A to B and from B to A are polynomial-size bounded.*

The notion of printability, or of ranking on sparse sets, can be considered a form of compression. Another approach to compression is found in the study of Kolmogorov complexity; a string is said to have "low information content" if it has low Kolmogorov complexity. We are interested in the space-bounded Kolmogorov complexity class defined by Hartmanis [Har83].

DEFINITION 2.8. *Let M_v be a Turing machine, and let f and s be functions on the natural numbers. Then we define*

$$KS_v[f(n), s(n)] = \{w : |w| = n \text{ and } \exists y(|y| \leq f(n) \text{ and } M_v(y) = w \text{ and } M_v \text{ uses } s(n) \text{ space})\}.$$

Following the notation of [AR88], we refer to y as the *compressed string*, $f(n)$ as the *compression*, and $s(n)$ as the *restoration space*. Hartmanis [Har83] shows that there exists a universal machine M_u such that for all v, there exists a constant c such that $KS_v[f(n), s(n)] \subseteq KS_u[f(n) + c, cs(n) + c]$. We will drop the subscript and let $KS[f(n), s(n)] = KS_u[f(n), s(n)]$.

3. Basic results. We begin by formalizing some observations from the previous section.

OBSERVATION 3.1. *If A is* L*-printable, then A has polynomially bounded density, i.e., A is sparse.*

This follows immediately from the fact that logspace computable functions are P-time computable (i.e., L-printability implies P-printability), and from the observations on P-printable sets.

PROPOSITION 3.2 (see [JK89]). *If A is* L*-printable, then $A \in$ L.*

Proof. To decide $x \in A$, simulate the L-printing function for A with input $1^{|x|}$. As each $y \in A$ is "printed," compare it, bit by bit, with x. If $y = x$, accept. Because the comparisons can be done using $O(1)$ space, and the L-printing function takes $O(\log |x|)$ space, this is a logspace procedure. □

PROPOSITION 3.3. *If A is* L*-rankable, then $A \in$ L.*

Proof. Note that the function $x - 1$ (the lexicographic predecessor of x) can be computed (though not written) in space logarithmic in $|x|$. Since logspace computable functions are closed under composition, $r_A(x - 1)$ can be computed in logspace, as can $r_A(x) - r_A(x - 1) = \chi_A(x)$. □

PROPOSITION 3.4. *If A is* L*-printable, then A is* L*-rankable.*

Proof. To compute the rank of x, we print the strings of A up to $|x|$ and count the ones that are lexicographically smaller than x. Since A is sparse, by Observation 3.1, we can store this counter in logspace. □

We can now prove the following, first shown by [JK89] with a different proof.

PROPOSITION 3.5 (see [JK89]). *If A is* L*-printable, then A is* L*-printable in lexicographically increasing order.*

Proof. To prove this, we use a variation on selection sort. Suppose the logspace machine M L-prints A. Then we can construct another machine, N, to L-print A in lexicographically increasing order. Note that it is possible to store an instantaneous description of a logspace machine, i.e., the position of the input head, the state, the contents of the worktape, and the character just output, in $O(\log |x|)$ space.

The basic idea is that we store, during the computation, enough information to produce three strings: the most recently printed string (in the lexicographically ordered printing), the current candidate for the next string to be printed, and the current contender. We can certainly store three IDs for M in logspace. Each ID describes the state of M immediately prior to printing the desired string.

In addition to storing the IDs, we must simulate M on these three computations in parallel, so that we can compare the resulting strings bit by bit. If the contender string is greater than the last string output (so it has not already been output) and less than the candidate, it becomes the new candidate. Otherwise, the final ID of the computation becomes the new contender. These simulated computations do not produce output for N; when the next string is found for N to print, its initial ID is available, and the simulation is repeated, with output. □

Using the same technique as in the previous proof, one can easily show the following.

PROPOSITION 3.6. *If A is* L*-printable, and $A \cong_{log} B$, then B is* L*-printable as well.* □

4. L-printable sets. We begin this section with a very simple example of a class of L-printable sets.

PROPOSITION 4.1 (see [JK89]). *The tally sets in* L *are* L*-printable.*

Proof. On input of length n, decide whether $1^n \in A$. If so, print it. □

One may ask: are all of the L-printable sets as trivial as Proposition 4.1? We demonstrate in the following sections that every regular language or context-free language that is sparse is also L-printable (see Theorem 4.8 and Corollary 4.14). We also give an L-printable set that is neither regular nor context-free (see Proposition 4.15).

4.1. Sparse regular languages. We show that the sparse regular languages are L-printable. In order to do so, we give some preliminary results about regular expressions.

DEFINITION 4.2 (see [BEGO71]). *Let r be a regular expression. We say r is* unambiguous *if every string has at most one derivation from r.*

THEOREM 4.3 (see [BEGO71]). *For every regular language L, there exists an unambiguous regular expression r such that $L(r) = L$.*

Proof (sketch). Represent L as the union of disjoint languages whose deterministic finite automatons (DFAs) have a unique final state. Using the standard union construction of a nondeterministic finite automaton (NFA) from a DFA, we get an NFA with the property that each string has a unique accepting path. Now, using state elimination to construct a regular expression from this NFA, the unique path for each string becomes a unique derivation from the regular expression. □

We should note that even though removal of ambiguity from a regular expression is, in general, PSPACE-complete [SH85], this does not concern us. Theorem 4.3 guarantees the existence of an unambiguous regular expression, corresponding to every regular language, that is sufficient for our needs.

We now define a restricted form of regular expression that will generate precisely the sparse regular languages. (Note that a similar, although more involved, characterization was given in [SSYZ92]. They give characterizations for a variety of densities, whereas we are only concerned with sparse sets.)

DEFINITION 4.4. *We define a* static regular expression (SRE) *on an alphabet Σ inductively, as follows.*

1. *The empty expression is an SRE, and defines $\emptyset$, the empty set.*
2. *If $x \in \Sigma$ or $x = \lambda$ (the empty string), then x is an SRE.*

3. *If s and t are SREs, then st, the concatenation of s and t, is an SRE.*
4. *If s and t are SREs, then $s + t$, the union of s and t, is an SRE.*
5. *If s is an SRE, then s^* is an SRE if and only if:*
   a) *s does not contain a union of two SREs and*
   b) *s does not contain any use of the $*$ operator.*

Note the restriction of the $*$ operator in the above definition. That is, $*$ can only be applied to a string. This is the only difference between SREs and standard regular expressions.

We can alternatively define an SRE as a regular expression that is the sum of terms, each of which is a concatenation of letters and starred strings.

THEOREM 4.5. *Let R be an unambiguous regular expression. Then $L(R)$ is sparse if and only if R is static.*

Proof. We first prove two lemmas about "forbidden" subexpressions.

LEMMA 4.6. *Let α, β, S be nonempty regular expressions such that $S = (\alpha + \beta)^*$ and S is unambiguous. Then there is a constant $k > 0$ such that, for infinitely many n, $L(S)$ contains $2^{\frac{n}{k}}$ strings of length n.*

Proof. Let $u, v \in \Sigma^*$ such that $u \in L(\alpha)$ and $v \in L(\beta)$. Let $k = |u| \cdot |v|$. Because S is unambiguous, there must be at least two strings of length k in $L(S)$, namely, $u^{|v|}$ and $v^{|u|}$. So, for any length n such that $n = ik$, $i \geq 1$, there are at least $2^i = 2^{i \cdot \frac{k}{k}} = 2^{\frac{n}{k}}$ strings of length n in $L(S)$. □

LEMMA 4.7. *Let α, β, S be nonempty regular expressions such that S is unambiguous, where S is either of the form $(\alpha^*\beta)^*$ or of the form $(\alpha\beta^*)^*$. Then, there is a constant k such that, for infinitely many n, $L(S)$ contains $2^{\frac{n}{k}}$ strings of length n.*

Proof. Let $u, v \in \Sigma^*$ such that $u \in L(\alpha)$ and $v \in L(\beta)$. Suppose $S = (\alpha^*\beta)^*$. Let $k = |u| \cdot |v| + |v|$. If S is unambiguous, there are at least two distinct strings of length k in $L(S)$, namely, $u^{|v|}v$ and $v^{|u|+1}$. So, for any length n such that $n = ik$, $i \geq 1$, there are at least $2^i = 2^{\frac{n}{k}}$ strings of length n in $L(S)$.

The proof is very similar if $S = (\alpha\beta^*)^*$ is unambiguous. □

It is clear that unambiguity is necessary for both lemmas. For example, the expression $(a + a)^*$ is not static, but $L((a + a)^*) = L(a^*)$, which is sparse.

Note that if R is the empty expression, the theorem is true, since R is static, and $L(R) = \emptyset$, which is certainly sparse. So, for the rest of the proof, we will assume that R is nonempty.

To show one direction of Theorem 4.5, suppose R is not static. Then it contains a subexpression that is either of the form $(\gamma_0(\alpha + \beta)\gamma_1)^*$ or of the form $(\gamma_0\alpha^*\gamma_1)^*$. In the first case, by a small modification to the proof of Lemma 4.6, $L(R)$ is not sparse. In the second case, by a similar modification to the proof of Lemma 4.7, $L(R)$ cannot be sparse.

Now, suppose R is static. If $R = x$, $x \in \Sigma$, $L(R)$ contains only the string x. If $R = r^*$, where r is either a string of characters or a single character, $L(R)$ can have at most one string of any length.

Suppose $R = r + s$, where r and s are SREs. Let $p_r(n)$ and $p_s(n)$ bound the number of strings in $L(r)$ and $L(s)$, respectively. Then there are at most $p_r(n) + p_s(n)$ strings of length n.

Finally, suppose $R = rs$, where r and s are SREs. Let $p_r(n)$ and $p_s(n)$ bound the number of strings in $L(r)$ and $L(s)$, respectively. Then, the number of strings of length n is:

$$q(n) \leq \sum_{i=0}^{n} p_r(i) \cdot p_s(n - i).$$

The degree of q is bounded by $1 + \text{degree}(p_r(n)) + \text{degree}(p_s(n))$. By induction on the complexity of R, $L(R)$ is sparse. □

Note that the second half of the proof does not use unambiguity. Hence, any static regular expression generates a sparse regular language.

THEOREM 4.8. *Let R be an SRE. Then $L(R)$ is* L*-printable.*

Proof. Basically, we divide R into terms that are either starred expressions or nonstarred expressions. For example, we would divide $0(1+0)10(11)^*00(0+11)$ into three parts: $0(1+0)10$, $(11)^*$, and $00(0+11)$. Then, we internally L-print each term independently, and check to see if the strings generated have the correct length. In our example, to print strings of length 9, we might generate 0110, 11, and 0011, respectively, and check that the combined string is in fact 9 characters long. (In this case, the string is too long and is not printed.)

Let k be the number of stars that appear in R. Partition R into at most $2k+1$ subexpressions, k with stars, and the others containing no stars.

The machine to L-print $L(R)$ has two types of counters. For each starred subexpression, the machine counts how many times that subexpression has been used. For a string of length n, no starred subexpression can be used more than n times. Each counter for a starred subexpression only needs to count up to n.

Each nonstarred subexpression generates only a constant number of strings. Thus, up to $k+1$ additional counters, each with a constant bound, are needed. (Note that the production may intermix the two types of counters, for instance, if $(x^* + y^*)$ occurs.)

The machine uses two passes for each potential string. First, the machine generates a current string, counting its length. If the string is the correct length, it regenerates the string and prints it out. Otherwise, it increments the set of counters and continues. In this way, all strings of lengths $\leq n$ are generated, and all strings of length n are printed.

Lastly, we need to argue that this procedure can be done by a logspace machine. Each of the at most $2k+1$ counters must count up to n (for n sufficiently large, say, larger than $|R|$). Thus, the counting can be done in $\log n$ space. In addition, the actual production of a string requires an additional counter, to store a loop variable. The rest of the computation can be handled in $O(1)$ space, using the states of the machine. Thus, $L(R)$ is L-printable.

Note that this L-printing algorithm may generate some strings in $L(R)$ more than once. To get a nonredundant L-printer, simply modify the program to output the strings in lexicographic order, as in Proposition 3.5, or use an unambiguous SRE for $L(R)$. □

Theorem 4.8 does not characterize the L-printable sets, as we see below.

PROPOSITION 4.9. *There exists a set S such that S is* L*-printable and not regular.*

Proof. The language $S = \{0^k 1^k : k \in \mathcal{N}\}$ is L-printable (for any n, we print out $0^{\frac{n}{2}}1^{\frac{n}{2}}$ only if n is even), but not regular. □

4.2. Sparse context-free languages. Using the theory of bounded context-free languages we can also show that every sparse context-free language is L-printable.

DEFINITION 4.10. *A set A is* bounded *if there exist strings $w_1, \ldots, w_k$ such that*

$$A \subseteq (w_1)^* \cdots (w_k)^*.$$

Note the similarity between bounded languages and languages generated by SREs. Note also that every bounded language is sparse.

Ibarra and Ravikumar [IR86] prove the following.

THEOREM 4.11 (see [IR86]). *If A is a context-free language then A is sparse if and only if A is bounded.* □

Ginsburg [Gin66, p. 158] gives the following characterization of bounded context-free languages.

THEOREM 4.12 (see [Gin66]). *The class of bounded context-free languages is the smallest class consisting of the finite sets and fulfilling the following properties.*

1. *If A and B are bounded context-free languages then $A \cup B$ is also a bounded context-free language.*
2. *If A and B are bounded context-free languages then $AB = \{xy \mid x \in A \text{ and } y \in B\}$ is also a bounded context-free language.*
3. *If A is a bounded context-free language and x and y are fixed strings then the following set is also a bounded context-free language:*

$$\{x^n a y^n : \ a \in A \text{ and } n \in \mathcal{N}\}.$$ □

COROLLARY 4.13. *Every bounded context-free language is* L*-printable.*

Proof. Every finite set is L-printable. The L-printable sets are closed under the three properties in Theorem 4.12. □

COROLLARY 4.14. *Every sparse context-free language is* L*-printable.* □

This completely characterizes the L-printable context-free languages. However, the sparse context-free languages do not characterize the L-printable languages.

PROPOSITION 4.15. *There exists an* L*-printable set S such that S is not context-free.*

Proof. The language $S = \{0^n 1^n 0^n : n \in \mathcal{N}\}$ is L-printable, but it is not context-free. □

5. L-isomorphisms. It is easy to show that two P-printable sets, or P-rankable sets, of similar densities are P-isomorphic. Since the usual proof relies on binary search, it does not immediately extend to L-rankable sets. However, we are able to exploit the sparseness of L-printable sets to show the following.

THEOREM 5.1. *If A and B are* L*-printable and have similar densities, then A and B are* L*-isomorphic (i.e., $A \cong_{log} B$).*

Proof. For each x, define y_x to be the image of x in the lexicographic isomorphism from A to B. Since A and B are L-printable, they are both sparse. Let $p(n)$ be a strictly increasing polynomial that bounds the densities of both sets. If $x \notin A$, then x is "close" to y_x in the sense that there are at most $p(|x|)$ strings between them in the lexicographic ordering. (Recall Definition 2.7.) In fact, for all x, $|y_x| \leq p(|x|+1)$.

Let $r_A(x)$ be the rank of x in A. If $x \notin A$, then the rank of x in $\overline{A}$ is $x - r_A(x)$. Furthermore, $x - r_A(x) = y_x - r_B(y_x)$, and y_x is the unique element of $\overline{B}$ for which this holds. Note that both $r_A(x)$ and $r_B(y_x)$ can be written in space $O(\log |x|)$. Thus, to compute y_x, we need to compute $x - r_A(x) + r_B(y_x)$. We do so by maintaining a variable d that is initialized to $r_A(x)$. Counter c is initialized to 0. The following loop is iterated until c reaches $p(|x|+1)$:

1. L-print (in lexicographic order) the elements of B of length c; for each string that is lexicographically smaller than $(x-d)$, decrement d;
2. increment c.

Output $x - d$.

Note that, if d is written on the work tape, each bit of $x - d$ can be computed in logspace as needed, and the output of the L-printing function can be compared to $x - d$ in a bit-by-bit manner.

If $x \in A$, since the L-printing function outputs strings in lexicographic order, computing y_x is easy: compute $r_A(x)$, then "L-print" B internally, actually outputting the $r_A(x)$th string.

Without loss of generality, we can assume that the simulated L-printer for B prints B in lexicographic order. Thus, as soon as the $(r_A(x) - 1)$st element of B is printed internally, the simulation switches to output mode.

The following is an overview of the logspace algorithm computing the desired isomorphism.

1. Compute $A(x)$.
2. Compute $r_A(x)$, and write it on a work tape.
3. If $x \in A$, find the $r_A(x)$th element of B, and output it.
4. If $x \notin A$, find the unique string $y_x \notin B$ such that $x - r_A(x) = y_x - r_B(y_x)$, and output y_x. □

Using this theorem, we can now characterize the L-printable sets in terms of isomorphisms to tally sets, and in terms of sets of low Kolmogorov space complexity.

THEOREM 5.2. *The following are equivalent:*

1. *S is* L*-printable.*
2. *S is* L*-isomorphic to some tally set in* L.
3. *There exists a constant k such that $S \subseteq KS[k \log n, k \log n]$ and $S \in$ L.*

Although it is not known whether or not every sparse L-rankable set is L-isomorphic to a tally set (see Theorem 6.1), we can prove the following lemma, that will be of use in the proof of Theorem 5.2.

LEMMA 5.3. *Let A be sparse and* L*-rankable. Then there exists a tally set $T \in$ L such that A and T have similar density.*

Proof. Let $A^{\leq n}$ denote the strings of length at most n in A. Let $p(n)$ be an everywhere positive monotonic increasing polynomial such that $|A^{\leq n}| \leq p(n)$ for all n, and such that $p(n) - p(n-1)$ is greater than the number of strings of length n in A. Let $r(x)$ be the ranking function of A. We define the following tally set:

$$T = \{1^{p(|x|-1)+r(x)-r(1^{|x|-1})} : x \in A\}.$$

To show that $T \in L$, notice that of the tally strings 1^i, $p(n-1) < i \leq p(n)$, $1^i \in T$ if and only if $p(n-1) < i \leq p(n-1)+r(1^i)-r(1^{i-1})$. So, to decide $T(1^m)$, we first find the largest n such that $p(n-1) < m \leq p(n)$. (Note that n can be written in binary in space $O(\log m)$.) Then compute $d_1 = m - p(n-1)$. This difference is bounded by $p(n)$, and thus can be written in logspace. Finally, compute $d_2 = r(1^n) - r(1^{n-1})$ and compare to d_1. Accept if and only if $d_1 \leq d_2$.

Finally, we show that T and A have similar density. Let $f : A \to T$ be the lexicographic isomorphism between T and A. Note that f maps strings of length n to strings of length at most $p(n)$, so f is polynomially bounded. Note that p is always positive, which implies that f is length-increasing. So, f^{-1} must also be polynomially bounded. Thus, T and A have similar density. □

The following proof of Theorem 5.2 is very similar to the proof of the analogous theorem in [AR88].

Proof. [1 ⇒ 2] Let S be L-printable. Then it is sparse and L-rankable. Let T be the tally set guaranteed by Lemma 5.3. By Proposition 4.1, T is L-printable. Thus,

T and S are L-printable, and T and S have similar density. So, by Theorem 5.1, $S \cong_{log} T$.

[$2 \Rightarrow 3$] Let S be L-isomorphic to a tally set T, and let f be the L-isomorphism from S to T. Let $x \in S$ be a string of length n. Let $f(x) = 0^r$. Since f is logspace computable, there exists a constant c such that $r \leq n^c$, i.e., $|r| \leq c \log n$. In order to recover x from r, we only have to compute $f^{-1}(0^r)$. Computing 0^r given r requires $\log n$ space for one counter. Further, there exists a constant l such that computing $f^{-1}(0^r)$ requires at most $lc \log n$ space, since $r \leq n^c$. So, the total space needed to compute x given r is less than or equal to $\log n + lc \log n \leq k \log n$ for some k. Hence, $S \subseteq KS[k \log n, k \log n]$. If $T \in$ L, then $S \in$ L, since $S \cong_{log} T$.

[$3 \Rightarrow 1$] Assume $S \subseteq KS[k \log n, k \log n]$ for some k, and $S \in$ L. On input 0^n, we simulate M_u for each string of length $k \log n$. For a given string x, $|x| = k \log n$, we first simulate $M_u(x)$ and check whether it completes in space $k \log n$. If it does, we recompute $M_u(x)$, this time checking whether the output is of length n and in S. If it is, we recompute $M_u(x)$ and print out the result. The entire computation only needs $O(\log n)$ space, so S is L-printable. □

It was shown in [AR88] that a set has small generalized Kolmogorov complexity if and only if it is P-isomorphic to a tally set. (Note: this was an improvement of the result in [BB86], which showed that a set has small generalized Kolmogorov complexity if and only if it is "semi-isomorphic" to a tally set.) Using a similar argument and Theorem 5.2 we can show an analogous result for sets with small generalized Kolmogorov space complexity. First, we prove the following result.

PROPOSITION 5.4. *For all M_v and k, $KS_v[k \log n, k \log n]$ is L-printable.*

Proof. To L-print for length n, simulate M_v on each string of length less than or equal to $k \log n$ and output every string of length n produced. □

COROLLARY 5.5. *There exists a k such that $A \subseteq KS[k \log n, k \log n]$ if and only if A is L-isomorphic to a tally set.*

Proof. Suppose A is L-isomorphic to a tally set. Then, by the argument given in the proof of [$2 \Rightarrow 3$] in Theorem 5.2, $A \subseteq KS[k \log n, k \log n]$.

Now, suppose $A \subseteq KS[k \log n, k \log n]$. By Proposition 5.4 and Theorem 5.2, $KS[k \log n, k \log n]$ is L-isomorphic to a tally set in L via some L-isomorphism f. It is clear that A is L-isomorphic to $f(A)$. Since $f(A)$ is a subset of a tally set, $f(A)$ must also be a tally set. □

6. Printability, rankability, and decision. In this section we examine the relationship among L-printable sets, L-rankable sets, and L-decidable sets. We show that any collapse of these classes, even for sparse sets, is equivalent to some unlikely complexity class collapse.

THEOREM 6.1. *The following are equivalent:*

1. *Every sparse* L*-rankable set is* L*-printable.*
2. *There are no tally sets in* P − L.
3. *E = LinearSPACE.*

Proof. [$2 \Leftrightarrow 3$] This equivalence follows from techniques similar to those of Book [Boo74].

[$2 \Rightarrow 1$] Suppose A is a sparse L-rankable set. Note that $A \in$ L.

Let

$$T = \{1^{\langle i,j \rangle} : \text{ The } i\text{th bit of the } j\text{th string in } A \text{ is } 1\},$$

where

$$\langle i, j\rangle = \frac{(i+j)(i+j+1)}{2} + i.$$

Note that $\langle i, j\rangle$ can be computed in space linear in $|i| + |j|$. Since A is sparse, i and j are bounded by a polynomial in the length of the jth string. Hence, $\langle i, j\rangle$ can be computed using logarithmic space with respect to the length of the jth string.

Given $\langle i, j\rangle$, we can determine i and j in polynomial time, and we can find the jth string of A by using binary search and the ranking function of A. Hence, $T \in$ P. So, by assumption, $T \in$ L.

Next we give a method for printing A in logspace. Given a length n, we compute (and store) the ranks of 0^n and 1^n in A. Let r_{start} and r_{end} be the ranks of 0^n and 1^n, respectively. If $0^n \notin A$, the string with rank r_{start} has length less than n. First, we check to see if $0^n \in A$, and if so, print it. Then, for each j, $r_{start} < j \leq r_{end}$, we output the jth string by computing and printing $T(1^{\langle i,j\rangle})$ for each bit i. This procedure prints the strings of A of length n.

Note that since A is sparse, we can store r_{start} and r_{end} in $O(\log n)$ space. Since $i \leq n$, we can also store and increment the current value of i in $\log n$ space.

[1 $\Rightarrow$ 2] Let $T \in$ P be a tally set. Since the monotone circuit value problem is P-complete (see [GHR95]), there exists a logspace computable function f and a nondecreasing polynomial p such that $f(n)$ produces a circuit C_n with the following properties.

1. C_n is monotone (i.e., C_n uses only AND and OR gates).
2. C_n has $p(n)$ gates.
3. The only inputs to C_n are 0 and 1.
4. C_n outputs 1 if and only if 1^n is in T.

We can assume that the reduction orders the gates of C_n so that the value of gate g_i depends only on the constants 0 and 1 and the values of gates g_j for $j < i$ [GHR95]. Let x_n be the string of length $p(n)$ such that the ith bit of x_n is the value of gate g_i.

Let $A = \{x_n : n \in \mathcal{N}\}$. Then A contains exactly one string of length $p(n)$ for all n and no strings of any other lengths.

Claim 6.1.1. *The set A is* L*-rankable.*

Proof. To prove this claim, let w be any string. In logspace, we can find the greatest n such that $p(n) \leq |w|$. If $p(n) \neq |w|$ then $w \notin A$, and the rank of w is n. Suppose $|w| = p(n)$. Since x_n is the only string of length $p(n)$ in A, the rank of w is $n-1$ if $w < x_n$, and n otherwise.

Consider the ith bit of w as a potential value for gate g_i in C_n. Let j be the smallest value such that w_j is not the value of g_j. In order to find the value of a gate g_i, we first use $f(n)$ (our original reduction) to determine the inputs to g_i. By the time we consider the ith bit of w, we know that w is a correct encoding of all of the gates g_k such that $k < i$, so we can use those bits of w as the values for the gates. Thus, we can determine the value of g_i and compare it to the ith bit of w. If they differ, we are done. If they are the same, we continue with the next gate. We can count up to $p(n)$ in logspace, so this whole process needs only $O(\log p(n))$ space to compute.

Once j is found, there are three cases to consider.

1. If j doesn't exist then $w = x_n$.
2. If the jth bit of w is 0 then $w < x_n$.
3. If the jth bit of w is 1 then $w > x_n$.

These follow since the ith bit of x_n matches the ith bit of w for all $i < j$. □

Thus A is L-rankable and, by assumption, L-printable.

So, to determine if 1^n is in T, L-print A for length $p(n)$ to get x_n. The bit of x_n that encodes the output gate of C_n is 1 if and only if $1^n \in T$. Since every step of this algorithm is computable in logspace, $T \in L$.

This completes the proof of Theorem 6.1. □

COROLLARY 6.2. *There exist two non-*L*-isomorphic* L*-rankable sets of the same density, unless there are no tally sets in* P − L.

Proof. Consider the sets T and A from the second part of the proof of Theorem 6.1. The set $B = \{1^{p(n)} : n \in \mathcal{N}\}$ has the same density as A. By Proposition 4.1, B is L-printable. If A and B were L-isomorphic then by Proposition 3.6, A would also be L-printable and T would be in L. □

One may wonder whether every sparse set in L is L-printable or at least L-rankable. We show that either case would lead to the unlikely collapse of FewP and L. Recall that FewP consists of the languages in NP accepted by nondeterministic polynomial-time Turing machines with at most a polynomial number of accepting paths.

Fix a nondeterministic Turing machine M and an input x. Let p specify an accepting path of $M(x)$ represented as a list of configurations of each computation step along that path. Note that in logarithmic space we can verify whether p is such an accepting computation since if one configuration follows another only a constant number of bits of the configuration change.

We can assume without loss of generality that all paths have the same length and that no accepting path consists of all zeros or all ones.

Define the set P_M by

$$P_M = \{x\#p : p \text{ is an accepting path of } M \text{ on } x\}.$$

From the above discussion we have the following proposition that we will use in the proofs of Theorems 6.6 and 6.7.

PROPOSITION 6.3. *For any nondeterministic machine M, P_M is in* L. □

Allender and Rubinstein [AR88] showed the following about P-printable sets.

THEOREM 6.4 (see [AR88]). *Every sparse set in* P *is* P*-printable if and only if there are no sparse sets in* FewP − P. □

Allender [All86] also relates this question to inverting functions.

DEFINITION 6.5. *A function f is* strongly L-invertible *on a set S if there exists a logspace computable function g such that for every $x \in S$, $g(x)$ prints out all of the strings y such that $f(y) = x$.*

We extend the techniques of Allender [All86] and Allender and Rubinstein [AR88] to show the following.

THEOREM 6.6. *The following are equivalent.*

1. *There are no sparse sets in* FewP − L.
2. *Every sparse set in* L *is* L*-printable.*
3. *Every sparse set in* L *is* L*-rankable.*
4. *Every* L*-computable, polynomial-to-one, length-preserving function is strongly* L*-invertible on* $\{1\}^*$.
5. FewE = LinearSPACE.

Proof. [1 ⇒ 2] Let A be a sparse set in L. Then A is in P. By (1) we have that there are no sparse sets in FewP − P. By Theorem 6.4, A is P-printable.

Consider the following set B:

$$B = \{1^{\langle n,i,j,b\rangle} : \text{ the } i\text{th bit of the } j\text{th element of } A \text{ of length } n \text{ is } b\}.$$

Since A is P-printable then B is in P. By statement 1 (as B is sparse and in P $\subseteq$ FewP), we have that B is in L. Then A is L-printable by reading the bits off from B.

[$2 \Rightarrow 3$] Follows immediately from Proposition 3.4.

[$3 \Rightarrow 1$] Let A be a sparse set in FewP accepted by a nondeterministic machine M with computation paths of length $q(n)$ for inputs of length n.

Consider the set P_M defined as above. Note that P_M is sparse since for any length n, M only accepts a polynomial number of strings with at most a polynomial number of accepting paths each. Also, by Proposition 6.3, we have P_M in L.

By statement 3 we have that P_M is L-rankable. We can then determine in logarithmic space whether $M(x)$ accepts (and thus x is in A) by checking whether

$$r_{P_M}(x\#0^{q(|x|)}) < r_{P_M}(x\#1^{q(|x|)}).$$

[$2 \Rightarrow 4$] Let f be an L-computable, polynomial-to-one, length-preserving function. Consider $S = \{y : f(y) \in \{1\}^*\}$. Since S is in L, S is L-printable.

[$4 \Rightarrow 2$] Let A be a sparse set in L. Define $f(x) = 1^{|x|}$ if x is in A and x otherwise. If g is a strong L-inverse of f on $\{1\}^*$ then $g(1^n)$ will print out the strings of length n of A and 1^n. We can then print out the strings of length n in logspace by printing the strings output by $g(1^n)$, except we print 1^n only if 1^n is in A.

[$1 \Leftrightarrow 5$] In [RRW94], Rao, Rothe, and Watanabe show that there are no sparse sets in FewP $-$ P if and only if FewE = E. A straightforward modification of their proofs is sufficient to show that there are no sparse sets in FewP $-$ L if and only if FewE = LinearSPACE. □

Unlike L-printability, L-rankability does not imply sparseness. One may ask whether every set computable in logarithmic space may be rankable. We show this equivalent to the extremely unlikely collapse of PP and L.

THEOREM 6.7. *The following are equivalent.*

1. *Every* #P *function is computable in logarithmic space.*
2. L = PP.
3. *Every set in* L *is* L*-rankable.*

Our proof uses ideas from Blum (see [GS91]), who shows that every set in P is P-rankable if and only if every #P function is computable in polynomial time. Note that Hemachandra and Rudich [HR90] proved results similar to Blum's.

Proof. [$1 \Rightarrow 2$] If A is in PP then there is a #P function f such that x is in A if and only if the high-order bit of $f(x)$ is 1.

[$2 \Rightarrow 1$] Note that L = PP implies that P = PP implies that P = P^{PP} implies that P = $\mathrm{P}^{\#\mathrm{P}}$. Thus we have L = $\mathrm{P}^{\#\mathrm{P}}$ and we can compute every bit of a #P function in logarithmic space.

[$1 \Rightarrow 3$] Let A be in L. Consider the nondeterministic polynomial-time machine M that on input x guesses a $y \leq_{lex} x$ and accepts if y is in A. The number of accepting paths of $M(x)$ is a #P function equal to $r_A(x)$.

[$3 \Rightarrow 1$] Let f be a #P function. Let M be a nondeterministic polynomial-time machine such that $f(x)$ is the number of accepting computations of $M(x)$. Let $q(n)$ be the polynomial-sized bound on the length of the computation paths of M. Consider P_M as defined above. By Proposition 6.3 we have that P_M is in L, so by (3) P_M is L-rankable. We then can compute $f(x)$ in logarithmic space by noticing

$$f(x) = r_{P_M}(x\#1^{q(|x|)}) - r_{P_M}(x\#0^{q(|x|)}). \qquad \square$$

7. Conclusions. The class of L-printable sets has many properties analogous to its polynomial-time counterpart. For example, even without the ability to do binary searching, one can show that two L-printable sets of the same density are isomorphic. However, some properties do not appear to carry over: it is very unlikely that every sparse L-rankable set is L-printable.

Despite the strict computational limits on L-printability, this class still has some bite: every tally set in L, every sparse regular and context-free language, and every L-computable set of low space-bounded Kolmogorov complexity strings is L-printable.

Acknowledgments. The authors want to thank David Mix Barrington for a counterexample to a conjecture about sparse regular sets, Alan Selman for suggesting the tally set characterization of L-printable sets and Corollary 5.5, Chris Lusena for proofreading, and Amy Levy, John Rogers, and Duke Whang for helpful discussions. The simple proof sketch of Theorem 4.3 was provided by an anonymous referee. The last equivalence of Theorem 6.6 was suggested by another anonymous referee. The authors would like to thank both referees for many helpful suggestions and comments.

THE INVERSE SATISFIABILITY PROBLEM*

DIMITRIS KAVVADIAS† AND MARTHA SIDERI‡

Abstract. We study the complexity of telling whether a set of bit-vectors represents the set of all satisfying truth assignments of a Boolean expression of a certain type. We show that the problem is coNP-complete when the expression is required to be in conjunctive normal form with three literals per clause (3CNF). We also prove a dichotomy theorem analogous to the classical one by Schaefer, stating that, unless P=NP, the problem can be solved in polynomial time if and only if the clauses allowed are all Horn, or all anti-Horn, or all 2CNF, or all equivalent to equations modulo two.

Key words. computational complexity, polynomial-time algorithms, coNP-completeness, Boolean satisfiability, model

1. Introduction. Logic deals with logical formulae, and more particularly with the *syntax* and the *semantics* of such formulae, as well as with the interplay between these two aspects [CK90]. In the domain of *Boolean logic*, for example, a Boolean formula ϕ may come in a variety of syntactic classes—conjunctive normal form (CNF), its subclasses 3CNF, 2CNF, Horn, etc.— and its semantics is captured by its *models* or satisfying truth assignments, that is, the set $\mu(\phi)$ of all truth assignments that satisfy the formula (see Figure 1 for an example).

Going back and forth between these two representations of a formula is therefore of interest. One direction has been studied extensively from the standpoint of computational complexity: going from ϕ to $\mu(\phi)$. In particular, telling whether $\mu(\phi) = \emptyset$ is the famous *satisfiability problem* (SAT), which is known to be NP-complete in its generality and its special case 3SAT, among others, and polynomial-time solvable in its special cases Horn, 2SAT, and exclusive-or [Co71, Sc78, Pa94]. All in all, this direction is a much-studied computational problem. *In this paper we study, and in a certain sense completely settle, the complexity of the inverse problem, that is, going from $\mu(\phi)$ back to ϕ.* That is, for all the syntactic classes mentioned above, we identify the complexity of telling, given a set M of models, whether there is a formula ϕ in the class (3SAT, Horn, etc.) such that $M = \mu(\phi)$. We call this problem *inverse satisfiability.*

Besides its fundamental nature, there are many more factors that make inverse satisfiability a most interesting problem. A major motivation comes from AI (in fact, what we call here the inverse satisfiability problem is implicit in much of the recent AI literature [Ca93, DP92, KKS95, KKS93, KPS93]). A set of models such as those in Figure 1(b) can be seen as a *state of knowledge.* That is, it may mean that at present, for all we know, the state of our three-variable world can be in any one of the three states indicated. In this context, formula ϕ is some kind of *knowledge representation.* In AI there are many sophisticated competing methods for knowledge representation

FIG. 1. *A Boolean formula in* 3*CNF* (a), *and the corresponding set of models* (b).

(Boolean logic is perhaps the most primitive; see [GN87, Le86, Mc80, Mo84, Re80, SK90]), and it is important to understand the expressibility of each. This is a form of the inverse satisfiability problem.

The inverse satisfiability problem was also proposed in [DP92] as a form of *discovering structure in data*. For example, establishing that a complex binary relation is the set of models of a simple formula may indeed uncover the true structure and nature of the heretofore meaningless table. [DP92] only address this problem in certain fairly straightforward cases. The problem of *learning* a formula [AFP92] can be seen as a generalization of the inverse satisfiability problem.

A recent trend in AI is to *approximate* complex formulae by simple ones, such as Horn formulae [SK91, KPS93, GPS94]. Quantifying the quality and computational feasibility of such approximations also involves understanding the inverse satisfiability problem.

The basic computational problem we study is this: given a set of models M, is there a CNF formula ϕ with at most three literals per clause, such that $M = \mu(\phi)$? We call this problem INVERSE 3SAT. Our first result is that *INVERSE* 3*SAT is coNP-complete* (Theorem 1).

Note. INVERSE 3SAT, as well as all other problems we consider in this paper, can be solved in polynomial time if the given $m \times n$ table M has $m = 2^{\Theta(n)}$, that is, if there are exponentially many models in M. The interesting cases of the problem are therefore when $m = 2^{o(n)}$.

There are three well-known tractable cases of SAT: 2SAT (all clauses have two literals), HORNSAT (all clauses are Horn, with at most one positive literal each, and its symmetric case of *anti-Horn formulae*, in which all clauses have at most one *negative* literal), and XORSAT (the clauses are equations modulo two). Schaefer's elegant *dichotomy theorem* [Sc78] states that, unless P=NP, in a certain sense *these are precisely the only tractable cases of SAT.* Interestingly, the inverse problem for these three cases happens to also be tractable! That is, we can tell in polynomial time if a set of models is the set of models of a Horn (or anti-Horn) formula, of a 2CNF formula, or of an exclusive-or formula (interestingly, the latter two results were in fact pointed out by Schaefer himself [Sc78], while the first, left open in [Sc78], is from [DP92, KPS93]). The question comes to mind: are there other tractable cases of the inverse problem? Our Theorem 2 answers this in the negative; rather surprisingly, a strong dichotomy theorem similar to Schaefer's holds for the inverse satisfiability problem as well, in that the problem is coNP-complete for all syntactic classes of CNF formulae except for the cases of Horn (and anti-Horn), 2CNF, and exclusive-or. The proof of our dichotomy theorem draws from both that of Theorem 1 and Schaefer's proof, and in fact strengthens Schaefer's main expressibility result (Theorem 3.0 in [Sc78]).

2. Definitions. Most of the nonstandard terminology used in this paper comes from [Sc78].

Let $\{x_1, \ldots, x_n\}$ be a set of Boolean variables. A literal is a variable or its negation. A model is a vector in $\{0,1\}^n$, intuitively a truth assignment to the Boolean variables. We denote by $\vee$ and $\wedge$ the logical *or* and *and*, respectively. We also extend this notation to bitwise operations between models. If t is a model, we denote by t_i the constant (i.e., 0 or 1) in the ith position of t.

A k-place logical relation is a subset of $\{0,1\}^k$ (k integer). We use the notation $[\phi]$, where ϕ is a Boolean formula, to denote the relation defined by ϕ when the variables are taken in lexicographic order. Let R be a logical relation. Call R *Horn* if it is logically equivalent to a conjunction of clauses, each with at most one positive literal. We call it *anti-Horn* if it is equivalent to a conjunction of clauses with at most one negative literal. We call it *2CNF* if it is equivalent to a 2CNF expression. Finally, we call it *affine* if it is the solution of a system of equations in the two-element field.

Let $S = \{R_1, \ldots, R_m\}$ be a set of Boolean relations. An *S-clause* (of arity k) is an expression of the form $R(a_1, \ldots, a_k)$, where R is a k-ary relation in S and the a_i's are either Boolean literals or constants (0 or 1). Given a truth assignment, we consider an S-clause to be true if the combination of the constants, if any, and the values assigned to the variables form a tuple in R. Define an *S-formula* to be any conjuction of S-clauses defined by the relations in S.

The generalized satisfiability problem is the problem of deciding whether a given S-formula is satisfiable. Schaefer's dichotomy theorem [Sc78] states that the satisfiability of an S-formula can be decided in polynomial time in each of the following cases: (a) all relations in S are Horn, (b) all relations in S are anti-Horn, (c) all relations in S are 2CNF, (d) all relations in S are affine. In all other cases the problem is NP-complete. That is, Schaefer's result totally characterizes the complexity of the CNF satisfiability problem where in addition, the clauses are allowed to be arbitrary relations of bounded arity. It is interesting to note that several restricted forms of SAT such as ONE-IN-THREE 3SAT, NOT-ALL-EQUAL 3SAT etc., all follow as special cases of generalized satisfiability (see [GJ79, Pa94]). To make this point more clear, notice that the problem ONE-IN-THREE 3SAT can be considered as a set of four 3-ary relations $S = \{R_1, \ldots, R_4\}$. The first relation is $\{\{1,0,0\},\{0,1,0\},\{0,0,1\}\}$ and corresponds to the S-clause $R_1(x_1, x_2, x_3)$, the second relation is $\{\{0,0,0\},\{1,1,0\},\{1,0,1\}\}$ and corresponds to the S-clauses with one negated literal, e.g., $R_2(\overline{x_1}, x_2, x_3)$, and so on.

For any Boolean formula ϕ we denote by $\mu(\phi)$ its set of models. We say that a set of models M is *a 3CNF set* (kCNF in general) if there is a formula ϕ in 3CNF (respectively, kCNF) such that $M = \mu(\phi)$. Notice that for any model set M we can construct a kCNF formula that has M as its model set, but in general, this may require extra existentially quantified variables.

Based on the above we define the *INVERSE SAT problem for a set of relations* S as follows.

Given a set $M \subseteq \{0,1\}^n$, is there a conjunction of S-clauses over n variables that has M as its set of models?

Our main result states that if the relations fall in each of the four cases above, the INVERSE SAT problem is also polynomial. Otherwise it is coNP-complete.

Notice that we have excluded S from being part of the instance since we want to emphasize that INVERSE SAT is actually a collection of infinitely many subproblems. This means that all relations of S are of constant arity. Otherwise, relations of non-

constant arity could have exponentially many tuples and the problem becomes trivially intractable.

In the next section we prove that the INVERSE SAT problem is coNP-complete for 3CNF formulas. This proof includes the main construction that will be used in the proof of the main theorem in the last section. This last proof makes use of an expressibility result which is interesting on its own and partially relies on Schaefer's main theorem but with several interesting extensions.

3. coNP-completeness of inverse 3SAT. We begin this section with a technical definition that will be used throughout the paper.

DEFINITION. *Let n be a positive integer and let $M \subseteq \{0,1\}^n$ be a set of Boolean vectors. For $k > 1$, we say that a Boolean vector $m \in \{0,1\}^n$ is k-compatible with M if for any sequence of k positions $0 \leq i_1 < \cdots < i_k \leq n$, there exists a vector in M that agrees with m in these k positions.*

The above definition implies that a vector $m \in \{0,1\}^n$ is not k-compatible with a set of Boolean vectors M if there exists a sequence of k positions in m that does not agree with any vector of M. The following is a useful characterization of kCNF sets.

LEMMA 1. *Let $M \subseteq \{0,1\}^n$ be a set of models. Then the following are equivalent.*

(a) *M is a kCNF set.*

(b) *If $m \in \{0,1\}^n$ is k-compatible with M, then $m \in M$.*

Proof. Let ϕ_M be the conjuction of all possible kCNF clauses defined on n variables and satisfied by all models in M. Notice that ϕ_M is the most restricted kCNF formula (in terms of its model set) which is satisfied by all models in M. Hence if (a) holds, $M = \mu(\phi_M)$. Let $m \in \{0,1\}^n$ and $m \notin M$. Then m does not satisfy at least one clause of ϕ_M and concequently disagrees with all models in M in the same k positions corresponding to the variables in the clause, that is, m is not k-compatible with M.

Conversely, assume that any model not in M is not k-compatible with M. Then $m \notin M$ means m does not satisfy ϕ_M: m differs from all members of M in some k positions, so the k-clause indicating the complement of m in those k positions is in ϕ_M, and m does not satisfy ϕ_M. So $M = \mu(\phi_M)$ and M is a kCNF set. □

The INVERSE 3SAT problem is this: given a set of models M, is it a 3CNF set? We now state our first complexity result.

THEOREM 1. *INVERSE 3SAT is coNP-complete.*

Proof. Lemma 1 establishes that the problem is in coNP: given a set M of models, in order to prove that it is *not* a 3CNF set, it suffices to produce a model $m \notin M$ that is 3-compatible with M (obviously, 3-compatibility can be checked in polynomial time). Alternatively, given M, we immediately have a candidate 3CNF formula ϕ_M: the conjunction of all 3CNF clauses that are satisfied by all models in M. Thus M is *not* a 3CNF set iff there is a model not in M that satisfies ϕ_M.

To prove coNP-completeness, we shall reduce the following well-known coNP-complete problem to INVERSE 3SAT: given a 3CNF formula, is it unsatisfiable? Given a 3CNF formula ψ with $n \geq 4$ variables and c clauses, we shall construct a set of models M such that M is 3CNF iff ψ is unsatisfiable.

The set M will contain $k = 8\binom{n}{3} - c$ models, one for each set W of three variables, and each truth assignment T to these three variables *that does not contradict a clause of* ψ (since we may assume that ψ consists of clauses that have exactly three literals each). Let W be a set of three variables chosen among the variables $\{x_1, \ldots, x_n\}$ of formula ψ, and let $T : W \mapsto \{0,1\}$ be a truth assignment to the variables of W, such that ψ does not contain a clause not satisfied by T. Consider some total order among

the pairs (W,T), say the lexicographic one. The set M will contain a model $m_{W,T}$ for each W and T and no other model.

Every boolean vector $m_{W,T}$ is a concatenation $m_{W,T} = \tau^T_W(x_1)\cdots\tau^T_W(x_n)$ of the encodings $\tau^T_W(x_i)$ for each variable x_i occuring in the formula ψ. The encoding $\tau^T_W(x)$ of a variable x is a Boolean vector of length $k+2$ and is defined as follows:

$$\tau^T_W(x) = \begin{cases} 01\overbrace{0\cdots0\,0\cdots0}^{k \text{ positions}} & \text{if } x \in W \text{ and } T(x)=1,\\ 10\,0\cdots0\,0\cdots0 & \text{if } x \in W \text{ and } T(x)=0,\\ 00\underbrace{0\cdots0}_{i-1}1\cdots1 & \text{if } x \notin W, \end{cases}$$

where (W,T) is the ith pair in the total order mentioned above. Notice that if $x \in W$, the value of x in T is determined by the first two positions of τ^T_W: the code 01 stands for the value 1, and the code 10 stands for x being 0. In these two cases we call the string $\tau^T_W(x)$ a *value pattern*. When $x \notin W$, the code 00 in the first two positions denotes the absence of x from W, while the rest of the string uniquely determines the pair (W,T). In this case we call the string $\tau^T_W(x)$ a *padding pattern*. Notice that by our construction in a vector $m_{W,T} = \tau^T_W(x_1)\cdots\tau^T_W(x_n)$ there are exactly $n-3$ occurences of the unique padding pattern for (W,T), while the remaining three are value patterns. Hence, the length of each Boolean vector $m_{W,T}$ is $n(k+2)$; therefore, there is no exponential blow-up in the construction of the set M.

The proof of Theorem 1 now rests on the next claim.

Claim. *There is a model not in M that is 3-compatible with M if and only if ψ is satisfiable.*

Proof of the claim. For the moment, consider a Boolean vector $m = m_1\cdots m_n$, where the length of each substring m_i equals $k+2$. It is obvious that if the model m is 3-compatible with M, then it is 3-compatible in the positions restricted to one substring $m_i = m_{i1}\cdots m_{i(k+2)}$. That is, if we take three arbitrary positions of m_i, there is a vector $m_{W,T}$ in M that agrees with m_i in these three positions. The 3-compatibility of m_i with M also implies something stronger: that there is a vector $m_{W,T} \in M$ which contains a substring $\tau^T_W(x_i)$ identical to m_i. To see this, first assume that m_i does not have the value 1 in any position j for $3 \le j \le k+2$. Then 3-compatibility forces m_i to have the values 0 and 1 or 1 and 0 in the first and second positions; i.e., m_i is a value pattern. Now, if m_i has the values 0 and 1 in positions $j-1$ and j, $3 \le j \le k+2$, then the values in any triple of positions that includes positions $j-1$ and j can only agree with the values in the same positions of a specific model of M, namely, the one having the padding pattern with 0 in position $j-1$ and 1 in position j. Therefore, m_i is identical to this padding pattern. In this case, however, an analogous observation shows that the whole 3-compatible model m is identical to the model of M that has this pattern. So if m is 3-compatible with M, either it is in M or it consists of value patterns only.

Assume now that there exists a model $m \notin M$ that is 3-compatible with M. As already proved, this model $m = m_1\cdots m_n$ consists only of value patterns m_i. Model m encodes a satisfying truth assignment to the variables of ψ. For suppose it did conflict with a clause c of ψ over variables $\{x_i, x_j, x_\ell\}$. Consider the three value patterns m_i, m_j, m_ℓ of m in the positions of the variables of c. Since m is 3-compatible with M and each value pattern contains only one 1, we can conclude that there exists a model $m_{W,T} = \tau^T_W(x_1)\cdots\tau^T_W(x_n)$ in M, which encodes a truth assignment T to the set of variables $W = \{x_i, x_j, x_\ell\}$ such that $\tau^T_W(x_i) = m_i$, $\tau^T_W(x_j) = m_j$, and $\tau^T_W(x_\ell) = m_\ell$.

But since by construction T does not contradict a clause of ψ, we couldn't have conflicted with a clause of ψ. Therefore, the Boolean vector $m = m_1 \cdots m_n$ is an encoding of a satisfying assignment to the variables for formula ψ: string m_i is an encoding of the truth value assigned to the variable x_i for each $i = 1, \ldots, n$. Hence, formula ψ is satisfiable since every clause of ψ is satisfied by the truth assignment described by vector m.

Conversely, assume that ψ is satisfiable; i.e., there exists a satisfying truth assignment s for the variables $\{x_1, \ldots, x_n\}$. Construct the model $m = m_1 \cdots m_n$ as a concatenation of value patterns, where every string m_i is defined as follows:

$$m_i = \begin{cases} 01\ \overbrace{0\cdots0}^{k \text{ positions}} & \text{if } s(x_i) = 1, \\ 10\ 0\cdots0 & \text{if } s(x_i) = 0. \end{cases}$$

Obviously, model m is not included in the set M, since every model in M contains a padding pattern. Suppose that m is not 3-compatible with M. In this case m contains three positions that do not agree with any model in M. Since m is a concatenation of value patterns, it must contain three substrings m_i, m_j, m_ℓ that represent a truth assignment T for the set of variables $W = \{x_i, x_j, x_\ell\}$ such that the pair (W, T) is not encoded in any model of M. All $\binom{n}{3}$ sets of variables are, however, examined during the construction of M, and the only truth assignments that are not encoded are those conflicting with a clause of ψ. Since T does not conflict with any clause—because it is a restriction of s to three variables—we conclude that the pair (W, T) is encoded in some model of M. Hence, m is 3-compatible with M. So, if ψ is satisfiable, there exists a model 3-compatible with M, specifically the model encoding a satisfying truth assignment. □

4. The dichotomy theorem. Our main result is the following generalization of Theorem 1.

THEOREM 2. *The INVERSE SAT problem for S is in PTIME in each of the following cases.*

(a) *All relations in S are Horn.*
(b) *All relations in S are anti-Horn.*
(c) *All relations in S are 2CNF.*
(d) *All relations in S are affine.*

In all other cases, the INVERSE SAT problem for S is coNP-complete.

[Sc78] proves a surprisingly similar dichotomy theorem for SAT: SAT is in PTIME for all of these four classes, and NP-complete otherwise. Our proof is based on an interesting extension of Schaefer's main result, explained below.

DEFINITION. *Let S be a set of Boolean relations and let R be another Boolean relation, of arity r. We say that S faithfully represents R if there are binary Boolean functions $f_1, \ldots, f_s$ such that there is a conjunction of S-clauses over the variables $x_1, \ldots, x_{r+s}$ which is logically equivalent to the formula*

$$R(x_1, \ldots, x_r) \wedge \bigwedge_{\ell=1}^{s} \big(x_{r+\ell} \equiv f_\ell(x_{i_\ell}, x_{j_\ell})\big),$$

for some $i_\ell, j_\ell < r + \ell$, $\ell = 1, \ldots, s$. That is, S-clauses can express R with the help of uniquely defined auxiliary variables.

This is a substantial restriction of Schaefer's notion of "represents," which allows arbitrary existentially quantified conjunctions of S-clauses (our definition only allows

quantifiers which are logically equivalent to $\exists!x$). Hence our main technical result below extends the main result of [Sc78, Theorem 3.0]. Independently, Creignou and Hermann [CH96] have defined the concept "quasi-equivalent," which is the same as the concept of "faithful representation" defined in this paper.

THEOREM 3. *If S does not satisfy any of the four conditions of Theorem* 2, *then S faithfully represents all Boolean relations.*

Proof. Assuming that none of the four conditions are satisfied by S, the proof proceeds by finding more and more elaborate Boolean relations that are faithfully represented by S. Notice that, since the notion of faithful representation was defined as equivalence of two S-formulas, we shall restrict the proof to the construction of appropriate S-clauses—faithful representation of the corresponding relations will then follow immediately. In this process the allowed operations must preserve the uniqueness of the values of the auxiliary variables and produce a formula which is also in conjuctive form. Therefore, if C and C' are S-formulas, the allowed operations are: (a) $C \wedge C'$, i.e., conjuction of two S-formulas, (b) $C[a/x]$, i.e., substitution of a variable symbol by another symbol, (c) $C[0/x]$ and $C[1/x]$, i.e., substitution of a variable by a constant (this is actually a selection of the tuples that agree in the specified constant), and (d) $\exists!xC(x)$, i.e., existential quantification, where the bound variables are uniquely defined. Some of the steps are provided by Schaefer's proof, and some are new.

Step 1. *Expressing* $[x \equiv \overline{y}]$. This was shown in [Sc78, Lemma 3.2 and Corollary 3.2.1]. The following exposition is somewhat simpler and is based on the fact that a set $M \subseteq \{0,1\}^n$ is the model set of a Horn formula iff it is closed under bitwise $\wedge$; see the Appendix and [KPS93].

Let R be any non-Horn relation of S (say of arity k). The closure property mentioned above implies that there exist models t and t' in R such that $t \wedge t' \notin R$. Based on R we may define the clause $R' = R(a_1, a_2, \ldots, a_k)$: set $a_i = 0$ (resp., 1) to all positions i where both t_i and ${t_i}'$ are 0 (resp., 1). Set $a_i = x$ to all positions where $t_i = 1$ and ${t_i}' = 0$, and $a_i = y$ to all positions where $t_i = 0$ and ${t_i}' = 1$. It is easy to see that both x and y actually appear in R'. (If not, then one of t and t' coincides with their conjunction.) Now 01 and 10 are models of R', but 00 is not. Hence R' is either $(x \equiv \overline{y})$ or $(x \vee y)$. If, in addition, S contains a relation which is not anti-Horn, then a symmetric argument rules out tuple 11, resulting in a clause R'' which is either $(x \equiv \overline{y})$ or $(\overline{x} \vee \overline{y})$. Hence $R' \wedge R''$ is $(x \equiv \overline{y})$. Notice that since this is the case we shall henceforth feel free to use negative literals in our expressions.

Step 2. *Expressing* $[x \vee y]$. Schaefer shows in Lemma 3.3 that there is an S-clause involving variables x, y, z whose set of models contains $000, 101, 011$, but not 110. The proof is as follows: it is known (see the Appendix) that an S-clause is affine if and only if for any three models t_0, t_1, t_2, their *exclusive-or* $t_0 \oplus t_1 \oplus t_2$ is also a model. Consider, therefore, an S-clause that is not affine and assume that $[x \equiv \overline{y}]$ can be represented. By the observation in Step 1 we may negate the variables of the clause in the positions where t_0 is 1. Now the new S-clause, call it S', is satisfied by the all-zero truth assignment and moreover by the assignments ${t_1}' = t_1 \oplus t_0$ and ${t_2}' = t_2 \oplus t_0$, but not by $0 \oplus {t_1}' \oplus {t_2}'$. Construct a new clause $R(a_1, a_2, \ldots, a_k)$ from S' (k is the arity of $[S']$) as follows. Set $a_i = 0$ in all positions i where both ${t_1}'$ and ${t_2}'$ are 0, $a_i = z$ where both are 1, $a_i = x$ where ${t_1}'$ is 0 and ${t_2}'$ is 1, and finally $a_i = y$ where ${t_1}'$ is 1 and ${t_2}'$ is 0. The S-clause R defined on x, y, z, has models 000, 011, 101 (corresponding to the all-zero assignment, ${t_1}'$ and ${t_2}'$ of S', respectively), but not 110 (which corresponds to ${t_1}' \oplus {t_2}'$).

We will show that R faithfully represents one of the four versions of *or:* $(x \vee y)$, $(x \vee \overline{y})$, $(\overline{x} \vee y)$, and $(\overline{x} \vee \overline{y})$. Observe that at least two of x, y, z actually occur in R. If exactly two variables are present in R, then R represents a version of *or* as follows: if x and y are present, then $R(x, y) = (\overline{x} \vee \overline{y})$; if x and z are present, then $R(x, z) = (\overline{x} \vee z)$; if y and z are present, then $R(y, z) = (\overline{y} \vee z)$. If all three variables are present, depending on which of the remaining four possible models are also in the model set of the S-clause, we have sixteen possible relations. Of these, the strongest, with models identical to the set $M = \{000, 101, 011\}$, can be used to define $X(x, y, z)$ (which is true when exactly one of x, y, z is true) as follows: $X(x, y, z) = R(x, y, \overline{z})$, and in this case the current step is unnecessary. In each of the other fifteen cases, we show by exhaustive analysis that there is an R-clause, with one constant, which represents a version of *or*. If $[R] = M \cup \{001\}$, then $R(x, y, 1) = (\overline{x} \vee \overline{y})$. If $[R] = M \cup \{010\}$, then $R(0, y, z) = (y \vee \overline{z})$. If $[R] = M \cup \{100\}$, then $R(x, 0, z) = (x \vee \overline{z})$. If $[R] = M \cup \{111\}$, then $R(x, y, 1) = (x \vee y)$. If $[R] = M \cup \{001, 010\}$, then $R(x, y, 1) = (\overline{x} \vee \overline{y})$. If $[R] = M \cup \{001, 100\}$, then $R(x, y, 1) = (\overline{x} \vee \overline{y})$. If $[R] = M \cup \{001, 111\}$, then $R(0, y, z) = (\overline{y} \vee z)$. If $[R] = M \cup \{010, 100\}$, then $R(0, y, z) = (y \vee \overline{z})$. If $[R] = M \cup \{010, 111\}$, then $R(0, y, z) = (y \vee \overline{z})$. If $[R] = M \cup \{100, 111\}$, then $R(x, y, 1) = (x \vee y)$. If $[R] = M \cup \{001, 010, 100\}$, then $R(x, y, 1) = (\overline{x} \vee \overline{y})$. If $[R] = M \cup \{001, 010, 111\}$, then $R(x, 1, z) = (\overline{x} \vee z)$. If $[R] = M \cup \{001, 111, 100\}$, then $R(x, 0, z) = (x \vee z)$. If $[R] = M \cup \{111, 010, 100\}$, then $R(x, y, 1) = (x \vee y)$. If $[R] = M \cup \{001, 010, 100, 111\}$, then $R(x, 1, z) = (\overline{x} \vee z)$. Since we can also faithfully express $[w \equiv \overline{x}]$, by Step 1, we have all four versions of *or*.

Step 3. *Expressing* $X(x, y, z)$. X is a formula which is satisfied if exactly one of the three variables has the value 1. It is known (see the Appendix) that an S-clause is 2CNF iff for any set of three satisfying assignments t_0, t_1, t_2, the assignment $(t_0 \vee t_1) \wedge (t_1 \vee t_2) \wedge (t_2 \vee t_0)$ is also a satisfying assignment.

We use this characterization to prove that if a relation set S contains a relation which is not 2CNF and also contains relations which are not Horn, anti-Horn, and affine, then $X(x, y, z)$ can be faithfully represented.

Consider an S-clause which is not 2CNF. We may therefore find three satisfying assignments t_0, t_1, t_2 such that the expression $(t_0 \vee t_1) \wedge (t_1 \vee t_2) \wedge (t_2 \vee t_0)$ is not a satisfying assignment. As in the previous step we may negate the variables in the positions where t_0 has the value 1, resulting in a new clause S', which is satisfied by the all-zero assignment, by $t_1' = t_1 \oplus t_0$ and by $t_2' = t_2 \oplus t_0$, but not by $t_1' \wedge (t_1' \vee t_2') \wedge t_2'$, which is equal to $t_1' \wedge t_2'$. Set 0 to all positions where both t_1' and t_2' are 0, x to all positions where both t_1' and t_2' are 1, y where t_1' is 0 and t_2' is 1, and finally z where t_1' is 1 and t_2' is 0. Observe that all three variables actually occur in the constructed clause R: if x is not present then $t_1' \wedge t_2'$ is identical to the all-zero assignment, a contradiction; if either y or z is not present then $t_1' \wedge t_2'$ is identical to t_1' or t_2', again a contradiction. The clause $R = (x, y, z)$ so constructed includes models 000, 110, and 101, but not 100. Now the S-clause $R(\overline{x}, y, z) \wedge (\overline{x} \vee \overline{y}) \wedge (\overline{y} \vee \overline{z}) \wedge (\overline{z} \vee \overline{x})$ has exactly the models 100, 010, and 001; i.e., it is $X(x, y, z)$.

Step 4. *Expressing* $[x \equiv (y \vee z)]$. Notice that the expression $X(\overline{x}, s, y) \wedge X(\overline{x}, t, z) \wedge X(s, t, u)$ is equivalent to

$$\big(x \equiv (y \vee z)\big) \wedge \big(s \equiv (\overline{y} \wedge z)\big) \wedge \big(t \equiv (y \wedge \overline{z})\big) \wedge \big(u \equiv (y \equiv z)\big).$$

Thus we prove that we can faithfully represent a relation in which a variable is logically equivalent to the *or* of two other variables. Notice that the auxiliary variables s, t, u are uniquely defined by the values of y and z.

Step 5. Using repeatedly $[x \equiv (y \vee z)]$ and $[x \equiv \overline{y}]$ we can faithfully represent any clause, and by taking conjunctions of arbitrary clauses we can faithfully represent any Boolean relation, completing the proof of Theorem 3. □

Proof of Theorem 2. Let S be a set of relations satisfying one of conditions (a)–(d), and let r be the maximum arity of any relation in S; we can solve the inverse satisfiability problem for S as follows.

Given a set of models M, we first identify in time $O(n^r|M|)$ all S-clauses that are satisfied by all models in M; call the conjunction of these S-clauses ϕ. Clearly, if there is a conjunction of S-clauses that has M as its set of models, then by the arguments used in Lemma 1, it is precisely ϕ. To tell whether the set of models of ϕ is indeed M, we show how to *generate* the set of models of ϕ with *polynomial delay* between consecutive outputs [JPY88]. Provided that such generation is possible, we can decide whether $M = \mu(\phi)$ by checking if the generated models belong in M. If a model not in M is generated, then we reply "no"; otherwise, if the set of models generated is exactly M, we reply "yes." Observe that the answer will be obtained after at most $|M| + 1$ generations, i.e., in overall polynomial time.

Our generation algorithm is based on a more general observation that also explains the analogy of our dichotomy theorem to the one of Schaefer's. Call a syntactic form of a Boolean formula *hereditary* if the substitution of a variable by a constant results in a new formula of the same syntactic form. Observe that the four cases for which we claim that the inverse satisfiability problem is polynomial are indeed hereditary and coincide with the polynomial cases of satisfiability [Sc78].

THEOREM 4. *If the following two conditions hold for a class of Boolean formulas:*

(a) *the syntactic form of the class is hereditary, and*

(b) *the satisfiability problem for the class is in PTIME,*

then the models of any formula in the class can be generated with polynomial delay between consecutive outputs.

Proof. Here is an informal description of the generation algorithm: at each step we substitute a variable by a constant, first by the value 1 and then by 0. Since (a) holds, the substitution results in a new formula of the same syntactic form. We then ask a polynomial-time oracle whether the produced formula is satisfiable. Since (b) holds, such an oracle exists. If the produced formula is satisfiable, we proceed recursively and substitute the next variable until all variables have been assigned a value, in which case we return the model. When at a certain step we are through with the value 1 for a variable (either by discovering a model or by rejecting the value because the produced formula is unsatisfiable), we try the value 0, and when finished, we backtrack to the previous step. It is easy to see that after at most $2n$ queries to the oracle (where n is the number of variables) we either generate a new model or we know that all models of the formula have been generated. □

Now, to show coNP-completeness of all other cases, let S be a set of Boolean relations not satisfying conditions (a)–(d). It is clear that the INVERSE SAT problem for S is in coNP: let $r \geq 3$ be the largest arity of any relation in S. Given a set of models M, we construct all S-clauses satisfied by all models in M—this takes $O(|M|n^r)$ time. M is the set of models of a conjunction of S-clauses if and only if all models not in M fail to satisfy at least one of these S-clauses.

To show completeness, we shall reduce UNSATISFIABILITY, the problem of telling whether a 3CNF expression ψ is unsatisfiable, to the INVERSE SAT(S). We suppose that ψ is a 3CNF expression on $n > 3r$ variables. Set M contains a model for each $3r$-tuple of variables and values for these variables that don't contradict any

clause of ψ. Let k be the cardinality of M, a quantity bounded by a function of r and of the number of variables and clauses of ψ. Notice that since r is constant, the number of models is not exponential. Our construction is a generalization of that of Theorem 1: we consider some total order among the pairs (W, T), where W is a set of $3r$ variables and T a truth assignment to those variables that does not contradict any clause of ψ. Every Boolean vector $m_{W,T}$ in M is a concatenation of two strings: $m_{W,T} = \beta_W^T \epsilon_W^T$.

String β_W^T is a concatenation of the encodings $\tau_W^T(x_i)$ for each variable x_i occuring in the formula ψ: $\beta_W^T = \tau_W^T(x_1) \cdots \tau_W^T(x_n)$. The encoding of $\tau_W^T(x)$ of a variable x is a Boolean vector of length $k+2$ and is defined in the proof of Theorem 1. Notice that in this construction the unique padding pattern for (W, T) occurs $n - 3r$ times in the string β_W^T. Call $N = n(k+2)$ the length of a string β_W^T.

The string ϵ_W^T is constructed as follows: we consider all 3CNF clauses on N variables satisfied by the set of strings β_W^T for all sets of $3r$ variables W and assignments T to those variables. Call ϕ the conjuction of all these clauses. We express ϕ faithfully by S-clauses. This will involve auxiliary variables $x_{N+1}, \ldots, x_{N+s}$. From the definition of faithful representation we see that $x_{N+\ell} \equiv f_\ell(x_{i_\ell}, x_{j_\ell})$, where $\ell = 1, \ldots, s$ and $i_\ell, j_\ell < N+\ell$. Notice, however, that each of the auxiliary variables depends on at most three of the N variables appearing in the 3CNF clauses. This follows from the fact that we are representing 3CNF clauses, and consequently, we can express each 3CNF clause separately by S-clauses and then take the conjunction of the representations. Thus, the overall dependency of an auxiliary variable $x_{N+\ell}, \ell = 1, \ldots, s$, is through a Boolean function $f_\ell(x_{i_\ell}, x_{j_\ell}, x_{k_\ell}), 1 \leq i_\ell, j_\ell, k_\ell \leq N$. Let $b_1 \cdots b_N$ be a string β_W^T. The values in the s positions of the corresponding string $\epsilon_W^T = b_{N+1} \cdots b_{N+s}$ are the values of the auxiliary variables: $b_{N+\ell} = f_\ell(b_{i_\ell}, b_{j_\ell}, b_{k_\ell})$, $\ell = 1, \ldots, s$. (Note that these values are stated explicitly, i.e., not encoded as value patterns.) This is where the concept of faithful representation is necessary: for each string β_W^T there is a unique string ϵ_W^T. With ordinary representation the multiple ways to extend a string β_W^T via the auxiliary variables would result in an exponential increase of our model set.

Let $M \subseteq \{0,1\}^{N+s}$ be the constructed set of models. We claim that M is the set of models of a conjunction of S-clauses iff the original 3CNF expression ψ is unsatisfiable.

If ψ is satisfiable, then M is not the set of models of any rCNF expression. Consider the model corresponding to the satisfying truth assignment. This model is a concatenation of two parts: the first has N positions and consists of the value patterns encoding the values of all variables in the satisfying truth assignment, exactly as in the proof of Theorem 1, and the second consists of the corresponding values of the s auxiliary variables. This model is r-compatible with M: any r-tuple restricted to the first N positions certainly matches a corresponding tuple in some model, by the construction of M. In fact, when the tuple is restricted to the first part, any $3r$-tuple can be matched. This is precisely why an r-tuple that is not restricted to the first N positions is also r-compatible: by the dependency of each auxiliary value to at most 3 of the first N, a compatibility of an i-tuple ($i \leq r$) in the second part holds if a $3i$-compatibility in the first part holds. Alternatively, instead of looking at a position in the second part, we can look at the three corresponding positions of the first part. Therefore, the whole model corresponding to the satisfying truth assignment is r-compatible with M. It follows by Lemma 1 that M is not rCNF, and as a result, M is not the set of models of any conjunction of S-clauses (recall that the maximum arity in S is r).

Suppose then that ψ is unsatisfiable. Let M' be M restricted to the first N positions. Then M' is exactly the set of models of ϕ (the conjuction of all 3CNF clauses on N variables which don't disagree with M') by the reasoning in Theorem 1: no model is 3-compatible with M' except those in M'. Since M' is the set of models of ϕ, it follows that M is the set of models of the corresponding conjunction of S-expressions that faithfully represents ϕ. □

Appendix. This appendix contains the proof of the closure properties of Horn, anti-Horn 2CNF, and affine sets of models, which are used in the proof of Theorem 3. In what follows, $M \subseteq \{0,1\}^n$ denotes a set of models.

HORN SETS. *M is Horn iff for any two models $t, t' \in M$ the model $(t \wedge t')$ is also in M.*

The proof is based on the following proposition from [KPS93]. If t and t' are bit-vectors we use the notation $t \leq t'$ to denote that $t_i = 1$ implies $t_i{}' = 1$.

PROPOSITION. *The following are equivalent.*

(a) *There is a Horn formula whose model set is M.*
(b) *For each $t \notin M$ either there is no $t' \in M$ with $t \leq t'$, or there is a unique minimal $t' \in M$ such that $t \leq t'$.*
(c) *If $t, t' \in M$, then also $t \wedge t' \in M$.*

Proof. That (a) implies (c) is easy. To establish (b) from (c), take t' to be the $\wedge$ of all $t'' \in M$ such that $t \leq t''$. Finally, if we have property (b), we can construct the following set of Horn clauses: for each $t \notin M$ let t' be the model guaranteed by (b); create a Horn clause $((\bigwedge_{t_i=1} x_i) \rightarrow x_j)$ for each j such that $t_j = 0$ and $t'_j = 1$. It is easy to see that the set of all these Horn clauses comprises the desired ϕ.

ANTI-HORN SETS. This case is symmetric to the above. Just replace 1 with 0 and $\wedge$ with $\vee$.

2CNF SETS. *M is 2CNF iff for any set of three models $t_0, t_1, t_2 \in M$ the model $(t_0 \vee t_1) \wedge (t_1 \vee t_2) \wedge (t_2 \vee t_0)$ is also in M.*

Proof. This was shown in [Sc78, Lemma 3.1B]. We give a different proof, which is simpler and is based on Lemma 1 for $k = 2$. First notice that the model $t = (t_0 \vee t_1) \wedge (t_1 \vee t_2) \wedge (t_2 \vee t_0)$ has the following property. The value of t in each position $i = 1, \ldots, n$ is equal to a value, which is the *majority* among the three values of the models t_0, t_1, t_2 in this position (e.g., if the values of models t_0, t_1, t_2 in position i are $(1, 1, 0)$, respectively, the value of t in position i is 1). Call the outcome of the operation $(t_0 \vee t_1) \wedge (t_1 \vee t_2) \wedge (t_2 \vee t_0)$ the *majority* model of t_0, t_1, t_2.

Only if: Suppose M is 2CNF. By Lemma 1 any 2-compatible model with M is in M. It is easy to see that the majority model of any three models is 2-compatible with these three models.

If: Suppose that the majority model of any set of three models $t_0, t_1, t_2 \in M$ is also in M. We shall prove that any 2-compatible model with M is in M. We prove this inductively, by showing that any 2-compatible model is in fact n-compatible. Consider a model m k-compatible with M and a $(k+1)$-tuple of positions in this model. The k distinct k-tuples of this $(k+1)$-tuple agree with some model in M. Take three of those not necessarily distinct k models. (If the models are less than three, then $m \in M$.) Notice that any one of those differs in at most one position of the $(k+1)$-tuple with m. Therefore, the $(k+1)$-tuple of m agrees with the majority model of those three models. Hence, m is $(k+1)$-compatible with M. Therefore, any 2-compatible model with M is in M and, by Lemma 1, M is a 2CNF set.

AFFINE SETS. *M is affine iff for any three models t_0, t_1, t_2 the model $t_0 \oplus t_1 \oplus t_2$ is also in M.*

Proof. This fact follows from linear algebra and especially the theory of diophantine linear equations. It states the intuitive observation (and its converse) that every convex polytope is the convex hull of its vertices. For more on that see the book of Schrijver [Sc86].

Acknowledgments. We are grateful to Christos Papadimitriou for helpful discussions and suggestions. We are also indebted to the anonymous referees for their detailed comments and suggestions that decisively helped us improve the presentation by making it more complete and precise.

ON SYNTACTIC VERSUS COMPUTATIONAL VIEWS OF APPROXIMABILITY*

SANJEEV KHANNA†, RAJEEV MOTWANI‡, MADHU SUDAN§, AND UMESH VAZIRANI¶

Abstract. We attempt to reconcile the two distinct views of approximation classes: *syntactic* and *computational*. Syntactic classes such as MAX SNP permit structural results and have natural complete problems, while computational classes such as APX allow us to work with classes of problems whose approximability is well understood. Our results provide a syntactic characterization of computational classes and give a computational framework for syntactic classes.

We compare the syntactically defined class MAX SNP with the computationally defined class APX and show that every problem in APX can be "placed" (i.e., has approximation-preserving reduction to a problem) in MAX SNP. Our methods introduce a simple, yet general, technique for creating approximation-preserving reductions which shows that any "well"-approximable problem can be reduced in an approximation-preserving manner to a problem which is hard to approximate to corresponding factors. The reduction then follows easily from the recent nonapproximability results for MAX SNP-hard problems. We demonstrate the generality of this technique by applying it to other classes such as MAX SNP-RMAX(2) and MIN $F^+\Pi_2(1)$ which have the clique problem and the set cover problem, respectively, as complete problems.

The syntactic nature of MAX SNP was used by Papadimitriou and Yannakakis [*J. Comput. System Sci.*, 43 (1991), pp. 425–440] to provide approximation algorithms for every problem in the class. We provide an alternate approach to demonstrating this result using the syntactic nature of MAX SNP. We develop a general paradigm, *nonoblivious local search*, useful for developing simple yet efficient approximation algorithms. We show that such algorithms can find good approximations for all MAX SNP problems, yielding approximation ratios comparable to the best known for a variety of specific MAX SNP-hard problems. Nonoblivious local search provably outperforms standard local search in both the degree of approximation achieved and the efficiency of the resulting algorithms.

1. Introduction.

The approximability of NP optimization (NPO) problems has been investigated in the past via the definition of two different types of problem classes: syntactically defined classes such as MAX SNP (the class of NPO problems expressible as bounded-arity constraint satisfaction problems) and computationally defined classes such as APX (the class of NPO problems to which a constant-factor approximation can be found in polynomial time); see section 2 for formal definitions. The former

is useful for obtaining structural results and has natural complete problems, while the latter allows us to work with classes of problems whose approximability is completely determined. We attempt to develop linkages between these two views of approximation problems and thereby obtain new insights into both types of classes. We show that a natural generalization of MAX SNP renders it identical to the class APX. This further validates Papadimitriou and Yannakakis's definition [23] of MAX SNP as providing a structural basis for the study of approximability. As a side-effect, we resolve the open problem of identifying complete problems for MAX NP. Our techniques extend to a generic theorem that can be used to create an approximation hierarchy. We also develop a generic algorithmic paradigm which is guaranteed to provide good approximations for MAX SNP problems and may also have other applications.

1.1. Background and motivation. A wide variety of classes is defined based directly on the polynomial-time approximability of the problems contained within, e.g., APX (constant-factor approximable problems), PTAS (problems with polynomial-time approximation schemes), and FPTAS (problems with fully-polynomial-time approximation schemes). The advantage of working with classes defined using approximability as the criterion is that it allows us to work with problems whose approximability is well understood. Crescenzi and Panconesi [8] have recently also been able to exhibit complete problems for such classes, particularly APX. Unfortunately such complete problems seem to be rare and artificial, and do not seem to provide insight into the more natural problems in the class. Research in this direction has to find approximation-preserving reductions from the known complete but artificial problems in such classes to the natural problems therein, with a view to understanding the approximability of the latter.

The second family of classes of NPO problems that have been studied are those defined via syntactic considerations, based on a syntactic characterization of NP due to Fagin [10]. Research in this direction, initiated by Papadimitriou and Yannakakis [23] and followed by Panconesi and Ranjan [22] and Kolaitis and Thakur [20], has led to the identification of approximation classes such as MAX SNP, RMAX(2), and MIN $F^+\Pi_2(1)$. The syntactic prescription in the definition of these classes has proved very useful in the establishment of complete problems. Moreover, the recent results of Arora et al. [2] have established the hardness of approximating complete problems for MAX SNP to within (specific) constant factors unless P = NP. It is natural to wonder why the hardest problems in this syntactic subclass of APX should bear any relation to all of NP.

Though the computational view allows us to precisely classify the problems based on their approximability, it does not yield structural insights into natural questions such as: Why are certain problems easier to approximate than some others? What is the canonical structure of the hardest representative problems of a given approximation class? and so on. Furthermore, intuitively speaking, this view is too abstract to facilitate identification of, and reductions to establish, natural complete problems for a class. The syntactic view, on the other hand, is essentially a structural view. The syntactic prescription gives a natural way of identifying canonical hard problems in the class and performing approximation-preserving reductions to establish complete problems.

Attempts at trying to find a class with both the above-mentioned properties, i.e., natural complete problems and capturing all problems of a specified approximability, have not been very successful. Typically the focus has been to relax the syntactic criteria to allow a wider class of problems to be included in the class. However, in

all such cases it seems inevitable that these classes cannot be expressive enough to encompass all problems with a given approximability. This is because each of these syntactically defined approximation classes is strictly contained in the class NPO; the strict containment can be shown by syntactic considerations alone. As a result, if we could show that any of these classes contains all of P, then we would have separated P from NP. We would expect that every class of this nature would be missing some problems from P, and this has indeed been the case with all current definitions.

We explore a different direction by studying the structure of the syntactically defined classes when we look at their closure under approximation-preserving reductions. The idea of looking at the closure of a class is implicit in the work of Papadimitriou and Yannakakis [23] who state that *minimization problems will be "placed" in the classes through L-reductions to maximization problems.* The advantage of looking at the closure of a set is that it maintains the complete problems of the set, while managing to include all of P in the closure (for problems in P, the reduction is to simply use a polynomial-time algorithm to compute an exact solution). It now becomes interesting, for example, to compare the closure of MAX SNP (denoted $\overline{\text{MAX SNP}}$) with APX. A positive resolution, i.e., $\overline{\text{MAX SNP}} = \text{APX}$, would immediately imply the nonexistence of a PTAS for MAX SNP-hard problems, since it is known that PTAS is a strict subset of APX, if $\text{P} \neq \text{NP}$. On the other hand, an unconditional negative result would be difficult to obtain, since it would imply $\text{P} \neq \text{NP}$.

Here we resolve this question in the affirmative. The exact nature of the result obtained depends upon the precise notion of an approximation-preserving reduction used to define the closure of the class MAX SNP. The strictest notion of such reductions available in the literature are the *L*-reductions due to Papadimitriou and Yannakakis [23]. We work with a slight extension of the reduction, which we call *E*-reductions. Using such reductions to define the class $\overline{\text{MAX SNP}}$ we show that this equals APX-PB, the class of all polynomially bounded NPO problems which are approximable to within constant factors. By using slightly looser definitions of approximation-preserving reductions (and in particular the PTAS-reductions of Crescenzi and Trevisan [9]) this can be extended to include all of APX in $\overline{\text{MAX SNP}}$. We then build upon this result to identify an interesting hierarchy of such approximability classes. An interesting side-effect of our results is the positive answer to the question of Papadimitriou and Yannakakis [23] about whether MAX NP has any complete problems.

The syntactic view seems useful not only in obtaining structural complexity results but also in developing paradigms for designing efficient approximation algorithms. This was demonstrated first by Papadimitriou and Yannakakis [23] who show approximation algorithms for every problem in MAX SNP. We further exploit the syntactic nature of MAX SNP to develop another paradigm for designing good approximation algorithms for problems in that class and thereby provide an alternate computational view of it. We refer to this paradigm as *nonoblivious local search*, and it is a modification of the standard local search technique [25]. We show that every MAX SNP problem can be approximated to within constant factors by such algorithms. It turns out that the performance of nonoblivious local search is comparable to that of the best-known approximation algorithms for several interesting and representative problems in MAX SNP. An intriguing possibility is that this is not a coincidence, but rather a hint at the universality of the paradigm or some variant thereof.

Our results are related to some extent to those of Ausiello and Protasi [4]. They

define a class GLO (for guaranteed local optima) of NPO problems which have the property that for all locally optimum solutions, the ratio between the values of the global and the local optima is bounded by a constant. It follows that GLO is a subset of APX, and it was shown that it is in fact a strict subset. We show that a MAX SNP problem is not contained in GLO, thereby establishing that MAX SNP is not contained in GLO. This contrasts with our notion of nonoblivious local search which is guaranteed to provide constant-factor approximations for all problems in MAX SNP. In fact, our results indicate that nonoblivious local search is significantly more powerful than standard local search in that it delivers strictly better constant ratios, and will also provide constant-factor approximations to problems not in GLO. Independently of our work, Alimonti [1] has used a similar local search technique for the approximation of a specific problem not contained in GLO or MAX SNP.

1.2. Summary of results. In section 2, we present the definitions required to state our results, and in particular the definitions of an E-reduction, APX, APX-PB, MAX SNP, and $\overline{\text{MAX SNP}}$. In section 3, we show that $\overline{\text{MAX SNP}} = \text{APX-PB}$. A generic theorem which allows us to equate the closure of syntactic classes to appropriate computational classes is outlined in section 4; we also develop an approximation hierarchy based on this result.

The notion of nonoblivious local search and NONOBLIVIOUS GLO is developed in section 5. In section 6, we illustrate the power of nonobliviousness by first showing that oblivious local search can achieve at most the performance ratio 3/2 for MAX 2-SAT, even if it is allowed to search *exponentially* large neighborhoods; in contrast, a very simple nonoblivious local search algorithm achieves a performance ratio of 4/3. We then establish that this paradigm yields a $2^k/(2^k - 1)$ approximation to MAX k-SAT. In section 7, we provide an alternate characterization of MAX SNP via a class of problems called MAX k-CSP. It is shown that a simple nonoblivious algorithm achieves the best-known approximation for this problem, thereby providing a *uniform* approximation for all of MAX SNP. In section 8, we further illustrate the power of this class of algorithm by showing that it can achieve the best-known ratio for a specific MAX SNP problem and for VERTEX COVER (which is not contained in GLO). This implies that MAX SNP is not contained in GLO, and that GLO is a strict subset of NONOBLIVIOUS GLO. In section 9, we apply it to approximating the traveling salesman problem. Finally, in section 10, we apply this technique to improving a long-standing approximation bound for maximum independent sets in bounded-degree graphs.

2. Preliminaries and definitions. Given an NPO problem Π and an instance $\mathcal{I}$ of Π, we use $|\mathcal{I}|$ to denote the length of $\mathcal{I}$ and $OPT(\mathcal{I})$ to denote the optimum value for this instance. For any solution S to $\mathcal{I}$, the value of the solution, denoted by $V(\mathcal{I}, S)$, is assumed to be a polynomial-time computable function which takes positive integer values (see [7] for a precise definition of NPO).

DEFINITION 1 (error). *Given a solution S to an instance $\mathcal{I}$ of an* NPO *problem* Π*, we define its* error $\mathcal{E}(\mathcal{I}, S)$ *as*

$$\mathcal{E}(\mathcal{I}, S) = \max\left\{\frac{V(\mathcal{I}, S)}{OPT(\mathcal{I})}, \frac{OPT(\mathcal{I})}{V(\mathcal{I}, S)}\right\} - 1.$$

Notice that the above definition of error applies uniformly to the minimization and maximization problems at all levels of approximability.

DEFINITION 2 (performance ratio). *An approximation algorithm A for an optimization problem Π has* performance ratio $\mathcal{R}(n)$ *if, given an instance $\mathcal{I}$ of Π with $|\mathcal{I}| = n$, the solution $A(\mathcal{I})$ satisfies*

$$\max\left\{\frac{V(\mathcal{I}, A(\mathcal{I}))}{OPT(\mathcal{I})}, \frac{OPT(\mathcal{I})}{V(\mathcal{I}, A(\mathcal{I}))}\right\} \leq \mathcal{R}(n).$$

A solution of value within a multiplicative factor r of the optimal value is referred to as an r-approximation.

The performance ratio for A is $\mathcal{R}$ if it always computes a solution with error at most $\mathcal{R} - 1$.

2.1. *E*-reductions. We now describe the precise approximation-preserving reduction we will use in this paper. This reduction, which we call the E-reduction, is essentially the same as the L-reduction of Papadimitriou and Yannakakis [23] and differs from it in only one relatively minor aspect.

DEFINITION 3 (E-reduction). *A problem Π* E-reduces *to a problem Π' (denoted $\Pi \propto_E \Pi'$) if there exist polynomial-time computable functions f, g and a constant β such that*

- *f maps an instance $\mathcal{I}$ of Π to an instance $\mathcal{I}'$ of Π' such that $OPT(\mathcal{I})$ and $OPT(\mathcal{I}')$ are related by a polynomial factor; i.e., there exists a polynomial $p(n)$ such that $OPT(\mathcal{I}') \leq p(|\mathcal{I}|)OPT(\mathcal{I})$.*
- *g maps solutions S' of $\mathcal{I}'$ to solutions S of $\mathcal{I}$ such that*

$$\mathcal{E}(\mathcal{I}, S) \leq \beta\mathcal{E}(\mathcal{I}', S').$$

Remark 1. Among the many approximation-preserving reductions in the literature, the L-reduction appears to be the strictest. The E-reduction appears to be slightly weaker (in that it allows polynomial scaling of the problems), but is stricter than any of the other known reductions. Since all the reductions given in this paper are E-reductions, they would also qualify as approximation-preserving reductions under most other definitions, and in particular, they fit the definitions of F-reductions and P-reductions of Crescenzi and Panconesi [8].

Remark 2. Having $\Pi \propto_E \Pi'$ implies that Π is as well approximable as Π'; in fact, an E-reduction is an FPTAS-preserving reduction. An important benefit is that this reduction can be applied uniformly at all levels of approximability. This is not the case with the other existing definitions of FPTAS-preserving reduction in the literature. For example, the FPTAS-preserving reduction (F-reduction) of Crescenzi and Panconesi [8] is much more unrestricted in scope and does not share this important property of the E-reduction. Note that Crescenzi and Panconesi [8] showed that there exists a problem $\Pi' \in$ PTAS such that for any problem $\Pi \in$ APX, $\Pi \propto_F \Pi'$. Thus, there is the undesirable situation that a problem Π with no PTAS has an FPTAS-preserving reduction to a problem Π' with a PTAS.

Remark 3. The L-reduction of Papadimitriou and Yannakakis [23] enforces the condition that the optima of an instance $\mathcal{I}$ of Π be linearly related to the optima of the instance $\mathcal{I}'$ of Π' to which it is mapped. This appears to be an unnatural restriction considering that the reduction itself is allowed to be an arbitrary polynomial-time computation. This is the only real difference between their L-reduction and our E-reduction, and an E-reduction in which the linearity relation of the optimas is satisfied is an L-reduction. Intuitively, however, in the study of approximability the desirable attribute is simply that the errors in the corresponding solutions are closely

(linearly) related. The somewhat artificial requirement of a linear relation between the optimum values precludes reductions between problems which are related to each other by some *scaling factor*. For instance, it seems desirable that two problems whose objective functions are simply related by any fixed polynomial factor should be interreducible under any reasonable definition of an approximation-preserving reduction. Our relaxation of the L-reduction constraint is motivated precisely by this consideration.

Let $\mathcal{C}$ be any class of NPO problems. Using the notion of an E-reduction, we define hardness and completeness of problems with respect to $\mathcal{C}$, as well as its closure and polynomially bounded subclass.

DEFINITION 4 (hard and complete problems). *A problem* Π' *is said to be* $\mathcal{C}$-hard *if for all problems* $\Pi \in \mathcal{C}$*, we have* $\Pi \propto_E \Pi'$*. A* $\mathcal{C}$*-hard problem* Π *is said to be* $\mathcal{C}$-complete *if, in addition,* $\Pi \in \mathcal{C}$*.*

DEFINITION 5 (closure). *The* closure *of* $\mathcal{C}$*, denoted by* $\overline{\mathcal{C}}$*, is the set of all* NPO *problems* Π *such that* $\Pi \propto_E \Pi'$ *for some* $\Pi' \in \mathcal{C}$*.*

Remark 4. The closure operation maintains the set of complete problems for a class.

DEFINITION 6 (polynomially bounded subset). *The* polynomially bounded subset *of* $\mathcal{C}$*, denoted* $\mathcal{C}$*-PB, is the set of all problems* $\Pi \in \mathcal{C}$ *for which there exists a polynomial* $p(n)$ *such that for all instances* $\mathcal{I} \in \Pi$*,* $OPT(\mathcal{I}) \leq p(|\mathcal{I}|)$*.*

2.2. Computational and syntactic classes. We first define the basic computational class APX.

DEFINITION 7 (APX). *An* NPO *problem* Π *is in the class* APX *if there exists a polynomial-time algorithm* A *for* Π *with performance ratio bounded by some constant* c*.*

The class APX-PB consists of all polynomially bounded NPO problems which can be approximated to within constant factors in polynomial time.

If we let F-APX denote the class of NPO problems that are approximable to within a factor F, then we obtain a *hierarchy* of approximation classes. For instance, poly-APX and log-APX are the classes of NPO problems which have polynomial-time algorithms with performance ratio bounded polynomially and logarithmically, respectively, in the input length. More precise versions of these definitions are provided in section 4.

Let us briefly review the definitions of some syntactic classes.

DEFINITION 8 (MAX SNP and MAX NP [23]). MAX SNP *is the class of* NPO *problems expressible as finding the structure* S *which maximizes the objective function*

$$V(\mathcal{I}, S) = |\{\vec{x} \mid \Phi(\mathcal{I}, S, \vec{x})\}|,$$

where $\mathcal{I} = (U; \mathcal{P})$ *denotes the input (consisting of a finite universe* U *and a finite set of bounded arity predicates* $\mathcal{P}$*),* S *is a finite structure, and* Φ *is a quantifier-free first-order formula. The class* MAX NP *is defined analogously, but the objective function is*

$$V(\mathcal{I}, S) = |\{\vec{x} \mid \exists \vec{y}, \Phi(\mathcal{I}, S, \vec{x}, \vec{y})\}|.$$

A natural extension is to associate a weight with every tuple $\vec{x}$; the modified objective is to find an S which maximizes $V(\mathcal{I}, S) = \sum_{\vec{x}} w(\vec{x})\Phi(\mathcal{I}, S, \vec{x})$, where $w(\vec{x})$ denotes the weight associated with the tuple $\vec{x}$.

Example 1 (MAX k-SAT). The MAX k-SAT problem is: given a collection of m clauses on n boolean variables where each (possibly weighted) clause is a disjunction of precisely k literals, find a truth assignment satisfying a maximum weight collection of clauses. For any fixed integer k, MAX k-SAT belongs to the class MAX SNP. The results of Papadimitriou and Yannakakis [23] can be adapted to show that for $k \geq 2$, MAX k-SAT is complete under E-reductions for the class MAX SNP.

DEFINITION 9 (RMAX(k) [22]). RMAX(k) *is the class of* NPO *problems expressible as finding a structure* S *which maximizes the objective function*

$$V(\mathcal{I}, S) = \begin{cases} |\{\vec{x} \mid S(\vec{x})\}| & \text{if } \forall \vec{y}, \Phi(\mathcal{I}, S, \vec{y}), \\ 0 & \text{otherwise}, \end{cases}$$

where S *is a single predicate and* $\Phi(\mathcal{I}, S, \vec{y})$ *is a quantifier-free CNF formula in which* S *occurs at most* k *times in each clause and all its occurrences are negative.*

The results of Panconesi and Ranjan [22] can be adapted to show that MAX CLIQUE is complete under E-reductions for the class RMAX(2).

DEFINITION 10 (MIN $\mathrm{F}^+\mathbf{\Pi_2(}k\mathbf{)}$ [20]). MIN $\mathrm{F}^+\Pi_2(k)$ *is the class of* NPO *problems expressible as finding a structure* S *which minimizes the objective function*

$$V(\mathcal{I}, S) = \begin{cases} |\{\vec{x} : S(\vec{x})\}| & \text{if } \forall \vec{x}, \exists \vec{y}, \Phi(\mathcal{I}, S, \vec{x}, \vec{y}), \\ 0 & \text{otherwise}, \end{cases}$$

where S *is a single predicate,* $\Phi(\mathcal{I}, S, \vec{y})$ *is a quantifier-free CNF formula in which* S *occurs at most* k *times in each clause, and all its occurrences are positive.*

The results of Kolaitis and Thakur [20] can be adapted to show that SET COVER is complete under E-reductions for the class MIN $\mathrm{F}^+\Pi_2(1)$.

3. MAX SNP closure and APX-PB. In this section, we will establish the following theorem and examine its implications. The proof is based on the results of Arora et al. [2] on efficient proof verifications.

THEOREM 1. $\overline{\text{MAX SNP}} = \text{APX-PB}$.

Remark 5. The seeming weakness that $\overline{\text{MAX SNP}}$ only captures polynomially bounded APX problems can be removed by using looser forms of approximation-preserving reduction in defining the closure. In particular, Crescenzi and Trevisan [9] define the notion of a PTAS-preserving reduction under which $\text{APX} = \overline{\text{APX-PB}}$. Using their result in conjunction with the above theorem, it is easily seen that $\overline{\text{MAX SNP}} = \text{APX}$. This weaker reduction is necessary to allow for reductions from fine-grained optimization problems to coarser (polynomially bounded) optimization problems (cf. [9]).

The following is a surprising consequence of Theorem 1.

THEOREM 2. $\overline{\text{MAX NP}} = \overline{\text{MAX SNP}}$.

Papadimitriou and Yannakakis [23] (implicitly) introduced both these closure classes but did not conjecture them to be the same. It would be interesting to see if this equality can be shown independent of the result of Arora et al. [2]. We also obtain the following resolution to the problem posed by Papadimitriou and Yannakakis [23] of finding complete problems for MAX NP.

THEOREM 3. MAX SAT *is complete for* MAX NP.

The following subsections establish that $\overline{\text{MAX SNP}} \supseteq \text{APX-PB}$. The idea is to first E-reduce any minimization problem in APX-PB to a maximization problem in APX-PB, and to then E-reduce any maximization problem in APX-PB to a specific complete problem for MAX SNP, viz., MAX 3-SAT. Since an E-reduction forces the

optima of the two problems involved to be related by polynomial factors, it is easy to see that $\overline{\text{MAX SNP}} \subseteq$ APX-PB. Combining these two facts, we obtain Theorem 1.

3.1. Reducing minimization to maximization. Observe that the fact that Π belongs to APX implies the existence of an approximation algorithm A and a constant c such that

$$\frac{OPT(\mathcal{I})}{c} \leq V(\mathcal{I}, A(\mathcal{I})) \leq c \times OPT(\mathcal{I}).$$

Henceforth, we will use $a(\mathcal{I})$ to denote $V(\mathcal{I}, A(\mathcal{I}))$. We first reduce any minimization problem $\Pi \in$ APX-PB to a maximization problem $\Pi' \in$ APX-PB, where the latter is obtained by merely modifying the objective function for Π, as follows. Let Π' have the objective function

$$V'(\mathcal{I}, S) = \max\{1, (c+1)a(\mathcal{I}) - cV(\mathcal{I}, S)\}$$

for all instances $\mathcal{I}$ and solutions S for Π. Clearly, $V'(\mathcal{I}, S)$ takes only positive values. To ensure that $V'(\mathcal{I}, S)$ is integer-valued, we can assume, without loss of generality, that c is an integer (a real-valued performance ratio can always be rounded up to the next integer). It can be verified that the optimum value for any instance $\mathcal{I}$ of Π' always lies between $a(\mathcal{I})$ and $(c+1)a(\mathcal{I})$. Thus A is a $(c+1)$-approximation algorithm for Π'.

Now, given a solution S', for instance, $\mathcal{I}$, of Π' such that it has error δ, we want to construct a solution S, for instance, $\mathcal{I}$, of Π such that the error is at most $\beta\delta$ for some β. We will show this for $\beta = (c+1)$.

First consider the case when $V'(\mathcal{I}, S') = 1$; i.e., $\delta = a(\mathcal{I}) - 1$. In this case, we simply output the solution $S = A(\mathcal{I})$. If $a(\mathcal{I}) = 1$ then we are trivially done; else we observe that

$$\mathcal{E}(I, S) \leq (c-1) \leq (c+1)(a(\mathcal{I}) - 1) \leq \beta\mathcal{E}'(I, S').$$

On the other hand, if $V'(\mathcal{I}, S') > 1$, we may proceed as follows. If S' is a δ-error solution to the optimum of Π', i.e.,

$$V'(\mathcal{I}, S) \geq \frac{OPT'(\mathcal{I})}{1+\delta} \geq (1-\delta)OPT'(\mathcal{I}),$$

where $OPT'(\mathcal{I})$ is the optimal value of V' for $\mathcal{I}$, we can conclude that

$$\begin{aligned} V(\mathcal{I}, S) &= \frac{(c+1)a(\mathcal{I}) - V'(\mathcal{I}, S)}{c} \\ &\leq \frac{(c+1)a(\mathcal{I}) - OPT'(\mathcal{I}) + \delta \times OPT'(\mathcal{I})}{c} \\ &\leq \frac{c \times OPT(\mathcal{I}) + \delta \times OPT'(\mathcal{I})}{c} \\ &\leq OPT(\mathcal{I}) + (c+1)\delta\, OPT(\mathcal{I}). \end{aligned}$$

Thus a solution s to Π' with error δ is a solution to Π with error at most $(c+1)\delta$, implying an E-reduction with $\beta = c+1$.

3.2. NP languages and MAX 3-SAT. The following theorem, adapted from a result of Arora et al. [2], is critical to our E-reduction of maximization problems to MAX 3-SAT.

THEOREM 4 (see [2]). *Given a language $L \in$ NP and an instance $x \in \Sigma^n$, one can compute in polynomial time an instance $\mathcal{F}_x$ of* MAX 3-SAT*, with the following properties.*

1. *The formula $\mathcal{F}_x$ has m clauses, where m depends only on n.*
2. *There exists a constant $\epsilon > 0$, independent of the input x, such that $(1-\epsilon)m$ clauses of $\mathcal{F}_x$ are satisfied by some truth assignment.*
3. *If $x \in L$, then $\mathcal{F}_x$ is (completely) satisfiable.*
4. *If $x \notin L$, then no truth assignment satisfies more than $(1-\epsilon)m$ clauses of $\mathcal{F}_x$.*
5. *Given a truth assignment which satisfies more than $(1-\epsilon)m$ clauses of $\mathcal{F}_x$, a truth assignment which satisfies $\mathcal{F}_x$ completely (or, alternatively, a witness showing $x \in L$) can be constructed in polynomial time.*

Some of the properties above may not be immediately obvious from the construction given by Arora et al. [2]. It is easy to verify that they provide a reduction with properties 1, 3, and 4. Property 5 is obtained from the fact that all assignments which satisfy most clauses are actually close (in terms of Hamming distance) to valid codewords from a linear code, and the uniquely error-corrected codeword obtained from this "corrupted codeword" will satisfy all the clauses of $\mathcal{F}_x$.

Property 2 requires a bit more care, and we provide a brief sketch of how it may be ensured. The idea is to revert back to the PCP model and redefine the proof verification game. Suppose that the original game had the properties that for $x \in L$ there exists a proof such that the verifier accepts with probability 1; and otherwise, for $x \notin L$, the verifier accepts with probability at most $1/2$. We now augment this game by adding to the proof a zeroth bit which the prover uses as follows: if the bit is set to 1, then the prover "chooses" to play the old game; else he is effectively "giving up" on the game. The verifier in turn first looks at the zeroth bit of the proof. If this is set, then she performs the usual verification; else she tosses an unbiased coin and accepts if and only if it turns up heads. It is clear that for $x \in L$ there exists a proof on which the verifier always accepts. Also, for $x \notin L$, no proof can cause the verifier to accept with probability greater than $1/2$. Finally, by setting the zeroth bit to 0, the prover can create a proof which the verifier accepts with probability exactly $1/2$. This proof system can now be transformed into a 3-CNF formula of the desired form.

3.3. Reducing maximization to MAX 3-SAT. We have already established that, without loss of generality, we only need to worry about maximization problems $\Pi \in$ APX-PB. Consider such a problem Π, and let A be a polynomial-time algorithm which delivers a c-approximation for Π, where c is some constant. Given any instance $\mathcal{I}$ of Π, let $p = ca(\mathcal{I})$ be the bound on the optimum value for $\mathcal{I}$ obtained by running A on input $\mathcal{I}$. Note that this may be a stronger bound than the a priori polynomial bound on the optimum value for any instance of length $|\mathcal{I}|$. An important consequence is that $p \leq cOPT(\mathcal{I})$.

We generate a sequence of NP decision problems $L_i = \{\mathcal{I} | \, OPT(\mathcal{I}) \geq i\}$ for $1 \leq i \leq p$. Given an instance $\mathcal{I}$, we create p formulas $\mathcal{F}_i$, for $1 \leq i \leq p$, using the reduction from Theorem 4, where the ith formula is obtained from the NP language L_i.

Consider now the formula $\mathcal{F} = \bigwedge_{i=1}^{p} \mathcal{F}_i$ that has the following features.

- The number of satisfiable clauses of $\mathcal{F}$ is exactly

$$\text{MAX} = (1-\epsilon)mp + \epsilon m\, OPT(\mathcal{I}),$$

  where ϵ and m are as guaranteed by Theorem 4.
- Given an assignment which satisfies $(1-\epsilon)mp + \epsilon mj$ clauses of $\mathcal{F}$, we can construct in polynomial time a solution to $\mathcal{I}$ of value at least j. To see this, observe the following: any assignment with so many clauses must satisfy more than $(1-\epsilon)m$ clauses in at least j of the formulas $\mathcal{F}_i$. Let i be the largest index for which this happens; clearly, $i \geq j$. Furthermore, by property (5) of Theorem 4, we can now construct a truth assignment which satisfies $\mathcal{F}_i$ completely. This truth assignment can be used to obtain a solution S such that $V(\mathcal{I}, S) \geq i \geq j$.

In order to complete the proof it remains to be shown that given any truth assignment with error δ, i.e., which satisfies $\text{MAX}/(1+\delta)$ clauses of $\mathcal{F}$, we can find a solution S for $\mathcal{I}$ with error $\mathcal{E}(\mathcal{I}, S) \leq \beta\delta$ for some constant β. We show that this is possible for $\beta = (c^2 + c\epsilon)/\epsilon$. The main idea behind finding such a solution is to use the second property above to find a "good" solution to $\mathcal{I}$ using a "good" truth assignment for $\mathcal{F}$.

Suppose we are given a solution which satisfies $\text{MAX}/(1+\delta)$ clauses. Since $\text{MAX}/(1+\delta) \geq (1-\delta)\,\text{MAX}$ and $\text{MAX} = (1-\epsilon)mp + \epsilon m\, OPT(\mathcal{I})$, we can use the second feature from above to construct a solution S_1 such that

$$\begin{aligned} V(\mathcal{I}, S_1) &\geq \frac{(1-\delta)\,\text{MAX} - (1-\epsilon)mp}{\epsilon m} \\ &\geq (1-\delta)\, OPT(\mathcal{I}) - \frac{\delta}{\epsilon} p \\ &\geq \left(1 - \delta\left(1 + \frac{c}{\epsilon}\right)\right) OPT(\mathcal{I}). \end{aligned}$$

Suppose $\delta \leq (c-1)\epsilon/(c(c+\epsilon))$. Let $\delta^* = \delta(1 + c/\epsilon)$ and $\gamma = \delta^*/(1-\delta^*)$. Then it is readily seen that

$$V(\mathcal{I}, S_1) \geq \frac{OPT(\mathcal{I})}{1+\gamma}$$

and that

$$0 \leq \gamma \leq \left(\frac{c^2 + c\epsilon}{\epsilon}\right)\delta.$$

On the other hand, if $\delta > (c-1)\epsilon/(c(c+\epsilon))$, then the error in a solution S_2 obtained by running the c-approximation algorithm for Π is given by

$$c - 1 \leq \left(\frac{c^2 + c\epsilon}{\epsilon}\right)\delta.$$

Therefore, choosing $\beta = (c^2 + c\epsilon)/\epsilon$, we immediately obtain that the solution with larger value, among S_1 and S_2, has error at most $\beta\delta$. Thus, this reduction is indeed an E-reduction.

4. Generic reductions and an approximation hierarchy. In this section we describe a generic technique for turning a hardness result into an approximation-preserving reduction.

We start by listing the kind of constraints imposed on the hardness reduction, the approximation class, and the optimization problem. We will observe at the end that these restrictions are obeyed by all known hardness results and the corresponding approximation classes.

DEFINITION 11 (additive problems). *An* NPO *problem* Π *is said to be* additive *if there exists an operator* $+$ *and a polynomial-time computable function* f *such that* $+$ *maps a pair of instances* $\mathcal{I}_1$ *and* $\mathcal{I}_2$ *to an instance* $\mathcal{I}_1 + \mathcal{I}_2$ *such that* $OPT(\mathcal{I}_1 + \mathcal{I}_2) = OPT(\mathcal{I}_1) + OPT(\mathcal{I}_2)$*, and* f *maps a solution* s *to* $\mathcal{I}_1 + \mathcal{I}_2$ *to a pair of solutions* s_1 *and* s_2 *to* $\mathcal{I}_1$ *and* $\mathcal{I}_2$*, respectively, such that* $V(\mathcal{I}_1 + \mathcal{I}_2, s) = V(\mathcal{I}_1, s_1) + V(\mathcal{I}_2, s_2)$.

DEFINITION 12 (downward closed family). *A family of functions* $F = \{f : \mathcal{Z}^+ \to \mathcal{Z}^+\}$ *is said to be* downward closed *if for all* $g \in F$ *and for all constants* c *(and in particular for all integers* $c > 1$*),* $g'(n) \in O(g(n^c))$ *implies that* $g' \in F$*. A function* g *is said to be* hard *for the family* F *if for all* $g' \in F$*, there exists a constant* c *such that* $g'(n) \in O(g(n^c))$*; the function* g *is said to be* complete *for* F *if* g *is hard for* F *and* $g \in F$.

DEFINITION 13 (F-APX). *For a downward closed family* F*, the class* F-APX *consists of all polynomially bounded optimization problems approximable to within a ratio of* $g(|\mathcal{I}|)$ *for some function* $g \in F$.

DEFINITION 14 (canonical hardness). *An* NP *maximization problem* Π *is said to be* canonically hard *for the class* F-APX *if there exists a transformation* T *mapping instances of* 3-SAT *to instances of* Π*, constants* n_0 *and* c*, and a gap function* G *which is hard for the family* F*, such that given an instance* x *of* 3-SAT *on* $n \geq n_0$ *variables and* $N \geq n^c$*,* $\mathcal{I} = T(x, N)$ *is an instance of* Π *with the following properties.*

- *If* $x \in$ 3-SAT*, then* $OPT(\mathcal{I}) = N$.
- *If* $x \notin$ 3-SAT*, then* $OPT(\mathcal{I}) = N/G(N)$.
- *Given a solution* S *to* $\mathcal{I}$ *with* $V(\mathcal{I}, S) > N/G(N)$*, a truth assignment satisfying* x *can be found in polynomial time.*

In the above definition, the transformation T from 3-SAT to Π is somewhat special in that one can specify the size/optimum of the reduced problem and T can produce a mapped instance of the desired size. This additional property is easily obtained for additive problems by using a sufficient number of additions until the optimum of the reduced problem is close to the target optimum, and then adding a problem of known optimum value to the reduced problem.

Canonical hardness for NP *minimization problems* is analogously defined: $OPT(\mathcal{I}) = N$ when the formula is satisfiable, and $OPT(\mathcal{I}) = NG(N)$ otherwise. Given any solution with value less than $NG(N)$, one can construct a satisfying assignment in polynomial time.

4.1. The reduction.

THEOREM 5. *If* F *is a downward closed family of functions, and an additive* NPO *problem* Ω *is canonically hard for the class* F-APX-PB*, then all problems in* F-APX-PB *E-reduce to* Ω.

Proof. Let Π be a polynomially bounded optimization problem in F-APX, approximable to within $c(.)$ by an algorithm A, and let Ω be a problem shown to be hard to within a factor $G(.)$ where G is hard for F. Let V and V' denote the objective functions of Π and Ω, respectively. We start with the special case where both Π and Ω are maximization problems. We describe the functions f, g and the constant β as

required for an E-reduction.

Let $\mathcal{I} \in \Pi$ be an instance of size n; pick N so that $c(n)$ is $O(G(N))$. To describe our reduction, we need to specify the functions f and g. The function f is defined as follows. Let $m = V(\mathcal{I}, A(\mathcal{I}))$. For each $i \in \{1, \ldots, mc(n)\}$, let L_i denote the NP-language $\{\mathcal{I} | \, OPT(\mathcal{I}) \geq i\}$. Now, for each i, we create an instance $\phi_i \in \Omega$ of size N such that if $\mathcal{I} \in L_i$ then $OPT(\phi_i)$ is N, and it is $N/G(N)$ otherwise. We define $f(\mathcal{I}) = \phi = \sum_i \phi_i$.

We now construct the function g. Given an instance $\mathcal{I} \in \Pi$ and a solution s' to $f(\mathcal{I})$, we compute a solution s to $\mathcal{I}$ in the following manner. We first use A to find a solution s_1. We also compute a second solution s_2 to $\mathcal{I}$ as follows. Let j be the largest index such that the solution s' projects down to a solution s'_j to the instance ϕ_j such that $V'(\phi_j, s'_j) > N/G(N)$. This in turn implies that we can find a solution s_2 to witness $V(\mathcal{I}, s_2) \geq j$. Our solution s is the one among s_1 and s_2 that yields the larger objective function value.

We now show that the reduction is an E-reduction with $\beta = 1 + c(n)/(G(N) - 1)$.

Let $\alpha = OPT(I)/m$. Observe that

$$OPT(I') = Nm \left(\alpha + \frac{c(n)}{G(N)} - \frac{\alpha}{G(N)} \right).$$

Consider the following two cases.

Case 1 [$j \leq m$]: In this case, $V(\mathcal{I}, s) = m$. Since s is a solution to $\mathcal{I}$ of error at most $(\alpha - 1)$, it suffices to argue that the error of s' as a solution to ϕ is at least $(\alpha - 1)/\beta$. We start with the following upper bound on $V(\phi, s')$.

$$V(\phi, s') \leq Nm \left(1 + \frac{c(n)}{G(N)} - \frac{1}{G(N)} \right).$$

Thus the approximation factor achieved by s' is given by

$$\begin{aligned} \mathcal{E}(\phi, s') &\geq \left(\frac{Nm \left(\alpha + \frac{c(n)}{G(N)} - \frac{\alpha}{G(N)} \right)}{Nm \left(1 + \frac{c(n)}{G(N)} - \frac{1}{G(N)} \right)} \right) - 1 \\ &= (\alpha - 1) \left(\frac{G(N) - 1}{G(N) + c(n) - 1} \right) \\ &= \frac{\alpha - 1}{\beta}. \end{aligned}$$

So in this case s_1 (and hence s) is a solution to $\mathcal{I}$ with an error of at most $\beta\epsilon$, if s' is a solution to ϕ with an error of ϵ.

Case 2 [$j \geq m$]: Let $j = \gamma m$. Note that $\gamma > 1$ and that the error of s as a solution to $\mathcal{I}$ is $(\alpha - \gamma)/\gamma$. We bound the value of the solution s' to ϕ as

$$V(\phi, s') \leq Nm \left(\gamma + \frac{c(n)}{G(N)} - \frac{\gamma}{G(N)} \right),$$

and its error as

$$\mathcal{E}(\phi, s') = \left(\frac{\alpha + \frac{c(n)}{G(N)} - \frac{\alpha}{G(N)}}{\gamma + \frac{c(n)}{G(N)} - \frac{\gamma}{G(N)}} \right) - 1$$

$$= \left(\frac{\alpha-\gamma}{\gamma}\right)\left(\frac{1}{1+\frac{c(n)}{\gamma(G(N)-1)}}\right)$$
$$\geq \left(\frac{\alpha-\gamma}{\gamma}\right)\frac{1}{\beta}.$$

The final inequality follows from the fact that

$$1+\frac{c(n)}{\gamma(G(N)-1)} \leq 1+\frac{c(n)}{(G(N)-1)} = \beta.$$

Thus, in this case also, we find that s (by virtue of s_2) is a solution to $\mathcal{I}$ of error at most $\beta\epsilon$ if s' is a solution to ϕ of error ϵ.

We now consider the more general cases where Π and Ω are not both maximization problems. For the case where both are minimization problems, the above transformation works with one minor change. When creating ϕ_i, the NP language consists of instances $(\mathcal{I}, i)$ such that there exists s with $V(\mathcal{I}, s) \leq i$.

For the case where Π is a minimization problem and Ω is a maximization problem, we first E-reduce Π to a maximization problem Π' and then proceed as before. The reduction proceeds as follows. Since Π is a polynomially bounded optimization problem, we can compute an upper bound on the value of any solution s to an instance $\mathcal{I}$. Let m be such a bound for an instance $\mathcal{I}$. The objective function of Π' on the instance $\mathcal{I}$ is defined as $V'(\mathcal{I}, s) = \lfloor 2m^2/V(\mathcal{I}, s)\rfloor$. To begin with, it is easy to verify that $\Pi \in F$-APX implies $\Pi' \in F$-APX.

Let s be a solution to instance $\mathcal{I}$ of Π of error β. We will show that s as a solution to instance $\mathcal{I}$ of Π' has an error of at least $\beta/2$. Assume, without loss of generality, that $\beta \neq 0$. Then

$$V(\mathcal{I}, s) - OPT(\mathcal{I}) = \beta\, OPT(\mathcal{I}) \geq 1.$$

Multiplying by $2m^2/(OPT(\mathcal{I})V(\mathcal{I}, s))$, we get

$$\frac{2m^2}{OPT(\mathcal{I})} - \frac{2m^2}{V(\mathcal{I}, s)} = \beta\frac{2m^2}{V(\mathcal{I}, s)} \geq 2.$$

This implies that

$$\frac{2m^2}{OPT(\mathcal{I})} - \frac{2m^2}{V(\mathcal{I}, s)} \geq 1 + \frac{1}{2}\times\frac{2m^2}{OPT(\mathcal{I})} - \frac{2m^2}{V(\mathcal{I}, s)}$$
$$= 1 + \frac{\beta}{2}\times\frac{2m^2}{V(\mathcal{I}, s)}.$$

Upon rearranging,

$$V'(\mathcal{I}, s) \leq \frac{1}{(1+\beta/2)}\left(\frac{2m^2}{OPT(\mathcal{I})} - 1\right) \leq \frac{1}{(1+\beta/2)}\left\lfloor\frac{2m^2}{OPT(\mathcal{I})}\right\rfloor.$$

Thus the reduction from Π to Π' is an E-reduction.

Finally, the last remaining case, i.e., Π being a maximization problem and Ω being a minimization problem, is dealt with similarly: we transform Π into a minimization problem Π'. □

Remark 6. This theorem appears to merge two different notions of the relative ease of approximation of optimization problems. One such notion would consider a problem Π_1 easier than Π_2 if there exists an approximation-preserving reduction from Π_1 to Π_2. A different notion would regard Π_1 to be easier than Π_2 if one seems to have a better factor of approximation than the other. The above statement essentially states that these two comparisons are indeed the same. For instance, the MAX CLIQUE problem and the CHROMATIC NUMBER problem, which are both in poly-APX, are interreducible to each other. The above observation motivates the search for other interesting function classes f, for which the class f-APX may contain interesting optimization problems.

4.2. Applications. The following is a consequence of Theorem 5.

THEOREM 6.

1. $\overline{\text{RMAX}(2)} = \text{poly-APX}$.
2. *If* SET COVER *is canonically hard to approximate to within a factor of* $\Omega(\log n)$*, then* $\text{log-APX} = \overline{\text{MIN F}^+\Pi_2(1)}$.

We briefly sketch the proof of this theorem. The hardness reduction for MAX SAT and CLIQUE are canonical [2, 11]. The classes APX-PB, poly-APX, log-APX are expressible as classes F-APX for downward closed function families. The problems MAX SAT, MAX CLIQUE, and SET COVER are additive. Thus, we can now apply Theorem 5.

Remark 7. We would like to point out that almost all known instances of hardness results seem to be shown for problems which are additive. In particular, this is true for all MAX SNP problems, MAX CLIQUE, CHROMATIC NUMBER, and SET COVER. Two cases where a hardness result does not seem to directly apply to an additive problem is that of LONGEST PATH [17] and BIN PACKING. In the former case, the closely related LONGEST S-T PATH problem is easily seen to be additive, and the hardness result essentially stems from this problem. As for the case of BIN PACKING, which does not admit a PTAS, the hardness result is not of a multiplicative nature, and in fact this problem can be approximated to within arbitrarily small factors, provided a small additive error term is allowed. This yields a reason why this problem will not be additive. Lastly, the most interesting optimization problems which do not seem to be additive are problems related to GRAPH BISECTION or PARTITION, and these also happen to be notable instances where no hardness of approximation results have been achieved!

5. Local search and MAX SNP. In this section we present a formal definition of the paradigm of nonoblivious local search. The idea of nonoblivious local search has been implicitly present in some well-known techniques such as the interior-point methods. We will formalize this idea in the context of MAX SNP and illustrate its application to MAX SNP problems. Given a MAX SNP problem Π, recall that the goal is to find a structure S which maximizes the objective function: $V(\mathcal{I}, S) = \sum_{\vec{x}} \Phi(\mathcal{I}, S, \vec{x})$. In the subsequent discussion, we view S as a k-dimensional boolean vector.

5.1. Classical local search. We start by reviewing the standard mechanism for constructing a local search algorithm. A δ-local algorithm $\mathcal{A}$ for Π is based on a *distance function* $\mathcal{D}(S_1, S_2)$ which is the Hamming distance between two k-dimensional vectors. The δ-*neighborhood* of a structure S is given by $N(S, \delta) = \{S' \subseteq U^n \mid D(S, S') \leq \delta\}$, where U is the universe. A structure S is called δ-*optimal* if $\forall S' \in N(S, \delta)$, we have $V(\mathcal{I}, S) \geq V(\mathcal{I}, S')$. The algorithm computes a δ-optimum

by performing a series of greedy improvements to an initial structure S_0, where each iteration moves from the current structure S_i to some $S_{i+1} \in N(S_i, \delta)$ of better value (if any). For constant δ, a δ-local search algorithm for a polynomially bounded NPO problem runs in polynomial time because:

- each local change is polynomially computable, and
- the number of iterations is polynomially bounded since the value of the objective function improves monotonically by an integral amount with each iteration, and the optimum is polynomially bounded.

5.2. Nonoblivious local search. A nonoblivious local search algorithm is based on a 3-tuple $\langle S_0, \mathcal{F}, \mathcal{D} \rangle$, where S_0 is the initial solution structure which must be independent of the input, $\mathcal{F}(\mathcal{I}, S)$ is a real-valued function referred to as the *weight function*, and $\mathcal{D}$ is a real-valued *distance function* which returns the distance between two structures in some appropriately chosen metric. The weight function $\mathcal{F}$ should be such that the number of distinct values taken by $\mathcal{F}(\mathcal{I}, S)$ is polynomially bounded in the input size. Moreover, the distance function $\mathcal{D}$ should be such that given a structure S and a fixed δ, $N(S, \delta)$ can be computed in time polynomial in $|S|$. Then, as in classical local search, for constant δ, a nonoblivious δ-local algorithm terminates in time polynomial in the input size.

The classical local search paradigm, which we call *oblivious local search*, makes the natural choice for the function $\mathcal{F}(\mathcal{I}, S)$ and the distance function $\mathcal{D}$, i.e., it chooses them to be $V(\mathcal{I}, S)$ and the Hamming distance. However, as we show later, this choice does not always yield a good approximation ratio. We now formalize our notion of this more general type of local search.

DEFINITION 15 (nonoblivious local search algorithm). *A* nonoblivious local search *algorithm is a δ-local search algorithm whose weight function is defined to be*

$$\mathcal{F}(\mathcal{I}, S) = \sum_{\vec{x}} \sum_{i=1}^{r} p_i \Phi_i(\mathcal{I}, S, \vec{x}) \ ,$$

where r is a constant, Φ_i's are quantifier-free first-order formulas, and the profits p_i are real constants. The distance function $\mathcal{D}$ is an arbitrary polynomial-time computable function.

A nonoblivious local search can be implemented in polynomial time in much the same way as the oblivious local search. Note that the we are only considering polynomially bounded weight functions and the profits p_i are fixed independent of the input size. In general, the nonoblivious weight functions do not direct the search in the direction of the actual objective function. In fact, as we will see, this is exactly the reason why they are more powerful and allow for better approximations.

We now define two classes of NPO problems.

DEFINITION 16 (oblivious GLO). *The class of problems* OBLIVIOUS GLO *consists of all* NPO *problems which can be approximated within constant factors by an oblivious δ-local search algorithm for some constant δ.*

DEFINITION 17 (nonoblivious GLO). *The class of problems* NONOBLIVIOUS GLO *consists of all* NPO *problems which can be approximated within constant factors by a nonoblivious δ-local search algorithm for some constant δ.*

Remark 8. It would be perfectly reasonable to allow weight functions that are nonlinear, but we stay with the above definition for the purposes of this paper. Allowing only a constant number of predicates in the weight functions enables us to prevent

the encoding of arbitrarily complicated approximation algorithms. The structure S is a k-dimensional vector, and so a natural metric for the distance function $\mathcal{D}$ is the Hamming distance. In fact, classical local search is indeed based on the Hamming metric and this is useful in proving negative results for the paradigm. In contrast, the definition of nonoblivious local search allows for other distance functions, but we will use only the Hamming metric in proving positive results in the remainder of this paper. However, we have found that it is sometimes useful to modify this, for example, by modifying the Hamming distance so that the complement of a vector is considered to be at distance 1 from it. Finally, it is sometimes convenient to assume that the local search makes the best possible move in the bounded neighborhood, rather than an arbitrary move which improves the weight function. We believe that this does not increase the power of nonoblivious local search.

6. The power of nonoblivious local search. We will show that there exists a choice of a nonoblivious weight function for MAX k-SAT such that any assignment which is 1-optimal with respect to this weight function yields a performance ratio of $2^k/(2^k-1)$ with respect to the optimal. But first, we obtain tight bounds on the performance of oblivious local search for MAX 2-SAT, establishing that its performance is significantly weaker than the best-known result even when allowed to search exponentially large neighborhoods. We use the following notation: for any fixed truth assignment $\vec{Z}$, S_i is the set of clauses in which exactly i literals are true; and, for a set of clauses S, $W(S)$ denotes the total weight of the clauses in S.

6.1. Oblivious local search for MAX 2-SAT**.** We show a strong separation in the performance of oblivious and nonoblivious local search for MAX 2-SAT. Suppose we use a δ-local strategy with the weight function $\mathcal{F}$ being the total weight of the clauses satisfied by the assignment, i.e., $\mathcal{F} = W(S_1) + W(S_2)$. The following theorem shows that for any $\delta = o(n)$, an oblivious δ-local strategy cannot deliver a performance ratio better than $3/2$. This is rather surprising given that we are willing to allow near-exponential time for the oblivious algorithm.

THEOREM 7. *The asymptotic performance ratio for an oblivious δ-local search algorithm for* MAX 2-SAT *is* $3/2$ *for any positive $\delta = o(n)$. This ratio is still bounded by* $5/4$ *when δ may take any value less than $n/2$.*

Proof. We first show the existence of an input instance for MAX 2-SAT which may elicit a relatively poor performance ratio for any δ-local algorithm provided $\delta = o(n)$. In our construction of such an input instance, we assume that $n \geq 2\delta + 1$. The input instance comprises a disjoint union of four sets of clauses, say $\Gamma_1, \Gamma_2, \Gamma_3$, and Γ_4, defined as below:

$$\Gamma_1 = \bigcup_{1 \leq i < j \leq n} (z_i + \overline{z}_j),$$

$$\Gamma_2 = \bigcup_{1 \leq i < j \leq n} (\overline{z}_i + z_j),$$

$$\Gamma_3 = \bigcup_{0 \leq i \leq \delta} \zeta_{2i+1},$$

$$\Gamma_4 = \bigcup_{2\delta+2 \leq i \leq n} \zeta_i,$$

$$\zeta_i = \bigcup_{i < j \leq n} (\overline{z}_i + \overline{z}_j).$$

Clearly, $|\Gamma_1| = |\Gamma_2| = \binom{n}{2}$ and $|\Gamma_3| + |\Gamma_4| = \binom{n}{2} - n\delta + \delta(\delta+1)$. Without loss of generality, assume that the current input assignment is $\vec{Z} = (1, 1, \ldots, 1)$. This satisfies all clauses in Γ_1 and Γ_2. But none of the clauses in Γ_3 and Γ_4, are satisfied. If we flip the assignment of values to any $k \leq \delta$ variables, it would unsatisfy precisely $k(n-k)$ clauses in $\Gamma_1 + \Gamma_2$. This is the number of clauses in $\Gamma_1 + \Gamma_2$ where a flipped variable occurs with an unflipped variable.

On the other hand, flipping the assigned values of any $k \leq \delta$ variables can satisfy at most $k(n-k)$ clauses in $\Gamma_3 + \Gamma_4$, as we next show.

Let $\Pi(n, \delta)$ denote the set of clauses on n variables given by $\bigcup_{0 \leq i \leq \delta} \zeta_{2i+1} + \bigcup_{2\delta+2 \leq i \leq n} \zeta_i$, where $2\delta + 1 \leq n$. We claim the following.

LEMMA 1. *Any assignment of values to the n variables such that at most $k \leq \delta$ variables have been assigned value false, can satisfy at most $k(n-k)$ clauses in $\Pi(n, \delta)$.*

Proof. We prove by simultaneous induction on n and δ that the statement is true for any instance $\Pi(n, \delta)$ where n and δ are nonnegative integers such that $2\delta + 1 \leq n$. The base case includes $n = 1$ and $n = 2$ and is trivially verified to be true for the only allowable value of δ, namely $\delta = 0$. We now assume that the statement is true for any instance $\Pi(n', \delta')$ such that $n' < n$ and $2\delta' + 1 \leq n'$. Consider now the instance $\Pi(n, \delta)$. The statement is trivially true for $\delta = 0$. Now consider any $\delta > 0$ such that $2\delta + 1 \leq n$. Let $\{z_{j_1}, z_{j_2}, \ldots z_{j_k}\}$ be any choice of $k \leq \delta$ variables such that $j_p < j_q$ for $p < q$. Again the assertion is trivially true if $k = 0$ or $k = 1$. We assume that $k \geq 2$ from now on. If we delete all clauses containing the variables z_1 and z_2 from $\Pi(n, \delta)$, we get the instance $\Pi(n-2, \delta-1)$. We now consider three cases.

Case 1 [$j_1 \geq 3$]: In this case, we are reduced to the problem of finding an upper bound on the maximum number of clauses satisfied by setting any k variables to false in $\Pi(n-2, \delta-1)$. If $k \leq \delta - 1$, we may use the inductive hypothesis to conclude that no more than $(n-2-k)(k)$ clauses will be satisfied. Thus the assertion holds in this case. However, we may not directly use the inductive hypothesis if $k = \delta$. But in this case we observe that since by the inductive hypothesis, setting any $k-1$ variables in $\Pi(n-2, \delta-1)$ to false satisfies at most $(n-2-(k-1))(k-1)$ clauses, assigning the value false to any set of k variables can satisfy at most

$$(n-2-(k-1))(k-1) + \frac{1}{k-1}(n-2-(k-1))(k-1) = (n-k)k - k^2$$

clauses. Hence the assertion holds in this case also.

Case 2 [$j_1 = 2$]: In this case, z_{j_1} satisfies one clause and the remaining $k-1$ variables satisfy at most $(n-2-(k-1))(k-1)$ clauses by the inductive hypothesis on $\Pi(n-2, \delta-1)$. Adding up the two terms, we see that the assertion holds.

Case 3 [$j_1 = 1$]: We analyze this case based on whether $j_2 = 2$ or $j_2 \geq 3$. If $j_2 = 2$, then z_1 and z_2 together satisfy precisely $n-1$ clauses, and the remaining $k-2$ variables satisfy at most $(n-2-(k-2))(k-2)$ clauses using the inductive hypothesis. Thus the assertion still holds. Otherwise, z_1 satisfies precisely $n-1$ clauses and the remaining $k-1$ variables satisfy no more than $(n-1-(k-1))(k-1)$ clauses using the inductive hypothesis. Summing up the two terms, we get $(n-k)k$ as the upper bound on the total number of clauses satisfied. Thus the assertion holds in this case also.

To see that this bound is tight, simply consider the situation when the k variables set to false are $z_1, z_3, \ldots, z_{2k-1}$, for any $k \leq \delta$. The total number of clauses satisfied is given by $\sum_{i=1}^{k} |\zeta_{2i-1}| = (n-k)k$. ∎

Assuming that each clause has the same weight, Lemma 1 allows us to conclude that a δ-local algorithm cannot increase the total weight of satisfied clauses with this starting assignment. An optimal assignment, on the other hand, can satisfy all the clauses by choosing the vector $\vec{Z} = (0, 0, \ldots, 0)$. Thus the performance ratio of a δ-local algorithm, say R_δ, is bounded as

$$R_\delta = \frac{|\Gamma_1| + |\Gamma_2| + |\Gamma_3| + |\Gamma_4|}{|\Gamma_1| + |\Gamma_2|} \leq \frac{3\binom{n}{2} + \delta(\delta+1) - \delta n}{2\binom{n}{2}}.$$

For any $\delta = o(n)$, this ratio asymptotically converges to 3/2. We next show that this bound is tight since a 1-local algorithm achieves it. However, before we do so, we make another intriguing observation, namely, that for any $\delta < n/2$, the ratio R_δ is bounded by 5/4.

Now, to see that a 1-local algorithm ensures a performance ratio of 3/2, consider any 1-optimal assignment $\vec{Z}$ and let α_i denote the set of clauses containing the variable z_i such that no literal in any clause of α_i is satisfied by $\vec{Z}$. Similarly, let β_i denote the set of clauses containing the variable z_i such that precisely one literal is satisfied in any clause in β_i, and furthermore, it is precisely the literal containing the variable z_i. If we complement the value assigned to the variable z_i, it is exactly the set of clauses in α_i which becomes satisfied and the set of clauses in β_i which is no longer satisfied. Since $\vec{Z}$ is 1-optimal, it must be the case that $W(\alpha_i) \leq W(\beta_i)$. If we sum up this inequality over all the variables, then we get the inequality $\sum_{i=1}^{n} W(\alpha_i) \leq \sum_{i=1}^{n} W(\beta_i)$. We observe that $\sum_{i=1}^{n} W(\alpha_i) = 2W(S_0)$ and $\sum_{i=1}^{n} W(\beta_i) = W(S_1)$ because each clause in S_0 gets counted twice while each clause in S_1 gets counted exactly once. Thus the fractional weight of the number of clauses not satisfied by a 1-local assignment is bounded as

$$\frac{W(S_0)}{W(S_0) + W(S_1) + W(S_2)} \leq \frac{W(S_0)}{3W(S_0) + W(S_2)} \leq \frac{W(S_0)}{3W(S_0)} = \frac{1}{3}.$$

Hence the performance ratio achieved by a 1-local algorithm is bounded from above by 3/2. Combining this with the upper bound derived earlier, we conclude that $R_1 = 3/2$. This concludes the proof of the theorem. □

6.2. Nonoblivious local search for MAX 2-SAT**.** We now illustrate the power of nonoblivious local search by showing that it achieves a performance ratio of 4/3 for MAX 2-SAT, using 1-local search with a simple nonoblivious weight function.

THEOREM 8. *Nonoblivious* 1*-local search achieves a performance ratio of* 4/3 *for* MAX 2-SAT.

Proof. We use the nonoblivious weight function

$$\mathcal{F}(\mathcal{I}, \vec{Z}) = \frac{3}{2}W(S_1) + 2W(S_2).$$

Consider any assignment $\vec{Z}$ which is 1-optimal with respect to this weight function. Without loss of generality, we assume that the variables have been renamed such that each unnegated literal gets assigned the value true. Let $P_{i,j}$ and $N_{i,j}$, respectively, denote the total weight of clauses in S_i containing the literals z_j and $\overline{z}_j$, respectively. Since $\vec{Z}$ is a 1-optimal assignment, each variable z_j must satisfy the following equation.

$$-\frac{1}{2}P_{2,j} - \frac{3}{2}P_{1,j} + \frac{1}{2}N_{1,j} + \frac{3}{2}N_{0,j} \leq 0.$$

Summing this inequality over all the variables and using

$$\sum_{j=1}^{n} P_{1,j} = \sum_{j=1}^{n} N_{1,j} = W(S_1),$$
$$\sum_{j=1}^{n} P_{2,j} = 2W(S_2),$$
$$\sum_{j=1}^{n} N_{0,j} = 2W(S_0),$$

we obtain the following inequality:

$$W(S_2) + W(S_1) \geq 3W(S_0).$$

This immediately implies that the total weight of the unsatisfied clauses at this local optimum is no more than 1/4 times the total weight of all the clauses. Thus, this algorithm ensures a performance ratio of 4/3. □

Remark 9. The same result can be achieved by using the oblivious weight function and instead modifying the distance function so that it corresponds to distances in a hypercube augmented by edges between nodes whose addresses complement each other.

6.3. Generalization to MAX *k*-SAT. We can also design a nonoblivious weight function for MAX k-SAT such that a 1-local strategy ensures a performance ratio of $2^k/(2^k - 1)$. The weight function $\mathcal{F}$ will be of the form $\mathcal{F} = \sum_{i=0}^{k} c_i W(S_i)$ where the coefficients c_i's will be specified later.

THEOREM 9. *Nonoblivious* 1*-local search achieves a performance ratio of* $2^k/(2^k - 1)$ *for* MAX k-SAT.

Proof. Again, without loss of generality, we will assume that the variables have been renamed so that each unnegated literal is assigned true under the current truth assignment. Thus the set S_i is the set of clauses with i unnegated literals.

Let $\Delta_i = c_i - c_{i-1}$ and let $\frac{\partial \mathcal{F}}{\partial z_j}$ denote the change in the current weight when we flip the value of z_j, that is, set it to 0. It is easy to verify the following equation:

$$\frac{\partial \mathcal{F}}{\partial z_j} = -\Delta_k P_{k,j} + \sum_{i=k}^{2} (\Delta_i N_{i-1,j} - \Delta_{i-1} P_{i-1,j}) + \Delta_1 N_{0,j}. \tag{6.1}$$

Thus when the algorithm terminates, we know that $\frac{\partial \mathcal{F}}{\partial z_j} \leq 0$, for $1 \leq j \leq n$. Summing over all values of j, and using the fact $\sum_{j=1}^{n} P_{i,j} = iW(S_i)$ and $\sum_{j=1}^{n} N_{i,j} = (k - i)W(S_i)$ we get the following inequality.

$$k\Delta_k W(S_k) + \sum_{i=k-1}^{2} (i\Delta_i - (k - i)\Delta_{i+1}) W(S_i) \geq k\Delta_1 W(S_0). \tag{6.2}$$

We now determine the values of Δ_i's such that the coefficient of each term on the left-hand side is unity. It can be verified that

$$\Delta_i = \frac{1}{(k - i + 1)\binom{k}{i-1}} \sum_{j=0}^{k-i} \binom{k}{j}$$

achieves this goal. Thus the coefficient of $W(S_0)$ on the right-hand side of equation (6.2) is $2^k - 1$. Clearly, the weight of the clauses not satisfied is bounded by $1/2^k$ times the total weight of all the clauses. It is worthwhile to note that this is regardless of the value chosen for the coefficient c_0. □

7. Local search for CSP and MAX SNP. We now introduce a class of constraint satisfaction problems such that the problems in MAX SNP are exactly equivalent to the problems in this class. Furthermore, every problem in this class can be approximated to within a constant factor by a nonoblivious local search algorithm.

7.1. Constraint satisfaction problems. The connection between the syntactic description of optimization problems and their approximability through nonoblivious local search is made via a problem called MAX k-CSP which captures all the problems in MAX SNP as a special case.

DEFINITION 18 (k-ary constraint). *Let $Z = \{z_1, \ldots, z_n\}$ be a set of boolean variables. A k-ary constraint on Z is $C = (V; P)$, where V is a size k subset of Z, and $P : \{T, F\}^k \to \{T, F\}$ is a k-ary boolean predicate.*

DEFINITION 19 (MAX k-CSP). *Given a collection C_1, ..., C_m of weighted k-ary constraints over the variables $Z = \{z_1, \ldots, z_n\}$, the* MAX k-CSP *problem is to find a truth assignment satisfying a maximum weight subcollection of the constraints.*

The following theorem shows that the MAX k-CSP problem is a "universal" MAX SNP problem, in that it contains as special cases all problems in MAX SNP.

THEOREM 10.

1. *For fixed k,* MAX k-CSP $\in$ MAX SNP.
2. *Let* $\Pi \in$ MAX SNP. *Then, for some constant k,* Π *is a* MAX k-CSP *problem. Moreover, the* k-CSP *instance corresponding to any instance of this problem can be computed in polynomial time.*

Proof. The proof of part 2 is implicit in Theorem 1 in [23], and so we concentrate on proving part 1. Our goal is to obtain a representation of the k-CSP problem in the MAX SNP syntax:

$$\max_S |\{x \mid \Phi(\mathcal{I}, S, x)\}|.$$

The input structure is $\mathcal{I} = (Z \cup \{T, F\} \cup \text{MAX}; \{\text{ARG}, \text{EVAL}\})$, where $Z = \{z_1, \ldots, z_n\}$, MAX contains the integers $[1, \max\{k, n, m\}]$, the predicate ARG encodes the sets V_i, and the predicate EVAL encodes the predicates P_i, as described below.

- ARG(r, s, z_t) is a 3-ary predicate which is true if and only if the rth argument of C_s is the variable z_t, for $1 \le r \le k$, $1 \le s \le m$, and $1 \le t \le n$.
- EVAL$(s, v_1, \ldots, v_k)$ is a $(k+1)$-ary predicate which is true if and only if $P_s(v_1, \ldots, v_k)$ evaluates to true, for $1 \le s \le m$ and all $v_i \in \{T, F\}$.

The structure S is defined as $(Z; \{\text{TRUE}\})$, where TRUE is a unary predicate which denotes an assignment of truth values to the variables in Z. The vector x has $k+1$ components which will be called x_1, ..., x_k and s, for convenience. The intention is that the x_i's refer to the arguments of the sth constraint.

All that remains is to specify the quantifier-free formula Φ. The basic idea is that $\Phi(\mathcal{I}, S, x)$ should evaluate to true if and only if the following two conditions are satisfied:

- the arguments of the constraint C_s are given by the variables x_1, ..., x_k, in that order, and
- the values given to these variables under the truth assignment specified by S are such that the constraint is satisfied.

The formula Φ is given by the following expression, with the two subformulas ensuring these two conditions.

$$\left(\bigwedge_{r=1}^{k} \text{ARG}(r, s, x_r)\right) \wedge \left(\bigvee_{v_1,\ldots,v_k \in \{T,F\}} \left(\text{EVAL}(s, v_1, \ldots, v_k) \wedge \left(\bigwedge_{r=1}^{k} v_r \Leftrightarrow \text{TRUE}(x_r)\right)\right)\right).$$

It is easy to see that the first subformula has the desired effect of checking that the x_r's correspond to the arguments of C_s. The second subformula considers all possible truth assignments to these k variables and checks that the particular set of values assigned by the structure S will make P_s evaluate to true.

For a fixed structure S, there is exactly one choice of x per constraint that could make Φ evaluate to true, and this happens if and only if that constraint is satisfied. Thus, the value of the solution given by any particular truth assignment structure S is exactly the number of constraints that are satisfied. This shows that the MAX SNP problem always has the same value as intended in the k-CSP problem.

Finally, there are still a few things which need to be checked to ensure that this is a valid MAX SNP formulation. Notice that all the predicates are of bounded arity and the structures consist of a bounded number of such predicates, i.e., independent of the input size which is given by MAX. Further, although the length of the formula is exponential in k, it is independent of the input. □

7.2. Nonoblivious local search for MAX k-CSP. A suitable generalization of the nonoblivious local search algorithm for MAX k-SAT yields the following result.

THEOREM 11. *A nonoblivious* 1*-local search algorithm has performance ratio* 2^k *for* MAX k-CSP.

Proof. We use an approach similar to the one used in the previous section to design a nonoblivious weight function $\mathcal{F}$ for the weighted version of the MAX k-CSP problem such that a 1-local algorithm yields a 2^k performance ratio to this problem.

We consider only the constraints with at least one satisfying assignment. Each such constraint can be replaced by a monomial which is the conjunction of some k literals such that when the monomial evaluates to true the corresponding literal assignment represents a satisfying assignment for the constraint. Furthermore, each such monomial has precisely one satisfying assignment. We assign to each monomial the weight of the constraint it represents. Thus any assignment of variables which satisfies monomials of total weight W_0 also satisfies constraints in the original problem of total weight W_0.

Let S_i denote the monomials with i true literals and assume that the weight function $\mathcal{F}$ is of the form $\sum_{i=1}^{k} c_i W(S_i)$. Thus, assuming that the variables have been renamed so that the current assignment gives value true to each variable, we know that for any variable z_j, $\frac{\partial \mathcal{F}}{\partial z_j}$ is given by equation (6.1). As before, using the fact that for any 1-optimal assignment, $\frac{\partial \mathcal{F}}{\partial z_j} \leq 0$ for $1 \leq j \leq n$, and summing over all values of j, we can write the following inequality.

$$k\Delta_1 W(S_0) + \sum_{i=2}^{k-1}((k-i)\Delta_{i+1} - i\Delta_i)W(S_i) \leq k\Delta_k W(S_k)\ . \tag{7.1}$$

We now determine the values of Δ_i's such that the coefficient of each term on the left-hand side is unity. It can be verified that

$$\Delta_i = \frac{1}{i\binom{k}{i}} \sum_{j=0}^{i-1} \binom{k}{j}$$

achieves this goal. Thus the coefficient of $W(S_k)$ on the right-hand side of equation (6.1) is $2^k - 1$. Clearly, the total weight of clauses satisfied is at least $1/2^k$ times the total weight of all the clauses with at least one satisfiable assignment. □

We conclude as in the following theorem.

THEOREM 12. *Every optimization problem* $\Pi \in$ MAX SNP *can be approximated to within some constant factor by a (uniform) nonoblivious* 1*-local search algorithm, i.e.,*

$$\text{MAX SNP} \subseteq \text{NONOBLIVIOUS GLO}.$$

For a problem expressible as k-CSP*, the performance ratio is at most* 2^k*.*

8. Nonoblivious versus oblivious GLO. In this section, we show that there exist problems for which no constant-factor approximation can be obtained by any δ-local search algorithm with oblivious weight function, even when we allow δ to grow with the input size. However, a simple 1-local search algorithm using an appropriate nonoblivious weight function can ensure a constant performance ratio.

8.1. MAX 2-CSP. The first problem is an instance of MAX 2-CSP where we are given a collection of monomials such that each monomial is an "and" of precisely two literals. The objective is to find an assignment to maximize the number of monomials satisfied.

We show an instance of this problem such that for every $\delta = o(n)$, there exists an instance one of whose local optima has value that is a vanishingly small fraction of the global optimum.

The input instance consists of a disjoint union of two sets of monomials, say Γ_1 and Γ_2, defined as below:

$$\Gamma_1 = \bigcup_{1 \le i < j \le n} (\overline{z}_i \wedge \overline{z}_j),$$

$$\Gamma_2 = \bigcup_{1 \le i \le \delta} \bigcup_{i < j \le n} (z_i \wedge z_j).$$

Clearly, $|\Gamma_1| = \binom{n}{2}$ and $|\Gamma_2| = n\delta - \binom{\delta+1}{2}$. Consider the truth assignment $\vec{Z} = (1, 1, \ldots, 1)$. It satisfies all monomials in Γ_2 but none of the monomials in Γ_1. We claim that this assignment is δ-optimal with respect to the oblivious weight function. To see this, observe that complementing the value of any $p \le \delta$ variables will unsatisfy at least $\delta p/2$ monomials in Γ_2 for any $\delta = o(n)$. On the other hand, this will satisfy precisely $\binom{p}{2}$ monomials in Γ_1. For any $p \le \delta$, we have $(\delta p)/2 \ge \binom{p}{2}$, and so Z is a δ-local optimum.

The optimal assignment, on the other hand, namely $\vec{Z}_{OPT} = (0, 0, \ldots, 0)$, satisfies all monomials in Γ_1. Thus, for $\delta < n/2$, the performance ratio achieved by any δ-local algorithm is no more than $\binom{n}{2}/(n\delta - \binom{\delta+1}{2})$ which asymptotically diverges to infinity for any $\delta = o(n)$. We have already seen in section 7 that a 1-local nonoblivious algorithm ensures a performance ratio of 4 for this problem. Since this problem is in MAX SNP, we obtain the following theorem.

THEOREM 13. *There exist problems in* MAX SNP *such that for* $\delta = o(n)$*, no* δ*-local oblivious algorithm can approximate them to within a constant performance ratio, i.e.,*

$$\text{MAX SNP} \not\subseteq \text{OBLIVIOUS GLO}.$$

8.2. Vertex cover. Ausiello and Protasi [4] have shown that VERTEX COVER does not belong to the class GLO and, hence, there does not exist any constant δ such that an oblivious δ-local search algorithm can compute a constant factor approximation. In fact, their example can be used to show that for any $\delta = o(n)$, the performance ratio ensured by δ-local search asymptotically diverges to infinity. However, we show that there exists a rather simple nonoblivious weight function which ensures a factor 2 approximation via a 1-local search. In fact, the algorithm simply enforces the behavior of the standard approximation algorithm which iteratively builds a vertex cover by simply including both endpoints of any currently uncovered edge.

We assume that the input graph G is given as a structure $(V, \{E\})$ where V is the set of vertices and $E \subseteq V \times V$ encodes the edges of the graph. Our solution is represented by a 2-ary predicate M which is iteratively constructed so as to represent a maximal matching. Clearly, the endpoints of any maximal matching constitute a valid vertex cover and such a vertex cover can be at most twice as large as any other vertex cover in the graph. Thus M is an encoding of the vertex cover computed by the algorithm.

The algorithm starts with M initialized to the empty relation, and at each iteration, at most one new pair is included in it. The nonoblivious weight function used is as below:

$$\mathcal{F}(\mathcal{I}, M) = \sum_{\langle x,y,z\rangle \in V^3} [\Phi_1(x,y,z) - 2\Phi_2(x,y,z) - \Phi_3(x,y,z)],$$

where

$$\begin{aligned}
\Phi_1(x,y,z) &= (M(x,y) \wedge E(x,y) \wedge (x = z)),\\
\Phi_2(x,y,z) &= (M(x,y) \wedge M(x,z)),\\
\Phi_3(x,y,z) &= (M(x,y) \wedge \overline{E(x,y)}).
\end{aligned}$$

Let M encode a valid matching in the graph G. We make the following observations.

- Any relation M' obtained from M by deleting an edge from it, or including an edge which is incident on an edge of M, or including a nonexistent edge, has the property that $\mathcal{F}(\mathcal{I}, M') \leq \mathcal{F}(\mathcal{I}, M)$. Thus in a 1-local search from M, we will never move to a relation M' which does not encode a valid matching of G.
- On the other hand, if a relation M' corresponds to the encoding of a matching in G which is larger than the matching encoded by M, then $\mathcal{F}(\mathcal{I}, M') > \mathcal{F}(\mathcal{I}, M)$. Thus if M does not encode a maximal matching in G, there always exist a relation in its 1-neighborhood of larger weight than itself.

These two observations, combined with the fact that we start with a valid initial matching (the empty matching), immediately allow us to conclude that any 1-optimal relation M always encodes a maximal matching in G. We have established the following.

THEOREM 14. *A* 1*-local search algorithm using the above nonoblivious weight function achieves a performance ratio of* 2 *for the* VERTEX COVER *problem.*

THEOREM 15. GLO *is a* strict *subset of* NONOBLIVIOUS GLO.

As an aside, it can be seen that this algorithm has the same performance starting with an arbitrary initial solution. This is because for any relation M not encoding a matching of the input graph, deleting one of the violating members strictly increases $\mathcal{F}(\mathcal{I}, M)$.

9. The traveling salesman problem. The TSP(1,2) problem is the traveling salesman problem restricted to complete graphs where all edge weights are either 1 or 2; clearly, this satisfies the triangle inequality. Papadimitriou and Yannakakis [24] showed that this problem is hard for MAX SNP. The natural weight function for TSP(1,2), that is, the weight of the tour, can be used to show that a 4-local algorithm yields a 3/2 performance ratio. The algorithm starts with an arbitrary tour, and in each iteration, it checks if there exist two disjoint edges (a, b) and (c, d) on the tour such that deleting them and replacing them with the edges (a, c) and (b, d) yields a tour of lesser cost.

THEOREM 16. *A 4-local search algorithm using the oblivious weight function achieves a* 3/2 *performance ratio for* TSP(1,2).

Proof. Let C be a 4-optimal solution and let π be a permutation such that the vertices in C occur in the order $v_{\pi_1}, v_{\pi_2}, \ldots, v_{\pi_n}$. Consider any optimal solution O. With each unit cost edge e in O, we associate a unit cost edge e' in C as follows. Let $e = (v_{\pi_i}, v_{\pi_j})$ where $i < j$. If $j = i + 1$ then $e' = e$. Otherwise, consider the edges $e_1 = (v_{\pi_i}, v_{\pi_{i+1}})$ and $e_2 = (v_{\pi_j}, v_{\pi_{j+1}})$ on C. We claim that either e_1 or e_2 must be of unit cost. Suppose not; then the tour C' which is obtained by simply deleting both e_1 and e_2 and inserting the edges e and $f = (v_{\pi_{i+1}}, v_{\pi_{j+1}})$ has cost at least one less than C. But C is 4-optimal and thus this is a contradiction.

Let U_O denote the set of unit cost edges in O and let U_C be the set of unit cost edges in C which form the image of U_O under the above mapping. Since an edge $e' = (v_{\pi_i}, v_{\pi_{i+1}})$ in U_C can only be the image of unit cost edges incident on v_{π_i} in O and since O is a tour, there are at most two edges in U_O which map to e'. Thus $|U_C| \geq |U_O|/2$ and hence

$$\frac{cost(O)}{cost(C)} \geq \frac{|U_O| + 2(n - |U_O|)}{|U_O|/2 + 2(n - |U_O|/2)} \geq \frac{2}{3}. \qquad \square$$

In fact, the above bound can be shown to be tight.

10. Maximum independent sets in bounded-degree graphs. The input instance to the maximum independent set problem in bounded-degree graphs, denoted MIS-B, is a graph G such that the degree of any vertex in G is bounded by a constant Δ. We present an algorithm with performance ratio $(\sqrt{8\Delta^2 + 4\Delta + 1} - 2\Delta + 1)/2$ for this problem when $\Delta \geq 10$.

Our algorithm uses two local search algorithms such that the larger of the two independent sets computed by these algorithms gives us the above-claimed performance ratio. We refer to these two algorithms as $\mathcal{A}_1$ and $\mathcal{A}_2$.

In our framework, the algorithm $\mathcal{A}_1$ can be characterized as a 3-local algorithm with the weight function simply being $|I| - 3|(I \times I) \cap E|$. Thus if we start with I initialized to empty set, it is easy to see that at each iteration, I will correspond to an independent set in G. A convenient way of looking at this algorithm is as follows. We define an $i \leftrightarrow j$ swap to be the process of deleting i vertices from S and including j vertices from the set $V - S$ to the set S. In each iteration, the algorithm $\mathcal{A}_1$ performs either a $0 \leftrightarrow j$ swap where $1 \leq j \leq 3$, or a $1 \leftrightarrow 2$ swap. A $0 \leftrightarrow j$ swap, however, can be interpreted as j applications of $0 \leftrightarrow 1$ swaps. Thus the algorithm may be viewed as executing a $0 \leftrightarrow 1$ swap or a $1 \leftrightarrow 2$ swap at each iteration. The algorithm terminates when neither of these two operations is applicable.

Let I denote the 3-optimal independent set produced by the algorithm $\mathcal{A}_1$. Furthermore, let O be any optimal independent set and let $X = I \cap O$. We make the following useful observations.

- Since for no vertex in I, a $0 \leftrightarrow 1$ swap can be performed, it implies that each vertex in $V - I$ must have at least one incoming edge to I.
- Similarly, since no $1 \leftrightarrow 2$ swaps can be performed, it implies that at most $|I - X|$ vertices in $O - I$ can have precisely one edge coming into I. Thus $|O - X| - |I - X| = |O| - |I|$ vertices in $O - X$ must have at least two edges entering the set I.

A rather straightforward consequence of these two observations is the following lemma.

LEMMA 2. *The algorithm $\mathcal{A}_1$ has performance ratio $(\Delta + 1)/2$ for* MIS-B.

Proof. The above two observations imply that the minimum number of edges entering I from the vertices in $O - X$ is $|I - X| + 2(|O| - |I|)$. On the other hand, the maximum number of edges coming out of the vertices in I to the vertices in $O - X$ is bounded by $|I - X|\Delta$. Thus we must have

$$|I - X|\Delta \geq |I - X| + 2(|O| - |I|) \ .$$

Rearranging, we get

$$\frac{|I|}{|O|} \geq \frac{2}{\Delta + 1} + \frac{|X|(\Delta - 1)}{|O|(\Delta + 1)},$$

which yields the desired result. □

This nearly matches the approximation ratio of $\Delta/2$ due to Hochbaum [15]. It should be noted that the above result holds for a broader class of graphs, viz., k-claw free graphs. A graph is called *k-claw free* if there does not exist an independent set of size k or larger such that all the vertices in the independent set are adjacent to the same vertex. Lemma 2 applies to $(\Delta + 1)$-claw free graphs.

Our next objective is to further improve this ratio by using the algorithm $\mathcal{A}_1$ in combination with the algorithm $\mathcal{A}_2$. The following lemma uses a slightly different counting argument to give an alternative bound on the approximation ratio of the algorithm $\mathcal{A}_1$ when there is a constraint on the size of the optimal solution.

LEMMA 3. *For any real number $c < \Delta$, the algorithm $\mathcal{A}_1$ has performance ratio $(\Delta - c)/2$ for* MIS-B *when the optimal value itself is no more than*

$$\frac{(\Delta - c)|V|}{\Delta + c + 4}.$$

Proof. As noted earlier, each vertex in $V - I$ must have at least one edge coming into the set I, and at least $|O| - |I|$ vertices in O must have at least two edges coming into I. Therefore, the following inequality must be satisfied:

$$|I|\Delta \geq |V| - |I| + |O| - |I| \ .$$

Thus $|I| \geq (|V| + |O|)/(\Delta + 2)$. Finally, observe that

$$\frac{|V| + |O|}{\Delta + 2} \geq \frac{2}{\Delta - c}|O|$$

whenever $|O| \leq (\Delta - c)|V|/(\Delta + c + 4)$. □

The above lemma shows that the algorithm $\mathcal{A}_1$ yields a better approximation ratio when the size of the optimal independent set is relatively small.

The algorithm $\mathcal{A}_2$ is simply the classical greedy algorithm. This algorithm can be conveniently included in our framework if we use directed local search. If we let $N(I)$ denote the set of neighbors of the vertices in I, then the weight function is simply $|I|(\Delta+1)+|V-(I+N(I))|-|(I\times I)\cap E|(\Delta+1)$. It is not difficult to see that starting with an empty independent set, a 1-local algorithm with directed search on the above weight function simply simulates a greedy algorithm. The greedy algorithm exploits the situation when the optimal independent set is relatively large in size. It does so by using the fact that the existence of a large independent set in G ensures a large subset of vertices in G with relatively small average degree. The following two lemmas characterize the performance of the greedy algorithm.

LEMMA 4. *Suppose there exists an independent set $X\subseteq V$ such that the average degree of vertices in X is bounded by α. Then, for any $\alpha\geq 1$, the greedy algorithm produces an independent set of size at least $|X|/(1+\alpha)$.*

Proof. The greedy algorithm iteratively chooses a vertex of smallest degree in the remaining graph and then deletes this vertex and all its neighbors from the graph. We examine the behavior of the greedy algorithm by considering two types of iterations. First consider the iterations in which it picks a vertex outside X. Suppose that in the ith such iteration, it picks a vertex in $V-X$ with exactly k_i neighbors in the set X in the remaining graph. Since each one of these k_i vertices must also have at least k_i edges incident on them, we lose at least k_i^2 edges incident on X. Suppose only p such iterations occur and let $\sum_{i=1}^{p}k_i=x$. We observe that $\sum_{i=1}^{p}k_i^2\leq\alpha|X|$. Second, we consider the iterations when the greedy algorithm selects a vertex in X. Then we do not lose any other vertices in X because X is an independent set. Thus the total size of the independent set constructed by the greedy algorithm is at least $p+q$ where $q=|X|-x$.

By the Cauchy–Schwartz inequality, $\sum_{i=1}^{p}k_i^2\geq x^2/p$. Therefore, we have $(1+\alpha)|X|\geq x^2/p+x$. Rearranging, we obtain that

$$p\geq\frac{x^2}{(1+\alpha)|X|-x}\geq\frac{x^2}{(1+\alpha)|X|}\geq\frac{|X|}{1+\alpha}+\frac{q^2}{(1+\alpha)|X|}-\frac{2q}{1+\alpha}.$$

Thus

$$p+q\geq\frac{|X|}{1+\alpha}+\frac{q^2}{(1+\alpha)|X|}-\frac{2q}{1+\alpha}+q.$$

But $2q/(1+\alpha)\leq q$ for $\alpha\geq 1$, and the result follows. □

LEMMA 5. *For $\Delta\geq 10$ and any nonnegative real number $c\leq 3\Delta-\sqrt{8\Delta^2+4\Delta+1}-1$, the algorithm $\mathcal{A}_2$ has performance ratio $(\Delta-c)/2$ for* MIS-B *when the optimal value itself is at least $((\Delta-c)|V|)/(\Delta+c+4)$.*

Proof. Observe that the average degree of vertices in O is bounded by $(|V-O|\Delta/|O|)$ and thus, using the fact that $|O|\geq(\Delta-c)|V|/(\Delta+c+4)$, we know that the algorithm $\mathcal{A}_2$ computes an independent set of size at least $|O|/(1+\alpha)$ where $\alpha=(4\Delta+2\Delta c)/(\Delta-c)$, and $\alpha\geq 1$ for $c\geq 0$. Hence it is sufficient to determine the range of values c can take such that the following inequality is satisfied:

$$\frac{|O|}{1+\alpha}\geq\left(\frac{2}{\Delta-c}\right)|O|.$$

Substituting the bound on the value of α and rearranging the terms of the equation yields the following quadratic equation:

$$c^2-(6\Delta-2)c+\Delta^2-10\Delta\geq 0\ .$$

Since c must be strictly bounded by Δ, the above quadratic equation is satisfied for any choice of $c \leq 3\Delta - \sqrt{8\Delta^2 + 4\Delta + 1} - 1$ if $\Delta \geq 10$. □

Combining the results of Lemmas 3 and 5 and choosing the largest allowable value for c, we get the following result.

THEOREM 17. *An approximation algorithm which simply outputs the larger of the two independent sets computed by the algorithms $\mathcal{A}_1$ and $\mathcal{A}_2$ has performance ratio $(\sqrt{8\Delta^2 + 4\Delta + 1} - 2\Delta + 1)/2$ for* MIS-B.

The performance ratio claimed above is essentially $\Delta/2.414$. This improves upon the long-standing approximation ratio of $\Delta/2$ due to Hochbaum [15], when $\Delta \geq 10$. However, very recently, there has been a flurry of new results for this problem. Berman and Furer [6] have given an algorithm with performance ratio $(\Delta+3)/5+\epsilon$ when Δ is even, and $(\Delta+3.25)/5+\epsilon$ for odd Δ, where $\epsilon > 0$ is a fixed constant. Halldorsson and Radhakrishnan [14] have shown that algorithm $\mathcal{A}_1$, when run on k-clique free graphs, yields an independent set of size at least $2n/(\Delta + k)$. They combine this algorithm with a clique-removal-based scheme to achieve a performance ratio of $\Delta/6(1 + o(1))$.

In conclusion, note that Khanna, Motwani and Vishwanathan [19] have recently shown that a semidefinite programming technique can be used to obtain a $(\Delta \log\log \Delta)/(\log \Delta)$-approximation algorithm for this problem.

Acknowledgments. Many thanks to Phokion Kolaitis for his helpful comments and suggestions and to Giorgio Ausiello and Pierluigi Crescenzi for guiding us through the intricacies of approximation-preserving reductions and the available literature on them. Thanks also to the anonymous referees for their detailed comments and corrections on a previous draft.

MAXIMUM k-CHAINS IN PLANAR POINT SETS: COMBINATORIAL STRUCTURE AND ALGORITHMS*

STEFAN FELSNER† AND LORENZ WERNISCH†

Abstract. A chain of a set P of n points in the plane is a chain of the dominance order on P. A k-chain is a subset C of P that can be covered by k chains. A k-chain C is a *maximum k-chain* if no other k-chain contains more elements than C. This paper deals with the problem of finding a maximum k-chain of P in the cardinality and in the weighted case.

Using the skeleton $S(P)$ of a point set P introduced by Viennot we describe a fairly simple algorithm that computes maximum k-chains in time $O(kn \log n)$ and linear space. The basic idea is that the canonical chain partition of a maximum $(k-1)$-chain in the skeleton $S(P)$ provides k regions in the plane such that a maximum k-chain for P can be obtained as the union of a maximal chain from each of these regions.

By the symmetry between chains and antichains in the dominance order we may use the algorithm for maximum k-chains to compute maximum k-antichains for planar points in time $O(kn \log n)$. However, for large k one can do better. We describe an algorithm computing maximum k-antichains (and, by symmetry, k-chains) in time $O((n^2/k) \log n)$ and linear space. Consequently, a maximum k-chain can be computed in time $O(n^{3/2} \log n)$ for arbitrary k.

The background for the algorithms is a geometric approach to the Greene–Kleitman theory for permutations. We include a skeleton-based exposition of this theory and give some hints on connections with the theory of Young tableaux.

The concept of the skeleton of a planar point set is extended to the case of a weighted point set. This extension allows to compute maximum weighted k-chains with an algorithm that is similar to the algorithm for the cardinality case. The time and space requirements of the algorithm for weighted k-chains are $O(2^k n \log(2^k n))$ and $O(2^k n)$, respectively.

1. Introduction.

The *dominance order* on points in the plane is given by the relations $p \leq q$ if $p_x \leq q_x$ and $p_y \leq q_y$. Here and throughout the paper p_x and p_y denote the x- and y-coordinates of a point p. The symbol P will always be an n-element set of points in the plane together with the dominance relation. A subset C of P is a *chain* if any two members p, q of C are comparable, i.e., either $p \leq q$ or $q \leq p$. On the other hand, a set $A \subseteq P$ with no two different points comparable is an *antichain*. If a subset C of P can be covered by k chains it is called a *k-chain*. If C is a k-chain but not a $(k-1)$-chain we call C a *strict k-chain*. A k-chain C is *maximum* if no other k-chain contains more elements than C. This paper deals with the problem of finding such k-chains in P. Note that the "greedy method" that repeatedly removes maximum chains may fail in computing a maximum k-chain even for $k = 2$ (see, e.g., the point set of Figure 1).

A permutation $\sigma: \{1, \ldots, n\} \to \{1, \ldots, n\}$ may be represented by points $(i, \sigma(i))$ in the plane. Chains and antichains of a point set correspond to increasing and

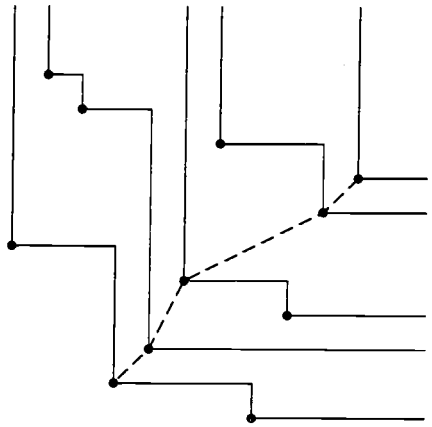

FIG. 1. *The canonical antichain partition and a maximum chain.*

decreasing subsequences of a permutation. Hence, finding maximum k-chains amounts to computing maximum k increasing subsequences. Fredman [3] shows that finding a maximum increasing subsequence requires $\Omega(n \log n)$ comparisons. Of course, this also gives a lower bound for k-chains, $k \geq 2$. On the other hand, an algorithm to compute a longest increasing subsequence in a permutation in time $O(n \log n)$ pertains to mathematicians folklore. A careful treatment of the algorithm can be found in [3]; older sources are, e.g., [1] or [8].

Interest in k-chains of orders goes back to Greene [6] and Greene and Kleitman [7] who discovered a rich duality between maximum k-chains and maximum ℓ-antichains. From this theory we quote a theorem relating maximum k-chains to maximum ℓ-antichains.

THEOREM 1.1. *For an order P with n elements there exists a partition α of n such that the Ferrers diagram F_α of α has the following properties.*

(1) *The number of squares in the k longest rows of F_α equals the size of a maximum k-chain for $1 \leq k \leq n$.*

(2) *The number of squares in the ℓ longest columns of F_α equals the size of a maximum ℓ-antichain for $1 \leq \ell \leq n$.*

The history of algorithms for maximum k-chains seems to start in some of the many alternative proofs for the Greene–Kleitman theorems; we mention two of these approaches. In [13] Viennot deals with the case of permutations or point sets, respectively, and indicates how to find k-chains in time $O((n^2/k) \log n)$. For general orders Frank [2] uses network flows which result in algorithms to compute maximum k-chains in an arbitrary order in time $O(n^3)$. Gavril [4] uses a network designed specifically for k-chain computations and improves the time bound to $O(kn^2)$. Gavril's approach was adapted to handle the weighted case within the same complexity by Sarrafzadeh and Lou [12]. For the case of planar point sets Lou and Sarrafzadeh [9] and Lou, Sarrafzadeh, and Lee [10] propose algorithms to compute 2- and 3-chains in optimal time $O(n \log n)$. They are motivated to consider k-chains in planar point sets by problems in VLSI design, e.g., multilayered via minimization for two-sided channels. Maximum k-chains also turn out to be useful in computational geometry, e.g., for counting points in triangles (see [11]).

We describe a fairly simple method to find maximum k-chains for arbitrary k in time $O(kn \log n)$ and linear space. Our approach is based on the useful concept of the *skeleton* of P introduced by Viennot [14] (see also [13]). We use a maximum $(k-1)$-chain in the skeleton to partition the plane into k regions. Taking a maximum chain from each of the regions already yields a maximum k-chain. Our method leads to a kind of complementary algorithm to the $O((n^2/k) \log n)$ algorithm of Viennot.

In section 2 the notion of skeletons is introduced. We give an algorithm to compute them and show that a point set P is determined by the skeleton $S(P)$ and two additional chains of *marginal points*. The notion of skeletons leads to a geometric interpretation of the well-known bijective correspondence between permutations and pairs of Young tableaux (the Robinson–Schensted correspondence, see, e.g., [8]). The section ends with a brief exposition of this connection.

Section 3 starts with the development of the combinatorial background for the algorithm. The algorithm is described in fairly detailed pseudocode and its correctness is proved. As a by-product we provide a direct geometric proof for part (1) of Theorem 1.1 for permutations. Section 4 is devoted to a complete presentation of Viennot's $O((n^2/k) \log n)$ algorithm for k-antichains. A by-product of the analysis is the direct geometric proof for part (2) of Theorem 1.1 for permutations. The constructions from sections 3 and 4 both imply a result of Greene [5] stating that the shape of the Ferrers diagram F_α in Theorem 1.1 is just the shape of the Young tableaux corresponding to the permutation.

In section 5 we extend the concept of skeletons to the case where a real weight $w(p)$ is associated with each point p in P. The algorithm of section 3 is extended to work with weighted planar point sets and weighted skeletons. This yields a maximum weighted k-chain in time $O(2^k n \log(2^k n))$ and space $O(2^k n)$. Of course, this makes sense only for small values of k. But note that even for constant k no better algorithm than that of Sarrafzadeh and Lou [12] with running time $O(kn^2)$ was known. Unfortunately, it is not obvious how to extend the algorithm of section 4 computing a maximum k-antichain in a similar way to the weighted case.

2. Skeleton and Young tableaux. Let P be our planar point set with n elements. We will always assume that the points of P are in *general position*, i.e., no two points have the same x- or y-coordinate. Arguments are simpler if we assume this generality. In the case of duplicate coordinates we can perturb the points such that they are in general position without changing the comparability relations. Simply change the values of the x-coordinate of points with the same x-coordinate—by definition they are comparable—by a small amount such that they get increasing x-coordinates with increasing y-coordinates. Points with the same y-coordinate are perturbed analogously. Such perturbations can be made in a single sweep, i.e., in time $O(n \log n)$. As is easily seen, the complexity of all algorithms in this paper remains as claimed even if we make such a sweep whenever we start working with a new set of points.

The *height* of a point $p \in P$ is the size of a longest chain with p as maximal element. Of course, two points of the same height cannot be comparable. Hence, collecting points with the same height in the same set yield a partition $\mathcal{A}$ of P into antichains, the *canonical antichain partition*. Observe that this partition is also obtained by a repeated removal of the set of minimal elements. By definition, the number of antichains in a canonical partition is the *height of* P, i.e., the size of a largest chain in P (see Figure 1). Since, obviously, a chain and an antichain can have at most one point in common, there can be no partition into fewer antichains than there are in $\mathcal{A}$; i.e., it is a *minimal antichain partition*.

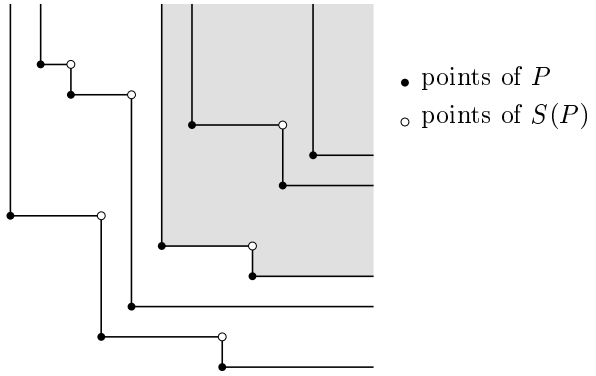

FIG. 2. *Point set P, its skeleton, and the shadow of the third layer.*

Following Viennot, we define the *left shadow* of point p as the set of all points (u, v) *dominating* p, i.e., with $u \geq p_x$ and $v \geq p_y$. For a set E of points, the *shadow of E* is the union of the left shadows of the points of E, i.e., the set of all points q dominating at least one point of E. The *right shadow* of p is the set of all points (u, v) with $u \leq p_x$ and $v \geq p_y$. The term shadow suggests some light coming from the left below or from the right below in the case of a right shadow (of course, this should not be taken literally, since the "shadows" have a form that is scarcely realizable physically). The *right down shadow* of p is the set of all points (u, v) with $u \leq p_x$ and $v \leq p_y$. The right and right down shadows of a set E are again defined as the union of the corresponding shadows of the points of E.

The *left jump line* or simply *jump line*, $L_{\nearrow}(E)$ or $L(E)$, of a point set E is the topological boundary of the left shadow of E. The *right jump line* $L_{\nwarrow}(E)$ and the *right down jump line* $L_{\swarrow}(E)$ are the topological boundaries of the right and the right down shadow of E. Let the unbounded half line of the jump line extending upward be the *top outgoing line*, and let the unbounded half line extending to the right be the *right outgoing line*. Additionally, we use the term *left outgoing line* when dealing with right or right down jump lines. It is easily seen that the jump line $L(A)$ of an antichain A is a downward staircase with the points of A in its lower corners. Collect the points in the upper corners of $L(A)$ in the set $S_{\nearrow}(A) = S(A)$; this is the set of *skeleton points* or briefly the *skeleton* of the antichain A. Formally, if $(x_1, y_1), \ldots, (x_k, y_k)$ are the points of A ordered by increasing x-coordinate then $S(A)$ consists of the points $(x_2, y_1), \ldots, (x_k, y_{k-1})$. Hence, $L(A)$ has exactly $|A|-1$ skeleton points (see Figure 2).

The minimal elements of a point set P form an antichain A such that the rest of $P - A$ lies completely in the shadow of A. Hence, by removing A and treating $P - A$ in the same way, we recursively obtain the canonical antichain partition $A = A_0, \ldots, A_{\lambda-1}$ with nonintersecting jump lines $L(A_i)$, $0 \leq i < \lambda$, which will be called the *layers $L_i(P)$ of P*. The *skeleton* or *left skeleton of P*, denoted by $S(P)$ or $S_{\nearrow}(P)$, is then defined as the union of the skeletons $S(A_i)$, $0 \leq i < \lambda$. Since, as noted above, the ith layer $L_i(P)$ has $|A_i| - 1$ skeleton points, the size of $S(P)$ is $|P| - \lambda$. A picture of a point set P, its skeleton $S(P)$, its antichain layer partition, and the shadow of antichain 2 can be found in Figure 2. Let us state an easy but quite useful observation.

LEMMA 2.1. *Suppose a point set P is partitioned into k antichains A_i in such a way that the jump lines $L(A_i)$ are pairwise disjoint. Then $A_1, \ldots, A_k$ is the canonical antichain partition of P.*

```

FIG. 3. *Algorithm* SKELETON.

Proof. Suppose the A_i are ordered by increasing x-coordinates of the top outgoing lines of the $L(A_i)$. Then $P - A_0$ is in the shadow of A_0. Hence, by the definition of the shadow, each point of $P - A_0$ dominates at least one of A_0 and no point of A_0 dominates any other point in P; i.e., A_0 are just the minimal elements of P. Repeat the procedure on $P - A_0$. □

Let us describe a simple algorithm to compute the skeleton, a maximum chain, and the canonical antichain partition of a point set P (see Figure 3). Essentially, this is the well-known algorithm for longest increasing sequences of permutations (for a geometrically inspired version see [10]). A sweep line L going from left to right halts at every point of P. It contains an ordered set of markers m. A marker m on L has a y-coordinate m_y, and m is said to be above a point p if $m_y > p_y$.

Suppose L halts at some point p and the layers have been constructed for all points to the left of L. Find the next layer with right outgoing line above p. If there is no such layer (i.e., the marker found equals the dummy point), open a new one with p as its (yet) sole point. If there is one, add p to this layer and generate a new skeleton point. It is easily seen that the jump lines thus constructed cannot intersect and hence are the layers of a canonical antichain partition, by Lemma 2.1. Finally, a maximum chain is obtained by extracting a point from each of the antichains along a chain of properly established links. With L implemented as a dynamic binary tree we have Theorem 2.2.

THEOREM 2.2. *Algorithm* SKELETON *computes the skeleton, a maximum chain, and the canonical antichain partition of a point set P of size n in time $O(n \log(n))$ and linear space.* □

For the definition of the *right skeleton* $S_{\nwarrow}(P)$ use the right shadow and the right jump lines. And for the *right down skeleton* $S_{\swarrow}(P)$ use right down shadow and right down jump lines. Of course, with $S_{\nwarrow}(P)$ we obtain the canonical chain

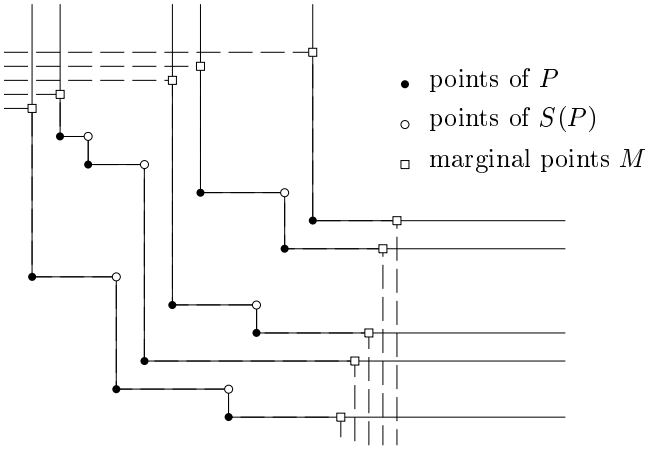

FIG. 4. *P is the right down skeleton of $S(P) \cup M(P)$.*

partition instead of the antichain partition. By symmetry, a lemma corresponding to Lemma 2.1 but dealing with chains instead of antichains is again true. With $S_{\swarrow}(P)$ we again obtain an antichain partition. A layer of this partition contains all the points with the same dual height (the dual height of p is the length of a maximum chain that has p as its minimal element).

It is convenient to conceive the construction of the skeleton as an operator on finite point sets consisting of points in general position, since the points of the skeleton $S(P)$ again have pairwise different x- and y-coordinates. Thus, we may apply operators $S_{\nearrow}$ and $S_{\nwarrow}$ to $S(P)$. As usual, the k-fold iteration of an operator O will be denoted by O^k; O^0 means identity. $S^k(P)$ will be called the *kth skeleton* of P. An interesting algebraic property of $S_{\nearrow}$ and $S_{\nwarrow}$, that they are commutative, is shown in [15].

One of the properties that seems to lie behind the usefulness of skeletons is the fact that it is possible to reconstruct P from $S(P)$ with a small amount of additional information. Let $x_{\max}$ be the maximal x-coordinate of points in P, and let $y_{\max}$ be defined analogously. Then the *right marginal points* $M_R(P)$ of P are the points $(x_{\max}+1, y_1), \ldots, (x_{\max}+\lambda, y_\lambda)$, where λ is the number of layers of P and $y_1, \ldots, y_\lambda$ are the y-coordinates of the right outgoing lines of the layers ordered increasingly (see Figure 4). Assuming $x_1, \ldots, x_\lambda$ are the x-coordinates of the top outgoing lines of the layers in increasing order, the *top marginal points* $M_T(P)$ of P are $(x_1, y_{\max}+1)$, $\ldots, (x_\lambda, y_{\max}+\lambda)$ (see Figure 4). Note that each of $M_R(P)$ and $M_T(P)$ is a chain of length height of P. With $M(P)$ we denote the collection of marginal points of P, i.e., $M(P) = M_R(P) \cup M_T(P)$.

THEOREM 2.3. *A point set P is the right down skeleton of the skeleton $S(P)$ together with the marginal points of P, i.e., $P = S_{\swarrow}(S(P) \cup M(P))$.*

Proof. The jump line $L(A)$ of an antichain A nearly coincides with the right down jump line $L_1 = L_{\swarrow}(S(A \cup \{s,t\}))$ of the skeleton of A with an arbitrary point s somewhere on the top outgoing line of $L(A)$ and some point t on the right outgoing line. More precisely, between s and t the two jump lines are equal. As the marginal points on the top and right outgoing lines are chosen so that they form chains, we may bend the original jump lines of P at the marginal points, and the bent lines remain nonintersecting. Each bent line L is the right down jump line of the points

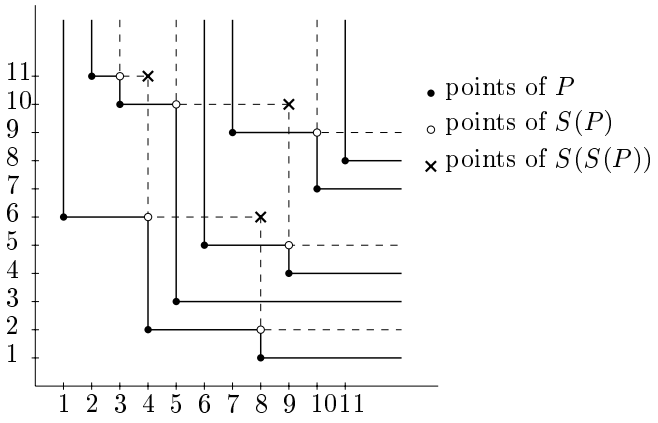

FIG. 5. *A point set P with $\lambda_0(P) = 5$ and $\lambda_1(P) = 3$.*

of $S(P) \cup M(P)$ contained in it. Moreover, the points of $S(P) \cup M(P)$ contained in each of these lines form an antichain and each point is on one of these lines. Hence, the right down version of Lemma 2.1 applies and we are done. □

A *partition* of an integer n is a sequence of integers $\lambda_0 \geq \lambda_1 \geq \cdots \geq \lambda_{\mu-1} > 0$ such that $n = \lambda_0 + \cdots \lambda_{\mu-1}$. Such a partition may be represented graphically by Ferrers diagram also called the *Young shape*. This is a shape as that of the two figures in Figure 6, which consist of μ rows of rectangles or *cells* with λ_i cells in row i, when rows are taken from bottom to top (also called "French notation"). If numbers[1] are put in these cells in increasing order from left to right and from bottom to top we obtain a *Young tableau*.

Since we will often refer to the number of layers of P, let us adopt the following notation. Let $\mu(P)$ be minimal with $S^{\mu(P)}(P) = \emptyset$. Then $\lambda_i(P)$, $0 \leq i < \mu(P)$, denotes the number of layers of $S^i(P)$ (see Figure 5). It is convenient to assume $\lambda_i(P) = 0$ for $i \geq \mu(P)$.

LEMMA 2.4. *Let P be a point set; then $\lambda_0(P) \geq \lambda_1(P) \geq \cdots \geq \lambda_{\mu(P)-1} > 0$, and $|S^k(P)| = \sum_{k \leq i < \mu} \lambda_i(P)$, where $\mu = \mu(P)$. In particular, $\lambda_0(P), \lambda_1(P), \ldots, \lambda_{\mu(P)-1} > 0$ is a partition of n.*

Proof. By Theorem 2.3, the number of antichains in a minimal antichain partition of $S(P) \cup M(P)$ is the same as $\lambda_0(P)$, the size of the canonical antichain partition of P. Hence, $\lambda_1(P)$, the size of a minimal antichain partition of $S(P)$, is at most $\lambda_0(P)$. The same argument shows the other inequalities. The sum over the $\lambda_i(P)$ is computed easily by using $|S(P)| = |P| - \lambda_0(P)$ and induction. □

Let P be a planar set of n points. We associate two tableaux $\mathbf{P}(P)$ and $\mathbf{Q}(P)$ (the $\mathbf{P}$- and $\mathbf{Q}$-*symbol of* P) with P in the following way. The kth rows of $\mathbf{P}(P)$, $k \geq 0$, are the y-coordinates of the right outgoing lines of $S^k(P)$ in increasing order. The kth row of $\mathbf{Q}(P)$, $k \geq 0$, are the x-coordinates of the top outgoing lines of $S^k(P)$ in increasing order. Compare the 5 and 3 outgoing lines of the first two layers of Figure 5 with the first two rows of the Young tableaux in Figure 6. According to Lemma 2.4, $\mathbf{P}(P)$ and $\mathbf{Q}(P)$ have $\lambda_i(P)$ cells in their ith row from below and $|P|$ cells altogether. Hence, the shape of the tableaux $\mathbf{P}(P)$ and $\mathbf{Q}(P)$ is a Young shape. We

[1] In the classical theory these are the numbers $1, \ldots, n$ which give a correspondence between pairs of Young tableaux and permutations. In the present context it is convenient to allow real entries.

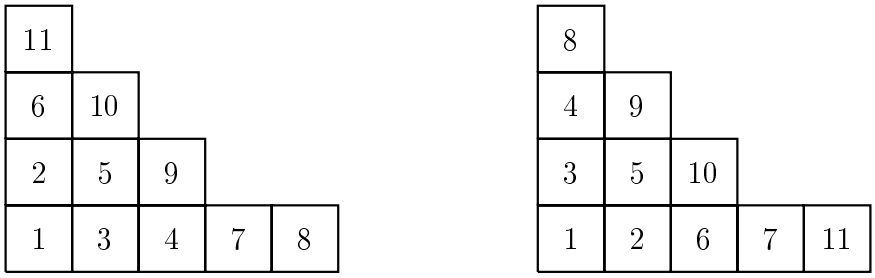

FIG. 6. *The* **P***- and* **Q***-symbol of point set* P *of Figure* 5.

denote the number of cells in the ith column (from the left) with $\lambda_i^*(P)$. Obviously, $\lambda_0^*(P) \geq \lambda_1^*(P) \geq \cdots \geq \lambda_{\ell-1}^*(P)$ and $\sum_{0 \leq i < \ell} \lambda_i^*(P) = |P|$, where $\ell = \lambda_0(P)$. The $\lambda_i^*(P)$ is the *conjugate partition* of the $\lambda_i(P)$ for the integer $|P|$.

Our first observation about the **P**- and **Q**-symbol concerns the *inverse* P^{-1} *of* P, which is the point set that is obtained from P by the transposition $(x, y) \to (y, x)$, i.e., by reflection on the diagonal line $x = y$. Obviously, the corresponding **P**- and **Q**-symbols are simply interchanged.

THEOREM 2.5. *For the inverse* P^{-1} *of a point set* P, $\mathbf{P}(P^{-1}) = \mathbf{Q}(P)$ *and* $\mathbf{Q}(P^{-1}) = \mathbf{P}(P)$. □

THEOREM 2.6 (Robinson–Schensted). *The tableaux* $\mathbf{P}(P)$ *and* $\mathbf{Q}(P)$ *of a point set* P *are Young tableaux. Moreover, for any two Young tableaux* $\mathbf{P}$ *and* $\mathbf{Q}$ *with the same shape there exists a point set* P *with* $\mathbf{P} = \mathbf{P}(P)$ *and* $\mathbf{Q} = \mathbf{Q}(P)$*; i.e., there is a bijection between point sets and pairs of Young tableaux with the same shape.*

The reader interested in the proof of this theorem and in a more comprehensive treatment of geometric approaches to the theory of the Young tableaux is referred to Viennot [14] and Wernisch [15].

3. Maximum *k*-chains. Suppose a subset C_S of the skeleton $S(P)$ of a planar point set P is given and let $C_1, \ldots, C_k$ be the canonical chain partition of C_S. The existence of such a chain partition implies that C_S is a k-chain (the converse is false; a k-chain can have a partition into fewer chains). We define the *ith region of* C_S, for $2 \leq i \leq k$, to be the intersection of the right shadow of C_{i-1} with the complement of the right shadow of C_i, i.e., the region between the jump lines of C_{i-1} and C_i, containing the jump line of C_{i-1} but excluding that of C_i (see Figure 7). The *first region* is the complement of the right shadow of C_1, and the $(k+1)$*st region* is the right shadow of C_k. These $k+1$ regions partition the whole plane.

A description of the main steps of an algorithm computing k-chains can be given with this concept of the region (a more detailed description can be found in Figure 9). The reader may want to visualize the following steps on Figure 7.

1. Compute the skeleton $S(P)$ of a planar point set P.
2. Compute recursively a $(k-1)$-chain C_{k-1} of $S(P)$.
3. For all regions R defined by C_{k-1}, extract a maximum chain from P intersected with R. The union of all chains is a maximum k-chain for P.

To demonstrate the correctness of the approach we need another definition. An antichain A of P and its jump line are said to *cross region* R *well* if $R \cap L(A) = R \cap L(A \cap R)$. That is, A crosses R well exactly if the jump line $L(A)$ enters R vertically and leaves R horizontally (see Figure 8).

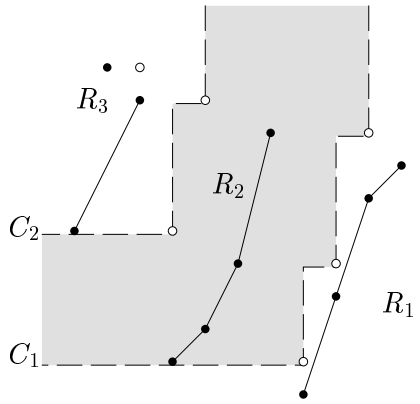

FIG. 7. *Three regions defined by a maximum* 2*-chain of the skeleton each containing one chain.*

The next lemma expresses the key property of antichains that cross well that makes them useful for our purposes.

LEMMA 3.1. *Let R be a region of $C_S \subseteq S(P)$ and let $A_1, \dots, A_\lambda$ be the canonical antichain partition of P. If I is the set of all indices i such that A_i is crossing R well, then the collection $\{A_i \cap R \mid i \in I\}$ is the canonical antichain partition of the underlying point set $\bigcup_{i\in I} A_i \cap R$.*

Proof. Let R be the ℓth region and let $p = L(A_i) \cap L_\diagdown(C_\ell)$ and $p' = L(A_j) \cap L_\diagdown(C_\ell)$ with $i < j$. Note that any two points on $L_\diagdown(C_\ell)$ are comparable. Since $L(A_j)$ is in the shadow of $L(A_i)$ we cannot have p' dominated by p; hence p' dominates p. Since A_i is crossing R well, the line segment of $L(A_i \cap R)$ that ends in p is vertical. The same holds for $L(A_j \cap R)$ and p'. As the two jump lines are disjoint we obtain $p_x < p'_x$. Therefore, we can extend $L(A_i \cap R)$ and $L(A_j \cap R)$ by vertical half lines without introducing an intersection.

A similar argument shows that the y-coordinates of $q = L(A_i) \cap L_\diagdown(C_{\ell-1})$ and $q' = L(A_j) \cap L_\diagdown(C_{\ell-1})$ are related by $q_y < q'_y$. Hence, the corresponding right half lines do not cross. Altogether the jump lines $L(A_i \cup R)$ are pairwise disjoint and, by Lemma 2.1, $\{A_i \cap R \mid i \in I\}$ is the canonical antichain partition of the underlying set. □

LEMMA 3.2. *Let $C_S \subseteq S(P)$ and let A be an antichain of the canonical partition of P. If m is the number of skeleton points on A that are in C_S, then the number of regions of C_S crossed well by A is at least $m + 1$.*

Proof. Let c be a point of C_S on the jump line L of A. Let p and q be the points of A to the left and below c that define it (see Figure 8). Then it is obvious that L leaves the region containing p horizontally and enters that of q vertically. Of course, the top outgoing line of L is vertical and the right outgoing line is horizontal.

Note that if L leaves one region vertically the region of the next point of A to the right is entered vertically too. Now consider the $m+1$ sections of L from left to right before, between, and after its m points in C_S (possibly m equals 0). Since in each such section A enters its first region vertically and leaves its last region horizontally, there must be some region crossed well by A in between. □

LEMMA 3.3. *Let C_S be a $(k-1)$-chain in the skeleton $S(P)$ of P and let λ be the height of P. Taking a maximum chain of $P \cap R$ in each region R of C_S yields a k-chain of P of size at least $|C_S| + \lambda$.*

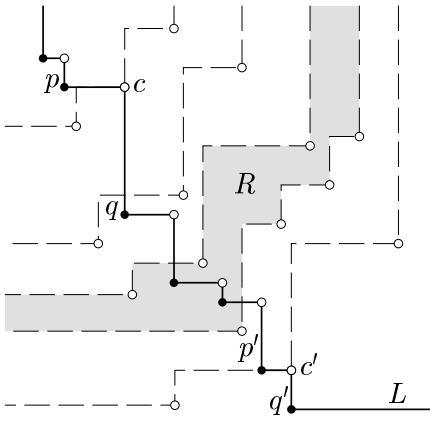

FIG. 8. *L crosses some region R well in the section between c and c'.*

Proof. Let $A_1, \ldots, A_\lambda$ be the canonical antichain partition of P. Each point of C_S is a skeleton point of exactly one antichain A_i. If m_i is the number of skeleton points of A_i in C_S, for $1 \leq i \leq \lambda$, then, according to Lemma 3.2, the antichains A_i cross the regions well in altogether at least $\sum_{1 \leq i \leq \lambda}(m_i + 1) = |C_S| + \lambda$ sections. On the other hand, by Lemma 3.1, each such section crossing some region well contributes one more point to the maximum chain of that region. □

Note that Lemma 3.3 does not require the $(k-1)$-chain C_S to be maximum. We now show a kind of reverse to Lemma 3.3.

LEMMA 3.4. *Let C be a k-chain in P. There exists a $(k-1)$-chain in the skeleton $S(P)$ with size at least $|C| - \lambda$, where λ is the height of P.*

Proof. By Theorem 2.3, P is the right down skeleton of $S(P) \cup M(P)$. The chains $M_R(P)$ and $M_T(P)$ of marginal points both have size λ. Hence, we may reason similarly as in the proof of Lemma 3.3 after reflection of all points on the diagonal $x = -y$, i.e., after the transformation $T(x, y) = (-x, -y)$ of the plane. The right down skeleton P is thus transformed to a skeleton $T(P)$ of $T(S(P) \cup M(P))$. The image $T(C)$ of the k-chain $C \subseteq P$ is a k-chain in the skeleton $T(P)$ defining $k + 1$ regions. Observe that $T(M_R)$ lies in the first region and $T(M_T)$ lies in the $(k + 1)$st region of $T(C)$ and that both are maximum chains of length λ. We apply Lemma 3.3 and obtain a $(k + 2)$-chain C'_S in $T(S(P) \cup M(P))$ with $|C'_S| \geq |C| + \lambda$. According to the above observation, we may further assume that $T(M_R)$ and $T(M_T)$ are in C_S. When these two chains are removed from C'_S we obtain a $(k-1)$-chain $C_S \subseteq T(S(P))$ of size at least $|C| - \lambda$ and $T(C_S) \subseteq S(P)$ is the $(k-1)$-chain searched for. □

We denote the k-chain in P obtained from a $(k-1)$-chain C_S in $S(P)$ according to Lemma 3.3 by $\sigma_k(C_S)$.

THEOREM 3.5. *Let C_1 be a maximum chain of $S^{k-1}(P)$ and $C_i = \sigma_i(C_{i-1})$ for $2 \leq i \leq k$; then C_k is a maximum k-chain in P.*

Proof. By induction, suppose that C_{k-1} is a maximum $(k-1)$-chain in $S(P)$ and let λ be the height of P. If there were a k-chain $C \subseteq P$ with more points than $\sigma_k(C_{k-1})$ then C would have more than $|C_{k-1}| + \lambda$ points, according to Lemma 3.3. Hence, by Lemma 3.4, there would be a $(k-1)$-chain of size larger than $|C_{k-1}|$ in $S(P)$, a contradiction. □

Note that the proof of the above theorem also shows that the number of additional

```

```

FIG. 9. *Algorithm* MAXMULTICHAIN.

points in each application of σ_ℓ to a maximum $(\ell-1)$-chain of $S^{k-\ell+1}(P)$ is equal to the height of $S^{k-\ell}(P)$ for $2 \le \ell \le k$. Hence, we obtain the following corollary that is part (1) of Greene's theorem for permutations (see Theorem 1.1).

COROLLARY 3.6. *A maximum k-chain of a point set P has size $\sum_{0\le i<k} \lambda_i(P)$ where $\lambda_i(P)$ is the height of $S^i(P)$.* □

We are now prepared to provide an algorithm MAXMULTICHAIN (see Figure 9) that, given a point set P and some k, computes a maximum k-chain of P. Some remarks about this algorithm are in order. To dispose P means to release any memory space holding the points of P, which is necessary to keep the space requirement small. Recall that a maximum $(k-1)$-chain may consist of fewer than $k-1$ chains. This happens if C_S equals S and can be partitioned into less than $k-1$ chains. Hence, there may be fewer than k regions of C_S. If C_S is empty (e.g., when $k=1$), we assume that R_1 is the whole plane.

The partitioning of P according to the regions R_i of C_S can be done with a single sweep from left to right halting at every point of P. The sweep line L contains its intersection with all the right layers of C_S and is initialized to the y-coordinates of the left outgoing lines of these layers. Now a point $p \in P$ is easily assigned to its region. If the skeleton point immediately above p is in C_S, then the height of the intersection point of the corresponding right layer with the sweep line has to be adapted.

THEOREM 3.7. *Algorithm* MAXMULTICHAIN(P,k) *computes a maximum k-chain for a point set P of size n in time $O(kn\log n)$ and linear space.*

Proof. According to Theorem 2.2, the skeleton, marginal points, and the canonical chain partition of a point set of size n can be computed in $O(n\log n)$ time. The partitioning of P described above takes the same amount of time. The computation of the maximum chains in each region take, again by Theorem 2.2, time $O(\sum_{i=1}^{l} |P_i|\log(|P_i|))$ which is $O(n\log n)$. Since these estimations hold true in each recursive step, we have an overall time $O(kn\log n)$.

As far as the space requirement is concerned, the main problem is the computation of a new skeleton in each recursive step. But P is disposed and only its skeleton together with the marginal points is retained. The number of marginal points in the ith step equals twice the number $\lambda_i(P)$ of layers of the ith skeleton $S^i(P)$, $0 \le i \le k$. Thus, the amount of space that is needed for k recursions is $O(2\sum_{i=0}^{k} \lambda_i(P) + |S^k(P)|)$

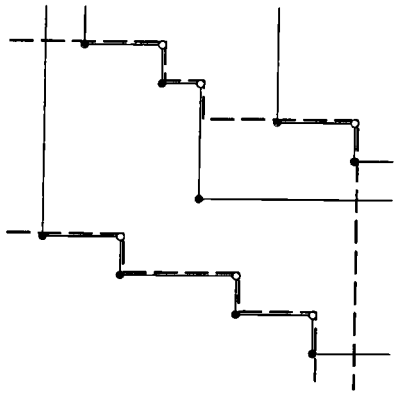

FIG. 10. *The Δ-operator.*

which, by Lemma 2.4, is $O(|P|)$. □

4. Maximum k-antichains. In this section we prove some assertions made by Viennot [13] leading to an algorithm that efficiently computes k-antichains of a point set P.

Let A_S be a k-antichain in the skeleton $S(P)$ and let $A_{S,1}, \ldots, A_{S,k}$ be the canonical antichain partition of A_S. It is easily seen that the intersection of P with the right down jump line $L_{\swarrow}(A_{S,i})$ is an antichain in P. Let us denote the k-antichain $\bigcup_{i=1}^{k} L_{\swarrow}(A_{S,i}) \cap P$ of P by $\Delta(A_S)$ (see Figure 10). On the other hand, given a k-antichain A with canonical partition $A_1, \ldots, A_k$ we define the k-antichain $\delta(A) = \bigcup_{i=1}^{k} L(A_i) \cap S(P)$ of $S(P)$. Recall that a strict k-antichain is one that cannot be covered by less than k antichains.

LEMMA 4.1. *Let P be a planar point set.*

1. *If A_S is a strict k-antichain of $S(P)$, then $\Delta(A_S)$ is a k-antichain of P of size at least $|A_S| + k$.*
2. *If A is a strict k-antichain of P, then $\delta(A)$ is a k-antichain of $S(P)$ of size at least $|A| - k$.*
3. *If A_S is a strict maximum k-antichain, then equality holds in item 1 of this lemma and $\Delta(A_S)$ is a strict maximum k-antichain, too.*

Proof. Let $A_{S,1}, \ldots, A_{S,k}$ be the canonical right down antichain partition of A_S. Each skeleton point $s \in S(P)$ has two defining points $p_L(s), p_D(s) \in P$, one with the same y-coordinate to the left, the other with the same x-coordinate below. If we walk along a right down jump line $L_{\swarrow}(A_{S,i})$ from left to right we find between any two consecutive skeleton points s_1, s_2 of $A_{S,i}$ at least one of the defining points $p_D(s_1)$ or $p_L(s_2)$ on the jump line. Otherwise, the defining point $p_D(s_1)$ would have a y-coordinate smaller than that of s_2, and point $p_L(s_2)$ would have x-coordinate smaller than that of s_1. But this implies that two layers of the canonical layer structure of P intersect, which is impossible (see Figure 11). Since the left and down defining point $p_L(s_L)$ and $p_D(s_R)$ of the leftmost and rightmost skeleton points s_L and s_R of $A_{S,i}$ are always on the right down jump line, $P \cap L_{\swarrow}(A_{S,i})$ contains at least one point more than $A_{S,i}$. Summing over all $A_{S,i}$ we get the first inequality of the lemma.

The second inequality is obtained similarly. One may extend P by the two marginal chains and use the transformation $T(x, y) = (-x, -y)$. By Theorem 2.3,

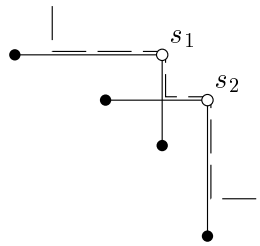

FIG. 11. *Intersecting layers.*

$T(P)$ is the skeleton of $T(S(P) \cup M(P))$. Hence, by the above argument, $|\delta(A)| \geq |\Delta(T(A))| - 2k \geq |T(A)| - k$ since the two chains $T(M_T)$ and $T(M_R)$ contribute at most $2k$ points to the k-antichain $\Delta(T(A))$ in $T(S(P) \cup M(P))$.

Suppose A_S is a strict maximum k-antichain and let $\Delta(A_S)$ be a strict k'-antichain with $k' \leq k$. Then $\delta(\Delta(A_S))$ is a k'-antichain, hence a k-antichain, of size at least $|\Delta(A_S)| - k' \geq |A_S| + k - k'$ in $S(P)$ and $k' = k$ since A_S is maximum. Consequently, if A' is a k-antichain of P, $|\Delta(A_S)| - k \geq |A_S| \geq \delta(A') \geq |A'| - k$, which implies that $\Delta(A_S)$ is a maximum k-antichain. □

THEOREM 4.2. *Let P be a point set and let $k \leq \lambda_0(P)$. There is an ℓ with $0 \leq \ell < \mu(P)$ and $\lambda_{\ell+1}(P) \leq k < \lambda_\ell(P)$. The ℓth skeleton $S^\ell(P)$ contains a strict maximum k-antichain A_ℓ, and $\Delta^\ell(A_\ell)$ is a maximum k-antichain of P of size $|S^{\ell+1}(P)| + k\ell = \sum_{i=0}^{k} \lambda_i^*(P)$.*

Proof. Since, by Lemma 2.4, the $\lambda_i(P)$ are decreasing in i and $\lambda_{\mu(P)}(P) = 0$, there is an ℓ such that the inequalities are satisfied. $S^{\ell+1}(P)$ itself is a strict maximum $\lambda_{\ell+1}(P)$-antichain and $\Delta(S^{\ell+1}(P))$ is a strict maximum $\lambda_{\ell+1}(P)$-antichain of $S^\ell(P)$. The size of $\Delta(S^{\ell+1}(P))$ is $|S^{\ell+1}(P)| + \lambda_{\ell+1}(P)$ by Lemma 4.1. Take a maximum chain C in $S^\ell(P)$; it has size $\lambda_\ell(P)$. Since $\Delta(S^{\ell+1}(P))$ intersects C in at most $\lambda_{\ell+1}(P)$ points and $S^\ell(P)$ has size $|S^{\ell+1}(P)| + \lambda_\ell(P)$, there is no point of $S^\ell(P)$ outside $C \cup \Delta(S^{\ell+1}(P))$ and we may add $k - \lambda_{\ell+1}(P)$ arbitrary points of $S^\ell(P)$ to $\Delta(S^{\ell+1}(P))$ to get a strict maximum k-antichain A_ℓ in $S^\ell(P)$ of size $|S^{\ell+1}(P)| + k$. Now induction and application of Lemma 4.1 shows the theorem. □

An algorithm computing a maximum k-antichain of P for given P and k is now easy to provide. For algorithm MAXMULTIANTICHAIN see Figure 12.

THEOREM 4.3. *Algorithm* MAXMULTIANTICHAIN(P, k) *computes a maximum k-antichain for a point set P of size n in time $O((n^2/k) \log n)$ and linear space.*

Proof. Since the algorithm simply mimics the proof of Theorem 4.2, it certainly computes a maximum k-antichain. The computation of the skeleton, marginal points, and the number of layers takes time $O(n \log n)$. The Δ operator is implemented straightforwardly. For a sweep line going from right to left computing the right down layers of A_S may halt at points of P, too, and check whether they lie on a layer or not. Hence, the time needed for one recursive step is $O(n \log n)$. According to Theorem 4.2, a maximum k-antichain has size $|S^{\ell+1}| + k\ell \leq n$. Thus, the number $\ell + 1$ of recursions is bounded by $n/k + 1$. That the amount of space needed remains linear is seen as in the proof of Theorem 3.7. □

5. Maximum weighted k-chains. Given some weight $w\colon P \to \mathbf{R}$ on the points of a set P, we define the weight of a k-chain as the sum of the weights of its points. A *maximum weighted* k-chain has maximum weight among all weights of k-chains of P. Such maximum weighted k-chains can be found in a similar way as maximum

```
MAXMULTIANTICHAIN(P, k)
λ ← number of layers of (P);
if λ ≤ k then
    return (P, λ);
else
    S ← skeleton(P);
    M ← marginal points(P);
    dispose P;
    (A_S, λ') ← MAXMULTIANTICHAIN(S, k);
    P ← right down skeleton(S ∪ M);
    A ← Δ(A_S);
    if λ' < k then
        add k − λ' arbitrary points of P to A;
    return (A, k);
```

FIG. 12. *Algorithm* MAXMULTIANTICHAIN.

k-chains. Unfortunately, the corresponding algorithm is efficient only if k is small.

In the following assume that the weights w are positive integers. With this assumption the weighted case can be simulated by the unweighted one. Although the algorithms work on the weighted point set itself, the proofs of correctness are based on the following idea. We expand each point $p \in P$ into a tiny chain $C(p)$ of $w(p)$ points, where tiny means that the chain is contained within a tiny box of sidelength ϵ where ϵ is less than the minimum distance in x- or y-coordinates of the points of P (recall that we assume all points to have different x- and y-coordinates). Denote the expanded set of points by P'. Now consider the skeleton $S(P')$ of P'. Let p, q be two points of P with $p_x < q_x$. It is easily seen that if there are any skeleton points in $S(P')$ having their defining points in the tiny chains $C(p)$ and $C(q)$, then all skeleton points with this property again fit into a box B of sidelength ϵ. In this case, locate a *weighted skeleton point* between p and q (i.e., at (q_x, p_y)) and give it a weight equal to the number of skeleton points contained in box B. The resulting set of weighted skeleton points is the *weighted skeleton* $S(P, w)$.

The weighted skeleton $S(P, w)$ can also be obtained without resorting to set P' of multiplied points. We translate the actions of Algorithm SKELETON (see Figure 3 of section 2) that construct the skeleton $S(P')$ of P' with sweep line L' into actions of an Algorithm SKELETON-WEIGHTED (see Figure 13) that construct the corresponding weighted skeleton $S(P, w)$ of P with sweep line L. As a by-product Algorithm SKELETON-WEIGHTED also computes a maximum weighted chain of P.

If the y-coordinates of a set M of markers on L' differ by an amount smaller than ϵ, then they correspond to a *weighted marker* m on L with weight $W(m) = |M|$. The insertion of a point $p \in P$ with weight $w(p)$ in L corresponds to the $w(p)$ insertions of points from $C(p) \subseteq P'$ into L'. Let m be the next marker above p. If $|C(p)|$ is greater than or equal to the number $W(m)$ of markers on L' that correspond to m, then $W(m)$ new skeleton points in $S(P')$ are generated. Hence, we have to generate a new skeleton point in $S(P, w)$ of weight $W(m)$ and remove marker m. If $|C(p)| > W(m)$ there remain $W = |C(p)| - W(m)$ points of $C(p)$ for insertion. Hence, the next marker on L is searched and the procedure is repeated until there is

```
SKELETON-WEIGHTED(P, w)
insert dummy d_u in L with W(d_u) ← +∞ at height +∞;
link(d_u) ← nil;
S ← ∅;
for each p ∈ P from left to right do
    insert a new marker m' in L with m'_y ← p_y;
    W(m') ← w(p);
    point(m') ← p;
    m ← next marker below p on L;
    link(p) ← point(m);
    m ← next marker above p on L;
    W ← w(p);
    while W ≥ W(m) do
        add skeleton point (L_x, m_y) with weight W(m) to S;
        W ← W − W(m);
        remove m from L;
        m ← next marker above p on L;
    if m ≠ d_u and W > 0 then
        add skeleton point (L_x, m_y) with weight W to S;
        W(m) ← W(m) − W;
v ← point(m), m uppermost marker on L; C ← {v};
while link(v) ≠ nil do
    v ← link(v); C ← C ∪ {v};
return S, C;
```

FIG. 13. *Algorithm* SKELETON-WEIGHTED.

no further marker on L or there is one marker m_0 with $W(m_0) > W$. Comparing with the corresponding situation in P' we find the necessary action. A skeleton point of weight W is generated and the weight of marker m_0 is updated to $W(m_0) - W$. With this kind of consideration it can be verified that Algorithm SKELETON-WEIGHTED yields the weighted skeleton of (P, w).

For the maximum weighted chain computation observe that either all or none of the points of $C(p)$, for some $p \in P$, are contained in a maximum chain in P'. Thus, a maximum chain in P' corresponds to a maximum weighted chain in P and vice versa. As will be seen later the same holds true of maximum weighted k-chains in P and maximum k-chains in P'.

The weighted skeleton thus computed has many points with an equal x- or y-coordinate, and we want to compute the weighted skeleton of a skeleton repeatedly. Thus, we perturb them according to the simple procedure mentioned in section 2 before we use them in any further computation. Consequently, we may assume that all coordinates of points of the input instance are different.

Computing the weighted skeleton $S(P, w)$ with algorithm SKELETON-WEIGHTED takes time $O((|P|+|S(P,w)|)\log(|P|+|S(P,w)|))$. In contrast to the unweighted case, the weighted skeleton may contain more points than the original point set. Fortunately, there cannot be many more such points.

LEMMA 5.1. *The number of weighted skeleton points in $S(P, w)$ is at most twice the number of points in P.*

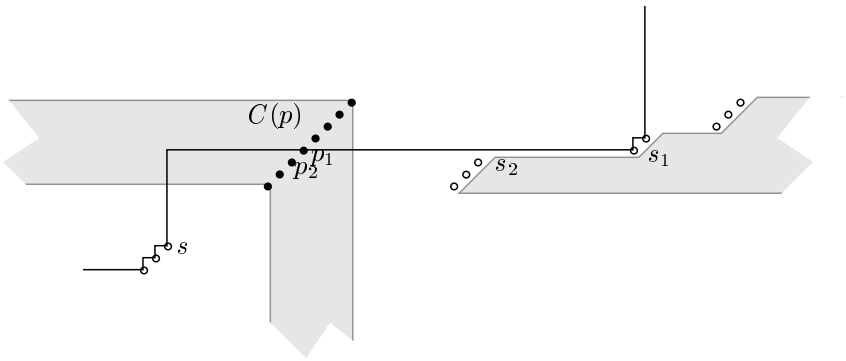

FIG. 14. *This cannot happen—a jump line of C_S separating $C(p)$. Gray areas do not contain points of P' or $S(P')$.*

Proof. If a skeleton point $s \in S(P, w)$ has no other skeleton point s' above, it is assigned to its defining point $p \in P$ below. Otherwise, it is assigned to its defining point to the left. Note that in the second case skeleton point s was generated under the condition $W \geq W(m)$; hence, m was removed and, consequently, there is no skeleton point s' to the right of s. A point $p \in P$ gets assigned the highest skeleton point above it or the furthest skeleton point to its right or both. Therefore, no point p gets assigned more than two skeleton points. □

The interesting fact now is that Algorithm MAXMULTICHAIN (see Figure 9 of section 3) may be used nearly without changes to compute a maximum weighted k-chain. The only problem is that we have not yet defined what the marginal points of a weighted point set should be. But we can do without marginal points if we resign to dispose any set of points. This does no harm since the space requirement will be high anyway.

THEOREM 5.2. *Let C_S be a maximum weighted $(k-1)$-chain in $S(P, w)$. Then taking a maximum weighted chain of points $P \cap R$ in each of the k regions R of C_S yields a maximum weighted k-chain of P.*

Proof. By induction, a maximum weighted $(k-1)$-chain C_S of $S(P)$ corresponds to a maximum $(k-1)$-chain C'_S of the skeleton $S(P')$ of P'. The selection of a maximum chain in the point sets $P' \cap R$ for each region R of the k regions of C'_S would give a maximum k-chain of P'. This does not immediately yield a maximum weighted k-chain of P since some points of the chain $C(p) \subseteq P'$ replacing a point p of P might fall in one region and some in another. We claim that this cannot happen. Since there is no skeleton point in the ϵ box containing $C(p)$, it is separated either by a vertical or horizontal segment of a jump line of some chain. It cannot be vertical, for there is no skeleton point below $C(p)$.

Now suppose that a horizontal segment between two skeleton points s and s_1 separates $C(p)$ (see Figure 14). The y-coordinate of s_1 equals the y-coordinate of some point $p_1 \in C(p)$. Let p_2 be the immediate predecessor of p_1 in $C(p)$. Since there is no skeleton point to the left of $C(p)$, the point s has to be dominated by p_2 and by s_2, the skeleton point on the outgoing line of p_2. Also $s_2 < s_1$; hence, $C_S \cup \{s_2\}$ is a $(k-1)$-chain. If s_2 is not a member of C_S this contradicts the maximality of C_S. On the other hand, s_2 cannot be a member of C_S, since C_S has a decomposition into $(k-1)$ noncrossing jump lines, one of them joining s and s_1. A jump line containing

s_2, however, has to leave s_2 upward and hence crosses the jump line of s and s_1.

We have thus proved that there is a correspondence between the regions R'_i of C'_S and the regions R_i of C_S, for $1 \le i \le k$, in such a way that a chain $C(p)$ is completely contained in R'_i iff p is contained in R_i. Applying Theorem 3.5 to the expanded point set, we obtain that all maximum weighted chains from regions R_i together form a maximum weighted k-chain. □

In analogy to the unweighted case, we set $S^0_w(P) = P$ and let $S^k_w(P) = S(S^{k-1}_w(P), w)$ be the *kth weighted skeleton* of P. We denote the weighted k-chain in P obtained from a weighted $(k-1)$-chain C_S in $S(P, w)$ according to Theorem 5.2 by $\rho_k(C_S)$.

THEOREM 5.3. *Let C_1 be a maximum weighted chain of $S^{k-1}_w(P)$ and $C_\ell = \rho_\ell(C_{\ell-1})$ for $2 \le \ell \le k$; then C_k is a maximum weighted k-chain in P.* □

THEOREM 5.4. *A maximum weighted k-chain of a weighted point set P can be obtained in $O(2^k|P| \log(2^k|P|))$ time and $O(2^k|P|)$ space.*

Proof. As was already pointed out, to construct the weighted skeleton for a weighted point set P takes time $O(|P| \log |P|)$. The point location of points P in the regions defined by a $(k-1)$-chain C_S can be done with the help of a sweep line in time $O(|P| \log |C_S| + |C_S|)$. This amounts to a total running time of $O(\sum_{1 \le i \le k} 2^i|P| \times \log(2^i|P|))$, since $|S^i_w| \le 2^i|P|$ by Lemma 5.1. The bound on the space is given by $O(\sum_{1 \le i \le k} 2^i|P|)$. □

A maximum weighted k-chain of a point set P with rational or real weights can be computed by the very same algorithm. The proof of correctness then requires some additional standard rescaling and approximation arguments.

As the algorithm of this section makes sense only for small values of k it would have been nice to have a complementary method for large k. Unfortunately, we have not been able to extend the algorithm of section 4 to the weighted case so that the running time remains independent from the weights.

FAST ALGORITHMS FOR CONSTRUCTING t-SPANNERS AND PATHS WITH STRETCH t*

EDITH COHEN†

Abstract. The distance between two vertices in a weighted graph is the weight of a minimum-weight path between them (where the weight of a path is the sum of the weights of the edges in the path). A path has *stretch* t if its weight is at most t times the distance between its end points. We present algorithms that compute paths of stretch $2 \leq t \leq \log n$ on undirected graphs $G = (V, E)$ with nonnegative weights. The stretch t is of the form $t = \beta(2 + \epsilon')$, where β is integral and $\epsilon' > 0$ is at least as large as some fixed $\epsilon > 0$. We present an $\tilde{O}((m + k)n^{(2+\epsilon)/t})$ time randomized algorithm that finds paths between k specified pairs of vertices and an $\tilde{O}((m + ns)n^{2(1+\log_n m+\epsilon)/t})$ deterministic algorithm that finds paths from s specified sources to all other vertices (for any fixed $\epsilon > 0$), where $n = |V|$ and $m = |E|$. This improves significantly over the slower $\tilde{O}(\min\{k, n\}m)$ exact shortest paths algorithms and a previous $\tilde{O}(mn^{64/t} + kn^{32/t})$ time algorithm by Awerbuch et al. [*Proc. 34th IEEE Annual Symposium on Foundations of Computer Science*, IEEE, Piscataway, NJ, 1993, pp. 638–647]. A t-spanner of a graph G is a set of weighted edges on the vertices of G such that distances in the spanner are not smaller and within a factor of t from the corresponding distances in G. Previous work was concerned with bounding the size and efficiently constructing t-spanners. We construct t-spanners of size $\tilde{O}(n^{1+(2+\epsilon)/t})$ in $\tilde{O}(mn^{(2+\epsilon)/t})$ expected time (for any fixed $\epsilon > 0$), which constitutes a faster construction (by a factor of $n^{3+2/t}/m$) of sparser spanners than was previously attainable. We also provide efficient parallel constructions. Our algorithms are based on pairwise covers and a novel approach to construct them efficiently.

1. Introduction.

The shortest-path problem amounts to finding paths of minimum weight between specified pairs of vertices on a weighted input graph. We consider the relaxed version of computing paths with *stretch* t, where the ratio between the weight of the path and the minimum-weight path connecting the same two vertices is at most t. We provide algorithms that compute paths of stretch t (typically $2 < t < \log n$) on weighted undirected graphs much more efficiently than known previously. A related concept is t-spanners of weighted graphs. A t-spanner is a weighted graph on the same set of vertices such that the distances between pairs of vertices in the spanner are not smaller and within a factor of t of the corresponding distances on the original graph. Numerous recent works focused on bounding the size of t-spanners, constructing them efficiently, and applying them to other problems (see, e.g., Peleg and Ullman [12], Peleg and Schäffer [11], Althöfer et al. [1], and Chandra et al. [4]). We obtain significantly more efficient parallel and sequential constructions of sparse t-spanners along with improved upper bounds on their size. We note that our stretch-t paths algorithm essentially computes a sparse t-spanner and produces paths that consist of spanner edges. Our algorithms are favorable in scenarios where one needs to find short paths but has severe limitations on resources (e.g., time or number of processors) that prohibit the use of shortest-paths algorithms or when there is a flat high cost associated with each edge that is being used for some short path, and,

hence, it is desirable to find a set of short paths that utilizes only a small subset of the edges (note that shortest paths may require the use of all the edges). In addition, our algorithms are suited to find short paths on line where we allow a small amount of preprocessing and are supplied on line with query pairs of vertices. Furthermore, they can be adapted to find short paths on line on dynamic networks, where weighted edges are inserted or deleted much faster than known shortest-paths algorithms.

We consider undirected graphs $G = (V, E)$ where V is the set of vertices and E the set of edges. Associated with the edges are positive weights $w : E \to R_+$. We denote $n = |V|$ and $m = |E|$. The weight of a path is the sum of the weights of the edges on the path. A *shortest path* between $\{u_1, u_2\} \subset V$ is a path of minimum weight among all paths connecting u_1 and u_2. The *distance* between $\{u_1, u_2\} \subset V$, denoted $\mathrm{dist}\{u_1, u_2\}$, is the weight of the respective shortest path. A path between $\{u_1, u_2\} \subset V$ has *stretch* t if the ratio between the weight of the path and the distance between $\{u_1, u_2\}$ is at most t. We use the $\tilde{O}$ asymptotic notation to eliminate polylogarithmic factors in n, e.g., $\tilde{O}(f) \equiv O(f \operatorname{polylog} n)$. The parallel algorithms and resource bounds discussed in this paper are for the EREW PRAM model.

1.1. Our results. We obtain the following results. Consider a weighted graph G, a set of query pairs $Q \subset V \times V$, and a stretch factor $2 < t = O(\log n)$. The stretch t is of the form $t = \beta(2+\epsilon')$, where β is integral and $\epsilon' > 0$ is at least as large as some fixed $\epsilon > 0$. We present bounds for computing for all $(v, u) \in Q$, stretched distances $\tilde{\mathrm{dist}}\{v, u\}$ such that

$$\mathrm{dist}\{v, u\} \le \tilde{\mathrm{dist}}\{v, u\} \le t\mathrm{dist}\{v, u\} \ ,$$

with the following tradeoffs between the stretch t, the time, and the work performed:

- deterministically,

(1) when Q contains all the pairs consisting of one vertex from a set S of sources and any other vertex;
by a sequential algorithm for any fixed $\epsilon > 0$ and t such that $t/((2+\epsilon)(1+\log_n m))$ is integral, in (see Theorem 6.6) $O(n^{(2+\epsilon)(1+\log_n m)/t}(m \log n + |S| n \log n))$ time;

- with probability $1 - O(1/\operatorname{poly}(n))$. These are Las Vegas algorithms. The randomization is on the expected termination time and not on the correctness.

(2) By a sequential algorithm for any fixed $\epsilon > 0$ and t such that $t/(2+\epsilon)$ is integral in (see section 6) $O((m + |Q|)n^{(2+\epsilon)/t} t \log^2 n)$ time.

(3) For a fixed $0 \le \delta \le 1$, any fixed $\epsilon > 0$, and $\beta = O(\log n)$ (see Theorem 2.8) $t = (2\beta)^{\lceil 1/\delta \rceil}(1+\epsilon)$ in $O(n^\delta \beta^2 \log n)$ time using $\tilde{O}(n^{1+2/\beta} + (m + |Q|)n^{1/\beta})$ work.

In an on-line problem, where we perform some preprocessing and the query pairs (or query sources) are given on line, the algorithm in (1) needs $O(n^{(2+\epsilon)(1+\log_n m)/t} m \log n)$ preprocessing time and $O(n^{(2+\epsilon)(1+\log_n m)/t} n \log n)$ time per source, and the algorithm in (2) needs $O(mn^{(2+\epsilon)/t} t \log^2 n)$ preprocessing time and $O(n^{(2+\epsilon)/t} t \log^2 n)$ time per query pair.

Graph spanners. We construct t-spanners of size (number of edges) $\tilde{O}(n^{1+(2+\epsilon)/t})$ (for any $\epsilon > 0$ and t such that $t/(2+\epsilon)$ is integral). These spanners can be constructed by a randomized algorithm that runs in $\tilde{O}(mn^{(2+\epsilon)/t})$ time. We present a deterministic algorithm that finds t-spanners of size $O(n^{1+(2+\epsilon)(1+\log_n m)/t})$ (for any $\epsilon > 0$ and t such that $t/((2+\epsilon)(1+\log_n m))$ is integral) and runs in $O(mn^{(2+\epsilon)(1+\log_n m)/t})$ time. We show that in parallel, t-spanners of size $O(n^{1+(2+\epsilon)/t})$ (for any $\epsilon > 0$ and t such that $t/(2+\epsilon/2)$ is integral) can be constructed in $O(R\beta^2 \log^2 n)$ expected time

using $O(n^{1/\beta} m\beta \log^2 n)$ work or, alternatively, in $O(\beta \log^3 n)$ expected time using $O(n^3 \beta \log n)$ work, where $R = w_{\max}/w_{\min}$ and $\beta = t/(2 + \epsilon/2)$.

1.2. Previous work. Peleg and Schäffer[11] proved the following bounds on the size of spanners of unweighted graphs. They showed that for infinitely many values of n there exist n-vertex graphs such that all their t-spanners contain $\Omega(n^{1+1/t})$ edges. They also gave a polynomial algorithm that computes t-spanners with $O(n^{1+4/t})$ edges. For weighted graphs, Althöfer et al. [1] gave a simple greedy algorithm that constructs t-spanners of size $O(n^{1+2/(t-1)})$. In a subsequent paper, Chandra et al. [4] showed that the greedy algorithm of [1] has an $O(n^{3+4/(t-1)})$ time implementation. Hence, we tighten the known upper bound on the size of t-spanners and present a significantly more efficient sequential and parallel constructions than previously known. The key to achieving these improvements is the fact that all previous constructions of t-spanners were based on solving many instances of the exact shortest-paths problem, where in this paper we avoid that.

The fastest known sequential algorithm for computing exact shortest paths from a set of sources S to all other vertices requires $\tilde{O}(|S|m)$ time using weighted breadth-first search (BFS). (See, e.g., [8].) Awerbuch, Berger, Cowen, and Peleg [2] presented a faster algorithm for computing paths of stretch $t > 64$. They showed that paths with stretch $64 \leq t = O(\log n)$ between k pairs of vertices can be obtained in $\tilde{O}((mt + nt^2)n^{64/t} + ktn^{32/t})$ time. Hence, in particular, paths with stretch t from a set of sources S to all other vertices can be obtained in $\tilde{O}((mt + nt^2)n^{64/t} + |S|tn^{1+32/t})$ time. Note that when $t = O(\log n)$ the algorithm produces paths with stretch $O(\log n)$ and runs in time $\tilde{O}(m + |S|n)$.

The best-known parallel shortest path algorithms generally perform significantly more work (product of time and number of processors) than their sequential counterparts. The best-known work bound for an $\mathcal{NC}$ algorithm for the (weighted) single-source shortest-paths problem is $\tilde{O}(n^3)$ (the algorithm essentially solves the more general all-pairs problem). Other algorithms exhibit tradeoffs between work and time. Spencer [13] presented an algorithm for the single-source problem that runs in $\tilde{O}(\delta)$ time using $\tilde{O}(n^3/\delta^2 + m)$ work, where the ratio of the largest edge weight to the smallest edge weight is polynomial in n. The author gave an algorithm that computes shortest paths from $|S|$ sources in $\tilde{O}(\delta)$ time using $O(|S|n^2 + n^3/\delta^3)$ work [6]. The algorithm computes shortest paths if the ratio of the largest edge weight to the smallest edge weight is polynomial in n and otherwise can be adapted to find paths whose weights are within a factor of $(1+1/\operatorname{poly}(n))$ from the respective distances. In addition, the author showed that paths with stretch $(1+\epsilon)$ (for a fixed ϵ) can be computed in $\tilde{O}(\delta)$ time using $\tilde{O}(|S|(n^2/\delta + m) + n^3/\delta^2)$ work. Another work-time tradeoff for the single-source shortest paths problem was given by Klein and Sairam [10] who presented a randomized algorithm that finds paths with stretch $(1 + \epsilon)$ (for a fixed ϵ) in $\tilde{O}(n^{0.5})$ time using $\tilde{O}(mn^{0.5})$ work.

Note that the tradeoffs obtained by our sequential randomized algorithm (see (2)) improve over the algorithm of Awerbuch et al. [2]. The tradeoffs obtained by our deterministic sequential algorithm (see (1)) improve over the algorithm of Awerbuch et al. for multisource short-paths problems. The improvements reduce the time bound significantly and are particularly meaningful in the more interesting range where the stretch is small. As a concrete example consider computing paths between $O(m)$ arbitrary pairs of vertices. The best shortest-paths algorithm for this problem runs in time $\tilde{O}(mn)$ (essentially solves the all-pairs problem). Our randomized algorithm in time $\tilde{O}(mn^{0.5})$ finds paths with stretch 4. The Awerbuch et al. algorithm cannot

guarantee paths of stretch 4 and in time $\tilde{O}(mn^{0.5})$ computes paths with stretch 128. Implications of our parallel tradeoffs are that for any fixed $\epsilon > 0$, paths from s sources to all other vertices with a fixed constant stretch can be computed in $O(n^{\epsilon})$ time using $O((m+sn)n^{\epsilon})$ work and with a polylogarithmic stretch, in $O(n^{\epsilon})$ time using $\tilde{O}(m+sn)$ work.

1.3. Overview. The main tool that we use to compute spanners and paths of stretch t are *pairwise covers* of graphs and efficient novel constructions of these covers. Pairwise covers are a modification of sparse neighborhood covers (see Awerbuch and Peleg [3]). Sparse neighborhood covers were employed by Awerbuch et al. [2] to obtain a sequential algorithm for paths of a specified stretch. Pairwise covers turn out to be a more correct notion for computing paths of stretch t. Our constructions allow for significantly improved sequential bounds. In addition, we present parallel algorithms based on efficient parallel cover constructions. The construction of neighborhood covers in [2] seems to be inherently sequential.

A pairwise cover of a graph is defined with respect to parameters W and β. It consists of a collection of subsets of vertices (*clusters*) with the following properties: the sum of the sizes of the clusters is $\tilde{O}(n^{1+1/\beta})$, the maximal distance between any pair of vertices which are in the same cluster is at most $2\beta W$, and for every pair of vertices of distance at most W from each other there exists at least one cluster in the cover that contains both vertices. The value of β determines a tradeoff between the maximum diameter of a cluster (that we would like to be as small a multiple of W as possible) and the total size of the cover (that we would like to be as close to $O(n)$ as possible). For any $\beta \geq 2$ and a fixed $\epsilon > 0$, a logarithmic number of pairwise covers for different values of W can be used to compute paths with stretch $t = 2(1+\epsilon)\beta$. The work performed depends on the size of the cover. To achieve efficient parallel constructions of pairwise covers, we refine the definition to be with respect to an additional "path size" parameter ℓ. For a parameter $1 \leq \ell \leq n$, the ℓ-limited distance between a pair of vertices is the weight of the minimum-weight path connecting them among paths consisting of at most ℓ edges (this terminology is from [10]). In pairwise covers with parameter ℓ, we have a relaxed condition that pairs of vertices where the ℓ-limited distance between them is at most W must be both contained in at least one cluster. This relaxed requirement allows us to construct pairwise covers efficiently in parallel in time $\tilde{O}(\ell)$. The most technical and novel part of this paper is the construction of pairwise covers. It is also the only place where randomization is used.

We sketch our t-spanner constructions. For any $\beta \geq 2$ and a fixed $\epsilon > 0$, we construct a logarithmic number of pairwise covers for different values of W. We use $W \in \{(1+\epsilon)^i W_{\min} | i > 0\}$, where $W_{\min}$ is the smallest path weight. Our construction of pairwise covers has the property that for every cluster, the algorithm computes a shortest-path tree rooted at a vertex of the cluster such that distances from the root to all other vertices in the cluster are at most β. Hence, distances on the tree between any two vertices in the cluster are bounded by 2β. Roughly, for $t = 2(1+\epsilon)\beta$, the algorithm constructs a t-spanner by considering each cluster in each of the covers and augmenting the spanner with the edges of the respective shortest-paths tree. Our spanner contains a path of stretch t between every pair of vertices. We can obtain t-spanners with the additional property of size-2 paths if the property that the spanner is a subgraph of the original graph is compromised. This can be achieved if for each cluster, instead of adding the edges of the tree to the spanner, we add edges from the root to all other vertices in the cluster with appropriate weights. For every pair of

vertices, our spanner contains a path of stretch t that uses at most two edges. We comment that the sparse neighborhood covers constructed by Awerbuch et al. [2] can similarly be used to obtain spanners, but the resulting spanners have very large size compared with previous spanner algorithms.

The paper is organized as follows. In section 2 we define pairwise covers, state the resource bounds for computing them, and employ them to compute stretch-t paths. In section 3 we discuss the computation of a pairwise cover with respect to parameters W and ℓ. We reduce the problem to finding a cover with respect to a set of integral weights and parameters $\ell' = n$ and $W' = O(\ell)$. In section 4 we discuss computing neighborhoods of vertices up to specified distances using work linear in the size of the neighborhood. Sections 5 and 6 contain the most novel part of the paper. In section 5 we present a parallel algorithm for computing a pairwise cover in integral weighted graphs. The running time of the algorithm is linearly dependent on W, and the work performed is roughly the sum over the clusters of the number of edges incident at cluster vertices. The neighborhoods of section 4 are used in section 5 as the clusters constituting a cover. In section 6 we discuss sequential stretch-t paths algorithms. A randomized sequential algorithm is obtained as a simplified version of the parallel randomized algorithm introduced in previous sections. We note that for the sequential randomized algorithm Sections 2.3, 2.4, 3, and 4 may be skipped. We also present a deterministic algorithm that is based on deterministic construction of covers that is fairly different from the randomized construction used in section 5. Section 7 is concerned with applications to graph spanners. In section 8 we discuss computing stretch-t distances on dynamic networks, where edges are inserted and deleted. In section 9 we discuss issues and open problems that arise from this work.

We remark that although the algorithms presented in this paper compute distances, a concise representation of paths with corresponding weights can be produced within the same resource bounds.

Notation. Consider an undirected graph $G = (V, E)$, with positive weights $w : E \to R_+$ associated with the edges. The *size* of a path is the number of edges in the path. For $\ell \in \mathcal{N}$, an ℓ-limited path is a path of size at most ℓ. We use the terms *shortest-path* and *minimum-weight* path interchangeably for a path of minimum weight. For a subset of edges $E' \subseteq E$, we denote $w(E') = \sum_{e \in E'} w(e)$. For a subset of vertices $V' \subseteq V$, we denote by $\mathcal{E}(V') = \{(u_1, u_2) \in E | u_1 \in V' \wedge u_2 \in V'\}$ the edges in the subgraph induced by V'. For a subset of edges $E' \subseteq E$, two vertices $\{u_1, u_2\} \subseteq V$, an integer $1 \leq \ell \leq n$, and a weight function $\hat{w} : E' \to R_+$, we denote by $\mathrm{dist}^{\ell}_{E',\hat{w}}\{u_1, u_2\}$ the weight, according to $\hat{w}$, of the minimum weight path in E' between u_1 and u_2 that consists of at most ℓ edges. (When ℓ is omitted, presume $\ell = n$, and when E' is omitted, presume $E' = E$. Generally, when the weights $\hat{w}$ are clear from the context they are omitted from the subscript.) For a subset $V' \subseteq V$, a vertex $v \in V'$, an integer $1 \leq \ell \leq n$, and a scalar $W \in R_+$, denote by $N^{\ell}_{W}(V', v) \subset V'$ the set of all the vertices $u \in V'$ such that there exists a path from u to v of size at most ℓ and weight at most W in the subgraph induced by V'. (When $V' = V$, we omit the first parameter. If ℓ is omitted, presume $\ell = n$.) When we state that an algorithm terminates with probability of success $1 - O(1/\operatorname{poly}(n))$, it mean that we can replace $\operatorname{poly}(n)$ by any polynomial by adjusting constant factors in the resource bounds of the algorithm. Note that if algorithms with probability of success $1 - O(1/\operatorname{poly}(n))$ are called as subroutines a polynomial number of times, then all of them terminate successfully with probability $1 - O(1/\operatorname{poly}(n))$.

2. Using pairwise covers for stretched distances. In this section we define pairwise covers and employ them to compute stretch-t paths. We note that in the context of shortest-path computations, the assumption that the weights are strictly positive does not limit the generality since (i) edges of zero weight can be contracted (the contractions can be performed well within the resource bounds of the algorithms presented here by using a connected components algorithm), and (ii) edges of negative weight induce negative cycles (by traversing the edge back and forth) that implies that all the distances between vertices that are in the same connected component as the negative weight edge are unbounded from below.

REMARK 2.1. *We make the following assumption throughout the paper and argue that it does not limit generality. We assume that the ratio of the largest to smallest edge weight in a graph is* $O(\text{poly}(n))$. *(That is,* $\max_{e\in E} w(e)/\min_{e\in E} w(e) = O(\text{poly}(n))$.*) We justify this assumption by using the following reduction of Klein and Sairam* [10] (*see also* [6]) *when the weights are general. Klein and Sairam had shown how to compute for a weighted input graph* G *a collection of weighted graphs with a total number of vertices* $O(n \log n)$ *and total size* $O(m \log n)$ *such that* (i) *in each of the graphs in the collection, the ratio of the largest to smallest edge weights is* $O(\text{poly}(n))$ *and* (ii) *a shortest-path problem on the original graph can be translated efficiently to a shortest-path problem on the graphs of the collection. A path in* G *obtained this way is guaranteed only to have stretch* $(1 + 1/\text{poly}(n))$, *but since in this paper we obtain paths of stretch no better than* 2, *we can safely allow that. The computation involved in obtaining this collection amounts to applying a connected components algorithm and is well within the resource bounds of the algorithms presented here.*

This section is arranged as follows. In subsection 2.1 we define pairwise covers. A pairwise cover of a graph is, roughly, a collection of subsets of vertices (clusters) defined with respect to a scalar $W \in R_+$, an integer ℓ (the *path size* of the cover), and a parameter β. The clusters are such that every pair of vertices with ℓ-limited distance of at most W must be contained in at least one cluster. The parameter β determines a tradeoff between the maximum diameter of a cluster and the size of the cover. In later sections we present algorithms for computing a pairwise cover. We shall see that the parallel running time depends linearly on the path size ℓ, and hence we would like to use covers with small path sizes. In subsection 2.2 we present an algorithm that computes stretched ℓ-limited distances from a set of query vertices to all other vertices. The algorithm utilizes a logarithmic number of pairwise covers with path size ℓ but with different values for the parameter W. Recall that the time bound of our cover algorithm depends linearly on the path size ℓ, and hence we would like to avoid using the algorithm for large values of ℓ. Unfortunately, however, ℓ-limited distances for $\ell < n$ may not yield any information about the actual distances in the graph. To overcome this difficulty we seek a method to replace the current set of edges E by a set of weighted edges E' such that for some $\ell << n$, the ℓ-limited distances in E' are within some factor of the distances with respect to E. The following definition formalizes this concept.

DEFINITION 2.2. *Consider a graph* $G = (V, E)$ *with weights* $w : E \to R_+$, *and a set* $E' \subset V \times V$ *of edges with weights* $w' : E' \to R_+$. *We say that the weighted graph* (V, E') (ℓ, t)-approximates G *if for every pair of vertices* $\{u_1, u_2\} \subset V$, *the following inequalities hold:*

$$\text{dist}_E\{u_1, u_2\} \le \text{dist}_{E'}\{u_1, u_2\} \le \text{dist}^{\ell}_{E'}\{u_1, u_2\} \le t\text{dist}_E\{u_1, u_2\} \ .$$

We refer to the parameter ℓ as the *path size* of the approximation and to the parameter t as the *stretch*. Note that since minimum-weight paths are of size at most n, any graph $(n,1)$-approximates itself. In subsection 2.3 we introduce an algorithm that for an input graph G produces a graph G' that (ℓ,t)-approximates G for some $\ell << n$. The algorithm utilizes pairwise covers with typical path size of n^μ (for small $\mu > 0$) and exhibits a tradeoff between the magnitude of μ and the stretch factor. In subsection 2.4 we combine the algorithms of subsections 2.2 and 2.3 to obtain stretched distances: initially we apply the algorithm of subsection 2.3 to the graph G and obtain an approximation G' of G. Subsequently, we apply the algorithm of subsection 2.2 to G'.

2.1. pairwise covers. Pairwise covers are a modification of sparse neighborhood covers that were introduced by Awerbuch and Peleg [3]. Sparse neighborhood covers were employed by Awerbuch et al. [2] for stretch-t path computations.

DEFINITION 2.3 (pairwise cover). *Consider a graph $G = (V,E)$ with weights $w : E \to R_+$, integers $1 \leq \ell \leq n$ and $\beta = O(\log n)$, and scalars $\rho \in R_+$ and $0 \leq \hat{\epsilon} < 1/2$. A* pairwise $(\ell,\beta,\rho,\hat{\epsilon})$-cover *(for brevity, $(\ell,\beta,\rho,\hat{\epsilon})$-cover) of G is a collection of sets of vertices $X_1,\ldots,X_k$* (clusters) *and vertices $v_1,\ldots,v_k$ (where for $1 \leq i \leq k$, $v_i \in X_i$ is the* center *of the cluster X_i) such that*

1. *$\forall \{u,v\} \subset V$, such that $\mathrm{dist}^\ell\{u,v\} \leq \rho/(1+\hat{\epsilon})$, $\exists i$ such that $\{u,v\} \subset X_i$,*
2. *$\forall i$, $\forall u \in X_i$, $\mathrm{dist}\{v_i,u\} \leq \beta\rho$, and*
3. *$\forall v \in V$, $|\{i | v \in X_i\}| = O(n^{1/\beta}\beta \log n)$. (Every vertex belongs to $O(n^{1/\beta}\beta\log n)$ clusters.)*

In sections 3–5 we present an algorithm that computes an $(\ell,\beta,\rho,\hat{\epsilon})$-cover within the following bounds.

THEOREM 2.4. *An $(\ell,\beta,\rho,\hat{\epsilon})$-cover of G can be computed with probability $1 - O(1/\mathrm{poly}(n))$ in $O(\ell\hat{\epsilon}^{-1}\beta^2 \log n)$ time using $O(n^{1/\beta}m\hat{\epsilon}(\log n)/(\ell\beta))$ processors. If we allow $O(\ell\hat{\epsilon}^{-1}n^\alpha\beta^2)$ time (for a fixed $\alpha > 0$), the cover algorithm uses $O(\beta n^{1/\beta}m \log n)$ work.*

REMARK 2.5. *We remark that a simpler sequential version of the algorithm produces an $(n,\beta,\rho,0)$-cover in $O(mn^{1/\beta}\beta\log n)$ time. The sequential version is immediate after presenting the parallel algorithm, and hence it is omitted.*

The probabilistic behavior manifests itself either in not terminating within the stated resource bounds or by producing a set of clusters for which property 3 of Definition 2.3 does not hold. Note that properties 1 and 2 always hold and property 3 can be easily verified. Hence, we can assume that if the algorithm terminates within the stated resource bounds it returns a valid cover. The algorithm can be modified to compute for each cluster a shortest-paths tree rooted at the center vertex. The tree distances from the center to other vertices in the cluster are at most $\beta\rho$.

2.2. Obtaining stretched limited distances. The inputs to the following algorithm are a graph G with weights $w : E \to R_+$, integers $1 \leq \ell \leq n$ and $\beta \geq 1$, a scalar $0 \leq \hat{\epsilon} \leq 1/2$, and a set of query pairs $Q \subset V \times V$. The algorithm computes for every $\{v,u\} \in Q$ a stretched distance $\tilde{\mathrm{dist}}\{v,u\}$ such that

$$\mathrm{dist}_E\{v,u\} \leq \tilde{\mathrm{dist}}\{v,u\} \leq 2\beta(1+\hat{\epsilon})^2\mathrm{dist}^\ell_E\{v,u\} \ .$$

We remark that the algorithm employs pairwise covers in a similar manner to the use of sparse neighborhood covers made by the Awerbuch et al. [2] algorithm.

ALGORITHM 2.6 (compute distances).

1. $w_{\min} \leftarrow \min_{e \in E} w(e)$
   $w_{\max} \leftarrow \max_{e \in E} w(e)$
   $r \leftarrow \lceil \log_{1+\hat{\epsilon}}(n w_{\max}/w_{\min}) \rceil$
   For $i = 0, \ldots, r$: $w_i \leftarrow w_{\min}(1+\hat{\epsilon})^i$
2. *For* $i = 0, \ldots, r$ *do (in parallel):*
   (a) *Compute* $(\ell, \beta, w_i, \hat{\epsilon})$*-cover* χ_i
   (b) *For each vertex* $v \in V$, $x(i,v) \leftarrow \{X \in \chi_i | v \in X\}$.
   (The sets $x(i,v)$ *are sorted lists of indexes of clusters.)*
3. *For all* $\{v,u\} \in Q$: $\tilde{\text{dist}}\{v,u\} \leftarrow 2\beta w_i$,
   where $i \leftarrow \min\{j | x(j,u) \cap x(j,v) \neq \emptyset\}$.

Correctness. Consider a pair of vertices $\{v,u\} \in Q$. Let $i = \min\{j | x(j,u) \cap x(j,v) \neq \emptyset\}$. It suffices to show that

1. $\text{dist}_E\{v,u\} \leq 2\beta w_i = \tilde{\text{dist}}_E\{v,u\}$ and
2. $\tilde{\text{dist}}_E\{v,u\}/(2\beta(1+\hat{\epsilon})^2) = w_i/(1+\hat{\epsilon})^2 \leq \text{dist}^{\ell}_E\{v,u\}$.

Let $X \in \chi_i$ be such that $\{u,v\} \subset X$. (The existence of such an X is immediate from the selection of i.) The first inequality follows from property 2 of a cover (see Definition 2.3). We prove that the second inequality holds. If $i = 0$, the proof is immediate since for any two vertices $\{u_1,u_2\}$, $\text{dist}^{\ell}_E\{u_1,u_2\} \geq \text{dist}_E\{u_1,u_2\} \geq w_0$. It follows from property 1 of a cover that if some j is such that $\text{dist}^{\ell}_E\{v,u\} \leq w_j/(1+\hat{\epsilon})$, then there exists $X \in \chi_j$ for which $\{v,u\} \subset X$, and hence, $x(j,u) \cap x(j,v) \neq \emptyset$. For every $j < i$, $x(j,u) \cap x(j,v) \neq \emptyset$. Therefore, $\text{dist}^{\ell}_E\{v,u\} > w_j/(1+\hat{\epsilon})$. Thus, taking $j = i-1$ we get $\text{dist}^{\ell}_E\{v,u\} > w_{i-1}/(1+\hat{\epsilon}) = w_i/(1+\hat{\epsilon})^2$.

Complexity. Recall (see Remark 2.1) that we assume $w_{\max}/w_{\min} = O(\log n)$ and therefore $r = O(\log n/\log(1+\hat{\epsilon})) = O(\hat{\epsilon}^{-1}\log n)$. Consider performing step 2 for one value $0 \leq i \leq r$. It follows from Theorem 2.4 that with probability $1 - O(1/\text{poly}(n))$, the construction of the cover χ_i can be performed in $O(\ell\hat{\epsilon}^{-1}\log n\beta^2)$ time using $O(mn^{1/\beta}\hat{\epsilon}/(\ell\beta))$ processors. (Thus, using $O(mn^{1/\beta}\beta\log n)$ work.) Hence, with probability $(1-1/\text{poly}(n))^r = 1 - O(1/\text{poly}(n))$, the computation of all the covers $\chi_1, \ldots, \chi_r$ terminates within $O(\ell\hat{\epsilon}^{-1}\log n\beta^2)$ time and $O(\hat{\epsilon}^{-1}mn^{1/\beta}\beta\log^2 n)$ work. It follows from standard PRAM techniques that the construction of the sets $x(i,v)$ (for all $v \in V$) can be performed in $T = \Omega(\log n)$ time using $O(\sum_{X \in \chi_i}|X|(\log n)/T) = O(n^{1+1/\beta}\beta\log^2 n/T)$ processors or, when allowing $\Omega(n^{\alpha})$ time for a fixed $\alpha > 0$, using $O(n^{1+1/\beta}\beta\log n)$ work. (Since property 3 of Definition 2.3 implies that $\sum_{X \in \chi_i}|X| = O(n^{1+1/\beta}\beta\log n)$.) The computation of the stretched distances (step 3) can be performed in $T = \Omega(r)$ time using

$$O\left(\sum_{\{v,u\} \in Q}\sum_{i}(|x(i,u)| + |x(i,v)|)/T\right) = O(\hat{\epsilon}^{-1}|Q|n^{1/\beta}\beta\log^2 n/T)$$

processors (since property 3 asserts that for all $v \in V$ and $1 \leq i \leq r$, $|x(i,v)| \leq n^{1/\beta}\beta\log n$). Hence, Algorithm 2.6 can be implemented to run in $O(\ell\hat{\epsilon}^{-1}\log n\beta^2)$ time using $O((m+|Q|)n^{1/\beta}\hat{\epsilon}^{-1}\beta\log^3 n)$ work and have probability of success $1 - O(1/\text{poly}(n))$ (or when allowing $\Omega(\ell\hat{\epsilon}^{-1}n^{\alpha}\beta^2)$ time using $O((m+|Q|)n^{1/\beta}\hat{\epsilon}^{-1}\beta\log^3 n)$ work).

2.3. Obtaining approximations with small path size. In this subsection we present an algorithm that produces approximations (in the sense of Definition 2.2) with small path sizes for input graphs. The algorithm inputs a weighted graph $G =$

(V,E), with weights $w : E \to R_+$, integers $1 \leq \ell' \leq n$ and $\beta \geq 1$, and a scalar $0 \leq \hat{\epsilon} \leq 1/2$. The algorithm computes a set of edges $E' \subset V \times V$ with weights $w' : E' \to R_+$ such that

1. $|E'| = O(\hat{\epsilon}^{-1} n^{1+1/\beta} \beta \log^2 n)$, and
2. for every $\ell' \leq \ell \leq n$ and every pair of vertices $\{u_1, u_2\} \subset V$ the following holds:

$$\mathrm{dist}_E\{u_1,u_2\} \leq \mathrm{dist}_{E'}\{u_1,u_2\}$$

$$\leq \mathrm{dist}^{2\lceil \ell/\ell' \rceil}_{E'}\{u_1,u_2\} \leq 2\beta(1+\hat{\epsilon})^2 \mathrm{dist}^{\ell}_{E}\{u_1,u_2\} \ .$$

Hence, the graph (V,E') is a $(2\lceil n/\ell' \rceil, 2\beta(1+\hat{\epsilon})^2)$-approximation of G. Furthermore, if $G=(V,E)$ is an (ℓ,t)-approximation of some graph $(V,\hat{E})$ for some parameters ℓ and t, then the graph (V,E') produced by the algorithm is a $(2\lceil \ell/\ell' \rceil, 2t\beta(1+\hat{\epsilon})^2)$-approximation of $(V,\hat{E})$. We first present the algorithm and analyze its resource bounds. Later on we study and analyze the resource bounds of repeated applications of the algorithm.

ALGORITHM 2.7 (approximation with small path size).

1. $w_{\min} \leftarrow \min_{e \in E} w(e)$
   $w_{\max} \leftarrow \max_{e \in E} w(e)$
   $r \leftarrow \lceil \log_{1+\hat{\epsilon}}(n w_{\max}/w_{\min}) \rceil$
   For $i = 0, \ldots, r$: $w_i \leftarrow w_{\min}(1+\hat{\epsilon})^i$
   $E' \leftarrow \emptyset$

2. *For* $i = 0, \ldots, r$ *do (in parallel):*
   (a) *Compute* $(\ell', \beta, w_i, \hat{\epsilon})$*-cover* χ_i
   (b) *For each cluster* $X \in \chi_i$ *with center* $v \in X$*:*
   add to E' *edges of weight* $w_i\beta$ *from* v *to all other vertices in* X*:*
   $E' \leftarrow E' \bigcup_{X \in \chi_i} \{(v,u) | u \in X\}$
   $\forall u \in X, w'((v,u)) \leftarrow w_i\beta$

Correctness. We first bound the size of E'. Observe that when executing step 2 for some value $0 \leq i \leq r$, at most $\sum_{X \in \chi_i} |X-1|$ edges are produced for E'. Hence, it follows from property 3 of Definition 2.3 and the assumption that $r = O(\hat{\epsilon}^{-1} \log n)$ (see subsection 2.2) that when the algorithm terminates $|E'| = O(\hat{\epsilon}^{-1} n^{1+1/\beta} \beta \log^2 n)$. It remains to show that distances in (V,E') comply with the stated inequalities. It follows from the construction of E' and property 2 of Definition 2.3 that if $e = (u_1,u_2) \in E'$ then $w'(e) \geq \mathrm{dist}_E\{u_1,u_2\}$. Hence, for every pair of vertices $\{u_1,u_2\} \subset V$, $\mathrm{dist}_E\{u_1,u_2\} \leq \mathrm{dist}_{E'}\{u_1,u_2\}$. (Thus, the leftmost inequality holds.) We show that the rightmost inequality holds. Consider a pair of vertices $\{u_1,u_2\} \subset V$ and let $D = \mathrm{dist}^{\ell'}_E\{u_1,u_2\}$. We show that there exists a path p of size at most 2 between u_1 and u_2 in E' such that $w'(p) \leq 2\beta(1+\hat{\epsilon})^2 D$. Let $i = \min\{j | \exists X \in \chi_j \text{ s.t. } \{u_1,u_2\} \subset X\}$. We have $D > w_i/(1+\hat{\epsilon})^2$ (by an argument similar to the one given in the correctness analysis of Algorithm 2.6). Let $X \in \chi_i$ be such that $\{u_1,u_2\} \subset X$ and let v be the center of X. We assume (without loss of generality) that if $v \in \{u_1,u_2\}$ then $v = u_2$. By definition of E', the edges $e_1 = (v,u_1)$ and (if $u_2 \neq v$) $e_2 = (v,u_2)$ are contained in E' and are such that $w'(e_1) = w'(e_2) = \beta w_i$. Hence (if $u_2 \neq v$), the edges e_1 and e_2 constitute a path p of size 2 between u_1 and u_2 in E' of weight $w'(p) = 2\beta w_i$. If $u_2 = v$, then the edge $e_1 = (u_1,u_2) \in E'$ constitutes a path p of size 1 and weight $w'(e_1) = \beta w_i$ between u_1 and u_2. Since $D > w_i/(1+\hat{\epsilon})^2$, we conclude that $w'(p) \leq 2\beta(1+\hat{\epsilon})^2 D$.

Consider a path p of size at most ℓ in E. To conclude the correctness proof, it suffices to show that there exists a path p' of size at most $2\lceil \ell/\ell' \rceil$ in E' such that $w'(p') \leq 2\beta(1+\hat{\epsilon})^2 w(p)$. Treat p as a list of edges and consider a partition of p to $k \leq \lceil \ell/\ell' \rceil$ segments $p_1, \ldots, p_k$, each of size at most ℓ'. By the argument given above, for each segment p_i $(1 \leq i \leq k)$ there is a corresponding path p'_i in E' of size at most 2 between the end vertices of p_i such that $w'(p'_i) \leq 2\beta(1+\hat{\epsilon})^2 w(p_i)$. Denote $p' = \bigcup_{i=1}^{k} p'_i$. Note that the size of p' is at most $2k \leq 2\lceil \ell/\ell' \rceil$ and that

$$w'(p') = \sum_{i=1}^{k} w'(p'_i) \leq 2\beta(1+\hat{\epsilon})^2 \sum_{i=1}^{k} w(p_i) = w(p) \ .$$

Complexity. The complexity of the algorithm is dominated by the computation of the covers at step 2. The algorithm performs step 2 in parallel for $r = O(\hat{\epsilon}^{-1} \log n)$ values of i. Hence, it follows from Theorem 2.4 that Algorithm 2.7 can be implemented to run with probability of success $1 - O(1/\operatorname{poly}(n))$ in $O(\ell' \hat{\epsilon}^{-1} \log n \beta^2)$ time using $O(\hat{\epsilon}^{-1} m n^{1/\beta} \beta \log^3 n)$ work (or, alternatively, in $\Omega(\ell' \hat{\epsilon}^{-1} n^{\alpha} \beta^2)$ time using $O(\hat{\epsilon}^{-1} m n^{1/\beta} \beta \log^2 n)$ work).

Repeated applications of Algorithm 2.7. Algorithm 2.7 can be applied repeatedly to obtain approximations of smaller path size but larger stretch. In each run, the algorithm is applied to the set of edges produced by the previous run. Suppose a graph (V, E) is an (ℓ, t)-approximation of some graph $(V, \hat{E})$. Consider k (for meaningful results we always have $k = o(\log n)$) repeated applications of Algorithm 2.7 starting with (V, E). Denote by E_i the set of edges computed by the ith run of the algorithm (where $E_0 \equiv E$). The graph (V, E_i) is the input for the $i+1$st run of the algorithm. Note that for $i > 0$, $|E_i| = O(\hat{\epsilon}^{-1} n^{1+1/\beta} \beta \log^2 n)$. Hence, the resulting resource bounds for k repeated applications of the algorithm are $O(k\ell' \hat{\epsilon}^{-1} \log n \beta^2)$ time using $O(\hat{\epsilon}^{-1} m n^{1/\beta} \beta \log^2 n + k\hat{\epsilon}^{-2} n^{1+2/\beta} \beta^2 \log^4 n)$ work. The set E_k produced by the kth run of the algorithm is such that (V, E_k) constitutes a $(2^k \lceil \ell/(\ell')^k \rceil, t(1+\hat{\epsilon})^{2k}(2\beta)^k)$-approximation of $(V, \hat{E})$. We typically use the above where $\hat{\epsilon}$ and k are fixed constants. We remark that under some conditions we can get further improvements on the above bounds. Note that the work bound stated above may have an imbalance between the two terms. If $m >> n^{1+1/\beta}$ we can "afford" smaller values of β and within the same resource bounds achieve smaller stretch. Suppose we use for the parameter β the values β_1 and $\beta_2 = 1/(\log_n m - 1)$ alternatingly in repeated applications of the algorithm. In the first run, that is applied to the graph (V, E), we use β_1. We assume that k and $\hat{\epsilon}$ are fixed. It follows that the algorithm runs in $O(\ell' \log n(\beta_1^2 + \beta_2^2))$ time using $O(m n^{1/\beta_1} \log^4 n)$ work. The graph (V, E_k) is a $(2^k \lceil \ell/(\ell')^k \rceil, t 2^k \beta_1^{\lceil k/2 \rceil} \beta_2^{\lfloor k/2 \rfloor} (1+\hat{\epsilon})^{2k})$-approximation of $(V, \hat{E})$.

2.4. Computing stretched distances. Observe that any weighted graph is an $(n, 1)$-approximation of itself. We can obtain stretch-t paths in a graph (V, E) by (i) applying Algorithm 2.7 repeatedly to obtain an approximation (V, E') of (V, E) with small path size, and (ii) applying Algorithm 2.6 to (V, E').

THEOREM 2.8. *For a weighted graph $G = (V, E)$, a set of query pairs $Q \subset V \times V$, a scalar $\beta \geq 1$, and fixed $0 \leq \epsilon \leq 1$ and $0 \leq \delta \leq 1$, we can obtain paths with stretch*

$$(2\beta)^{\lceil 1/\delta \rceil}(1+\epsilon)$$

between all pairs of vertices in Q in $O(n^{\delta} \log n \beta^2)$ time using $O(n^{1+2/\beta} \beta^2 \log^4 n + (m + |Q|) n^{1/\beta} \beta \log^2 n)$ work with probability of success $1 - O(1/\operatorname{poly}(n))$.

Proof. We choose $k = \lceil 1/\delta \rceil - 1$ and $\hat{\epsilon} < (1+\epsilon)^{(-2\lceil 1/\delta \rceil)} - 1$. We apply k repeated application of Algorithm 2.7 to (V, E) with $\ell' = 2n^{\delta}$. Denote by (V, E') the resulting graph (obtained with probability $1 - O(1/\operatorname{poly}(n))$. It follows (see subsection 2.3) that (V, E') constitutes an approximation of (V, E) with path size $\lceil n^{\delta} \rceil$ and stretch

$$(2\beta(1+\hat{\epsilon})^2)^k.$$

The graph (V, E') is obtained in $O(n^{\delta} \log n \beta^2)$ time using

$$O(n^{1+2/\beta}\beta^2 \log^4 n + mn^{1/\beta}\beta \log^2 n)$$

work. We apply Algorithm 2.6 to (V, E') with parameter $\ell = \lceil n^{\delta} \rceil$ and query set Q. We return the stretched distances found by Algorithm 2.6. It is easy to verify that these distances are within a factor of

$$(2\beta(1+\hat{\epsilon})^2)^{\lceil 1/\delta \rceil} \leq (2\beta)^{\lceil 1/\delta \rceil}(1+\epsilon)$$

of the corresponding shortest distances in G. The resource bounds of the application of Algorithm 2.6 are $O(n^{\delta} \log n \beta^2)$ time using $O((|E'| + |Q|)n^{1/\beta}\beta \log^2 n)$ work. By combining the above we obtain the stretch and resource bounds claimed in the statement of the theorem.

It follows that for any fixed $\epsilon > 0$, by choosing $\delta < \epsilon$ and $\beta > 2/\epsilon$, paths with constant stretch can be obtained in $O(n^{\epsilon})$ time using $O(n^{\epsilon}(|Q| + n))$ work. In [6] the author presented an algorithm that for an input graph $G = (V, E)$ and parameter $\mu \geq 0.5$ produces a graph that is a $(6n^{1-\mu} \log^3 n, 1 + 1/\operatorname{poly}(n))$-approximation of G. The graph obtained has $O(m + n^{1+\mu} \log n)$ edges and the algorithm uses $O(n^{1+2\mu} \log n)$ work and runs in $\Omega(\log^2 n \log^* n)$ time, We utilize this to improve on the tradeoffs stated in Theorem 2.8. We obtain the following theorem.

THEOREM 2.9. *For $0.5 \leq \mu \leq 1$ and fixed constants $0 \leq \delta \leq 1$ and $\epsilon > 0$, we can obtain (with probability $1 - O(1/\operatorname{poly}(n))$) paths with stretch*

$$(2\beta)^{\lceil (1-\mu)/\delta \rceil}(1+\epsilon)$$

between all pairs of vertices in a given set $Q \subset V \times V$ in $O(n^{\delta} \log n \beta^2)$ time using

$$O(n^{1+2\mu} \log n + n^{1+2/\beta}\beta^2 \log^4 n + (m + n^{1+\mu} \log n + |Q|)n^{1/\beta}\beta \log^2 n)$$

work.

Proof. We use a simple modification of the proof of Theorem 2.8 where we start with the graph G obtained by applying the algorithm of [6] with parameter μ.

3. Computing an $(\ell, \beta, \rho, \hat{\epsilon})$-cover. In this section we reduce the problem of finding an $(\ell, \beta, \rho, \hat{\epsilon})$-cover in a graph $G = (V, E)$ with weights $w : E \to R_+$ to a problem of finding a $(\beta, 2\ell\hat{\epsilon}^{-1})$-cover in (V, E) with respect to some integral weights $\bar{w} : E \to \mathcal{N}$. We define (β, W)-cover of a weighted graph to be an $(n, \beta, W, 0)$-cover of the graph (see Definition 2.3). The weights $\bar{w}$ are obtained by scaling and rounding up the weights w. The reduction is based on a technique and ideas from Klein and Sairam [10]. The weights $\bar{w}$ are computed as follows.

ALGORITHM 3.1 (generate integral weights $\bar{w}$).

1. $\pi \leftarrow 2\ell\hat{\epsilon}^{-1}/\rho$
2. *For all $e \in E$, let $\bar{w}(e) \leftarrow \lceil \pi w(e) \rceil$ $(e \in E)$*

Complexity. Using standard PRAM techniques, Algorithm 3.1 can be performed in $O(\log n)$ time using $O(m)$ work.

The weights $\bar{w} : E \to \mathcal{N}$ have the following properties.

PROPOSITION 3.2. *For every pair of vertices, $\{u_1, u_2\} \subset V$,*

1. $\pi \text{dist}^{\ell}_{E,w}\{u_1, u_2\} \geq \text{dist}_{E,\bar{w}}\{u_1, u_2\} - \ell$ *and*
2. $\pi \text{dist}_{E,w}\{u_1, u_2\} \leq \text{dist}_{E,\bar{w}}\{u_1, u_2\}$.

Proof. Observe that for every path p of size $k = |p|$,

$$\bar{w}(p) - k \leq \pi w(p) \leq \bar{w}(p) \ .$$

Part 2 is immediate from the right inequality. We apply the left inequality to prove part 1. Let $\hat{p}$ be the path that minimizes $w(\hat{p})$ among all paths of size at most ℓ between u_1 and u_2. We have

$$\pi \text{dist}^{\ell}_{E,w}\{u_1, u_2\} = \pi w(\hat{p}) \geq \bar{w}(\hat{p}) - |p| \geq \text{dist}_{E,\bar{w}}\{u_1, u_2\} - \ell \ .$$

DEFINITION 3.3 ((β, W)-covers of graphs). *For a given graph $G = (V, E)$ with integral weights $w : E \to \mathcal{N}$, a scalar $W \geq 1$ and an integer $\beta = O(\log n)$, a (β, W)-cover of G is a collection of sets of vertices $X_1, \ldots, X_k$ (clusters) and vertices $v_1, \ldots, v_k$ where $v_i \in X_i$ (centers) such that*

1. *$\forall \{u, v\} \subset V$ such that $\text{dist}\{u, v\} \leq W$, $\exists i$ such that $\{u, v\} \subset X_i$,*
2. *$\forall i$ for all $u \in X_i$, $\text{dist}\{v_i, u\} \leq \beta W$, and*
3. *for every $v \in V$, $|\{i | v \in X_i\}| = O(n^{1/\beta} \beta \log n)$.*

In section 5 we present a randomized algorithm that computes a (β, W)-cover of an input graph G with integral edge weights. The algorithm runs in $O(W\beta^2 \log n)$ time using $O(n^{1/\beta} m/(W\beta))$ processors and computes a cover with probability $1 - O(1/\text{poly}(n))$.

We discuss computing an $(\ell, \beta, \rho, \hat{\epsilon})$-cover in a graph $G = (V, E)$ with weights $w : E \to R_+$. Consider applying Algorithm 3.1 to obtain the weights $\bar{w} : E \to \mathcal{N}$. Define $W = \pi\rho = 2\ell\hat{\epsilon}^{-1}$. Let $X_1, \ldots, X_k$ with corresponding centers $v_1, \ldots, v_k$ be a (β, W)-cover of (V, E) with respect to the weights $\bar{w}$.

PROPOSITION 3.4. *The sets $X_1, \ldots, X_k$ with corresponding centers $v_1, \ldots, v_k$ constitute an $(\ell, \beta, \rho, \hat{\epsilon})$-cover of G.*

Proof. We prove that condition 1 of Definition 2.3 holds for $X_1, \ldots, X_k$. Consider a pair of vertices $\{u_1, u_2\} \subset V$ such that $\text{dist}^{\ell}_{E,w}\{u_1, u_2\} \leq \rho/(1 + \hat{\epsilon})$. It follows from Proposition 3.2 that

$$\text{dist}_{E,\bar{w}}\{u_1, u_2\} \leq \pi \text{dist}^{\ell}_{E,w}\{u_1, u_2\} + \ell \leq W(1/(1 + \hat{\epsilon}) + \hat{\epsilon}/2) \leq W \ .$$

Hence, from condition 1 of Definition 3.3, for some i, $\{u_1, u_2\} \subset X_i$. We show that condition 2 of Definition 2.3 holds. Consider $1 \leq i \leq k$ and $u \in X_i$. It follows from Proposition 3.2 that $\pi \text{dist}_{E,w}\{v_i, u\} \leq \text{dist}_{E,\bar{w}}\{v_i, u\}$. Condition 2 of Definition 3.3 asserts that $\text{dist}_{E,\bar{w}}\{v_i, u\} \leq \beta W \leq \pi\beta\rho$. Hence, $\text{dist}_{E,w}\{v_i, u\} \leq \beta\rho$ and thus condition 2 holds. The validity of condition 3 is immediate from condition 3 of Definition 3.3.

Proposition 3.4 asserts that an $(\ell, \beta, \rho, \hat{\epsilon})$-cover of G with weights w can be computed within the same resource bounds as a $(\beta, 2\ell\hat{\epsilon}^{-1})$-cover of G with weights $\bar{w}$. The proof of Theorem 2.4 follows using the bounds for computing a (β, W)-cover stated above.

4. Computing neighborhoods. In this section we present a parallel algorithm for computing neighborhoods of vertices in a graph $G = (V, E)$ with integral weights $w : E \rightarrow \mathcal{N}$. The k-neighborhood of a vertex v, $N_k(v)$ is the set of vertices of distance at most k from v. The time depends linearly on k (the radius of the neighborhood) and the work performed is linear in $\mathcal{E}(N_k(v))$, the number of edges between vertices in the neighborhood.

We assume that the input is such that at each vertex, the incident edges are sorted into a list of "buckets" according to increasing weights. (Note that this can be achieved in $O(\log^2 n)$ time and either $O(m \log n)$ work using comparison-based sorting or $O(m)$ work, since weights are integral and for the purposes of this paper it suffices to consider weights that are of size at most $W = O(\hat{\epsilon}^{-1}n)$.) We prove the following.

PROPOSITION 4.1. *For a set of integers $k_1, \ldots, k_r$, and a set of vertices $s_1, \ldots, s_r$, the computation of $N_{k_i}(s_i)$ for $i = 1. \ldots, r$ can be performed using p processors in time*

$$O\left((\max_i k_i \log n) + \sum_{i=1}^{r} |\mathcal{E}(N_{k_i}(s_i))|(\log n)/p\right) .$$

Or, alternatively, for any fixed $\alpha > 0$, in

$$\text{time } \Omega(\max_i k_i n^{\alpha}) \text{ and work } O\left(\sum_{i=1}^{r} |\mathcal{E}(N_{k_i}(s_i))|\right) .$$

The algorithm essentially amounts to performing, in parallel for s_i $(1 \leq i \leq r)$ a weighted parallel BFS computation from s_i while considering only paths of weight at most k_i.

We present a weighted parallel BFS algorithm from a vertex s in G. The algorithm is a straightforward generalization of a parallelization of the standard sequential BFS algorithm used by Ullman and Yannakakis [14]. A weighted version of the parallel BFS algorithm was also used by Klein and Sairam [10].

The algorithm consists of iterations where in the ith iteration $(i \geq 0)$ the algorithm computes the set $\text{level}_i(s) \subset V$ of all vertices of distance i from s. The algorithm terminates when a stopping condition is met.

ALGORITHM 4.2 (weighted Parallel BFS from s).

1. $\text{level}_0(s) \leftarrow \{s\}$
   $F = \{s\}$
   $i \leftarrow 0$
2. **Repeat:**
   $i \leftarrow i + 1$
   $\text{level}_i(s) \leftarrow \{v \in V \setminus F | \exists j < i \exists u \in \text{level}_j(s) \text{ s.t. } (v, u) \in E \wedge w(v, u) = i - j\}$
   $F = F \cup \text{level}_i(s)$
   Until: *stopping condition is satisfied*

Correctness. It is easy to verify that after the ith iteration,

$$\text{level}_i(s) = \{u \in V | \text{dist}_E\{s, u\} = i\} .$$

Complexity. We outline an EREW PRAM implementation of the algorithm and analyze the resulting resource bounds.

We assume that at each vertex $u \in V$ there is a list of "buckets" containing a partition of the vertices adjacent to u. The partitioning of adjacent vertices to buckets is done by sorting the edges incident at u. Adjacent vertices are placed in buckets

according to the weight of the edge to the vertex u. The buckets are maintained in a list, according to increasing weights, such that each bucket has a pointer to the nonempty bucket of next larger weight. For a vertex u and integer j, we denote by $B(u,j)$ the bucket of adjacent vertices to u through edges of weight j. The algorithm also maintains a partition of the vertices in F as a list of sets A_j ($j > 0$). The partition is modified in the course of the algorithm. At the termination of iteration i, a vertex $u \in \text{level}_j(s)$ (for $j < i$) is placed in the set A_{c_u+j}, where c_u is the smallest weight of an edge incident at u such that $c_u + j > i$. Note that at iteration i it suffices to examine vertices in A_{i+1} to determine the $i+1$st level.

We specify the actions of the algorithm in the ith iteration. The algorithm examines (in parallel) the vertices in A_i. For each $u \in A_i \cap \text{level}_j(s)$, the algorithm scans the vertices in $B(u, i-j)$. For each $u' \in B(u, i-j)$ the algorithm does as follows. If $u' \notin F$, it is placed in $\text{level}_i(s)$. The vertex u' is placed in a set $A_{i'}$, where $i' = i + \min\{j' | B(u', j') \neq \emptyset\}$. The vertex u is replaced in a different set $A_{i''}$ ($i'' > i$), according to the weight of the next nonempty bucket on its bucket list $i'' = i + \min\{j' > i - j | B(u, j') \neq \emptyset\}$. It follows from standard EREW PRAM techniques that the ith iteration can be performed in $O(\log n)$ time using $\sum_{j<i} \sum_{u \in \text{level}_j(s)} |B(u, i-j)| \log n$ work or, alternatively, in $\Omega(n^\alpha)$ time using $\sum_{j<i} \sum_{u \in \text{level}_j(s)} |B(u, i-j)|$ work.

Consider performing instances of the above computation in parallel for a set of sources $s_1, \ldots, s_r$, where the computation for a source s_i is done for up to $k_i \leq \ell$ ($1 \leq i \leq r$) iterations. The ith iterations (for $0 \leq i \leq \ell$) of all instances are performed in parallel. Hence, with p available processors, the ith iterations of all instances can be performed in

$$O\left(\log n + \sum_{h=1}^{r} \sum_{j<i} \sum_{u \in \text{level}_j(s_h)} |B(u, i-j)|(\log n)/p\right)$$

time or alternatively in

$$O\left(n^\alpha + \sum_{h=1}^{r} \sum_{j<i} \sum_{u \in \text{level}_j(s_h)} |B(u, i-j)|/p\right)$$

time. For $1 \leq j \leq r$, denote by F_j the set F generated by the instance of the algorithm for the source s_j. Note that for all $1 \leq h \leq r$,

$$\sum_{i \leq r} \sum_{j<i} \sum_{u \in \text{level}_j(s_h)} |B(u, i-j)| = 2|\mathcal{E}(F_h)| \ .$$

It follows that the ℓ iteration of Algorithm 4.2 can be performed in time

$$O\left(\ell \log n + \sum_{s \in S} |\mathcal{E}(F_s)|(\log n)/p\right)$$

(or, alternatively, in time $O(\ell n^\alpha)$ and work $O(\sum_{s \in S} |\mathcal{E}(F_s)|/p)$). This concludes the proof of Proposition 4.1.

REMARK 4.3 (computing neighborhoods sequentially). *Consider a graph with weights $w : E \to R_+$, a scalar ρ, and a vertex s. The goal is to compute $N_{k\rho}(s)$ where*

k is the first j such that $N_{j\rho}(s)$ satisfies some desired easy-to-check property. Assume that G is represented in a way that the edges incident at each vertex can be accessed in order according to increasing weight. A simple modification of the sequential BFS algorithm can compute $N_{k\rho}(s)$ in $|\mathcal{E}(N_{k_i\rho}(s_i))|$ time. The algorithm uses $O(k+n)$ additional storage for maintaining a partition of the vertices into sets $A_j (1 \le j \le k)$. The latter partition is used in a similar fashion to the partition maintained by the parallel algorithm stated above.

5. Computing a (β, W)-cover. In this section we present and analyze an algorithm that computes a (β, W)-cover χ for an input graph $G = (V, E)$ with integral weights $w : E \to \mathcal{N}$.

DEFINITION 5.1. *For $V' \subset V$, $v \in V'$, and an integer $k \ge 0$, define*

1. $\mathrm{core}(v, k, V') = N_{kW}(V', v)$ *and*
2. $\mathrm{cluster}(v, k, V') = N_{(k+1)W}(V', v)$.

The following proposition states some easy-to-verify properties.

PROPOSITION 5.2.

1. *For $V' \subset V$, $k \in \mathcal{N}$, and $\{v_1, v_2\} \subset V'$: $v_1 \in \mathrm{core}(v_2, k, V')$ if and only if $v_2 \in \mathrm{core}(v_1, k, V')$. Similarly, $v_1 \in \mathrm{cluster}(v_2, k, V')$ if and only if $v_2 \in \mathrm{cluster}(v_1, k, V')$.*
2. *For $V' \subset V$, $k \in \mathcal{N}$, and $u \in \mathrm{cluster}(v, k, V')$, $\mathrm{dist}_E\{v, u\} \le \mathrm{dist}_{\mathcal{E}(V')}\{v, u\} \le (k+1)W$.*
3. *For integers $k_2 < k_1$, subsets $V_2 \subseteq V_1 \subseteq V$, and $v \in V_2$:*

$$\mathrm{core}(v, k_2, V_2) \subseteq \mathrm{cluster}(v, k_2, V_2) \subseteq \mathrm{core}(v, k_1, V_1) \subseteq \mathrm{cluster}(v, k_1, V_1) \ .$$

ALGORITHM 5.3 (compute a (β, W)-cover χ).

1. $V_1 \leftarrow V$, $\chi \leftarrow \emptyset$
2. *For $i = 1, \ldots, \beta$:*
   (a) *Choose uniformly at random a set $S_i \subset V_i$ of size $\lceil Cn^{i/\beta}|V_i|(\log n)/n \rceil$ ($C \ge 1$ is some constant, where the value of C determines the probability that the algorithm terminates correctly.)*
   If $|V_i| < \lceil Cn^{i/\beta}|V_i|(\log n)/n \rceil$ choose $S_i \leftarrow V_i$
   Let $k_i \leftarrow \beta - i$
   (b) *Perform, in parallel for $v \in S_i$, a computation of* $\mathrm{core}(v, k_i, V_i)$, $\mathrm{cluster}(v, k_i, V_i)$.
   (*Use the algorithm of section* 4.)
   (c) $\chi \leftarrow \chi \cup \{\mathrm{cluster}(v, k_i, V_i) | v \in S_i\}$
   (d) $V_{i+1} \leftarrow V_i \setminus \bigcup_{v \in S_i} \mathrm{core}(v, k_i, V_i)$
   If $V_{i+1} = \emptyset$, stop.

Figure 1 illustrates the clusters produced by the algorithm. In the first iteration, we select a small number of neighborhoods with a large radius. In following iterations, we select larger number of neighborhoods with smaller radiuses. The algorithm is such that with high probability these neighborhoods do not contain many vertices.

Note that the condition $|V_i| < \lceil Cn^{i/\beta}|V_i|(\log n)/n \rceil$ must occur for some i. When $|V_i| < \lceil Cn^{i/\beta}|V_i|(\log n)/n \rceil$, the current iteration is last. Since $S_i = V_i$, for all $v \in V_i$, $v \in \mathrm{core}(v, k_i, V_i)$ and hence $V_{i+1} = \emptyset$. Therefore, we have $V \equiv V_1 \supset V_2 \supset \cdots \supset V_t = \emptyset$, where $i = t - 1$ in the last iteration.

In the remaining part of this section we prove the following theorem.

THEOREM 5.4. *With probability $1 - O(1/\mathrm{poly}(n))$, Algorithm* 5.3 *is*

1. *correct, that is, χ constitutes a (β, W)-cover of G; and*

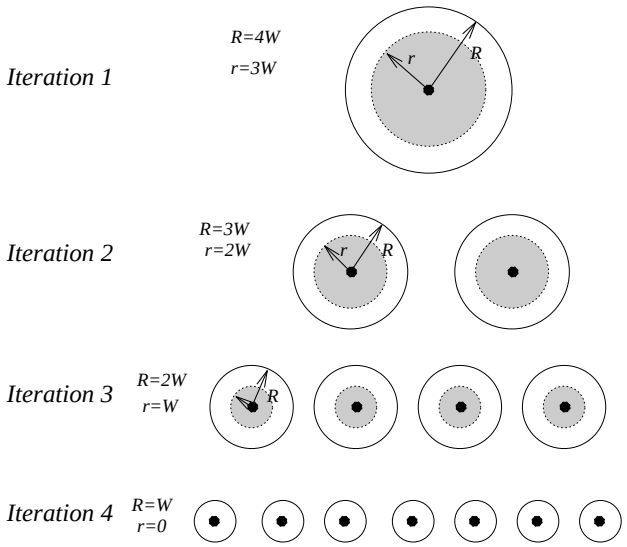

FIG. 1. *Clusters produced by the algorithm with* $\beta = 4$.

2. *can be implemented to run in* $O(W\beta^2 \log n)$ *time using* $O(n^{1/\beta}m/(W\beta))$ *processors; hence, performing* $O(n^{1/\beta}m\beta \log n)$ *work.*

PROPOSITION 5.5. *For every pair of vertices* $\{u_1, u_2\} \subset V$, *if* $\text{dist}_E\{u_1, u_2\} \leq W$, *then* $\exists X \in \chi$ *such that* $\{u_1, u_2\} \subset X$.

Proof. Let $\{u_1, u_2\} \subset V$ be such that $\text{dist}_E\{u_1, u_2\} \leq W$ and let p be a path in (V, E) of weight at most W between u_1 and u_2. During this proof we interchangeably refer to p as the path as a whole or as the set of vertices of p. Since $\{u_1, u_2\} \subset p$, it suffices to show that $p \subset X$ for some $X \in \chi$. Let j be such that $p \subset V_j$ but $p \not\subset V_{j+1}$. Note that j is well defined since the sets V_i $(i \geq 1)$ are monotonically decreasing and include the set of all vertices and the empty set. Denote by χ_j the assignment of χ at the end of the jth iteration. We show that $\exists X \in \chi_j$ such that $p \subset X$. Let $u \in p$ be such that $u \notin V_{j+1}$. It follows from the algorithm that $u \in \text{core}(s, k_j, V_j)$ for some $s \in S_j$. Hence, from the definition, $N_W(V_j, u) \subset \text{cluster}(s, k_j, V_j)$. Since p is of weight at most W and $p \subset V_j$, it follows that $p \subset N_W(V_j, u)$. Hence,

$$\{u_1, u_2\} \subset p \subset N_W(V_j, u) \subset \text{cluster}(s, k_j, V_j) \in \chi \ .$$

PROPOSITION 5.6. *For every* $v \in V$ *and* $1 \leq i \leq \beta$,

$$\text{core}(v, k_{i+1}, V_{i+1}) \subseteq \text{cluster}(v, k_{i+1}, V_{i+1}) \subseteq \text{core}(v, k_i, V_i) \subseteq \text{cluster}(v, k_i, V_i) \ .$$

Proof. The proof is immediate from part 3 of Proposition 5.2.

PROPOSITION 5.7. *With probability* $1 - O(1/\text{poly}(n))$, *for* $j > i$

$$\forall v \in V_j, |\text{cluster}(v, k_j, V_j)| < n^{1-i/\beta} \ .$$

Proof. If i is the last iteration, $V_{i+1} = \emptyset$ and the proposition follows. Otherwise, $|S_i| = \Omega(n^{i/\beta}|V_i|(\log n)/n)$. Since $\text{cluster}(v, k_j, V_j) \subset \text{core}(v, k_i, V_i)$ (see Proposition 5.6) and $V_j \subset V_i$,

$$\{v \in V_j \mid |\text{cluster}(v, k_j, V_j)| \geq n^{1-i/\beta}\} \subset \{v \in V_i \mid |\text{core}(v, k_i, V_i)| \geq n^{1-i/\beta}\} \ .$$

It is therefore sufficient to prove that with probability $1 - O(1/\operatorname{poly}(n))$,

$$\{v \in V_i| \ |\mathrm{core}(v, k_i, V_i)| \geq n^{1-i/\beta}\} \cap V_{i+1} = \emptyset \ .$$

Consider a vertex $v \in V_i$ such that $|\mathrm{core}(v, k_i, V_i)| \geq n^{1-i/\beta}$. We prove that with probability $1 - O(1/\operatorname{poly}(n))$, $v \in \bigcup_{s \in S_i} \mathrm{core}(s, k_i, V_i)$ (and, hence, using part 1 of Proposition 5.2, $v \notin V_{i+1}$). Since the elements of S_i are chosen uniformly at random, for $s \in S_i$ we have

$$\mathrm{Prob}\{v \in \mathrm{core}(s, k_i, V_i)\} = |\mathrm{core}(v, k_i, V_i)|/|V_i| \geq n^{1-i/\beta}/|V_i| \ .$$

Hence, since the elements of S_i are chosen independently,

$$\begin{aligned}&\mathrm{Prob}\{v \in V_{i+1}\} = \mathrm{Prob}\left\{v \notin \textstyle\bigcup_{s \in S_i} \mathrm{core}(s, k_i, V_i)\right\} \leq (1 - n^{1-i/\beta}/|V_i|)^{|S_i|} \\ &= (1 - n^{1-i/\beta}/|V_i|)^{\Omega(|V_i| n^{i/\beta - 1} \log n)} = O(1/\operatorname{poly}(n)) \ .\end{aligned}$$

To conclude the proof note that

$$\begin{aligned}&\mathrm{Prob}\left\{\{v \in V_i| \ |\mathrm{core}(v, k_i, V_i)| \geq n^{1-i/\beta}\} \cap V_{i+1} \neq \emptyset\right\} \\ &\leq \textstyle\sum_{v \in V_i} \mathrm{Prob}\{|\mathrm{core}(v, k_i, V_i)| \geq n^{1-i/\beta} \wedge v \in V_{i+1}\} \leq |V_i|/\operatorname{poly}(n) \leq O(1/\operatorname{poly}(n)) \ .\end{aligned}$$

PROPOSITION 5.8. *With probability* $1 - O(1/\operatorname{poly}(n))$, *for all* $e \in E$ *and all* $v \in V$,

$$\begin{aligned}|\{X \in \chi | e \in \mathcal{E}(X)\}| &= O(n^{1/\beta} \beta \log n) \ \textit{and} \\ |\{X \in \chi | v \in X\}| &= O(n^{1/\beta} \beta \log n) \ .\end{aligned}$$

Proof. The claim for edges follows from the claim for vertices. Consider the ith iteration and a vertex v. It follows from Proposition 5.7 that with probability $1 - O(1/\operatorname{poly}(n))$,

$$\text{for all } u \in V_i, \ \ |\mathrm{cluster}(u, k_i, V_i)| \leq n^{1-(i-1)/\beta} \ .$$

Using part 1 of Proposition 5.2 we have that for $u \in V_i$, $v \in \mathrm{cluster}(u, k_i, V_i)$ if and only if $u \in \mathrm{cluster}(v, k_i, V_i)$. Hence, for any $u \in V_i$ chosen uniformly at random

$$\mathrm{Prob}\{v \in \mathrm{cluster}(u, k_i, V_i)\} \leq |\mathrm{cluster}(v, k_i, V_i)|/|V_i| \leq n^{1-(i-1)/\beta}/|V_i| \ .$$

Therefore, the expected number of vertices $s \in S_i$ for which $v \in \mathrm{cluster}(s, k_i, V_i)$ is bounded by $|S_i| n^{1-(i-1)/\beta}/|V_i| = O(n^{1/\beta} \log n)$. From Chernoff bound [5] we obtain

$$\mathrm{Prob}\{|\{s \in S_i | v \in \mathrm{cluster}(s, k_i, V_i)\}| = O(n^{1/\beta} \log n)\} \geq 1 - O(1/\operatorname{poly}(n)) \ .$$

Since $\beta = O(\log n) = O(\operatorname{poly} n)$, it follows that for all $v \in V$,

$$\mathrm{Prob}\left\{\sum_{i=1}^{\beta} |\{s \in S_i | v \in \mathrm{cluster}(s, k_i, V_i)\}| = O(\beta n^{1/\beta} \log n)\right\} \geq 1 - O(1/\operatorname{poly}(n)) \ .$$

Since $|V| = O(n)$, we can deduce that with probability $1 - O(1/\operatorname{poly}(n))$,

$$\forall v \in V, \sum_i |\{s \in S_i | v \in \mathrm{cluster}(s, k_i, V_i)\}| = O(n^{1/\beta} \beta \log n) \ .$$

COROLLARY 5.9. *With probability* $1 - O(1/\operatorname{poly}(n))$,

$$\sum_{X \in \chi} |\mathcal{E}(X)| = O(n^{1/\beta} m\beta \log n) \text{ and}$$
$$\sum_{X \in \chi} |X| = O(n^{1+1/\beta}\beta \log n) .$$

Proof. Note that

$$\sum_{X \in \chi} |\mathcal{E}(X)| = \sum_{e \in E} |\{X \in \chi | e \in X\}| \text{ and } \sum_{X \in \chi} |X| = \sum_{v \in V} |\{X \in \chi | v \in X\}| .$$

The proof follows using Proposition 5.8.

We conclude the proof of Theorem 5.4. To prove the correctness of Algorithm 5.3 we verify that with probability $1 - O(1/\operatorname{poly}(n))$, χ constitutes a (β, W)-cover of G. We show that χ satisfies properties 1 and 2 of Definition 3.3, and with probability $1 - O(1/\operatorname{poly}(n))$, χ satisfies property 3 of the definition. Proposition 5.5 establishes that property 1 holds for χ. The validity of property 2 follows from the fact that for all i, $k_i \leq \beta - 1$. Proposition 5.8 asserts that χ satisfies property 3 (with probability $1 - O(1/\operatorname{poly}(n))$).

We furnish resource bounds for Algorithm 5.3. The computation of clusters in step 2b assumes that the graph is represented in a certain format (see section 4). This representation allowed us to compute clusters with work proportional to the combined size of the clusters computed (instead of having to look at all the edges in the graph). We remark that this representation can be easily generated and revised (for the subgraphs induced by V_i where $i > 0$) within the resource bounds of the algorithm. Consider a single iteration of Algorithm 5.3. The computation in step 2b dominates the complexity. It follows from Proposition 4.1 that the computation of step 2b in the ith iteration can be performed in

$$O\left(W\beta \log n + \sum_{s \in S_i} |\mathcal{E}(\text{cluster}(s, k_i, V_i))|(\log n)/p\right)$$

time using p processors (and in $O(\sum_{s \in S_i} |\mathcal{E}(\text{cluster}(s, k_i, V_i))|)$ work, when allowing $O(W\beta n^{\alpha})$ time). Hence, since there are at most β iterations, the algorithm can be performed in

$$O\left(W\beta^2 \log n + \sum_{x \in \chi} |\mathcal{E}(X)|(\log n)/p\right)$$

time using p processors. By substituting the bound from Corollary 5.9 we deduce that with probability $1 - O(1/\operatorname{poly}(n))$, the algorithm can be performed in $O(W\beta^2 \log n)$ time using $p = O(n^{1/\beta} m(\log n)/(W\beta))$ processors. The work performed by the algorithm is $O(n^{1/\beta} m\beta \log^2 n)$. When allowing $O(W\beta^2 n^{\alpha})$ time (for fixed α), the work is reduced to $O(n^{1/\beta} m\beta \log n)$.

6. Sequential algorithms. This section is concerned with sequential stretch-t paths algorithms. We first discuss a sequential version of the randomized algorithm presented in previous sections. In the main part of this section we present a deterministic algorithm. Our sequential algorithms are both simpler than the previous Awerbuch et al. [2] algorithm and significantly improve the tradeoffs between the stretch and the running time.

6.1. A randomized sequential algorithm. In subsection 2.2 we presented a parallel algorithm (Algorithm 2.6) that computes stretched ℓ-limited distances, where $1 \leq \ell \leq n$. Hence, when $\ell = n$, the algorithm produces stretch-t paths. The resulting algorithm inputs a graph G, with weights $w : E \rightarrow R_+$, integer $\beta \geq 1$, a scalar $0 \leq \hat{\epsilon} \leq 1/2$, and a set of query pairs $Q \subset V \times V$. The algorithm runs in time $O((m + |Q|)n^{1/\beta}\beta \log^2 n)$ and with probability $1 - O(1/\operatorname{poly}(n))$ computes for all $\{v, u\} \in Q$, stretched distance $\tilde{\operatorname{dist}}\{v, u\}$ such that

$$\operatorname{dist}_E\{v, u\} \leq \tilde{\operatorname{dist}}\{v, u\} \leq 2\beta(1 + \hat{\epsilon})^2 \operatorname{dist}_E\{v, u\} \ .$$

A simplified sequential algorithm with slightly worse time bounds and slightly better stretch can be obtained by avoiding the reduction to small integral weights performed in section 3. Small integral weights are necessary for efficient parallel computation of neighborhoods but are not crucial in the sequential version. The simplified algorithm applies a sequential version of Algorithm 2.6 and uses $(n, \beta, w_i, 0)$-covers instead of $(\ell, \beta, w_i, \hat{\epsilon})$-covers (for $i = 1, \ldots, r$). $(n, \beta, w_i, 0)$-covers can be computed directly by Algorithm 5.3. In the implementation of Algorithm 5.3 we disregard the assumption that the weights are integral and utilize a slightly modified version of Dijkstra's algorithm to compute neighborhoods. If edges are initially sorted according to their weight at the vertices, we can compute a neighborhood with V' vertices in time $O(|\mathcal{E}(V')| + |V'| \log |V'|)$ (using Fibonnaci heaps). The simplified algorithm inputs a graph G, with weights $w : E \rightarrow R_+$, integer $\beta \geq 1$, a scalar $0 \leq \hat{\epsilon} \leq 1/2$, and a set of query pairs $Q \subset V \times V$. The algorithm runs in time $O((m + n \log n + |Q|)n^{1/\beta}\beta \log^2 n)$ and with probability $1 - O(1/\operatorname{poly}(n))$ computes for all $\{v, u\} \in Q$, stretched distance $\tilde{\operatorname{dist}}\{v, u\}$ such that

$$\operatorname{dist}_E\{v, u\} \leq \tilde{\operatorname{dist}}\{v, u\} \leq 2\beta(1 + \hat{\epsilon}) \operatorname{dist}_E\{v, u\} \ .$$

6.2. The deterministic algorithm. We present a deterministic stretch-t paths algorithm. For a weighted graph $G = (V, E)$ and a set of sources $S \subset V$, the algorithm computes stretched distances for all pairs of vertices in $S \times V$. For an integer β and any fixed $\epsilon > 0$, the algorithm obtains stretched distances to within a factor of $2(1 + \log_n m)\beta(1 + \epsilon)$ using $\tilde{O}(n^{1/\beta}(m + n|S|))$ time. For the all-pairs problem (when $|S| = n$), the running time is $\tilde{O}(n^{2+1/\beta})$. A modification of the algorithm achieves stretch $4\beta(1 + \epsilon)$ using $\tilde{O}(n^{2+1/\beta})$ time. For dense graphs $\log_n m \approx 2$, and hence the modification yields improved stretch (by a factor of $2/3$) within comparable time bounds. In contrast, the Awerbuch et al. [2] algorithm obtains stretch 32β using $\tilde{O}(n^{2/\beta}m + n^{1+1/\beta}|S|)$ time. We remark, however, that the Awerbuch et al. [2] algorithm is more general since stretched distances between any k specified pairs of vertices can be obtained in $\tilde{O}(n^{2/\beta}m + n^{1/\beta}k)$ time.

We use the following definition for pairwise covers. Note that it differs from Definition 2.3 that was used for the randomized algorithm.

DEFINITION 6.1. *Consider a graph $G = (V, E)$ with weights $w : E \rightarrow R_+$, an integer $\beta = O(\log n)$, and a scalar $\rho \in R_+$. A* pairwise (β, ρ)-cover *of G is a collection*

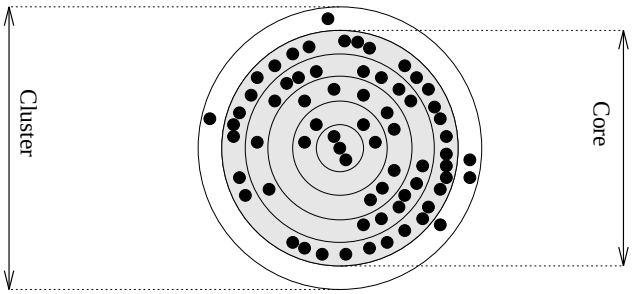

FIG. 2. *Example of a cluster and respective core for* $n^{1/\beta} < 2$.

of sets of vertices $X_1, \ldots, X_k$ (clusters) *and vertices* $v_1, \ldots, v_k$, *where* $v_i \in X_i$ *is the* center *of* X_i, *such that*

1. $\forall \{u, v\} \subset V$ *such that* $\text{dist}\{u, v\} \leq \rho$ $\exists i$ *such that* $\{u, v\} \subset X_i$,
2. $\forall i$, $\forall u \in X_i$, $\text{dist}\{v_i, u\} \leq (1 + \log_n m)\beta\rho$, *and*
3. $\sum_{i=1}^{k} |X_i| = O(n^{1+1/\beta})$.

We claim that a (β, ρ)-cover of G can be computed in $O(mn^{1/\beta})$ time. We first discuss the structure of the clusters we choose to constitute the cover.

6.3. Structure of clusters. We consider a graph $G = (V, E)$ with weights $w : E \to R_+$ and parameters β and $\rho \in R_+$. We discuss the structure and properties of subsets of vertices we call *clusters*. We use carefully chosen clusters as the building blocks of a (β, ρ)-cover.

A cluster is a subset of vertices that is defined with respect to two parameters: a subset of vertices $V' \subset V$ and a vertex $v \in V'$ (the *center* of the cluster). The cluster comprises a neighborhood of the center v in the graph $(V', \mathcal{E}(V'))$ up to a certain distance (that is an integral multiple of ρ). The *core* of a cluster is the subset of cluster vertices whose neighborhoods up to distance ρ in $(V', \mathcal{E}(V'))$ are contained in the cluster. For the parameters (v, V'), we define $\text{core}(v, V')$ and $\text{cluster}(v, V')$ to be the sets obtained by performing the following computation.

1. $\text{cluster}(v) \leftarrow \{v\}$
2. $i \leftarrow 1$
3. **Repeat:**
   (a) $\text{core}(v) \leftarrow \text{cluster}(v)$
   (b) $\text{cluster}(v) \leftarrow \{u \in V' | \text{dist}_{\mathcal{E}(V')}\{v, u\} \leq i\rho\}$
   (c) $i \leftarrow i + 1$
4. **Until:** $|\text{cluster}(v)| \leq n^{1/\beta}(|\text{core}(v)| + 1) \wedge$
   $|\mathcal{E}(\text{cluster}(v))| \leq n^{1/\beta}(|\mathcal{E}(\text{core}(v))| + 1)$

Figure 2 illustrates a cluster. The shells correspond to neighborhoods of the center that are integral multiples of ρ. In the example, $n^{1/\beta} < 2$. Hence the cluster stops growing when annexing the next shell does not double the number of vertices. The external shell defines the cluster, and the previous shell defines the core.

PROPOSITION 6.2. *At termination,* $i \leq (1 + \log_n m)\beta - 1$.

Proof. Note that the size of at least one of $\text{cluster}(v)$ or $\mathcal{E}(\text{cluster}(v))$ increases by more than a factor of $n^{1/\beta}$ in every iteration except for the last one. Observe that $|\text{cluster}(v)| \leq |V'| \leq n$ and $|\mathcal{E}(\text{core})| \leq m$. Thus, $|\text{cluster}(v)|$ can increase by a factor of more than $n^{1/\beta}$ at most $\beta - 1$ times and $|\mathcal{E}(\text{cluster}(v))|$ can increase by a factor

of more than $n^{1/\beta}$ at most $\beta \log_n m - 1$ times. Hence, the stopping condition occurs within $(1 + \log_n m)\beta - 1$ iterations.

Consider a subset $V' \subset V$ and $v \in V'$.

COROLLARY 6.3. *For all* $u \in \text{cluster}(v, V')$,

$$\text{dist}_E\{u, v\} \leq \text{dist}_{\mathcal{E}(V')}\{u, v\} \leq (1 + \log_n m)\beta\rho \ .$$

The following proposition is immediate.

PROPOSITION 6.4.

1. *For all* $u \in \text{core}(v, V')$, $N_W(V', u) \subset \text{cluster}(v, V')$.
2. $|\text{cluster}(v, V')| \leq n^{1/\beta}(|\text{core}(v, V')| + 1)$.
3. $|\mathcal{E}(\text{cluster}(v, V'))| \leq n^{1/\beta}(|\mathcal{E}(\text{core}(v, V'))| + 1)$.

We discuss the construction of clusters. We assume that the edges incident at each vertex are initially sorted according to their weight. Remark 4.3 asserts that a simple modification of the standard BFS algorithm yields the following bound: for all $V' \subset V$ and $v \in V'$, the sets $\text{cluster}(v, V')$ and $\text{core}(v, V')$ can be computed in $O(|\mathcal{E}(\text{cluster}(v, V'))|)$ time.

6.4. The cover algorithm. The following algorithm produces a pairwise cover.

ALGORITHM 6.5 (compute a (β, ρ)-cover).

1. $V' \leftarrow V$, $\chi \leftarrow \emptyset$

- **Main Loop:**

2. *Choose* $v \in V'$
   Compute $\text{cluster}(v, V')$ *and* $\text{core}(v, V')$.
   $\chi \leftarrow \chi \cup \{\text{cluster}(v, V')\}$
   $V' \leftarrow V' \setminus \text{core}(v, V')$
   If $V' \neq \emptyset$, *go to step* 2

We show that χ is indeed a (β, ρ)-cover as in Definition 6.1. Property 2 is immediate from Corollary 6.3. Property 3 follows from Proposition 6.4 and the fact that the cores of the clusters in χ are disjoint. In order to prove that property 1 holds, consider a pair of vertices $\{v_1, v_2\} \subset V$ such that $\text{dist}_E\{v_1, v_2\} \leq \rho$. Let p be a set of vertices constituting a path between v_1 and v_2 of weight at most ρ. Consider the first iteration where $p \cap \text{core}(v, V') \neq \emptyset$ (V' and v denote the respective assignments of values to V' and v during this iteration). It follows that $p \subset V'$. By definition, $\text{cluster}(v, V')$ contains all vertices of distance at most ρ from $\text{core}(v, V')$ in $\mathcal{E}(V')$. Hence, since $\mathcal{E}(p) \subset \mathcal{E}(V')$ and $p \cap \text{core}(v, V') \neq \emptyset$, we have $p \subset \text{cluster}(v, V')$. Therefore, $\{v_1, v_2\} \subset p \subset \text{cluster}(v, V')$. The running time of the algorithm is dominated by the construction of the clusters. We assume that at each vertex the incident edges are sorted according to weight. We argued above that the computation of a cluster $X \in \chi$ can be performed in $O(|\mathcal{E}(X)|)$ time. Hence, using property 3 of Definition 6.1, we obtain the following bound on the running time

$$O\left(\sum_{X \in \chi} |\mathcal{E}(X)|\right) = O(n^{1/\beta} m) \ .$$

6.5. Computing stretched distances. A cover as in Definition 6.1 can be used in a similar manner to Algorithm 2.6 of subsection 2.2 to compute stretched distances from a set of sources $S \subset V$ to all other vertices.

THEOREM 6.6. *For a weighted graph* G, *an integer* $\beta \geq 1$, *a fixed* $\epsilon \geq 0$, *and a set of query sources* $S \subset V$, *the following algorithm computes for all* $v \in S$ *and for*

all $u \in V$, stretched distance $\tilde{\text{dist}}(v,u)$ such that

$$\text{dist}_E(v,u) \le \tilde{\text{dist}}(v,u) \le 2\beta(1+\log_n m)(1+\epsilon)\text{dist}_E(v,u)$$

in $O(n^{1/\beta}m\log n + |S|n^{1+1/\beta}\log n)$ time.

ALGORITHM 6.7 (compute distances).

1. $w_{\min} \leftarrow \min_{e\in E} w(e)$
   $w_{\max} \leftarrow \max_{e\in E} w(e)$
   $r \leftarrow \lceil \log_{1+\hat{\epsilon}}(nw_{\max}/w_{\min})\rceil$
   For $i = 0,\ldots,r$: $w_i \leftarrow w_{\min}(1+\hat{\epsilon})^i$
2. *For $i = 0,\ldots,r$ do (in parallel):*
   (a) *Compute (β, w_i)-cover χ_i*
   (b) *For each vertex $v \in S$, $x(i,v) \leftarrow \bigcup\{X \in \chi_i | v \in X\}$.*
3. *For all $v \in S$:*
   For all $u \in V$:
   $\tilde{\text{dist}}(v,u) \leftarrow 2(1+\log_n m)\beta w_i$, *where* $i \leftarrow \min\{j | u \in x(j,v)\}$.

The correctness follows from arguments similar to the ones given in subsection 2.2. The computation amounts to first computing $r = O(\epsilon^{-1}\log n)$ covers for different values of ρ and, second, for every source $v \in S$ computing $x(j,v)$ for $1 \le j \le r$. The computation per source can be performed in time linear in the sum of the sizes of the covers. Recall that the computation of covers using Algorithm 6.5 assumes that the edges are sorted according to weight at vertices. Hence, the running time is $O(m\log n)$ for the sorting of edges, $O(\epsilon^{-1}n^{1/\beta}m\log n)$ for computing the covers, and $O(n^{1+1/\beta}\epsilon^{-1}\log n)$ time per source.

REMARK 6.8. *Consider relaxing the termination conditions in the definition of clusters and not requiring that $|\mathcal{E}(\text{cluster}(v))| \le n^{1/\beta}(|\mathcal{E}(\text{core}(v))|+1)$. We obtain improved stretch (the diameter of cluster is shorter by a factor of $(1+\log_n m)$ but has worse time bounds). The tradeoffs for stretched all-pairs distances in dense graphs improve. We obtain an $O(n^{2+2/\beta}\log n)$ time algorithm for computing stretched distances to within a factor of 2β between all pairs of vertices.*

7. Applications to graph spanners. Consider a weighted graph $G = (V,E)$. A t-spanner of G is a weighted graph (V,E') such that for all pairs $\{u_1,u_2\} \subset V$ we have

$$\text{dist}_E\{u_1,u_2\} \le \text{dist}_{E'}\{u_1,u_2\} \le t\text{dist}_E\{u_1,u_2\}\ .$$

We utilize our constructions of pairwise covers to obtain t-spanners for weighted graphs. We present a randomized construction of spanners of size (number of edges) $O(n^{1+(2+\epsilon)/t})$ in time $O(mn^{(2+\epsilon)/t})$ (for any $\epsilon > 0$ and t such that $t/(2+\epsilon)$ is integral). We give a deterministic algorithm that finds t-spanners of size $O(n^{1+(2+\epsilon)(1+\log_n m)/t})$ and runs in $O(mn^{(2+\epsilon)(1+\log_n m)/t})$ time (for any $\epsilon > 0$ and t such that $t/((1+\log_n m)(2+\epsilon))$ is integral). In addition, we discuss parallel constructions of spanners.

7.1. Computing spanners sequentially. We show how to obtain sparse (small size) spanners. Our spanners are constructed from a collection of pairwise covers (see Definitions 3.3 and 6.1). Let $R = w_{\max}/w_{\min}$. Using considerations similar to Remark 2.1, we may assume that $R = O(\text{poly}(n))$. Let $r = \lceil \log_{1+\epsilon} R\rceil$. It follows that $r = O(\epsilon^{-1}\log n)$. Let $\beta = t/(2+\epsilon/2)$ if the randomized construction of covers is used (see Definition 3.3) and let $\beta = t/((1+\log_n m)(2+\epsilon/2))$ if the deterministic construction is used (see Definition 6.1). For each $0 \le i \le r$, let χ_i be a (β, w_i)-cover of

G , where $w_i = w_{min}(1+\epsilon)^i$. The t-spanner $S \subset E$ is constructed as follows. For each $0 \leq i \leq r$ and each cluster $X \in \chi_i$, add to S the edges of the partial BFS tree used to construct X. It follows immediately from the properties of our construction of covers that for every edge $e \in E$ there is a path in S of weight at most $tw(e)$ connecting the end points of e. Hence, for every path $p \subset E$, there is a path in S of weight at most $tw(p)$. Therefore, S indeed comprises a t-spanner. To bound the size of the spanner S, note that the number of edges in S is bounded by $\sum_{i=0}^{r} \sum_{X \in \chi_i} (|X| - 1)$. Hence, it follows from the properties of covers that $|S| = O(rn^{1+1/\beta}\beta \log n)$. To obtain a time bound for the spanner algorithm, note that it amounts to computing r covers. The time bounds for computing a single cover are $O(mn^{1/\beta})$ time for the deterministic cover algorithm and $O(mn^{1/\beta} \log n)$ time for the randomized cover algorithm.

Additional properties of our spanners. The spanner S consists of a collection of subtrees $\mathcal{T}$ of the graph G. The following stronger statement holds: for any two vertices $\{u_1, u_2\} \subset V$, the minimum over all the trees $T \in \mathcal{T}$ such that $\{u_1, u_2\} \subset T$ of the distance between u_1 and u_2 in T, is within a factor t of $\text{dist}_E\{u_1, u_2\}$. Furthermore, if the covers produced by the randomized construction are used, then every vertex is contained in at most $O(rn^{1/\beta}\beta \log n)$ subtrees in $\mathcal{T}$. Consider a variant where we do not require the spanner S to consist of edges from E, but we want limited distances on the spanner (using small size paths) to be within a small factor of distances on the graph. Construct a spanner S' as follows. Take $R = nw_{\max}/w_{\min}$ and $r = \lceil \log_{1+\epsilon} R \rceil = O(\epsilon^{-1} \log n)$. For each $0 \leq i \leq r$, let χ_i be a (β, w_i)-cover of G, where $w_i = w_{min}(1+\epsilon)^i$. For each $0 \leq i \leq r$, each cluster $X \in \chi_i$ with respective center $u(X)$, and each $v \in X$, include in S' an edge $(u(X), v)$ of weight equal to the distance from $u(X)$ to v in X. The spanner S' has a stronger property that the 2-limited distances in S' are within a factor t of the respective distances in G.

7.2. Computing spanners in parallel. We provide three methods for computing spanners in parallel. In this subsection we assume that $\beta = t/(2 + \epsilon/2)$ and use Definition 3.3 for covers.

Straightforward parallel implementation. We describe a parallel implementation of the sequential algorithm above that has the same work bound and runs in time linearly dependent on $R = w_{\max}/w_{\min}$. Hence, this implementation is of interest when R is sufficiently small. In particular, the algorithm is in $\mathcal{NC}$ for unweighted graphs. Note that for the covers computed by the spanner algorithm we have $w_{\min} \leq w_i \leq (1+\epsilon)w_{\max}$ $(0 \leq i \leq r)$. By definition, for any cluster $X \in \chi_i$, the distance from the center of X to any vertex $v \in X$ is at most βw_i, and, hence, the partial BFS tree generated while computing X has path size of $O(R\beta)$. Consider an application of Algorithm 5.3 to compute χ_i, where in step 2b we compute clusters by a weighted parallel BFS algorithm (see section 4). It follows that the cover algorithm runs in expected time $O(R\beta^2 \log n)$ and performs $O(n^{1/\beta} m\beta \log n)$ work. Hence, t-spanners of size $O(n^{1+(2+\epsilon)/t})$ can be obtained in $O(R\beta^2 \log^2 n)$ expected time using $O(n^{1/\beta} m\beta \log^2 n)$ work.

Using (exact) all-pairs shortest paths. We showed above that computing a spanner amounts to concurrently computing $r = O(\log n)$ covers. Consider a single application of Algorithm 5.3 to compute a cover. The complexity of the algorithm is dominated by step 2b. Note that step 2b can be performed (with worse work bounds) as follows. First compute all-pairs distances on the graph induced by the vertices V_i. The sets $\text{core}(v, k_i, V_i)$ and $\text{cluster}(v, k_i, V_i)$ for $v \in S_i$ can be easily generated using the all-pairs distances table. The parallel all-pairs shortest-paths computation can be performed in $O(\log^2 n)$ time with $O(n^3)$ work on an EREW PRAM. The generation of the sets $\text{core}(v, k_i, V_i)$ and $\text{cluster}(v, k_i, V_i)$ for $v \in S_i$ can be performed within the same time

bounds using work proportional to the sum of the sizes of these sets. Note that the resource bounds of the all-pairs shortest paths computation dominate all other steps. A shortest-paths computation is performed in each one of the β iterations of Algorithm 5.3. It follows that a pairwise cover can be computed in $O(\beta \log^2 n)$ time using $O(\beta n^3)$ work. Hence, t-spanners of size $O(n^{1+(2+\epsilon)/t})$ can be obtained in $O(\beta \log^3 n)$ expected time using $O(n^3 \beta \log n)$ work. We remark that although the work bound is worse than the sequential time bound achieved above, it is better than even the sequential time bounds of previous algorithms.

Tradeoffs between time and stretch. This method is based on the same technique used to obtain a fast parallel stretch-t paths algorithm (see subsection 2.3). We sketch the algorithm. Consider some parameter $\ell' < R$, and let $k = \lceil \log_{\ell'/2} R \rceil$. We repeatedly apply k times a version of Algorithm 2.7, with parameter ℓ', where in step 1 we use $r \leftarrow \lceil \log_{1+\hat{\epsilon}} R \rceil$. The above guarantees that if $\mathrm{dist}_E\{u_1, u_2\} \leq w_{\max}$ then for all $\ell' \leq \ell$,

$$\mathrm{dist}_{E'}^{2\lceil \ell/\ell' \rceil}\{u_1, u_2\} \leq 2\beta(1+\hat{\epsilon})^2 \mathrm{dist}_E^{\ell}\{u_1, u_2\} \ ,$$

where E' is the set of edges obtained by applying the algorithm to (V, E). Note that the running time is $\tilde{O}(k\ell')$. We consider the BFS trees obtained by the covers computed at the last repetition of the algorithm and "expand" them back to consist of original edges. The resulting spanners are t^k-spanners, but their size and the work performed is the same as for the sequential t-spanner algorithm.

8. Stretch t paths on dynamic networks. The dynamic shortest-paths problem amounts to resolving on-line distance queries between pairs of vertices when weighted edges (and possibly new vertices) are inserted to or deleted from the graph. Unfortunately, even when only insertions are permitted, the currently best-known solution amounts to the brute force method of applying Dijkstra's $O(m + n \log n)$ time algorithm to resolve each distance query. The pairwise covers and stretch-t paths algorithms introduced here enable us to obtain more efficient algorithms for dynamic stretch-t distances. We consider a dynamic stretch-t paths problem where we are allowed to insert edges (while possibly introducing new vertices), delete recently inserted edges, and perform stretch-t distance queries. Another relevant setting is when some large graph is fixed, but we allow insertions to and deletions from a small set of new edges. The distance queries are performed with respect to the augmented graph.

Consider the sequential version of Algorithm 2.6 (see subsection 6.1). In the first part of the algorithm, it produces a set of pairwise covers as to be able to answer on-line distance queries. The first part takes $\tilde{O}(mn^{(2+\epsilon)/t})$ time. Consequently, in the second part of the algorithm, each distance query takes $\tilde{O}(n^{(2+\epsilon)/t})$ time. Our dynamic algorithms utilize Algorithm 2.6. Note that since Algorithm 2.6 is randomized, the time bounds mentioned below are for the expected running time.

We first consider the following problem: the graph G is fixed, and there is a dynamic set of new weighted edges I. Some of the edges in I may introduce new vertices. We denote by $V(I)$ the vertices in I. The operations allowed are to insert edges to I, delete edges from I, and ask stretch-t distance queries between vertices in $V \cup V(I)$, with respect to the graph $(V \cup V(I), E \cup I)$. We sketch an algorithm for this problem and analyze its performance. The initialization step is to apply the first part of Algorithm 2.6 to the fixed graph G and generate a collection of pairwise covers. The algorithm dynamically maintains a graph $G_I = (V_I, E_I)$ as follows. $V_I = V(I) \cup C$, where C is a collection of all centers of clusters that contain vertices from $V(I)$. The set E_I contains I and for each occurrence of a vertex $v \in V(I)$ in a cluster X with

center $c \in C$, E_I contains the edge (v, c) weighted by the radius of X. Recall (see Definition 2.3) that each vertex $v \in V$ belongs to $\tilde{O}(n^{(2+\epsilon)/t})$ clusters. Hence, $|C| = \tilde{O}(|V(I)|n^{(2+\epsilon)/t})$, and $E_I \setminus I = \tilde{O}(|V(I)|n^{(2+\epsilon)/t})$. It is easy to see that an insertion or deletion of an edge takes $O(1)$ time, if $V(I)$ is not modified, and $\tilde{O}(n^{(2+\epsilon)/t})$ time otherwise. To perform a stretch-t distance query for a pair $\{u_1, u_2\} \subset V \cup V(I)$, we proceed as follows. We utilize the second part of Algorithm 2.6, applied to the set of pairwise covers produced earlier, to compute stretch-t distances on G from u_1 and from u_2 to every vertex in $V(I) \cap V$. We perform a single-source shortest-paths computation, rooted at u_1, on G_I augmented as follows: by the vertices $\{u_1, u_2\}$ and edges between $\{u_1, u_2\}$ and $V(I) \cap V$, weighted by the stretch-t G-distances computed above. The answer to the query is the distance between u_1 and u_2 in the augmented G_I. It is easy to verify that the distance between u_1 and u_2 in the augmented G_I is within a factor of t of the distance in $(V \cup V(I), E \cup I)$. We bound the time required for performing a query. The stretch-t distances computations in G can be performed in time $\tilde{O}(|V(I) \cap V|n^{(2+\epsilon)/t})$. The single-source shortest-paths computation take time $\tilde{O}(|V(I)| + |E_I||) = \tilde{O}(|I| + |V(I)|n^{(2+\epsilon)/t})$ (using, e.g., Dijkstra's algorithm). Hence, the total query time is $\tilde{O}(|I|n^{(2+\epsilon)/t})$. We remark that the time is improved when $|V(I)| \ll |I|$.

Consider now the following problem. Let k be a parameter. The weighted edges are maintained in a list M. The allowed operations are to insert edges to the head of M, to delete edges that are of distance at most k from the head of M, and to ask t-stretch distance queries. We sketch an algorithm that operates in stages. Each stage amounts to an instance of the problem discussed in the previous paragraph. In the beginning of each stage, we consider a suffix of M denoted by M' that contains all edges in M except the initial $2k$ edges. The set M' constitutes the fixed graph, and we initialize $I = M \setminus M'$. Within a stage, the insertions, deletions, and distance queries are handles as sketched in the previous paragraph. The current stage terminates (and a new stage begins) when there is a request to delete an edge in M' or when $|M \setminus M'| \geq 4k$. It is easy to see that each stage consists of at least k deletions or insertions. Using standard dynamic algorithms methods, we can amortize the cost of the operations such that insertions or deletions take $\tilde{O}((k + m/k)n^{(2+\epsilon)/t})$ time and queries take $\tilde{O}(kn^{(2+\epsilon)/t})$ time. Note that when $k = m^{0.5}$, each operation takes $\tilde{O}(m^{0.5}n^{(2+\epsilon)/t})$ time. In general, k can be determined according to the ratio of edge insertions/deletions and queries.

9. Concluding remarks. We discuss some issues and open problems that arise from this work.

We remark that stretch-n paths can be obtained using a minimum spanning tree (MST). For a pair of vertices, consider the MST path p between them and the heaviest edge e on this path. It is easy to see that the distance between the vertices is bounded from below by $w(e)$ and bounded from above by $w(p) \leq nw(e)$. An MST can be computed sequentially in $O(m \log n)$ time and in parallel in $\mathcal{NC}$ using $\tilde{O}(m)$ work.

The techniques used in this paper and in the previous work of Awerbuch et al. [2] do not seem to generalize to directed graphs. A natural question regards obtaining comparable work-stretch tradeoffs for directed graphs. We conjecture that for directed graphs, obtaining stretch-t paths where t is constant or polylogarithmic is nearly as hard as finding shortest paths.

A result due to Karger, Koller, and Phillips [9] provides some indication that for directed graphs, either comparable time-stretch tradeoffs are not obtainable or stretch-t paths are indeed strictly easier to find than shortest paths. Karger, Koller, and Phillips proved a lower bound of $\Omega(mn)$ on the amount of work required by path-comparison-based algorithm for all-pairs shortest-paths computations. Note, however, that this lower bound is applicable for a restricted class of algorithms (that does not include the algorithms presented in this paper) and is applicable only to the all-pairs problem. Karger conjectured that the lower bound is likely to hold for undirected graphs as well [15].

We point out some additional properties of the pairwise covers constructed in this paper that were not needed for the applications used here. The first property of a (β, w)-cover stated that if two vertices $\{u_1, u_2\} \subset V$ have distance at most w, then at least one cluster in the cover contains all the vertices on some path of weight w between u_1 and u_2. It is easy to prove the stronger property that at least one cluster must contain *all* paths of weight at most w between u_1 and u_2. Moreover, the (β, w)-covers introduced here actually constitute neighborhood covers: for every vertex $u \in V$, the $w/2$ neighborhood of u must be contained in at least one cluster. Recall that pairwise covers were introduced here as a more correct (in the context of short paths computations) and constructible in parallel alternative for the neighborhood covers of Awerbuch and Peleg [3]. This indicates that our constructions may have other applications.

We presented efficient algorithms to produce sparse spanners. Some of the previous work on spanners (see Chandra et al. [4]) is concerned with finding spanners that are not only sparse but in addition have small weight (that is, within a small factor of the weight of the MST). It is likely that our methods can be extended to efficiently generate sparse spanners with small weight.

We presented parallel algorithms that compute stretch-t paths, where t is a constant or polylogarithmic, while performing significantly less work than exact shortest-paths algorithms. This is notable because, typically, parallel shortest-paths algorithms perform much more work than their sequential counterparts. A particular example is the single-source shortest-paths problem on graphs with nonnegative weights. It is solved sequentially in $\tilde{O}(m)$ time, but the currently best-known work bound of a polylog time algorithm is $O(n^3)$. We remark that the author, in a later work [7], that employs our parallel pairwise cover constructions, presented an $\tilde{O}(mn^{\epsilon_0} + s(m + n^{1+\epsilon_0}))$ work polylog-time randomized algorithm that computes paths within $(1 + O(1/\operatorname{polylog} n))$ of shortest path from s source nodes to all other nodes in weighted undirected networks (for any fixed $\epsilon_0 > 0$). Another implication of the work in [7] is efficiently parallelizing the randomized t-spanners, stretch-t paths, and pairwise covers algorithms presented in the current paper. Namely, obtaining polylogarithmic time parallel algorithms that perform work comparable to the respective sequential running times presented here and an additional additive term of $O(mn^{\epsilon_0})$ (where $\epsilon_0 > 0$ is any fixed constant).

Acknowledgments. The author would like to thank Lenore Cowen for presenting the Awerbuch et al. [2] work at Bell Labs and discussing it and the current work with the author, to thank Lenore Cowen, David Johnson, Alex Wang, Uri Zwick, and the anonymous referee for suggestions that improved the write up, and Andrew Goldberg, Monika Rauch, and Peter Shor for useful discussions and bibliographic pointers.

SMART SMART BOUNDS FOR WEIGHTED RESPONSE TIME SCHEDULING*

UWE SCHWIEGELSHOHN†, WALTER LUDWIG‡, JOEL L. WOLF§, JOHN TUREK§, AND PHILIP S. YU§

Abstract. Consider a system of independent tasks to be scheduled without preemption on a parallel computer. For each task the number of processors required, the execution time, and a weight are known. The problem is to find a schedule with minimum weighted average response time. We present an algorithm called SMART (which stands for scheduling to minimize average response time) for this problem that produces solutions that are within a factor of 8.53 of optimal. To our knowledge this is the first polynomial-time algorithm for the minimum weighted average response time problem that achieves a constant bound. In addition, for the unweighted case (that is, where all the weights are unity) we describe a variant of SMART that produces solutions that are within a factor of 8 of optimal, improving upon the best known bound of 32 for this special case.

1. Introduction.

Consider a parallel computer composed of P processors, on which a system τ consisting of M independent tasks is to be scheduled. Suppose that any given task $i \in \{1, \ldots, M\}$ requires $w_i \leq P$ processors for h_i units of time. All of the processors allotted to a task are required to execute that task in unison and without preemption. That is, w_i processors are all required to start task i at the same *starting time* t_i. They will then complete task i at *completion time* $t_i + h_i$. (One can therefore think of the execution of task i as taking place within a rectangle whose height h_i stretches along a *time* axis and whose width w_i stretches along a *processor* axis.) A *schedule* will consist of a starting time t_i for each task i and must be *legal* in the sense that for any time t the number of active processors does not exceed the total number of processors. In other words, $\sum_{\{i|t_i \leq t < t_i + h_i\}} w_i \leq P$ for all t. The classic problem of finding a schedule with minimum *makespan*, defined by $\max_{1 \leq i \leq M}\{t_i + h_i\}$, has been studied extensively in the literature. (The makespan corresponds to the last completion time and thus represents the length of the entire schedule.) The minimum makespan problem is NP-hard in the strong sense [5], and efforts have accordingly focused on finding polynomial-time algorithms whose solution in the worst case is within a fixed multiplicative constant of the optimal solution [4, 1, 3, 9].

In this paper we consider the corresponding problem, also NP-hard in the strong sense [2], where the goal is to minimize the *average response time* instead. The average response time can be written as $\frac{1}{M}\sum_{i=1}^{M}(t_i + h_i)$ and is an important and standard measure in computer performance. Note that *all* completion times count, not just the last completion time. Modulo the factor $\frac{1}{M}$ (which can be removed without affecting the solution to the problem), we are attempting to minimize the *sum of the completion times*, namely, $\sum_{i=1}^{M}(t_i + h_i)$.

Our approach is analogous to that of the minimum makespan problem literature: we give an algorithm that takes polynomial time and produces schedules whose completion time sums are within a multiplicative constant of optimal. At this time, the best known constant is achieved by an algorithm called SMART [12]. Unfortunately, this constant (32) is not nearly as close to 1 as the best known constant (2) for the minimum makespan problem [4].

In this paper we devise a variant of the original SMART algorithm with an improved bound of 8. (It should be noted that the results of this paper can also be used to improve the bound of the original algorithm to 9.)

We also tackle the more general minimum *weighted* response time problem. That is, we assume that each task i is given a weight u_i, and that the objective is to minimize the weighted average response time $\frac{1}{C}\sum_{i=1}^{M} u_i(t_i + h_i)$, where $C = \sum_{i=1}^{M} u_i$. (Again the factor of $\frac{1}{C}$ can be removed without affecting the solution, so we speak instead of minimizing the weighted sum of the completion times, given by $\sum_{i=1}^{M} u_i(t_i + h_i)$.) When all weights are unity this problem reduces to the unweighted minimum response time special case described above.

We present a generalization of the original SMART algorithm for the minimum weighted response time problem. We show that this algorithm achieves a bound of 8.53. To our knowledge this is the first polynomial-time algorithm for the weighted problem that achieves a constant bound.

In section 2 we recall the original SMART algorithm and deal with the unweighted case. Section 3 deals with the weighted case. In section 4 we give examples to show that the bounds are within less than a factor of 2 of being tight. Section 5 contains conclusions.

2. The unweighted case. We begin by briefly reminding the reader of the original SMART algorithm; then we will present the variant that gives the better bound. SMART belongs to the category of so-called *shelf*-based algorithms.

Shelf solutions can be characterized by the following simple properties, illustrated in the left-hand side of Figure 1: the tasks are assigned to *shelves*, with all tasks on any given shelf having the same starting time. The sum of the required processors for all tasks on a given shelf must not exceed the total number of processors. The first shelf is placed at time zero. The *height* of a shelf is the largest task execution time of any task assigned to that shelf, and the next shelf is placed this height above the previous shelf. (If we think of the tasks as rectangles, the physical analogy becomes clear: rectangles are packed onto shelves, they must fit on the shelves, the first shelf sits on the floor, and each new shelf rests on the highest rectangle of the shelf before it.) If $\tau = \{(h_i, w_i) | i = 1, \ldots, M\}$ is a task system, we can think of a shelf assignment as a surjective function $\mathcal{S} : \{1, \ldots, M\} \to \{1, \ldots, S\}$ such that $\sum_{\mathcal{S}(i)=k} w_i \leq P$ for all $k = 1, \ldots, S$. Let $\mathcal{M}_k = \text{card}\{\mathcal{S}^{-1}(k)\}$ denote the number of tasks on shelf k, so that $\sum_{k=1}^{S} \mathcal{M}_k = M$. Let $\mathcal{H}_k = \max_{\mathcal{S}(i)=k} h_i$ denote the height of shelf k. Observe that the total area in the right-hand side of Figure 1, viewed as an integral, represents the sum of the completion times. Specifically, there is one "column" of unit width for each task. The unshaded portion of a given column has height equal to the execution time of the appropriate task. The shaded portion of the column has height equal to the waiting time of the task, which is the time until the task starts. This waiting time is simply the sum of the heights of the earlier shelves. Thus the entire column has height equal to the completion time of the task.

Consider a task system $\tau = \{(h_i, w_i) | i = 1, \ldots, M\}$. By normalization we will assume, without loss of generality, that the minimum task execution time $\min_{1 \leq i \leq M} h_i$

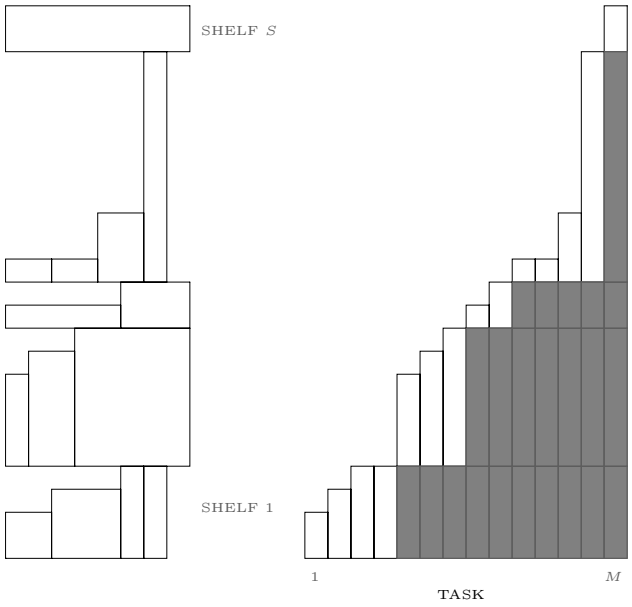

FIG. 1. *Shelf solution and its completion time sum.*

is equal to 1. Let $\hat{h} = \max_{1 \le i \le M} 2^{\lceil \log h_i \rceil}$. We partition τ into (at most) $1 + \log \hat{h}$ components by assigning task i to the component $j \in \{0, \ldots, \log \hat{h}\}$ that satisfies $2^{j-1} < h_i \le 2^j$. Now we assign tasks in each component j to shelves according to the *NFIW* (for *next fit increasing width*) bin packing algorithm [6, 7]: In other words, we reindex the tasks within component j in order of increasing width and assign them in sequence to shelves, which we regard as bins of size P. Each task is assigned to the current shelf, which is initialized to be shelf number one and incremented by one whenever a task does not fit. Now in order to obtain the SMART solution it remains to combine all the shelves in the various partitions into an overall ordering.

Note that for any shelf assignment $\mathcal{S}$, we can view the pair $(\tau, \mathcal{S})$ as a set of shelves. But these shelves can be permuted arbitrarily, resulting in solutions of varying quality. (In contrast, the ordering of shelves is irrelevant when employing a makespan objective function, since the makespan is simply the sum of the heights of the shelves.) The SMART algorithm arranges its shelves in the best way possible, according to the dictates of the following lemma.

LEMMA 2.1. *For any set of shelves $(\tau, \mathcal{S})$, an ordering of these shelves is optimal among all possible such shelf orderings if and only if $\frac{\mathcal{H}_1}{\mathcal{M}_1} \le \cdots \le \frac{\mathcal{H}_S}{\mathcal{M}_S}$.*

We will state and prove a generalization of this lemma in section 3. (See Lemma 3.1.)

Let $\sigma(\tau, \mathcal{S})$ be the schedule that results from ordering the shelves $(\tau, \mathcal{S})$ as specified by Lemma 2.1, and let $c(\tau, \mathcal{S})$ be its completion time sum.

Let s_τ and o_τ denote the objective function values for the SMART and optimal solutions for τ, respectively. In [12] it was shown that the SMART algorithm has time complexity $O(M \log M)$ and satisfies $\frac{s_\tau}{o_\tau} \le 32$. (This term is sometimes called an *approximation factor*.) In fact, using the techniques in section 3 we can now show that $\frac{s_\tau}{o_\tau} \le 9$, a significant improvement. To obtain a further improvement, we now consider a variant of the original algorithm. Specifically, instead of assigning tasks to shelves

via NFIW, we employ *FFIA* (*first fit increasing area*) [6, 7]: in other words, we reindex the tasks within component j in order of increasing area and assign them in sequence to shelves, which we again regard as bins of size P. Each task is assigned to the first shelf on which it fits, and the number of shelves is incremented by one whenever a task does not fit on any preceding shelf. (The rest of the algorithm, including the partitioning and combining, remains intact.) We regard this new algorithm as being in the same family of algorithms as the original one, and we use subscripts to differentiate the two algorithms when necessary: we denote the original and new algorithms by $\text{SMART}_{\text{NFIW}}$ and $\text{SMART}_{\text{FFIA}}$, respectively.

We illustrate the distinction between NFIW and FFIA with a simple example: suppose $P = 8$, and consider a task system in which there are four tasks. Specifically, there are two *narrow* tasks of width 3 and height 2, and two *wide* tasks of width 5 and height just greater than 1. These tasks might thus correspond to the first height component in a larger task system. NFIW would place the two narrow tasks on one shelf, followed by two shelves with a single wide task each. The areas of the wide tasks, however, are smaller than the areas of the narrow tasks. So FFIA would place the two wide tasks on separate shelves and then add one narrow task to each shelf.

The main new result in this section is the following theorem.

THEOREM 2.1. *For any task system $\tau = \{(h_i, w_i) | i = 1, \ldots, M\}$, the $\text{SMART}_{\text{FFIA}}$ algorithm has time complexity $O(M \log M)$ and satisfies $\frac{s_\tau}{o_\tau} \leq 8$.*

The time complexity remains unchanged from that of $\text{SMART}_{\text{NFIW}}$. To prove the bound, we will make use of two more lemmas from [12] (Lemmas 2.2 and 2.5 — part of this lemma is from [8]), as well as a number of entirely new results.

To get an upper bound on $\frac{s_\tau}{o_\tau}$, we will make use of lower bounds on o_τ. We now remind the reader of three such lower bounds.

LEMMA 2.2. *Let $\tau = \{(h_i, w_i) | i = 1, \ldots, M\}$ denote a task system indexed by increasing area $a_i = h_i w_i$. If $A_\tau = \frac{1}{P} \sum_{i=1}^{M} a_i (M - i + 1)$, $H_\tau = \sum_{i=1}^{M} h_i$, and $W_\tau = \frac{1}{P} \sum_{i=1}^{M} a_i$, then the optimal average response time solution o_τ satisfies $A_\tau \leq o_\tau$, $H_\tau \leq o_\tau$, and $A_\tau + \frac{1}{2} H_\tau - \frac{1}{2} W_\tau \leq o_\tau$.*

COROLLARY 2.1. *If a solution to the minimum average response time problem for task system τ has completion time sum v, where $v \leq \beta_1 [A_\tau + \frac{1}{2} H_\tau - \frac{1}{2} W_\tau] + \beta_2 H_\tau$, then $\frac{v}{o_\tau} \leq \beta_1 + \beta_2$.*

Once again, we delay the proof of Lemma 2.2 until section 3, when we will state and prove a more general result. (See Lemma 3.2.)

We will refer to A_τ and H_τ as the *squashed area* and *height* bounds, respectively. We will refer to the third bound as the *combined* bound. Note that the combined bound is tighter than the squashed area bound, since $W_\tau \leq H_\tau$. The height bound can be viewed as the area of the unshaded region in the right-hand side of Figure 1. The squashed area bound and W_τ are illustrated in Figure 2. The term W_τ is given by the area of the right-most of the M columns, while the squashed area bound is given by the total area of all the columns. The definition corresponds to vertical integration. But note that [12] gives an alternative expression corresponding to horizontal integration, namely, $A_\tau = \frac{1}{P} \sum_{j=1}^{M} \sum_{i=1}^{j} a_i$. This leads to the following expression for the squashed area bound, which is useful in situations where the tasks are not necessarily arranged in order of increasing area.

LEMMA 2.3. *Let $\tau = \{(h_i, w_i) | i = 1, \ldots, M\}$ denote a task system, indexed arbitrarily. Then $A_\tau = \frac{1}{P} \sum_{j=1}^{M} \sum_{i=1}^{j} \min(a_i, a_j)$.*

Proof. Observe that $\sum_{j=1}^{M} \sum_{i=1}^{j} \min(a_i, a_j) = \sum_{i \leq j} \min(a_i, a_j)$ is the sum over all pairs of elements of the minimum of each pair. This sum is independent of the way

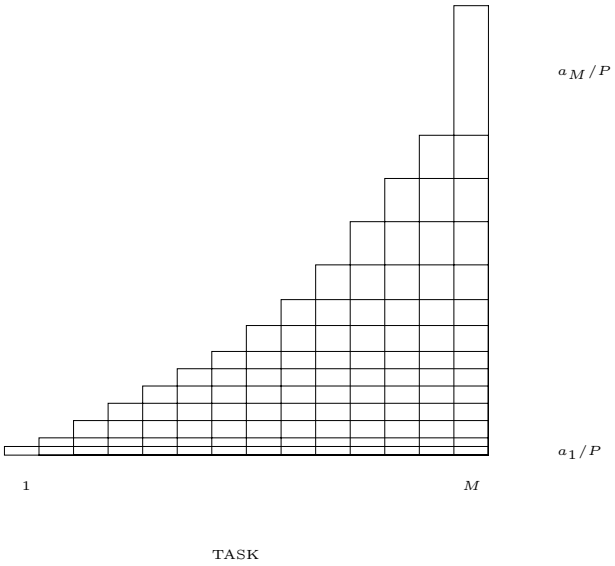

FIG. 2. *The squashed area bound.*

the elements are indexed. Suppose, then, that they are indexed in increasing order, $a_1 \le a_2 \le \cdots \le a_M$. Then $\frac{1}{P}\sum_{j=1}^{M}\sum_{i=1}^{j}\min(a_i, a_j) = \frac{1}{P}\sum_{j=1}^{M}\sum_{i=1}^{j} a_i = A_\tau$. □

In addition to lower bounds on o_τ, we will also need an upper bound on s_τ. To get this bound, we will partition the task system τ into two subsets and also adjust the task heights to facilitate the analysis. We will then consider schedules for the two subsets separately, proving bounds for each. Finally, we will consider the result of combining the two schedules to obtain a schedule for τ.

Consider the shelf assignment that results from applying $\text{SMART}_{\text{FFIA}}$ to the task system τ. We partition the tasks in τ into two subsets as follows. The first subset τ_1 will contain the tasks on the *first shelf* (if any) of each height component — that is, in each height component, the first shelf created by the FFIA packing. The second subset τ_2 will contain the tasks on all *remaining* shelves. (This partitioning is, in a sense, orthogonal to the original partitioning into components based on height. To avoid confusion we shall consistently use the term *component* when referring to the first partitioning, and the term *subset* when referring to the second partitioning. Also note that a similar partitioning into three subsets was given in [12].)

We now create a new task system $\hat{\tau}$, called the *double height* construction, whose tasks are in natural one-to-one correspondence with the tasks in τ. The number of processors required for each task in $\hat{\tau}$ will be identical to that of its counterpart in τ, while the task execution times will be at least as large but less than doubled, according to the following rule. Observe that the new task system $\hat{\tau} = \{(\hat{h}_i, w_i) | i = 1, \ldots, M\}$ will also partition into two subsets $\hat{\tau}_1$ and $\hat{\tau}_2$ corresponding task for task to τ_1 and τ_2. The height $\hat{h}_i$ of a task in the subset $\hat{\tau}_1$ will be $2^{\lceil \log h_i \rceil}$. The height $\hat{h}_i$ of a task in the subset $\hat{\tau}_2$ will be the height $\max_{\{j|\mathcal{S}(j)=\mathcal{S}(i)\}} h_j$ of the shelf containing the corresponding task i in τ. (This is similar to the double construction in [12], although here only the heights are modified, not the widths.)

Observe that all tasks in $\hat{\tau}$ on any given shelf have identical heights. Also note that by construction we have $H_\tau \le H_{\hat{\tau}} \le 2H_\tau$. Corresponding statements hold for the two subsets τ_1 and τ_2.

Let $\mathcal{S}_\tau$ denote the shelf assignment that results from applying $\text{SMART}_{\text{FFIA}}$ to the task system τ. (Then $s_\tau = c(\tau, \mathcal{S}_\tau)$.) To get a bound on s_τ, we will bound $c(\hat{\tau}, \mathcal{S}_\tau)$. First we establish a relationship between these two quantities.

LEMMA 2.4. *Any task system τ satisfies $c(\tau, \mathcal{S}_\tau) \leq c(\hat{\tau}, \mathcal{S}_\tau) + H_\tau - H_{\hat{\tau}}$.*

Proof. Note that the sets of shelves $(\tau, \mathcal{S}_\tau)$ and $(\hat{\tau}, \mathcal{S}_\tau)$ are identical except for the task heights, with each shelf in $(\hat{\tau}, \mathcal{S}_\tau)$ being at least as tall as its counterpart in $(\tau, \mathcal{S}_\tau)$. Let v_τ denote the sum of the completion times of the schedule that results from starting each shelf of $(\tau, \mathcal{S}_\tau)$ at the time the corresponding shelf starts in $\sigma(\hat{\tau}, \mathcal{S}_\tau)$. Since the shelves are potentially reordered and gaps potentially introduced, we have $c(\tau, \mathcal{S}_\tau) \leq v_\tau$. But $c(\hat{\tau}, \mathcal{S}_\tau) - H_{\hat{\tau}} = v_\tau - H_\tau$ represents the sum of the starting times of the tasks in $\sigma(\hat{\tau}, \mathcal{S}_\tau)$ and the new schedule for $(\tau, \mathcal{S}_\tau)$, respectively. The result follows. □

The next step is to bound the quantities $c(\hat{\tau}_1, \mathcal{S}_\tau)$ and $c(\hat{\tau}_2, \mathcal{S}_\tau)$.

LEMMA 2.5. *The partition $\hat{\tau}_1$ satisfies $c(\hat{\tau}_1, \mathcal{S}_\tau) \leq 2H_{\hat{\tau}_1}$.*

We will state and prove a generalization of this lemma in section 3. (See Lemma 3.4.)

LEMMA 2.6. *The partition $\hat{\tau}_2$ satisfies $c(\hat{\tau}_2, \mathcal{S}_\tau) \leq 2A_\tau - 2A_{\tau_1}$.*

The proof of this lemma is fairly elaborate, and we delay it until the end of this section. It is worth noting that Lemma 2.6 is the reason for using FFIA rather than NFIW. We can form analogues of all the other lemmas using $\text{SMART}_{\text{NFIW}}$, but we cannot prove an analogue to Lemma 2.6.

The final step is to get a bound on $c(\hat{\tau}, \mathcal{S}_\tau)$ in terms of $c(\hat{\tau}_1, \mathcal{S}_\tau)$ and $c(\hat{\tau}_2, \mathcal{S}_\tau)$.

LEMMA 2.7. *For any task system τ and any $\delta > 0$, the double height construction $\hat{\tau}$ satisfies $c(\hat{\tau}, \mathcal{S}_\tau) \leq (\delta + 1) \cdot c(\hat{\tau}_1, \mathcal{S}_\tau) + (\frac{1}{\delta} + 1) \cdot c(\hat{\tau}_2, \mathcal{S}_\tau)$.*

Proof. Let y_k denote the completion time of shelf k in its respective schedule, either $\sigma(\hat{\tau}_1, \mathcal{S}_\tau)$ or $\sigma(\hat{\tau}_2, \mathcal{S}_\tau)$. (Recall that all the tasks on each shelf in these schedules complete at the same time.) For each shelf k in $(\hat{\tau}_1, \mathcal{S}_\tau)$, let $y'_k = \delta y_k$, and for each shelf k in $(\hat{\tau}_2, \mathcal{S}_\tau)$, let $y'_k = y_k$. Then construct a schedule of all the shelves in $(\hat{\tau}, \mathcal{S}_\tau)$ by arranging them in order of ascending y'_k. Call this schedule $\mathcal{Z}$, and let z_k denote the completion time of shelf k in $\mathcal{Z}$.

Now consider a shelf k in $(\hat{\tau}_1, \mathcal{S}_\tau)$. Let l be the last shelf in $(\hat{\tau}_2, \mathcal{S}_\tau)$ that is completed before shelf k in $\mathcal{Z}$. Since l comes before k, we have $y_l = y'_l \leq y'_k = \delta y_k$. Then $z_k = y_k + y_l \leq (1 + \delta) y_k$. Therefore, the completion time of each task in $(\hat{\tau}_1, \mathcal{S}_\tau)$ in the schedule $\mathcal{Z}$ is not more than $\delta + 1$ times its completion time in the schedule $\sigma(\hat{\tau}_1, \mathcal{S}_\tau)$.

Next consider a shelf k in $(\hat{\tau}_2, \mathcal{S}_\tau)$. Let l be the last shelf in $(\hat{\tau}_1, \mathcal{S}_\tau)$ that is completed before shelf k in $\mathcal{Z}$. Since l comes before k, we have $\delta y_l = y'_l \leq y'_k = y_k$. Then $z_k = y_k + y_l \leq (1 + \frac{1}{\delta}) y_k$. Therefore, the completion time of each task in $(\hat{\tau}_2, \mathcal{S}_\tau)$ in the schedule $\mathcal{Z}$ is not more than $\frac{1}{\delta} + 1$ times its completion time in the schedule $\sigma(\hat{\tau}_2, \mathcal{S}_\tau)$.

Now the result follows from the fact that reordering the shelves according to Lemma 2.1 will not increase the sum of the completion times. □

Lemma 2.7 is a generalization of Lemma 3.5 in [12]. When $\delta = 1$, notice that both coefficients on the right-hand side become 2, as in the original lemma. Choosing a value of δ different from 1 will ultimately result in reducing the bound in Theorem 2.1 from 9 to 8, as will be seen.

Now we apply the above lemmas and observations together with some bookkeep-

ing to get the following string of inequalities:

$$\begin{aligned}
s_\tau &\le c(\hat{\tau}, \mathcal{S}_\tau) + H_\tau - H_{\hat{\tau}} \\
&\le (\delta+1)\cdot c(\hat{\tau}_1, \mathcal{S}_\tau) + \left(\frac{1}{\delta}+1\right)\cdot c(\hat{\tau}_2, \mathcal{S}_\tau) + H_\tau - H_{\hat{\tau}} \\
&\le 2\left(\frac{1}{\delta}+1\right) A_\tau - 2\left(\frac{1}{\delta}+1\right) A_{\tau_1} + H_\tau + 2(\delta+1)H_{\hat{\tau}_1} - H_{\hat{\tau}} \\
&\le 2\left(\frac{1}{\delta}+1\right) A_\tau + H_\tau + (2\delta+1)H_{\hat{\tau}} - 2(\delta+1)H_{\hat{\tau}_2} - 2\left(\frac{1}{\delta}+1\right) W_{\tau_1} \\
&\le 2\left(\frac{1}{\delta}+1\right) A_\tau + (4\delta+3)H_\tau - 2(\delta+1)H_{\tau_2} - 2\left(\frac{1}{\delta}+1\right) W_{\tau_1} \\
&\le 2\left(\frac{1}{\delta}+1\right) A_\tau + (4\delta+3)H_\tau - 2(\delta+1)W_{\tau_2} - 2\left(\frac{1}{\delta}+1\right) W_{\tau_1} \\
&\le 2\left(\frac{1}{\delta}+1\right) A_\tau + (4\delta+3)H_\tau - 2\min\left(\delta+1, \frac{1}{\delta}+1\right) W_\tau. \qquad (1)
\end{aligned}$$

Now choosing $\delta = \frac{1}{2}$, we get

$$s_\tau \le 6A_\tau + 5H_\tau - 3W_\tau = 6\left(A_\tau + \frac{1}{2}H_\tau - \frac{1}{2}W_\tau\right) + 2H_\tau \le 8o_\tau. \qquad (2)$$

This completes the proof of Theorem 2.1. (Note that choosing $\delta = 1$ yields instead a slightly poorer bound of 9.) We now return to the proofs that we omitted.

Proof of Lemma 2.6. Consider the following schedule of the shelves in $(\hat{\tau}_2, \mathcal{S}_\tau)$. Instead of arranging them in the order dictated by Lemma 2.1, arrange them in the following way. Let $\psi(k) = \min_{\mathcal{S}_\tau(i)=k}\{a_i\}$ be the area of the smallest-area task in τ on shelf k. Note that the area in question is the task's *original* area, not its area in the double height construction. Then reindex the shelves in $(\hat{\tau}, \mathcal{S}_\tau)$ so that $\psi(j) \le \psi(j+1)$ for all j. That is, we are ordering the shelves by increasing area of the least-area task. Take the shelves of $(\hat{\tau}_2, \mathcal{S}_\tau)$ in the order they are indexed, and call this schedule $\mathcal{D}$.

Let g_i denote the completion time of task $i \in \hat{\tau}_2$ in the schedule $\mathcal{D}$. Reordering the shelves according to Lemma 2.1 cannot increase the sum of the completion times, and therefore $c(\hat{\tau}_2, \mathcal{S}_\tau) \le \sum_{i\in\hat{\tau}_2} g_i$.

Reindex the tasks so that $\mathcal{S}_\tau(i) < \mathcal{S}_\tau(j) \Rightarrow i < j$. That is, tasks that appear on lower shelves have lower indices. Then define $\alpha_i = \sum_{j=1}^{i} \min\{a_i, a_j\}$. By Lemma 2.3, $A_\tau = \frac{1}{P}\sum_{i=1}^{M} \alpha_i$.

Our goal is to show that $g_i \le \frac{2}{P}\alpha_i$ for all $i \in \hat{\tau}_2$. From this we can conclude that

$$c(\hat{\tau}_2, \mathcal{S}_\tau) \le \sum_{i\in\hat{\tau}_2} g_i \le \frac{2}{P}\sum_{i\in\hat{\tau}_2}\alpha_i = 2\left(A_\tau - \frac{1}{P}\sum_{i\in\tau_1}\alpha_i\right) \le 2(A_\tau - A_{\tau_1}). \qquad (3)$$

For the analysis, we wish to treat each height component separately, and to this end we introduce the following notation. For any two tasks i and j, we write $i \sim j$ if they are in the same height component, i.e., $\lceil \log_2 h_i \rceil = \lceil \log_2 h_j \rceil$. For a given task i, consider the schedule consisting only of the shelves in $\mathcal{D}$ that contain tasks which are in the same height component as i, with the shelves ordered as they are in $\mathcal{D}$. Note that this is the order in which the shelves are created when the tasks are being packed onto shelves. Call this schedule $\mathcal{D}(i)$. For $i \in \hat{\tau}_2$, let $\tilde{g}_i$ denote the completion

time of task i in $\mathcal{D}(i)$. Also let $\tilde{\alpha}_i = \sum_{j \le i \wedge j \sim i} \min\{a_i, a_j\}$. The following lemma demonstrates a relationship between $\tilde{g}_i$ and $\tilde{\alpha}_i$.

LEMMA 2.8. *$\tilde{g}_i \le \frac{2}{P}\tilde{\alpha}_i$ for all $i \in \hat{\tau}_2$.*

We delay the proof of Lemma 2.8 until the completion of the proof of Lemma 2.6.

Now we are ready to show that $g_i \le \frac{2}{P}\alpha_i$ for all $i \in \hat{\tau}_2$. Pick any task $i_0 \in \hat{\tau}_2$. Suppose that there are r height components, other than the component containing the task i_0 itself, that contain a shelf which comes before i_0 in the schedule $\mathcal{D}$. For each such component $l \in \{1, \dots, r\}$, let i_l be the least-area task on the last shelf of the component l that comes before the shelf containing i_0. Note that the indexing of the shelves and the indexing of the tasks guarantee that $i_l < i_0$ for all $l \in \{1, \dots, r\}$. Also note that $a_{i_l} \le a_{i_0}$ for all $l \in \{1, \dots, r\}$. Now we have

$$\begin{aligned} g_{i_0} &= \sum_{l=0}^{r} \tilde{g}_{i_l} \le \frac{2}{P} \sum_{l=0}^{r} \tilde{\alpha}_{i_l} = \frac{2}{P} \sum_{l=0}^{r} \sum_{j \le i_l \wedge j \sim i_l} \min\{a_{i_l}, a_j\} \\ &\le \frac{2}{P} \sum_{l=0}^{r} \sum_{j \le i_0 \wedge j \sim i_l} \min\{a_{i_0}, a_j\} = \frac{2}{P} \sum_{j=1}^{i_0} \min\{a_{i_0}, a_j\} = \frac{2}{P}\alpha_{i_0}. \end{aligned} \tag{4}$$

Proof of Lemma 2.8. Pick some task $i_0 \in \hat{\tau}_2$. We will show that $\tilde{g}_{i_0} \le \frac{2}{P}\tilde{\alpha}_{i_0}$.

Let $\mathcal{S}_\tau^{-1}(k)$ denote the set of tasks on shelf k. Let $T_{i_0} = \{j \in \hat{\tau} : j \sim i_0\}$ denote the height component containing task i_0, and let $K = \{k : k < \mathcal{S}_\tau(i_0) \text{ and } \mathcal{S}_\tau^{-1}(k) \subseteq T_{i_0}\}$ be the set of shelves containing tasks in the same height component as i_0 that are indexed lower than the shelf containing i_0. These are the shelves that precede the task i_0 in the schedule $\mathcal{D}(i_0)$, plus the single shelf containing tasks from $T_{i_0} \cap \hat{\tau}_1$. We will examine the shelves in K and determine the contribution of each to $\tilde{g}_{i_0}$ and to $\tilde{\alpha}_{i_0}$. For this purpose, we will partition K into three subsets. Some additional notation is required first.

Define the *gap* of shelf k with respect to task i_0 to be $d_k = P - \sum_{\{i \in \mathcal{S}_\tau^{-1}(k) : a_i \le a_{i_0}\}} w_i$. Then d_k is "how much room" is left on shelf k at the time when task i_0 is assigned to a shelf. (If there are tasks on shelf k with the same area as i_0, then d_k may be less than the amount of room that is left on shelf k when i_0 is assigned to a shelf.) Note that $d_k < w_{i_0}$ for all $k \in K$ due to the use of first fit. Also note that there is at most one shelf $k \in K$ such that $d_k \ge \frac{P}{2}$. Let v denote this shelf if it exists; otherwise, let $v = \infty$. Let $k_0 = \min\{k \in K\}$ be the lowest-indexed shelf in T_{i_0}. Then the tasks on the shelf k_0 are in $\hat{\tau}_1$, not in $\hat{\tau}_2$, and so k_0 is not in $\mathcal{D}$ or $\mathcal{D}(i_0)$. Let $K^- = K \setminus \{k_0\}$.

Now we are ready to partition K into three subsets. Let $K_1 = \{k \in K^- : \exists i \in \mathcal{S}_\tau^{-1}(k) \text{ such that } a_i > a_{i_0}\}$ be the set of shelves containing a task larger than i_0 but not including the shelf k_0. Let $K_2 = \{k \in K^- \setminus K_1 : k > v\}$ be the set of shelves that do not contain any tasks larger than i_0 and that are scheduled after the shelf with $d_v \ge \frac{P}{2}$. Finally, let $K_3 = \{k \in K^- \setminus K_1 : k \le v\} \cup \{k_0\}$ be the remaining shelves — the shelf k_0 along with all shelves that do not contain any tasks larger than i_0 and that are scheduled not later than the shelf with $d_v \ge \frac{P}{2}$.

Let $h = \hat{h}_{i_0} = 2^{\lceil log_2 h_{i_0} \rceil}$, and let the height of shelf k be given by $\frac{h}{2} + x_k$, where $0 < x_k \le \frac{h}{2}$. Then the completion time of task i_0 in $\mathcal{D}(i_0)$ does not exceed h plus the sum of the heights of the shelves that precede it in $\mathcal{D}(i_0)$. That is,

$$\tilde{g}_{i_0} \le \sum_{k \in K^-} \left(x_k + \frac{h}{2} \right) + h. \tag{5}$$

We also have

$$\tilde{\alpha}_{i_0} = \sum_{j \le i_0 \wedge j \sim i_0} \min\{a_{i_0}, a_j\} \ge \sum_{k \in K} \sum_{j \in \mathcal{S}_\tau^{-1}(k)} \min\{a_{i_0}, a_j\} + a_{i_0}. \tag{6}$$

Now for $k \in K^-$, let

$$\lambda_k = \frac{2}{P} \sum_{j \in \mathcal{S}_\tau^{-1}(k)} \min\{a_{i_0}, a_j\} - \left(x_k + \frac{h}{2}\right). \tag{7}$$

Then from (5), (6), and (7) we have

$$\frac{2}{P}\tilde{\alpha}_{i_0} - \tilde{g}_{i_0} \ge \sum_{k \in K^-} \lambda_k + \frac{2}{P} \sum_{j \in \mathcal{S}_\tau^{-1}(k_0)} \min\{a_{i_0}, a_j\} + \frac{2}{P} a_{i_0} - h. \tag{8}$$

Now our goal is to show that the quantity in (8) is positive, and, to this end, we consider each of K_1, K_2, and K_3 in turn. Suppose that $k \in K_1$. Then there is at least one task on shelf k with area greater than a_{i_0}, so

$$\begin{aligned} \sum_{j \in \mathcal{S}_\tau^{-1}(k)} \min\{a_{i_0}, a_j\} &\ge a_{i_0} + \sum_{\{j \in \mathcal{S}_\tau^{-1}(k) : a_j \le a_{i_0}\}} a_j \\ &\ge a_{i_0} + \frac{h}{2} \left(\sum_{\{j \in \mathcal{S}_\tau^{-1}(k) : a_j \le a_{i_0}\}} w_j \right) \\ &= a_{i_0} + \frac{h}{2}(P - d_k). \end{aligned} \tag{9}$$

It follows from (7) and (9) that

$$\lambda_k \ge \frac{2a_{i_0}}{P} + h - \frac{hd_k}{P} - \left(x_k + \frac{h}{2}\right) > 0, \tag{10}$$

because $a_{i_0} = h_{i_0} w_{i_0} > \frac{h}{2} d_k$, and $h \ge x_k + \frac{h}{2}$.

Next consider $k \in K_2$. Suppose $q \in \mathcal{S}_\tau^{-1}(k)$. By the definition of K_2, we have $\mathcal{S}_\tau(q) > v$ and $a_q \le a_{i_0}$, and so $w_q > d_v \ge \frac{P}{2}$. Therefore, shelf k contains only one task q. We conclude that

$$\lambda_k = \frac{2}{P} a_q - h_q = \frac{2}{P} h_q w_q - h_q > 0, \tag{11}$$

because $w_q > \frac{P}{2}$.

Finally, consider the shelves in K_3. Let $k_0 < k_1 < \cdots < k_r$ denote all the shelves in K_3. For $q \ge 1$, we have

$$\sum_{j \in \mathcal{S}_\tau^{-1}(k_q)} \min\{a_{i_0}, a_j\} = \sum_{j \in \mathcal{S}_\tau^{-1}(k_q)} a_j \ge \frac{h}{2}(P - d_{k_q}) + x_{k_q} d_{k_{q-1}}. \tag{12}$$

This is because all tasks $j \in \mathcal{S}_\tau^{-1}(k_q)$ have $h_j > \frac{h}{2}$ and $w_j > d_{k_{q-1}}$. The latter is important only for the tallest task on shelf k_q, which has height $\frac{h}{2} + x_{k_q}$.

For $q = 0$, we have

$$\sum_{j \in \mathcal{S}_\tau^{-1}(k_0)} \min\{a_{i_0}, a_j\} \geq \sum_{\{j \in \mathcal{S}_\tau^{-1}(k_0) : a_j \leq a_{i_0}\}} a_j \geq \frac{h}{2} \sum_{\{j \in \mathcal{S}_\tau^{-1}(k_0) : a_j \leq a_{i_0}\}} w_j = \frac{h}{2}(P - d_{k_0}). \tag{13}$$

Then from (7), (12), and (13), we have

$$\begin{aligned}
&\sum_{k \in K_3 \setminus \{k_0\}} \lambda_k + \frac{2}{P} \sum_{j \in \mathcal{S}_\tau^{-1}(k_0)} \min\{a_{i_0}, a_j\} + \frac{2}{P} a_{i_0} - h \\
&\geq \sum_{q=1}^{r} \left(h - \frac{h d_{k_q}}{P} + \frac{2 x_{k_q} d_{k_{q-1}}}{P} - x_{k_q} - \frac{h}{2} \right) + h - \frac{h d_{k_0}}{P} + \frac{2 a_{i_0}}{P} - h \\
&= \sum_{q=1}^{r} \left(\frac{h}{2} - x_{k_q} - \frac{h d_{k_q}}{P} + \frac{2 x_{k_q} d_{k_{q-1}}}{P} \right) - \frac{h d_{k_0}}{P} + \frac{2 a_{i_0}}{P} \\
&= \sum_{q=1}^{r} \left(\frac{h}{2} - x_{k_q} - \frac{h d_{k_{q-1}}}{P} + \frac{2 x_{k_q} d_{k_{q-1}}}{P} \right) - \frac{h d_{k_r}}{P} + \frac{2 a_{i_0}}{P} \\
&= \sum_{q=1}^{r} \left(\frac{h}{2} - x_{k_q} \right) \left(1 - \frac{2 d_{k_{q-1}}}{P} \right) - \frac{h d_{k_r}}{P} + \frac{2 a_{i_0}}{P} \\
&> 0. \qquad (14)
\end{aligned}$$

The last inequality holds because $q-1 < r \leq u$, and so $d_{k_{q-1}} < \frac{P}{2}$ for all $q \in \{1, \ldots, r\}$, and because $a_{i_0} = h_{i_0} w_{i_0} > \frac{h}{2} d_{k_r}$.

Now from (7), (8), (10), (11), and (14), we conclude that $\tilde{g}_{i_0} \leq \frac{2}{P} \tilde{\alpha}_{i_0}$. □

3. The weighted case. Consider a task system $\tau = \{(h_i, w_i) | i = 1, \ldots, M\}$, and suppose now that each task i has weight u_i. In this section our goal is to minimize the weighted sum of the completion times given by $\sum_{i=1}^{M} u_i(t_i + h_i)$. Our algorithm for this problem is a generalization in two ways of the original $\text{SMART}_{\text{NFIW}}$ algorithm. We now describe each of these.

Recall that the original algorithm partitions tasks by height based on powers of 2. More generally, we can base the partitions on any power $\gamma > 1$. In other words, partition τ into components by assigning task i to the component j that satisfies $\gamma^{j-1} < h_i \leq \gamma^j$. If the rest of the algorithms $\text{SMART}_{\text{NFIW}}$ and $\text{SMART}_{\text{FFIA}}$ are unchanged, we obtain parametrized versions γ-$\text{SMART}_{\text{NFIW}}$ and γ-$\text{SMART}_{\text{FFIA}}$ of these algorithms, with the original algorithms corresponding to the special case $\gamma = 2$. We will employ γ-$\text{SMART}_{\text{NFIW}}$ here. (While we could have introduced this generalization in the previous section, we chose not to do so because it turns out not to improve the bound there.)

The second generalization allows us to effectively handle weighted tasks. Specifically, we now compute for each task i a ratio $\frac{w_i}{u_i}$ of width to weight, and we assign tasks in each component to shelves according to a *next fit increasing width to weight* bin packing algorithm. Let $\mathcal{U}_k$ be the total weight of the tasks on shelf k. (Note that if all the weights are unity, then $\mathcal{U}_k = \mathcal{M}_k$.) The shelves are combined in the order dictated by the following lemma.

LEMMA 3.1. *For any set of shelves $(\tau, \mathcal{S})$, an ordering of these shelves is optimal among all possible such shelf orderings if and only if $\frac{\mathcal{H}_1}{\mathcal{U}_1} \leq \cdots \leq \frac{\mathcal{H}_S}{\mathcal{U}_S}$.*

As in section 2, let $\sigma(\tau, \mathcal{S})$ be the schedule that results from ordering the shelves $(\tau, \mathcal{S})$ as specified by Lemma 3.1, and let $c(\tau, \mathcal{S})$ be the weighted sum of the completion times. This method of ordering the shelves amounts to Smith's ratio rule for scheduling tasks of width 1 on a single processor [10] and has the same proof of optimality.

Proof. Suppose that the shelves are not in order of nondecreasing $\frac{\mathcal{H}_k}{\mathcal{U}_k}$. Then there is a shelf k such that $\frac{\mathcal{H}_k}{\mathcal{U}_k} > \frac{\mathcal{H}_{k+1}}{\mathcal{U}_{k+1}}$. If the two shelves are interchanged, then the completion times of the tasks on shelf k will increase by $\mathcal{H}_{k+1}$ and the completion times of the tasks on shelf $k+1$ will decrease by $\mathcal{H}_k$. Therefore, interchanging the shelves decreases the weighted sum of the completion times by $\mathcal{U}_{k+1}\mathcal{H}_k - \mathcal{U}_k\mathcal{H}_{k+1} = \mathcal{U}_k\mathcal{U}_{k+1}(\frac{\mathcal{H}_k}{\mathcal{U}_k} - \frac{\mathcal{H}_{k+1}}{\mathcal{U}_{k+1}}) > 0$. □

The algorithm for weighted tasks is a straightforward generalization of its unweighted counterpart γ-SMART$_{\text{NFIW}}$, and we will refer to it by the same name. We will also retain the notation s_τ and o_τ to denote the weighted completion time sum for the γ-SMART$_{\text{NFIW}}$ and optimal solutions for τ, respectively.

THEOREM 3.1. *For any weighted task system $\tau = \{(h_i, w_i, u_i) | i = 1, \ldots, M\}$, the 1.65-SMART$_{\text{NFIW}}$ algorithm has time complexity $O(M \log M)$ and satisfies $\frac{s_\tau}{o_\tau} \leq 8.53$.*

As in section 2, we will begin with lower bounds on o_τ and then move on to upper bounds on s_τ. In order to obtain lower bounds on the total weighted response time, we extend the definitions of H_τ, A_τ, and W_τ. Specifically, we let $H_\tau = \sum_{i=1}^{M} u_i h_i$ be the weighted sum of the task heights. Suppose that the tasks are ordered such that $\frac{a_i}{u_i} \leq \frac{a_{i+1}}{u_{i+1}}$ for all tasks $i \in \{1, \ldots, M-1\}$. Then we define $A_\tau = \frac{1}{P}\sum_{i=1}^{M} u_i(\sum_{j=1}^{i} a_j)$. Note that we are now ordering the tasks according to Smith's ratio rule [10]. Finally, let $W_\tau = \frac{1}{P}\sum_{i=1}^{M} u_i a_i$. Then Lemma 2.2 and Corollary 2.1 can be extended to weighted tasks.

LEMMA 3.2. *The optimal solution o_τ satisfies $A_\tau \leq o_\tau$, $H_\tau \leq o_\tau$, and $A_\tau + \frac{1}{2}H_\tau - \frac{1}{2}W_\tau \leq o_\tau$.*

Proof. Given a schedule for the task system τ, let $f_\tau = \sum_{i=1}^{M} u_i(t_i + h_i)$ be its weighted completion time sum. Then $H_\tau = \sum_{i=1}^{M} u_i h_i \leq \sum_{i=1}^{M} u_i(t_i + h_i) = f_\tau$. This holds for any schedule of τ, and therefore $H_\tau \leq o_\tau$.

Next we will show that $A_\tau + \frac{1}{2}H_\tau - \frac{1}{2}W_\tau \leq o_\tau$, and from this it also follows that $A_\tau \leq o_\tau$, since $H_\tau \geq W_\tau$. Given a schedule for the task system τ, let $r_i(t)$ denote the fraction of task i that is not yet completed at time t. That is, let

$$r_i(t) = \begin{cases} 1 & \text{if } t \leq t_i, \\ 1 - \frac{t - t_i}{h_i} & \text{if } t_i < t \leq t_i + h_i, \\ 0 & \text{if } t_i + h_i < t. \end{cases} \tag{15}$$

Now let $r(t) = \sum_{i=1}^{M} u_i r_i(t)$ be the weighted number of tasks remaining at time t, including fractional tasks. Then

$$\begin{aligned} \int_0^\infty r(t)dt &= \sum_{i=1}^{M} u_i \int_0^\infty r_i(t)dt \\ &= \sum_{i=1}^{M} u_i \left[\int_0^{t_i+h_i} dt - \int_{t_i}^{t_i+h_i} \frac{t - t_i}{h_i} dt \right] \end{aligned}$$

$$= \sum_{i=1}^{M} u_i \left[(t_i + h_i) - \frac{h_i}{2} \right]$$

$$= f_\tau - \frac{1}{2} H_\tau. \tag{16}$$

Now we seek a lower bound on $r(t)$. Define a "squashed" task set $\dot{\tau}$ corresponding to τ in the following way. For each task $i \in \tau$, there is a corresponding task in $\dot{\tau}$ with width P, height $\frac{a_i}{P}$, and weight u_i. Then the squashed task has the same area and weight as the original task. Consider the schedule in which the tasks in $\dot{\tau}$ are ordered by increasing ratio of area to weight. Let $r^*(t)$ denote the function $r(t)$ for this schedule.

LEMMA 3.3. *For any schedule of τ, the corresponding function $r(t)$ satisfies $r(t) \geq r^*(t)$ for all t.*

We delay the proof of Lemma 3.3 until the completion of the proof of Lemma 3.2.

Let $f^*_{\dot{\tau}}$ be the weighted completion time sum of the squashed schedule. Then from (16) we have

$$\int_0^\infty r^*(t)dt = f^*_{\dot{\tau}} - \frac{1}{2} H_{\dot{\tau}}. \tag{17}$$

Now observe that $f^*_{\dot{\tau}} = A_\tau$ and $H_{\dot{\tau}} = W_\tau$. Then we have

$$f_\tau - \frac{1}{2} H_\tau = \int_0^\infty r(t)dt \geq \int_0^\infty r^*(t)dt = f^*_{\dot{\tau}} - \frac{1}{2} H_{\dot{\tau}} = A_\tau - \frac{1}{2} W_\tau. \tag{18}$$

We conclude that $o_\tau \geq A_\tau + \frac{1}{2} H_\tau - \frac{1}{2} W_\tau$.

Proof of Lemma 3.3. Consider the more general P processor parallel scheduling problem in which task i requires a_i units of processor time to complete, but there are no other restrictions. In other words, preemption without penalty is allowed, and the task execution need not take place within a rectangle of a given height and width. Given an arbitrary solution for this scheduling problem, let $X_i(t)$ denote the units of processor time completed for task i at time t. Then the fraction of task i that is not yet completed at time t can be written as $r_i(t) = 1 - X_i(t)/a_i$, a generalization of (15). We minimize $r(t) = \sum_{i=1}^{M} u_i r_i(t)$ over all possible schedules for τ, including those which are legal for our original rectangle packing scheduling problem. Formally, we wish to minimize $\sum_{i=1}^{M} u_i(1 - X_i(t)/a_i)$ subject to the constraints $X_i(t) \leq a_i$ for each i, and $\sum_{i=1}^{M} X_i(t) \leq Pt$. Removing the constant $\sum_{i=1}^{M} u_i$, we wish equivalently to maximize $\sum_{i=1}^{M} (u_i/a_i) X_i$. This trivial linear program can be solved exactly via a greedy algorithm. The solution corresponds precisely to ordering the squashed tasks by decreasing ratio of weight to area and processing as many of them sequentially as can be accomplished by time t. The resulting cost is $r^*(t)$. □

We now obtain an upper bound on s_τ in the same manner as in section 2. We partition the task system τ in the same way and prove bounds for schedules for the two subsets separately. Then we consider the result of combining the two schedules. However, we make use of a slightly different "double height" construction. In particular, we use the height $\hat{h}_i = \gamma^{\lceil \log_\gamma h_i \rceil}$ for *every* task i, not just those in the first subset $\hat{\tau}_1$. Then with the exception of Lemma 2.6, the relevant results from section 2 (Lemmas 2.4, 2.5, and 2.7) carry over directly to the modified algorithm and double height construction.

As before, we will let $\mathcal{S}_\tau$ denote the shelf assignment that results from applying $\text{SMART}_{\text{NFIW}}$ to the task system τ.

We now present a generalization of Lemma 2.5 incorporating γ.

LEMMA 3.4. *The partition $\hat{\tau}_1$ satisfies $c(\hat{\tau}_1, \mathcal{S}_\tau) \le \frac{\gamma}{\gamma-1} H_{\hat{\tau}_1}$.*

Proof. Consider a schedule in which the shelves in $\hat{\tau}_1$ are arranged in order of increasing height. Recall that the shelf heights are powers of γ, and that there is at most one shelf of each height. Therefore, if a given shelf has height h, then its completion time in this schedule is at most $h + \frac{1}{\gamma}h + \frac{1}{\gamma^2}h + \cdots \le \frac{1}{1-\frac{1}{\gamma}}h = \frac{\gamma}{\gamma-1}h$. Every task on a given shelf has the same height, and so the height of a task is the same as the height of its shelf. It follows that the completion time of a task $i \in \hat{\tau}_1$ does not exceed $\frac{\gamma}{\gamma-1}\hat{h}_i$. Now observe that reordering the shelves according to Lemma 3.1 can only reduce the weighted completion time sum of the schedule, and the result follows. ∎

In place of Lemma 2.6, we have the following pair of lemmas.

LEMMA 3.5. *For any task system τ, the double height construction $\hat{\tau}$ satisfies $A_{\hat{\tau}} \le \gamma A_\tau$ and $H_{\hat{\tau}} \le \gamma H_\tau$.*

Proof. First observe that $\hat{h}_i = \gamma^{\lceil \log_\gamma h_i \rceil} < \gamma^{\log_\gamma h_i + 1} = \gamma h_i$. It follows directly that $H_{\hat{\tau}} < \gamma H_\tau$. Suppose that the tasks are ordered by nondecreasing ratio of area to weight, i.e., $\frac{a_1}{u_1} \le \frac{a_2}{u_2} \le \cdots \le \frac{a_M}{u_M}$. Note that altering the task heights may put the tasks out of order with respect to the ratio of area to weight, but still we have $A_{\hat{\tau}} \le \frac{1}{P}\sum_{i=1}^{M}(\sum_{k=1}^{i}\hat{a}_k)u_i \le \gamma A_\tau$. ∎

LEMMA 3.6. *The partition $\hat{\tau}_2$ satisfies $c(\hat{\tau}_2, S_\tau) \le A_{\hat{\tau}} + A_{\hat{\tau}_2} - A_{\hat{\tau}_1}$.*

Proof. Consider the following schedule of the tasks in $\hat{\tau}_2$. Assign the tasks to shelves as in $\text{SMART}_{\text{NFIW}}$, but then do not arrange the shelves according to Lemma 3.1. Instead, arrange them according to the area to weight ratio of the task on each shelf with the smallest ratio, so that the shelves are in increasing order according to that ratio. Call this schedule $\mathcal{D}$. Let g_i denote the completion time of task $i \in \hat{\tau}_2$ in the schedule $\mathcal{D}$. Reordering the shelves according to Lemma 3.1 cannot increase the sum of the completion times, and, therefore, $c(\hat{\tau}_2, \mathcal{S}_\tau) \le \sum_{i\in\hat{\tau}_2} u_i g_i$. Suppose that the tasks in $\hat{\tau}$ are ordered by increasing ratio of area to weight, i.e., $\frac{\hat{a}_i}{u_i} \le \frac{\hat{a}_{i+1}}{u_{i+1}}$ for all $i \in \{1, \ldots, M-1\}$. Let $\alpha_i = \sum_{k=1}^{i}\hat{a}_k$ and $\beta_i = \sum_{k\le i \wedge k\in\hat{\tau}_2}\hat{a_k}$. Then $A_{\hat{\tau}} = \frac{1}{P}\sum_{i=1}^{M} u_i\alpha_i$ and $A_{\hat{\tau}_2} = \frac{1}{P}\sum_{i=1}^{M} u_i\beta_i$. Our goal is to show that $g_i \le \frac{\alpha_i+\beta_i}{P}$ for all $i \in \hat{\tau}_2$. From this we can conclude that

$$c(\hat{\tau}_2, \mathcal{S}_\tau) \le \sum_{i\in\hat{\tau}_2} u_i g_i \le \frac{1}{P}\sum_{i\in\hat{\tau}_2} u_i(\alpha_i+\beta_i) = A_{\hat{\tau}} - \frac{1}{P}\sum_{i\in\hat{\tau}_1} u_i\alpha_i + A_{\hat{\tau}_2} \le A_{\hat{\tau}} - A_{\hat{\tau}_1} + A_{\hat{\tau}_2}. \tag{19}$$

For the analysis, we wish to treat each height component separately, and to this end we recall the following notation. For any two tasks i and j, we write $i \sim j$ if they are in the same height component, i.e., $\lceil \log_\gamma h_i \rceil = \lceil \log_\gamma h_j \rceil$. For a given task i, consider the schedule consisting only of the shelves in $\mathcal{D}$ that contain tasks which are in the same height component as i, with the shelves ordered as they are in $\mathcal{D}$. Note that this is the order in which the shelves are created when the tasks are being packed onto shelves. Call this schedule $\mathcal{D}(i)$. For $i \in \hat{\tau}_2$, let $\tilde{g}_i$ denote the completion time of task i in $\mathcal{D}(i)$. Also let $\tilde{\alpha}_i = \sum_{j\le i\wedge j\sim i}\hat{a}_j$ and $\tilde{\beta}_i = \sum_{j\le i\wedge j\sim i\wedge j\in\hat{\tau}_2}\hat{a}_j$.

LEMMA 3.7. *$\tilde{g}_i \le \frac{\tilde{\alpha}_i+\tilde{\beta}_i}{P}$ for all $i \in \hat{\tau}_2$.*

We delay the proof of Lemma 3.7 until the completion of the proof of Lemma 3.6.

Now we are ready to show that $g_i \le \frac{\alpha_i+\beta_i}{P}$ for all $i \in \hat{\tau}_2$. Pick any task $i_0 \in \hat{\tau}_2$. Suppose that there are r height components, other than the component containing the task i_0 itself, that contain a shelf which comes before i_0 in the schedule $\mathcal{D}$. For

each such component $l \in \{1, \ldots, r\}$, let i_l be the task with the least area to weight ratio on the last shelf of the component l that comes before the shelf containing i_0. Note that the ordering of the shelves guarantees that $i_l < i_0$ for all $l \in \{1, \ldots, r\}$. Now we have

$$\begin{aligned}
g_{i_0} &= \sum_{l=0}^{r} \tilde{g}_{i_l} \\
&\leq \frac{1}{P} \sum_{l=0}^{r} (\tilde{\alpha}_{i_l} + \tilde{\beta}_{i_l}) \\
&= \frac{1}{P} \sum_{l=0}^{r} \left(\sum_{j \leq i_l \wedge j \sim i_l} \hat{a}_j + \sum_{j \leq i_l \wedge j \sim i_l \wedge j \in \hat{\tau}_2} \hat{a}_j \right) \\
&\leq \frac{1}{P} \sum_{l=0}^{r} \left(\sum_{j \leq i_0 \wedge j \sim i_l} \hat{a}_j + \sum_{j \leq i_0 \wedge j \sim i_l \wedge j \in \hat{\tau}_2} \hat{a}_j \right) \\
&= \frac{1}{P} \left(\sum_{j=1}^{i_0} \hat{a}_j + \sum_{j=1 \wedge j \in \hat{\tau}_2}^{i_0} \hat{a}_j \right) \\
&= \frac{\alpha_{i_0} + \beta_{i_0}}{P}. \qquad \square \qquad (20)
\end{aligned}$$

Proof of Lemma 3.7. Let i_0 be any task in $\hat{\tau}_2$. Let $T_{i_0} = \{i \in \hat{\tau} : i \sim i_0\}$ be the height component containing task i_0. Let $h = \hat{h}_{i_0} = \gamma^{\lceil \log_\gamma h_{i_0} \rceil}$ be the height of each task in T_{i_0}. Let the shelves in T_{i_0} be numbered consecutively according to the order in which they were created. Then shelf 1 is in $\hat{\tau}_1$ and shelf 2 is the first shelf in $\mathcal{D}(i_0)$.

Let us define $\phi(k)$ to be the first task $i \in T_{i_0}$ assigned to shelf k. Observe that $\phi(k)$ for $k > 1$ is too wide to fit on shelf $k-1$, and so the total width of any shelf k plus the width of $\phi(k+1)$ is greater than P. Since every task in T_{i_0} has height h, it follows that the total area of any shelf k plus the area of $\phi(k+1)$ is greater than hP. It also follows that ordering the tasks by increasing width to weight ratio is the same as ordering the tasks by increasing area to weight ratio. Thus, if task i_0 is assigned to shelf k, then the total area of all tasks in T up to and including i_0 satisfies $\tilde{\alpha}_{i_0} \geq (k-1)hP - \sum_{j=2}^{k} \hat{a}_{\phi(j)} \geq (k-1)hP - \tilde{\beta}_{i_0}$. On the other hand, the completion time of task i_0 in $\mathcal{D}(i_0)$ is $\tilde{g}_{i_0} = (k-1)h$. $\square$

Putting all of these lemmas together we get

$$\begin{aligned}
s_\tau &\leq c(\hat{\tau}, S_\tau) + H_\tau - H_{\hat{\tau}} \\
&\leq (\delta+1) c(\hat{\tau}_1, S_\tau) + \left(\frac{1}{\delta} + 1\right) c(\hat{\tau}_2, S_\tau) + H_\tau - H_{\hat{\tau}} \\
&\leq \left(\frac{1}{\delta} + 1\right) A_{\hat{\tau}} + \left(\frac{1}{\delta} + 1\right) A_{\hat{\tau}_2} - \left(\frac{1}{\delta} + 1\right) A_{\hat{\tau}_1} \\
&\quad + \frac{\gamma}{\gamma - 1} (\delta + 1) H_{\hat{\tau}_1} + H_\tau - H_{\hat{\tau}} \\
&= \left(\frac{1}{\delta} + 1\right) A_{\hat{\tau}} + \left(\frac{1}{\delta} + 1\right) A_{\hat{\tau}_2} - \left(\frac{1}{\delta} + 1\right) A_{\hat{\tau}_1} \\
&\quad + \left(\frac{1}{\delta} + 1\right) H_{\hat{\tau}_1} + \left[\frac{\gamma}{\gamma - 1}(\delta + 1) - \frac{1}{\delta} - 2\right] H_{\hat{\tau}}
\end{aligned}$$

$$
\begin{aligned}
&- \left[\frac{\gamma}{\gamma-1}(\delta+1) - \frac{1}{\delta} - 1\right] H_{\hat{\tau}_2} + H_\tau \\
&\le \gamma\left(\frac{1}{\delta}+1\right) A_\tau + \gamma\left(\frac{1}{\delta}+1\right) A_{\tau_2} - \left(\frac{1}{\delta}+1\right) A_{\tau_1} \\
&\quad + \gamma\left(\frac{1}{\delta}+1\right) H_{\tau_1} + \left[\frac{\gamma^2}{\gamma-1}(\delta+1) - \frac{\gamma}{\delta} - 2\gamma + 1\right] H_\tau \\
&\quad - \left[\frac{\gamma}{\gamma-1}(\delta+1) - \frac{1}{\delta} - 1\right] H_{\tau_2} \\
&\le \gamma\left(\frac{1}{\delta}+1\right) o_\tau + \gamma\left(\frac{1}{\delta}+1\right) A_\tau \\
&\quad + \left[\frac{\gamma^2}{\gamma-1}(\delta+1) - \frac{\gamma}{\delta} - 2\gamma + 1\right] H_\tau \\
&\quad - \min\left\{\frac{1}{\delta}+1, \left[\frac{\gamma}{\gamma-1}(\delta+1) - \frac{1}{\delta} - 1\right]\right\} W_\tau. \qquad (21)
\end{aligned}
$$

The next-to-last inequality is actually only guaranteed to hold if the term $\frac{\gamma}{\gamma-1}(\delta+1) - \frac{1}{\delta} - 2$ is nonnegative. In any case, the optimal values $\gamma = 1.65$ and $\delta = 0.72$ satisfy this condition, and yield $\frac{s_\tau}{o_\tau} \le 8.53$.

Note from (21) that choosing $\gamma = 2$ and $\delta = 1$ yields $\frac{s_\tau}{o_\tau} \le 9$, and thus the original algorithm of [12] for the unweighted problem is 9-approximate.

4. Examples. We first present a family of task systems for the unweighted minimum response time problem with the property that $\text{SMART}_{\text{FFIA}}$ produces a ratio $\frac{s_\tau}{o_\tau}$ approaching 4.5 asymptotically. There are two groups of tasks, a *height* group and an *area* group.

The tasks in the height group fit onto $n-1$ shelves of heights $4, 8, 16, \ldots, 2^n$, with the number of tasks on each shelf being equal to the height of that shelf. On each such shelf k with $2 \le k \le n$ there is one task of full height 2^k. All other tasks on that shelf are of height slightly larger than 2^{k-1}. The width of each task in the height group is 1, and P is chosen large enough so that the total number of tasks in the height group is less than or equal to $\frac{P}{4} - 3$. $\text{SMART}_{\text{FFIA}}$ will produce a schedule with cost $2^{2n+1} - 7 \cdot 2^n + 6$, while in the optimal case all tasks start concurrently and produce overall costs of $\frac{1}{3}(2^{2n+1} + 3 \cdot 2^n - 14)$.

The area group consists of q tasks of width $\frac{P}{2} + 1$ and height $1 + \frac{4}{P}$ and q tasks of width $\frac{P}{4} + \frac{2}{P} + 1.5$ and height 2. Note that all tasks in this group have the same area. Therefore, we may assume that $\text{SMART}_{\text{FFIA}}$ will produce a schedule with q shelves such that each shelf contains a wide and a narrow task. Assuming $P \to \infty$ the cost of this schedule is $2q^2 + q$. On the other hand, if q is a multiple of 6 the optimal schedule is achieved by placing all q wide tasks on top of each other side by side with a stack of $\frac{q}{2}$ of the narrow tasks. The remaining narrow tasks are divided into three equal stacks of $\frac{q}{6}$ tasks each and started after the completion of the wide and narrow stacks. (Three narrow tasks fit side by side.) The cost of this schedule is $\frac{4q^2}{3} + \frac{3q}{2}$. (For values of q which are not multiples of 6 this is a close approximation.)

Note that all shelves k in both groups have $\frac{\mathcal{H}_k}{\mathcal{M}_k} = 1$, so that the ordering of them is immaterial. It can therefore be assumed that $\text{SMART}_{\text{FFIA}}$ puts all shelves of the height group on top of the shelves of the area group, thus producing an additional cost

of $(2^{n+1} - 4)2q$. However, the optimal schedule is obtained by placing the optimal schedules for both the height and the area group side by side. For $q \approx 2^{n-1}$, the ratio $\frac{s_\tau}{o_\tau}$ then approaches 4.5 asymptotically as $q \to \infty$.

For the weighted minimum response time problem, there is a similar family of task systems for which γ-SMART$_{\text{NFIW}}$ produces a ratio $\frac{s_\tau}{o_\tau}$ approaching approximately 6.75 asymptotically for the value of γ specified in section 3. Once again, there is a height group and an area group.

The tasks in the height group fit onto $n-1$ shelves of heights $\gamma^2, \gamma^3, \ldots, \gamma^n$, and there are two tasks of width 1 on each shelf. On shelf k, where $2 \le k \le n$, there is one task of height γ^k and weight ϵ, where ϵ is small. The other task is of height slightly greater than γ^{k-1} and weight $\gamma^k - \epsilon$. Note that the total number of tasks in the height group is $2n-2$. For large values of n, the γ-SMART$_{\text{NFIW}}$ produces a schedule with one shelf per height group and cost $\gamma^{2n}\frac{\gamma(2\gamma-1)}{(\gamma^2-1)(\gamma-1)}$. The optimal schedule places all tasks of the height group side by side and has cost $\gamma^{2n}\frac{\gamma}{\gamma^2-1}$.

The area group consists of q tasks of width $\frac{P-2n+2}{2}$, height slightly greater than 1, and weight $\frac{\gamma(P-2n+2)}{P+2n}$, and q tasks of width $2n-1$, height γ, and weight $\frac{2\gamma(2n-1)}{P+2n}$. Note that all tasks have the same width to weight ratio. Therefore, assuming $P \gg n$, γ-SMART$_{\text{NFIW}}$ may produce a schedule with one task of each type per shelf. For large values of q, the cost of this schedule is $q^2\frac{\gamma^2}{2}$. The optimal schedule consists of two stacks of wide tasks placed side by side, with the narrow tasks placed on top. The cost of this schedule is $q^2\frac{\gamma}{4}$.

Once again, all shelves k in both groups have $\frac{\mathcal{H}_k}{\mathcal{U}_k} = 1$, so that the ordering of these shelves is immaterial. Combining both shelf schedules thus produces a further cost of $q \cdot \gamma^n \frac{\gamma^2}{\gamma-1}$. For $P \gg qn$, the combined optimal schedule consists of the optimal schedules of both the height and area groups placed side by side. For $q \approx 1.47 \cdot \gamma^n$ the ratio $\frac{s_\tau}{o_\tau}$ approaches approximately 6.75 asymptotically.

5. Conclusions. In this paper we have

1. developed a variant SMART$_{\text{FFIA}}$ of the original SMART algorithm for the (unweighted) minimum average response time problem and shown that this new algorithm has an approximation factor of 8;
2. developed a generalization γ-SMART$_{\text{NFIW}}$ of the original SMART algorithm and shown that this new algorithm handles the weighted minimum average response time problem with an approximation factor of 8.53;
3. shown that the original SMART algorithm has an approximation factor of 9 when applied to the unweighted problem;
4. given examples that show that the bounds for the new algorithms are tight to within a factor of less than 2.

We should point out that in the unweighted case these algorithms generalize as before to the so-called *malleable* [13, 14] versions of the problems, yielding the same bounds while retaining polynomial-time complexity. (Malleability here means that a task can be run on an arbitrary number of processors with an execution time that depends on the number of processors assigned. Thus the number of processors each task will use becomes a decision variable rather than an input parameter.) Malleable response time algorithms with significantly improved bounds can be achieved under certain reasonable special conditions. See [11, 8] for details.

NEW APPROXIMATION GUARANTEES FOR MINIMUM-WEIGHT k-TREES AND PRIZE-COLLECTING SALESMEN*

BARUCH AWERBUCH†, YOSSI AZAR‡, AVRIM BLUM§, AND SANTOSH VEMPALA§

Abstract. We consider a formalization of the following problem. A salesperson must sell some quota of brushes in order to win a trip to Hawaii. This salesperson has a map (a weighted graph) in which each city has an attached demand specifying the number of brushes that can be sold in that city. What is the best route to take to sell the quota while traveling the least distance possible? Notice that unlike the standard traveling salesman problem, not only do we need to figure out the order in which to visit the cities, but we must decide the more fundamental question: which cities do we want to visit?

In this paper we give the first approximation algorithm having a polylogarithmic performance guarantee for this problem, as well as for the slightly more general "prize-collecting traveling salesman problem" (PCTSP) of Balas, and a variation we call the "bank robber problem" (also called the "orienteering problem" by Golden, Levi, and Vohra). We do this by providing an $O(\log^2 k)$ approximation to the somewhat cleaner k-MST problem which is defined as follows. Given an undirected graph on n nodes with nonnegative edge weights and an integer $k \leq n$, find the tree of least weight that spans k vertices. (If desired, one may specify in the problem a "root vertex" that must be in the tree as well.) Our result improves on the previous best bound of $O(\sqrt{k})$ of Ravi et al.

Key words. approximation algorithm, prize-collecting traveling salesman problem, k-MST

1. Introduction.

1.1. The problem. Consider a salesperson who must sell some quota of R brushes in order to win a trip to Hawaii. This salesperson has a map (a weighted graph) of n cities in which each city has an attached demand specifying the number of brushes that can be sold in that city. What is the best route to take to sell the quota while traveling the least distance possible? Notice that unlike the standard traveling salesman problem (TSP), not only do we need to figure out the order in which to visit the cities, but we must decide the more fundamental question: which cities do we want to visit?

R. Ravi et al. [17] considered the cleanest case of the above problem, called the minimum-weight k-tree, or k-MST problem. In this problem, one is given a graph on n vertices with nonnegative distances on the edges, and a number $k \leq n$, and the goal is to find a tree of least total cost that spans k vertices. For $k = n$ this is the (easy) minimum spanning tree problem. For general k, however, the problem is

NP-complete and has the same main difficulty faced by the above salesperson: which points to include and which to ignore? In fact, the k-MST problem nicely focuses on just that issue since once the set is determined, the least weight tree on that set is easy to find.

Cheung and Kumar [8] call this problem the "quorum-cast" problem; its applications are in the domain of communication networks.

The bank robber problem is the following: given the map of a city including the amounts of money in each bank, and a car with bounded gas tank, the robber has to rob the maximum amount of money without refueling after the first robbery (thus avoiding being reported to the police). This problem is also called the "orienteering problem" by Golden, Levi, and Vohra [13].

1.2. Prior work. Ravi et al. [17] provide an algorithm that achieves an approximation ratio of $O(\sqrt{k})$ for the k-MST problem on general graphs (i.e., the tree found is at most $O(\sqrt{k})$ times heavier than the optimal tree) and ratio $O(k^{1/4})$ for the special case of points in two-dimensional Euclidean space. Garg and Hochbaum [10] improved the ratio for the latter case to $O(\log k)$, which was then improved to a constant factor by Blum, Chalasani, and Vempala [6]. Heuristics for problems described above have been given by Balas [4] and by Cheung and Kumar [8].

1.3. Results of this paper. In this paper, we describe an algorithm that achieves an approximation ratio $O(\log^2 k)$ for the k-MST problem on general graphs, improving the previous bound of $O(\sqrt{k})$ [17]. Our results hold for both the rooted and unrooted versions of the problem. (In the rooted version there is a specified root vertex that must be in the tree produced.) This result immediately implies an $O(\log^2 R)$ approximation for the quota-driven salesperson described above (R is the quota): namely, just treat a vertex with "demand" d as a cluster of d vertices, find the R-MST, and then tour the tree in the standard way. In fact, our algorithm actually achieves the somewhat better bound of $O(\log^2(\min(R, n)))$ for this problem, and does not require the demands to be polynomial in n.

Our algorithm also extends easily to an $O(\log^2(\min(R, n)))$ bound for the prize-collecting traveling salesman problem (PCTSP) due to Balas [4] on undirected graphs. The PCTSP problem is just like the quota TSP problem above, but in addition, there are nonnegative penalties attached to each city and the salesperson's cost is the sum of the distance traveled plus the penalties on cities *not* visited. Thus, the quota problem can be thought of as the special case in which penalties are 0. The $O(\log^2(\min(R, n)))$ bound for the PCTSP follows immediately by concatenating the tour found by our algorithm (which ignores the penalties) to a tour found by an algorithm of Goemans and Williamson [12] that provides a factor-of-2 approximation to a relaxed version of the PCTSP in which the quota requirement is removed. (In the original PCTSP there is also a restriction that each city not be visited more than once; if this is desired and if the graph is a metric space, then we can achieve the same bound in the usual way.)

We also derive an approximation algorithm with similar bounds for the bank robber problem.

It is worthwhile to point out that our algorithms are easily implementable in a distributed environment, since they operate on the basis of local information.

1.4. Subsequent results. Since the initial (conference) publication of this paper [2], several results have appeared that build and improve upon those here. Rajagopalan and Vazirani [16] describe an algorithm that can be viewed as a somewhat "smoothed" version of the algorithm of this paper and prove that it achieves an

$O(\log k)$ approximation to the k-MST. In a further improvement, Blum, Ravi, and Vempala [7] prove that a version of the Goemans–Williamson [12] algorithm achieves a constant-factor approximation. Most recently, Garg [9] has improved this constant factor to 3. Also very recently, for the case of points in the plane with the Euclidean distance metric, Arora [1] and Mitchell [15] (see also [14]) have independently developed a polynomial-time approximation scheme (PTAS) for the k-MST problem, that is, an algorithm that for any fixed $\epsilon > 0$ can achieve a $(1 + \epsilon)$ approximation in polynomial time. Their result applies to a variety of related problems such as the TSP and the minimum Steiner tree problem.

2. The k-MST problem. We begin by presenting an algorithm for the k-MST problem that achieves an approximation ratio of $O(\log^3 k)$. We then describe an improvement that removes one of the logarithmic factors to achieve the ratio of $O(\log^2 k)$. Before presenting the algorithm, however, let us point out that the "rooted" and "unrooted" versions of the problem are essentially equivalent from the point of view of approximation for the following reason.

Given an algorithm for the rooted problem, to solve the unrooted case one can simply try all possible start vertices and then choose the smallest tree found. Given an algorithm for the unrooted version, to solve the rooted case when the weight ℓ of the optimal tree is known, just throw out all vertices of distance greater than ℓ from the root, solve the unrooted problem, and then connect the tree to the root for an added cost of at most ℓ. Note that the approximation factor may increase by 1. If the optimal cost ℓ is not known, simply sort the distances from the root to each of the n points in increasing order, run the algorithm n times throwing out the i farthest points in the ith iteration, and pick the best result.

In the rest of this section we will use OPT to denote the optimal k-tree and ℓ to denote its total weight.

Our algorithm and analysis contain two main ideas. The first is a measure used for grouping points into components in a Kruskal's-algorithm-like manner. The second is a bucketing technique that allows one to prove this measure to be useful. The measure we use is the following: given two components C_i, C_j, we examine the ratio: $d(C_i, C_j)/\min(|C_i|, |C_j|)$, where $d(\cdot, \cdot)$ is the distance according to the shortest-path metric and $|\cdot|$ is the size in terms of number of points. The general step of the algorithm will be joining together (using the shortest path) the two components for which this ratio is smallest.

The bulk of the argument will be for proving correctness of an algorithm for the following slight relaxation of our goal, which is similar to the "maximal dense" tree concept in [3]. Given k, we will find a tree on at least $k/4$ points whose weight is at most $O(\log^2 k)$ times the weight of the minimum k-tree. With this algorithm in place, it will be easy to remove the relaxation and solve our original problem. The Kruskal-like algorithm for this relaxed problem is as follows.

Algorithm Merge-Cluster.

1. Begin with n components, one for each point.
2. Join (using the shortest path) the two components such that the ratio of the distance between the components to the number of points in the smaller one is least. That is, join the pair C_i, C_j that minimize $d(C_i, C_j)/\min(|C_i|, |C_j|)$.
3. Repeat step 2 until some component has size at least $k/4$.

Theorem 1. *The weight of the largest component produced by Algorithm Merge-Cluster is at most* $4(\log_2 k)^2$ *times the weight of the optimal k-tree.*

The proof of Theorem 1 follows immediately from Lemmas 1 and 2 below.

LEMMA 1. *If at any time the largest ratio used by Algorithm Merge-Cluster so far is r, then any component of p points will have total weight at most $rp \log_2 p$.*

LEMMA 2. *Algorithm Merge-Cluster never uses a ratio larger than $\frac{8\ell \log_2 k}{k}$ where ℓ is the weight of the optimal k-tree.*

To prove Theorem 1 from these lemmas, just note that the only way in which the largest component produced could have size greater than $k/2$ is for the additional vertices to be included "for free" in the shortest path that makes up the final connection. Thus combining the bounds of the two lemmas yields the theorem.

We begin with a proof of the simpler lemma.

Proof of Lemma 1. Consider a joining of two components. Since the length of the connection used is at most r times the number of points in the smaller component, we can "pay for" the connection by charging a cost of at most r to each of the points in the smaller component. Any time a point is charged, the size of the component it belongs to at least doubles. So, any point in a component of p points has been charged a total cost at most $r \log_2 p$. Since the weight of a component is at most the total charge to points inside it, this proves the lemma. □

Proof of Lemma 2. In contradiction, suppose that at some time all components produced by the algorithm have size less than $k/4$ and the distance between any two is greater than $r = (8\ell \log_2 k)/k$ times the number of points in the smaller. Group the components into buckets based on size, where the ith bucket contains those components with between $k/2^i$ and $k/2^{i+1}$ points ($i = 2, 3, \ldots$). Now, throw out all components that do not intersect the optimal k-tree. Clearly, the optimal k-tree can have at most $k/4 + k/8 + \cdots < k/2$ points inside buckets that contain only one component. So, there is some bucket containing at least two components such that OPT has at least $k/(2 \log_2 k)$ points inside that bucket. Say all components in this bucket have size between s and $2s$. This means that the balls of radius $rs/2$ about each component do not touch each other, and OPT must intersect at least $k/(4s \log_2 k)$ components. Therefore OPT must have a connection cost greater than $rk/(8 \log_2 k) = \ell$, a contradiction. □

Algorithm Merge-Cluster immediately gives us a simple $O(\log^3 k)$ approximation algorithm for the k-MST problem as follows. For simplicity, we consider the rooted version. Also, for the moment, suppose that we know the weight ℓ of the optimal k-tree. In the procedure below, we view Algorithm Merge-Cluster as taking "k" as an argument.

ALGORITHM CONNECT-CLUSTERS.

1. Mark as "to be ignored" all vertices of distance greater than ℓ from the root.
2. While $k > 0$ do the following:
   (a) Run Algorithm Merge-Cluster on the unmarked vertices. (By this we mean that the distance between two components is still the shortest-path distance in the original graph, but only unmarked vertices are considered in computing a component's size.)
   (b) Let s be the size of the component that was found and mark its vertices as "to be ignored."
   (c) Set $k = k - s$ (number of vertices we still need).
3. Connect together all the components found in Step 2.

THEOREM 2. *Algorithm Connect-Clusters finds a tree of at least k points whose weight is at most $O(\log^3 k)$ times the optimal.*

Proof. Suppose that in the invocations of Algorithm Merge-Cluster so far we have found components with k' points total. Then, the optimal k-tree contains at least

$k - k'$ points in the graph remaining, and all these are within distance ℓ from the root. Thus, the next invocation of the algorithm will find a tree on at least $(k-k')/4$ points, at cost at most $O(\ell \log^2 k)$. So, the algorithm will be run at most $O(\log k)$ times and the sum total cost of all components found is at most $O(\ell \log^3 k)$. The cost to connect them together is a low-order $O(\ell \log k)$. □

We can remove the knowledge of the optimal cost ℓ from the above algorithm in the same manner as was done for converting the rooted version of the k-MST problem to the unrooted version. For improved efficiency, note that the true ℓ satisfies $\lambda \leq \ell \leq k\lambda$, where λ is the distance of the kth farthest vertex from the root. So we can begin with a guess of $\ell = \lambda$ and then double our guess if the numbers and sizes of the components found do not satisfy the guaranteed bounds, for a total of $O(\log k)$ iterations maximum.

We now show how to modify Algorithm Connect-Clusters to achieve an $O(\log^2 k)$ approximation. To do this, we use the following corollary to a result by Goemans and Williamson [12]. In [5] this is called a $(3, 6)$-TSP approximator. (Goemans and Kleinberg [11] have recently improved this to a $(2, 3)$-TSP approximator.)

FACT 1. *Given a weighted graph on n points and an $\epsilon > 0$, let L_ϵ be the length of the shortest tour that visits at least $(1-\epsilon)n$ points. One can find in polynomial time a path of length at most $6L_\epsilon$ that visits at least $(1-3\epsilon)n$ points.*

For simplicity, we describe the modified algorithm as either finding a tree of k points with cost at most $O(\ell \log^2 k)$ or else finding a tree on at least $k/4$ points with cost $O(\ell)$. It is not hard to see that this suffices because the latter case removes an $O(\log^2 k)$ factor from the bounds of Theorem 1 (which is even better). Let us also assume for simplicity that the algorithm is given the value of ℓ; this assumption can be removed, as was done for Algorithm Connect-Clusters above. The new algorithm works as follows.

ALGORITHM IMPROVED-CONNECT. Run Algorithm Connect-Clusters until components totaling at least $\frac{15}{16}k$ points have been found. This requires only a constant number of applications of Algorithm Merge-Cluster. For simplicity, if the number of points found exceeds $\frac{15}{16}k$, then discard points until we have only $\frac{15}{16}k$ left. Call this set of points S.

Now, apply the algorithm of Fact 1 with $\epsilon = \frac{3}{15}$ to the graph induced by the set S. Notice that if the optimal k-tree intersects at least a $(1 - \frac{3}{15})$ fraction of S, then this algorithm is guaranteed to find a path of length at most 6ℓ that visits at least $(1 - \frac{9}{15})\frac{15}{16}k = \frac{3}{8}k$ points. If the algorithm produces such a path, then halt: the MST on these points is a tree of cost $O(\ell)$ on more than $k/4$ points as desired.

On the other hand, if the algorithm of Fact 1 returns a path that either is longer than 6ℓ or else visits insufficiently many points, then we know that the optimal k-tree intersects less than a $(1 - \frac{3}{15})$ fraction of S (and so contains at least $k/4$ new points). We now apply Merge-Cluster, with argument $k/4$, on the remaining graph to find a new component with at least $k/16$ points. Connecting this component to the components in S results in a tree of k points of cost $O(\ell \log^2 k)$, and we are done.

We thus have the following theorem.

THEOREM 3. *Algorithm Improved-Connect provides an $O(\log^2 k)$ approximation for the k-MST problem and runs in polynomial time.*

3. Extensions of the basic k-MST algorithm. We now describe how the algorithms of the previous section can be used to give guaranteed approximations to the other problems mentioned in the introduction, such as

- the quota TSP problem,

- the PCTSP, and
- the bank robber (orienteering) problem.

3.1. Algorithms for quota-driven salesmen. In the quota TSP problem each vertex in the graph has some attached integral value $w_i \geq 0$ and the salesman has a target quota R. The goal is to find a route as short as possible that visits vertices whose sum total value is at least R. The salesman may visit a city several times, but if he does so he only receives its value once.

First, it is immediate that we can approximate the quota TSP to a factor of $O(\log^2 R)$. Simply replace each vertex of value w by w vertices all at the same location, find the approximate R-MST, and then traverse it at most twice. Notice that this bound might not be so good if R is much larger than n. Also, this approach naively requires R to be only polynomially large; however, since the first step of the k-MST approximation algorithm is to reconnect vertices at the same location into a cluster, we can view the replacement described above as just a thought experiment. We show now that the algorithm in fact achieves the better bound of $O(\log^2(\min(R, n)))$.

It will be simplest to view Algorithm Merge-Cluster as acting directly on the weighted vertices, merging the two components C_i, C_j that minimize

$$d(C_i, C_j)/\min(wt(C_i), wt(C_j))$$

where $wt(C)$ is the sum of the values of the vertices contained in C. Let us call this algorithm Merge-Weighted-Cluster even though it is really exactly the same algorithm, except for running time, as the thought experiment described above. For the analysis corresponding to Lemma 1, however, when two components are merged we will "pay for" the cost by charging to the smaller one in *number*, not in weight. This still means that for a connection of ratio r a vertex of weight w will be charged at most rw, if we charge vertices proportionally to their weight. But, now it is clear that a vertex will be charged at most $\log(p)$ times if it is in a component of p vertices, as opposed to a component having *weight* p. Thus we have the following lemma. (We also give a more formal proof below.)

LEMMA 3. *If at any time, the largest ratio used by the algorithm Merge-Weighted-Cluster so far is r, then any component of p points and total vertex weight w will have total edge weight (cost) at most $rw \log_2 p$.*

Proof. We prove the lemma by induction. It is true initially since the cost begins at 0. When merging two clusters C_i and C_j into C we note that

$$\begin{aligned} cost(C) &= cost(C_i) + cost(C_j) + d(C_i, C_j) \\ &\leq r \cdot wt(C_i) \cdot \log(|C_i|) + r \cdot wt(C_j) \\ &\quad \cdot \log(|C_j|) + r \cdot \min\{wt(C_i), wt(C_j)\} \\ &\leq r \cdot (wt(C_i) + wt(C_j)) \cdot \log(|C_i| + |C_j|) \\ &\leq r \cdot wt(C) \cdot \log(|C|). \qquad \square \end{aligned}$$

We can similarly improve Lemma 2 as follows.

LEMMA 4. *Algorithm Merge-Weighted-Cluster never uses a ratio larger than $O(\ell(\log_2 n)/R)$ where ℓ is the (edge) weight of the optimal tree having vertex weight R.*

Proof. Following the proof of Lemma 2 we have buckets containing the components of vertex weight $R/4$ to $R/8$, $R/8$ to $R/16$, etc. We stop, however, at weight $R/(10n)$ and put all components of that weight or less into one single bucket. Now

there are only $O(\log n)$ buckets instead of $O(\log R)$ and the final small bucket intersects the optimal tree in at most $R/10$ total weight, and so can be "thrown out" in the analysis. The rest of the proof of Lemma 2 then can be followed directly. □

The above two lemmas imply that Algorithm Improved-Connect of Theorem 3 in fact achieves a ratio of $O(\log^2 n)$ as well as $O(\log^2 R)$, which gives us our desired bound.

One technical point: the algorithm of Fact 1, which is just the PCTSP algorithm of Goemans and Williamson [12] with an appropriate setting of the prize values, works also for the vertex-weighted case. Therefore, Algorithm Improved-Connect runs in polynomial time even if R is large.

3.2. Algorithms for prize-collecting salesmen. As mentioned in the introduction, an approximation algorithm to the quota TSP problem can be transformed into an approximation algorithm to the PCTSP problem of [4]. The PCTSP is the following. You are given an undirected edge-weighted graph in which each vertex has a prize value and a penalty value. You are also given a quota R. The goal is to find a tour of minimum "cost" such that the sum of the prizes on the vertices visited is at least R, where *cost* is defined to be the length of the tour plus the sum of the penalties on vertices not visited. In other words, the PCTSP is the same as the quota TSP problem, but with the additional complication of vertices having penalties for *not* being on the tour.

The Goemans–Williamson algorithm [12] provides a 2-approximation to a version of the PCTSP in which the quota requirement R is removed. That is, the goal is simply to minimize the cost of the tour as defined above. To approximate the PCTSP problem of Balas, simply concatenate the tour found by the quota TSP approximator to a (rooted) tour found by the Goemans–Williamson algorithm. The tour found by the quota TSP approximator is guaranteed to meet the quota requirement and have length at most $O(\log^2(\min(R, n)))$ times the cost of the optimum solution. The second tour guarantees that the final result incurs a penalty totaling at most twice the cost of the optimum solution, while introducing only a small increase in the length. (Removing the quota restriction only decreases the cost of the optimum solution.) Thus we have the following theorem.

THEOREM 4. *There is a polynomial-time algorithm that approximates the PCTSP problem of Balas* [4] *on n-vertex undirected weighted graphs with a ratio $O(\log^2(\min(R, n)))$, where R is the required vertex weight to be visited.*

3.3. The bank robber (orienteering) algorithm. The bank robber (orienteering) problem [13] is much like the problem faced by our quota-driven salesperson, except that the distance d that may be traveled is fixed and the goal is to maximize the total value R of points visited. If we do not require a specified starting point, then we can approximate this problem to the same ratio as the quota-TSP problem as follows. We "guess" the value R, we run the quota TSP-approximator to find a path of length $O(d \log^2(\min(n, R)))$ visiting vertex weight R, we break the path found into segments of length $d/2$, and then we choose the segment that contains the most vertex value inside. Notice, however, that this does not approximate the orienteering problem with a specified start vertex (root) since there is no guarantee the "good" segment found will intersect the root.

4. A hard example for our algorithm. Our basic algorithm, Merge-Cluster, finds a tree on at least $k/4$ points with cost at most $O(\ell \log^2 k)$, where ℓ is the cost of the optimal k-tree. In fact, there exist examples that force the algorithm to pay

$\Omega(\ell \log^2 k)$, and we describe one such example here.

Define a 1-block to be a single point, a 2-block to be two points separated by distance 1, a 4-block to be two 2-blocks separated by distance 2, and more generally a 2^t-block to be two 2^{t-1}-blocks separated by distance 2^{t-1}. Note that a 2^t-block has 2^t points. Also, notice that all the points in such a block would be connected together by Merge-Cluster using connections of ratio 1.

Suppose we have a cluster of A points (by a cluster, we just mean that all the points are at the same location) separated by some distance from a cluster of B points. Let us define a "filling in" of the region between the two clusters as follows. First, if $A = 1$ or $B = 1$ then we do nothing. Otherwise, let $C = \lfloor \min(A/2, B/2) \rfloor$ and place a cluster of C points halfway between the A-point cluster and the B-point cluster. Then recursively fill in the region between the A-point and C-point clusters and the region between the C-point and B-point clusters.

A hard example for the algorithm can now be described as follows. The graph consists of two sets of points separated by a large distance. The first set of points is a k-block. The second set of points is constructed by placing two clusters of $4k/\log k$ points at a distance of $8k/\log k$ from each other, and then "filling in" the region between the clusters as described above. Given such a graph, there exists a tree on at least k points with total length $8k/\log k$. In particular, just connect all the points in the second set. However, the algorithm will instead connect together points in the first set, since the ratios are better there (1 versus 2), and pay a total cost of $\Omega(k \log k)$.

5. Open questions. The obvious open question is whether there are polynomial-time algorithms with better approximation ratios, i.e. logarithmic, or even constant, for the problems considered in this paper. As noted above, this question has been answered in the affirmative by subsequent work.

Another interesting open question is finding a polynomial-time polylogarithmic approximation for the rooted version of the bank robber (orienteering) problem. This problem appears to be much more difficult than the unrooted version. Intuitively, the difficulty with approximating the rooted problem is that many of the points on the optimal tour might be in a clump at distance just about $d/2$ from the root. Thus, a strategy that opportunistically visits nearer vertices on its way to that clump may find that it cannot reach those vertices and return in the given distance d.

Acknowledgments. We thank Noga Alon and Prasad Chalasani for helpful discussions, and the anonymous referees for their suggestions for improving the presentation of this paper.

NEAR-LINEAR TIME CONSTRUCTION OF SPARSE NEIGHBORHOOD COVERS*

BARUCH AWERBUCH†, BONNIE BERGER‡, LENORE COWEN§, AND DAVID PELEG¶

Abstract. This paper introduces a near-linear time sequential algorithm for constructing a sparse neighborhood cover. This implies analogous improvements (from quadratic to near-linear time) for any problem whose solution relies on network decompositions, including small edge cuts in planar graphs, approximate shortest paths, and weight- and distance-preserving graph spanners. In particular, an $O(\log n)$ approximation to the k-shortest paths problem on an n-vertex, E-edge graph is obtained that runs in $\tilde{O}(n + E + k)$ time.

Key words. neighborhood covers, network decompositions, approximate shortest paths, spanners

1. Introduction.

1.1. Background. An *r-neighborhood* of a vertex in an undirected weighted graph is the set of vertices within distance r away from it in the graph. An *r-neighborhood cover* is a set of overlapping sets of vertices in the graph (called *clusters*) with the property that every vertex has its entire r-neighborhood contained in one of these clusters. An r-neighborhood cover efficiently represents the local neighborhoods in a graph when all clusters in the cover have low diameter and the overlap among clusters (measured by the maximum number of clusters that intersect at a vertex) is minimized.

There is an inherent tradeoff between achieving low diameter and low overlap. If the clusters are chosen to be all r-neighborhoods (namely, the balls of radius r around every vertex), then all clusters have diameter r, but each vertex can be in as many as n clusters, where n is the number of vertices in the network. On the other hand, the entire network can be considered a single cluster, in which case each vertex is in just one cluster, but the diameter of this cluster can be as large as n.

Sparse neighborhood covers were first introduced in [9] in the context of distributed computing. A general r-neighborhood cover construction with $O(r \log n)$ cluster diameter and $O(\log n)$ cluster overlap is presented in [9]. It is also shown

therein how to achieve an essentially optimal tradeoff between the diameter and overlap parameters. However, the construction of [9] takes $O(nE)$ time and space, where E is the number of edges of the graph.

1.2. Summary of results. In this paper, we present a new efficient construction method that achieves the optimal tradeoff in near-linear time. More specifically, the main result of this paper is a deterministic sequential algorithm for the construction of a sparse r-neighborhood cover with $O(r \log n)$ cluster diameter and $O(\log n)$ cluster overlap with running time and space $O(E \log n + n \log^2 n)$. The algorithm can also be applied for constructing an r-neighborhood cover with $O(\beta r)$ diameter and $O(\beta n^{1/\beta})$ overlap, in time and space $O((E\beta + n\beta^2)n^{2/\beta})$, where β is given an input to the algorithm, representing the desired tradeoff between diameter and overlap.

To achieve this, we refine the "set coarsening" method of [9] and show how to construct the cover by only producing breadth-first search (BFS) trees from carefully selected vertices. The novel aspect of our approach is that a BFS tree is carved out in such a way that one can bound the overlap with other BFS trees. It turns out that for $r > 1$, bounding the overlap between BFS trees poses significant difficulties. In order to derive good complexity bounds, we need to charge the work performed in overlapping regions against the work performed in disjoint regions. Also, we need to lower-bound the fraction of r-neighborhoods that have "escaped carving" in a given iteration.

While most previous applications of neighborhood covers were in the distributed domain, the new algorithm makes the r-neighborhood cover a viable data structure for speeding up certain *sequential* algorithms. In particular, the results in this paper automatically imply analogous improvements (i.e., from quadratic to near-linear time) to many of the results in the literature that rely on neighborhood covers as a "black box." These include finding small edge cuts in planar graphs in $\tilde{O}(E)$ time and space[1] (as a consequence of using the algorithm of this paper in conjunction with the algorithm in [24], thus improving the $O(n^2)$ time and space complexity obtained by using the construction method of [9] in [24]), and weight- and distance-preserving graph spanners with $\tilde{O}(E)$ running time and space (see [5, 12], down from $O(nE)$ time using [11] or a combination of [5] and [9]).

Another application that is derived explicitly in the sequel is a sequential algorithm for approximating k-pairs shortest paths. We describe this application next.

1.3. Approximating k-pairs shortest paths. The *k-pairs shortest paths* problem, as discussed in the sequel, is defined as follows. Given an undirected graph $G(V, \mathcal{E})$ (where $|V| = n$ and $|\mathcal{E}| = E$), nonnegative edge weights, and k pairs of vertices, find the length of the shortest path between each of these pairs.

Another version, henceforth referred to as the *explicit shortest paths (ESP)* problem, requires the algorithm to actually produce the paths. Clearly, the time complexity of the ESP version is lower-bounded by the length of the output, which is proportional to the total length of the requested paths.

The best known bounds for exact solution of the k-pairs shortest paths problem are based on one of two approaches: implementations of Dijkstra's algorithm and solutions based on matrix multiplication.

The first approach involves running Dijkstra's algorithm with a binary heap implementation of the priority queue, yielding time $O(kE \log n)$ [13], or with a Fibonacci heap implementation, yielding time $O(kn \log n + kE)$ [14]. For the all-pairs shortest

[1] We use the $\tilde{O}(R)$ notation to denote $O(R \log^{O(1)} R)$, for cleaner statement of bounds.

paths problem, the time bounds become $O(n^2 \log n + nE)$ and $O(nE \log n)$, respectively [13, 14].

There have been other improvements on the running time for the all-pairs shortest paths problem for some special case graphs [2, 10, 15, 16, 17, 18, 19, 22, 26], but they all have worst-case time $O(nE)$. Karger, Koller, and Phillips [19] show that $\Omega(nE)$ is a lower bound for directed graphs on the running time of any algorithm which is "path-comparison based," which is evidence that it is hard to improve exact algorithms with this approach.

The second approach is based on computing (exact) all-pairs shortest paths relying on matrix multiplication. Alon, Galil, and Margalit [3] describe an $O((nW)^{2.688})$ time algorithm for the case of integer edge weights whose absolute value is less than W. This result has been improved to give an algorithm for the unweighted case which runs in time $O(M(n) \log n)$, where $M(n)$ is the time for matrix multiplication (currently known to be $o(n^{2.376})$) [25]. Subsequently, this result has been further improved in [4], solving exact all-pairs shortest paths in the case of integer edge weights between 0 and W in $O(W^2 M(n) \log n)$ time. Notice that the algorithm presented in this paper runs faster than these recent algorithms in both the unweighted and weighted cases.

Hence the bottlenecks in the running time of the exact algorithms stem either from repeated application of Dijkstra's single-source shortest paths algorithm or from matrix multiplication. We bypass these bottlenecks at the cost of producing an approximate solution.

There has also been recent work on approximation algorithms for shortest paths in the domain of parallel computation. Klein [20] extended the work of Ullman and Yannakakis [27] to the weighted case, obtaining a randomized PRAM algorithm that can $(1+\epsilon)$-approximate shortest paths between k pairs of vertices in $O(\sqrt{n}\epsilon^{-2} \log n \cdot \log^* n)$ time using $(kE \log n)\epsilon^2$ processors (where ϵ is constant). When this algorithm is run sequentially, the time is not as good as known sequential algorithms for the exact problem. Hence, Klein's approximation algorithm is strictly of interest for parallel computation.

As a corollary of our near-linear cost construction of sparse neighborhood covers, we obtain an $O(\log n)$-approximation algorithm for this problem that runs in $\tilde{O}(E + k)$ time. Our improvement in running time is achieved through our ability to construct a data structure of $\delta = \lceil \log \text{Diam}(G) \rceil$ sparse neighborhood covers (where $\text{Diam}(G)$ is the diameter of the graph) in time $O((E \log n + n \log^2 n)\delta)$, thereby allowing us to then quickly retrieve short paths. (The previous construction of [9] has been insufficient to produce any improvement over existing algorithms for the shortest paths application.) Once the data structure is in place, we show how to query it for the approximate distance between two vertices in $O(\log n \log \delta)$ time. (For ESP, the explicit version of the problem, the cost increases (inherently) by the length of the path.) Thus we approximate k-pairs shortest paths in time $O((E \log n + n \log^2 n)\delta + k(\log n \log \delta))$ (plus the total length of the k paths, for the ESP version).

More generally, a tradeoff can be achieved between the quality of the approximation and the running time; for example, a 32β approximation takes $O((E\beta + n\beta^2)n^{2/\beta}\delta + k\beta n^{1/\beta} \log \delta)$ time, for any $\beta \geq 1$. Note that we can achieve a better running time than known exact algorithms even for paths that are only a constant factor times the length of the shortest path. Further work in this direction is reported by Cohen [12].

We remark that there are no algorithms known for the single-pair shortest path problem that run asymptotically faster than the best single-source algorithms in the worst case [13]. Consequently, classical algorithms for k-pairs shortest paths have

done just as well using single-source shortest paths algorithms repeatedly.

1.4. Structure of this paper. The remainder of the paper is organized as follows. In section 2, we provide the graph-theoretic definition of neighborhood covers [9]. Section 3 presents an overview of the sparse neighborhood covers construction algorithm, followed by a formal presentation of the algorithm. The analysis of the algorithm is given in section 4. Finally, section 5 presents the application of the new algorithm to near-shortest path computation.

2. Network covers. Let $\mathrm{dist}(u,v)$ denote the minimum distance between u and v in the graph G. For a cluster of vertices $S_i \subseteq V$, let $\mathrm{dist}_{S_i}(u,v)$ denote the minimum distance from u to v in the subgraph induced by S_i. The *diameter* of the cluster is defined as $\mathrm{Diam}(S_i) = \max_{u,v \in S_i}(\mathrm{dist}_{S_i}(u,v))$.

The *r-neighborhood* of a vertex v is defined as $N_r(v) = \{u \mid \mathrm{dist}\ (u,v) \leq r\}$.

A *sparse neighborhood cover* is defined as follows. A *(β, r)-neighborhood cover* is a collection of sets (also called *clusters*) of vertices $S_1, \ldots, S_l$, with the following properties.

1. For every vertex v there exists some $1 \leq i \leq l$ s.t. $N_r(v) \subseteq S_i$.
2. For every i, $\mathrm{Diam}(S_i) \leq O(\beta r)$.

The *overlap* of the cover is the maximum number of clusters a vertex belongs to. A (β, r)-neighborhood cover is said to be *sparse* if its overlap is at most $\beta n^{1/\beta}$.

For the applications, β can be used to control the tradeoffs between complexity and the quality of the approximation, and we typically set $\beta = \log n$. Then a sparse $(\log n, r)$-neighborhood cover is a collection of sets that contain all r-neighborhoods such that the diameter of the sets is bounded by $O(r \log n)$, and each vertex is contained in at most $O(\log n)$ sets.

We remark that the diameter/sparsity tradeoff in this definition is tight to within a constant factor. In particular, for $\beta = \log n$, there exist graphs for which any $(\log n, r)$-neighborhood cover places some vertex in at least $\Omega(\log n)$ sets [21].

A *sparse neighborhood covers data structure* is a family of sparse neighborhood covers for a fixed β and different values of r. Applications typically require the construction of sparse r-neighborhood covers for $O(\log \mathrm{Diam}(G))$ successively doubled values of r (namely, $r = 1, 2, 4, 8, \ldots$).

3. The cover construction algorithm.

3.1. Overview. Let us start with an overview of the algorithm. The algorithm builds the cover $\mathcal{X}$ in phases. Each phase produces a new subcollection $\mathcal{Y}$ of sets to be added to the cover. All sets added to the cover have low diameter, and each vertex will appear in at most one set per phase. In addition, an $\Omega(n^{-1/\beta})$ fraction of the vertices whose r-neighborhoods have so far remained uncovered by any set already in the cover, will have their r-neighborhoods placed in some set constructed in the current phase. Hence, in $\beta n^{1/\beta}$ phases the algorithm finishes covering the r-neighborhood of all vertices in the graph. Since each vertex appears in at most one set per phase, each vertex will appear in at most $\beta n^{1/\beta}$ sets in the output cover.

Fix a phase of the algorithm, and let U be the collection of vertices whose r-neighborhood remains uncovered. Let $\mathcal{Y}$ denote the subcollection of sets we will place in the cover in the current phase.

We now sketch how to construct the sets $\mathcal{Y}$, in near-linear time. Low diameter sets Y are constructed one at a time, in a breadth-first manner, and added to $\mathcal{Y}$. The key element is a new "guarded" BFS technique, which carefully controls how new sets are grown around existing sets in $\mathcal{Y}$. In particular, a two-layer "shield" is grown

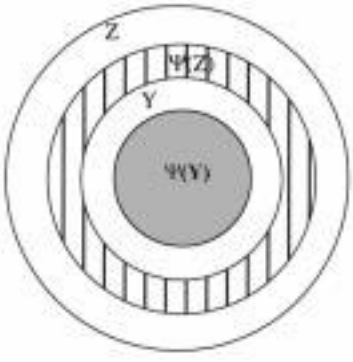

FIG. 1. *The layers of a grown cluster. The sets Y, $\Psi(Z)$, and Z all grow in successive bands of width r around $\Psi(Y)$.*

around each set Y. The shield serves a dual purpose: it keeps different sets in $\mathcal{Y}$ from overlapping, and it also insures that several sets do not duplicate work by performing BFS forays again and again into the same area of the graph.

Section 3.2 describes how the algorithm constructs a single set Y in the cover, and section 3.3 shows how a new nonoverlapping set Y grows around existing sets Y in the collection $\mathcal{Y}$. The details of the algorithm, including the code for the procedures, are presented in section 3.4. A formal correctness proof and complexity analysis of the algorithm appear in section 4.

3.2. Growth of a single set. We show how to grow a single set Y for the cover. Procedure `Cluster` grows Y iteratively, in layers, and outer layers form a shield around Y. We keep track of four layers around an "internal kernel" called $\Psi(Y)$. The set $\Psi(Y)$ consists of those vertices whose r-neighborhood is fully subsumed in the set Y; Z is the $2r$-neighborhood of Y; and $\Psi(Z)$ consists of those vertices whose r-neighborhood is subsumed by Z (see Figure 1). Note that

$$\Psi(Y) \subset Y \subset Z \quad \text{and} \quad \Psi(Y) \subset \Psi(Z) \subset Z.$$

We will sometimes refer to the set Z as the set Y's associated *cluster*.

The set Y starts growing as follows. Initially $\Psi(Y)$ is just the single vertex v, and Y is its r-neighborhood. The sets Y, $\Psi(Z)$, and Z all grow in successive bands of width r around $\Psi(Y)$. Specifically, if the stopping condition of Procedure `Cluster` is not met, then at the next growth iteration, Y grows to include the whole of the old Z, $\Psi(Y)$ grows to the old $\Psi(Z)$, the algorithm grows the BFS to construct a new Z which contains the entire $2r$-neighborhood of the new Y, and the new $\Psi(Z)$ consists of those vertices whose r-neighborhood lies in the new Z. Note that Y, $\Psi(Z)$, and Z in this picture are entire balls, not just rings; i.e., they contain all vertices within their borders. However, also note that it is not necessarily the case that $Y \subset \Psi(Z)$ (see section 3.3).

The stopping condition of Procedure `Cluster` is actually the conjunction of three separate conditions. The first stopping condition says that the number of still uncovered vertices in Y must be an appropriately large (specifically, $\Omega(n^{-1/\beta})$) fraction of those in Z. The second condition says that the number of still uncovered vertices in $\Psi(Y)$, i.e., the interior of the set Y, must be a sufficiently large fraction of those in

$\Psi(Z)$. These two conditions help guarantee that the cover is sparse, as will be argued below. A third stopping condition makes sure that the BFS exploration of the outer Z layer does not involve too much computation. Define $\lambda(v)$ to be the degree of vertex v in the graph G. For a set of vertices W, let $\lambda(W) = \sum_{v \in W} \lambda(v)$. The final stopping condition says that $\lambda(Y)$ is a sufficiently large fraction times $\lambda(Z)$. We argue below that all three stopping conditions are guaranteed to be met simultaneously within $O(\beta)$ iterations of Procedure `Cluster`. Thus, the diameter of a Y will be at most $O(r\beta)$.

3.3. A subcollection of sets. In this section, we show how a set Y and its cluster grow around previously built nonoverlapping sets Y from the same subcollection $\mathcal{Y}$ in the cover $\mathcal{X}$. A new cluster is always grown starting from a vertex v which lies outside the shielding ball $\Psi(Z)$ of any previous Y. Notice that this insures that the entire r-neighborhood of v lies outside any previous Y.

When a new cluster then grows into territory already occupied by a previous cluster, its BFS growth is curtailed by the previous cluster's layers. Each of the successive shields around an existing cluster permit a different degree of penetration.

- No cluster is allowed to grow into a previous cluster's Y. This ensures that the sets put in $\mathcal{Y}$ are disjoint. (See Figure 2.)
- A cluster's layer $\Psi(Z)$ does not grow into previous sets $\Psi(Z)$.
- The Z level is entirely permeable. (We control the cost of repeated BFS forays into previous Z instead by a stopping condition on the growth of a single cluster.)

We point out, to aid comprehension, that the relation $Y \subseteq \Psi(Z)$ may not hold for clusters grown after the first cluster (see Figure 3), since $\Psi(Z)$ is restricted to include new vertices if they have not already been placed in some previous cluster's associated set $\Psi(Z)$.

Figures 2–4 give snapshots of how new clusters grow. Figure 2 depicts how a new cluster begins growing, with $\Psi(Y)$ selected to be any single vertex outside the previous sets $\Psi(Z)$. Notice that this ensures that Y, the r-neighborhood of $\Psi(Y)$, will not overlap with previous Y's. Hence previous Y's form an impenetrable barrier (bold line) that nothing else can enter. In addition, the new cluster's $\Psi(Z) \setminus Y$ (striped region) does not enter previous sets $\Psi(Z)$.

Figure 3 illustrates the formation of the second layer of the new cluster (when the stopping condition was not met in the first iteration). Notice that the new $\Psi(Y)$ does not contain all of Y from the previous iteration, since $\Psi(Y)$ is the old $\Psi(Z)$, which does not extend through previous clusters' $\Psi(Z)$ sets. Even though Y and Z do not extend into the territory of previous clusters' Y sets, Y contains the r-neighborhood of $\Psi(Y)$, and Z contains the r-neighborhood of $\Psi(Z)$.

Finally, Figure 4 illustrates how a third cluster begins to grow. As before, the kernels $\Psi(Y)$ are shaded, the sets Y are marked with a bold line, the $\Psi(Z)$ is striped, and Z is within the outside ring. Excepting the participation of vertices in the outer Z ring, every vertex participates in the BFSs at most twice: a vertex can lie in at most one set Y, and prior to being placed in Y, it could lie in at most one $\Psi(Z)$. The BFS performed in the Z layer can be charged to the Y cluster for which it was grown. When subcollection $\mathcal{Y}$ is complete, every vertex appears in a $\Psi(Z)$, for some cluster Z, and the stopping conditions ensure that a sufficiently large fraction of the vertices appear in $\Psi(Y)$ for some Y. Thus every vertex appears in at most one Y, and the same fraction of the vertices have their r-neighborhoods contained in Y as well.

We stop growing clusters in the subcollection $\mathcal{Y}$ when every vertex is in $\Psi(Z)$ for

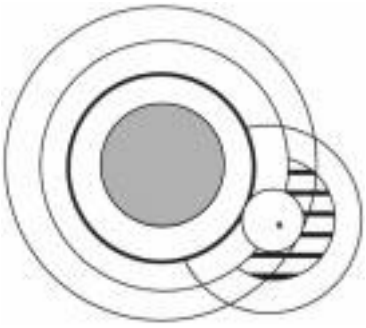

FIG. 2. *A new cluster begins growing around a single-vertex set* $\Psi(Y)$ *outside the previous sets* $\Psi(Z)$.

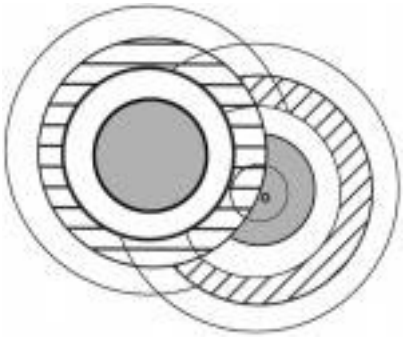

FIG. 3. *Formation of the second layer of the new cluster.*

some cluster Z.

3.4. Details of the algorithm. This subsection introduces Algorithm `All_Cover` that, given β and r, constructs a sparse (β, r)-neighborhood cover. The algorithm is built from two intermediate subprocedures: Procedure `Cluster` (see Figure 5), which grows a single set to be placed in the cover, and Procedure `Cover`, which calls `Cluster` to produce a subcollection $\mathcal{Y}$ of the sets in the cover $\mathcal{X}$ (see Figure 6). Procedure `Cover` produces what was earlier called a single phase, in the overview section.

The input to the algorithm is a graph $G = (V, \mathcal{E})$ (where $|V| = n$ and $|\mathcal{E}| = E$) and integers $r, \beta \geq 1$. The output collection of cover clusters, $\mathcal{X}$, is initially empty. The algorithm maintains the set of "remaining" vertices R. These are the vertices whose neighborhoods are not yet subsumed by the constructed cover. Initially, $R = V$, and the algorithm terminates once $R = \emptyset$. The code for Algorithm `All_Cover` appears in Figure 7.

The algorithm operates in (at most $\beta n^{1/\beta}$) phases. Each phase consists of the activation of Procedure `Cover`(R), which adds a subcollection of output clusters $\mathcal{Y}$ to $\mathcal{X}$ and removes the set of vertices $\Psi(R)$ whose r-neighborhood appears in some $Y \in \mathcal{Y}$ from R.

The collection of clusters $\mathcal{Y}$ returned by Procedure `Cover` are placed in the sparse neighborhood cover built by Algorithm `All_Cover`. The collection of clusters $\mathcal{Z}$ returned by Procedure `Cover` themselves form an *average degree cover* (see section 6).

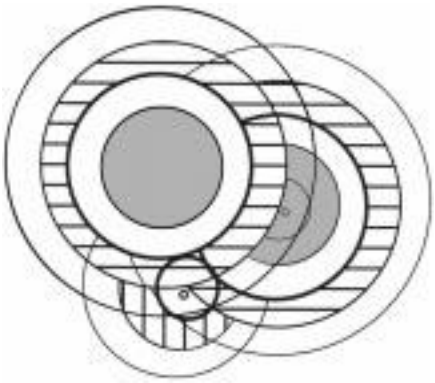

FIG. 4. *The growth of a third cluster. As before, the kernels $\Psi(Y)$ are shaded, the sets Y are marked with a bold line, $\Psi(Z)$ is striped, and Z is the outside ring.*

  and $\lambda(Z) \leq n^{1/\beta} \cdot \lambda(Y)$
return $(\Psi(Y), Y, \Psi(Z), Z)$

FIG. 5. *Procedure* `Cluster`$(R, U, v, \mathcal{Y})$.

4. Analysis. In this section, we first analyze the properties of the procedures in section 3.4 and prove that Algorithm `All_Cover` constructs a sparse neighborhood cover. The complexity analysis then follows in section 4.2.

4.1. Correctness of the algorithm.

LEMMA 4.1. *A set Y produced by Procedure* `Cluster` *has diameter at most $O(\beta r)$.*

Proof. Recall the three stopping conditions on the growth of a cluster. If the first stopping condition fails to be met, this means that $|Z| \geq n^{1/\beta} \cdot |Y|$. Since each time the stopping condition fails we increase Y by a factor of $n^{1/\beta}$, this stopping condition can fail at most β times.

If the second stopping condition fails to be met, this means that $|\Psi(Z)| \geq |R|^{1/\beta} \cdot |\Psi(Y)|$. Note that whenever Procedure `Cluster` is invoked within Procedure `Cover`, we have $U \subseteq R$. Since each time the second stopping condition fails we increase $\Psi(Y)$ by a factor of $|R|^{1/\beta}$, and $\Psi(Y)$ is restricted to U, this stopping condition can again fail at most β times.

The third stopping condition says that $\lambda(Z)$ is less than or equal to $n^{1/\beta}$ times

$U \leftarrow R$
$\Psi(R) \leftarrow \emptyset$.
$\mathcal{Y}, \mathcal{Z} \leftarrow \emptyset$.
while $U \neq \emptyset$ **do**
  Select an arbitrary vertex $v \in U$
  $(\Psi(Y), Y, \Psi(Z), Z) \leftarrow$ `Cluster`$(R, U, v, \mathcal{Y})$
  $\Psi(R) \leftarrow \Psi(R) \cup \Psi(Y)$
  $U \leftarrow U \setminus \Psi(Z)$
  $\mathcal{Y} \leftarrow \mathcal{Y} \cup \{Y\}$
  $\mathcal{Z} \leftarrow \mathcal{Z} \cup \{Z\}$
end-while
return $(\Psi(R), \mathcal{Y}, \mathcal{Z})$

FIG. 6. *Procedure* `Cover`(R).

$R \leftarrow V$
$\mathcal{X} \leftarrow \emptyset$
repeat
  $(\Psi(R), \mathcal{Y}, \mathcal{Z}) \leftarrow$ `Cover`(R)
  $\mathcal{X} \leftarrow \mathcal{X} \cup \mathcal{Y}$
  $R \leftarrow R \setminus \Psi(R)$
until $R = \emptyset$
return $\mathcal{X}$

FIG. 7. *Algorithm* `All_Cover`.

$\lambda(Y)$, and since the sum of the degrees of the entire graph is at most $E \leq n^2$, the third stopping condition can successively fail at most 2β times.

Therefore, the number of iterations of the growth process for which *any* of the stopping conditions fail is at worst 4β, and so, for one of the first $4\beta + 1$ iterations, all three stopping conditions will hold, and the cluster will stop growing. Since each time we grow Y, we add an additional distance r to the radius, the diameter of the sets is bounded by $O(\beta r)$. □

LEMMA 4.2. *The r-neighborhood of any vertex in a cluster's set Y is contained in $\Psi(Z)$ for that cluster or some previous cluster's set $\Psi(Z)$.*

Proof. Let v be a vertex in the r-neighborhood of Y. Then v is certainly in the $2r$-neighborhood of Y, so Procedure `Cluster` places $v \in Z$ for that cluster. Procedure `Cluster` then makes $\Psi(Z) = \{v \mid v \in U \cap Z, \ \ \mathrm{dist}(v, Y) \leq r\}$, so if v is not placed in $\Psi(Z)$, it means v is not in U. Now we examine the set U as it is modified over each invocation of Procedure `Cover`. The set U initially contains the entire graph G, and Procedure `Cover` only deletes those vertices from U which lie in some previous cluster's set $\Psi(Z)$. □

LEMMA 4.3. *For every $w \in G$, each invocation of Procedure* `Cover` *places w into at most one set Y.*

Proof. The proof is by contradiction. Suppose w was placed in Y_1 and Y_2, and without loss of generality, let Y_1 be constructed by `Cover` before Y_2. Note that since $w \in Y_1$, then $w \in \Psi(Z)$ for Y_1. When `Cover` constructs Y_2, it picks some center vertex v and invokes Procedure `Cluster`. We consider three cases: either w is v, or

w is in the r-neighborhood of v, or w is not in the r-neighborhood of v. First, w cannot be v, since w is in $\Psi(Y)$ for Y_1, $\Psi(Y) \subseteq \Psi(Z)$, and thus Procedure `Cover` has removed w from the set U of vertices from which it chooses centers v. In fact, since v is outside $\Psi(Z)$ for all previous Y, its entire r-neighborhood cannot contain anything in a previous Y, by Lemma 4.2. Thus w is not in the r-neighborhood of v, and so it will not be placed into Y when `Cluster` is initialized. As `Cluster` grows cluster Y_2, by construction, it will only place vertices w into Y_2 that it first places in the Z layer. However, members of previous Y are barred from entering into any subsequent Z layer, by construction. □

LEMMA 4.4. *An $\Omega(|R|^{-1/\beta})$ fraction of the vertices whose r-neighborhood still remains to be covered (i.e., vertices in R) have their r-neighborhoods covered each time Algorithm* `All_Cover` *calls Procedure* `Cover`. *Thus Procedure* `Cover` *is invoked $O(\beta n^{1/\beta})$ times.*

Proof. The vertices that lie in $\Psi(Y)$ for some cluster Y are the vertices that have their r-neighborhoods covered. The stopping condition guarantees that for each cluster, an $\Omega(|R|^{-1/\beta})$ fraction of the vertices in $\Psi(Z)$ (in R) lie in $\Psi(Y)$. Since every vertex in R is in some $\Psi(Z)$ (by the termination condition for Procedure `Cover`), and since the Y sets, and hence the $\Psi(Y)$ sets, are all disjoint (by Lemma 4.3), summing over all clusters produced in one invocation of `Cover` gives the result (as $|R| \leq n$). Hence, after $O(\beta n^{1/\beta})$ iterations of Procedure `Cover`, all vertices have their r-neighborhoods covered, and Algorithm `All_Cover` returns the desired cover. □

We can now complete the correctness proof.

THEOREM 4.5. *Given a graph $G = (V, \mathcal{E})$ (where $|V| = n, |\mathcal{E}| = E$) and integer parameters $\beta, r \geq 1$, Algorithm* `All_Cover` *constructs a sparse neighborhood cover.*

Proof. By Lemma 4.4, Algorithm `All_Cover` succeeds in covering all r-neighborhoods after $O(\beta n^{1/\beta})$ iterations of Procedure `Cover`. All clusters in the cover are constructed by Procedure `Cluster`, and hence have low diameter, by Lemma 4.1. Finally, by Lemma 4.3, each vertex appears in at most one set for each invocation of Procedure `Cover`, and by Lemma 4.4, Procedure `Cover` is invoked at most $O(\beta n^{1/\beta})$ times. Thus each vertex is in at most $O(\beta n^{1/\beta})$ sets, and hence the cover is sparse. □

4.2. Complexity analysis. We compute the cost of checking the stopping conditions and then performing the appropriate BFS explorations to construct $\mathcal{Y}$. The stopping conditions need to be checked at most $O(\beta)$ times for each cluster, since the conditions will be met within $O(\beta)$ iterations. To check the stopping conditions, we count vertices in Z, for all $Z \in \mathcal{Z}$. Recall that one of the stopping conditions insures that for all Z the number of vertices in Z is less than $O(n^{1/\beta})$ times the number of vertices in Y. Therefore, $O(\sum_{Z \in \mathcal{Z}} |Z|) = O(n^{1/\beta} \sum_{Y \in \mathcal{Y}} |Y|) = O(n^{1+1/\beta})$, since the sets Y are disjoint. Thus, the cost of checking the stopping conditions to construct $\mathcal{Y}$ is $O(\beta n^{1+1/\beta})$.

Now we turn to estimating the cost of performing the BFSs. Ignore for the moment the cost of the BFS exploration of the final layer $Z \setminus \Psi(Z)$ for each cluster. Then for the construction of $\mathcal{Y}$, each vertex participates at most twice in BFSs: each edge is placed in at most one set Y, and prior to being placed in Y, it could lie in at most one $\Psi(Z)$. Thus, without the Z layer, each edge has been examined at most twice in the construction of $\mathcal{Y}$.

Now consider the complexity of examining edges in Z. Notice that when $r = 1$, this is trivial, since every edge in $Z \setminus \Psi(Z)$ has an endpoint in $\Psi(Z)$, and every vertex is in a unique $\Psi(Z)$. For $r > 1$, bounding the amount of work done in Z is controlled

by means of the third stopping condition on the growth of individual clusters. In particular, if we have done too much work on exploring the layer $Z \setminus Y$, we are then obligated to grow Y to contain Z.

Recall that the final stopping condition on clusters ensures $\lambda(Z)$ is less than or equal to $O(n^{1/\beta})$ times $\lambda(Y)$. Let Z_Y denote the set Z associated with cluster Y. Then this gives

$$\sum_{Y \in \mathcal{Y}} |Z_Y| \leq \sum_{Y \in \mathcal{Y}} O(n^{1/\beta})\lambda(Y) \leq O(n^{1/\beta})\lambda(G) \leq O(n^{1/\beta}E).$$

Constructing $\beta n^{1/\beta}$ subcollections $\mathcal{Y}$ to complete the cover $\mathcal{X}$, we thus obtain the following theorem.

THEOREM 4.6. *Algorithm* `All_Cover` *produces a sparse* (β, r)*-neighborhood cover in time* $O((E\beta + n\beta^2)n^{2/\beta})$.

Setting $\beta = \log n$, we obtain the following corollary.

COROLLARY 4.7. *Algorithm* `All_Cover` *produces a sparse* $(\log n, r)$*-neighborhood cover in time* $O(E \log n + n \log^2 n)$.

5. Application: Approximating *k*-pairs shortest paths. In this section we present an approximation algorithm for the k-pairs shortest paths problem on undirected graphs with nonnegative edge weights. We exhibit a tradeoff between the quality of the approximation and running time. Specifically, we obtain a 32β approximation to the k-pairs shortest paths problem in time $O((E\beta + n\beta^2)n^{2/\beta}\delta + k\beta n^{1/\beta} \log\log n)$, for integer $\beta \geq 1$. This means that we can achieve a better running time than known exact algorithms even for paths that are only a constant factor times the length of the shortest path. Further work in this direction is reported in [12].

For $\beta = \log n$ we get an $O(\log n)$ times optimal approximation algorithm for the problem that runs in $\tilde{O}(E + k)$ time. Finding approximate shortest paths for *all* pairs will take $\tilde{O}\left(E + n^2\right) = \tilde{O}\left(n^2\right)$ time.

5.1. Sparse tree covers. The explanation of the algorithm is made simpler through the notion of *sparse tree covers*. We give these definitions here for unit edge weights; the extension to nonnegative edge weights is straightforward, as explained later.

DEFINITION 5.1. *For an undirected graph* $G(V, \mathcal{E})$ *and integers* $\beta, r \geq 1$*, a* (β, r)-tree cover *is a collection* $\mathcal{F}_{\beta,r}$ *of trees in* G*, that satisfies the following properties.*

1. *Every tree* $F \in \mathcal{F}_{\beta,r}$ *has depth* $8\beta r$ *or less.*
2. *For every two vertices* $u, v \in V$ *whose distance in* G *is* r *or less, there exists a common tree* $F \in \mathcal{F}_{\beta,r}$*, containing both.*

A (β, r)*-tree cover is said to be* sparse*, if each vertex is in at most* $\beta n^{1/\beta}$ *sets.*

Note that it is easy to modify Algorithm `All_Cover` so that it produces a sparse tree cover, not just a sparse neighborhood cover. In fact, Procedure `Cluster` actually constructs a BFS spanning tree for each cluster it builds, so the main change necessary is to include these trees in the output. The resulting (β, r)-tree cover will have the property that each tree in it is a BFS spanning tree of a set in the corresponding (β, r)-neighborhood cover. The time complexity remains $O((E\beta + n\beta^2)n^{2/\beta})$, which is $O(E \log n + n \log^2 n)$ when we set $\beta = \log n$.

5.2. The algorithm. We first give our algorithm for approximating k-pairs shortest paths with unit edge weights, and later explain how to extend this to the case when the edge weights are nonnegative.

Preprocessing. Let $\delta = \lceil \log \mathrm{Diam}(G) \rceil$. For every level $1 \leq i \leq \delta$, construct a sparse tree cover $\mathcal{F}_{\beta,2^i}$ for G, and number the trees in the cover. For every vertex v, and for every level i, store (in order of increasing tree ID) a list of all trees $F \in \mathcal{F}_{\beta,2^i}$ that contain v.

Query response. For any given pair of vertices u, v, for which a shortest path is sought, do the following.

Perform a binary search over the levels $1 \leq i \leq \delta$: for a given level i, if there exists a tree $F \in \mathcal{F}_{\beta,2^i}$ that contains both u and v, then restrict the search to lower values of i; otherwise, restrict the search to higher values of i.

The binary search will produce a level J such that $2^{J-1} \leq d(u,v) \leq 2^J 16\beta$, and a tree $F \in \mathcal{F}_{\beta,2^J}$ that contains both u and v.

Return the value $16\beta 2^J$ as the approximate distance between u and v. (For the ESP version of the problem, also return the unique path connecting a pair u, v in the common tree F as the approximate shortest path between u and v.)

The weighted case. The algorithms for sparse neighborhood covers presented in section 3 can easily be modified to produce a *weighted* tree cover by forming shortest path trees rather than BFS trees. The algorithm presented in this section can in turn be trivially modified to handle weights. As we will see below, the running time of our algorithms remains asymptotically unchanged.

5.3. Analysis. First we wish to prove that our algorithm is an $O(\beta)$-approximation algorithm for the shortest paths problem.

LEMMA 5.2. *For each of the k pairs of vertices given, our algorithm returns a path length between them within 32β times the length of the shortest path.*

Proof. We will argue this for a given pair u, v. Note that by Definition 5.1, if $\mathrm{dist}(u,v) \leq 2^i$, then the tree cover of level i has a tree containing both u and v. Since J is the minimum level i for which this is so, it must be that $2^{J-1} < \mathrm{dist}(u,v) \leq 2^J$. Also by Definition 5.1, the common tree has depth at most $8\beta \cdot 2^J < 16\beta \cdot \mathrm{dist}(u,v)$. That is, our algorithm returns the maximum length of the unique path connecting u and v in the common tree: $16\beta \cdot 2^J < 32\beta \cdot \mathrm{dist}(u,v)$. ∎

Now we address the running time of our algorithm.

LEMMA 5.3. *Our algorithm for approximating k-pairs shortest paths takes*

$$O((E\beta + n\beta^2)n^{2/\beta}\delta + k(\beta n^{1/\beta} \cdot \log \delta))$$

time. For the ESP version, the complexity increases (inherently) by the total length of the paths.

Proof. We have already noted that the algorithm for sparse neighborhood covers in this paper can produce the tree cover as it goes along at no additional payment in time. As we actually set up a data structure consisting of δ different tree covers, one for each level, the time bound for setting up the data structure is $O((E\beta + n\beta^2)n^{2/\beta}\delta)$ by Theorem 4.6.

As for the bound on a single query, the binary search for finding the right level requires checking $O(\log \delta)$ levels, and for a given level i, a common tree F can be found in $\beta n^{1/\beta}$ time by searching the ordered lists of tree IDs to which the two vertices belong. (Recall that by the sparsity property, every vertex belongs to at most $\beta n^{1/\beta}$ different trees in the ith-level tree cover $\mathcal{F}_{\beta,2^i}$.)

For the *ESP* version, retrieving the unique path connecting a pair u, v in the common tree F takes time proportional to the length of that path. ∎

Lemmas 5.2 and 5.3 yield the following theorem.

THEOREM 5.4. *Our algorithm for approximating k-pairs shortest paths takes* $O((E\beta + n\beta^2)n^{2/\beta}\delta + k(\beta n^{1/\beta} \cdot \log \delta))$ *time, and returns a solution that is within* $O(\beta)$ *of the exact one.*

Setting $\beta = \log n$, we get the following corollary.

COROLLARY 5.5. *Our algorithm provides an* $O(\log n)$ *approximation to the k-pairs shortest paths problem in* $O((E \log n + n \log^2 n)\delta + k(\log n \cdot \log \delta))$ *time.*

For the *all*-pairs shortest paths problem we get the following corollary.

COROLLARY 5.6. *Our algorithm for approximating* all*-pairs shortest paths takes* $O((E\beta + n\beta^2)n^{2/\beta}\delta + n^2(\beta n^{1/\beta} \cdot \log \delta))$ *time, and returns a solution that is within* $O(\beta)$ *of the exact one.*

And again, setting $\beta = \log n$, we have the following corollary.

COROLLARY 5.7. *Our algorithm provides an* $O(\log n)$ *approximation to the all-pairs shortest paths problem in* $O((E \log n + n \log^2 n)\delta + n^2(\log n \cdot \log \delta))$ *time.*

6. Discussion. We close the paper by discussing two final points. First, the construction algorithm described in this paper can be adapted to work in a (synchronous or asynchronous) distributed network. The asynchronous implementation requires additional techniques in order to guarantee maintaining a bound of $\tilde{O}(1)$ messages per edge on the message complexity. Roughly speaking, a synchronous distributed variant of the cover construction algorithm needs to be bootstrapped concurrently with the synchronizer protocol of [8] in a mutually recursive fashion. This distributed implementation will be described in full elsewhere; concise description of the essential details can be found in [8, 7, 6]. Let us comment that this distributed algorithm implies similar improvements in message complexity to a variety of distributed applications that make use of sparse covers, including adaptive routing schemes and a distributed *from-scratch* BFS and network synchronizer construction.

Second, it is worth mentioning that there exists a somewhat weaker notion of neighborhood covers: a small *average degree cover* [23, 9], where the *average* cluster overlaps over all vertices is small. In contrast, our neighborhood cover algorithm produces a cover with small *maximum* cluster that overlaps over all vertices. The average degree cover problem is known to be significantly easier [23, 9]; in fact, the maximum degree cover algorithm in this paper can be thought of as constructed through a logarithmic number of iterations, each producing an average degree cover in the "remaining graph."

Average degree covers are not sufficient for an efficient solution to the k-pairs shortest paths problem, because the "imbalance" (of high and low overlaps) cannot be amortized over many queries. (Unlike the algorithms in this paper, other constructions of average degree covers [23, 12] cannot be run for multiple iterations to produce a small maximum degree cover.)

However, as pointed out in [1, 12], in the special case of the *all*-pairs shortest paths application, an average degree cover suffices and leads to a better tradeoff between running time and approximation; namely, the constant of approximation can be improved. Specifically, the approximation constant of 32β derived earlier can be improved in this case to 4β by running our sparse neighborhood cover algorithm and taking the $2r$-neighborhoods of the sets constructed in one iteration, thereby producing a sparse average degree cover, and by eliminating two of the stopping conditions of the algorithm. Cohen [12] observed that the extra stopping condition can be removed in this case, and she also introduced a randomized parallel algorithm for approximate all-pairs shortest paths. The randomized algorithm constructs *pairwise covers* along the lines of [21]. Pairwise covers satisfy the weaker condition that any

pair of points at distance $\leq r$ lie together in the same cluster (but 3 points in the same r-neighborhood may not all appear together in any one cluster).

UNORIENTED Θ-MAXIMA IN THE PLANE: COMPLEXITY AND ALGORITHMS*

DAVID AVIS†, BRYAN BERESFORD-SMITH‡, LUC DEVROYE†, HOSSAM ELGINDY‡, ERIC GUÉVREMONT§, FERRAN HURTADO¶, AND BINHAI ZHU‖

Abstract. We introduce the unoriented Θ-maximum as a new criterion for describing the shape of a set of planar points. We present efficient algorithms for computing the unoriented Θ-maximum of a set of planar points. We also propose a simple linear expected time algorithm for computing the unoriented Θ-maximum of a set of planar points when $\Theta = \pi/2$.

Key words. maxima, plane sweep, lower bound, probabilistic analysis, expected complexity

1. Introduction. The development of image processing has motivated the investigation of properties of point sets for the purpose of image classification and/or understanding. Connectivity graphs and various enclosing boundary sets have been used to characterize the shape of point sets. The minimum spanning tree, the Gabriel graph, and the Delaunay triangulation are important connectivity graphs. Convex, maximal, and α-hulls [KLP75, EKS83] are instances of boundary sets. The kth iterated hull [Ch85] and the related concept of k-hull [CSY87] have also been proposed.

In this paper we introduce unoriented Θ-maxima as a generalization of extreme and maximal vectors. These are useful as boundary descriptors, and remain invariant under rotation.

Let S be a set of n planar points. A ray from a point $p \in S$ is the collection of all points $\{p + \lambda(v - p) : \lambda > 0\}$, where v is a fixed point in the plane not equal to p. A ray from a point $p \in S$ is called a *maximal ray* if it passes through another point $q \in S$. A cone is defined by a point p and two rays A and B emanating from it: it is the convex set $\{\lambda u + (1-\lambda)v : u \in A, v \in B, \lambda \in [0,1]\}$. A point $p \in S$ is said to be a *maximum* (or *maximal*) with respect to S if there exist two rays, A and B, emanating from p such that A and B are parallel to the $+x$- and $+y$-axes, respectively (thus, $v = p + (1,0)$ and $v = p + (0,1)$ in the definition of A and B), and the points of S lie outside the ($\pi/2$-angle) cone defined by p, A, and B. A point $p \in S$ is an unoriented Θ-maximum with respect to S if and only if there exist two *maximal* rays, A and B, emanating from p with an angle at least Θ between them so that the points of S lie outside the (Θ-angle) cone defined by p, A, and B (see Figure 1). We let S_Θ denote the subset of S whose elements are unoriented Θ-maxima. For the remainder of this

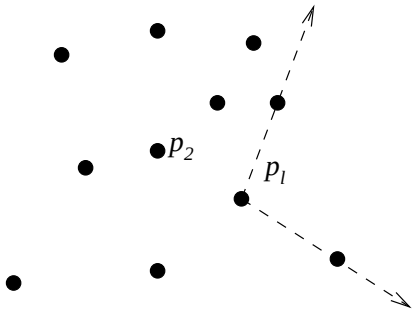

FIG. 1. *Point p_1 is an unoriented $\pi/2$-maximum whereas p_2 is not.*

paper, we only consider the problem of computing $S_{\pi/2}$. The algorithms apply to other values of $\Theta > \pi/2$. The additional technique for handling values of $\Theta < \pi/2$ is discussed in the appendix.

For each $p \in S_{\pi/2}$, our algorithms report two witnesses in the form of two maximal rays with an included angle, denoted by $\alpha_p \geq \pi/2$. Each of these maximal rays intersects the same edge of the convex hull of S and contains a ray parallel to either the x- or the y-axis in the cone between the two maximal rays. The above properties lead to two different approaches for computing $S_{\pi/2}$, which we outline in the following paragraphs.

1.1. Convex hull approach. The following geometric properties of $S_{\pi/2}$ (to be proven later) form the pillars of this approach and allow for a reduction of the problem into simpler tasks equal in number to the convex hull of S.

1. For each point $p \in S_{\pi/2}$, there exist two maximal rays emanating from p which intersect the same edge of the convex hull of S and such that the points of S lie outside the $\pi/2$-cone between the two rays.
2. For each point $p \in S_{\pi/2}$ there exist no more than *three* pairs of maximal rays which satisfy the previous property.
3. A pair of maximal rays which satisfies the first property includes the perpendicular from p to the corresponding convex hull edge in the $\pi/2$-cone between them.

The first task involves reporting unoriented maxima whose corresponding maximal rays intersect the same convex hull edge of S, and the other two properties facilitate the use of efficient computational geometry tools to develop an optimal running time algorithm. A detailed description of this approach is given in section 2.

1.2. Restricted unoriented maximum approach. This approach is based on the following simple property: for each point $p \in S_{\pi/2}$ there exist two maximal rays emanating from p which contain the $+x$-, the $-x$-, the $+y$-, or the $-y$-axis in the $\pi/2$-angle cone between them.

The problem is thus reduced to reporting for each of the four (directed) axes the unoriented maxima whose corresponding maximal rays contain it. For each axis, e.g., the $+y$-axis, we first sort points of the set in the direction perpendicular to the selected axis. We then perform two more linear passes. In the first pass, we scan the points of S from left to right constructing the convex hull of the visited points. Before $p \in S$ is processed, we compute the empty angle between the tangent from p to the convex hull and the selected axis, and call it θ. Perform a similar pass from right to left, storing the angle at p in ξ. A simple geometric argument shows that with respect

to the selected axis a point $p \in S_{\pi/2}$ if and only if $\theta + \xi \geq \pi/2$.

It is natural to observe the similarity between the two approaches. However, the restricted unoriented maxima (RUM) approach is more suitable for handling the discrete versions of the problem, namely, answering unoriented maximum queries, and identifying unoriented maxima of a set in parallel models of computation. This follows from the fact that focusing on a particular direction allows for the use of the divide-and-conquer technique with an efficient merging process. Moreover, the RUM approach is more suitable for probabilistic analysis. A detailed description and the probabilistic analysis of this approach is given in section 4.

The rest of the paper is organized as follows. Section 2 is dedicated to the details of computing unoriented $\pi/2$-maxima for a given set of planar points. In section 3 a lower bound for the algebraic computation tree model is developed, which implies that our algorithm is optimal. Finally, in section 4 the expected number of unoriented $\pi/2$-maxima is analyzed (and used) to obtain a linear expected running time algorithm. In conclusion, we discuss an approach for handling arbitrary values of Θ and some related results and unsolved problems.

2. Computing unoriented $\pi/2$-maxima. Let $S = \{X_1, X_2, \ldots, X_n\}$ denote a set of n planar points in general position (no three points are collinear). Its convex hull $CH(S)$ is the pair $(V(S), E(S))$, where $V(S)$ is the set of vertices and $E(S)$ is the set of edges. We denote the size of the convex hull by h ($h = |V(S)| = |E(S)|$). A point $p \in S - V(S)$ is called a *candidate* for an edge $e \in E(S)$ if there exist two rays emanating from p with a $\pi/2$-angle cone between them which intersect the edge e. Clearly, a point which is an unoriented maximum must be a candidate for some edge of the convex hull, and all convex hull points are candidates. From now on, we pay attention to candidate points that are not on the convex hull. To report the elements of the set $S_{\pi/2}$, based on the convex hull approach, we first identify the *candidates* for each edge of $E(S)$; then we consider each subset separately and check whether a candidate is a true unoriented $\pi/2$-maximum (i.e., whether the $\pi/2$-cone defined by the candidate is empty or not). The following geometric properties of candidates are critical to the efficiency of our algorithm.

LEMMA 1. *Each point $p \in S - V(S)$ may be a candidate for at most three edges of $E(S)$.*

Proof. The circular angle around p is 2π and, moreover, the points are in general position. Therefore, if p is the candidate for more than three edges, then one of the cones must have angle less than $\pi/2$. □

LEMMA 2. *If point p is a candidate for the edge $e \in E(S)$, then p lies in the semicircle of diameter e which has a nonempty intersection with the interior of the polygon defined by $E(S)$.*

Proof. The proof is elementary and omitted. □

Therefore, we have h semicircles with the constraint that no point in $S - V(S)$ belongs to more than three semicircles. In the following subsection, we establish a linear bound on the number of intersections of such curves. Algorithms for identifying candidates for each edge and for reporting unoriented maxima are then presented in sections 2.2 and 2.3, respectively.

2.1. A combinatorial property of constrained circles. Let $C^{(h)} = \{C_1, \ldots, C_h\}$ be a set of h planar circles with the constraint that no point in the plane belongs to more than k circles ($k \leq h$). Let x_i and r_i denote, respectively, the center and the radius of the ith circle C_i.

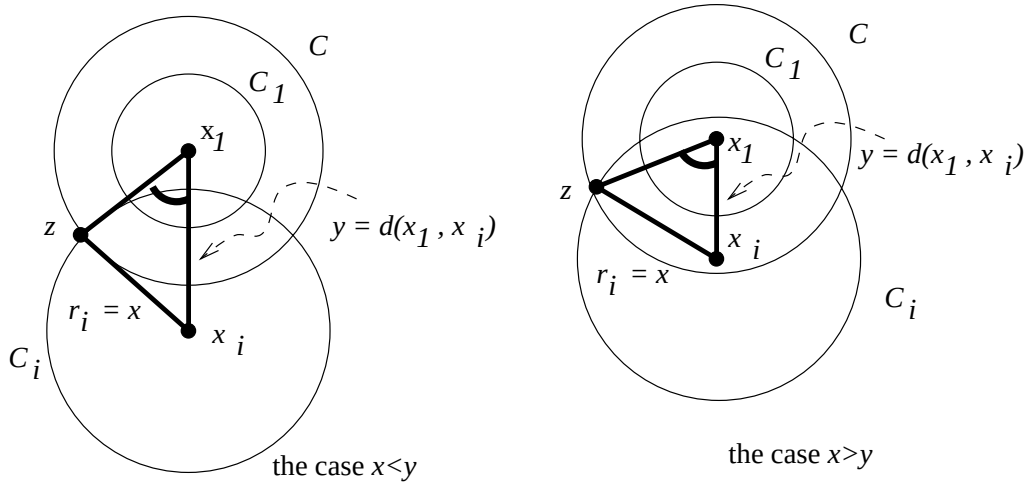

FIG. 2. *Finding a bound on θ.*

Without loss of generality, we assume that C_1 is the circle of $C^{(h)}$ with the smallest radius and that $r_1 = \min_{1 \le i \le h}\{r_i\} = 1$.

LEMMA 3. *At most $k-1$ circles can have their centers inside C_1.*

Proof. C_1 is the circle with smallest radius. Therefore, any circle C_i having x_i inside C_1 must contain x_1. Since x_1 cannot belong to more than k circles, the lemma follows. □

Let C be the circle concentric to C_1 with radius $\sqrt{3}$, let D_i be the disc consisting of circle C_i with its interior, and let the arc A_i be the intersection of D_i and the boundary of C if it exists. It is easy to see that any circle in $C^{(h)} - C_1$ that intersects C_1 and has a center outside C_1 must intersect C. The following lemma is based on Avis and Horton [AH81].

LEMMA 4. *If C_i intersects C_1 and x_i lies outside of C_1, then A_i subtends an angle of at least $\pi/3$ radians.*

Proof. Refer to Figure 2 for illustration. Let x, y and $\theta = \angle x_i x_1 z$ be as shown in Figure 2. Since C_i intersects C_1 and x_i lies outside of C_1, $y = d(x_1, x_i) \le r_1 + r_i = 1+x$. Therefore, we have $1 \le x, y \le 1+x$ and $\cos\theta = (3+y^2-x^2)/(2\sqrt{3}y)$; elementary geometry shows that $\cos\theta \le \sqrt{3}/2$. Therefore, $\theta \ge \pi/6$ radians, and thus the lemma follows. □

THEOREM 1. *At most $7k$ circles can intersect C_1.*

Proof. No point of the plane can belong to more than k circles. Therefore, Lemma 4 implies that no more than $6k$ circles can intersect C_1 and have their center outside C_1. Also, Lemma 3 implies that no more than k circles can intersect C_1 and have their center inside C_1. □

COROLLARY 1. *$C^{(h)}$ induces at most $14kh$ intersection points.*

Proof. Theorem 1 implies that C_1 can have at most $14k$ intersection points. By an inductive argument (removing C_1 from $C^{(h)}$ to obtain $C^{(h-1)}$), we can conclude that $C^{(h)}$ induces at most $14kh$ intersection points. □

It is clear that Corollary 1 holds for semicircles too.

COROLLARY 2. *In the arrangement of semicircles that was introduced in Lemma 2, there are at most $42h$ intersection points.*

Proof. The proof follows from Corollary 1 and Lemma 1. □

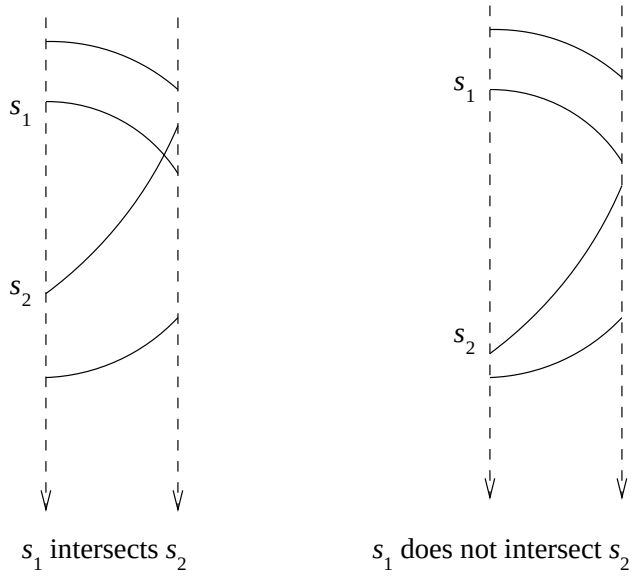

FIG. 3. *An example illustrating the idea of plane sweep.*

In this subsection, we showed that there are only a linear number of intersections among all the semicircles. We show in the next subsection how to apply this result to report candidates with respect to each hull edge.

2.2. Reporting candidates for each hull edge. In this section we will describe a procedure for reporting the candidates for $E(S)$. The procedure is based on the plane sweep technique of Bentley and Ottmann [BO79]. The idea of plane sweep can be described with the following simple example. Assume that we have two segments s_1, s_2, and without loss of generality, assume that the x-coordinates of the left (right) endpoints of s_1, s_2 are the same. The problem is to decide whether s_1 intersects s_2. We can see that s_1 intersects s_2 if and only if the order from top to bottom of the y-coordinates of the right endpoints of s_1, s_2 differs from the top-to-bottom order of the y-coordinates of the left endpoints of s_1, s_2. In general, the plane sweep method maintains a total order of some geometric objects (e.g., $O(n)$ segments) at a given stage. To check certain properties of two valid objects (e.g., whether s_1 intersects s_2), it simply checks whether the top-to-bottom order of these two objects switches at a later stage. Usually a dynamic balanced binary search tree is sufficient for the plane sweep method (to maintain the total order) [BO79]. In Figure 3 we illustrate an example for plane sweep for some xy-monotone (i.e., monotone in both the x- and y-directions) circular segments.

First we give a description of the procedure and then explain the essential details and analyze its correctness and performance.

PROCEDURE CANDIDATES

INPUT: A set S of n planar points.

OUTPUT: The list of edges of $E(S)$ together with a list of candidate points for each edge.

METHOD:

1. Compute the convex hull of S and store the edges of $CH(S)$, $E(S)$ in a doubly linked list.
2. Compute the semicircles having as diameters the edges of $E(S)$.
3. Partition each semicircle into at most three parts such that every (circular) segment produced is xy-monotone. Let H be the set of segments obtained (note that $|H| \in O(n)$).
4. Apply the Bentley and Ottmann [BO79] plane sweep algorithm on $H \cup (S - V(S))$ to report the intersection points of the monotone segments in H. When a point $p \in S - V(S)$ is met by the sweep line, an $O(\log n)$ search in a balanced search data structure T may be used to identify those edges of $CH(S)$ for which p is a candidate. At the end of this step, all candidates of $S - V(S)$ are known.
5. Produce the list of candidates for each edge of $E(S)$ using the output of step 4.

End of Procedure

Correctness of Procedure Candidates in computing the intersection points of the elements in $H \cup (S - V(S))$ follows directly from correctness of the sweep line algorithm in [BO79]. Computing such intersections is essential to maintaining a total vertical ordering of the segments in a search structure T where the following four operations can be implemented in $O(\log n)$ time.

1. `INSERT`(s, T) inserts the segment s into the total order maintained by T.
2. `DELETE`(s, T) deletes segment s from T.
3. `ABOVE`(s, T) returns the name of the segment immediately above s in T.
4. `BELOW`(s, T) returns the name of the segment immediately below s in T.

These operations are listed in [SH76] and referred to by [BO79]. They can be implemented using a balanced binary search tree.

For a given vertical sweep line L, T contains the total ordering of the monotone segments (of semicircles) intersecting L. They define vertical intervals on L, each of which corresponds to a unique intersection region. We modify the balanced search tree by keeping for each vertical interval (uniquely determined by two adjacent elements of H) the list of semicircles containing that segment. By Lemma 1, at most three such semicircles may exist. Therefore, the space complexity of the data structure is still linear. When a new semicircle is encountered (and two monotone segments are to be inserted), we use the information in its neighbor vertical intervals to establish its linked list. A deletion of a semicircle can be handled similarly. Finally, when an intersection point of two segments of semicircles is encountered, the appropriate linked list can be updated in constant time. Handling point $p \in S - V(S)$ requires performing a search of the structure T which returns the vertical interval that contains p. We can then determine the semicircles that contain p in constant time, and update the list of candidates for each of the corresponding convex hull edges in $E(S)$.

Step 1 can be done in $O(n \log n)$ time, and steps 2, 3, and 5 can be accomplished in $O(n)$ time. The Bentley and Ottmann [BO79] algorithm has an $O(n \log n + k \log n)$ running time, where k is the number of intersection points to be reported. Since we have $O(n)$ intersection points by Corollary 2, the execution time of step 4 is $O(n \log n)$. Therefore, Procedure Candidates reports the set of candidates for the convex hull edges in $O(n \log n)$ time and $O(n)$ space.

2.3. Computing unoriented maxima among candidates. Given the output of Procedure Candidates (i.e., a set of candidates for each edge of $E(S)$), we now

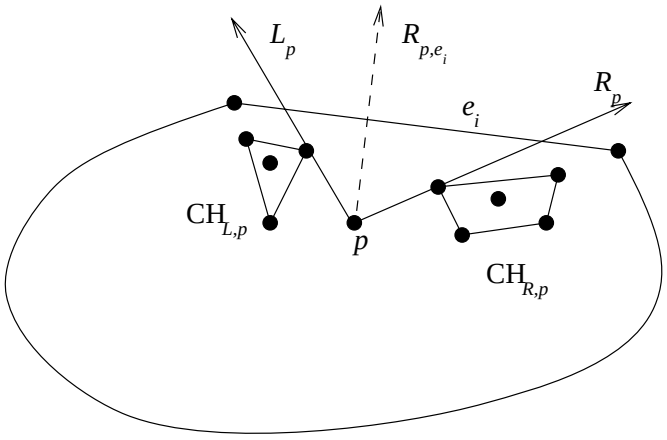

FIG. 4. *Computing unoriented maxima from candidates.*

develop a procedure to identify for each convex hull edge the unoriented maxima among its list of candidates.

Let $\mathcal{C}_i$ denote the set of candidates for the ith edge e_i of $E(S)$, and let k_i denote its size. If $p \in \mathcal{C}_i$, then the ray emanating from p and perpendicular to the edge e_i, denoted by R_{p,e_i}, properly intersects e_i since p lies inside the semicircle of diameter e_i. Let *wedge*(p, e_i) be the largest angle at p which does not contain points of S and is bounded by two maximal rays, L_p and R_p, that emanate from p and intersect e_i (Figure 4).

LEMMA 5. *If point p is an unoriented maximum with respect to edge e_i, then R_{p,e_i} must belong to the cone defined by p and the maximal rays L_p and R_p.*

Proof. If R_{p,e_i} does not lie between the maximal rays L_p and R_p, then *wedge*$(p, e_i) < \pi/2$, a contradiction. □

LEMMA 6. *If the convex hulls of points in $\mathcal{C}_i - \{p\}$ to the left and to the right of R_{p,e_i}, denoted by $CH_{L,p}$ and $CH_{R,p}$ respectively, are known, then we can compute wedge(p, e_i) in $O(\log n)$ time.*

Proof. Refer to Figure 4. Our problem is to compute the rightmost and leftmost (maximal) rays, R_p and L_p, emanating from p, intersecting e_i, and containing R_{p,e_i} in the cone (p, L_p, R_p). R_p (L_p) can be computed by finding the ray from p tangent to the convex hull to the right (left) of R_{p,e_i}, which can be done in $O(\log n)$ time [PS85]. If the angle between R_p and L_p (defined by the cone containing R_{p,e_i}) is $\geq \pi/2$, then p is an unoriented maximum. □

PROCEDURE UNORIENTED MAXIMA

INPUT: A list of candidates for the ith edge of *E(S)*.

OUTPUT: The unoriented maximal points and the rays defining their widest angles.

METHOD:

1. Sort the k_i points of $\mathcal{C}_i$ along e_i. Note that the sorted points define a simple polygonal chain.
2. Compute L_p for all points $p \in \mathcal{C}_i$ as follows:
   - $CH_L \leftarrow$ endpoint of e_i
   - Going from left to right using the order of the points of step 1:
     - Compute L_p using CH_L (as explained in Lemma 6).

– Insert p in CH_L using the rules of the convex hull algorithm of Avis, ElGindy, and Seidel [AES85].

3. Compute R_p for all points $p \in \mathcal{C}_i$ in a similar fashion to step 2, by scanning them from right to left.
4. For each $p \in \mathcal{C}_i$, compute angle *wedge*(p, e_i) between L_p and R_p, and if $\alpha_p \geq \pi/2$, output (p,L_p,R_p).
5. Output $V(S)$.

End of Procedure

Correctness of the above procedure follows from the correctness of the on-line convex hull algorithm in [AES85] and from Lemma 6.

Step 1 is performed in $O(k_i \log k_i)$ time. Since the algorithm in [AES85] updates the convex hull of k_i points by insertion in $O(\log k_i)$ time, and since searching for L_p and R_p requires $O(\log k_i)$ time at most as explained in Lemma 6, then steps 2 and 3 require $O(k_i \log k_i)$ time. Step 4 is clearly performed in $O(k_i)$ time, hence $O(k_i \log k_i)$ total time is spent for edge e_i. Lemma 1 implies that $\sum_{i=1}^{h} k_i \log k_i \leq \log n \sum_{i=1}^{h} k_i \leq 3n \log n \in O(n \log n)$. Therefore, we can state the final result of this section as follows.

THEOREM 2. *All unoriented maximal points of S can be computed in $O(n \log n)$ time and $O(n)$ space.*

In the next section, we establish an $\Omega(n \log n)$ lower bound for computing unoriented maxima in the plane, thus proving that our algorithm is optimal.

3. Lower bound for the algebraic computation tree model. In this section we establish an $\Omega(n \log n)$ lower bound for computing unoriented Θ-maxima in the plane. This $\Omega(n \log n)$ lower bound for computing the unoriented maxima $S_\Theta \subseteq S$ in the plane, for $\pi/2 \leq \Theta \leq \pi$, is achieved by a reduction from the integer element uniqueness problem. Note that when $\Theta \geq \pi$, the unoriented maxima $S_\Theta \subseteq S$ are exactly the convex hull (extreme) points, and it is well known that computing the extreme points of a set of n points has a lower bound of $\Omega(n \log n)$ under the algebraic computation tree model [PS85]. Our result is as follows.

THEOREM 3. *The problem of computing $S_\Theta \subseteq S$ for $\pi/2 \leq \Theta \leq \pi$ is $\Omega(n \log n)$ under the algebraic computation tree model, where $|S| = n$.*

Proof. We use a reduction from integer element uniqueness. In Yao [Ya89] this problem is shown to have a lower bound of $\Omega(n \log n)$ under the algebraic computation tree model.

We are given a set of integers $M = \{x_1, \ldots, x_n\}$, input to the integer element uniqueness problem. For each x_i, produce the following six points: $(i + \epsilon, (nx_i)^2)$, $(i+\epsilon, (nx_i)^2+\epsilon)$, $(i+\epsilon, (nx_i)^2-\epsilon)$, $(i-\epsilon, (nx_i)^2)$, $(i-\epsilon, (nx_i)^2+\epsilon)$, and $(i-\epsilon, (nx_i)^2-\epsilon)$. The value of $\epsilon = 1/4$ is used for our proof. Let S be the set containing all of these points.

If $x_i = x_j$ then at least two out of the twelve induced points cannot be unoriented maxima (Figure 5). On the other hand, if x_i is unique in M, then the six points created for x_i are all unoriented maxima. Hence all x_i's in M are distinct if and only if there are exactly $6n$ unoriented maxima in S. We have thus reduced integer element uniqueness to computing the unoriented maxima in linear time. Since the integer element uniqueness problem has a lower bound of $\Omega(n \log n)$ under the algebraic computation tree model, the theorem follows. □

We have thus obtained an optimal algorithm for computing unoriented Θ-maxima in the plane. In the next section we present the RUM algorithm which will beat the $\Omega(n \log n)$ lower bound when the points are drawn from a common distribution. This is obtained via a careful probabilistic analysis of the expected number of unoriented

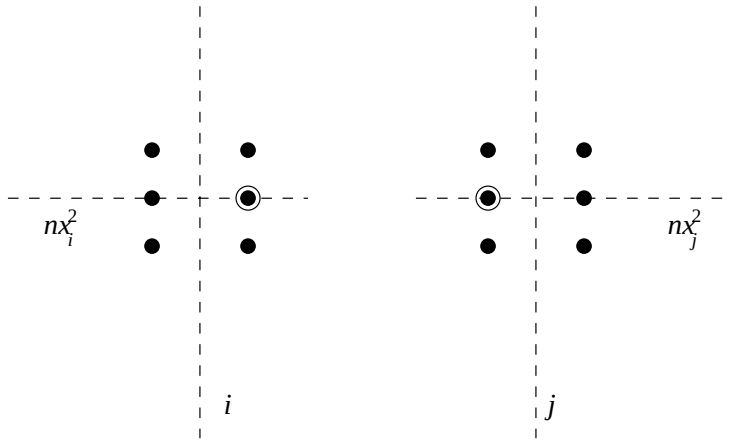

FIG. 5. *Lower bound proof: the case when $x_i = x_j$. The marked points cannot be unoriented maxima.*

maxima, together with a simple divide-and-conquer algorithm.

4. Expected number of unoriented maxima. In this section, we analyze the expected number of unoriented maxima when elements of the set S are independently drawn from a common distribution. Since n points on the perimeter of a convex set are all unoriented maxima, it is only natural to exclude such pathological cases. This is done by assuming that the distribution of the prototype data point is absolutely continuous; i.e., it has a density f. This has the added benefit that with probability one, no two points have the same coordinates. We also assume that f has compact support. Without loss of generality, we can then assume that f vanishes off $[0,1]^2$. We will show that under a mild condition on f, which is satisfied for most distributions that appear in probabilistic models, the expected number of unoriented maxima is $O(\sqrt{n})$. In section 4.4, we describe a divide-and-conquer algorithm that runs in linear expected time for this class of distributions.

The notion of unoriented maximum generalizes that of a maximal vector, for which algorithms can be found in [BS78, BKST78, De80, De85, GBT84, BCL90, Go94, KS85, KLP75]. The expected time was considered in all but the last two of these papers. For additional analysis, see [Dw90, Bu89]. All linear expected time algorithms described in these papers have conditions on the distribution that are more restrictive than the ones used in this paper.

4.1. Preliminaries. We define a cone $C_\theta(x,\eta)$ for $x \in \mathbb{R}^2$, $\theta \in [0,2\pi)$, and $\eta \in [0,2\pi)$ as the collection of all points $y \in \mathbb{R}^2$ with polar coordinate representation $y = x + re^{i\phi}$ for some $r > 0$ and $\phi \in (\theta - \eta/2, \theta + \eta/2)$. Thus, x is the top of the cone, and θ is the direction of the bisector, while η is the opening angle. Given a set of vectors $\mathcal{X}_n = \{X_1, \ldots, X_n\}$ in $\mathbb{R}^2$, we say that X_j is an UNORIENTED MAXIMUM if there exists a θ such that $C_\theta(X_j, \pi/2) \cap \mathcal{X}_n = \emptyset$. Thus, every maximal vector and every point on the convex hull of $\mathcal{X}_n$ is an unoriented maximum of $\mathcal{X}_n$.

It is helpful to cut the problem into manageable subproblems. To do so, we introduce the notion of a restricted unoriented maximum or RUM. Fix a direction $\zeta \in [0,2\pi)$. Call X_j a RUM of $\mathcal{X}_n$ if there exists a direction θ such that

$$C_\theta(X_j, \pi/2) \cap \mathcal{X}_n = \emptyset$$

and

$$C_\theta(X_j, \pi/2) \supseteq C_\zeta(X_j, \pi/3) \ .$$

Call this collection of directional unoriented maxima S_ζ. Obviously, if S is the collection of all unoriented maxima, we have

$$S = \cup_{\zeta \in [0,2\pi)} S_\zeta = \cup_{j=0}^{11} S_{j\pi/6} \ .$$

This property allows us to focus on RUMs. In what follows, we fix $\zeta = \pi/2$ and abbreviate the restricted unoriented maxima with respect to this ζ to RUMs. The set of all RUMs among $X_1, \ldots, X_n$ is denoted by $\mathcal{S}_n$. We list three structural properties of $\mathcal{S}_n$.

1. The Lipschitz property. If $X_i \in \mathcal{S}_n$, $X_j \in \mathcal{S}_n$, then the line segment joining X_i and X_j has an angle with the x-axis within $\pi/3$ of 0 or π. Suppose that the segment forms an angle of ξ degrees, with $\pi/2 \geq \xi > \pi/3$. Then either

$$X_j \in C_\theta(X_i, \pi/2) \supseteq C_\zeta(X_i, \pi/3)$$

for some θ, or vice versa,

$$X_i \in C_\theta(X_j, \pi/2) \supseteq C_\zeta(X_j, \pi/3) \ .$$

In the former case, X_i is not a RUM, and in the latter case, X_j is not a RUM. If we sort all the RUMs from left to right and join them by straight line segments, we obtain a piecewise linear curve that is Lipschitz of constant not more than $\pi/3$. (A function f is Lipschitz of constant C if $|f(x) - f(y)| \leq C|x - y|$.)

2. The monotonicity property.

$$\text{RUM}(X_1, \ldots, X_{n+1}) \subseteq \text{RUM}(X_1, \ldots, X_n) \cup \{X_{n+1}\} \ .$$

3. The transitive property.

$$\text{RUM}(X_1, \ldots, X_{n+m}) = \text{RUM}(\text{RUM}(X_1, \ldots, X_n), \text{RUM}(X_{n+1}, \ldots, X_{n+m})) \ .$$

We will need the following elementary lemma.

LEMMA 7. *If N is a binomial (n, p) random variable, then $\mathbf{P}\{N > enp\} \leq e^{-np}$.*

Proof. By Chernoff's bounding method [Ch52], for $t > 0$ and $\lambda > 0$,

$$\begin{aligned}
\mathbf{P}\{N > t\} &\leq \mathbf{E}\left\{e^{\lambda N - t}\right\} \\
&\leq \left(e^\lambda p + 1 - p\right)^n e^{-\lambda t} \\
&\leq \exp\left((e^\lambda - 1)np - \lambda t\right) \\
&= \exp\left(t - np - t\log\left(\frac{t}{np}\right)\right) \quad (\text{take } \ \lambda = \log(t/(np)) \ )
\end{aligned}$$

so that

$$\mathbf{P}\left\{N > enp\right\} \leq e^{-np} \ . \qquad \square$$

Theorem 4 deals with distributions having a bounded density: for such distributions, there is limited dependence between the components of the random vector X. In a later section, we will obtain analogous results for unbounded densities. In the

bounds presented in this paper, the dependence upon f is measured through $\|f\|_\infty$ or $\int f^\alpha$.

THEOREM 4. *Let X be a random vector on $[0,1]^2$ whose density is bounded by $\|f\|_\infty$. For an i.i.d. sample $X_1, \ldots, X_n$ drawn from X, let $\mathcal{S}_n$ be the collection of* RUM*s. Then*

$$\lim_{n\to\infty} \mathbf{P}\{|\mathcal{S}_n| > C\sqrt{n}\} = 0,$$

where $C = e\sqrt{2(1+2/\sqrt{3})\|f\|_\infty \log 4}$. *Also,*

$$\limsup_{n\to\infty} \frac{\mathbf{E}\{|\mathcal{S}_n|\}}{C\sqrt{n}} \le 1 \ .$$

Proof. As described in the caption of Figure 6, the unit square is covered by a circumscribed rhombus with angles 120, 60, 120, and 60 degrees. From top to bottom, it measures $2a = 1+\sqrt{3}$, and from left to right $2b = 1+1/\sqrt{3}$. The area of the rhombus is $1+2\sqrt{3}$. Partition the rhombus into $m \times m$ equal rhombi as shown in the figure. This is achieved by taking m slabs A_i and m slabs B_j, and defining rhombi by the intersections $A_i \cap B_j$. There are m^2 small rhombi that can be addressed by index pairs (i,j), $1 \le i,j \le m$. A chain of cells is an ordered collection of such pairs, beginning with $(1,1)$ and ending with (m,m), satisfying the successor rule: (i,j) must be followed by either $(i,j+1)$ or $(i+1,j)$. See the lightly shaded collection in Figure 6. Thus, the chain contains precisely $2m-1$ cells, and by a simple counting argument, it is easy to see that there are exactly

$$\binom{2m-2}{m-1}$$

possible chains. Let us mark each cell that contains at least one RUM (dark in Figure 6). We claim that the marked cells are contained in a chain. This, of course, follows from the Lipschitz curve property we established above and our choice of angles when defining the partition. We let $N(\mathcal{C})$ denote the number of data points in the chain $\mathcal{C}$. Thus,

$$|\mathcal{S}_n| \le \max_{\text{all chains } \mathcal{C}} N(\mathcal{C}).$$

By the inclusion–exclusion inequality, we have

$$\begin{aligned}
\mathbf{P}\{|\mathcal{S}_n| > t\} &\le \mathbf{P}\left\{\max_{\text{all chains } \mathcal{C}} N(\mathcal{C}) > t\right\} \\
&\le \sum_{\text{all chains } \mathcal{C}} \mathbf{P}\{N(\mathcal{C}) > t\} \\
&\le \binom{2m-2}{m-1} \sup_{\text{all chains } \mathcal{C}} \mathbf{P}\{N(\mathcal{C}) > t\} \ .
\end{aligned}$$

Next, observe that the probability of a cell is given by

$$\int_{A_i \cap B_j} f(x,y)\,dx\,dy \le \|f\|_\infty \int_{A_i \cap B_j \cap [0,1]^2} dx\,dy \le \frac{\|f\|_\infty (1+2/\sqrt{3})}{m^2} \ .$$

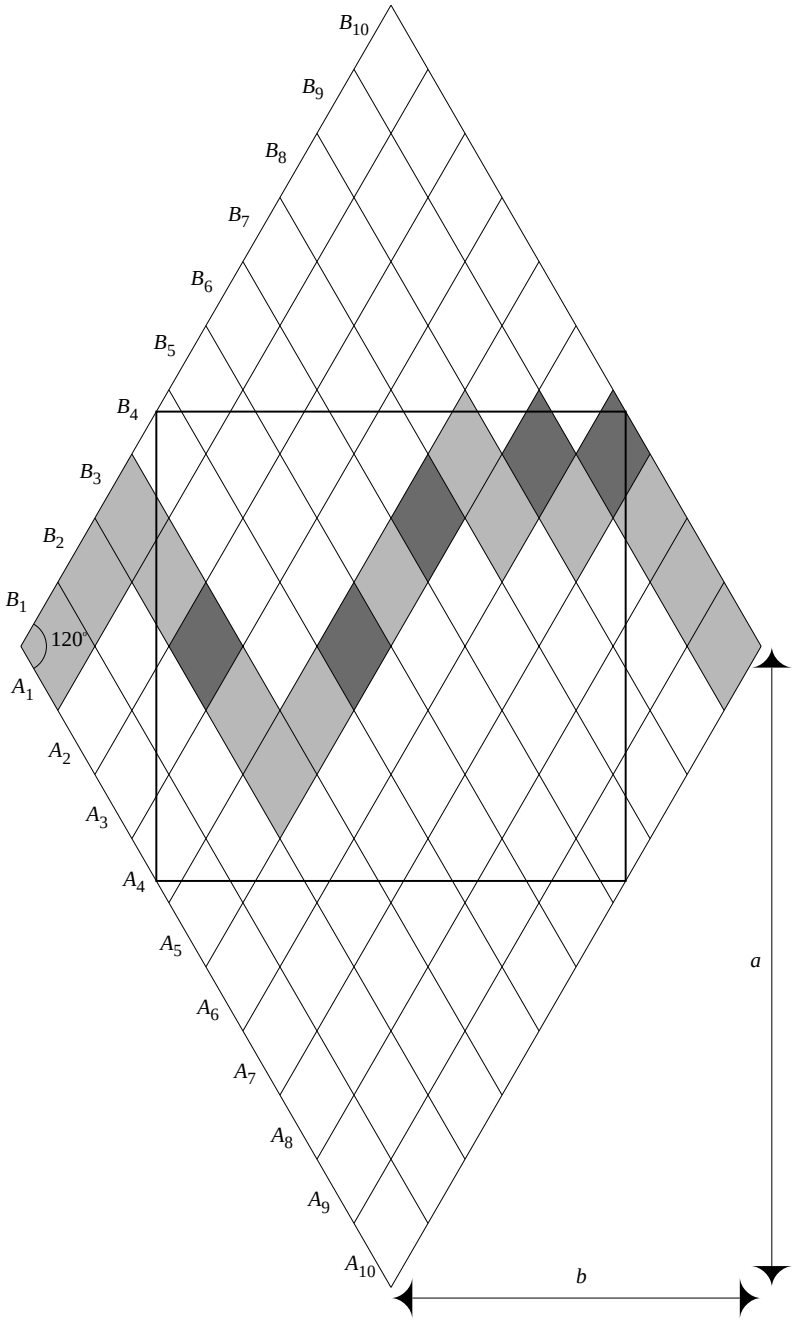

FIG. 6. *The unit square* $[0,1]^2$ *is shown in dark lines. Consider the rhombus of angle* 120 *degrees that circumscribes the square. Partition the rhombus into a grid of* $m \times m$ *similar small rhombi. A chain (in lightest shading) is any collection of small rhombi where the first and last rhombus are the leftmost and rightmost rhombi, respectively, and intermediate rhombi share one side. The rhombi in a chain must have increasing* x*-coordinate values of their centers. The dark shaded rhombi are those that contain at least one restricted unoriented maximum. Observe that these cells always belong to a chain.*

Thus, for a chain of $2m-1$ cells $\mathcal{C}$, $N(\mathcal{C})$ is binomial with parameters n and

$$\int_{\mathcal{C}} f \le \frac{\|f\|_\infty (1+2/\sqrt{3})(2m-1)}{m^2} \le \frac{2\|f\|_\infty (1+2/\sqrt{3})}{m} \stackrel{\text{def}}{=} q \ .$$

Hence, $\mathbf{P}\{N(\mathcal{C}) > t\} \le \mathbf{P}\{\text{Binomial}(n,q) > t\}$. Therefore, by Lemma 7, if $m \to \infty$ as $n \to \infty$,

$$\begin{aligned}
\mathbf{P}\left\{|\mathcal{S}_n| > enq\right\} &\le \binom{2m-2}{m-1} \sup_{\text{all chains } \mathcal{C}} \mathbf{P}\left\{N(\mathcal{C}) > enq\right\} \\
&\sim \frac{2^{2m-2}}{\sqrt{\pi m}} \sup_{\text{all chains } \mathcal{C}} \mathbf{P}\left\{N(\mathcal{C}) > t\right\} \\
&\le \frac{2^{2m-2}}{\sqrt{\pi m}} \mathbf{P}\left\{\text{Binomial}(n,q) > enq\right\} \\
&\le \frac{2^{2m-2} e^{-nq}}{\sqrt{\pi m}} \ .
\end{aligned}$$

Define $q' = mq$. First, take

$$m = \left\lceil \sqrt{\frac{nq'}{\log 4}} \right\rceil \ .$$

Then

$$\mathbf{P}\left\{|\mathcal{S}_n| > enq\right\} \le (1+o(1)) \frac{\exp(m \log 4 - nq'/m)}{4\sqrt{\pi m}} \le \frac{4+o(1)}{\sqrt{\pi m}} \to 0 \ .$$

This proves the first part of Theorem 4. For the second part, choose $\epsilon > 0$ very small and set

$$m = \left\lfloor (1-\epsilon) \sqrt{\frac{nq'}{\log 4}} \right\rfloor \ .$$

We verify quickly that

$$\mathbf{P}\left\{|\mathcal{S}_n| > enq\right\} \le e^{-c\sqrt{n}}$$

for some constant $c > 0$ depending upon ϵ. Then,

$$\mathbf{E}|\mathcal{S}_n| \le enq + n\mathbf{P}\{|\mathcal{S}_n| > enq\} = enq + o(1) \sim e\sqrt{nq' \log 4}/(1-\epsilon) \ .$$

Theorem 4 now follows since ϵ was arbitrary. □

4.2. Lower bounds. The number of unoriented maxima is larger than the number of maximal vectors, i.e., the number of data points X_i for which one of $C_{\pi/4}(X_i, \pi/2)$, $C_{3\pi/4}(X_i, \pi/2)$, $C_{5\pi/4}(X_i, \pi/2)$, and $C_{7\pi/4}(X_i, \pi/2)$ has a nonempty intersection with $X_1, \ldots, X_n$. We denote the set of maximal vectors for $X_1, \ldots, X_n$ by $\mathcal{M}_n$. Thus, $|\mathcal{S}_n| \ge |\mathcal{M}_n|$. This can be used to show that the bound of Theorem 4 cannot be improved for many simple distributions. To clarify this, just take the uniform distribution on the trapezoid T formed by intersecting $[0,1]^2$ with $\{(x,y) : y <$

$x < y + c\}$, with $0 < c \leq 1$. The area of the trapezoid is $1/2(1-(1-c)^2) = c - c^2/2$. Hence,

$$f(x,y) = \frac{1}{c - c^2/2} I_T(x,y) \ .$$

Thus, $\|f\|_\infty = 1/(c - c^2/2)$. We take an integer m large enough such that $1/m < c$. Then partition the unit square into a rectangular grid of m by m with sides equal to $1/m$. Mark the m grid cells that straddle the diagonal of the square. Let $E_1, \ldots, E_m$ be the indicators of the events that the marked grid cells contain at least one data point, with E_1 referring to the cell with the largest y-values, and so on down. A simple geometric argument shows that

$$|\mathcal{M}_n| \geq \sum_{i=1}^{m} E_i \ .$$

Hence, if the marked grid cells intersected with our trapezoid T yield the triangles $S_1, \ldots, S_m$,

$$\begin{aligned}
\mathbf{E}|\mathcal{M}_n| &\geq m\mathbf{E}E_1 \\
&= m\left(1 - (1 - \|f\|_\infty \text{ area}(S_1))^n\right) \\
&= m\left(1 - (1 - \|f\|_\infty/(2m^2))^n\right) \\
&\geq m\left(1 - \exp(-\|f\|_\infty n/(2m^2))\right) \\
&\geq m/2 \\
&\geq \sqrt{\|f\|_\infty n/4\log 4} - 1
\end{aligned}$$

if we choose $m = \lfloor \sqrt{\|f\|_\infty n/\log 4} \rfloor$. Recall that n has to be large enough to insure that $1/m < c$. Thus, we have

$$\mathbf{E}|\mathcal{M}_n| \geq \sqrt{\|f\|_\infty n/4\log 4} - 1 \ .$$

The upper bound in Theorem 4 cannot be improved upon in terms of $\|f\|_\infty$ and n unless the class of distributions is further restricted.

4.3. Random vectors with very dependent coordinates. If f is unbounded, Theorem 4 becomes useless. It is possible, however, that $\int f^\alpha < \infty$ for some $\alpha > 1$. This fact can be used to obtain a different collection of upper bounds.

THEOREM 5. *Let X be a random vector on $[0,1]^2$ whose density satisfies $\int f^\alpha < \infty$ for some $\alpha > 1$. For an i.i.d. sample $X_1, \ldots, X_n$ drawn from X, let $\mathcal{S}_n$ be the collection of* RUMs. *Then*

$$\lim_{n\to\infty} \mathbf{P}\{|\mathcal{S}_n| > Cn^{\alpha/(2\alpha-1)}\} = 0,$$

where

$$C = e\left(\left(\int f^\alpha\right)^{1/\alpha} \left(2(1+2/\sqrt{3})\right)^{1-1/\alpha}\right)^{\alpha/(2\alpha-1)} (\log 4)^{(2\alpha-1)/(\alpha-1)} \ .$$

Also,

$$\limsup_{n\to\infty} \frac{\mathbf{E}\{|\mathcal{S}_n|\}}{Cn^{\alpha/(2\alpha-1)}} \leq 1 \ .$$

Proof. We follow the proof of Theorem 4. Note that $N(\mathcal{C})$ is binomial with parameters n and p, with p given by

$$\begin{aligned}\int_{\mathcal{C}} f(x,y)\,dx\,dy &\le \left(\int f^\alpha\right)^{1/\alpha} \left(\int_{\mathcal{C}\cap[0,1]^2} dx\,dy\right)^{1-1/\alpha} \\ &\le \left(\int f^\alpha\right)^{1/\alpha} \left(\frac{2(1+2/\sqrt{3})}{m}\right)^{1-1/\alpha} \\ &\stackrel{\text{def}}{=} q \stackrel{\text{def}}{=} q'/m^{1-1/\alpha}\ .\end{aligned}$$

Here we used Hölder's inequality and an inequality from the proof of Theorem 4. Therefore, $N(\mathcal{C})$ is binomial with parameters n and p where $p \le q$, and $\mathbf{P}\{N(\mathcal{C}) > t\} \le \mathbf{P}\{\text{ Binomial}(n,q) > t\}$. As in the proof of Theorem 4, when $m \to \infty$ as $n \to \infty$,

$$\mathbf{P}\left\{|\mathcal{S}_n| > enq\right\} \le \frac{(1+o(1))2^{2m-2}e^{-nq}}{\sqrt{\pi m}}\ .$$

With

$$m = \left\lceil \left(\frac{nq'}{\log 4}\right)^{\alpha/(2\alpha-1)} \right\rceil\ ,$$

we obtain

$$\begin{aligned}\mathbf{P}\left\{|\mathcal{S}_n| > enq\right\} &\le (1+o(1))\frac{\exp(m\log 4 - nq'/m^{1-1/\alpha})}{4\sqrt{\pi m}} \\ &\le \frac{4+o(1)}{\sqrt{\pi m}} \\ &\to 0\ .\end{aligned}$$

This proves the first part of Theorem 5. The second part follows from the first part by using arguments analogous to those of Theorem 4. □

Remark 1. We note that the condition $\int f^\alpha < \infty$ imposes a condition on the peakedness of the density f. For bounded densities, we clearly have $\int f^\alpha < \infty$. Theorem 4 is obtained as a limit of Theorem 5 when we let $\alpha \to \infty$. □

Remark 2. If ψ is a positive convex strictly increasing function, then for the chain $\mathcal{C}$ in the proof, we have by Jensen's inequality,

$$\int_{\mathcal{C}} f \le \int_{\mathcal{C}\cap[0,1]^2} dx\,dy \times \psi^{\text{inv}}\left(A/\int_{\mathcal{C}\cap[0,1]^2} dx\,dy\right)\ ,$$

where $A = \int \psi(f)$. Using this instead of Hölder's inequality, with $\psi(u) = u\log^a(1+u)$ for $a > 0$, we see that

$$\mathbf{E}|\mathcal{S}_n| = O\left(\frac{n}{\log^a n}\right)$$

whenever $\int f\log^a(1+f) < \infty$. Observe also that this condition is satisfied whenever $\int f^b < \infty$ for some $b > 1$. □

Remark 3. Theorems 4 and 5 remain valid with different constants for cones $C_\theta(x,\eta)$, $\eta \in (0,\pi]$. □

4.4. Divide-and-conquer algorithms for unoriented maxima. At least five strategically different algorithms can be used for finding the outer layer $\mathcal{M}_n$ of $X_1, \ldots, X_n$ in the plane. Let $L_n = |\mathcal{M}_n|$ denote the number of points on the outer layer.

1. **The naive algorithm.** For each X_i, determine in linear time whether a point is a maximal vector. The time taken by this algorithm is $\Theta(n^2)$, while the space is $\Theta(n)$.
2. **One sort and one elimination pass.** Sort the data points according to their y-coordinates, and eliminate unwanted points in a second stage by passing through the sorted array and keeping partial extrema in the x-direction. This may be implemented in $O(n \log n)$ worst-case time.
3. **Divide-and-conquer** [BS78]. Start with n singleton outer layers, marry (merge) all outer layers pairwise, and repeat these pairwise marriages until one outer layer is left. Noting that outer layers of sizes k and m can be married in $O(k + m)$ time, and that about $\log_2 n$ rounds of merging are needed, it is easy to see that the time taken by this algorithm is $O(n \log n)$. However, since many points are thrown away at early stages, there is reasonable hope of obtaining linear expected time $\mathbf{E}T$. The following is known: $\mathbf{E}T = O(n)$ when the components of X_1 are independent [BS78, De83]. In the general case, $\mathbf{E}T = O(n)$ if and only if $\sum_n \mathbf{E}L_n/n^2 < \infty$ by a general theorem on the expected time analysis of divide-and-conquer algorithms [De83]. An important class of problems is that in which f is bounded, in which case we see that $\mathbf{E}L_n = O(\sqrt{n})$ and thus $\mathbf{E}T = O(n)$ [De85].
4. **Bucketing methods.** Partition $[0, 1]$ into a grid of size about $\sqrt{n} \times \sqrt{n}$, assign all points to grid locations, and mark in all columns (rows) the topmost (leftmost) and bottommost (rightmost) occupied grid cells, together with their inner neighbors. Finally, use the naive algorithm (1) to obtain the outer layer among the points in all the marked cells [De86]. This too yields linear expected time for bounded densities, but it uses a different computational model because truncation is assumed to be available at unit time cost. [Ma84] use another grid in which in each cell, the outer layer is found, and the overall outer layer is found in a second step.
5. **Output-sensitive algorithms based on lazy sorting.** In [KS85], algorithms are presented that take worst-case time bounded by $O(n \log L_n)$. The expected time therefore is bounded by a constant times $\mathbf{E}n \log L_n \leq n \log \mathbf{E}L_n$.

In this section, using the results of the previous sections, we offer a linear expected time divide-and-conquer algorithm for finding the set $\mathcal{S}_n$ of all RUMs that runs under conditions weaker than any condition mentioned above for linear expected time for outer layers. A similarly adapted divide-and-conquer algorithm for outer layers would yield linear expected time under the same general conditions.

PROCEDURE RESTRICTED UNORIENTED MAXIMA

INPUT: A set of n planar points $X_1, \ldots, X_n$.

OUTPUT: The set $\mathcal{S}_n$ of all RUMs of $X_1, \ldots, X_n$.

METHOD:

1. Put all data points X_i in singleton sets S_i.
2. Put all sets S_i in a queue Q.

3. WHILE $|Q| > 1$ DO
   - Dequeue sets S and T from Q.
   - Compute $V = \text{RUM}(S \cup T)$.
   - Enqueue Q with V.

End of Procedure

THEOREM 6. *If the divide-and-conquer algorithm is used on data that are i.i.d. and have a density of compact support such that* $\int f \log^a(1+f) < \infty$ *for some* $a > 1$, *and if the merging of two sets of* RUMs *is supported in linear time, then the overall expected time is* $O(n)$. *The running time is* $O(n \log n)$ *in the worst case.*

Proof. The expected time analysis of general divide-and-conquer algorithms given in [De83] shows that linear expected time is obtained if the data constitute an i.i.d. sequence, the MERGE step takes linear time in the size $|S| + |T|$, and

$$\sum_{n=1}^{\infty} \frac{\mathbf{E}|\mathcal{S}_n|}{n^2} < \infty \ .$$

By Remark 2,

$$\mathbf{E}|\mathcal{S}_n| = O\left(\frac{n}{\log^a n}\right)$$

when f has compact support and $\int f \log^a(1+f) < \infty$. Theorem 6 follows when $a > 1$. □

Remark 4. The condition mentioned in the proof above was rediscovered later in the context of randomized incremental algorithms by Clarkson and Shor [CS88, CS89]. For a slightly different approach with conditions deduced from recursions, see [BS78].

Remark 5. One can push things further and get linear expected time if f has compact support and if for some $a > 1$, $\int f \log(1+f) \log^a \log(1+f) < \infty$. □

Remark 6*: On merging sets of* RUMS. Performing the MERGE step in linear time requires keeping track of the sets of RUMs according to increasing x-coordinates. First, we merge the sorted sets S and T into a set W, sorted by x-coordinate. We then perform two more linear passes. In the first pass, we construct the convex hull in clockwise fashion from left to right as we visit points of W (in fact, this only gives the upper part of the convex hull; the lower part is not needed). This is done by Graham's incremental algorithm [Gr72]. As X_i is processed, we note the angle between the convex hull edge leading to X_i, and the y-axis, and call it θ_i. Repeat a similar pass in counterclockwise manner from right to left, storing the angles in ξ_i. A simple geometric argument shows that $X_i \in \text{RUM}(W)$ if and only if $\theta_i + \xi_i \le \pi/2$. The entire procedure takes linear time. □

Remark 7*: Lazy merging of rums.* If we find $\text{RUM}(W)$ in time $O(|W| \log |W|)$, results from [De83] guarantee overall linear expected time if

$$\sum_{n=1}^{\infty} \frac{\mathbf{E}|\mathcal{S}_n| \log |\mathcal{S}_n|}{n^2} < \infty \ .$$

Since $\log |\mathcal{S}_n| \le \log n$, it suffices to verify that

$$\sum_{n=1}^{\infty} \frac{\mathbf{E}|\mathcal{S}_n| \log n}{n^2} < \infty \ .$$

By Theorem 5, this is satisfied if for some $\alpha > 1$, $\int f^\alpha < \infty$. By Remark 2, it also suffices that $\int f \log^a(1+f) < \infty$ for some $a > 2$. □

5. Concluding remarks. We introduced unoriented Θ-maximal points and described an optimal $O(n \log n)$ algorithm for identifying them when $\Theta \geq \pi/2$. The case $\Theta < \pi/2$ is handled in the Appendix. We also showed that if the points are random and have a common density (satisfying mild regularity conditions), then we can compute the unoriented $\pi/2$-maxima in $O(n)$ expected time.

6. Appendix. For values of $\Theta < \pi/2$, the geometric properties of Lemmas 2 and 5 become useless. However, we are able to modify them slightly as shown below to obtain efficient algorithms for this case.

LEMMA 8. *If point p is a candidate for the edge $e \in E(S)$, then p lies in the part of the circle which has e as a chord, and p makes an angle Θ with e which has a nonempty intersection with the interior of $CH(S)$.*

LEMMA 9. *If point p is an unoriented Θ-maximum with respect to edge e_i, then the angle between the rays L_p and R_p must contain either R_{p,e_i} or one of $\pi/\Theta - 2$ directions which are separated from R_{p,e_i} by integer multiples of Θ.*

A point $p \in S - V(S)$ may be a candidate for at most $2\pi/\Theta$ edges of $CH(S)$. Therefore, Corollary 1 implies that the circles defined in Lemma 8 cannot have more than $14(2\pi/\Theta)h$ $(\in O(n/\Theta))$ intersections, which changes the running time of Procedure Candidates to $O((n/\Theta)\log n)$. In addition, the procedure of section 2.3 for computing unoriented Θ-maxima among candidates needs to be executed $(\pi/\Theta) - 1$ times for each convex hull edge. As a result, we can compute the set S_Θ, for $\Theta < \pi/2$, in $O((n/\Theta)\log n)$ running time. The algorithm is clearly optimal for fixed values of Θ. However, no matching lower bound is known when Θ is part of the input.

A SPECTRAL ALGORITHM FOR SERIATION AND THE CONSECUTIVE ONES PROBLEM*

JONATHAN E. ATKINS†, ERIK G. BOMAN‡, AND BRUCE HENDRICKSON§

Abstract. In applications ranging from DNA sequencing through archeological dating to sparse matrix reordering, a recurrent problem is the sequencing of elements in such a way that highly correlated pairs of elements are near each other. That is, given a correlation function f reflecting the desire for each pair of elements to be near each other, find all permutations π with the property that if $\pi(i) < \pi(j) < \pi(k)$ then $f(i,j) \geq f(i,k)$ and $f(j,k) \geq f(i,k)$. This *seriation problem* is a generalization of the well-studied consecutive ones problem. We present a spectral algorithm for this problem that has a number of interesting features. Whereas most previous applications of spectral techniques provide only bounds or heuristics, our result is an algorithm that correctly solves a nontrivial combinatorial problem. In addition, spectral methods are being successfully applied as heuristics to a variety of sequencing problems, and our result helps explain and justify these applications.

Key words. seriation, consecutive ones property, eigenvector, Fiedler vector, analysis of algorithms

1. Introduction.

Many applied computational problems involve ordering a set so that closely coupled elements are placed near each other. This is the underlying problem in such diverse applications as genomic sequencing, sparse matrix envelope reduction, and graph linear arrangement as well as less familiar settings such as archeological dating. In this paper we present a *spectral algorithm* for this class of problems. Unlike traditional combinatorial methods, our approach uses an eigenvector of a matrix to order the elements. Our main result is that this approach correctly solves an important ordering problem we call the *seriation problem* which includes the well-known consecutive ones problem (C1P) [5] as a special case.

More formally, we are given a set of n elements to sequence; that is, we wish to bijectively map the elements to the integers $1, \ldots, n$. We also have a symmetric, real valued *correlation function* (sometimes called a *similarity function*) that reflects the desire for elements i and j to be near each other in the sequence. We now wish to find all ways to sequence the elements so that the correlations are *consistent*; that is, if π is our permutation of elements and $\pi(i) < \pi(j) < \pi(k)$ then $f(i,j) \geq f(i,k)$ and $f(j,k) \geq f(i,k)$. Although there may be an exponential number of such orderings, they can all be described in a compact data structure known as a PQ-tree [5], which we review in the next section. Not all correlation functions allow for a consistent sequencing. If a consistent ordering is possible we will say the problem is *well posed*.

Determining an ordering from a correlation function is what we will call the *seriation problem*, reflecting its origins in archeology [29, 33].

C1P is a closely related ordering problem. A $(0,1)$-matrix C has the *consecutive ones property* if there exists a permutation matrix Π such that for each column in ΠC, all the ones form a consecutive sequence. If a matrix has the consecutive ones property, then the C1P is to find all such permutations. As shown by Kendall [19] and reviewed in section 6, C1P is a special case of the seriation problem.

Our algorithm orders elements using their value in an eigenvector of a *Laplacian matrix* which we formally define in section 2. Eigenvectors related to graphs have been studied since the 1950s (see, for example, the survey books by Cvetković et al. [8, 7]). Most of the early work involved eigenvectors of adjacency matrices. Laplacian eigenvectors were first studied by Fiedler [10, 11] and independently by Donath and Hoffman [9]. More recently, there have been a number of attempts to apply spectral graph theory to problems in combinatorial optimization. For example, spectral algorithms have been developed for graph coloring [3], graph partitioning [9, 28], and envelope reduction [4], and more examples can be found in the survey papers of Mohar [23, 24]. However, in most previous applications, these techniques have been used to provide bounds, heuristics, or in a few cases, approximation algorithms [2, 6, 14] for NP-hard problems. There are only a small number of previous results in which eigenvector techniques have been used to exactly solve combinatorial problems including finding the number of connected components of a graph [10], coloring k-partite graphs [3], and finding stable sets (independent sets) in perfect graphs [16]. This paper describes another such application.

Spectral methods are closely related to the more general method of *semidefinite programming*, which has been applied successfully to many combinatorial problems (e.g., MAX-CUT and MAX-2SAT [14] and graph coloring [18]). See Alizadeh [1] for a survey of semidefinite programming with applications to combinatorial optimization.

Our result is important for several reasons. First, it provides new insight into the well-studied C1P. Second, some important practical problems like envelope reduction for matrices and genomic reconstruction can be thought of as variations on seriation. For example, if biological experiments were error-free, the genomic reconstruction problem would be precisely C1P. Unfortunately, real experimental data always contain errors, and attempts to generalize the consecutive ones concept to data with errors seems to invariably lead to NP-complete problems [31, 15]. A spectral heuristic based upon our approach has recently been applied to such problems and found to be highly successful in practice [15]. Our result helps explain this empirical success by revealing that in the error-free case the technique will correctly solve the problem. This places the spectral method on a stronger theoretical footing as a cross between a heuristic and an exact algorithm. Similar comments apply to envelope reduction. Matrices with dense envelopes are closely related to matrices with the consecutive ones property. Recent work has shown spectral techniques to be better in practice than any existing combinatorial approaches at reducing envelopes [4]. Our result sheds some light on this success.

Another way to interpret our result is that we provide an algorithm for C1P that generalizes to become an attractive heuristic in the presence of errors. Designed as decision algorithms for the consecutive ones property, existing combinatorial approaches for C1P break down if there are errors and fail to provide useful approximate orderings. However, our goal here is not to analyze the approach as an approximation algorithm, but rather to prove that it correctly solves error-free problem instances.

This paper is organized in the following way. In the next section we introduce the mathematical notation and the results from matrix theory that we will need later. We also describe a spectral heuristic for ordering problems which motivates the remainder of the paper. The theorem that underpins our algorithm is proved in section 3, the proof of which requires the use of a classical theorem from matrix analysis. Several additional results in section 4 lead us to an algorithm and its analysis in section 5. We review the connection to C1P in section 6.

2. Mathematical background.

2.1. Notation and definitions. Matrix concepts are useful because the correlation function defined above can be considered as a real, symmetric matrix. A permutation of the elements corresponds to a symmetric permutation of this matrix, a permutation of the matrix elements formed by permuting the rows and the columns in the same fashion. The question of whether or not the ordering problem is well posed can also be asked as a property of this matrix. Specifically, suppose the matrix has been permuted to reflect a consistent solution to the ordering problem. The off-diagonal matrix entries must now be nonincreasing as we move away from the diagonal. More formally, we will say a matrix A is an *R-matrix*[1] if and only if A is symmetric and

$$\begin{aligned} a_{i,j} &\leq a_{i,k} \qquad \text{for } j < k < i, \\ a_{i,j} &\geq a_{i,k} \qquad \text{for } i < j < k. \end{aligned}$$

The diagonal entries of an R-matrix are unspecified. If A can be symmetrically permuted to become an R-matrix, then we say that A is *pre-R*. Note that pre-R matrices correspond precisely to well-posed ordering problems. Also, the R-matrix property is preserved if we add a constant to all off-diagonal entries, so we can assume without loss of generality that all off-diagonal values are nonnegative.

When π is a permutation of the natural numbers $\{1, \ldots, n\}$ and x is a column vector, i.e. $x = [x_1, \ldots, x_n]^T$, we will denote by x^π the permutation of x by π, i.e., $x_i^\pi = x_{\pi(i)}$. Similarly, A^π is the symmetric permutation of A by π, i.e., $a_{i,j}^\pi = a_{\pi(i),\pi(j)}$. We denote by e the vector whose entries are all 1, by e_i the vector consisting of zeros except for a 1 in position i, and by I the identity matrix. A symmetric matrix A is *reducible* if there exists a permutation π such that

$$A^\pi = \begin{bmatrix} B & 0 \\ 0 & C \end{bmatrix},$$

where B and C are nonempty square matrices. If no such permutation exists then A is *irreducible*. If B and C are themselves irreducible, then we refer to them as the *irreducible blocks* of A.

We say that λ is an *eigenvalue* of A if $Ax = \lambda x$ for some vector $x \neq 0$. A corresponding vector x is an *eigenvector*. An $n \times n$ real, symmetric matrix has n eigenvectors that can be constructed to be pairwise orthogonal, and its eigenvalues are all real. We will assume that the eigenvalues are sorted by increasing value, and refer to them as λ_i, $i = 1, \ldots, n$. The *(algebraic) multiplicity* of an eigenvalue λ is defined as the number of times λ occurs as a root in the characteristic polynomial

[1] This class of matrices is named after W. S. Robinson who first defined this property in his work on seriation methods in archaeology [29].

$p(z) = \det(A - zI)$. A value that occurs only once is called *simple*; the eigenvector of a simple eigenvalue is unique (up to normalization). We write $A \geq 0$ and say A is nonnegative if all its elements $a_{i,j}$ are nonnegative. A real vector x is *monotone* if $x_i \leq x_{i+1}$ for all $1 \leq i < n$ or if $x_i \geq x_{i+1}$ for all $1 \leq i < n$.

We define the *Laplacian* of a symmetric matrix A to be $L_A = D_A - A$, where D_A is a diagonal matrix with $d_{i,i} = \sum_{j=1}^{n} a_{i,j}$. The minimum eigenvalue with an eigenvector orthogonal to e (the vector of all ones) is called the *Fiedler value*, and a corresponding eigenvector is called a *Fiedler vector*.[2] Alternatively, the Fiedler value is given by

$$\min_{x^T e=0, x^T x=1} x^T L_A x,$$

and a Fiedler vector is any vector x that achieves this minimum while satisfying these constraints. When $A \geq 0$ and irreducible, it is not hard to show that the Fiedler value is the smallest nonzero eigenvalue and a Fiedler vector is any corresponding eigenvector. We will be notationally cavalier and refer to the Fiedler value and vector of A when we really mean those of L_A.

2.2. PQ-trees. A *PQ-tree* is a data structure introduced by Booth and Lueker to efficiently encode a set of related permutations [5]. A PQ-tree over a set $U = \{u_1, u_2, \ldots, u_n\}$ is a rooted, ordered tree whose leaves are elements of U and whose internal nodes are distinguished as either P-nodes or Q-nodes. A PQ-tree is *proper* when the following three conditions hold.

1. Every element $u_i \in U$ appears precisely once as a leaf.
2. Every P-node has at least two children.
3. Every Q-node has at least three children.

Two PQ-trees are said to be equivalent if one can be transformed into the other by applying a sequence of the following two equivalence transformations.

1. Arbitrarily permute the children of a P-node.
2. Reverse the children of a Q-node.

Conveniently, the equivalence class represented by a PQ-tree corresponds precisely to the set of permutations consistent with an instance of a seriation problem. In section 5 we describe an algorithm which uses Laplacian eigenvectors to construct a PQ-tree for an instance of the seriation problem.

2.3. Motivation for spectral methods. With the above definitions we can describe a simple heuristic for the seriation problem that will motivate the remainder of the paper. This heuristic is at the heart of the more complex algorithms we will devise, and underlies many previous applications of spectral algorithms [17]. We begin by constructing a simple penalty function g whose value will be small when closely correlated elements are close to each other. We define $g(\pi) = \sum_{(i,j)} f(i,j)(\pi_i - \pi_j)^2$. Unfortunately, minimizing g is NP-hard due to the discrete nature of the permutation [13]. Instead we approximate it by a function h of continuous variables x_i that we can minimize and that maintains much of the structure of g. We define $h(x) = \sum_{(i,j)} f(i,j)(x_i - x_j)^2$. Note that h does not have a unique minimizer, since its value does not change if we add a constant to each x component. To avoid this

[2] This is in recognition of the work of Miroslav Fiedler [10, 11].

ambiguity, we need to add a constraint like $\sum_i x_i = 0$. We still have a trivial solution when all the x_i's are zero, so we need a second constraint like $\sum_i x_i^2 = 1$. The resulting minimization problem is now well defined.

$$\text{Minimize } h(x) = \sum_{(i,j)} f(i,j)(x_i - x_j)^2 \tag{1}$$
$$\text{subject to } \sum_i x_i = 0, \text{ and } \sum_i x_i^2 = 1.$$

The solution to this continuous problem can be used as a heuristic for sequencing. Merely construct the solution vector x, sort the elements x_i, and sequence based upon their sorted order. One reason this heuristic is attractive is that the minimization problem has an elegant solution. We can rewrite $h(x)$ as $x^T L_F x$ where $F = \{f_{ij}\}$ is the correlation matrix. The constraints require that x be a unit vector orthogonal to e, and since L_A is symmetric, all other eigenvectors satisfy the constraints. Consequently, a solution to the constrained minimization problem is just a Fiedler vector.

Even if the problem is not well posed, sorting the entries of the Fiedler vector generates an ordering that tries to keep highly correlated elements near each other. As mentioned above, this technique is being used for a variety of sequencing problems [4, 15, 17]. The algorithm we describe in the remainder of the paper is based upon this idea. However, when we encounter ties in entries of the Fiedler vector, we need to recurse on the subproblem encompassing the tied values. In this way, we are able to find all permutations which make a pre-R-matrix into an R-matrix.

3. The key theorem. Our main result is that a modification of the simple heuristic presented in section 2.3 is actually an algorithm for well-posed instances of the seriation problem. Completely proving this will require us to deal with the special cases of multiple Fiedler vectors and ties within the Fiedler vector. The cornerstone of our analysis is a classical result in matrix theory due to Perron and Frobenius [27]. The particular formulation below can be found on p. 46 of [30].

THEOREM 3.1 (Perron–Frobenius). *Let M be a real, nonnegative matrix. If we define $\rho(M) = \max_i |\lambda_i(M)|$, then*

1. *$\rho(M)$ is an eigenvalue of M, and*
2. *there is a vector $x \geq 0$ such that $Mx = \rho(M)x$.*

We are now ready to state and prove our main theorem.

THEOREM 3.2. *If A is an R-matrix then it has a monotone Fiedler vector.*

Proof. Our proof uses the Perron–Frobenius Theorem 3.1. The nonnegative vector in that theorem will consist of differences between neighboring entries in the Fiedler vector of the Laplacian of A.

First define the matrix $S \in \mathbb{R}^{(n-1)\times n}$ as

$$S = \begin{bmatrix} -1 & 1 & 0 & \cdots & 0 \\ 0 & -1 & 1 & \ddots & \vdots \\ \vdots & \ddots & \ddots & \ddots & 0 \\ 0 & \cdots & 0 & -1 & 1 \end{bmatrix}.$$

Note that for any vector x, $Sx = (x_2 - x_1, \ldots, x_n - x_{n-1})^T$. Define $T \in \mathbb{R}^{n\times(n-1)}$ by

$$T = \begin{bmatrix} 0 & 0 & \cdots & 0 \\ 1 & 0 & & 0 \\ 1 & 1 & \ddots & \vdots \\ \vdots & \vdots & \ddots & 0 \\ 1 & 1 & \cdots & 1 \end{bmatrix}.$$

It is easy to verify that $ST = I_{n-1}$, and that $TS = I_n - ee_1^T$. We define $M_A = SL_AT = \{m_{i,j}\}$ and let $L_A = \{l_{i,j}\}$. We now show that Sx is an eigenvector of M_A if and only if x is an eigenvector of L_A and $x \neq \alpha e$.

$$\begin{aligned} L_Ax = \lambda x, \;\; x \neq \alpha e \iff \\ SL_Ax = \lambda Sx, \; x \neq \alpha e \iff \\ SL_A(I - ee_1^T)x = \lambda Sx, \; x \neq \alpha e \iff \\ SL_ATSx = \lambda Sx, \; x \neq \alpha e \iff \\ M_Ay = \lambda y, \text{ where } y = Sx \neq 0. \end{aligned}$$

The transformation from the second to the third lines follows from $L_Ae = 0$. Equivalence holds between all the above equations, so λ is an eigenvalue for both L_A and M_A for eigenvectors of L_A other than e. Hence the eigenvalues of M_A are the same as the eigenvalues of L_A with the zero eigenvalue removed, and the eigenvectors of M_A are differences between neighboring entries of the corresponding eigenvectors of L_A.

It is easily seen that $(SL_A)_{i,k} = -l_{i,k} + l_{i+1,k}$ for all i, k, so

$$m_{i,j} = \sum_{k=1}^{n} (SL_A)_{i,k} T_{k,j} = \sum_{k=j+1}^{n} (-l_{i,k} + l_{i+1,k}) = \sum_{k=j+1}^{n} (a_{i,k} - a_{i+1,k}).$$

Since, by assumption, A is an R-matrix, $a_{i,k} \leq a_{i+1,k}$ for $i < k+1$, and therefore $m_{i,j} \leq 0$ for $i < j$. For $i > j$ we can use the fact that $\sum_{k=1}^{n} l_{i,k} = 0$ to obtain

$$m_{i,j} = \sum_{k=j+1}^{n} (-l_{i,k} + l_{i+1,k}) = \sum_{k=1}^{j} (l_{i,k} - l_{i+1,k}) = \sum_{k=1}^{j} (-a_{i,k} + a_{i+1,k}).$$

Again, from the R-matrix property we conclude that $m_{ij} \leq 0$ for $i > j$. Consequently, all the off-diagonal elements in M_A are nonpositive.

Now let β be a value greater than $\max_i\{\lambda_i, m_{ii}\}$, where λ_i are the eigenvalues of M_A. Then $\tilde{M}_A = \beta I - M_A$ is nonnegative with eigenvalues $\tilde{\lambda}_i = \beta - \lambda_i$. Also, $\tilde{M}_A$ and M_A share the same set of eigenvectors. By Theorem 3.1, there exists a nonnegative eigenvector y of $\tilde{M}_A$ corresponding to the largest eigenvalue of $\tilde{M}_A$. But y is also an eigenvector of M_A corresponding to M_A's smallest eigenvalue. And this is just Sx, where x is a Fiedler vector of L_A. Since $y = Sx$ is nonnegative, the corresponding Fiedler vector of L_A is nondecreasing and the theorem follows. (Note that since the sign of an eigenvector is unspecified, the Fiedler vector could also be nonincreasing.) □

THEOREM 3.3. *Let A be a pre-R-matrix with a simple Fiedler value and a Fiedler vector with no repeated values. Let π_1 (respectively, π_2) be the permutation induced by sorting the values in the Fiedler vector in increasing (decreasing) order. Then A^{π_1} and A^{π_2} are R-matrices, and no other permutations of A produce R-matrices.*

Proof. First note that since the Fiedler value is simple, the Fiedler vector is unique up to a multiplicative constant. Next observe that if x is the Fiedler vector of A, then x^π is the Fiedler vector of A^π. So applying a permutation to A merely changes the order of the entries in the Fiedler vector. Now let π_* be a permutation such that A^{π_*} is an R-matrix. By Theorem 3.2, x^{π_*} is monotone since x is the only Fiedler vector. Since x has no repeated values, π_* must be either π_1 or π_2. □

Theorem 3.3 provides the essence of our algorithm for the seriation problem, but it is too restrictive, as the Fiedler value must be simple and contain no repeated values. We will show how to remove these limitations in the next section.

4. Removing the restrictions. Several observations about the seriation problem will simplify our analysis. First note that if we add a constant to all the correlation values the set of solutions is unchanged. Consequently, we can assume without loss of generality that the smallest value of the correlation function is zero. Note that subtracting the smallest value from all correlation values does not change whether or not the matrix is pre-R. In our algebraic formulation this translates into the following.

LEMMA 4.1. *Let A be a symmetric matrix and let $\bar{A} = A - \alpha ee^T$ for some real α. A vector x is a Fiedler vector of A if and only if x is a Fiedler vector of $\bar{A}$. So without loss of generality we can assume that the smallest off-diagonal entry of A is zero.*

Proof. By the definition of a Laplacian it follows that $L_{\bar{A}} = L_A + \alpha ee^T - \alpha nI$, where n is the dimension of A. Then $L_{\bar{A}}e = 0$, but for any other eigenvector x of L_A, $L_{\bar{A}}x = L_A x + 0 - \alpha nx$. That is, the eigenvalues are simply shifted down by αn while the eigenvectors are preserved. □

This will justify the first step of our algorithm, which subtracts the value of the smallest correlation from every correlation. Accordingly, we now make the assumption that our pre-R-matrix has smallest off-diagonal entry of zero. Next observe that if A is reducible, then the seriation problem can be decoupled. The irreducible blocks of the matrix correspond to connected components in the graph of the nonzero values of the correlation function. We can solve the subproblems induced by each of these connected components and link the pieces together in an arbitrary order. More formally, we have the following lemma.

LEMMA 4.2. *Let A_i, $i = 1, \ldots, k$, be the irreducible blocks of a pre-R-matrix A, and let π_i be a permutation of block A_i such that the submatrix $A_i^{\pi_i}$ is an R-matrix. Then any permutation formed by concatenating the π_i's will make A become an R-matrix. In terms of a PQ-tree, the π_i permutations are children of a single P-node.*

Proof. By Lemma 4.1, we can assume all entries in the irreducible blocks are nonnegative. Consequently, the correlation between elements within a block will always be at least as strong as the correlation between elements in different blocks. Also, by the definition of irreducibility, each element within a block must have some positive correlation with another element in that block. Hence, any ordering that makes A_i an R-matrix must not interleave elements between different irreducible blocks. As long as the blocks themselves are ordered to be R-matrices, any ordering of blocks will make A an R-matrix since correlations across blocks are all identical. □

With these preliminaries, we will now assume that the smallest off-diagonal value is zero and that the matrix is irreducible. As the following three lemmas and theorem show, this is sufficient to ensure that the Fiedler vector is unique up to a multiplicative constant.

LEMMA 4.3. *Let A be an $n \times n$ R-matrix with a monotone Fiedler vector x. If $\mathcal{J} = [r, s]$ is a maximal interval such that $x_r = x_s$, then for any $k \notin \mathcal{J}$, $a_{r,k} =$*

$a_{r+1,k} = \cdots = a_{s,k}$.

Proof. We can without loss of generality assume x is nondecreasing since $-x$ is also a Fiedler vector. We will show that $a_{r,k} = a_{s,k}$ for all $k \notin \mathcal{J}$, and since A is an R-matrix then all elements between $a_{r,k}$ and $a_{s,k}$ must also be equal. Consider rows r and s in the equation $L_A x = \lambda x$:

$$\sum_{k=1}^{n} (l_{s,k} - l_{r,k}) x_k = \lambda (x_s - x_r) = 0.$$

Since L_A is a Laplacian, we know that $\sum_{k=1}^{n} l_{i,k} = 0$ for all i. We get

$$\begin{aligned} 0 &= \sum_{k=1}^{n} (l_{sk} - l_{rk})(x_r - x_k) \\ &= \sum_{k=1}^{r-1} \underbrace{(l_{s,k} - l_{r,k})}_{\geq 0} \underbrace{(x_r - x_k)}_{>0} + \sum_{k=s+1}^{n} \underbrace{(l_{s,k} - l_{r,k})}_{\leq 0} \underbrace{(x_r - x_k)}_{<0} \end{aligned}$$

where we have used the fact that x is nondecreasing. Because all terms in the sum are nonnegative, all terms must be exactly zero. By assumption, $x_k \neq x_r$ for $k \notin \mathcal{J}$ and consequently $l_{r,k} = l_{s,k}$ for $k \notin \mathcal{J}$ and the result follows. ∎

The following lemma is essentially a converse of this. Its proof requires detailed algebra, but it is not fundamental to what follows. Consequently, the proof is relegated to the end of this section.

LEMMA 4.4. *Let A be an irreducible $n \times n$ R-matrix with $a_{n,1} = 0$. If $\mathcal{J} = [r, s] \neq [1, n]$ is an interval such that $a_{r,k} = a_{s,k}$ for all $k \notin \mathcal{J}$, then $x_r = x_{r+1} = \cdots = x_s$ for any Fiedler vector x.*

LEMMA 4.5. *Let A be an irreducible R-matrix with $a_{n,1} = 0$, and x, a monotone Fiedler vector of A. If $\mathcal{J} = [r, s]$ is an interval such that $x_r = x_{r+1} = \cdots = x_s$, then for any Fiedler vector y, $y_r = y_{r+1} = \cdots = y_s$.*

Proof. First apply Lemma 4.3 to conclude that for any $k \notin \mathcal{J}$, $a_{r,k} = a_{r+1,k} = \cdots = a_{s,k}$. Since $x^T e = 0$, it follows that $\mathcal{J} \neq [1, n]$. Now use this in conjunction with Lemma 4.4 to obtain the result. ∎

THEOREM 4.6. *If A is an irreducible R-matrix with $a_{n,1} = 0$, then the Fiedler value λ_2 is a simple eigenvalue.*

Proof. We will assume that λ_2 is a repeated eigenvalue and produce a contradiction. Let x and y be two linearly independent Fiedler vectors with x nondecreasing. Define $z(\theta) = \cos(\theta)x + \sin(\theta)y$, with $0 \leq \theta \leq \pi$. Let θ^* be the smallest value of θ that makes $z_k = z_{k+1}$ for some k where $x_k \neq x_{k+1}$. Such a θ^* must exist since x and y are linearly independent.

By Lemma 4.5 the indices of any repeated values in x are indices of repeated values in y and $z(\theta)$. Coupled with the monotonicity of x, this implies that $z(\theta^*)$ is monotone. By Lemma 4.5 the indices of any repeated values in $z(\theta^*)$ must be repeated in x, which gives the desired contradiction. ∎

All that remains is to handle the situation where the Fiedler vector has repeated values. As the following theorem shows, repeated values decouple the problem into pieces that can be solved recursively.

THEOREM 4.7. *Let A be a pre-R-matrix with a simple Fiedler value and Fiedler vector x. Suppose there is some repeated value β in x and define $\mathcal{I}$, $\mathcal{J}$, and $\mathcal{K}$ to be the indices for which*

1. $x_i < \beta$ *for all* $i \in \mathcal{I}$,
2. $x_i = \beta$ *for all* $i \in \mathcal{J}$,
3. $x_i > \beta$ *for all* $i \in \mathcal{K}$.

Then π *is an R-matrix ordering for* A *if and only if* π *or its reversal can be expressed as* (π_i, π_j, π_k), *where* π_j *is an R-matrix ordering for the submatrix* $A(\mathcal{J}, \mathcal{J})$ *of* A *induced by* $\mathcal{J}$, *and* π_i *and* π_k *are the restrictions of some R-matrix ordering for* A *to* $\mathcal{I}$ *and* $\mathcal{K}$, *respectively.*

Proof. From Theorem 3.2 we know that for any R-matrix ordering A^π, x^π is monotone, so elements in $\mathcal{I}$ must appear before (after) elements from $\mathcal{J}$ and elements from $\mathcal{K}$ must appear after (before) elements from $\mathcal{J}$. By Lemma 4.3, we have $a_{ik} = a_{jk}$ for all $i, j \in \mathcal{J}$ and $k \notin \mathcal{J}$. Hence the orderings of elements inside $\mathcal{J}$ must be indifferent to the ordering outside of $\mathcal{J}$ and vice versa. Consequently, the R-matrix ordering of elements in $\mathcal{J}$ depends only on $A(\mathcal{J}, \mathcal{J})$. ∎

Algorithmically, this theorem means that we can break ties in the Fiedler vector by recursing on the submatrix $A(\mathcal{J}, \mathcal{J})$ where $\mathcal{J}$ corresponds to the set of repeated values. The distinct values in the Fiedler vector of A constrain R-matrix orderings, but repeated values need to be handled recursively. In the language of PQ-trees, the distinct values are combined via a Q-node, and the components (subtrees) of the Q-node must then be expanded recursively.

Proof of Lemma 4.4. First we recall that the Fiedler value is the value obtained by

$$\min_{x^T e = 0, x^T x = 1} x^T L_A x = \min_{x^T e = 0, x^T x = 1} \sum_{i>j} a_{i,j}(x_i - x_j)^2, \tag{2}$$

and a Fiedler vector is a vector that achieves this minimum. We note that if we replace A by a matrix that is at least as large on an elementwise comparison, then $x^T L_A x$ cannot decrease for any vector x.

We consider $A(\mathcal{J}, \mathcal{J})$, the diagonal block of A indexed by $\mathcal{J}$. By the definition of an R-matrix, all values in $A(\mathcal{J}, \mathcal{J})$ must be at least as large as $a_{r,s}$. However, $a_{r,s}$ must be greater than zero. Otherwise, by the R-matrix property, $a_{i,j} = 0$ for all $i \geq r$ and $j < s$ and for all $j \geq r$ and $i < s$. But then, by the statement of the theorem, $a_{i,j} = 0$ for all $i \geq s$ and $j < s$ and all $j \geq r$ and $j < s$, which would make the matrix reducible.

The remainder of the proof will proceed in two stages. First we will force all the off-diagonal values in $A(\mathcal{J}, \mathcal{J})$ to be $a_{r,s}$ and show the result for this modified matrix. We will then extend the result to our original matrix.

Stage 1. We define the matrix B to be identical to A outside of $B(\mathcal{J}, \mathcal{J})$, but all off-diagonal values of B within $B(\mathcal{J}, \mathcal{J})$ are set to $\alpha = a_{r,s}$. It follows from the hypotheses that B is an R-matrix. We define $\delta = l_{i,i}$ for $i \in \mathcal{J}$ and note that, by the R-matrix property, $\delta \leq (n-1)\alpha$.

We now define $\tilde{L_B} = L_B - (\delta + \alpha)I$ and consider the eigenvalue equation $\tilde{L_B} x = \tilde{\lambda}_2 x$. This matrix has the same eigenvectors as L_B with eigenvalues shifted by $\delta + \alpha$. Since $\tilde{l}_{ii} = \delta - (\delta + \alpha) = \alpha$ for $i \in \mathcal{J}$, all rows of $\tilde{L_B}$ in $\mathcal{J}$ are identical. Consequently, either all elements of x in $\mathcal{J}$ are equal, or $\tilde{\lambda}_2 = 0$ (which is equivalent to $\lambda_2 = \delta + \alpha$). We will show that irreducibility and $a_{n1} = 0$ implies $\lambda_2 \neq \delta + \alpha$, which will complete the proof of Stage 1.

We assume $\lambda_2 = \delta + \alpha$ and look for a contradiction. We introduce a new matrix

$\hat{B}$ as follows:

$$\hat{b}_{i,j} = \begin{cases} b_{i,j} & \text{if } i < r \text{ and } j < r, \\ b_{i,j} & \text{if } i > s \text{ and } j > s, \\ \alpha & \text{otherwise.} \end{cases}$$

Since B is an R-matrix, $\hat{B}$ is at least as large as B elementwise, so $\lambda_2(\hat{B}) \geq \lambda_2(B)$. We define the vector $\hat{y}$ by

$$\hat{y}_i = \begin{cases} -(n-s), & \text{if } i < r, \\ 0, & \text{if } r \leq i \leq s, \\ r-1, & \text{if } i > s, \end{cases}$$

and $\hat{x}$ to be the unit vector in the direction of $\hat{y}$. We note that $\hat{x}^T e = 0$, and that $\hat{x}^T L_{\hat{B}} \hat{x} = n\alpha$. We have the following chain of inequalities:

$$\lambda_2 = \min_{x^T e = 0, x^T x = 1} x^T L_B x \leq \hat{x}^T L_B \hat{x} < \hat{x}^T L_{\hat{B}} \hat{x} = n\alpha. \tag{3}$$

The last inequality is strict since $\hat{b}_{n,1} = \alpha$ while $b_{n,1} = 0$ and $(\hat{x}_n - \hat{x}_1)^2 > 0$.

If $\lambda_2 = \delta + \alpha$, then we can combine an inequality due to Fiedler [10],

$$\lambda_2 \leq \frac{n}{n-1} \min_i l_{ii},$$

with the observation that $\min_i l_{i,i} \leq \delta$ to obtain $\lambda_2 \leq \frac{n}{n-1}\delta \leq \delta + \alpha = \lambda_2$. This can only be true if equality holds throughout, implying that $\delta = (n-1)\alpha$ and $\lambda_2 = n\alpha$. But this contradicts (3), so $\lambda_2 \neq \delta + \alpha$ and the proof of Stage 1 is complete.

Stage 2. We will now show that A and B have the same Fiedler vectors. Since A is elementwise at least as large as B, for any vector z, $z^T L_A z \geq z^T L_B z$. From Stage 1 we know that any Fiedler vector of B satisfies $x_r = x_{r+1} = \cdots = x_s$. In this vector, $(x_i - x_j) = 0$ for $i, j \in \mathcal{J}$, so the contribution to the sum in (2) from $B(\mathcal{J}, \mathcal{J})$ is zero. But this contribution will also be zero when applied to $A(\mathcal{J}, \mathcal{J})$. Since A and B are identical outside of $A(\mathcal{J}, \mathcal{J})$ and $B(\mathcal{J}, \mathcal{J})$, we now have that a Fiedler vector of B gives an upper bound for the Fiedler value of A; that is, $\lambda_2(A) \leq \lambda_2(B)$. It follows that the Fiedler vectors of B are also Fiedler vectors of A and vice versa. □

5. A spectral algorithm for the seriation problem. We can now bring all the preceding results together to produce an algorithm for well-posed instances of the seriation problem. Specifically, given a well-posed correlation function we will generate all consistent orderings. Given a pre-R-matrix, our algorithm constructs a PQ-tree for the set of permutations that produce an R-matrix.

Our Spectral-Sort algorithm is presented in Fig. 1. It begins by translating all the correlations so that the smallest is 0. It then separates the irreducible blocks (if there are more than one) into the children of a P-node and recurses. If there is only one such block, it sorts the elements into the children of a Q-node based on their values in a Fielder vector. If there are ties in the entries of the Fiedler vector, the algorithm is invoked recursively.

We now prove that the algorithm is correct. Step (1) is justified by Lemma 4.1, and requires time proportional to the number of nonzeros in the matrix. The identification of irreducible blocks in step (2) can be performed with a breadth-first or depth-first search algorithm, also requiring time proportional to the number of nonzeros. Combining the permutations of the resulting blocks with a P-node is correct by Lemma 4.2.

```
     Input:    A, an n × n pre-R-matrix
               U, a set of indices for the rows/columns of A
     Output:   T, a PQ-tree that encodes the set of all permutations π
               such that A^π is an R-matrix
     begin
(1)      α := min_{i≠j} a_{i,j}
(1)      A := A − αee^T
(2)      {A_1, ..., A_k} := the irreducible blocks of A
(2)      {U_1, ..., U_k} := the corresponding index sets
(2)      if k > 1
(2)          for j := 1 : k
(2)              T_j := Spectral-Sort(A_j, U_j)
(2)          end
(2)          T := P-node(T_1, T_2, ..., T_k)
         else
(3)          if (n = 1)
(3)              T := u_1
(3)          else if (n = 2)
(3)              T := P-node(u_1, u_2)
             else
(4)              x := Fiedler vector for L_A
(4)              Sort x
(5)              t := number of distinct values in x
(5)              for j := 1 : t
(5)                  V_j := indices of elements in x with jth value
(5)                  T_j := Spectral-Sort(A(V_j, V_j), V_j)
(5)              end
                 T := Q-node(T_1, ..., T_T)
             end
         end
     end
```

FIG. 1. *Algorithm* Spectral-Sort.

Step (3) handles the boundary conditions of the recursion, while in step (4) the Fiedler vector is computed and sorted. If there are no repeated elements in the Fiedler vector then the Q-node for the permutation is correct by Theorem 3.3. Steps (3) and (4) are the dominant computational steps and we will discuss their run time below. The recursion in step (5) is justified by Theorem 4.7.

Note that this algorithm produces a tree whether A is pre-R or not. To determine whether A is pre-R, simply apply one of the generated permutations. If the result is an R-matrix, then all permutations in the PQ-tree will solve the seriation problem; otherwise the problem is not well posed.

The most expensive steps in algorithm Spectral-Sort are the generation and sorting of the eigenvector. Since the algorithm can invoke itself recursively, these operations can occur on problems of size n, $n-1$, ...,1. So if the time for an eigencalculation on a matrix of size n is $T(n)$, the run time of algorithm Spectral-Sort is $O(n(T(n) + n \log n))$.

A formal analysis of the complexity of the eigenvector calculation can be simpli-

fied by noting that for a pre-R-matrix, all that matters is the dominance relationships between matrix entries. So, without loss of generality, we can assume that all entries are integers less than n^2. With this observation, it is possible to compute the components of the Fiedler vector to a sufficient precision such that the components can be correctly sorted in polynomial time. We now sketch one way this can be done, although we don't recommend this procedure in a real-world implementation.

Let λ denote a specific eigenvalue of L, in our case the Fiedler value. This can be computed in polynomial time as discussed in [25]. Then we can compute the corresponding eigenvector x symbolically by solving

$$(L - zI)x = 0 \bmod p(z),$$

where $p(z)$ is the characteristic polynomial of L. Gaussian elimination over a field is in P [21], so if $p(z)$ is irreducible we obtain a solution x where each component x_i is given by a polynomial in z with bounded integer coefficients. We note that letting z be any eigenvalue will force x to be a true eigenvector. If $p(z)$ is reducible, we try the above. If we fail to solve the equation, we will instead find a factorization of $p(z)$ and proceed by replacing $p(z)$ with the factor containing λ as a root. This yields a polynomial formula for each x_i, and we can identify equal elements by, e.g., the method in [22]. To decide the order of the remaining components, we evaluate the root λ to a sufficient precision and then compute the x_i's numerically and sort. Since λ is algebraic, the x_i's cannot be arbitrarily close [22] and polynomial precision is sufficient.

In practice, eigencalculations are a mainstay of the numerical analysis community. To calculate eigenvectors corresponding to the few highest or lowest eigenvalues (like the Fiedler vector), the method of choice is known as the Lanczos algorithm. This is an iterative algorithm in which the dominant cost in each iteration is a matrix-vector multiplication which requires $O(m)$ time. The algorithm generally converges in many fewer than n iterations, often only $O(\sqrt{n})$ [26]. However, a careful analysis reveals a dependence on the difference between the distinct eigenvalues.

6. C1P. Ordering an R-matrix is closely related to C1P. As mentioned in section 1, a $(0,1)$-matrix C has the *consecutive ones property* if there exists a permutation matrix Π such that for each column in ΠC, all the ones form a consecutive sequence.[3] A matrix that has this property without any rearrangement (i.e., $\Pi = I$) is in Petrie form[4] and is called a P-matrix. Analogous to R-matrices, we say a matrix with the consecutive ones property is *pre-P*. C1P can be restated as: given a pre-P-matrix C, find a permutation matrix Π such that ΠC is a P-matrix.

There is a close relationship between P-matrices and R-matrices. The following results are due to D.G. Kendall and are proved in [19] and [33].

LEMMA 6.1. *If C is a P-matrix, then $A = CC^T$ is an R-matrix.*

LEMMA 6.2. *If C is pre-P and $A = CC^T$ is an R-matrix, then C is a P-matrix.*

THEOREM 6.3. *Let C be a pre-P matrix, let $A = CC^T$, and let Π be a permutation matrix. Then ΠC is a P-matrix if and only if $\Pi A \Pi^T$ is an R-matrix.*

This theorem allows us to use algorithm Spectral-Sort to solve C1P. First construct $A = CC^T$, and then apply our algorithm to A (note that the elements of A are small nonnegative integers). Now apply one of the permutations generated by the

[3] Some authors define this property in terms of rows instead of columns.

[4] Sir William M. F. Petrie was an archeologist who studied mathematical methods for seriation in the 1890s.

algorithm to C. If the result is a P-matrix then all the permutations produce C1P orderings. If not, then C has no C1P orderings.

The run time for this technique is not competitive with the linear time algorithm for this problem due to Booth and Lueker [5]. However, unlike their approach, our Spectral-Sort algorithm does not break down in the presence of errors and can instead serve as a heuristic.

Several other combinatorial problems have been shown to be equivalent to C1P. Among these are recognizing interval graphs [5, 12] and finding dense envelope orderings of matrices [5].

One generalization of P-matrices is to matrices with unimodal columns (a unimodal sequence is a sequence that is nondecreasing until it reaches its maximum, then nonincreasing). These matrices are called unimodal matrices [32]. Kendall [20] showed that the results of Lemmas 6.1 and 6.2 and Theorem 6.3 are also valid for unimodal matrices if the regular matrix product is replaced by the matrix *circle product* defined by

$$(A \circ B)_{ij} = \sum_k \min(a_{ik}, b_{kj}).$$

Note that P-matrices are just a special case of unimodal matrices, and that the circle product is equivalent to the matrix product for $(0, 1)$-matrices. Kendall's result implies that our spectral algorithm will correctly identify and order unimodal matrices.

Acknowledgments. We are indebted to Robert Leland for innumerable discussions about spectral techniques and to Sorin Istrail for his insights into the consecutive ones problem and his constructive feedback on an earlier version of this paper. We are further indebted to David Greenberg for his experimental testing of our approach on simulated genomic data and to Nabil Kahale for showing us how to simplify the proof of Theorem 3.2. We also appreciate the highly constructive feedback provided by an anonymous referee.

NEW COLLAPSE CONSEQUENCES OF NP HAVING SMALL CIRCUITS*

JOHANNES KÖBLER† AND OSAMU WATANABE‡

Abstract. We show that if a self-reducible set has polynomial-size circuits, then it is low for the probabilistic class ZPP(NP). As a consequence we get a deeper collapse of the polynomial-time hierarchy PH to ZPP(NP) under the assumption that NP has polynomial-size circuits. This improves on the well-known result in Karp and Lipton [*Proceedings of the 12th ACM Symposium on Theory of Computing*, ACM Press, New York, 1980, pp. 302–309] stating a collapse of PH to its second level Σ_2^{P} under the same assumption. Furthermore, we derive new collapse consequences under the assumption that complexity classes like UP, FewP, and $\mathrm{C}_{=}\mathrm{P}$ have polynomial-size circuits.

Finally, we investigate the circuit-size complexity of several language classes. In particular, we show that for every fixed polynomial s, there is a set in ZPP(NP) which does not have $O(s(n))$-size circuits.

Key words. polynomial-size circuits, advice classes, lowness, randomized computation

1. Introduction.

The question of whether intractable sets can be efficiently decided by nonuniform models of computation has motivated much work in structural complexity theory. In research from the early 1980s to the present, a variety of results has been obtained showing that this is impossible under plausible assumptions (see, e.g., the survey [18]). A typical model for nonuniform computations are circuit families. In the notation of Karp and Lipton [22], sets decidable by polynomial-size circuits are precisely the sets in P/poly; i.e., they are decidable in polynomial time with the help of a polynomial length bounded advice function [32].

Karp and Lipton (together with Sipser) [22] proved that no NP-complete set has polynomial size circuits (in symbols $\mathrm{NP} \not\subseteq \mathrm{P/poly}$) unless the polynomial-time hierarchy collapses to its second level. The proof given in [22] exploits a certain kind of self-reducibility of the well-known NP-complete problem SAT. More generally, it is shown in [8, 7] that every (Turing) self-reducible set in P/poly is low for the second level Σ_2^{P} of the polynomial time hierarchy. Intuitively speaking, a set is low for a relativizable complexity class if it gives no additional power when used as an oracle for that class.

In this paper, we show that every self-reducible set in P/poly is even low for the probabilistic class ZPP(NP), meaning that $\mathrm{ZPP}(\mathrm{NP}(A)) = \mathrm{ZPP}(\mathrm{NP})$. Since for every oracle A, $\Sigma_2^{\mathrm{P}}(A) = \exists \cdot \mathrm{ZPP}(\mathrm{NP}(A))$, lowness for ZPP(NP) implies lowness for Σ_2^{P}. As a consequence of our lowness result we get a deeper collapse of the polynomial-time hierarchy to ZPP(NP) under the assumption that NP has polynomial-size circuits. At least in some relativized world, the new collapse level is quite close to optimal: there

is an oracle relative to which NP is contained in P/poly, but PH does not collapse to P(NP) [17, 39].

We also derive new collapse consequences from the assumption that complexity classes like UP, FewP, and $C_=P$ have polynomial-size circuits. Furthermore, our lowness result implies new *relativizable* collapses for the case that $\mathrm{Mod}_m P$, PSPACE, or EXP have polynomial-size circuits. As a final application, we derive new circuit-size lower bounds. In particular, it is shown (by relativizing proof techniques) that for every fixed polynomial s, there is a set in ZPP(NP) which does not have $O(s(n))$-size circuits. This improves on the result of Kannan [21] that for every polynomial s, the class $\Sigma_2^P \cap \Pi_2^P$ contains such a set. It further follows that in every relativized world, there exist sets in the class ZPEXP(NP) that do not have polynomial-size circuits. It should be noted that there is a nonrelativizing proof for a stronger result. As a corollary to the result in [4], which is proved by a nonrelativizing technique, it is provable that $\mathrm{MA}_{\mathrm{exp}} \cap \text{co-}\mathrm{MA}_{\mathrm{exp}}$ (a subclass of ZPEXP(NP)) contains non-P/poly sets [12, 36].

Some explanation of how our work builds on prior techniques is in order. The proof of our lowness result heavily uses the universal hashing technique [13, 34] and builds on ideas from [2, 14, 24]. For the design of a *zero error* probabilistic algorithm which, with the help of an NP oracle, simulates a given ZPP(NP(A)) computation (where A is a self-reducible set in P/poly) we further make use of the newly defined concept of half-collisions. More precisely, we show how to compute on input 0^n in expected polynomial time a hash family H that can be used to decide all instances of A of length up to n by a strong NP computation. The way H is used to decide (non)membership to A is by checking whether H leads to a half-collision on certain sets. Very recently, Bshouty, Cleve, Gavaldà, Kannan, and Tamon [11] building on a result from [19] have shown that the class of all circuits is exactly learnable in (randomized) expected polynomial time with equivalence queries and the aid of an NP oracle. This immediately implies that for every set A in P/poly an advice function can be computed in FZPP(NP(A)), i.e., by a probabilistic oracle transducer T in expected polynomial time under an oracle in NP(A). More precisely, since the circuit produced by the probabilistic learning algorithm of [11] depends on the outcome of the coin flips, T computes a *multivalued* advice function; i.e., on input 0^n, T accepts with probability at least 1/2, and on every accepting path, T outputs some circuit that correctly decides all instances of length n w.r.t. A. Using the technique in [11] we are able to show that every self-reducible set A in P/poly even has an advice function in FZPP(NP). Although this provides a different way to deduce the ZPP(NP) lowness of all self-reducible sets in P/poly, we prefer to give a self-contained proof using the "half-collision technique" that does not rely on the mentioned results in [11, 19].

The paper is organized as follows: section 2 introduces notation and defines the self-reducibility that we use. In section 3 we prove the ZPP(NP) lowness of all self-reducible sets in P/poly. In section 4 we state the collapse consequences, and the new circuit-size lower bounds are derived in section 5.

2. Preliminaries and notation. All languages are over the binary alphabet $\Sigma = \{0, 1\}$. As usual, we denote the lexicographic order on Σ^* by $\leq$. The *length* of a string $x \in \Sigma^*$ is denoted by $|x|$. $\Sigma^{\leq n}$ ($\Sigma^{<n}$) is the set of all strings of length at most n (resp., of length smaller than n). For a language A, $A^{=n} = A \cap \Sigma^n$ and $A^{\leq n} = A \cap \Sigma^{\leq n}$. The cardinality of a finite set A is denoted by $|A|$. The *characteristic function* of A is defined as $A(x) = 1$ if $x \in A$, and $A(x) = 0$ otherwise. For a class $\mathcal{C}$ of sets, co-$\mathcal{C}$ denotes the class $\{\Sigma^* - A \mid A \in \mathcal{C}\}$. To encode pairs (or tuples) of

strings we use a standard polynomial-time computable pairing function denoted by $\langle \cdot, \cdot \rangle$ whose inverses are also computable in polynomial time. Where intent is clear we write $f(x_1, \ldots, x_k)$ in place of $f(\langle x_1, \ldots, x_k \rangle)$. $\mathcal{N}$ denotes the set of nonnegative integers. Throughout the paper, the base of log is 2.

The textbooks [9, 10, 25, 31, 33] can be consulted for the standard notation used in the paper and for basic results in complexity theory. For definitions of probabilistic complexity classes like ZPP, see also [15].

An *NP machine* M is a polynomial-time nondeterministic Turing machine. We assume that each computation path of M on a given input x either accepts, rejects, or outputs "?". *M accepts* on input x, if M performs at least one accepting computation, otherwise *M rejects x*. *M strongly accepts (strongly rejects) x* [26] if

- there is at least one accepting (resp., rejecting) computation path and
- there are no rejecting (resp., accepting) computation paths.

If M strongly accepts or strongly rejects x, M is said to perform a *strong computation* on input x. An NP machine that on every input performs a strong computation is called a *strong NP machine*. It is well known that exactly the sets in NP $\cap$ co-NP are accepted by strong NP machines [26].

Next we define the kind of self-reducibility that we use in this paper.

DEFINITION 2.1. *Let $\succ$ be an irreflexive and transitive order relation on Σ^*. A sequence $x_0, x_1, \ldots, x_k$ of strings is called a $\succ$-chain (of length k) from x_0 to x_k if $x_0 \succ x_1 \succ \cdots \succ x_k$. Relation $\succ$ is called* length checkable *if there is a polynomial q such that*

1. *for all $x, y \in \Sigma^*$, $x \succ y$ implies $|y| \leq q(|x|)$,*
2. *the language $\{\langle x, y, k \rangle \mid$ there is a $\succ$-chain of length k from x to $y\}$ is in* NP.

DEFINITION 2.2. *A set A is* self-reducible *if there is a polynomial-time oracle machine M_{self} and a length checkable order relation $\succ$ such that $A = L(M_{self}, A)$ and on any input x, M_{self} queries the oracle only about strings $y \prec x$.*

It is straightforward to check that the polynomially related self-reducible sets introduced by Ko [23] as well as the length-decreasing and word-decreasing self-reducible sets of Balcázar [6] are self-reducible in our sense. Furthermore, it is well-known (see, for example, [9, 6, 29]) that complexity classes like NP, Σ_k^{P}, Π_k^{P}, PP, $\mathrm{C}_{=}\mathrm{P}$, $\mathrm{Mod}_m\mathrm{P}$, PSPACE, and EXP have many-one complete self-reducible sets.

Karp and Lipton [22] introduced the notion of advice functions in order to characterize nonuniform complexity classes. A function $h : \mathcal{N} \to \Sigma^*$ is called a *polynomial-length function* if for some polynomial p and for all $n \geq 0$, $|h(n)| = p(n)$. For a class $\mathcal{C}$ of sets, let $\mathcal{C}/\mathrm{poly}$ be the class of sets A such that there are a set $I \in \mathcal{C}$ and a polynomial-length function h such that for all n and for all $x \in \Sigma^{\leq n}$,

$$x \in A \;\Leftrightarrow\; \langle x, h(n) \rangle \in I.$$

Function h is called an *advice function* for A, whereas I is the corresponding *interpreter set*.

In this paper we will heavily make use of the "hashing technique" which has been very fruitful in complexity theory. Here we review some notations and facts about hash families. We also extend the notion of "collision" by introducing the concept of a "half-collision" which is central to our proof technique.

Sipser [34] used universal hashing, originally invented by Carter and Wegman [13], to decide (probabilistically) whether a finite set X is large or small. A linear hash function h from Σ^m to Σ^k is given by a Boolean (k, m)-matrix (a_{ij}) and maps

any string $x = x_1 \dots x_m$ to a string $y = y_1 \dots y_k$, where y_i is the inner product $a_i \cdot x = \sum_{j=1}^{m} a_{ij} x_j \pmod 2$ of the ith row a_i and x.

Let $x \in \Sigma^m$, $Y \subseteq \Sigma^m$, and let h be a linear hash function from Σ^m to Σ^k. Then we say that x *has a collision on* Y *w.r.t.* h if there exists a string $y \in Y$, different from x, such that $h(x) = h(y)$. More generally, if X is a subset of Σ^m and H is a family[1] $(h_1, \dots, h_l)$ of linear hash functions from Σ^m to Σ^k, then we say that X *has a collision on* Y *w.r.t.* H (*Collision*(X, Y, H) for short) if there is some $x \in X$ that has a collision on Y w.r.t. every h_i in H. That is,

$$\begin{aligned} \textit{Collision}(X,Y,H) \quad \Leftrightarrow \quad & \exists\, x \in X\, \exists\, y_1, \dots, y_l \in Y : x \notin \{y_1, \dots y_l\} \\ & \text{and for all } i = 1, \dots, l : h_i(x) = h_i(y_i). \end{aligned}$$

If X has a collision on itself w.r.t. H, we simply say that X *has a collision w.r.t.* H. Next we extend the notion of "collision" in the following way. For any X and $Y \subseteq \Sigma^m$, and any family $H = (h_1, \dots, h_l)$ of linear hash functions, we say that X *has a half-collision on* Y *w.r.t.* H (*Half-Collision*(X, Y, H) for short) if there is some $x \in X$ that has a collision on Y w.r.t. at least $\lceil l/2 \rceil$ many of the hash functions h_i in H. That is,

$$\begin{aligned} \textit{Half-Collision}(X,Y,H) \quad \Leftrightarrow \quad & \exists\, x \in X\, \exists\, y_1, \dots, y_l \in Y : x \notin \{y_1, \dots y_l\} \\ & \text{and } |\{i \mid 1 \le i \le l, h_i(x) = h_i(y_i)\}| \ge \lceil l/2 \rceil. \end{aligned}$$

An important relationship between collisions and half-collisions is the following one: if X has a collision w.r.t. H on $Y = Y_1 \cup Y_2$, then X must have a half-collision w.r.t. H either on Y_1 or on Y_2.

Note that the predicate *Collision*(X, Y, H) can be decided in NP provided that membership in X and Y can be tested in NP. More precisely, the language $\{\langle v, H\rangle \mid \textit{Collision}(X_v, Y_v, H)\}$ (as well as the set $\{\langle v, H\rangle \mid \textit{Half-Collision}(X_v, Y_v, H)\}$) belongs to NP if the sets X_v and Y_v are succinctly represented in such a way that the languages $\{\langle x, v\rangle \mid x \in X_v\}$ and $\{\langle y, v\rangle \mid y \in Y_v\}$ are in NP.

We denote the set of all families $H = (h_1, \dots, h_l)$ of l linear hash functions from Σ^m to Σ^k by $\mathcal{H}(l, m, k)$. The following theorem is proved by a pigeon-hole argument. It says that every sufficiently large set must have a collision w.r.t. any hash family.

THEOREM 2.3 (see [34]). *For any hash family* $H \in \mathcal{H}(l, m, k)$ *and any set* $X \subseteq \Sigma^m$ *of cardinality* $|X| > l \cdot 2^k$, X *must have a collision w.r.t.* H.

On the other hand, we get from the next theorem (called the coding lemma in [34]) an upper bound on the collision probability for sufficiently small sets.

THEOREM 2.4 (see [34]). *Let* $X \subseteq \Sigma^m$ *be a set of cardinality at most* 2^{k-1}. *If we choose a hash family* H *uniformly at random from* $\mathcal{H}(k, m, k)$, *then the probability that* X *has a collision w.r.t.* H *is at most* $1/2$.

We will also make use of the following extension of Theorem 2.4 which can be proved along the same lines.

THEOREM 2.5. *Let* $X \subseteq \Sigma^m$ *be a set of cardinality at most* 2^{k-s}. *If we choose a hash family* H *uniformly at random from* $\mathcal{H}(l, m, k)$, *then the probability that* X *has a collision w.r.t.* H *is at most* $2^{k-s(l+1)}$.

Gavaldà [14] extended Sipser's coding lemma (Theorem 2.4) to the case of a collection $\mathcal{C}$ of exponentially many sets. The following theorem has a similar flavor.

THEOREM 2.6. *Let* $\mathcal{C}$ *be a collection of at most* 2^n *subsets of* Σ^m, *each of which has cardinality at most* 2^{k-s}. *If we choose a hash family* H *uniformly at random from*

[1] More precisely, sequence.

$\mathcal{H}(l,m,k)$, then the probability that some $X \in \mathcal{C}$ has a collision w.r.t. H is at most $2^{n+k-s(l+1)}$.

Proof. By Theorem 2.5, we have that for every fixed $X \in \mathcal{C}$, the probability that it has a collision w.r.t. a randomly chosen hash family $H \in \mathcal{H}(l,m,k)$ is at most $2^{k-s(l+1)}$. Hence, the probability that there exists such a set $X \in \mathcal{C}$ is at most $2^{n+k-s(l+1)}$. □

In this paper we make use of a corresponding result for the case of half-collisions.

THEOREM 2.7. *Let $X \subseteq \Sigma^m$ and let $\mathcal{C}$ be a collection of at most 2^n subsets of Σ^m, each of which has cardinality at most 2^{k-s-2}. If we choose a hash family H uniformly at random from $\mathcal{H}(l,m,k)$, then the probability that X has a half-collision on some $Y \in \mathcal{C}$ w.r.t. H is at most $|X| \cdot 2^{n-sl/2}$.*

Proof. For every fixed $Y \in \mathcal{C}$ and every fixed $x \in X$, the probability that x has a collision on Y w.r.t. a randomly chosen h is at most 2^{-s-2}. Hence, the probability that x has a collision on Y w.r.t. at least half of the functions in a randomly chosen hash family $H \in \mathcal{H}(l,m,k)$ is at most

$$\sum_{i=\lceil l/2 \rceil}^{l} \binom{l}{i} (2^{-s-2})^i (1-2^{-s-2})^{l-i} \leq 2^{-(s+2)l/2} \sum_{i=\lceil l/2 \rceil}^{l} \binom{l}{i} \leq 2^{l-(s+2)l/2} = 2^{-sl/2}.$$

That is, the probability that x has a half-collision on Y w.r.t. a randomly chosen hash family H is bounded by $2^{-sl/2}$. Hence, the probability that there exists a $Y \in \mathcal{C}$ and an $x \in X$ such that x has a half-collision on Y w.r.t. H is at most $|X| \cdot 2^{n-sl/2}$. □

3. Lowness of self-reducible sets in P/poly. In this section, we show that every self-reducible set A in (NP ∩ co-NP)/poly is low for ZPP(NP). Let $I \in$ NP ∩ co-NP be an interpreter set and h be an advice function for A. We construct a probabilistic algorithm T and an NP oracle O having the following two properties:

(a) The expected running time of T is polynomially bounded.
(b) On every computation path on input 0^n, T with oracle O outputs some information that can be used to determine the membership to A of any x up to length n by some strong NP computation (in the sense of [26]).

Using these properties, we can prove the lowness of A for ZPP(NP) as follows: in order to simulate any NP(A) computation, we first precompute the above-mentioned information for A (up to some length) by T^O, and then by using this information, we can simulate the NP(A) computation by some NP(NP ∩ co-NP) computation. Note that the precomputation (performed by T^O) can be done in ZPP(NP), and since NP(NP ∩ co-NP) = NP, the remaining computation can be done in NP. Hence, NP(A) ⊆ ZPP(NP), which implies further that ZPP(NP(A)) ⊆ ZPP(ZPP(NP)) (= ZPP(NP) [41]).

We will now make the term "information" precise. For this, we need some additional notation. Let the self-reducibility of A be witnessed by a polynomial-time oracle machine M_{self}, a length checkable order relation $\succ$, and a polynomial q. We assume that $|h(q(n))| = p(n)$ for some fixed polynomial $p > 0$. In the following, we fix n and consider instances of length up to $q(n)$ as well as advice strings of length exactly $p(n)$.

- A *sample* is a sequence $\langle x_1, b_1 \rangle \# \cdots \# \langle x_k, b_k \rangle$ of pairs, where the x_i's are instances of length up to $q(n)$ and $b_i = A(x_i)$ for $i = 1, \ldots, k$.
- For any sample $S = \langle x_1, b_1 \rangle \# \cdots \# \langle x_k, b_k \rangle$, let *Consistent*($S$) be the set of all advice strings w that are consistent with S, i.e.,

$$\mathit{Consistent}(S) = \{ w \in \Sigma^{p(n)} \mid \forall i \, (1 \leq i \leq k) : I(x_i, w) = b_i \}.$$

The cardinality of *Consistent*(S) is denoted by $c(S)$.

- For any sample S and any instance x, let *Accept*(x, S) (resp., *Reject*(x, S)) be the set of all consistent advice strings that *accept* x (resp., *reject* x):

$$\mathit{Accept}(x, S) = \{w \in \mathit{Consistent}(S) \mid I(x, w) = 1\}$$

and

$$\mathit{Reject}(x, S) = \{w \in \mathit{Consistent}(S) \mid I(x, w) = 0\}.$$

- Let *Correct*(x, S) be the set $\{w \in \mathit{Consistent}(S) \mid I(x, w) = A(x)\}$ of consistent advice strings that decide x correctly, and let *Incorrect*(x, S) be the complementary set $\{w \in \mathit{Consistent}(S) \mid I(x, w) \neq A(x)\}$.

Note that the sets *Accept*(x, S) and *Reject*(x, S) (as well as *Correct*(x, S) and *Incorrect*(x, S)) form a partition of the set *Consistent*(S), and that

$$\begin{array}{lll} x \in A & \Rightarrow & \mathit{Correct}(x, S) = \mathit{Accept}(x, S) \text{ and } \mathit{Incorrect}(x, S) = \mathit{Reject}(x, S), \\ x \notin A & \Rightarrow & \mathit{Correct}(x, S) = \mathit{Reject}(x, S) \text{ and } \mathit{Incorrect}(x, S) = \mathit{Accept}(x, S). \end{array}$$

The above condition (b) can now be precisely stated as follows.

(b) On every computation path on input 0^n, T^O outputs a pair $\langle S, H\rangle$ consisting of a sample S and a linear hash family H such that for all x up to length n, *Consistent*(S) has a half-collision w.r.t. H on *Correct*(x, S) but not on *Incorrect*(x, S).

Once we have a pair $\langle S, H\rangle$ satisfying condition (b), we can determine whether an instance x of length up to n is in A by simply checking whether *Consistent*(x, S) has a half-collision w.r.t. H on *Accept*(x, S) or on *Reject*(x, S). Since condition (b) guarantees that the half-collision can always be found, this checking can be done by a strong NP computation. Let us now prove our main lemma.

LEMMA 3.1. *For any self-reducible set A in* $(\mathrm{NP} \cap \text{co-NP})/\mathrm{poly}$*, there exist a probabilistic transducer T and an oracle O in NP satisfying the above two conditions.*

Proof. We use the notation introduced so far. Recall that $q(n)$ is a length bound on the queries occurring in the self-reduction tree produced by M_{self} on any instance of length n and that $p(n)$ is the advice length for the set of all instances of length up to $q(n)$. Let l be the polynomial defined as $l(n) = 2(q(n)+p(n)+1)$. Further, we denote by $\Sigma^{\preceq n}$ the set $\{y \mid \exists x \in \Sigma^{\leq n}, y \preceq x\}$. Then it is clear that $\Sigma^{\leq n} \subseteq \Sigma^{\preceq n} \subseteq \Sigma^{\leq q(n)}$. A description of T is given below.

input 0^n
$S := \emptyset$
loop
  for $k = 1, \ldots, p(n)$, choose H_k randomly from $\mathcal{H}(l(n), p(n), k)$,
  $k_{max} := \max\{k \mid \mathit{Consistent}(S)$ has a collision w.r.t. $H_k\}$
  if there exists an $x \in \Sigma^{\preceq n}$ such that *Consistent*(S) has
    a half-collision on *Incorrect*(x, S) w.r.t. $H_{k_{max}}$
  then
    use oracle O to find such a string x and to determine $A(x)$
    $S := S\#\langle x, A(x)\rangle$
  else exit(**loop**) **end**
end loop
output $\langle S, H_{k_{max}}\rangle$

Starting with the empty sample, T enters the main loop. During each execution of the loop, T first randomly guesses a series of $p(n)$ many hash families $H_k \in \mathcal{H}(l(n), p(n), k), 1 \leq k \leq p(n)$. Then T computes the integer k_{max} as the maximum $k \in \{1, \ldots, p(n)\}$ such that *Consistent*(S) has a collision w.r.t. H_k. Notice that by a padding trick we can assume that $c(S)$ is always larger than $2l(n)$, implying that *Consistent*(S) must have a collision w.r.t. H_1. Since, in particular, *Consistent*(S) has a collision w.r.t. $H_{k_{max}}$, it follows that for every instance $x \in \Sigma^{\preceq n}$, *Consistent*(S) has a half-collision w.r.t. $H_{k_{max}}$ on either *Correct*(x, S) or *Incorrect*(x, S). If there exists a string $x \in \Sigma^{\preceq n}$ such that *Consistent*(S) has a half-collision on *Incorrect*(x, S) w.r.t. $H_{k_{max}}$, then this string is added to the sample S, and T continues executing the loop. (We will describe below how T uses the NP oracle O to find x in this case.) Otherwise, the pair $\langle S, H_{k_{max}} \rangle$ fulfills the properties stated in condition (b) and T halts.

We now show that the expected running time of T is polynomially bounded. Since the initial size of *Consistent*(S) is $2^{p(n)}$, and since *Consistent*(S) never becomes empty, it suffices to prove that for some polynomial r, T eliminates in each single execution of the main loop with probability at least $1/r(n)$ at least a $1/r(n)$-fraction of the circuits in *Consistent*(S). In fact, we will show that each single extension of S by a pair $\langle x, A(x) \rangle$ reduces the size of *Consistent*(S) with probability at least $1 - 2^{-l(n)}$ by a factor smaller than $1 - 1/2^7 l(n)$. Since T can only perform more than $2^7 l(n) p(n)$ loop iterations if during some iteration of the main loop T extends S by a pair $\langle x, A(x) \rangle$ which does not shrink the size of *Consistent*(S) by a factor smaller than $1 - 1/2^7 l(n)$, the probability for this event is bounded by $2^7 l(n) p(n) \cdot 2^{-l(n)} = o(1)$.

Let S be a sample and let k_{max} be the corresponding integer as determined by T during some specific execution of the loop. We first derive a lower bound for k_{max}. Let k_0 be the smallest integer $k \geq 1$ such that $c(S) \leq l(n) 2^{k+1}$. Since either $k_{max} = p(n)$ or *Consistent*(S) does not have a collision w.r.t. the hash family $H_{k_{max}+1} \in \mathcal{H}(l(n), p(n), k_{max} + 1)$, we have (using Theorem 2.3) that $c(S) \leq l(n) 2^{k_{max}+1}$. Hence, $k_{max} \geq k_0$.

Since T expands S only by strings $x \in \Sigma^{\preceq n}$ such that *Consistent*(S) has a half-collision on *Incorrect*(x, S) w.r.t. $H_{k_{max}}$, and since *Consistent*$(S \# \langle x, A(x) \rangle) =$ *Consistent*$(S) -$ *Incorrect*(x, S), the probability that the size of *Consistent*(S) does not decrease by a factor smaller than $1 - 1/2^7 l(n)$ is bounded by the probability that, w.r.t. $H_{k_{max}}$, *Consistent*(S) has a half-collision on some set *Incorrect*(x, S) of size at most $c(S)/2^7 l(n)$. Let

$$\mathcal{C} = \{\textit{Incorrect}(x, S) \mid x \in \Sigma^{\preceq n}, |\textit{Incorrect}(x, S)| \leq c(S)/2^7 l(n)\}.$$

Since $|\mathcal{C}| < 2^{q(n)+1}$ and since $c(S)/2^7 l(n) \leq 2^{k_0 - 6} = 2^{k_0 + k - (k+4) - 2}$, it follows from Theorem 2.7 that the probability of *Consistent*(S) having a half-collision on some $Y \in \mathcal{C}$ w.r.t. a uniformly at random chosen hash family $H \in \mathcal{H}(l(n), p(n), k_0 + k)$ is at most

$$\begin{aligned} c(S) \cdot 2^{q(n)+1-(k+4)l(n)} &\leq 2^{p(n)+q(n)+1-(k+4)l(n)/2} \\ &= 2^{-(k+3)l(n)/2}. \end{aligned}$$

Thus the probability that for some $k \geq 0$, *Consistent*(S) has a half-collision w.r.t. H_{k_0+k} on some set *Incorrect*(x, S) which is of size at most $c(S)/2^7 l(n)$ is bounded by $\sum_{k \geq 0} 2^{-(k+3)l(n)/2} \leq 2^{-l(n)}$.

We finally show how T determines an instance $x \in \Sigma^{\preceq n}$ (if it exists) such that *Consistent*(S) has a half-collision on *Incorrect*(x, S) w.r.t. $H_{k_{max}}$. Intuitively, we use

the self-reducibility of A to test the "correctness" w.r.t. A of the "program" $\langle S, H_{k_{max}}\rangle$, where we say that

- a pair $\langle S, H\rangle$ accepts an instance x if *Consistent*(S) has a half-collision on *Accept*(x, S) w.r.t. H, and
- $\langle S, H\rangle$ rejects x if *Consistent*(S) has a half-collision on *Reject*(x, S) w.r.t. H.

Notice that an (incorrect) program might accept and at the same time reject an instance. The main idea to find out whether $\langle S, H_{k_{max}}\rangle$ is incorrect on some instance $x \in \Sigma^{\preceq n}$ (meaning that w.r.t. $H_{k_{max}}$ *Consistent*(S) has a half-collision on *Incorrect*(x, S)) is to test whether the program $\langle S, H_{k_{max}}\rangle$ is in accordance with the output of M_{self} when the oracle queries of M_{self} are answered according to the program $\langle S, H_{k_{max}}\rangle$. To be more precise, consider the NP set

$$\begin{aligned} B \;=\; \{\langle z, S, H\rangle \mid & \text{there is a computation path } \pi \text{ of } M_{self} \text{ on input } z \text{ fulfilling} \\ & \text{the following properties:} \\ & \text{- if a query } q \text{ is answered "yes," then } \langle S, H\rangle \text{ accepts } q, \\ & \text{- if a query } q \text{ is answered "no," then } \langle S, H\rangle \text{ rejects } q, \\ & \text{- if } \pi \text{ is accepting, then } \langle S, H\rangle \text{ rejects } z, \text{ and} \\ & \text{- if } \pi \text{ is rejecting, then } \langle S, H\rangle \text{ accepts } z\,\}. \end{aligned}$$

Then, as shown by the next claim, the correctness of $\langle S, H_{k_{max}}\rangle$ on an instance z can be decided by asking whether $\langle z, S, H_{k_{max}}\rangle$ belongs to B, provided that $\langle S, H_{k_{max}}\rangle$ is correct on all potential queries of M_{self} on input z.

CLAIM. *Assume that $\langle S, H_{k_{max}}\rangle$ is correct on all $y \prec z$. Then $\langle S, H_{k_{max}}\rangle$ is incorrect on z if and only if $\langle z, S, H_{k_{max}}\rangle$ belongs to B.*

Proof. Using the fact that for every instance $x \in \Sigma^{\preceq n}$, *Consistent*(S) has a half-collision w.r.t. $H_{k_{max}}$ on either *Correct*(x, S) or *Incorrect*(x, S), it is easy to see that if $\langle S, H_{k_{max}}\rangle$ is incorrect on z, then the computation path π followed by $M_{self}(z)$ under oracle A witnesses $\langle z, S, H_{k_{max}}\rangle \in B$. For the converse, assume that $\langle z, S, H_{k_{max}}\rangle$ belongs to B and let π be a computation path witnessing this fact. Note that all queries q on π are answered correctly w.r.t. A, since otherwise $\langle S, H_{k_{max}}\rangle$ were incorrect on $q \prec z$. Hence, π is the path followed by $M_{self}(z)$ under oracle A and therefore decides z correctly. On the other hand, since π witnesses $\langle z, S, H_{k_{max}}\rangle \in B$, $\langle S, H_{k_{max}}\rangle$ indeed is incorrect on z. □

Now we can define the oracle set O as $C \oplus D$, where

$$\begin{aligned} C \;=\; \{\langle 0^n, x, k, S, H\rangle \mid & \text{there is a } \succ\text{-chain of length (at least) } k \text{ from some} \\ & \text{string } y \in \Sigma^{\leq n} \text{ to some string } z \leq x \text{ such that } \langle z, S, H\rangle \in B\,\} \end{aligned}$$

and

$$\begin{aligned} D \;=\; \{\langle x, S, H\rangle \mid & \text{there is an accepting computation path } \pi \text{ of } M_{self} \text{ on} \\ & \text{input } x \text{ such that any query } q \text{ is only answered "yes" ("no") if} \\ & \textit{Consistent}(S) \text{ has a half-collision on } \textit{Accept}(q, S) \text{ (resp., } \textit{Reject}(q, S)) \\ & \text{w.r.t. } H\,\}. \end{aligned}$$

Note that the proof of the claim above also shows that for any $z \in \Sigma^{\preceq n}$ such that $\langle S, H_{k_{max}}\rangle$ is correct on all $y \prec z$, $z \in A$ if and only if $\langle z, S, H_{k_{max}}\rangle$ belongs to D. Now we can complete the description of T. T first asks whether the string $\langle 0^n, 1^{q(n)}, 0, S, H_{k_{max}}\rangle$ belongs to C. It is clear that a negative answer implies that $\langle S, H_{k_{max}}\rangle$ is correct on $\Sigma^{\preceq n}$. Otherwise, by asking queries of the form $\langle 0^n, 1^{q(n)}, i, S, H_{k_{max}}\rangle$, T computes by binary search i_{max} as the maximum value $i \leq 2^{q(n)+1}$ such that

input 0^n
$S := \emptyset$
loop
  for $k = 1, \ldots, p(n)$, choose H_k randomly from $\mathcal{H}(l(n), p(n), k)$,
  $k_{max} := \max\{k \mid \mathit{Consistent}(S)$ has a collision w.r.t. $H_k\}$
  if $\langle 0^n, 1^{q(n)}, 0, S, H_{k_{max}}\rangle \in C$ **then**
    $i_{max} := \max\{i \mid \langle 0^n, 1^{q(n)}, i, S, H_{k_{max}}\rangle \in C\}$
    $x_{min} := \min\{x \mid \langle 0^n, x, i_{max}, S, H_{k_{max}}\rangle \in C\}$
    $S := S\#\langle x, D(x_{min}, S, H_{k_{max}})\rangle$
  else exit(**loop**) **end**
end loop
output $\langle S, H_{k_{max}}\rangle$

$\langle 0^n, 1^{q(n)}, i, S, H_{k_{max}}\rangle$ belongs to C (a similar idea is used in [27]). Knowing i_{max}, T then determines the lexicographically smallest string x_{min} such that $\langle 0^n, x_{min}, i_{max}, S, H_{k_{max}}\rangle$ is in C. Since $\langle q, S, H_{k_{max}}\rangle \notin B$ holds for all instances $q \prec x_{min}$, it follows inductively from the claim that $\langle S, H_{k_{max}}\rangle$ is correct on all $q \prec x_{min}$. Hence, $\langle S, H_{k_{max}}\rangle$ must be incorrect on x_{min}, and, furthermore, T can determine the membership of x_{min} to A by asking whether the string $\langle x_{min}, S, H_{k_{max}}\rangle$ belongs to D. □

THEOREM 3.2. *Every self-reducible set A in the class* $(\mathrm{NP} \cap \text{co-NP})/\mathrm{poly}$ *is low for* $\mathrm{ZPP(NP)}$.

Proof. We first show that $\mathrm{NP}(A) \subseteq \mathrm{ZPP(NP)}$. Let L be a set in $\mathrm{NP}(A)$, and let M be a deterministic polynomial-time oracle machine such that for some polynomial t,

$$L = \{x \mid \exists y \in \Sigma^{t(|x|)} : \langle x, y\rangle \in L(M, A)\}.$$

Let $s(n)$ be a polynomial bounding the length of all oracle queries of M on some input $\langle x, y\rangle$ where x is of length n. Then L can be accepted by a probabilistic oracle machine N using the following NP oracle

$$O' = \{\langle x, S, H\rangle \mid \text{there is a } y \in \Sigma^{t(|x|)} \text{ such that } M \text{ on input } \langle x, y\rangle \text{ has an accepting path } \pi \text{ on which each query } q \text{ is answered "yes" ("no") only if } \mathit{Consistent}(S) \text{ has a half-collision on } \mathit{Accept}(q, S) \text{ (resp., } \mathit{Reject}(q, S)) \text{ w.r.t. } H\}.$$

Here is how N accepts L. On input x, N first simulates T on input $0^{s(|x|)}$ to compute a pair $\langle S, H_{k_{max}}\rangle$ as described above (T asks questions to some NP oracle O). Then N asks the query $\langle x, S, H_{k_{max}}\rangle$ to O' to find out whether x is in L.

This proves that $\mathrm{NP}(A) \subseteq \mathrm{ZPP(NP)}$. Since $\mathrm{ZPP(ZPP)} = \mathrm{ZPP}$ [41] via a proof that relativizes, it follows that $\mathrm{ZPP(NP}(A))$ is also contained in $\mathrm{ZPP(NP)}$, showing that A is low for $\mathrm{ZPP(NP)}$. □

4. Collapse consequences. As a direct consequence of Theorem 3.2 we get an improvement of Karp, Lipton, and Sipser's result in [22] that NP is not contained in P/poly unless the polynomial-time hierarchy collapses to Σ_2^{P}.

COROLLARY 4.1. *If* NP *is contained in* $(\mathrm{NP} \cap \text{co-NP})/\mathrm{poly}$ *then the polynomial-time hierarchy collapses to* $\mathrm{ZPP(NP)}$.

Proof. Since the NP-complete set SAT is self-reducible, the assumption that NP is contained in $(\mathrm{NP} \cap \text{co-NP})/\mathrm{poly}$ implies that SAT is low for $\mathrm{ZPP(NP)}$, and hence the polynomial-time hierarchy collapses to $\mathrm{ZPP(NP)}$. □

The collapse of the polynomial-time hierarchy deduced in Corollary 4.1 is quite close to optimal, at least in some relativized world [17, 39]: there is an oracle relative to which NP is contained in P/poly, but the polynomial-time hierarchy does not collapse to P(NP).

In the rest of this section we report some other interesting collapses which can be easily derived using (by now) standard techniques, and which have also been pointed out to the second author independently by several researchers. First, it is straightforward to check that Theorem 3.2 relativizes: for any oracle B, if A is a self-reducible set in the class $(\mathrm{NP}(B) \cap \text{co-NP}(B))/\mathrm{poly}$, then $\mathrm{NP}(A)$ is contained in $\mathrm{ZPP}(\mathrm{NP}(B))$. Consequently, Theorem 3.2 generalizes to the following result.

THEOREM 4.2. *If A is a self-reducible set in the class $(\Sigma_k^{\mathrm{P}} \cap \Pi_k^{\mathrm{P}})/\mathrm{poly}$, then $\mathrm{NP}(A) \subseteq \mathrm{ZPP}(\Sigma_k^{\mathrm{P}})$.*

As a direct consequence of Theorem 4.2 we get an improvement of results in [1, 20] stating (for $k = 1$) that Σ_k^{P} is not contained in $(\Sigma_k^{\mathrm{P}} \cap \Pi_k^{\mathrm{P}})/\mathrm{poly}$ unless the polynomial-time hierarchy collapses to $\Sigma_{k+1}^{\mathrm{P}}$.

COROLLARY 4.3. *Let $k \geq 1$. If Σ_k^{P} is contained in $(\Sigma_k^{\mathrm{P}} \cap \Pi_k^{\mathrm{P}})/\mathrm{poly}$, then the polynomial-time hierarchy collapses to $\mathrm{ZPP}(\Sigma_k^{\mathrm{P}})$.*

Proof. Since Σ_k^{P} contains complete self-reducible languages, the assumption that Σ_k^{P} is contained in $(\Sigma_k^{\mathrm{P}} \cap \Pi_k^{\mathrm{P}})/\mathrm{poly}$ implies that $\Sigma_{k+1}^{\mathrm{P}} = \mathrm{NP}(\Sigma_k^{\mathrm{P}}) \subseteq \mathrm{ZPP}(\Sigma_k^{\mathrm{P}})$. □

Yap [40] proved that Π_k^{P} is not contained in $\Sigma_k^{\mathrm{P}}/\mathrm{poly}$ unless the polynomial-time hierarchy collapses to $\Sigma_{k+2}^{\mathrm{P}}$. As a further consequence of Theorem 4.2 we get the following improvement of Yap's result.

COROLLARY 4.4. *For $k \geq 1$, if $\Pi_k^{\mathrm{P}} \subseteq \Sigma_k^{\mathrm{P}}/\mathrm{poly}$, then $\mathrm{PH} = \mathrm{ZPP}(\Sigma_{k+1}^{\mathrm{P}})$.*

Proof. The assumption that Π_k^{P} is contained in $\Sigma_k^{\mathrm{P}}/\mathrm{poly}$ implies that $\Sigma_{k+1}^{\mathrm{P}}$ is contained in $\Sigma_k^{\mathrm{P}}/\mathrm{poly} \subseteq (\Sigma_{k+1}^{\mathrm{P}} \cap \Pi_{k+1}^{\mathrm{P}})/\mathrm{poly}$. Hence we can apply Corollary 4.3. □

As corollaries to Theorem 4.2, we also have similar collapse results for many other complexity classes. What follows are some typical examples.

COROLLARY 4.5. *For $\mathcal{K} \in \{\mathrm{UP}, \mathrm{FewP}\}$, if $\mathcal{K} \subseteq (\mathrm{NP} \cap \text{co-NP})/\mathrm{poly}$ then $\mathcal{K}$ is low for $\mathrm{ZPP}(\mathrm{NP})$.*

Proof. It is well known that for every set A in UP (FewP), the left set of A [30] is word-decreasing self-reducible and in UP (resp., FewP). Thus, under the assumption that $\mathrm{UP} \subseteq (\mathrm{NP} \cap \text{co-NP})/\mathrm{poly}$ (resp., $\mathrm{FewP} \subseteq (\mathrm{NP} \cap \text{co-NP})/\mathrm{poly}$) it follows by Theorem 3.2 that the left set of A (and since A is polynomial-time many-one reducible to its left set, also A) is low for $\mathrm{ZPP}(\mathrm{NP})$. □

COROLLARY 4.6. *For every $k \geq 1$, if $\mathrm{C_{=}P} \subseteq (\Sigma_k^{\mathrm{P}} \cap \Pi_k^{\mathrm{P}})/\mathrm{poly}$ then $\mathrm{CH} = \mathrm{ZPP}(\Sigma_k^{\mathrm{P}})$.*

Proof. First, since $\mathrm{C_{=}P}$ has complete word-decreasing self-reducible languages [29], $\mathrm{C_{=}P} \subseteq (\Sigma_k^{\mathrm{P}} \cap \Pi_k^{\mathrm{P}})/\mathrm{poly}$ implies $\mathrm{C_{=}P} \subseteq \mathrm{ZPP}(\Sigma_k^{\mathrm{P}}) \subseteq \mathrm{PH}$. Second, since $\mathrm{PH} \subseteq \mathrm{BPP}(\mathrm{C_{=}P})$ [37, 35], $\mathrm{C_{=}P} \subseteq (\Sigma_k^{\mathrm{P}} \cap \Pi_k^{\mathrm{P}})/\mathrm{poly}$ implies $\mathrm{PH} \subseteq (\Sigma_k^{\mathrm{P}} \cap \Pi_k^{\mathrm{P}})/\mathrm{poly}$ and therefore PH collapses to $\mathrm{ZPP}(\Sigma_k^{\mathrm{P}})$ by Corollary 4.3. Finally, since $\mathrm{C_{=}P}(\mathrm{PH}) \subseteq \mathrm{BPP}(\mathrm{C_{=}P})$ [37], it follows that $\mathrm{C_{=}P}(\mathrm{PH}) \subseteq \mathrm{PH}$, and since $\mathrm{CH} = \mathrm{C_{=}P} \cup \mathrm{C_{=}P}(\mathrm{C_{=}P}) \cup \ldots$ (see [38]), we get inductively that $\mathrm{CH} \subseteq \mathrm{PH}$ $(\subseteq \mathrm{ZPP}(\Sigma_k^{\mathrm{P}}))$. □

COROLLARY 4.7. *Let $\mathcal{K} \in \{\mathrm{EXP}, \mathrm{PSPACE}, \mathrm{Mod}_m\mathrm{P}\}$, $m \geq 2$. If for some $k \geq 1$, $\mathcal{K} \subseteq (\Sigma_k^{\mathrm{P}} \cap \Pi_k^{\mathrm{P}})/\mathrm{poly}$, then $\mathcal{K} \subseteq \mathrm{PH}$ and PH collapses to $\mathrm{ZPP}(\Sigma_k^{\mathrm{P}})$.*

Proof. The proof for $\mathcal{K} \in \{\mathrm{EXP}, \mathrm{PSPACE}\}$ is immediate from Theorem 4.2 since PSPACE has complete (length-decreasing) self-reducible languages and since EXP has complete (word-decreasing) self-reducible languages [6].

The proof for $\mathcal{K} \in \{\mathrm{Mod}_m\mathrm{P} \mid m \geq 2\}$ is analogous to the one of Corollary 4.6

using the fact that $\mathrm{Mod}_m\mathrm{P}$ has complete word-decreasing self-reducible languages [29], and that $\mathrm{PH} \subseteq \mathrm{BPP}(\mathrm{Mod}_m\mathrm{P})$ [37, 35]. □

Since our proof technique is relativizable, the above results hold for every relativized world. On the other hand, it is known that for some classes stronger collapse consequences can be obtained by using nonrelativizable arguments.

THEOREM 4.8 (see [28, 4, 3]). *For* $\mathcal{K} \in \{\mathrm{PP}, \mathrm{Mod}_m\mathrm{P}, \mathrm{PSPACE}, \mathrm{EXP}\}$, *if* $\mathcal{K} \subseteq \mathrm{P/poly}$ *then* $\mathcal{K} \subseteq \mathrm{MA}$.

Harry Buhrman pointed out to us that Corollary 4.7 can also be derived from Theorem 4.8.

5. Circuit complexity. Kannan [21] proved that for every fixed polynomial s, there is a set in $\Sigma_2^{\mathrm{P}} \cap \Pi_2^{\mathrm{P}}$ which cannot be decided by circuits of size $s(n)$. Using a padding argument, he obtained the existence of sets in $\mathrm{NEXP(NP)} \cap \text{co-NEXP(NP)}$ not having polynomial-size circuits.

THEOREM 5.1 (see [21]).

1. *For every polynomial* s, *there is a set in* $\Sigma_2^{\mathrm{P}} \cap \Pi_2^{\mathrm{P}}$ *that does not have circuits of size* $s(n)$.
2. *For every increasing time-constructible super-polynomial function* $f(n)$, *there is a set in* $\mathrm{NTIME}[f(n)](\mathrm{NP}) \cap \text{co-NTIME}[f(n)](\mathrm{NP})$ *that does not have polynomial size circuits.*

As an application of our results in section 3, we can improve Kannan's results in every relativized world from the class $\Sigma_2^{\mathrm{P}} \cap \Pi_2^{\mathrm{P}}$ to $\mathrm{ZPP(NP)}$ and from the class $\mathrm{NTIME}[f(n)](\mathrm{NP}) \cap \text{co-NTIME}[f(n)](\mathrm{NP})$ to $\mathrm{ZPTIME}[f(n)](\mathrm{NP})$, respectively. Here $\mathrm{ZPTIME}[f(n)](\mathrm{NP})$ denotes the class of all sets that are accepted by some zero error probabilistic machine in expected running time $O(f(n))$ relative to some NP oracle.

Note that for all sets in the class P/poly we may fix the interpreter set to some appropriate one in P. Let I_{univ} denote such a fixed interpreter set. Furthermore, P/poly remains the same class if we relax the notion of an advice function h (w.r.t. I_{univ}) as follows: for every x, $A(x) = I_{univ}(x, h(|x|))$; i.e., $h(n)$ has to decide correctly only $A^{=n}$ (instead of $A^{\leq n}$).

A sequence of circuits C_n, $n \geq 0$, is called a circuit family for A if for every $n \geq 0$, C_n has n input gates, and for all n-bit strings $x_1 \cdots x_n$, $C_n(x_1, \ldots, x_n) = A(x_1 \cdots x_n)$. It is well known (see, e.g., [9]) that I_{univ} can be chosen in such a way that advice length and circuit size (i.e., number of gates) are polynomially related to each other. More precisely, we can assume that there is a polynomial p such that the following holds for every set A.

- If h is an advice function for A w.r.t. I_{univ}, then there exists a circuit family C_n, $n \geq 0$, for A of size $|C_n| \leq p(n + |h(n)|)$.
- If C_n, $n \geq 0$, is a circuit family for A, then there exists an advice function h for A w.r.t. I_{univ} of length $|h(n)| \leq p(|C_n|)$.

Moreover, we can assume that for every polynomial-time interpreter set I there is a constant c_I such that if h is an advice function for A w.r.t. I, then there exists an advice function h' for A w.r.t. I_{univ} of length $|h'(n)| \leq |h(n)| + c_I$ for all n.

The following lemma is obtained by a direct diagonalization (cf. the corresponding result in [21]). A set S is called $\mathrm{P}^{\mathcal{C}}$-printable (see [16]) if there is a polynomial-time oracle transducer T and an oracle set $A \in \mathcal{C}$ such that on any input 0^n, T^A outputs a list of all strings in $S^{\leq n}$.

LEMMA 5.2. *For every fixed polynomial* s, *there is a* Δ_3^{P}*-printable set* A *such that every advice function* h *for* A *is of length* $|h(n)| \geq s(n)$ *for almost all* n.

Proof. For a given n, let $x_1, x_2, \ldots, x_{2^n}$ be the sequence of strings of length n, enumerated in lexicographic order. Consider the two sets *Have-Advice* and *Find-A* defined as follows:

$$\langle n, a_1 \cdots a_{s(n)} \rangle \in \textit{Have-Advice} \Leftrightarrow \exists\, w \in \Sigma^{<s(n)},\, \forall\, i, 1 \le i \le \min(s(n), 2^n) : a_i = I_{univ}(x_i, w),$$

$$\langle n, a_1 \cdots a_j 10^{s(n)-j} \rangle \in \textit{Find-A} \Leftrightarrow \exists\, a_{j+1} \cdots a_{s(n)} : \langle n, a_1 \cdots a_j a_{j+1} \cdots a_{s(n)} \rangle \notin \textit{Have-Advice}.$$

Since there are only $2^{s(n)} - 1$ advice strings w in $\Sigma^{<s(n)}$, at least one pair of the form $\langle n, a_1 \cdots a_{s(n)} \rangle$ is not contained in *Have-Advice* (provided that $s(n) \le 2^n$). Let α_n denote the lexicographically smallest such pair $\langle n, a_1 \cdots a_{s(n)} \rangle$; i.e., there is no advice of length smaller than $s(n)$ that accepts the strings $x_1, \ldots, x_{s(n)}$ according to $a_1, \ldots, a_{s(n)}$.

Define A as the set of all strings x_i ($|x_i| = n$) such that $1 \le i \le s(n) \le 2^n$ and the ith bit of α_n (i.e., a_i) is 1. By a binary search using oracle *Find-A*, α_n is computable in polynomial time. Since *Have-Advice* is in NP and thus *Find-A* is in NP(NP), it follows that A is P(NP(NP))-printable. Since, furthermore, for almost all n, $A^{=n}$ has no advice of length smaller than $s(n)$, the lemma follows. □

Corollary 5.3. *For every fixed polynomial s, there is a set A in* ZPP(NP) *that does not have circuits of size $s(n)$.*

Proof. If NP does not have polynomial-size circuits, then we can take $A = \mathrm{SAT}$. Otherwise, PH = ZPP(NP) by Corollary 4.1, and thus the theorem easily follows from Lemma 5.2. □

Corollary 5.4. *Let f be an increasing, time-constructible, super-polynomial function. Then* ZPTIME$[f(n)]$(NP) *contains a set A that does not have polynomial-size circuits.*

Proof. If NP does not have polynomial-size circuits, then we can take $A = \mathrm{SAT}$. Otherwise, PH = ZPP(NP) by Corollary 4.1, and thus it follows from Lemma 5.2 that there is a set B in ZPTIME$[n^k]$(NP) such that every advice function h for B is of length $|h(n)| \ge n$ for almost all n. By the proof technique of Lemma 5.2, we can assume that in all length n strings of B, 1's only occur at the $O(\log n)$ rightmost positions. Now consider the following set (where n denotes $|x|$)

$$A = \{x \mid 0^{\lfloor f(n)^{1/k} \rfloor - n} x \in B\}$$

and the interpreter set

$$I = \{\langle 0^{\lfloor f(n)^{1/k} \rfloor - n} x, w \rangle \mid \langle x, w \rangle \in I_{univ}\}.$$

Clearly, A belongs to ZPTIME$[f(n)]$(NP) and I belongs to P. Furthermore, if h is an advice function for A, then we have for every y of the form $0^{\lfloor f(n)^{1/k} \rfloor - n} x$, $|x| = n$, that

$$\begin{aligned} y \in B &\Leftrightarrow \langle y, h(n) \rangle \in I \\ &\Leftrightarrow \langle y, h'(n) \rangle \in I_{univ}, \end{aligned}$$

where $h'(n)$ is a suitable advice function of length $|h'(n)| \le |h(n)| + c_I$. Thus, it follows for almost all n that

$$|h(n)| \ge |h'(n)| - c_I \ge |y| - c_I = \lfloor f(n)^{1/k} \rfloor - c_I.$$

This shows that the length of h is super-polynomial. □

COROLLARY 5.5. *In every relativized world,* ZPEXP(NP) *contains sets that do not have polynomial-size circuits.*

We remark that the above results are proved by relativizable arguments. On the other hand, Harry Buhrman [12] and independently Thomas Thierauf [36] pointed out to us that Theorem 4.8 (which is proved by a nonrelativizable proof technique) can be used to show that $\mathrm{MA}_{\mathrm{exp}} \cap \text{co-MA}_{\mathrm{exp}}$ contains non P/poly sets. Here, $\mathrm{MA}_{\mathrm{exp}}$ denotes the exponential-time version of Babai's class MA [5]. That is, $\mathrm{MA}_{\mathrm{exp}} = \mathrm{MA}[2^{n^{O(1)}}]$, where a language L is in $\mathrm{MA}[f(n)]$ if there exists a set $B \in \mathrm{DTIME}[O(n)]$ such that for all x of length n,

$$\begin{aligned} x \in L &\Rightarrow \exists y, |y| = f(n) : \Pr[\langle x, y, z\rangle \in B] > 2/3, \\ x \notin L &\Rightarrow \forall y, |y| = f(n) : \Pr[\langle x, y, z\rangle \in B] < 1/3, \end{aligned}$$

where z is chosen uniformly at random from $\Sigma^{f(n)}$.

COROLLARY 5.6 (see [12, 36]). $\mathrm{MA}_{\mathrm{exp}} \cap \text{co-MA}_{\mathrm{exp}}$ *contains sets that do not have polynomial-size circuits.*

Since there exist recursive oracles relative to which all sets in EXP(NP) have polynomial-size circuits [39, 17], it is not possible to extend Corollary 5.5 by relativizing techniques to the class EXP(NP).

6. Concluding remarks. An interesting question concerning complexity classes $\mathcal{C}$ that are known to be not contained in P/poly but are not known to have complete sets is whether the existence of sets in $\mathcal{C} - \mathrm{P/poly}$ can be *constructively* shown. For example, by Corollary 5.5 we know that the class ZPEXP(NP) contains sets that do not have polynomial-size circuits. But we were not able to give a *constructive* proof of this fact. To the best of our knowledge, no explicit set is known even in $\mathrm{NEXP(NP)} \cap \text{co-NEXP(NP)} - \mathrm{P/poly}$.

Acknowledgments. We thank the referees for several remarks that improved this paper. For helpful discussions and suggestions regarding this work we are very grateful to H. Buhrman, R. Gavaldà, L. Hemaspaandra, M. Ogihara, U. Schöning, R. Schuler, and T. Thierauf. We like to thank H. Buhrman, L. Hemaspaandra, and M. Ogihara for permitting us to include their observations in the paper.

SUBLOGARITHMIC BOUNDS ON SPACE AND REVERSALS*

VILIAM GEFFERT†, CARLO MEREGHETTI‡, AND GIOVANNI PIGHIZZINI‡

Abstract. The complexity measure under consideration is SPACE × REVERSALS for Turing machines that are able to branch both existentially and universally. We show that, for any function $h(n)$ between $\log\log n$ and $\log n$, Π_1SPACE × REVERSALS$(h(n))$ is separated from Σ_1SPACE × REVERSALS$(h(n))$ as well as from coΣ_1SPACE×REVERSALS$(h(n))$, for *middle*, *accept*, and *weak* modes of this complexity measure. This also separates determinism from the higher levels of the alternating hierarchy. For "well-behaved" functions $h(n)$ between $\log\log n$ and $\log n$, almost all of the above separations can be obtained by using *unary* witness languages.

In addition, the construction of separating languages contributes to the research on minimal resource requirements for computational devices capable of recognizing nonregular languages. For any (arbitrarily slow growing) unbounded monotone recursive function $f(n)$, a nonregular unary language is presented that can be accepted by a *middle* Π_1 alternating Turing machine in $s(n)$ space and $i(n)$ input head reversals, with $s(n) \cdot i(n) \in \mathcal{O}(\log\log n \cdot f(n))$. Thus, there is no exponential gap for the optimal lower bound on the product $s(n) \cdot i(n)$ between unary and general nonregular language acceptance—in sharp contrast with the one-way case.

1. Introduction.

In the last few years, some exciting results have been obtained in the field of space bounded computations. First of all, we have a surprisingly short proof that nondeterministic space is closed under complementation [12, 21]. Among others, this result has a fundamental consequence on alternation, namely, the collapse of the alternating space hierarchy to the Σ_1 level.

It is worth noticing that these results were obtained for *strong* space complexity classes with $s(n) \in \Omega(\log n)$. (A Turing machine M works in *strong* space $s(n)$ if no reachable configuration, on any input of length n, uses space above $s(n)$.) The closure under complementation does not hold for *weak* space complexity classes above $\log n$ [23]. (*weak* space $s(n)$: for any accepted input of length n, there exists at least one accepting computation not using more space than $s(n)$.) Below $\log n$, moreover, the above alternating hierarchy is infinite [2, 6, 15]. For the sublogarithmic world, many other results, almost self-evident in the superlogarithmic case, either do not hold or the proofs are quite different and are often highly involved.

In this paper, we continue in this line of research toward the simplest possible nonregular complexity classes by investigating Turing machines having sublogarithmic bounds on the product of *space*—in its different definitions—by the *number of input head reversals*. Turing machines working even within such limited resources can still

recognize nonregular languages [3, 4], while the corresponding bound on the product of space by *work head* reversals must be at least linear [9].

Besides *strong* and *weak* space, mentioned above, some intermediate measures have also been proposed. (*accept* space $s(n)$: all accepting computations obey the space bound, *middle* space $s(n)$: all computations obey the space bound for each accepted input of length n. For more precise definitions, see section 2.) Such differences are irrelevant for fully space constructible bounds above $\log n$, but several results (see, e.g., [23, 4, 7]) witness that one must pay special attention to the actual definition when dealing with such limited resources as is sublogarithmic space.

For the product of space by input head reversals, we are able to show several separation results that are still unknown if sublogarithmic bounds *on space only* are considered. Namely, for each of the modes $c \in \{middle, accept, weak\}$ and any function $h(n)$ between $\log\log n$ and $\log n$, c-Π_1SPACE$\times$REVERSALS$(h(n))$ is separated from c-Σ_1SPACE$\times$REVERSALS$(h(n))$ and, somewhat more surprisingly, also from *co*-c-Σ_1SPACE$\times$REVERSALS$(h(n))$. (Here c-XSPACE$\times$REVERSALS$(h(n))$ denotes the class of languages accepted by $X \in \{\Sigma_k, \Pi_k\}$ machines of type $c \in \{strong, middle, accept, weak\}$ in $s(n)$ space and $i(n)$ input head reversals, satisfying $s(n) \cdot i(n) \in \mathcal{O}(h(n))$. We add prefix "*co*-" for complements of such languages, and we use $X = \mathrm{D}$ for deterministic Turing machines, i.e., for $\Sigma_0 = \Pi_0$.)

In other words, for *middle*, *accept*, or *weak* space$\times$input head reversals bounded Turing machines, the class of languages accepted by machines making only universal decisions does not coincide with the class of complements of languages recognizable by machines making only existential decisions. Further, we get that *weak*-DSPACE$\times$REVERSALS$(h(n))$ is properly included in *weak*-Π_1-, *co-weak*-Π_1-, *weak*-Σ_1-, and in *co-weak*-Σ_1SPACE$\times$REVERSALS$(h(n))$, for each $h(n)$ between $\log\log n$ and $\log n$.

The input head motion for machines accepting nonregular languages has been studied in [3, 4]. It turns out that the minimal resource requirements for machines accepting *unary*[1] languages become important: a recognizer, already having too little space to remember an input head position, must also cope with the lack of any structure on the input tape. So the problem arises of whether these results hold even if the corresponding language classes are restricted to unary languages. Using an additional assumption that the function $h(n)$ is "well behaved," we are able to show that the above separations hold even in the case of unary languages, except for the separation of *weak*-Π_1SPACE$\times$REVERSALS$(h(n))$ from *co-weak*-Σ_1SPACE$\times$REVERSALS$(h(n))$, which we leave as an open problem.

Here "well behaved" means $h(n) \in o(\log n)$ with $\frac{h(n)}{\log\log n}$ unbounded and monotone increasing. We only require $h(n)$ to be recursive but do not claim any kind of space constructibility.

The above separations are obtained by exhibiting, for any (arbitrarily slow growing) unbounded monotone recursive function $f(n)$, a nonregular unary language $\mathcal{L}_f$ that can be accepted by a *middle* $s(n)$ space and $i(n)$ input head reversals bounded Π_1 machine with $s(n) \cdot i(n) \in \mathcal{O}(\log\log n \cdot f(n))$. On the other hand, using mainly number theoretical and pumping arguments, we show that, for every $h(n) \in o(\log n)$, $\mathcal{L}_f$ does not belong to *weak*-Σ_1SPACE$\times$REVERSALS$(h(n))$.

The complexity of recognizing $\mathcal{L}_f$ also gives meaningful insights into the study of *minimal resource requirements* for computational devices recognizing nonregular languages, an important research area dating back to works by J. Hartmanis, P. Lewis,

[1] That is, built over a single letter alphabet.

and R. Stearns in 1965. In [14, 19, 10], the authors settled the problem of determining the minimal *strong* space requirement for one–way and two–way, deterministic and nondeterministic Turing machines that accept nonregular languages. Subsequently, the same problem has been widely studied for other and more general paradigms of computation and space notions (for *strong* alternation in [20], for *middle* machines in [22], for *accept* machines in [4], and for *weak* machines in [1, 13]). The analysis of computational lower bounds for nonregular languages is tightly related to the world of sublogarithmic space (see, e.g., [23, 7]) and, more particularly, plays an important role in revealing sharp differences among various space definitions [4].

In this regard, we shall concentrate on the problem of determining the optimal lower bound on the product space×input head reversals for *middle* alternating Turing machines that accept unary nonregular languages. The reason why we focus on the *middle* mode of acceptance is that *one-way middle* alternating Turing machines exhibit a very interesting behavior having no analogue in any of the other space bounded computational models considered, e.g., in [23, 4]. On the one hand, we have an optimal $\log\log n$ space lower bound for nonregular languages built on binary alphabets (hence, on general alphabets as well) [22]. On the other hand, a tight $\log n$ space lower bound is proved in [16] whenever we restrict our machines to accept *unary* nonregular languages (see also Table 1.1).

A problem left open in [4] asks whether the same gap situation holds for the lower bound on $s(n) \cdot i(n)$ for *middle* space×input head reversals bounded alternating machines accepting nonregular languages. For such machines, a tight $\log\log n$ lower bound on $s(n) \cdot i(n)$ for general nonregular languages is observed in [4]. Should we expect a corresponding exponential gap when accepting unary nonregular languages, as in the one-way case?

Here we provide a negative answer to this open question since, as stated before, for any unbounded monotone recursive function $f(n)$, we have a unary nonregular language $\mathcal{L}_f$, recognizable by a *middle* space×input head reversals bounded alternating Turing machine satisfying $s(n) \cdot i(n) \in \mathcal{O}(\log\log n \cdot f(n))$. With $f(n)$ being *arbitrarily slow growing*, we can approach the optimal $\log\log n$ lower bound for binary languages as much as we like.

Though this does not completely prove the optimality of the lower bound $s(n) \cdot i(n) \notin o(\log\log n)$ for *middle* alternating Turing machines recognizing unary nonregular languages, it shows that such a lower bound cannot be raised to any "well-behaved" function $g(n)$ above $\log\log n$, i.e., to any $g(n)$ that is recursive with $\frac{g(n)}{\log\log n}$ unbounded and monotone increasing. This definitively rules out the possibility of an exponential gap observed on the corresponding one-way devices between the general and the unary cases.

Table 1.1 briefly summarizes the lower bounds for *middle* space×input head reversals bounded Turing machines recognizing nonregular languages (see Theorem 3.1 and [4, 16]).

This paper is organized as follows: section 2 contains basic definitions, in particular, the basic notions of space complexity and the SPACE×REVERSALS resource measure. In section 3, we state our main result: we exhibit, for any (arbitrarily slow growing) unbounded monotone recursive function $f(n)$, a unary nonregular language $\mathcal{L}_f$, mentioned above, and analyze the complexity of recognizing $\mathcal{L}_f$. As a consequence, section 4 proves the above-claimed separation results for the unary case. Finally, in section 5, we improve these separations for the case of general alphabets.

TABLE 1.1

Best lower bounds obtained for $s(n) \cdot i(n)$ on middle *alternating and nondeterministic* (Σ_1) *Turing machines accepting nonregular languages* ($i(n) = 1$ *for one-way machines*). *These bounds are known to be optimal* [4, 16] *except the bound for two-way alternating Turing machines on unary inputs which is "quasi" optimal* (*see Theorem* 3.1).

	Unary languages	General languages
One-way alternating	$\log n$	$\log \log n$
One-way nondeterministic (Σ_1)	$\log n$	$\log n$
Two-way alternating	**lower:** $\log \log n$ **upper:** $\log \log n \cdot f(n)$	$\log \log n$
Two-way nondeterministic (Σ_1)	$\log n$	$\log n$

2. Preliminaries. In this section, we briefly recall some very basic definitions concerning space bounded models of computation. For more details, we refer to [4, 23]. Furthermore, we consider machines having simultaneous bounds on both working space and number of input head reversals, and we introduce SPACE$\times$REVERSALS complexity classes.

Let Σ^* be the set of all strings over an alphabet Σ. Given any language $L \subseteq \Sigma^*$, $L^c = \Sigma^* \setminus L$ denotes the *complement* of L. L is said to be *unary* (or *tally*) whenever it is built on an alphabet consisting of exactly one symbol (usually "1").

The Turing machine model we shall deal with has been presented in [14, 19] to study sublinear space bounded computations. It consists of a finite state control, a two-way read-only input tape (with input enclosed between two end markers), and a separate semi-infinite two-way read-write work tape (initially empty, containing only *blank* symbols). A *memory state* of a Turing machine is an ordered triple $m = (q, u, j)$, where q is a control state, u is a string of work tape symbols (the nonblank content of the work tape), and j is an integer satisfying $1 \leq j \leq |u| + 1$ (the position of the work tape head). A *configuration* is an ordered pair $c = (m, i)$, where m is a memory state and i is an integer denoting the position of the input head.

The reader is assumed to be familiar with the notion of *alternating Turing machine*, introduced in [5], which is, at the same time, a generalization of nondeterminism and parallelism. A Σ_k (Π_k) *machine* is an alternating Turing machine beginning its computation in an existential (universal, respectively) state, and making at most $k - 1$ switches between existential and universal states along each computation path on any input. It can be easily seen that Σ_1 machines are actually nondeterministic machines. It is stipulated that Σ_0 and Π_0 machines are *deterministic* machines.

Let us now review notions of *space complexity* in the literature. In what follows, the space used by a computation of an alternating machine is, by definition, the maximal number of work tape cells used by any configuration in the tree corresponding to that computation. (For deterministic and nondeterministic machines, the computation reduces to a single computation path.) Let M be a deterministic, nondeterministic, or alternating Turing machine. Then the following hold.

- M works in *strong* $s(n)$ space if and only if, for each input of length n, no reachable configuration uses more space than $s(n)$ [14, 19, 10].
- M works in *middle* $s(n)$ space if and only if, for each accepted input of length n, no reachable configuration uses more space than $s(n)$ [22].
- M works in *accept*[2] $s(n)$ space if and only if, for each accepted input of length n, each accepting computation uses at most space $s(n)$ [11, 4, 18].

[2]The designation "*accept*" has been adopted first in [4].

- M works in *weak* $s(n)$ space if and only if, for each accepted input of length n, there exists an accepting computation using at most space $s(n)$ [17, 1, 13].

The above definitions are given in increasing order of generality, as one may easily verify. We remark that, although several differences have been emphasized in the literature [23, 4, 7], the above space notions turn out to be equivalent when considering *fully space constructible*[3] bounds, e.g., "normal" functions above $\log n$: once the space limit $s(n)$ can be computed in advance, each computation consuming too much space may be aborted. Also notice that, for Π_1 machines, *middle*, *accept*, and *weak* notions coincide for arbitrary space complexities.

With a slight abuse of terminology, we will often say, for instance, "a *middle* alternating Turing machine" instead of "an alternating Turing machine working in *middle* space."

The other computational resource we are interested in is the number of *input head reversals*. In general, we say that a Turing machine M is *one-way* if it can never move its input head toward the left; otherwise M is a *two-way* device. To emphasize the role of input head motion, we introduce a bound $i(n)$ on the number of input head reversals. We always compute $i(n)$ by considering those computations by which the space is defined. Thus, for instance, we say that a *middle* alternating Turing machine works *simultaneously* in $s(n)$ space and $i(n)$ input head reversals if, for each accepted input of length n, no reachable configuration uses more than $s(n)$ work tape cells, nor can it be accessed by a path that reverses the input head direction more than $i(n)$ times. For technical reasons, we stipulate $i(n) = 1$ for one-way machines.

Throughout the rest of the paper, we use the following notation for complexity classes. Let $c \in \{strong, middle, accept, weak\}$ and $X \in \{\Sigma_k, \Pi_k\}$. Then, we define

$$c\text{-}X\mathrm{SPACE}\times\mathrm{REVERSALS}(h(n))$$

to be the class of the languages accepted by X machines of type c in $s(n)$ space and $i(n)$ input head reversals satisfying $s(n) \cdot i(n) \in \mathcal{O}(h(n))$. In particular, we let $X = \mathrm{D}$ for $\Sigma_0 = \Pi_0$, i.e., for deterministic Turing machines. By *co-c-*$X\mathrm{SPACE}\times\mathrm{REVERSALS}(h(n))$, we denote the class of the languages L^c such that $L \in c\text{-}X\mathrm{SPACE}\times\mathrm{REVERSALS}(h(n))$. Finally, the restriction of these classes to unary languages will be denoted by $c\text{-}X\mathrm{SPACE}\times\mathrm{REVERSALS}^{1^*}(h(n))$ or by *co-c-*$X\mathrm{SPACE}\times\mathrm{REVERSALS}^{1^*}(h(n))$.

3. A family of nonregular unary languages. In this section, we introduce, for each unbounded (arbitrarily slow growing) monotone increasing recursive function $f(n)$, a nonregular unary language $\mathcal{L}_f$ that can be accepted by an alternating Turing machine in *middle* $s(n)$ space with $i(n)$ input head reversals satisfying $s(n) \cdot i(n) \in \mathcal{O}(\log\log n \cdot f(n))$. Hence, the optimal $\log\log n$ lower bound on $s(n) \cdot i(n)$ for general nonregular languages acceptance can be arbitrarily approached by unary languages. Subsequently, we prove that $\mathcal{L}_f$ cannot be accepted by any nondeterministic Turing machine working in *weak* $s(n)$ space and $i(n)$ input head reversals such that $s(n)\cdot i(n) \in o(\log n)$. This implies the nonregularity of $\mathcal{L}_f$ and will later be used to separate several $\mathrm{SPACE}\times\mathrm{REVERSALS}$ complexity classes.

In what follows, p_i denotes the ith prime. Furthermore, $f : \mathbf{N} \to \mathbf{N}$ is assumed to be any (effectively given) unbounded monotone increasing recursive function. That is, we have a deterministic Turing machine A which, for any binary input x, prints

[3] A function $s(n)$ is said to be *fully space constructible* whenever there exists a deterministic Turing machine which, on any input of length n, uses exactly space $s(n)$.

out a binary representation of $f(x)$. (Alternatively, we can avoid any ambiguity by using, in any standard enumeration $A_1, A_2, \ldots$ of Turing machines, the first machine computing f. It will be seen later that the upper and lower bounds proved in this section hold for any choice of A.)

We are now ready for the definition of $\mathcal{L}_f$. For each $n \in \mathbf{N}$, we first define the following statements.

(i) Let p_i be the first prime not dividing n.
(ii) Let x be the smallest integer satisfying $x \geq 2^{p_i}$ and $f(x) \geq p_i$.
(iii) Let $y = \max\{x, 2^{s_1}, 2^{s_2}, \ldots, 2^{s_x}\}$, where s_i denotes the amount of work tape space used by machine A when computing the value of $f(i)$.

Then $1^n \in \mathcal{L}_f$ if and only if the following holds:

(iv) for all prime powers ${p_j}^k \leq y$, with $p_j \leq \sqrt{y}$, $j \neq i$, and $k \geq 1$, we have that ${p_j}^k$ divides n.

In other words, item (iv) states that $1^n \in \mathcal{L}_f$ if and only if all the prime powers ${p_j}^k \leq y$, with $p_j \leq \sqrt{y}$, $j \neq i$, and $k \geq 1$, divide n, $\log y$ denoting the amount of space claimed by A to compute any of the values $f(1), f(2), \ldots, f(x)$ or to represent the integer x (see item (iii)), and $x \geq 2^{p_i}$ being the smallest integer satisfying $f(x) \geq p_i$ as required in (ii). Note that such x must exist: take the first x such that $f(x) > \max\{p_i - 1, f(1), f(2), \ldots, f(2^{p_i} - 1)\}$, using the fact that $f(x)$ is unbounded.

The proof of nonregularity of $\mathcal{L}_f$ will be given later as a consequence of Theorem 3.2. Now we shall study the complexity of $\mathcal{L}_f$ on alternating machines.

THEOREM 3.1. *Let $\mathcal{L}_f$ be a unary language defined as above. Then $\mathcal{L}_f$ can be accepted by a middle alternating Turing machine within $s(n)$ space and $i(n)$ input head reversals satisfying*

$$s(n) \cdot i(n) \in \mathcal{O}\left(\log\log n \cdot f(n)\right) .$$

Proof. First, we shall determine possible values of n so that the string 1^n belongs to $\mathcal{L}_f$. Let p_i, x, and y be defined as stated in items (i) – (iii). Item (iv) in the definition of $\mathcal{L}_f$ requires that possible factorizations of n must be of the following form:

$$n = {p_1}^{\alpha_1+\beta_1} \cdot {p_2}^{\alpha_2+\beta_2} \cdot \ldots \cdot {p_{i-1}}^{\alpha_{i-1}+\beta_{i-1}} \cdot {p_{i+1}}^{\alpha_{i+1}+\beta_{i+1}} \cdot \ldots \cdot {p_s}^{\alpha_s+\beta_s} \cdot \nu \,, \tag{3.1}$$

where p_s represents the largest prime less than or equal to $\sqrt{y}$. The prime p_i does not appear in (3.1) since it does not divide n. Numbers α_j, with $j \in \{1, 2, \ldots, s\} \setminus \{i\}$, are the maximal exponents which the corresponding primes p_j can be raised to in order to have ${p_j}^{\alpha_j} \leq y$. It is easy to see that $\alpha_j = \lfloor \log_{p_j} y \rfloor$ and $\beta_j \geq 0$, where, for any given number z, $\lfloor z \rfloor$ denotes the greatest integer less than or equal to z. Finally, ν contains the (possibly empty) part of the factorization consisting of powers of those primes greater than $\sqrt{y}$.

By (3.1), we are able to obtain a relation between n and y. In fact, we observe that

$$n \geq \prod_{p \leq \sqrt{y},\, p \neq p_i} p^{\lfloor \log_p y \rfloor} \,, \tag{3.2}$$

where the product is taken over all primes not exceeding $\sqrt{y}$ and different from p_i. By noticing that $\log_p y \geq 2$ for $p \leq \sqrt{y}$, we get the following limitation:

$$\sqrt{y} = p^{\frac{1}{2} \cdot \log_p y} < p^{\lfloor \log_p y \rfloor} \,,$$

which, together with (3.2), yields

$$n > \prod_{p \le \sqrt{y},\ p \ne p_i} \sqrt{y} = y^{\frac{1}{2}\cdot(\pi(\sqrt{y})-1)}. \tag{3.3}$$

Here $\pi(z)$ denotes the number of primes not exceeding $\lfloor z \rfloor$. A well-known theorem due to P. Čebyšev (see [8, Thm. 7]) states that

$$c_1 \cdot \frac{z}{\log z} \le \pi(z) \le c_2 \cdot \frac{z}{\log z}$$

for some positive constants c_1 and c_2. We can use this in (3.3) and obtain

$$n > y^{\frac{1}{2}\cdot\left(c_1 \cdot \frac{\sqrt{y}}{\log \sqrt{y}} - 1\right)} = 2^{\frac{\log y}{2}\cdot\left(\frac{2c_1\sqrt{y}}{\log y} - 1\right)} > d^{\sqrt{y}} \tag{3.4}$$

for a suitable constant $d > 1$.

With these results in our hands, we are now ready to estimate the amount of space and input head reversals sufficient for a *middle* alternating Turing machine M to accept $\mathcal{L}_f$. On input 1^n, M runs a two-phase algorithm. First, it computes the smallest prime p_i not dividing n. Then, it checks the truth of predicate in item (iv).

PHASE 1. M deterministically computes p_i by means of the following routine:

/* input is 1^n */
$p := 2$
while $n \bmod p = 0$ **do**
    begin
        $p := p + 1$
        while p not a prime **do** $p := p + 1$
    end
/* now p contains p_i */

The amount $s_1(n)$ of space used in this phase equals the number of bits needed to represent p_i in binary notation, i.e., $s_1(n) \in \mathcal{O}(\log p_i)$. Furthermore, it is easy to see that, for each value of p, the test "$n \bmod p = 0$" can be accomplished by scanning the input only once. Therefore, the number $i_1(n)$ of input head reversals equals the number of primes not exceeding p_i. By Čebyšev's theorem, we obtain $i_1(n) \in \mathcal{O}(\frac{p_i}{\log p_i})$.

PHASE 2. M deterministically computes the smallest integer $x \ge 2^{p_i}$ such that $f(x) \ge p_i$ (p_i being already stored on the work tape during the former phase). To this purpose, M simply loops as follows:

$x := 1$
while $x < 2^{p_i}$ or $f(x) < p_i$ **do**
    $x := x + 1$

Note that M computes each of the values $f(1), f(2), \ldots, f(x)$ by simulating A; therefore, it marks off exactly $\max\{\log x, s_1, s_2, \ldots, s_x\} = \log y$ space on the work tape. Recall that s_i denotes the amount of space used by A when computing $f(i)$.

Subsequently, M *universally* generates all the prime powers whose binary representation takes at most $\log y$ bits and checks whether each ${p_j}^k \le y$, with $p_j \le \sqrt{y}$, $j \ne i$, and $k \ge 1$, divides n. Clearly, the space requirement in this phase is bounded by $s_2(n) \in \mathcal{O}(\log y)$.

For input head reversals, we observe that the computations of $f(1), f(2), \ldots, f(x)$ are performed deterministically with the input head parked at one end marker, and that the divisibility of n by each ${p_j}^k$ is tested universally in parallel by one input scan, whence $i_2(n) = 1$.

Let us now evaluate $s(n) \cdot i(n)$ *in case* 1^n *belongs to* $\mathcal{L}_f$. The algorithm uses a total amount of space and input head reversals along each computation path of M to be estimated as

$$s(n) = s_1(n) + s_2(n) \in \mathcal{O}(\log p_i + \log y) = \mathcal{O}(\log y)\,,$$
$$i(n) = i_1(n) + i_2(n) \in \mathcal{O}\left(\frac{p_i}{\log p_i}\right)\,,$$

using $p_i \leq \log x \leq \log y$ by (ii) and (iii) in the definition of $\mathcal{L}_f$. This gives

$$s(n) \cdot i(n) \in \mathcal{O}\left(\log y \cdot \frac{p_i}{\log p_i}\right)\,.$$

Items (ii) and (iii) in the definition of $\mathcal{L}_f$ require that $p_i \leq f(x)$ and $x \leq y$. Further, $\frac{t}{\log t}$ is monotone increasing. Hence, $\frac{f(x)}{\log f(x)}$ is also monotone increasing whenever $f(x)$ is monotone increasing. Therefore, in case of $1^n \in \mathcal{L}_f$, we are able to obtain the following bounds:

$$\log y \cdot \frac{p_i}{\log p_i} \leq \log y \cdot \frac{f(x)}{\log f(x)} \leq \log y \cdot \frac{f(y)}{\log f(y)}\,.$$

Moreover, inequality (3.4) states that $n > d^{\sqrt{y}}$, i.e., $y \leq k \cdot \log^2 n$ for a suitable positive constant k. Hence, for sufficiently large n, we get

$$\begin{aligned}\log y \cdot \frac{f(y)}{\log f(y)} &\leq \log(k \cdot \log^2 n) \cdot \frac{f(k \cdot \log^2 n)}{\log f(k \cdot \log^2 n)} \\ &\leq \log(k \cdot \log^2 n) \cdot \frac{f(n)}{\log f(n)} \;\in\; \mathcal{O}\left(\log\log n \cdot f(n)\right)\,,\end{aligned}$$

which completes the proof. □

As a consequence of Theorem 3.1, it turns out that, using unary languages, we can arbitrarily approach the optimal $\log\log n$ lower bound on $s(n) \cdot i(n)$ holding for general nonregular language acceptance by *middle* space×input head reversals bounded alternating Turing machines (see Table 1.1). Take, for instance, $f(x) = \log^* x = \min\{k \in \mathbf{N} \mid \log^{(k)} x \leq 1\}$, with $\log^{(0)} x = x$ and, for each $k \geq 1$, $\log^{(k)} x = \log^{(k-1)} \log x$.

We now show that the language $\mathcal{L}_f$ is nonregular. Actually, we prove a stronger result that, together with Theorem 3.1, will also allow us to obtain some separations in the case of weakly bounded computations.

THEOREM 3.2. *Let* $\mathcal{L}_f$ *be a unary language defined as above. Then for any* $h(n) \in o(\log n)$, $\mathcal{L}_f$ *is not in weak-*Σ_1SPACE×REVERSALS$^{1^*}(h(n))$.

Proof. Suppose, by contradiction, that $\mathcal{L}_f$ can be accepted by a *weak* nondeterministic machine M in $s(n)$ space and $i(n)$ input head reversals, with $s(n) \cdot i(n) = h(n) \in o(\log n)$. The number of different memory states of M not using more space than $s(n)$ on the work tape can be bounded by $c^{s(n)}$, where c is a constant dependent on the number of work tape symbols and finite-control states of M. Since $\lim_{n\to\infty} \frac{s(n)\cdot i(n)}{\log n} = 0$, there exists $n_0 \in \mathbf{N}$ such that

$$c^{s(n)\cdot i(n)} < \sqrt{n} \quad \text{for each } n \geq n_0\,. \tag{3.5}$$

Now, consider the string $1^{n'}$, where n' is defined in the following way:

(i) First, let $p_i \geq 5$ be a sufficiently large prime such that there is another prime $\tilde{p}$ between n_0 and p_i, i.e., $p_i > \tilde{p} > n_0$.
(ii) Let x be the smallest integer satisfying $x \geq 2^{p_i}$ and $f(x) \geq p_i$.
(iii) Now, let $y = \max\{x, 2^{s_1}, 2^{s_2}, \ldots, 2^{s_x}\}$, where s_i denotes the space used by the machine A to compute $f(i)$.
(iv) Finally, define

$$n' = \prod_{p \leq \sqrt{y},\ p \neq p_i} p^{\lfloor \log_p y \rfloor},$$

where the product is taken over all primes not exceeding $\sqrt{y}$ and different from p_i.

We want to show that $1^{n'} \in \mathcal{L}_f$. First, we prove that p_i is the first prime that does not divide n'. Clearly, p_i does not divide n'. For primes $p < p_i$, we obtain

$$p^{\lfloor \log_p y \rfloor + 1} > y \geq \sqrt{y} \geq \log y \geq \log x \geq p_i > p = p^1,$$

using (iii) and (ii) in the definition of n'. (The inequality $\sqrt{y} \geq \log y$ follows from $\log y \geq p_i \geq 5$ by (i).) Thus, $\lfloor \log_p y \rfloor > 0$ and $p < \sqrt{y}$; i.e., n' is divisible by p for each prime $p < p_i$.

At this point, to conclude that $1^{n'} \in \mathcal{L}_f$, it is enough to prove that each prime power ${p_j}^k \leq y$, with $p_j \leq \sqrt{y}$, $j \neq i$, and $k \geq 1$, divides n'. This can be immediately shown by observing that $k \leq \log_{p_j} y$ and $k \in \mathbf{N}$; hence,

$$k = \lfloor k \rfloor \leq \lfloor \log_{p_j} y \rfloor.$$

This gives that $1^{n'} \in \mathcal{L}_f$.

As a consequence, there must exist an accepting computation path $\mathcal{C}$ of M on the input $1^{n'}$, using at most $s(n')$ space and $i(n')$ input head reversals. By (i) in the definition of n', we have a prime $\tilde{p}$ satisfying $p_i > \tilde{p} > n_0$. Since p_i is the first prime not dividing n', $\tilde{p}$ divides n', and hence $n' \geq \tilde{p} > n_0$. Therefore, by (3.5), the bounds $s(n')$ and $i(n')$ must satisfy

$$c^{s(n')} \leq c^{s(n') \cdot i(n')} < \sqrt{n'} \leq n'. \tag{3.6}$$

Along the path $\mathcal{C}$, we can consider $r_1, r_2, \ldots, r_A$, the sequence of all configurations in which the input head scans either of the end markers. Let $b_1, e_1, b_2, e_2, \ldots, b_B, e_B$ be the subsequence of $r_1, r_2, \ldots, r_A$ such that, for each $j = 1, 2, \ldots, B$, machine M begins with the input head positioned at the left or right end marker in b_j, traverses across the entire input $1^{n'}$, and ends in e_j positioned at the opposite end marker, without visiting either of the end markers in the meantime. The segments of computation between e_j and b_{j+1} always return the input head back to the same end marker (or, possibly, $e_j = b_{j+1}$).

Since, by (3.6), the number of different memory states is bounded by $c^{s(n')} < n'$, the machine must enter *a loop* when traversing the entire input $1^{n'}$ from b_j to e_j; i.e., it enters some memory state twice in some configurations (q_j, d_j) and $(q_j, d_j + \ell_j)$ for $\ell_j \neq 0$. To avoid any ambiguity, we take the first loop the machine gets into, i.e., the first pair of configurations having the same memory state, along each input traversal. Observe that

$$\begin{aligned} \ell_j &\leq c^{s(n')} \quad \text{for each } j = 1, 2, \ldots, B, \\ B &\leq i(n'), \end{aligned} \tag{3.7}$$

since M is simultaneously $s(n)$ space and $i(n)$ input head reversals bounded.

Now, define

$$\ell = \prod_{j=1}^{B} \ell_j \,. \tag{3.8}$$

It is not too hard to see that the machine M must also accept the inputs $1^{n'+\mu\cdot\ell}$ for each $\mu \in \mathbf{N}$. In fact, we can replace the accepting computation path $\mathcal{C}$ for the input $1^{n'}$ by a new computation path $\mathcal{C}_\mu$ that visits the end markers in the same sequence of configurations $r_1, r_2, \ldots, r_A$. The path $\mathcal{C}_\mu$ is obtained from $\mathcal{C}$ by iterating, $\frac{\mu\cdot\ell}{\ell_j}$ more times, the loop of length ℓ_j in the segment of computation connecting b_j and e_j, for each $j = 1, 2, \ldots, B$. Note that ℓ is a common multiple of $\ell_1, \ell_2, \ldots, \ell_B$ and hence $\frac{\mu\cdot\ell}{\ell_j} \in \mathbf{N}$; i.e., the new segments of computation traverse exactly $n' + \frac{\mu\cdot\ell}{\ell_j} \cdot \ell_j = n' + \mu\cdot\ell$ positions, beginning and ending in the same configurations b_j and e_j, respectively, for each $j = 1, 2, \ldots, B$. The segments between e_j and b_{j+1} (always returning back to the same end marker) are left unchanged. Hence, for each $\mu \in \mathbf{N}$, $\mathcal{C}_\mu$ is a valid accepting computation path on the input $1^{n'+\mu\cdot\ell}$.

To complete the proof, we are now going to show that $1^{n'+\mu'\cdot\ell} \notin \mathcal{L}_f$, where μ' is defined by

$$\mu' = \prod_{p \le p_i} p \,, \tag{3.9}$$

which is a contradiction. The product is taken over all primes not exceeding p_i; hence, $(n' + \mu'\cdot\ell) \bmod p = n' \bmod p$ for each prime $p \le p_i$. This gives that n' and $n' + \mu'\cdot\ell$ share the same "least prime nondivisor" p_i. Therefore, to show that $1^{n'+\mu'\cdot\ell} \notin \mathcal{L}_f$, there only remains to exhibit a prime power ${p_j}^k \le y$, with $p_j \le \sqrt{y}$, $j \ne i$, and $k \ge 1$, such that ${p_j}^k$ does not divide $n' + \mu'\cdot\ell$.

Since we have shown that $1^{n'} \in \mathcal{L}_f$, each such prime power divides n', and hence

$$(n' + \mu'\cdot\ell) \bmod {p_j}^k = (\mu'\cdot\ell) \bmod {p_j}^k \,. \tag{3.10}$$

Therefore, the problem reduces to exhibit ${p_j}^k$ not dividing $\mu'\cdot\ell$.

To this aim, observe that ℓ, as defined by (3.8), is bounded by

$$\ell = \prod_{j=1}^{B} \ell_j \le \prod_{j=1}^{B} c^{s(n')} = \left(c^{s(n')}\right)^B \le c^{s(n')\cdot i(n')} < \sqrt{n'} \,, \tag{3.11}$$

using (3.7) and (3.6). On the other hand, the factorization of ℓ must be of the form

$$\ell = \nu \cdot \prod_{p \le \sqrt{y},\ p \ne p_i} p^{\alpha_p} \,, \tag{3.12}$$

where the product is taken over all primes not exceeding $\sqrt{y}$ and different from p_i, while ν contains the (possibly empty) part of the factorization consisting of powers of those primes p greater than $\sqrt{y}$ or $p = p_i$.

Let us now show that there exists a prime $p' \le \sqrt{y}$, $p' \ne p_i$, such that $\alpha_{p'} < \lfloor \log_{p'} y \rfloor - 1$. Suppose, by contradiction, that $\alpha_p \ge \lfloor \log_p y \rfloor - 1$ for each prime $p \le \sqrt{y}$, $p \ne p_i$. Then $\log_p y \ge 2$ and hence

$$\lfloor \log_p y \rfloor - 1 \ge \frac{1}{2} \cdot \lfloor \log_p y \rfloor \,.$$

This gives

$$\ell = \nu \cdot \prod_{p \le \sqrt{y},\ p \ne p_i} p^{\alpha_p} \ge \prod_{p \le \sqrt{y},\ p \ne p_i} p^{\lfloor \log_p y \rfloor - 1} \ge \prod_{p \le \sqrt{y},\ p \ne p_i} p^{\frac{1}{2} \cdot \lfloor \log_p y \rfloor} = \sqrt{n'}\,,$$

i.e., $\ell \ge \sqrt{n'}$, which contradicts (3.11). Hence, there exists a prime $p' \le \sqrt{y}$, $p' \ne p_i$ such that $\alpha_{p'} < \lfloor \log_{p'} y \rfloor - 1$.

By (3.12), this implies that ℓ is not an integer multiple of $p'^{\lfloor \log_{p'} y \rfloor - 1}$ and therefore, by (3.9), $\mu' \cdot \ell$ is not an integer multiple of $p'^{\lfloor \log_{p'} y \rfloor}$. But then, we have a prime power $p'^{\lfloor \log_{p'} y \rfloor} \le y$, with $p' \le \sqrt{y}$ and $p' \ne p_i$, that does not divide $n' + \mu' \cdot \ell$, using (3.10). Therefore, $1^{n' + \mu' \cdot \ell} \notin \mathcal{L}_f$, which is a contradiction and completes the proof of the theorem. □

4. Separation results in the unary case. We now draw some important structural consequences from the previous results. Note that the alternating algorithm provided for $\mathcal{L}_f$ in Theorem 3.1 consists of a deterministic phase followed by a single universal branching. Hence, it can be run on a Π_1 machine. Moreover, a *middle* space×input head reversals bounded machine can be viewed as an *accept* device, which in turn is a special case of a *weak* machine. Thus we have the following corollary.

COROLLARY 4.1. *Let $\mathcal{L}_f$ be a unary language defined as above for any unbounded monotone increasing recursive function $f(n)$. Then $\mathcal{L}_f \in$ middle-Π_1SPACE×REVERSALS$^{1^*}(\log\log n \cdot f(n))$. Hence, for $c \in \{middle, accept, weak\}$, $\mathcal{L}_f \in c$-Π_1SPACE×REVERSALS$^{1^*}(\log\log n \cdot f(n))$.*

On the other hand, from Theorem 3.2 we get Corollary 4.2.

COROLLARY 4.2. *Let $\mathcal{L}_f$ be a unary language defined as above. Then $\mathcal{L}_f \notin$ weak-Σ_1SPACE × REVERSALS$(h(n))$ for any $h(n) \in o(\log n)$. Hence, for $c \in \{middle, accept, weak\}$ and any $h(n) \in o(\log n)$, $\mathcal{L}_f \notin c$-Σ_1SPACE × REVERSALS $(h(n))$.*

Combining the above two corollaries, we have the first separation for "well-behaved" functions $h(n)$ between $\log\log n$ and $\log n$ in Theorem 4.3.

THEOREM 4.3. *Let $h(n) \in o(\log n)$ be any recursive function such that $\frac{h(n)}{\log\log n}$ is unbounded and monotone increasing. Then, for $c \in \{middle, accept, weak\}$,*

$$c\text{-}\Pi_1\text{SPACE}\times\text{REVERSALS}^{1^*}(h(n)) \ne c\text{-}\Sigma_1\text{SPACE}\times\text{REVERSALS}^{1^*}(h(n))\,.$$

Proof. Clearly, if $h(n)$ is recursive, then so is $f(n) = \frac{h(n)}{\log\log n}$. Then, by Corollary 4.1, $\mathcal{L}_f$ belongs to c-Π_1SPACE × REVERSALS$^{1^*}(h(n))$ for each $c \in \{middle, accept, weak\}$. On the other hand, by Corollary 4.2, $\mathcal{L}_f$ is not in c-Σ_1SPACE × REVERSALS$^{1^*}(h(n))$, since $h(n) \in o(\log n)$. □

For further separations we need the fact that the class of regular languages is closed under complementation and that regular languages are accepted by one-way Turing machines working in constant space. Hence, from Theorem 3.2, we get Corollary 4.4.

COROLLARY 4.4. *Let $\mathcal{L}_f$ be a unary language defined as above. Then neither $\mathcal{L}_f$ nor $\mathcal{L}_f{}^{\mathrm{c}}$ are regular.*

As recalled in the Introduction, apart from *middle* alternation, for any other combination of determinism, nondeterminism, or alternation with the space notions defined in section 2, computational lower bounds for nonregular unary and general languages coincide and are optimal [4]. Thus, for *accept* alternating machines, Table 1.1 can be shrunk as shown in Table 4.1.

TABLE 4.1
Optimal lower bounds on $s(n) \cdot i(n)$ for accept *alternating and nondeterministic (Σ_1) Turing machines recognizing nonregular languages* [4].

	Unary and general languages
One-way alternating	$\log \log n$
One-way nondeterministic (Σ_1)	$\log n$
Two-way alternating	$\log \log n$
Two-way nondeterministic (Σ_1)	$\log n$

Now, from Table 4.1 (for proof, see [4, Thm. 6]), we get the following corollary.

COROLLARY 4.5. *Let L be a nonregular language. Then $L \notin$ accept-Σ_1SPACE$\times$ REVERSALS$(h(n))$ for any $h(n) \in o(\log n)$. Hence, for $c \in \{middle, accept\}$ and any $h(n) \in o(\log n)$, $L \notin c$-Σ_1SPACE$\times$REVERSALS$(h(n))$.*

This allows us to present some further separations for *middle* and *accept* complexity classes.

THEOREM 4.6. *Let $h(n) \in o(\log n)$ be any recursive function such that $\frac{h(n)}{\log \log n}$ is unbounded and monotone increasing. Then, for $c \in \{middle, accept\}$,*

$$c\text{-}\Pi_1\text{SPACE}\times\text{REVERSALS}^{1^*}(h(n)) \neq co\text{-}c\text{-}\Sigma_1\text{SPACE}\times\text{REVERSALS}^{1^*}(h(n))\,,$$
$$co\text{-}c\text{-}\Pi_1\text{SPACE}\times\text{REVERSALS}^{1^*}(h(n)) \neq c\text{-}\Sigma_1\text{SPACE}\times\text{REVERSALS}^{1^*}(h(n))\,.$$

Proof. Note that, by Corollary 4.5, the classes c-Σ_1SPACE$\times$REVERSALS$^{1^*}(h(n))$ and co-c-Σ_1SPACE$\times$REVERSALS$^{1^*}(h(n))$ coincide with the class of regular languages. On the other hand, for $f(n) = \frac{h(n)}{\log \log n}$, neither $\mathcal{L}_f$ nor $\mathcal{L}_f{}^{\mathrm{c}}$ are regular, by Corollary 4.4, and they belong, respectively, to c-Π_1SPACE$\times$REVERSALS$^{1^*}(h(n))$ and to co-c-Π_1SPACE$\times$REVERSALS$^{1^*}(h(n))$, by Corollary 4.1. □

Theorem 4.6 shows, for *middle* or *accept* SPACE$\times$REVERSALS complexity measure, that the class of the languages accepted by machines making only universal decisions does not coincide with the class of the complements of languages recognizable by machines making only existential decisions.

At this point, it is quite natural to investigate whether or not this separation can be extended even to the *weak* case. The argument of Theorem 4.6 cannot be applied here, since *weak*-Σ_1SPACE$\times$REVERSALS$(\log \log n)$ does contain unary nonregular languages [4]. We conjecture that even $\mathcal{L}_f{}^{\mathrm{c}}$ does not belong to *weak*-Σ_1SPACE$\times$ REVERSALS$^{1^*}(h(n))$ for a suitable function $h(n) \in o(\log n)$. Nevertheless, the "pumping" argument used to prove Theorem 3.2 does not work in the case of $\mathcal{L}_f{}^{\mathrm{c}}$. So, we leave the separation of *weak*-Π_1SPACE$\times$REVERSALS$^{1^*}(h(n))$ from *co-weak*-Σ_1SPACE$\times$REVERSALS$^{1^*}(h(n))$ as an open problem. However, in the next section, we will show how to solve this problem by using witness languages defined over a binary alphabet.

Finally, the separation of the higher levels of the alternating hierarchy from determinism can be obtained by recalling the following result in [4, Thm. 6].

THEOREM 4.7. *Let M be a* weak *deterministic (or nondeterministic) Turing machine recognizing a nonregular language within $s(n)$ space and $i(n)$ input head reversals. Then $s(n) \cdot i(n) \notin o(\log n)$ (or $s(n) \cdot i(n) \notin o(\log \log n)$, respectively). These bounds are optimal for both the unary and general cases.*

Using this result, we can easily get Theorem 4.8.

THEOREM 4.8. *Let $h(n)$ be a function satisfying $h(n) \in o(\log n) \cap \Omega(\log \log n)$.*

Then

weak-DSPACE$\times$REVERSALS$^{1^*}(h(n))$ *is properly included in*
weak-Σ_1SPACE$\times$REVERSALS$^{1^*}(h(n))$ *and in*
co-weak-Σ_1SPACE$\times$REVERSALS$^{1^*}(h(n))$.

If, moreover, $h(n)$ *is recursive, with* $\frac{h(n)}{\log\log n}$ *unbounded and monotone increasing, then*

weak-DSPACE$\times$REVERSALS$^{1^*}(h(n))$ *is properly included even in*
weak-Π_1SPACE$\times$REVERSALS$^{1^*}(h(n))$ *and in*
co-weak-Π_1SPACE$\times$REVERSALS$^{1^*}(h(n))$.

Proof. Just note that, by Theorem 4.7, *weak*-DSPACE $\times$ REVERSALS$(h(n))$ coincides with the class of regular languages for each $h(n) \in o(\log n)$. On the other hand, again by Theorem 4.7, *weak*-Σ_1SPACE $\times$ REVERSALS$^{1^*}(\log\log n)$ contains a nonregular unary language. Moreover, by Corollary 4.1, even *weak*-Π_1SPACE $\times$ REVERSALS$^{1^*}(h(n))$ contains unary nonregular languages whenever $h(n)$ satisfies the conditions of the theorem.

The remaining proper inclusions follow by observing that the class of nonregular languages is closed under complement. □

5. Separation results for general languages. In this section, we study separations in the case of languages defined over alphabets of at least two symbols. In particular, we show that all separations in section 4, proved in the unary case for "well-behaved" $h(n)$ between $\log\log n$ and $\log n$, hold in the general case for *any function* $h(n) \in o(\log n) \cap \Omega(\log\log n)$ and in particular for $\log\log n$.

Further, we get that, for general languages, *weak*-Π_1SPACE$\times$REVERSALS$(h(n))$ is separated from *co-weak*-Σ_1SPACE$\times$REVERSALS$(h(n))$. Symmetrically, we have *weak*-Σ_1SPACE$\times$REVERSALS$(h(n)) \neq$ *co-weak*-Π_1SPACE$\times$REVERSALS$(h(n))$ for any function $h(n) \in o(\log n) \cap \Omega(\log\log n)$.

In order to state these results, we consider the language $\mathcal{L}_1$ defined by

$$\mathcal{L}_1 = \{a^k b^{k+m} : m > 0 \text{ is a common multiple of all } r \leq k\}.$$

THEOREM 5.1. *Let* $\mathcal{L}_1$ *be the language defined as above. Then* $\mathcal{L}_1$ *can be accepted by a one-way* Π_1 *machine in* middle $\mathcal{O}(\log\log n)$ *space.*

Proof. The proof is similar to that of Theorem 3.2 in [22]. On input $x = a^k b^t$ of length $n = t + k$, the Π_1 machine M accepting $\mathcal{L}_1$ first counts, on the work tape, the number k of a's at the beginning of the input. Next, it moves the input head k positions to the right, rejecting if the right end marker is reached, i.e., if $t \leq k$. Finally, M universally generates all integers r less than or equal to k, and, by counting the length of the remaining part of the input modulo r, it checks whether each r divides $t - k$.

Clearly, M is a one-way machine. The space used by M on the input $x = a^k b^t$ is proportional to the space needed to represent k in binary notation, i.e., $\mathcal{O}(\log k)$. Moreover, if $x \in \mathcal{L}_1$, then $t - k$ is a common multiple of all $r \leq k$. Since the least common multiple of $\{1, 2, \ldots, k\}$ is bounded from below by d^k, for some constant $d > 1$ (for proof, see [23, Lem. 4.1.2]), we get $k \leq \log_d(t - k) \leq \log_d(t + k) = \log_d n$. Hence, $s(n) \in \mathcal{O}(\log\log n)$. □

COROLLARY 5.2. $\mathcal{L}_1 \in c$-Π_1SPACE$\times$REVERSALS$(\log\log n)$ *for* $c \in \{$*middle*, *accept*, *weak*$\}$.

We now state a lower bound on the product space$\times$input head reversals for *weak* nondeterministic Turing machines accepting $\mathcal{L}_1$.

THEOREM 5.3. *Let $\mathcal{L}_1$ be the language defined as above. Then, for any $h(n) \in o(\log n)$, $\mathcal{L}_1$ is not in weak-Σ_1SPACE$\times$REVERSALS$(h(n))$.*

Proof. Suppose, by contradiction, that $\mathcal{L}_1$ can be accepted by some nondeterministic machine in *weak* $s(n)$ space and $i(n)$ reversals, with $s(n) \cdot i(n) = h(n) \in o(\log n)$. Then $\mathcal{L}_1$ can even be accepted by a *one-way* nondeterministic machine M in *weak* $h(n)$ space. (The simulating machine nondeterministically guesses, at each input tape position, the crossing sequence of memory states that corresponds to an accepting computation path and checks the compatibility of the neighboring crossing sequences. Since the original *weak* machine is simultaneously $s(n)$ space and $i(n)$ input head reversals bounded, then *weak* $\mathcal{O}(s(n) \cdot i(n))$ space suffices for processing the input from left to right. For details, see [4, Lem. 5].)

The number of different memory states of M using no more than $h(n)$ work tape cells can be bounded by $c^{h(n)}$ for a suitable constant $c > 1$. Since $h(n) \in o(\log n)$, there exists $n_0 \in \mathbf{N}$ (cf. (3.5) in Theorem 3.2), such that

$$c^{h(n)} < \sqrt{n} \quad \text{for each } n \geq n_0\,. \tag{5.1}$$

Now, consider an input $x = a^k b^{k+m}$ of length $n = 2k + m \geq n_0$, such that m is the least common multiple of all $r \leq k$. Clearly, the string $x = a^k b^{k+m}$ belongs to $\mathcal{L}_1$. In addition, we choose $k > 0$ sufficiently large, so that $2k \leq d^k \leq m$. Here $d > 1$ is the constant used in the proof of Theorem 5.1; i.e., d^k is a lower bound for m, the least common multiple of $\{1, 2, \ldots, k\}$. Hence, b^m is a "dominant" portion of the input; i.e., we have

$$m \geq \frac{n}{2} > \sqrt{n}\,.$$

On input $x = a^k b^{k+m}$, M must have an accepting computation path $\mathcal{C}$ that uses at most $h(n)$ space. Since $m > \sqrt{n}$ and, by (5.1), the number of different memory states is bounded by $\sqrt{n}$, M must enter some memory state twice while traversing the segment b^m on the input. That is, $\mathcal{C}$ enters some configurations (q, d) and $(q, d+\ell)$, with $2k \leq d < d+\ell \leq n$.

But then M must also accept the input $a^k b^{k+m-\ell}$ by means of the accepting computation path $\mathcal{C}'$ obtained from $\mathcal{C}$ by "skipping" the segment between the configurations (q, d) and $(q, d+\ell)$. Since m is the *least* common multiple of all $r \leq k$ and $\ell > 0$, it turns out that $m - \ell$ is not a multiple of all $r \leq k$. Hence, M accepts $a^k b^{k+m-\ell} \notin \mathcal{L}_1$, which is a contradiction. □

Note that, as a consequence of Theorem 5.3, the language $\mathcal{L}_1$ is not regular. Using Corollary 5.2 and Theorem 5.3, we are now able to rewrite Theorem 4.3 for languages defined over general alphabets.

COROLLARY 5.4. *For each $h(n) \in o(\log n) \cap \Omega(\log \log n)$ and $c \in \{$middle, accept, weak$\}$,*

$$c\text{-}\Pi_1\text{SPACE}\times\text{REVERSALS}(h(n)) \neq c\text{-}\Sigma_1\text{SPACE}\times\text{REVERSALS}(h(n))\,.$$

Even Theorem 4.8 can easily be rewritten in the case of general alphabets as follows.

COROLLARY 5.5. *Let $h(n)$ be a function satisfying $h(n) \in o(\log n) \cap \Omega(\log \log n)$. Then weak-*DSPACE$\times$REVERSALS$(h(n))$ *is properly included in the following classes:*

weak-Σ_1SPACE$\times$REVERSALS$(h(n))$,

co-weak-Σ_1SPACE$\times$REVERSALS$(h(n))$,

weak-Π_1SPACE$\times$REVERSALS$(h(n))$,
co-weak-Π_1SPACE$\times$REVERSALS$(h(n))$.

Let us now compare the classes defined by machines making universal decisions with the classes of complements of languages accepted by machines making existential decisions. For sublogarithmic bounds in the unary case, these classes have been separated for the *middle* and *accept* modes (Theorem 4.6), while the separation is an open problem for the *weak* mode.

Here we prove this separation using witness languages defined over alphabets containing at least two symbols. To this purpose, we extend the lower bound of Theorem 5.3 to the language ${\mathcal{L}_1}^{\mathrm{c}}$. First, consider the following language:

$$\mathcal{L}_2 = \{a^k b^t : t \leq k \text{ or } \exists r \leq k \text{ which does not divide } t-k\}\,.$$

Note that $\mathcal{L}_2 = {\mathcal{L}_1}^{\mathrm{c}} \cap \{a\}^*\{b\}^*$.

THEOREM 5.6. *Let $\mathcal{L}_2$ be the language defined as above. Then, for any $h(n) \in o(\log n)$, $\mathcal{L}_2$ is not in weak-Σ_1SPACE$\times$REVERSALS$(h(n))$.*

Proof. As in Theorem 5.3, suppose, by contradiction, that $\mathcal{L}_2$ can be accepted by some nondeterministic machine in *weak* $s(n)$ space and $i(n)$ input head reversals, with $s(n) \cdot i(n) = h(n) \in o(\log n)$. Then $\mathcal{L}_2$ can even be accepted by a *one-way* nondeterministic machine M in *weak* $h(n)$ space [4, Lem. 5]. The number of different memory states of M using at most $h(n)$ work tape cells is bounded by $c^{h(n)}$ for a suitable constant $c > 1$. Since $h(n) \in o(\log n)$, there exists $n_0 \in \mathbf{N}$, such that

$$c^{h(n)} < \frac{n}{2} \quad \text{for each } n \geq n_0\,. \tag{5.2}$$

Now, for some even $n \geq n_0$, consider the string $x = a^{\frac{n}{2}} b^{\frac{n}{2}}$, easily seen to be in $\mathcal{L}_2$. Hence, M must have an accepting computation path on the input x, consisting of memory states that use at most space $h(n)$. Since, by (5.2), the number of different memory states is bounded by $\frac{n}{2}$, this computation path enters a *loop* while traversing the suffix $b^{\frac{n}{2}}$. More precisely, M enters some memory state twice, in some configurations (q, d) and $(q, d+\ell)$, with $d > \frac{n}{2}$ and $\ell > 0$. Thus, it is not hard to see that M must also accept the strings of the form

$$a^{\frac{n}{2}} b^{\frac{n}{2}+\mu\cdot\ell} \in \mathcal{L}_2 \quad \text{for each } \mu \in \mathbf{N}\,. \tag{5.3}$$

Now, let $\mu' = \left(\frac{n}{2}\right)!$. It is easy to see that $\mu' \cdot \ell > 0$ and that each integer $r \leq \frac{n}{2}$ divides $\mu' \cdot \ell$. That is, the string $a^{\frac{n}{2}} b^{\frac{n}{2}+\mu'\cdot\ell}$ does not belong to $\mathcal{L}_2$, which contradicts (5.3). □

Using Theorem 5.6, we are now able to show Corollary 5.7.

COROLLARY 5.7. *Let $\mathcal{L}_1$ be the language defined as above. Then the complement of $\mathcal{L}_1$ is not in weak-Σ_1SPACE$\times$REVERSALS$(h(n))$ for any $h(n) \in o(\log n)$.*

Proof. Should ${\mathcal{L}_1}^{\mathrm{c}}$ be in *weak*-Σ_1SPACE$\times$REVERSALS$(h(n))$, for some $h(n) \in o(\log n)$, then so would $\mathcal{L}_2 = {\mathcal{L}_1}^{\mathrm{c}} \cap \{a\}^*\{b\}^*$, which contradicts Theorem 5.6. □

Finally, by combining Corollaries 5.2 and 5.7, we get Theorem 5.8.

THEOREM 5.8. *Let $h(n)$ be a function satisfying $h(n) \in o(\log n) \cap \Omega(\log\log n)$. Then, for $c \in \{middle, accept, weak\}$,*

$$c\text{-}\Pi_1\text{SPACE}\times\text{REVERSALS}(h(n)) \neq co\text{-}c\text{-}\Sigma_1\text{SPACE}\times\text{REVERSALS}(h(n))\,,$$
$$c\text{-}\Sigma_1\text{SPACE}\times\text{REVERSALS}(h(n)) \neq co\text{-}c\text{-}\Pi_1\text{SPACE}\times\text{REVERSALS}(h(n))\,.$$

Acknowledgments. The authors wish to thank an anonymous referee for helpful comments and remarks.

SEPARATOR-BASED SPARSIFICATION II: EDGE AND VERTEX CONNECTIVITY*

DAVID EPPSTEIN†, ZVI GALIL‡, GIUSEPPE F. ITALIANO§, AND THOMAS H. SPENCER¶

Abstract. We consider the problem of maintaining a dynamic planar graph subject to edge insertions and edge deletions that preserve planarity but that can change the embedding. We describe algorithms and data structures for maintaining information about 2- and 3-vertex-connectivity, and 3- and 4-edge-connectivity in a planar graph in $O(n^{1/2})$ amortized time per insertion, deletion, or connectivity query. All of the data structures handle insertions that keep the graph planar without regard to any particular embedding of the graph. Our algorithms are based on a new type of sparsification combined with several properties of separators in planar graphs.

1. Introduction.

Sparse certificates, small graphs that retain some property of a larger graph, appear often in graph theory, especially in problems of edge and vertex connectivity [2, 13, 31, 35]. The main motivation for studying sparse certificates lies in the fact that they are effective tools for speeding up many graph algorithms. To check whether a graph G has a given property $\mathcal{P}$, one can first compute a sparse certificate $\mathcal{C}$ for property $\mathcal{P}$ and then run an algorithm for $\mathcal{P}$ on the certificate rather than on G itself. This is favorable whenever computing certificates is faster than checking property $\mathcal{P}$. This method has led to improved algorithms for testing k-edge- and k-vertex-connectivity sequentially [16, 31, 35] and in parallel [2], for finding three independent spanning trees [1], and for reliability in distributed networks [26]. With the *sparsification* technique [8], sparse certificates additionally became an important tool for speeding up dynamic graph algorithms, in which edges may be inserted into and deleted from a graph while some graph property must be maintained throughout the sequence of modifications.

While sparsification has many applications in algorithms for general graphs, it seemed unlikely that it could be used to speed up algorithms for special families of graphs that are already sparse, such as planar graphs. However, algorithms for planar graphs are especially important, as these graphs arise frequently in applications. In the companion paper [11] we developed a new, general technique for dynamic planar graph problems, based upon the notion of *compressed certificates*, which have both fewer edges and fewer vertices than the original graph. We expanded the notion of certificate to a definition for graphs in which a subset of the vertices is denoted as *interesting*; these *compressed certificates* may reduce the size of the graph by removing uninteresting vertices. Note that this is a generalization of the previous certificates, as compressed certificates reduce to sparse certificates in the special case where all the vertices are interesting. Using the notion of compressed certificates, we defined a type of *separator-based sparsification* based on *separators*, small sets of vertices the removal of which splits the graph into roughly equal-size components. We then applied separator-based sparsification to maintain information about the minimum spanning forest, connectivity, and 2-edge-connectivity of a planar graph. We further showed how to maintain a graph subject to *arbitrary* edge insertions and deletions, with queries that test whether the graph is currently planar or whether a potential new edge would violate planarity.

In this paper we extend these ideas in several ways. Our first constribution is to adapt separator-based sparsification from the companion paper [11] to work on more general certificates and properties. Namely, we extend the notion of compressed certificates to properties that can be defined with respect to a particular pair of vertices rather than on the whole graph. We refer to these as *local* certificates as opposed to *global* certificates. The most general notion of certificate is a *full* certificate, which is at the same time a local and global certificate.

Our second contribution is to prove a number of structural properties of certificates for edge connectivity in general graphs. Among these properties, we give necessary and sufficient conditions for a graph to be a local or global certificate of k-edge-connectivity for any k. This characterization is not only a powerful algorithmic tool, as we show in this paper, but also contributes a new insight into the structural properties of edge connectivity and improves our understanding of certificates. We believe that these structural properties may be of independent interest and find applications to other graph-theoretical areas.

Thirdly, as a first application of our compressed certificates, we use them to develop dynamic planar graph algorithms. We maintain information about 3- and 4-edge-, and 2- and 3-vertex-connectivity in a planar graph during an intermixed sequence of edge deletions, edge insertions that keep the graph planar, and connectivity queries in $O(n^{1/2})$ amortized time per operation. All our algorithms improve previous bounds: for 2- and 3-vertex- and 3-edge-connectivity, the best previous time bound was $O(n^{2/3})$ amortized [8, 19, 21], while for 4-edge-connectivity nothing better than testing the graph from scratch after each update was known. These bounds apply to problems in which insertions need not respect a fixed embedding of the graph; a number of other papers have worked on dynamic graph problems such as minimum spanning forests, connectivity, and planarity testing for graphs with a fixed planar embedding [12, 14, 15, 18, 19, 22, 21, 24, 32, 33].

Finally, our methods apply to static as well as dynamic graph problems. A general certificate construction method from our companion paper, together with the certificates defined here, gives a unified method of testing 3- and 4-edge-, and 2- and

3-vertex-connectivity in planar graphs, in linear time. In recent work, Eppstein [7] has shown how to compute k-edge- or k-vertex-connectivity in planar graphs in linear time for any constant k.

The remainder of this paper consists of the following sections. Section 2 contains basic definitions. In section 3 we recall some properties of separator-based sparsification and compressed certificates from reference [11]. In section 4 we prove the properties and describe the tools we will be using for our certificates for edge connectivity. In section 5 compressed certificates for edge connectivity are developed, and our bounds for 3- and 4-edge-connectivity are proved. In section 6 sparsification is applied to fully dynamic 2- and 3-vertex-connectivity by using compressed certificates already available in the literature. Finally, in section 7 we list some open problems and concluding remarks.

2. Preliminaries. In this section we introduce the notions of vertex and edge connectivity of a graph. Next, we review a generalized tree, due to Dinitz, Karzanov, and Lomonosov [4], that describes an elegant decomposition of a graph using its connectivity edge-cuts.

2.1. Edge and vertex connectivity. Let $G = (V, E)$ be an undirected graph, possibly with parallel edges. Throughout the paper, we denote by m the number of edges and by n the number of vertices in G. Given an integer $k \geq 2$, a pair of vertices $\langle u, v\rangle$ is said to be *k-edge-connected* in G if the removal of any $(k-1)$ edges in G leaves u and v connected. It is well known that u and v are k-edge-connected if and only if there are k edge-disjoint paths between u and v. k-edge-connectivity is an equivalence relationship, and we denote it by $\equiv_k$; i.e., if a pair of vertices $\langle x, y\rangle$ is k-edge-connected, we write $x \equiv_k y$. The vertices of a graph G are partitioned by this relationship into equivalence classes that we call *k-edge-connected classes*. Note that according to this definition a k-edge-connected class of G is a subset of vertices of G. G is said to be *k-edge-connected* if the removal of any $(k-1)$ edges leaves G connected. As a result of these definitions, G is k-edge-connected if and only if any two vertices of G are k-edge-connected. An edge set $E' \subseteq E$ is an *edge-cut for vertices x and y* if the removal of all the edges in E' disconnects G into two graphs, one containing x and the other containing y. An edge-set $E' \subseteq E$ is an *edge-cut for G* if the removal of all the edges in E' disconnects G into two graphs. An edge-cut E' for G (for x and y, respectively) is *minimal* if removing any edge from E' and re-inserting it back into G reconnects G (x and y, respectively). The cardinality of an edge-cut E', denoted by $|E'|$, is equal to the number of edges in E'. An edge-cut E' for G (for x and y, respectively) is said to be a *minimum edge-cut* or a *connectivity edge-cut*, if there is no other edge-cut E'' for G (for x and y, respectively) such that $|E''| < |E'|$. A connectivity edge-cut of cardinality 1 is called a *bridge*. The graphs left after deleting all the bridges of G are called the *2-edge-connected components* of G. Note the difference between 2-edge-connected classes and 2-edge-connected components: a 2-edge-connected class is a *subset of vertices* of G, while a 2-edge-connected component is a *subgraph* of G. However, 2-edge-connected classes and 2-edge-connected components are strictly related: indeed, a 2-edge-connected component is a subgraph of G induced by a 2-edge-connected class.

We now list some well-known properties that are an immediate consequence of the previous definitions and that will be used throughout this paper. First, any connectivity edge-cut must be minimal and must disconnect G exactly into two graphs. Furthermore, all the connectivity edge-cuts for G must have the same cardinality. Thus, the notion of *cardinality of the connectivity edge-cuts for G* is well defined: it

gives exactly the minimum number of edges whose deletion disconnects G. Similarly, given any two vertices x and y in G, all the connectivity edge-cuts for x and y have the same cardinality, and we speak about *the cardinality of the connectivity edge-cuts for x and y*. Given a graph G, the *edge connectivity of G* is defined as the cardinality of the connectivity edge-cuts for G, i.e., the minimum number of edges whose deletion disconnects G. We denote the edge connectivity of G by $\lambda(G)$: note that G is k-edge-connected if and only if $k \leq \lambda(G)$. Similarly, given any two vertices x and y in G, the *edge connectivity between x and y in G* is defined as the cardinality of the connectivity edge-cuts for x and y, i.e., the minimum number of edges whose deletion disconnects x and y in G. We denote the edge connectivity between x and y in G by $\lambda_{x,y}(G)$. As a consequence of this definition, $x \equiv_k y$ if and only if $k \leq \lambda_{x,y}(G)$.

Analogous definitions can be given for the case of vertex connectivity. A vertex set $V' \subset V$ (respectively, $V' \subseteq V - \{x, y\}$) is a *vertex-cut* for G (respectively, for vertices x and y) if the removal of all the vertices in V' disconnects G (respectively, x and y). The cardinality of a vertex-cut V', denoted by $|V'|$, is given by the number of vertices in V'. A vertex-cut V' for G (for x and y, respectively) is said to be a *minimum vertex-cut* or a *connectivity vertex-cut* if there is no other vertex-cut V'' for G (x and y, respectively) such that $|V''| < |V'|$. Two vertices x and y are k-vertex-connected if and only if a minimum vertex-cut for x and y contains at least k vertices. G is said to be *k-vertex-connected* if all its pairs of vertices are k-vertex-connected; equivalently, the minimum vertex-cut of G has cardinality k or more. A minimum vertex-cut of cardinality 1 is called an *articulation point*. Again, two vertices x and y in G are k-vertex-connected if and only if there are at least k vertex-disjoint paths between x and y.

2.2. The cactus tree. We now describe a tree-like decomposition of a k-edge-connected graph G into its $(k+1)$-edge-connected classes, which can be found in the beautiful work of Dinitz, Karzanov, and Lomonosov [4], and which we will be using throughout this paper. The generalized tree that describes this decomposition is called the *cactus tree*: note that it need not be a standard tree. We do not give many details here, referring the interested reader to references [4, 28]. The heart of this decomposition is the *Crossing Lemma* of [4], which can be informally stated as follows. Let G be a graph of edge connectivity λ: if any two λ-edge-cuts of G divide $V(G)$ into four (nonempty) parts, then shrinking these four parts produces a super-cycle having four super-nodes and exactly $\lambda/2$ parallel edges between any two neighbor super-nodes.

We mention some consequences of the Crossing Lemma, referring to [4, 28] for the full details and explanations. First of all, for λ odd, $\lambda/2$ is not an integer. Thus, according to the Crossing Lemma, for λ odd two different λ-edge-cuts of G cannot divide $V(G)$ into four nonempty parts. The Crossing Lemma also implies that there can be only $O(n)$ connectivity edge-cuts if λ is odd, and $O(n^2)$ of them if λ is even [4]. The set of all the connectivity edge-cuts of G can be compactly represented by a "tree-like" graph with weights on the edges, called the *cactus tree of G* and denoted by $\mathcal{T}(G)$, which can be constructed in $O(m + \lambda^2 n \log n)$ time [17]. Each vertex in G maps to exactly one node in $\mathcal{T}(G)$, so that any node of $\mathcal{T}(G)$ corresponds to a (possibly empty) subset of vertices from G. An edge-cut $(\mathcal{A}, \bar{\mathcal{A}})$ in $\mathcal{T}(G)$ corresponds to an edge-cut $(A, \bar{A})$ of G, where A consists of all the vertices of G that are mapped into nodes of $\mathcal{A}$. A λ-cut of $\mathcal{T}(G)$ is an edge-cut of $\mathcal{T}(G)$ of total weight λ. Each minimal edge-cut of $\mathcal{T}(G)$ (i.e., an edge-cut from which no edge can be removed) is also a λ-cut in $\mathcal{T}(G)$, and it corresponds to a connectivity edge-cut in G. Each connectivity edge-cut in G

corresponds to one or more λ-cuts in $\mathcal{T}(G)$. Thus, the minimal edge-cuts of $\mathcal{T}(G)$ compactly represent all the connectivity edge-cuts of G.

For λ odd, the cactus tree is particularly simple: it is actually a tree, all its edges are of weight λ, and any minimal edge-cut of $\mathcal{T}(G)$ is obtained by removing one of its edges. For λ even, we can have crossing connectivity edge-cuts, and $\mathcal{T}(G)$ is a tree of cycles. Namely, $\mathcal{T}(G)$ consists of cycles, such that any two cycles have at most one single node in common; thus, no edge of $\mathcal{T}(G)$ can be in more than one cycle. Every edge in a cycle is called a *cycle-edge* and has weight $\lambda/2$. Note that there can be cycles consisting only of two edges: we refer to these cycles as 2-*cycles*. Minimal edge-cuts of $\mathcal{T}(G)$ are obtained by removing any pair of cycle-edges that lies on the same cycle. Hence, a 2-cycle defines only one minimal edge-cut of $\mathcal{T}(G)$, while a cycle with $p \geq 3$ edges defines exactly $p(p-1)/2$ distinct minimal edge-cuts of $\mathcal{T}(G)$. The cactus tree of a graph is basically unique, up to the following convention: if λ is even, either three nodes can be in a triangle of cycle-edges, or they can all be joined to another new node with 2-cycles.

We now describe in more detail the cactus trees we will be using, namely, the cases $\lambda = 1, 2, 3$. The interested reader can find further details on cactus trees in references [4, 28]. If G has edge connectivity $\lambda = 1$, the cactus tree is actually a tree, called the *bridge-block tree of* G: its nodes correspond to the 2-edge-connected classes (and thus components) of G, and its edges to the bridges of G. For $\lambda = 2$, the cactus tree is a tree of cycles: indeed, if we shrink the 3-edge-connected classes of a 2-edge-connected graph, each biconnected component of the shrunken graph is a simple cycle. Even though the shrunken graph is not a tree, it can easily be represented as such (see Figure 1).

For $\lambda = 3$ the cactus tree is actually a tree having one node for each 4-edge-connected class and one edge for each 3-edge-cut. There might also be nodes in the cactus that correspond to no 4-edge-connected classes of G, as shown in Figure 2. We refer the interested reader to [4, 28] for a more detailed explanation about these nodes and only mention here that they are needed to keep the correspondence between minimal cuts of $\mathcal{T}(G)$ and connectivity edge-cuts of G.

3. Separator-based sparsification. *Sparsification* was introduced in [8] as a technique for designing fully dynamic graph algorithms, in which edges may be inserted into and deleted from a graph while some graph property must be maintained. This technique is based upon a suitable combination of graph decomposition and edge elimination and can be described as follows. Let G be a graph with m edges and n vertices: we partition the edges of G into a collection of sparse subgraphs (i.e., subgraphs with $O(n)$ edges) and summarize the relevant information for each subgraph in an even sparser *certificate*. Intuitively, a certificate for a given property is a smaller graph that retains the same property (we will give a more precise definition later). We merge certificates in pairs, producing larger subgraphs which we make sparse by again applying the certificate reduction. The result is a balanced binary tree in which each node is represented by a sparse certificate. Each edge insertion or deletion causes changes in $\log(m/n)$ tree nodes, but each such change occurs in a subgraph with $O(n)$ edges, reduced from the m edges in the original graph. This reduces a time bound of $T(m, n)$ to $O(T(O(n), n) \log(m/n))$. Using a more sophisticated approach (described in [9]), we can eliminate the logarithmic factor from this bound. This reduces the time bounds for many dynamic graph problems, including vertex and edge connectivity and minimum spanning forests, to exactly match the bounds known for sparse graphs.

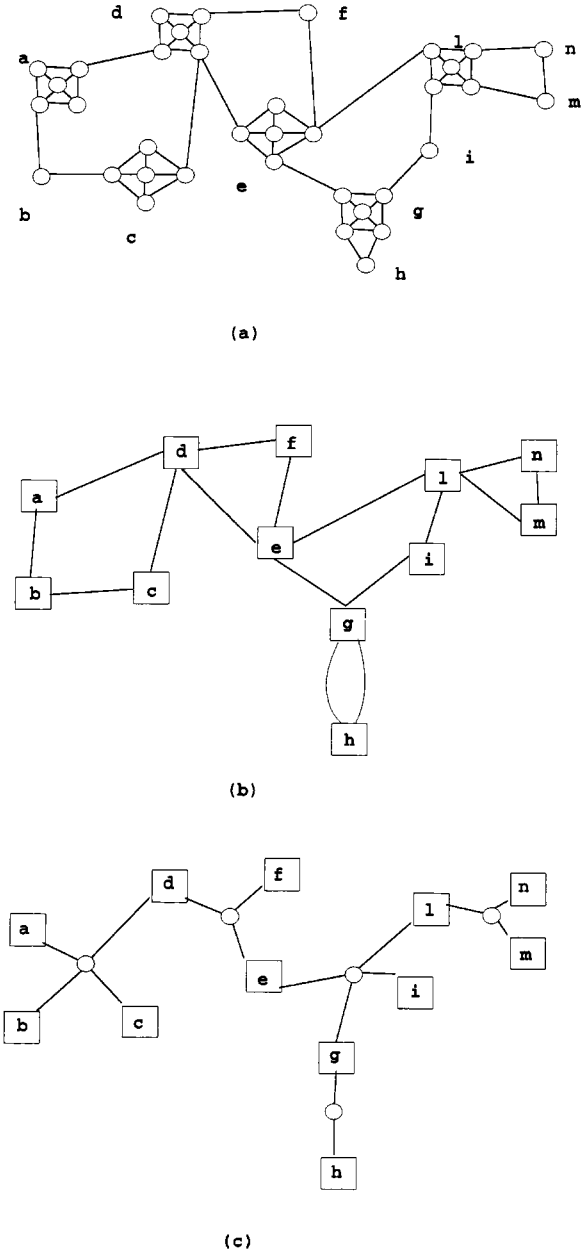

FIG. 1. (a) *A 2-edge-connected graph G;* (b) *the cactus tree of G;* (c) *the tree obtained by replacing each cycle of the cactus tree with a new vertex.*

In the companion paper [11], we developed a new, general technique for dynamic planar graph problems. In all these problems, we deal with either arbitrary or planarity-preserving insertions and therefore allow changes of the embedding. The new ideas behind this technique are the following. We expand the notion of a certificate to a definition for graphs in which a subset of the vertices is denoted as *interesting*; these *compressed certificates* may reduce the size of the graph by remov-

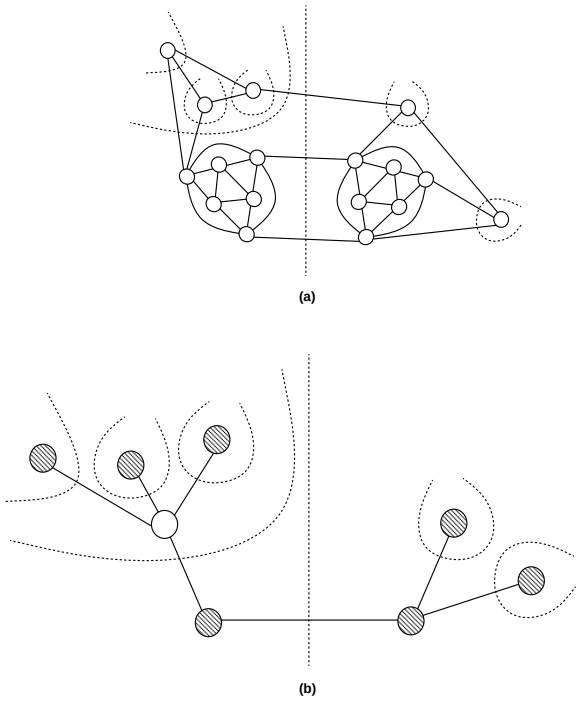

FIG. 2. *A 3-edge-connected graph G and its cactus tree. The 3-edge-cuts of G are shown as dashed lines. Nodes of the cactus not corresponding to 4-edge-connected classes of G are shown in white.*

ing uninteresting vertices. Using this notion of compressed certificates, we define a type of sparsification based on *separators*, small sets of vertices the removal of which splits the graph into roughly equal-size components. Recursively finding separators in these components gives a *separator tree* which we also use as our *sparsification tree*; the interesting vertices in each certificate will be those vertices used in separators at higher levels of the tree. We introduce the notion of a *balanced separator tree*, which also partitions the interesting vertices evenly in the tree. In [11], we show how to compute such a tree in linear time and how to maintain it dynamically. We call this technique *separator-based sparsification*.

Separator-based sparsification, as described in [11], applies to properties of the entire graph (such as planarity). However, there are some other properties that can be described either as a global graph property or in terms of pairs of vertices. More generally, let $\mathcal{P}$ a property of graphs: we say that $\mathcal{P}$ is *local* if it can be defined with respect to a particular pair (x, y) of vertices in the graph. A query related to property $\mathcal{P}$ is referred to as *global* if $\mathcal{P}$ is meant for the entire graph and is referred to as *local* if $\mathcal{P}$ is meant for a particular pair (x, y). Examples of local properties are edge and vertex connectivity, which are defined both for the entire graph (*global property*) and for any pair of vertices in the graph (*local property*). While maintaining a graph under edge insertions and deletions, at any time we might ask queries on whether the entire graph is k-vertex- (edge-) connected (*global k-connectivity query*), or rather, we might want to ask queries on whether any two given vertices are k-vertex- (edge-) connected (*local k-connectivity query*).

In this paper, we extend separator-based sparsification to work also on local properties. We first need the notion of *certificate* from [11], for which we adopt the new terminology of *global certificate*,

DEFINITION 3.1. *Let graph property $\mathcal{P}$ be fixed and let G be a graph with a set $X \subseteq V(G)$. A* global certificate for X in G *is a graph C, with $X \subseteq V(C)$, such that for any H with $V(G) \cap V(H) \subseteq X$, $V(C) \cap V(H) \subseteq X$, $G \cup H$ has property $\mathcal{P}$ if and only if $C \cup H$ has the property.*

The set X in Definition 3.1 represents the interesting vertices of G. According to this definition, a global certificate C captures the behavior of the entire graph G with respect to additions that only touch the interesting vertices. For instance, let $\mathcal{P}$ be k-edge-connectivity and let C be a global certificate for X in G: then, for any H such that $V(H) \cap V(G) \subseteq X$, $C \cup H$ is k-edge-connected if and only if $G \cup H$ is k-edge-connected. Note that when $X = V(G)$, this definition reduces to the one in [8].

For local properties, we need a slightly different notion of certificate, which we call a *local certificate*.

DEFINITION 3.2. *Let $\mathcal{P}$ be a local property of graphs and let G be a graph with a set $X \subseteq V(G)$. A graph C is a* local certificate *of $\mathcal{P}$ for X in G if and only if for any H with $V(H) \cap V(G) \subseteq X$, $V(C) \cap V(H) \subseteq X$, and any x and y in $V(H)$, $\mathcal{P}$ is true for (x, y) in $G \cup H$ if and only if it is true for (x, y) in $C \cup H$.*

Note that a local certificate C has to preserve the behavior of the property not only with respect to the interesting vertices in G, but also with respect to all vertices in H. For instance, let $\mathcal{P}$ be k-edge-connectivity, and let C be a local certificate for X in G: then, for any H such that $V(H) \cap V(G) \subseteq X$, and any $x, y \in V(H)$, $x \equiv_k y$ in $C \cup H$ if and only if $x \equiv_k y$ in $G \cup H$.

The two notions of global and local certificate can be combined together to yield a stronger notion of certificate.

DEFINITION 3.3. *Let graph property $\mathcal{P}$ be fixed and let G be a given graph with $X \subseteq V(G)$. A* full certificate for X in G *is graph C, which is both a global and a local certificate for X in G.*

For instance, let $\mathcal{P}$ be k-edge-connectivity and let C be a full certificate for X in G: then, for any H such that $V(H) \cap V(G) \subseteq X$, we have that

(i) $C \cup H$ is k-edge-connected if and only if $G \cup H$ is k-edge-connected; and
(ii) for any $x, y \in V(H)$, $x \equiv_k y$ in $C \cup H$ if and only if $x \equiv_k y$ in $G \cup H$.

Note that both conditions are needed, since neither (i) implies (ii), nor (ii) implies (i). As an example of full certificate, let $\mathcal{P}$ be connectivity. We partition the vertices of X into their connected components in G and replace each connected component by any spanning tree. We claim that this yields a full certificate for connectivity. Indeed, if two vertices in $G \cup H$ are connected by a path, then at each point the path switches between edges of G and edges of H, it will pass through a vertex $x \in X$, and the portion of the path in G can be replaced by a path through the spanning forest of the partition set containing x. Thus vertices are connected in $G \cup H$ if and only if they are connected in $C \cup H$ (i.e., C is a local certificate) and $G \cup H$ is connected if and only if $C \cup H$ is connected (i.e., C is a global certificate). This shows that C is indeed a full certificate.

We will use the term certificates to refer in general to certificates of all types (full, global, or local). We will use explicitly the terms full certificates, global certificates, and local certificates when we refer to these kinds of certificates only. Our method hinges upon the notion of *compressed* certificate.

DEFINITION 3.4. *Let graph property $\mathcal{P}$ be fixed and let G be a given graph with $X \subseteq V(G)$. A* compressed certificate for X in G *is a certificate C for X in G, such that $|C| = O(|X|)$.*

Some basic lemmas about global certificates were proved in the companion paper [11]. They can be easily extended to local and full certificates as well.

LEMMA 3.1 (see [11]). *Let C be a certificate for some set X in a given graph G and let C' be a certificate for X in C. Then C' is also a certificate for X in G.*

LEMMA 3.2 (see [11]). *Let C' be a certificate for X' in G' and let C'' be a certificate for X'' in G'', with $V(G') \cap V(G'') \subseteq X' \cap X''$. Then $C' \cup C''$ is a certificate for $X' \cup X''$ in $G' \cup G''$.*

The following lemma is an immediate consequence of the definition of certificate.

LEMMA 3.3. *Let C be a certificate for some set X in a given graph G. Then C is also a certificate for any set $X' \subset X$ in G.*

Proof. Fix any $X' \subset X$. Let H be given, with $V(H) \cap V(G) \subseteq X'$. Since $X' \subset X$, we have that $V(H) \cap V(G) \subset X$. We claim that this is enough to prove the lemma. Indeed, let $\mathcal{P}$ be the property for which C is a certificate. If C is a global certificate for X in G, it follows that $C \cup H$ has property $\mathcal{P}$ if and only if $G \cup H$ has property $\mathcal{P}$. Thus, C is a global certificate for X' in G. If C is a local certificate for X in G, it follows that, given any two vertices $x, y \in V(H)$, $\mathcal{P}$ is true for x and y in $C \cup H$ if and only if $\mathcal{P}$ is true for x and y in $G \cup H$. Thus, C is a local certificate for X' in G too. If C is both a local and a global certificate for X in G, then by the previous argument, C will be both a local and a global certificate for X' in G. □

We showed in [11] that, under certain weak assumptions, the existence of compressed certificates for all G and X is sufficient to prove the existence of a linear-time algorithm for computing such certificates. We require our certificates to satisfy the following additional property.

DEFINITION 3.5. *Given a graph G and a set of interesting vertices X, we say that a certificate C for X in G* preserves planarity *if, for any H such that $V(H) \cap V(G) \subseteq X$, if $G \cup H$ is planar, $C \cup H$ will also be planar.*

According to Definition 3.5, $C \cup H$ may be planar even when $G \cup H$ is not. As examples of planarity-preserving certificates, C may itself be a certificate for planarity; alternately, C may be a subgraph or minor of G.

The following lemma is proved in the companion paper [11] for global certificates and the proof can be easily extended to local and full certificates.

LEMMA 3.4 (see [11]). *Let $\mathcal{P}$ be a property for which there exist compressed certificates that preserve planarity. Then in linear time we can compute a compressed certificate for $\mathcal{P}$.*

We now describe an abstract version of our sparsification technique. We first consider global certificates (used to maintain global graph properties) and then show how the same technique can be made to work with local certificates, used to maintain local properties.

Let $\mathcal{P}$ be a property of planar graphs for which we can find compressed global certificates in time $T(n) = \Omega(n)$ and such that we can construct a data structure for testing property $\mathcal{P}$ in time $P(n)$ which can answer queries in time $Q(n)$. Then we wish to use these global certificates to maintain $\mathcal{P}$ quickly.

We construct a separator tree for the graph, by finding a set of $cn^{1/2}$ vertices (for some constant c) which splits the remaining graph into two components of less than $2n/3$ vertices each, and repeatedly split each component until there are $O(n^{1/2})$ components of size $O(n^{1/2})$ each; we call these the *leaf components*. This can all

be done in $O(n)$ time [23]. The resulting tree has height $O(\log n)$. When an edge connects two separator vertices, we arbitrarily choose which component to include it in, so each edge is included in a unique leaf component. Each time we insert a new edge, we will include its two endpoints in the separator for the node in the tree (if one exists) for which the two vertices are in the two separate components. After $O(n^{1/2})$ insertions, we reconstruct the separator tree, in amortized time $O(n^{1/2})$ per insertion.

At each node in the tree, the *interesting vertices* are those that are used either in the separator for that node or for separators at higher levels in the tree. Note that there will initially be at most

$$cn^{\frac{1}{2}} \sum_{i=0}^{\lceil \log n \rceil} \left(\frac{2}{3}\right)^{\frac{i}{2}} = O\left(n^{\frac{1}{2}}\right)$$

interesting vertices per tree node, and at most $O(n^{1/2})$ interesting vertices can be added by insertions before we reconstruct the tree. By the construction above, leaf components can share only interesting vertices. Furthermore, a vertex that is not interesting (in any leaf component) belongs to exactly one leaf component.

Each tree node corresponds to a subgraph which will be represented by a compressed global certificate for its interesting vertices. We form this global certificate by taking the union of the two compressed global certificates for the two daughter nodes (which by Lemma 3.2 is a global certificate for the graph at the node itself), and then computing a compressed global certificate of this union (which by Lemma 3.1 is also a global certificate for the node). We construct the data structure for testing property $\mathcal{P}$ using the global certificate at the tree root. This allows us to test property $\mathcal{P}$ in $Q(O(n^{1/2}))$ time.

When we reconstruct the separator tree, we must also reconstruct the global certificates, in $T(O(n^{1/2}))$ time per tree node. There are $O(n^{1/2})$ tree nodes, and we reconstruct after every $O(n^{1/2})$ insertions, so the amortized time per insertion is $T(O(n^{1/2}))$.

When we perform an insertion of an edge (x, y) that does not reconstruct the separator tree, we may move the two vertices x and y into the separator of a tree node N; then in all nodes descending from N and containing either of the two vertices, x and y may become newly interesting, and we must recompute the global certificates. However, this can happen only if either x or y was not interesting already. In other words, only the global certificates in the path between N and at most two leaves need to be updated. Furthermore, we must also recompute certificates for all tree nodes containing the newly inserted edge: these are exactly the nodes between N and the root of the separator tree. In either case, $O(\log n)$ tree nodes need recomputation, and the time to recompute certificates in each node is $T(O(n^{1/2}))$. Finally, we reconstruct the data structure for testing property $\mathcal{P}$ in the global certificate at the tree root in $P(O(n^{1/2}))$ time. The implementation of deletion is similar; here, too, we recompute global certificates in $O(\log n)$ nodes, in the same time bound.

Thus there is a fully dynamic algorithm for maintaining $\mathcal{P}$, which takes $P(O(n^{1/2}))$ $+ T(O(n^{1/2}))O(\log n)$ amortized time per edge insertion or deletion, and $Q(O(n^{1/2}))$ time per query. The amortized bound can be made worst-case by standard techniques of keeping two copies of the data structure, one of which can be gradually rebuilt while the other is being used.

In the companion paper [11], we develop a more complicated variant of this technique that allows us to save an $O(\log n)$ factor in the time bound above. The basic

idea is to use a separator tree which also partitions the interesting vertices evenly in the tree. In this way the nodes at lower levels of the separator tree will be able to have certificates smaller than $O(n^{1/2})$. In order to maintain this property of the separator tree we must then recompute lower-level separators after smaller numbers of updates.

DEFINITION 3.6. *Let G be a planar graph. A* balanced separator tree for G *is a separator tree such that a node at level i, $i \geq 0$, has at most $ab^i n^{1/2}$ interesting vertices, for some constants $a > 0$ and $0 < b < 1$.*

The proofs of the following two theorems are in [11].

THEOREM 3.1 (see [11]). *A balanced separator tree can be constructed in linear time.*

THEOREM 3.2 (see [11]). *Let $\mathcal{P}$ be a graph property for which we can find compressed global certificates in time $T(n) = \Omega(n)$ and such that we can construct, in $P(n)$ time, a data structure that tests property $\mathcal{P}$ in $Q(n)$ time. Then there is a fully dynamic algorithm for maintaining $\mathcal{P}$ in a planar graph subject to insertions and deletions preserving planarity, which takes $P(O(n^{1/2})) + T(O(n^{1/2}))$ amortized time per edge insertion or deletion and $Q(O(n^{1/2}))$ time per global query.*

We next describe how sparsification may apply to local properties such as vertex and edge connectivity.

THEOREM 3.3. *Let $\mathcal{P}$ be a local graph property for which we can find compressed local certificates in time $T(n) = \Omega(n)$ and such that we can construct a data structure for testing property $\mathcal{P}$ in time $Q(n)$. Then there is a fully dynamic algorithm for maintaining $\mathcal{P}$ in a planar graph, which takes amortized time $T(O(n^{1/2}))$ per edge insertion or deletion, and worst-case time $Q(O(n^{1/2})) + T(O(n^{1/2}))$ per local query.*

Proof. We use the balanced separator tree of Theorem 3.1, but this time we store at its nodes local certificates rather than global certificates. The amortized bound for updates follow now from Theorem 3.2. To test the local property $\mathcal{P}$ for two given vertices x and y, we first make x and y interesting vertices in the local certificate at the tree root. Once x and y are interesting, it is then easily verified that a local certificate for local property $\mathcal{P}$ is a global certificate for the simple property $\mathcal{P}(x, y)$. To make x and y interesting, we reconstruct the local certificates of all nodes containing either one of them. We do not reconstruct the separator tree even if the operation should normally do so. As in the proof of Theorem 3.2, this involves recomputing local certificates in $O(\log n)$ nodes in the separator tree of sizes increasing in a geometric series, and therefore can be done in $T(O(n^{1/2}))$ time. To answer a query regarding property $\mathcal{P}$ for vertices x and y, we construct the data structure for testing property $\mathcal{P}$ in the local certificate at the tree root in $P(O(n^{1/2}))$ time. Finally, we undo all the changes we made. □

Theorems 3.2 and 3.3 can be combined as follows.

THEOREM 3.4. *Let $\mathcal{P}$ be a local graph property for which we can find compressed full certificates in time $T(n) = \Omega(n)$ and such that we can construct a data structure for testing property $\mathcal{P}$ in time $Q(n)$. Then there is a fully dynamic algorithm for maintaining $\mathcal{P}$ in a planar graph, which takes amortized time $T(O(n^{1/2}))$ per edge insertion or deletion, and worst-case time $Q(O(n^{1/2})) + T(O(n^{1/2}))$ per either global or local query.*

4. Properties of certificates for edge connectivity. Let G be an undirected graph, with interesting vertices $X \subseteq V(G)$. In this section we give necessary and sufficient conditions for a graph C to be a full certificate of k-edge-connectivity for X in G. Namely, we will show that it is crucial to keep information about the connectivity edge-cuts that involve only the interesting vertices in X. This will be exploited in the

next sections in order to build our full certificates for edge connectivity.

Let V_1 and V_2 be any two nonempty disjoint subsets of vertices in G. We say that a set of edges $E' \subseteq E(G)$ *disconnects* V_1 *and* V_2 if removing all the edges in E' from G leaves no path between vertices in V_1 and vertices in V_2. We denote by $\lambda_{V_1,V_2}(G)$ the *minimum* number of edges of G whose removal disconnects V_1 and V_2. Note that $\lambda_{V_1,V_2}(G) = \lambda_{V_2,V_1}(G)$. When $V_1 = \{u\}$ and $V_2 = \{v\}$, we obtain the definition of edge connectivity between vertices u and v. The edge connectivity $\lambda(G)$ of G satisfies the equality

$$\lambda(G) = \min_{u,v \in V(G)} \{\lambda_{u,v}(G)\} = \min_{\substack{\emptyset \subset V_1, V_2 \subset V(G) \\ V_1 \cap V_2 = \emptyset}} \{\lambda_{V_1,V_2}(G)\}.$$

Let $\emptyset \subset R \subset X$; then we denote by $\lambda_R(G)$ the quantity $\lambda_{R,X-R}(G)$. If $R = \emptyset$ or $R = X$, we instead let $\lambda_R(G)$ denote the minimum number of edges that must be removed from G in order to disconnect X from at least one other vertex in $[V(G) - X]$.

We can use this notation to characterize full certificates of edge connectivity. Before doing this, we need a technical lemma. Often the easiest way to show that a graph C is a certificate of edge connectivity is to show that appropriate edge-cuts exist. These edge-cuts are edge-cuts of a graph that is the union of two other graphs. The following lemma gives sufficient conditions for constructing an edge-cut of $G \cup H$ from an edge-cut of G and an edge-cut of H.

LEMMA 4.1. *Let G and H be graphs such that $V(G) \cap V(H) \subseteq X$. Furthermore, let γ_G and γ_H be edge-cuts of G and H, respectively. Suppose that γ_G divides G into G_1 and G_2 and that γ_H divides H into H_1 and H_2. Then, if $(V(G_1) \cap V(H_2)) \cup (V(G_2) \cap V(H_1)) = \emptyset$, then $\gamma = \gamma_G \cup \gamma_H$ is an edge-cut of $G \cup H$ that divides it into $G_1 \cup H_1$ and $G_2 \cup H_2$.*

Proof. No edge outside $\gamma_G \cup \gamma_H$ can cross from $G_1 \cup H_1$ to $G_2 \cup H_2$. For if such an edge belonged to G, it would have to cross from $(G_1 \cup H_1) \cap G = G_1$ to $(G_2 \cup H_2) \cap G = G_2$ and would therefore belong to γ_G, and symmetrically, if such an edge belonged to H, it would belong to γ_H. □

Suppose that we are interested in k-edge-connectivity for $k \leq \mathcal{K}$. Then, for C to be a certificate of k-edge-connectivity for X in G, the edge-cuts with k or fewer edges in G should correspond to edge-cuts of the same size in C. Making this formal, we have the following.

LEMMA 4.2. *If C is a full certificate of k-edge-connectivity for X in G, for every $k \leq \mathcal{K}$, then, for any subset $\emptyset \subseteq R \subseteq X$ of interesting vertices,*

$$\min\{\lambda_R(G), \mathcal{K}\} = \min\{\lambda_R(C), \mathcal{K}\}. \tag{4.1}$$

Proof. Suppose that for some $\emptyset \subseteq R \subseteq X$, $\min\{\lambda_R(G), \mathcal{K}\} \neq \min\{\lambda_R(C), \mathcal{K}\}$. We want to find a graph H that shows that C is not a full certificate of k-edge-connectivity for X in G. Note that either $\lambda_R(C) < \mathcal{K}$ or $\lambda_R(G) < \mathcal{K}$.

If $R = \emptyset$ or $R = X$, let H have vertices $X \cup \{z\}$ and $\mathcal{K}$ edges between z and each vertex in X. Any minimal edge-cut of $G \cup H$ that contains any edges in H must then contain all $\mathcal{K}$ of the edges between z and some vertex $x \in X$. Any edge-cut that does not contain any edges from H must separate X from some other vertex in G. Thus, if $\lambda(G \cup H) < \mathcal{K}$, then $\lambda(G \cup H) = \lambda_\emptyset(G) = \lambda_R(G)$. Similarly, the edge connectivity $\lambda(C \cup H)$ is $\lambda_\emptyset(C) = \lambda_R(C)$ unless $\lambda_\emptyset(C) > \mathcal{K}$, in which case the edge connectivity is at least $\mathcal{K}$. Therefore, since $\lambda_\emptyset(C) < \mathcal{K}$ or $\lambda_\emptyset(G) < \mathcal{K}$, we have that

$\lambda(G \cup H) \neq \lambda(C \cup H)$, so C is not a global certificate of k-edge-connectivity for some $k \leq \mathcal{K}$.

Alternately, it may be the case that $\emptyset \subset R \subset X$. In this case, construct H with vertices $X \cup \{z_1, z_2\}$, $\mathcal{K}$ edges from z_1 to each vertex in R, and $\mathcal{K}$ edges from z_2 to each vertex in $X - R$. Again, no minimal edge-cut separating z_1 and z_2 in $G \cup H$ contains an edge of H unless it contains all $\mathcal{K}$ of the edges between two vertices in H. Thus, any edge-cut separating z_1 and z_2 and containing no edges of H must separate R and $X - R$. This implies that if $\lambda_{z_1,z_2}(G \cup H) < \mathcal{K}$, then $\lambda_{z_1,z_2}(G \cup H) = \lambda_R(G)$. Similarly, the edge-connectivity between z_1 and z_2 in $C \cup H$ is $\lambda_R(C)$ unless $\lambda_R(C) > \mathcal{K}$, in which case the edge-connectivity is at least $\mathcal{K}$. Therefore, since $\lambda_R(C) < \mathcal{K}$ or $\lambda_R(G) < \mathcal{K}$, we have that $\lambda_{z_1,z_2}(G \cup H) \neq \lambda_{z_1,z_2}(C \cup H)$, so C is not a local certificate of k-edge-connectivity for some $k \leq \mathcal{K}$. □

Not only is (4.1) a necessary condition for C to be a full certificate, it is also sufficient. First, let us see that it is a sufficient condition for C to be a local certificate.

LEMMA 4.3. *Let $\mathcal{K}$ be a given integer. Let G be a given graph, with interesting vertices $X \subseteq V(G)$. If for any proper subset R of interesting vertices, $\emptyset \subset R \subset X$:*

$$\min\{\lambda_R(G), \mathcal{K}\} = \min\{\lambda_R(C), \mathcal{K}\},$$

then C is a local certificate of k-edge-connectivity for X in G, for every $k \leq \mathcal{K}$.

Proof. This is equivalent to showing that, for any graph H such that $V(H) \cap V(G) \subseteq X$, $V(H) \cap V(C) \subseteq X$, and for any two vertices $x, y \in H$, the following is true:

1. if $\lambda_{x,y}(G \cup H) < \mathcal{K}$, then $\lambda_{x,y}(C \cup H) \leq \lambda_{x,y}(G \cup H)$, and
2. if $\lambda_{x,y}(C \cup H) < \mathcal{K}$, then $\lambda_{x,y}(G \cup H) \leq \lambda_{x,y}(C \cup H)$.

Now we would like to see that 1 holds. Let γ be a minimum edge-cut that disconnects x from y in $G \cup H$. Since it is a minimal edge-cut, it separates $G \cup H$ into exactly two pieces S_1 and S_2. Without loss of generality, assume that $x \in S_1$ and $y \in S_2$. Let $X_1 = S_1 \cap X$, $X_2 = S_2 \cap X$, $G_1 = S_1 \cap G$, $G_2 = S_2 \cap G$, $H_1 = S_1 \cap H$, and $H_2 = S_2 \cap H$. Note that $x \in H_1$ and $y \in H_2$. Further, let $\gamma_G = \gamma \cap E(G)$ and $\gamma_H = \gamma \cap E(H)$.

If $X_2 = \emptyset$, then $X = X_1$, $G_2 = \emptyset$, and $G = G_1$. So, $\gamma_G = \emptyset$ and $\gamma = \gamma_H$. In this case, $\gamma = \gamma_H$ disconnects $G \cup H$ into $G \cup H_1$ and H_2, with $x \in H_1$ and $y \in H_2$. Since $V(C) \cap V(H) \subseteq X = X_1$, replacing G with C yields that $\gamma = \gamma_H$ disconnects $C \cup H$ into $C \cup H_1$ and H_2, with $x \in (G \cup H_1)$ and $y \in H_2$. Hence, the very same edge-cut γ disconnects x and y in $C \cup H$. Similarly, we can assume that $X_1 \neq \emptyset$.

If $|\gamma| \geq \mathcal{K}$, there is nothing to prove. Otherwise, we need to construct γ' as an edge-cut of $C \cup H$ that disconnects x from y and such that $|\gamma'| \leq |\gamma|$. Note that γ_G disconnects X_1 from X_2 in G, so $|\gamma_G| \geq \lambda_{X_1,X_2}(G)$. Since $X = X_1 \cup X_2$, $\lambda_{X_1,X_2}(G) = \lambda_{X_1}(G)$. Moreover, since $|\gamma_G| \leq |\gamma| < \mathcal{K}$, $\lambda_{X_1}(G) = \lambda_{X_1}(C) = \lambda_{X_1,X_2}(C)$. This means that there is an edge-cut γ_C of C that disconnects X_1 from X_2 such that $|\gamma_C| \leq |\gamma_G|$. Thus, if $\gamma' = \gamma_H \cup \gamma_C$, then $|\gamma'| \leq |\gamma|$.

Now we would like to see that γ' disconnects x from y in $H \cup C$. Define C_1 and C_2 so that γ_C divides C into C_1 and C_2. Note that γ_C and γ_H both partition X in the same way, so we can assume that $X_1 \subseteq V(C_1)$ and $X_2 \subseteq V(C_2)$. Since $V(C) \cap V(H) \subseteq X$, this means that $(V(C_1) \cup V(H_1)) \cap (V(C_2) \cup V(H_2)) = \emptyset$, so Lemma 4.1 says that γ' is an edge-cut of $C \cup H$ that disconnects x from y.

To prove that 2 holds, we use exactly the same proof with the roles of G and C switched. Therefore, C is a local certificate of k-edge-connectivity for X in G. □

If the condition also holds when $R = \emptyset$ or $R = X$, then C is also a global certificate.

LEMMA 4.4. *Let $\mathcal{K}$ be a given integer. Let G be a given graph, with interesting vertices $X \subseteq V(G)$. If for any subset R of interesting vertices, $\emptyset \subseteq R \subseteq X$:*

$$\min\{\lambda_R(G), \mathcal{K}\} = \min\{\lambda_R(C), \mathcal{K}\},$$

then C is a global certificate of k-edge-connectivity for X in G, for every $k \leq \mathcal{K}$.

Proof. Let H be any graph such that $V(H) \cap V(G) \subseteq X$. Suppose that γ is a minimum k-edge-cut of $G \cup H$ that divides the graph into S_1 and S_2, and that $k < \mathcal{K}$. If both S_1 and S_2 contain vertices in H, then the fact that C is a local certificate of k-edge-connectivity for X in G shows that there is a k-edge-cut of $C \cup H$. Alternately, if S_1 (say) contains no vertices from H, then γ contains only edges from G, since every edge in a minimal edge-cut connects a vertex in S_1 to a vertex in S_2. This means that $\lambda_\emptyset(G) \leq k$. Since $k < \mathcal{K}$, $\lambda_\emptyset(G) = \lambda_\emptyset(C) \leq k$, so $C \cup H$ has a k-edge-cut as well.

Conversely, suppose that γ' is a minimum k-edge-cut of $C \cup H$ that divides the graph into S_1 and S_2, and that $k < \mathcal{K}$. If both S_1 and S_2 contain vertices in H, then the fact that C is a local certificate of k-edge-connectivity for X in G shows that there is a k-edge-cut of $G \cup H$. Alternately, if S_1 (say) contains no vertices from H, then γ' contains only edges from C. This means that $\lambda_\emptyset(C) \leq k$. Since $k < \mathcal{K}$, $\lambda_\emptyset(C) = \lambda_\emptyset(G) \leq k$, so $G \cup H$ has a k-edge-cut as well. Therefore, C is a global, as well as local, certificate of k-edge-connectivity provided that $k \leq \mathcal{K}$. □

Putting these three lemmas together, we have Theorem 4.1.

THEOREM 4.1. *Let $\mathcal{K}$ be a given integer. Let G be a given graph, with interesting vertices $X \subseteq V(G)$. C is a full certificate of k-edge-connectivity for X in G, for every $k \leq \mathcal{K}$, if and only if for any subset R of interesting vertices, $\emptyset \subseteq R \subseteq X$:*

$$\min\{\lambda_R(G), \mathcal{K}\} = \min\{\lambda_R(C), \mathcal{K}\}.$$

4.1. Split graphs and certificates. We now prove some properties about splitting 2-edge-connected graphs and computing their certificates for edge connectivity. Let G be a 2-edge-connected graph, and let $\{e_1, e_2\}$ be a 2-edge-cut in G. Let G_1 and G_2 be the two graphs obtained from G after the deletion of $\{e_1, e_2\}$, and let $e_1 = (u_1, u_2)$ and $e_2 = (v_1, v_2)$ be such that u_1, v_1 are in G_1 and u_2, v_2 are in G_2. We call this a *split* and call $G_1 \cup \{(u_1, v_1)\}$ and $G_2 \cup \{(u_2, v_2)\}$ the two *split graphs of G with respect to the 2-edge-cut $\{e_1, e_2\}$*. Note that $\{(u_1, v_1)\}$ and $\{(u_2, v_2)\}$ are not originally edges of G: they are called the *virtual edges* associated with the split. The operation inverse to a split is called a *merge*: it takes two split graphs with respect to the same 2-edge-cut and merges them back together, yielding the original graph. We observe that splits and merges preserve planarity. Indeed, the split graphs $G_1 \cup \{(u_1, v_1)\}$ and $G_2 \cup \{(u_2, v_2)\}$ can be obtained from G by means of edge contractions (for instance, $G_1 \cup \{(u_1, v_1)\}$ can be obtained after contracting e_1 and all the edges in G_2). Hence, if G is planar, the split graphs $G_1 \cup \{(u_1, v_1)\}$ and $G_2 \cup \{(u_2, v_2)\}$ obtained after a split are planar. Conversely, if the split graphs are planar, the graph obtained after a merge will be planar. Figure 3 illustrates splits and merges.

LEMMA 4.5. *Let G be a 2-edge-connected graph, and let $k \geq 2$ be an integer. Let $\{e_1, e_2\}$ be any 2-edge-cut of G. For $i = 1, 2$ let us denote by $G_i \cup \{(u_i, v_i)\}$ the split graphs of G with respect to the 2-edge-cut $\{e_1, e_2\}$. Let x and y be any two vertices in the same split graph $G_i \cup \{(u_i, v_i)\}$. Then x and y are k-edge-connected in $G_i \cup \{(u_i, v_i)\}$ if and only if they are k-edge-connected in G.*

Proof. Without loss of generality, let x and y be any two vertices of $G_1 \cup \{(u_1, v_1)\}$. Since G is 2-edge-connected, any two edges of G are contained in a cycle. In particular,

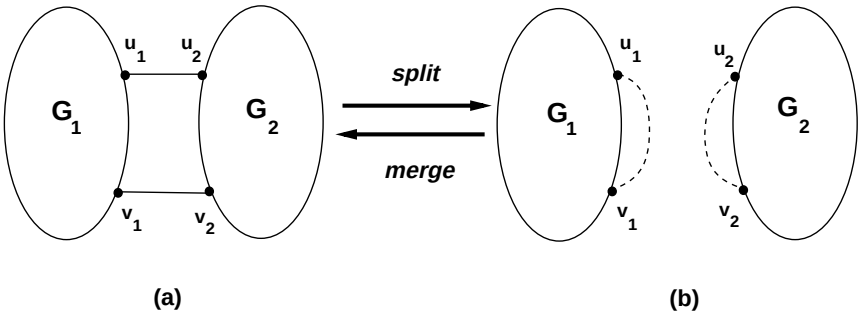

FIG. 3. *Splitting and merging a 2-edge-connected graph and its split graphs. Virtual edges are dashed.*

there is a cycle in G containing edges e_1 and e_2. This implies that there exists a path π_1 between vertices u_1 and v_1 that is entirely contained in G_1, and a path π_2 between u_2 and v_2 that is entirely contained in G_2.

Assume x and y are k-edge-connected in $G_1 \cup \{(u_1, v_1)\}$. Then there are k edge-disjoint paths in $G_1 \cup \{(u_1, v_1)\}$ between x and y, and at most one of them can use the edge (u_1, v_1). If none of these paths use (u_1, v_1), there will be k edge-disjoint paths between x and y in G. If one of these paths use (u_1, v_1), then the path in G containing e_1, π_2, and e_2 in place of (u_1, v_1) is a path between x and y that is edge-disjoint from the other $(k-1)$ paths in G_1. In both cases, x and y are k-edge-connected in G.

Conversely, assume that x and y are k-edge-connected in G. Again, at most one of the k edge-disjoint paths between x and y can go through G_2. If all the k-edge-disjoint paths between x and y are contained in G_1, x and y are k-edge-connected in $G_1 \cup \{(u_1, v_1)\}$ too. If one of these paths go through G_2, replacing this portion of the path with the edge (u_1, v_1) gives a path in $G_1 \cup \{(u_1, v_1)\}$ which is edge-disjoint from the other $(k-1)$ paths. □

The following corollary is an easy consequence of Lemma 4.5.

COROLLARY 4.1. *Let G be a 2-edge-connected graph, and let $\{e_1, e_2\}$ be any 2-edge-cut of G. The split graphs of G with respect to $\{e_1, e_2\}$ are 2-edge-connected.*

Since the split graphs of G are 2-edge-connected, the same splitting can be applied recursively to the split graphs of G, and to their split graphs, and so on. When no further splits are possible, each split graph left is 3-edge-connected and corresponds to exactly one 3-edge-connected class of the original graph. This gives another way of defining the cactus tree of a graph with edge connectivity 2. We call these final split graphs the 3-*edge-connected components* of G. We point out here a difference between 2-edge-connectivity and 3-edge-connectivity. For 2-edge-connectivity, the subgraph induced by a 2-edge-connected class is 2-edge-connected and coincides with a 2-edge-connected component. On the contrary, the subgraph induced by a 3-edge-connected class may differ from a 3-edge-connected component. Indeed, the subgraph induced by a 3-edge-connected class is not necessarily even connected, while the addition of the virtual edges makes a 3-edge-connected component 3-edge-connected. We remark that this decomposition of a 2-edge-connected graph is similar to the decomposition of a biconnected graph into its triconnected components [25], and it is implicit in the work of Dinitz [5].

Let G be a 2-edge-connected graph, and consider the following operation: split G and compute a full certificate of k-edge-connectivity, $k \geq 2$, for one of its split graphs; then merge this certificate with the other split graph. We will prove that by doing

so we obtain a full certificate of k-edge-connectivity, $k \geq 2$, for the original graph G. This property will be useful later on. We now summarize the notation used.

- G: a 2-edge-connected graph;
- $X \subseteq V(G)$: the interesting vertices of G;
- $\{e_1, e_2\}$: a 2-edge-cut in G, with $e_1 = (u_1, u_2)$ and $e_2 = (v_1, v_2)$;
- $\widehat{G}_1 = G_1 \cup \{(u_1, v_1)\}$, $\widehat{G}_2 = G_2 \cup \{(u_2, v_2)\}$: the split graphs of G with respect to $\{e_1, e_2\}$; $u_1, v_1 \in V(G_1)$ and $u_2, v_2 \in V(G_2)$;
- $X_1 = (X \cap V(G_1)) \cup \{u_1, v_1\}$: the interesting vertices in G_1 augmented with u_1 and v_1;
- $\widehat{C}_1 = C_1 \cup \{(u_1, v_1)\}$: a full certificate of k-edge-connectivity for X_1 in $\widehat{G}_1$ (note that this certificate keeps the virtual edge (u_1, v_1) of $\widehat{G}_1$);
- H: any graph such that $V(H) \cap V(G) \subseteq X$;
- $F = G_2 \cup H \cup \{e_1, e_2\}$. Namely, the vertices of F are u_1, v_1 plus the vertices of G_2 and H; the edges of F are e_1, e_2 plus the edges of G_2 and H.

Note that $G = G_1 \cup \{e_1, e_2\} \cup G_2$. We further define $C = C_1 \cup \{e_1, e_2\} \cup G_2$. The point of all of this is that C is a full certificate of k-edge-connectivity for X in G. To prove this, we first prove that it is a local certificate and then prove that it is a global certificate.

LEMMA 4.6. *Let $\mathcal{K}$ be a given integer. Let $\widehat{C}_1 = C_1 \cup \{(u_1, v_1)\}$ be a local certificate of k-edge-connectivity for X_1 in $\widehat{G}_1 = G_1 \cup \{(u_1, v_1)\}$ for every $k \leq \mathcal{K}$. Then $C = C_1 \cup \{e_1, e_2\} \cup G_2$ is a local certificate of k-edge-connectivity for X in G for every $k \leq \mathcal{K}$.*

Proof. Again, the idea behind the proof is to show that the appropriate edge-cuts exist. Specifically, we need to show that for any H such that $V(G) \cap V(H) \subseteq X$, $V(C) \cap V(H) \subseteq X$, and for any $x, y \in V(H)$:

1. if $\lambda_{x,y}(G \cup H) < \mathcal{K}$ then $\lambda_{x,y}(C \cup H) \leq \lambda_{x,y}(G \cup H)$, and
2. if $\lambda_{x,y}(C \cup H) < \mathcal{K}$ then $\lambda_{x,y}(G \cup H) \leq \lambda_{x,y}(C \cup H)$.

Suppose that γ is a minimum edge-cut that disconnects x from y in $G \cup H$ and that $|\gamma| < \mathcal{K}$. Since γ is a minimum edge-cut, it separates $G \cup H$ into two pieces $S^{(x)}$ and $S^{(y)}$, with $x \in S^{(x)}$ and $y \in S^{(y)}$. Let $G_1^{(x)} = G_1 \cap S^{(x)}$, $G_1^{(y)} = G_1 \cap S^{(y)}$, $F^{(x)} = F \cap S^{(x)}$, $F^{(y)} = F \cap S^{(y)}$, $X_1^{(x)} = X_1 \cap S^{(x)}$, and $X_1^{(y)} = X_1 \cap S^{(y)}$. Note that $G_1 = G_1^{(x)} \cup G_1^{(y)}$, $X_1 = X_1^{(x)} \cup X_1^{(y)}$, and $F = F^{(x)} \cup F^{(y)}$. Since $x \in (S^{(x)} \cap H)$ and $y \in (S^{(y)} \cap H)$, we must have $x \in F^{(x)}$ and $y \in F^{(y)}$. Also let $\gamma_{G_1} = \gamma \cap G_1$ and let $\gamma_F = \gamma - \gamma_{G_1}$. Note that γ_F disconnects $X_1^{(x)} \cap V(F)$ from $X_1^{(y)} \cap V(F)$ in F.

If γ_{G_1} is empty, then $\gamma_F = \gamma$. G_1 is connected by the assumption that G is biconnected, so one of $G_1^{(x)}$ or $G_1^{(y)}$ is empty and the other one contains all of G_1. Without loss of generality $G_1^{(x)} = \emptyset$. C_1 is not reachable from x in $C \cup H - \gamma$, since any path connecting x to C_1 in $C \cup H$ would connect x to G_1 in $G \cup H$, and so must be cut by γ. Then x is separated from y in $C \cup H - \gamma$, since no path from x can go through C_1, and since any path avoiding C_1 would also exist in $G \cup H - \gamma$.

Alternately, assume that γ_{G_1} is not empty. We claim that in this case neither $X_1^{(x)}$ nor $X_1^{(y)}$ can be empty. Indeed, if either $X_1^{(x)}$ or $X_1^{(y)}$ were empty, then the removal of all the edges of γ from $G \cup H$ would leave all the vertices of X_1 still connected. Since $V(H) \cap V(G_1) \subseteq X_1$, any path of $G \cup H$ between $x \in V(H)$ and $y \in V(H)$ that contains an edge of G_1 must also contain a vertex of X_1 (recall that, by definition, $u_1, v_1 \in X_1$). Thus, in this case, γ_F would be an edge-cut of $G \cup H$ that disconnects x from y. Since γ is by assumption a minimum edge-cut, this implies by contradiction that neither $X_1^{(x)}$ nor $X_1^{(y)}$ can be empty.

Without loss of generality, assume that $u_1 \in G_1^{(x)}$. We have two cases depending on whether $v_1 \in G_1^{(x)}$ or $v_1 \in G_1^{(y)}$. Suppose first that $v_1 \in G_1^{(x)}$. In this case, γ_{G_1} is an edge-cut of $\widehat{G_1}$ that disconnects $X_1^{(x)}$ from $X_1^{(y)}$. Consequently, $\lambda_{X_1^{(x)}}(\widehat{G_1}) \leq |\gamma_{G_1}|$. Since $\widehat{C_1}$ is a local certificate of k-edge-connectivity for X_1 in $\widehat{G_1}$, and $|\gamma_{G_1}| \leq |\gamma| < \mathcal{K}$, by Theorem 4.1 we have that $\lambda_{X_1^{(x)}}(\widehat{C_1}) = \lambda_{X_1^{(x)}}(\widehat{G_1}) \leq |\gamma_{G_1}|$. This is equivalent to saying that there is an edge-cut $\gamma_{\widehat{C_1}}$ of $\widehat{C_1}$ that disconnects $X_1^{(x)}$ from $X_1^{(y)}$ and such that $|\gamma_{\widehat{C_1}}| = \lambda_{X_1^{(x)}}(\widehat{C_1}) \leq |\gamma_{G_1}|$. Since we can take $\gamma_{\widehat{C_1}}$ to be a minimal edge-cut, it does not contain the edge (u_1, v_1), so it is an edge-cut of C_1. Thus $\gamma' = \gamma_{\widehat{C_1}} \cup \gamma_F$ is a set of edges of $C \cup H$ with $|\gamma'| \leq |\gamma|$. Moreover, $\gamma_{\widehat{C_1}}$ divides C_1 into $C_1^{(x)}$ and $C_1^{(y)}$. Since $X_1^{(x)} \subseteq V(C_1^{(x)})$ and $X_1^{(y)} \subseteq V(C_1^{(y)})$, we have that $C_1^{(x)} \cap F^{(y)} = \emptyset$ and $C_1^{(y)} \cap F^{(x)} = \emptyset$, so Lemma 4.1 shows that $\gamma' = \gamma_{\widehat{C_1}} \cup \gamma_F$ is an edge-cut of $C_1 \cup F = C \cup H$ that disconnects x from y.

Alternately, it could be the case that $v_1 \in G_1^{(y)}$. In this case, γ_{G_1} is not an edge-cut of $\widehat{G_1}$, but $\gamma_{G_1} \cup \{(u_1, v_1)\}$ is such an edge-cut. Again, Theorem 4.1 says that there is an edge-cut $\widehat{\gamma_{\widehat{C_1}}}$ that disconnects $X_1^{(x)}$ from $X_1^{(y)}$ in $\widehat{C_1}$ such that $|\widehat{\gamma_{\widehat{C_1}}}| \leq |\gamma_{\widehat{C_1}}| + 1$. Moreover, since $u_1 \in X_1^{(x)}$ and $v_1 \in X_1^{(y)}$, the edge-cut $\widehat{\gamma_{\widehat{C_1}}}$ contains the edge (u_1, v_1). Let $\gamma_{\widehat{C_1}} = \widehat{\gamma_{\widehat{C_1}}} - \{(u_1, v_1)\}$. Then $\gamma' = \gamma_{\widehat{C_1}} \cup \gamma_F$ is a set of edges in $C \cup H$ with $|\gamma'| \leq |\gamma|$. Moreover, $\gamma_{\widehat{C_1}}$ disconnects $X_1^{(x)}$ from $X_1^{(y)}$, so again, by Lemma 4.1, γ' is an edge-cut that disconnects x from y in $C \cup H$.

Therefore, in either case, γ' is the desired edge-cut, and the first property holds. Since $\widehat{C_1}$ is a certificate of k-edge-connectivity for X_1 in $\widehat{G_1}$, it is the case that $\widehat{G_1}$ is a certificate for k-edge-connectivity of X_1 in $\widehat{C_1}$. Therefore, the same proof can be used to prove property 2, and C is a global certificate of k-edge-connectivity for X in G. □

To prove that C is a full certificate, we also need to prove that it is a global certificate. The proof of this fact is annoyingly similar to the proof that C is a local certificate, but there seems to be no clear way to combine the proofs.

LEMMA 4.7. *Let $\mathcal{K}$ be a given integer. Let $\widehat{C}_1 = C_1 \cup \{(u_1, v_1)\}$ be a full certificate of k-edge-connectivity for X_1 in $\widehat{G}_1 = G_1 \cup \{(u_1, v_1)\}$ for every $k \leq \mathcal{K}$. Then $C = C_1 \cup \{e_1, e_2\} \cup G_2$ is a global certificate of k-edge-connectivity for X in G for every $k \leq \mathcal{K}$.*

Proof. Again it suffices to show that for any H with $V(H) \cap V(G) \subseteq X$, the following two properties hold:

1. if $\lambda(C \cup H) \leq \mathcal{K}$ then $\lambda(G \cup H) \leq \lambda(C \cup H)$, and
2. if $\lambda(G \cup H) \leq \mathcal{K}$ then $\lambda(C \cup H) \leq \lambda(G \cup H)$.

To prove property 1, let γ be a minimum edge-cut of $C \cup H$ that divides $C \cup H$ into S^* and S^{**}. Since γ is a minimum edge-cut in $C \cup H$, it must be of cardinality $\lambda(C \cup H)$: assume that $\lambda(C \cup H) \leq \mathcal{K}$. To prove that $\lambda(G \cup H) \leq \lambda(C \cup H)$, we distinguish several cases according to S^*, S^{**}, and H.

Assume first that both S^* and S^{**} contain vertices of H: thus, there exist two vertices, say x and y, in $V(H)$ that are separated by γ. By Lemma 4.6, we know that C is a local certificate of k-edge-connectivity for X in G, for every $k \leq \mathcal{K}$. Then, if $\lambda(C \cup H) \leq \mathcal{K}$, by Definition 3.2 there is an edge-cut γ' separating x and y in $G \cup H$ of cardinality exactly $\lambda(C \cup H)$. As a result, the minimum edge-cut of $G \cup H$ must have cardinality less than or equal to the cardinality of γ' and hence $\lambda(G \cup H) \leq \lambda(C \cup H)$.

Alternately, it may be the case that $V(H) \subseteq V(S^*)$. In this case, γ contains only edges in C. There are three subcases, depending on how many of the vertices v_1 and u_1 are in $V(S^{**})$. If neither vertex is in $V(S^{**})$, then either $\gamma \subseteq G_2 \cup \{e_1, e_2\}$, in which case γ is also an edge-cut of $G \cup H$, or $\gamma \subseteq C_1$. In the latter case, γ is also an edge-cut of $\widehat{C_1}$, so there is an edge-cut γ' of $\widehat{G_1}$ that is also an edge-cut of $G \cup H$ such that $|\gamma'| \leq |\gamma|$, since $\widehat{C_1}$ is a global certificate of k-edge-connectivity for X_1 in $\widehat{G_1}$.

Another possibility is that both u_1 and v_1 are in S^{**}. Here γ contains edges from both C_1 and G_2, since it is minimal. Let $\gamma_{C_1} = \gamma \cap C_1$ and $\gamma_F = \gamma - \gamma_{C_1}$. Then γ_{C_1} disconnects $\{u_1, v_1\}$ from the rest of X_1 in $\widehat{C_1}$. By Theorem 4.1, there is an edge-cut γ_{G_1} that disconnects $\{u_1, v_1\}$ from the rest of X_1 in $\widehat{G_1}$. Moreover, $|\gamma_{G_1}| \leq |\gamma_{C_1}|$, so if $\gamma' = \gamma_{G_1} \cup \gamma_F$, then $|\gamma'| \leq |\gamma|$. Moreover, since γ_F disconnects $\{u_1, v_1\}$ from X_2 in F, Lemma 4.1 says that γ' is an edge-cut of $G \cup H$.

The final possibility is that one vertex is in S^* and the other is in S^{**}. Without loss of generality, assume that $u_1 \in S^{**}$ but $v_1 \in S^*$. Again let $\gamma_{C_1} = \gamma \cap C_1$ and $\gamma_F = \gamma - \gamma_{C_1}$. Here, let $\widehat{\gamma_{C_1}} = \gamma_{c_1} \cup \{(u_1, v_1)\}$. Then $\widehat{\gamma_{C_1}}$ disconnects u_1 from the rest of X_1 in $\widehat{C_1}$. Therefore, by Theorem 4.1, there is an edge-cut $\widehat{\gamma_{G_1}}$ that disconnects u_1 from the rest of X_1 in $\widehat{G_1}$ such that $|\widehat{\gamma_{G_1}}| \leq |\widehat{\gamma_{C_1}}|$. Moreover, since $\widehat{\gamma_{G_1}}$ disconnects u_1 from v_1, $(u_1, v_1) \in \widehat{\gamma_{G_1}}$, so let $\gamma_{G_1} = \widehat{\gamma_{G_1}} - \{(u_1, v_1)\}$. Since $(u_1, v_1) \notin G_1$, the edge-cut γ_{G_1} disconnects u_1 from the rest of X_1 in G_1. Moreover, γ_F disconnects u_1 from X_2 in F, so, by applying Lemma 4.1 yet again, we discover that $\gamma' = \gamma_{G_1} \cup \gamma_F$ is an edge-cut of $G \cup H$. It is also the case that $|\gamma'| \leq |\gamma|$. Therefore, we have seen that in all cases $\lambda(G \cup H) \leq \lambda(C \cup H)$, and property 1 holds.

Since $\widehat{C_1}$ is a certificate of k-edge-connectivity for X_1 in $\widehat{G_1}$, it is the case that $\widehat{G_1}$ is a certificate for k-edge-connectivity of X_1 in $\widehat{C_1}$. Therefore, the same proof can be used to prove property 2, and C is a global certificate of k-edge-connectivity for X in G. □

THEOREM 4.2. *Let $\mathcal{K}$ be a given integer, let $X \subseteq V(G)$ be the interesting vertices of G, and let $X_1 = (X \cap V(G_1)) \cup \{u_1, v_1\}$: the interesting vertices in G_1 augmented with u_1 and v_1. Let $\widehat{C}_1 = C_1 \cup \{(u_1, v_1)\}$ be a full certificate of k-edge-connectivity for X_1 in $\widehat{G}_1 = G_1 \cup \{(u_1, v_1)\}$ for every $k \leq \mathcal{K}$. Then $C = C_1 \cup \{e_1, e_2\} \cup G_2$ is a full certificate of k-edge-connectivity for X in G for every $k \leq \mathcal{K}$.*

5. Edge connectivity. In this section we present compressed full certificates for 3- and 4-edge-connectivity. Using these certificates in Theorem 3.4 yields fast, fully dynamic algorithms for maintaining information about 3- and 4-edge-connectivity in a planar graph. Our certificates for edge connectivity will be constructed using the linear time algorithm of Lemma 3.4, so they will be required to preserve planarity as well as edge connectivity. To use this construction, we merely need to show that such certificates exist, by describing an algorithm for finding them. However, we need not analyze the time bounds of this algorithm, since Lemma 3.4 will then provide an alternate algorithm with linear complexity.

Let X be the set of interesting vertices in G. Our certificates are based upon a repeated compression of G during different phases. In the first phase we shrink some edges of G so as to reduce the number of 2-edge-connected classes (and thus components) to $O(|X|)$. After this phase we could easily get compressed full certificates for 2-edge-connectivity; however, as we mentioned earlier, these certificates for 2-edge-connectivity would yield time bounds that are worse than the polylogarithmic bounds we obtain in the companion paper [11], and so we will not describe them. In the second phase, we compress each 2-edge-connected component left so as to reduce

the total number of 3-edge-connected classes (and thus components) to $O(|X|)$: compressed full certificates for 3-edge-connectivity can be computed after this phase. In the third phase, we similarly reduce the number of 4-edge-connected classes. Finally, we compress each 4-edge-connected class left so as to reduce the overall size of the graph to $O(|X|)$.

To carry out these compressions, we use the decomposition of a k-edge-connected graph into its $(k+1)$-edge-connected classes described by the cactus tree (see section 2). In each phase we use a compression that follows many of the same ideas used in the companion paper [11] to compute the minimum spanning forest certificates of size $O(|X|)$. We recall here that for the minimum spanning forest certificate we started with a tree T and then repeatedly applied the following two rules until no more rule could be applied.

(1) If $v \in T - X$ touches a single edge (u, v) in T, remove both v and edge (u, v).
(2) If $v \in T - X$ touches two edges (u, v) and (v, w) in T, remove v and replace the two edges by a single edge (u, w).

Rule (1) cuts uninteresting branches (parts of the graph not containing interesting vertices) and rule (2) shortcuts uninteresting paths (paths not containing interesting vertices). If neither rule can be applied, the resulting tree has size $O(|X|)$.

A high-level description of our computation of certificates for 3- and 4-edge-connectivity follows. We proceed one level at the time, and at each level we compress the cactus tree. Namely, at level k, $1 \le k \le 3$, we have a tree or something like a tree describing the k-edge-cuts and $(k+1)$-edge-connected classes. To reduce the number of k-edge-cuts and $(k+1)$-edge-connected classes, we compress this tree by using rules which are the analog of rules (1) and (2) above. That is, we will cut uninteresting branches (parts of the graph not containing interesting vertices and separated by a k-edge-cut) and shortcut uninteresting paths (parts not containing interesting vertices and separated by two k-edge-cuts). There are only $O(1)$ ways a branch or path may be used to connect the rest of the graph, so we will replace each branch or path by the smallest possible graph having the same edge connectivity properties, and that graph will have size $O(1)$. Then we go on to the next level.

Our description of these compressions will be given in a top-down fashion. We will first abstract three different compression problems that we need to solve. Next, we will show how to solve these problems. Finally, we will combine the solutions to these problems to achieve our certificates. The three different problems we solve are the following.

PROBLEM 5.1. *Given a planar connected graph G_0 and a set $X_1 \subseteq V(G_0)$ of vertices in G_0, find a graph G_1 that satisfies the following properties:*

(a) *$X_1 \subseteq V(G_1)$;*
(b) *G_1 has $O(|X_1|)$ 2-edge-connected components;*
(c) *For every $k \ge 2$, G_1 is a full certificate of k-edge-connectivity for X_1 in G_0;*
(d) *G_1 preserves planarity and is connected.*

PROBLEM 5.2. *Given a planar 2-edge-connected graph G_0 and a set $X_2 \subseteq V(G_0)$ of vertices in G_0, find a graph G_2 that satisfies the following properties:*

(a) *$X_2 \subseteq V(G_2)$;*
(b) *G_2 has $O(|X_2|)$ 3-edge-connected components;*
(c) *For every $k \ge 2$, G_2 is a full certificate of k-edge-connectivity for X_2 in G_0;*
(d) *G_2 preserves planarity and is 2-edge-connected.*

PROBLEM 5.3. *Given a planar 3-edge-connected graph G_0, a set $X_3 \subseteq V(G_0)$ of vertices, and a set $Y_3 \subseteq E(G_0)$ of edges in G_0, denote by $Z_3 \subseteq V(G_0)$ the set of*

endpoints of edges in Y_3. *Find a graph* G_3 *that satisfies the following properties:*

(a) $X_3 \subseteq V(G_3)$ *and* $Y_3 \subseteq E(G_3)$*;*

(b) G_3 *is a compressed full certificate of* 3- *and* 4*-edge-connectivity for* $(X_3 \cup Z_3)$ *in* G_0*;*

(c) G_3 *preserves planarity and is* 3*-edge-connected.*

Note that Problems 5.1, 5.2, and 5.3 admit the trivial solutions $G_1 = G_0$, $G_2 = G_0$, $G_3 = G_0$ whenever, respectively, $X_1 = V(G_0)$, $X_2 = V(G_0)$, $X_3 \cup Z_3 = V(G_0)$. Hence, we look for nontrivial solutions when $X_1 \subset V(G_0)$, $X_2 \subset V(G_0)$, and $X_3 \cup Z_3 \subset V(G_0)$.

Let G be a graph and let X be a set of interesting vertices. We now give a very high-level description of our algorithm that computes a compressed full certificate for 3- and 4-edge-connectivity of X in G. We will first solve Problem 5.1 with $G = G_0$ and $X = X_1$. This will give us a graph G_1 that has only $O(|X|)$ 2-edge-connected components and bridges but is still a planarity-preserving full certificate for X in G. Next, we will solve Problem 5.2 for each 2-edge-connected component of G_1, so as to reduce the overall number of 3-edge-connected components to $O(|X|)$. Finally, we will obtain our planarity-preserving compressed full certificates by solving Problem 5.3 for each 3-edge-connected component left in the graph at this point.

In the next sections, we will fill in the low-level details of our approach. In section 5.1 we show how to solve Problem 5.1, in section 5.2 we deal with Problem 5.2, and in section 5.3 with Problem 5.3. The solutions to these three problems will then be combined in section 5.4, yielding our compressed full certificates for 3- and 4-edge-connectivity.

5.1. Compressing a connected graph. In this section we present our solution to Problem 5.1. Let G_0 be a planar connected graph, and let $X_1 \subseteq V(G_0)$. We start by computing the 2-edge-connected components of G_0 [34]. As said before, the 2-edge-connected components of a graph have a tree-like structure: indeed, shrinking each 2-edge-connected class of G_0 into a super-vertex yields a tree whose edges are all and only the bridges of G_0. This is called the *bridge-block tree* of G_0. To compute the graph G_1 we work on the bridge-block tree of G_0: namely, we will apply to the bridge-block tree rules (1) and (2) of section 5. This will reduce the total number of vertices and edges in the bridge-block tree to $O(|X_1|)$. In what follows, we will often interchange the term 2-edge-connected component of G_0 with the corresponding 2-edge-connected class and with the corresponding node of its bridge-block tree, and the term bridge of G_0 with the corresponding edge of its bridge-block tree.

We now give the details of the compression and prove that it yields a solution to Problem 5.1. Let (S, T) be a minimum edge-cut separating X_1 in G_0: without loss of generality, assume that $X_1 \subseteq S$, and pick arbitrarily a vertex $t_1 \in T$. Color red the vertices of $X_1 \cup \{t_1\}$. Note that the total number of red vertices of G_0 is $|X_1| + 1$. Define a 2-edge-connected component to be *red* if it contains at least one red vertex, and define it to be *black* otherwise. Clearly, there are $O(|X_1|)$ red 2-edge-connected components. Define the *degree of a* 2*-edge-connected component* to be the number of bridges incident to it (i.e., the degree of its corresponding node in the bridge-block tree). Black 2-edge-connected components of degree one are uninteresting leaves in the bridge-block tree, and adjacent black 2-edge-connected components of degree two yield uninteresting chains in the bridge-block tree. We compress the black leaves and black chains of the bridge-block tree by applying the following two rules (analogs of rules (1) and (2)).

(B1) Let B be a black 2-edge-connected component of degree one, and let $e = (u, v)$

be the bridge incident to B. Contract e. This corresponds to deleting a black leaf from the bridge-block tree.

(B2) Let B_1 and B_2 be two adjacent black 2-edge-connected components of degree two. Let $e_1 = (u_1, v_1)$ and $e_2 = (u_2, v_2)$ be the two bridges incident to B_1, and let e_2 and $e_3 = (u_3, v_3)$ be the two bridges adjacent to B_2. Contract e_2 identifying u_2 and v_2. This corresponds to merging two adjacent black nodes of degree two in the bridge-block tree.

Note that both rules (B1) and (B2) delete one bridge and keep the graph connected. After rule (B2) is applied, the subgraph $B_1 \cup B_2$ from the contraction of bridge e_2 is 2-edge-connected. Similarly, let B' be the 2-edge-connected component adjacent to B in rule (B1): after contracting e, $B \cup B'$ is 2-edge-connected.

Let G_1 be the graph obtained from G_0 after all the rules (B1) and (B2) have been applied. Let H be any graph with $V(H) \cap V(G_0) \subseteq X_1$: since $G_1 \cup H$ is obtained from $G_0 \cup H$ by means of edge contractions, $G_1 \cup H$ is planar whenever $G_0 \cup H$ is planar. Thus, G_1 preserves planarity according to Definition 3.5. Furthermore, red vertices of G are never contracted by (B1) or (B2), and therefore $X_1 \cup \{t_1\} \subseteq V(G_1)$. Consider the bridge-block tree of G_1: because of (B1) there are no black leaves, and because of (B2) there are no two adjacent degree-two black nodes. This implies that there are at most $O(|X_1|)$ nodes in the bridge-block tree of G_1, and therefore $O(|X_1|)$ 2-edge-connected components and $O(|X_1|)$ bridges in G_1. This shows that G_1 satisfies properties (a), (b), and (d) of Problem 5.1. The following two lemmas show also that property (c) is satisfied, and therefore G_1 is a solution to Problem 5.1.

LEMMA 5.1. *Let $\widehat{G}$ be obtained from G_0 by applying either rule* (B1) *or rule* (B2). *Let H be given with $V(G_0) \cap V(H) \subseteq X_1$, and let x and y be any two vertices of $X_1 \cup \{t_1\} \cup V(H)$. For every $k \geq 2$, x and y are k-edge-connected in $\widehat{G} \cup H$ if and only if they are k-edge-connected in $G_0 \cup H$.*

Proof. We observe that neither (B1) nor (B2) can contract edges incident to vertices of $X_1 \cup \{t_1\}$. Since $V(G_0) \cap (V(H) \cup X_1 \cup \{t_1\}) \subseteq X_1 \cup \{t_1\}$, this implies that $\widehat{G} \cup H$ is obtained from $G_0 \cup H$ by contracting an edge that is not incident to either x or y. So if x and y are k-edge-connected in $G_0 \cup H$, they are k-edge-connected in $\widehat{G} \cup H$. Assume now that x and y are k-edge-connected in $\widehat{G} \cup H$. Then there are k edge-disjoint paths between x and y in $\widehat{G} \cup H$.

If (B1) was applied, $e = (u, v)$ is a bridge and B is a black 2-edge-connected component of degree one. Since B is black, it contains no vertex of $X_1 \cup \{t_1\}$. Furthermore, since $V(G_0) \cap V(H) \subseteq X_1$, no edge of H is incident to a vertex in B. This implies that neither x nor y is in B. After applying rule (B1), e is contracted, identifying vertices u and v into a new vertex w. Conversely, $G_0 \cup H$ can be obtained from $\widehat{G} \cup H$ by the inverse operation of splitting vertex w so as to reconstruct $e = (u, v)$. Since e is a bridge of G_0 separating B from the rest of the graph, and no edge of H is incident to B, e is a bridge of $G_0 \cup H$ too. This implies that after contracting edge e, w will be an articulation point of $\widehat{G} \cup H$, again separating B from the rest of the graph. Since neither x nor y is in B, there are k edge-disjoint simple paths in $\widehat{G} \cup H$ that do not contain edges of B. Thus, after splitting vertex w, the same k paths are edge-disjoint in $G_0 \cup H$, and therefore x and y are k-edge-connected in $G_0 \cup H$ too.

If (B2) was applied, B_1 and B_2 are black 2-edge-connected components of degree two in G_0. Since they are black, neither B_1 nor B_2 contains vertices of $X_1 \cup \{t_1\}$. Furthermore, since $V(G_0) \cap V(H) \subseteq X_1$, no edge of H is incident to a vertex in either B_1 or B_2. This implies that x and y are outside both B_1 and B_2. After applying rule (B2), e_2 is contracted and u_2 and v_2 are identified into a new vertex, say w_2.

Conversely, $G_0 \cup H$ can be obtained from $\widehat{G} \cup H$ by the inverse operation of splitting vertex w_2 into vertices u_2 and v_2 joined by edge e_2. Since no edge of H is incident to either B_1 or B_2, $\{e_1, e_3\}$ is a 2-edge-cut in $\widehat{G} \cup H$. Since neither x nor y is in $B_1 \cup B_2$, at most one of the k edge-disjoint paths in $\widehat{G} \cup H$ contains e_1 and e_3 and goes through B_1 and B_2. If w is split into vertices u_2 and v_2 joined by edge e_2, there is a new path containing edges e_1, e_2, and e_3 and going through B_1 and B_2 that is still edge-disjoint from the other $k-1$ paths: there are still k edge-disjoint paths between x and y in $G_0 \cup H$, and therefore x and y are k-edge-connected. □

The following corollary follows from Lemma 5.1.

COROLLARY 5.1. *Let $\widehat{G}$ be obtained from G_0 by applying either rule* (B1) *or rule* (B2). *For every $k \geq 2$, $\widehat{G}$ is a local certificate of k-edge-connectivity for X_1 in G_0.*

LEMMA 5.2. *Let $\widehat{G}$ be obtained from G_0 by applying either rule* (B1) *or rule* (B2). *Then for every $k \geq 2$, $\widehat{G}$ is a global certificate of k-edge-connectivity for X_1 in G_0.*

Proof. Let H be given with $V(G_0) \cap V(H) \subseteq X_1$. Rules (B1) and (B2) can only increase the edge connectivity of $G_0 \cup H$, and thus $\lambda(\widehat{G} \cup H) \geq \lambda(G_0 \cup H)$. To prove the lemma, it remains to show that if there is a k-edge-cut in $G_0 \cup H$, then in $\widehat{G} \cup H$ there must be an edge-cut of cardinality $k' \leq k$.

Let (S, T) be a k-edge-cut in $G_0 \cup H$. If both S and T contain vertices of $V(H) \cup X_1 \cup \{t_1\}$, a k-edge-cut in $\widehat{G} \cup H$ exists by Lemma 5.1. Otherwise, assume without loss of generality that $V(H) \cup X_1 \cup \{t_1\} \subseteq S$. This implies that T contains only black vertices of G_0 and that all the edges of (S, T) are in G_0: thus, (S, T) is an edge-cut separating X_1 in G_0. Let (S', T') be a minimum edge-cut separating X_1 from t_1 in G_0, with $X_1 \subseteq S'$ and $t_1 \in T'$, and let k' denote the cardinality of (S', T'). Recall that by the definition of t_1, (S', T') has the smallest cardinality among all of the edge-cuts separating X_1 in G_0: thus $k' \leq k$. Since $V(G_0) \cap V(H) \subseteq X_1 \subseteq S'$, $(S' \cup V(H), T')$ is itself a k'-edge-cut in $G_0 \cup H$. Since t_1 was colored red, a k'-edge-cut, $k' \leq k$, must exist in $\widehat{G} \cup H$ because of Lemma 5.1. □

It is clear from the proof of Lemma 5.2 why we needed to choose vertex t_1. Indeed, if G_0 has a bridge that leaves all the vertices of X_1 on one side, then $\lambda(G_0 \cup H) = 1$ for every H such that $V(H) \cap V(G_0) \subseteq X_1$. Picking vertex t_1 and coloring it red guarantees that there will be a bridge that leaves all the vertices of X_1 on one side in $\widehat{G} \cup H$ too.

Corollary 5.1 and Lemma 5.2 imply that G_1 is a full certificate for G. However, we remark that G_1 is not necessarily a *compressed* certificate, since it can have more than $O(|X_1|)$ vertices and edges: indeed, each 2-edge-connected component of G_1 might contain many vertices and edges. In the next section we show how to compress a 2-edge-connected graph, solving Problem 5.2.

5.2. Compressing a 2-edge-connected graph. We now turn to Problem 5.2. Let G_0 be a 2-edge-connected graph, and let $X_2 \subseteq V(G_0)$ be a set of vertices of G_0. As said before, if each 3-edge-connected class of G_0 is shrunk into one super-vertex, the resulting graph consists of a collection of simple cycles such that no two cycles share more than one super-vertex. This graph is the *cactus tree* of G_0: each node in the cactus tree corresponds to a 3-edge-connected class (and thus component) of G. Let p be the number of 3-edge-connected classes of G_0: the cactus tree has the property of having only $O(p)$ edges, and the edges in the cactus tree define all the possible 2-edge-cuts of G_0. Indeed, any two edges in the same cycle of the cactus tree define a 2-edge-cut of G_0. Consequently, even though the number of 2-edge-cuts can be $\Omega(p^2)$ (for instance, if G_0 is a simple cycle of p edges), the cactus tree of G_0 always

has size $O(p)$.

Let (S,T) be a minimum edge-cut separating X_2 in G_0, and without loss of generality, assume that $X_2 \subseteq S$. Pick arbitrarily one vertex $t_2 \in T$ and color red all the vertices of $X_2 \cup \{t_2\}$: note that the total number of red vertices of G_0 is $|X_2|+1$. Define a 3-edge-connected class of G_0 to be *red* if it contains at least one red vertex, and define it to be *black* otherwise. Clearly, there are $O(|X_2|)$ red 3-edge-connected classes. Our compression follows many of the same ideas used in section 5.1, but this time applies rules that are the analogs of rules (1) and (2) to the cactus tree of a 2-edge-connected graph rather than to the bridge-block tree of a connected graph. However, there are more technicalities involved, since the cactus tree here is not really a tree, but rather a tree of cycles.

Define the *degree of a 3-edge-connected class* to be the number of 2-edge-cuts incident to it (i.e., the number of cycles in the cactus tree that the corresponding node belongs to). If C is a 3-edge-connected class of G_0, there is a node in the cactus tree corresponding to C. Since there is no danger of ambiguity, we call this cactus tree node C also, and we color it with the same color we used for the 3-edge-connected class C.

Given a set S of vertices in G_0, define the graph $\Gamma_G(S)$ having as vertices S and all neighbors of S, and having as edges all edges in G_0 with one or both endpoints in S.

To compress "uninteresting leaves" of the cactus tree, we delete black nodes that appear in only one cycle. To compress "uninteresting chains," we take a chain of black nodes of the cactus tree that appear in the same 2-cycle and merge them into a smaller certificate for that chain. The two rules (analogs of rules (1) and (2)) that we use are the following.

(T1) Let C be a black 3-edge-connected class of degree one, and let $\{e_1, e_2\}$ be the 2-edge-cut incident to C. Let $e_1 = (u_1, v_1)$ and $e_2 = (u_2, v_2)$, with u_1 and u_2 in C. Replace e_1, e_2, and C with an edge $e = (v_1, v_2)$.

(T2) Let $C_1, C_2, \ldots, C_\ell$ be a set of one or more black 3-edge-connected classes of degree two, such that each adjacent pair C_i, C_{i+1} shares an edge-cut $\{e_i, e_i'\}$. Let $\{e_0, e_0'\}$ and $\{e_\ell, e_\ell'\}$ be the two 2-edge-cuts separating $\bigcup C_i$ from the rest of the graph, and let $Y = \{v_0, v_0', v_\ell, v_\ell'\}$ be the endpoints of these cut edges in the rest of the graph. Let $B = \Gamma_G(C_1 \cup C_2 \cup \cdots \cup C_\ell)$; i.e., B consists of the edges induced by each C_i together with all cut edges e_i, e_i', $0 \le i \le \ell$. Then replace B by the minimum size planarity-preserving certificate B' of k-edge-connectivity (for all k) for B with the vertices of Y denoted as interesting.

The definition of rule (T2) may seem circular, as we are invoking the existence of certificates in the definition of an algorithm we are trying to use to prove that certificates exist. However, we know that there will always exist some planarity-preserving certificate: B itself is such a graph. Therefore, (T2) is well defined, although it may not be clear how to implement it efficiently. The reason for stating (T2) in this form is threefold: it is very general, and applies equally well to other forms of connectivity in other cactus trees; it motivates the seemingly more complicated rule (T2′) below, and it is immediately apparent that the result is a certificate. A general argument based on the possible connectivity requirements through vertices in Y, and on the different ways these vertices can be placed in an embedding of B, shows that only $O(1)$ different replacement certificates are needed in rule (T2), and hence B' has size $O(1)$. We do not elaborate, as this argument does not give good bounds on $|B'|$. Instead, we replace (T2) by rule (T2′) below. With rule (T2′), the size of B' is clearly

$O(1)$, but it is less clear that the resulting graph is a certificate. We prove this by showing that (T2) and (T2′) are equivalent.

Our description is based on *flows* in G. If we assign orientations and nonnegative *flow amounts* to the edges of G, the *excess* at any vertex is the sum of the flow amounts on incoming edges minus the sum of flow amounts on outgoing edges. A *flow* is an assignment of orientations and flow amounts such that, except at certain designated *terminals*, the excess at each vertex is zero. We will assume *integer flows* and *unit capacity edges*; i.e., all flow amounts should be zero or one. A *flow requirement* is the designation of values on certain terminal vertices; we say that a flow requirement is *satisfied* if there exists a flow such that, at each terminal, the excess equals the designated value. The *total flow* is the sum of positive flow requirement values; we call a flow with total flow k a *k-unit flow*. Any k-unit flow can be partitioned into k single-unit flows; a single-unit flow is just a path connecting its two terminals, possibly together with some cycles. This partitioning of a flow into paths forms one-half of the *max-flow min-cut theorem* [3], that x and y are k-connected if and only if there exists a flow (with integer edge capacities, and which can be restricted to an integer flow without loss of generality) with x and y as terminals having designated values $-k$ and k; for a proof of this connection between flows and connectivity, see any graph theory text.

First, we define the following term. Suppose that $\ell = 1$, so that B consists of the subgraph induced by a single black 3-edge-connected class C_1 together with the four vertices Y and the edges connecting Y to C_1. We say that B is *well connected* if, for any way of partitioning Y into two pairs of vertices, there is a two-unit flow in B with the first pair as the two sources and the second pair as the two sinks. For instance, if B consists of a star $K_{1,4}$, it is well connected. We are now ready to define rule (T2′).

(T2′) Let C_1, C_2, …, C_ℓ be a set of one or more black 3-edge-connected classes of degree two, such that each adjacent pair C_i, C_{i+1} shares an edge-cut $\{e_i, e_i'\}$. Let $\{e_0, e_0'\}$ and $\{e_\ell, e_\ell'\}$ be the two 2-edge-cuts separating $\bigcup C_i$ from the rest of the graph, and let $Y = \{v_0, v_0', v_\ell, v_\ell'\}$ be the endpoints of these cut edges in the rest of the graph. Let $B = \Gamma_G(C_1 \cup C_2 \cup \cdots \cup C_\ell)$.

- (i) If $\ell > 1$, form B' from B by contracting $C_1 \cup C_2 \cup \cdots \cup C_\ell$ to a single vertex.
- (ii) If $\ell = 1$, and C_1 is well connected, form B' from B by contracting C_1 to a single vertex.
- (iii) If $\ell = 1$, and C_1 is not well connected, let T be a spanning tree of B. (We show below that B is connected, so T exists.) Contract any edge in T adjacent to a vertex in C_1 of degree one or two, until no more contractions are possible; let B' be the resulting contracted tree.

In all cases replace B by B'.

LEMMA 5.3. *The graph B specified in rules* (T2) *and* (T2′) *is connected; moreover, the subgraph induced by each 3-edge-connected class C_i is connected.*

Proof. The connectedness of the subgraph induced by C_i follows because each pair of vertices in C_i is connected by three edge-disjoint paths, and only two such paths can pass through the four edges separating C_i from the rest of G. For each pair of classes C_i, C_{i+1} there is an edge connecting that pair, from which the overall connectedness of B follows. □

LEMMA 5.4. *Rule* (T2′) *preserves planarity.*

Proof. In all three cases of rule (T2′), the resulting graph B' is a minor of B and hence preserves planarity. □

We next show that the graph B' resulting from rule (T2′) is a certificate of k-edge-connectivity for B. A pair of vertices is k-edge-connected if and only if there is a k-unit flow with one vertex as source and the other as sink. If we consider the orientations and flow amounts of this flow, restricted to the edges of B, we can think of the excesses at each vertex of Y as giving flow requirements satisfied by this flow. (The excesses at vertices of $B - Y$ must be zero since all incident edges of such vertices are in B.) Replacing this flow on B by any other flow satisfying the same requirements will produce a k-unit flow in B, so it is enough to show that, whenever a flow requirement F with terminals in Y can be satisfied in B, it can also be satisfied in B'.

Note that we need only consider flow requirements of at most one unit at each vertex of Y, since each vertex of Y is adjacent to a single edge in B. Thus larger flow requirements could not be satisfied in B. So, overall, there are at most two single-unit sources and two single-unit sinks. If there is one source or sink only, the satisfiability of the flow requirements follows from the connectedness of B (Lemma 5.3) and from the connectedness of B' (obvious from the definition of rule (T2′)).

Let the remaining two-unit flow requirements be denoted F_1, having sources $\{v_0, v_0'\}$ and sinks $\{v_\ell, v_\ell'\}$; F_2, having sources $\{v_0, v_\ell\}$ and sinks $\{v_0', v_\ell'\}$; and F_3, having sources $\{v_0, v_\ell'\}$ and sinks $\{v_0', v_\ell\}$. (Any other collection of two sources and two sinks can be found by switching sources and sinks in some F_i.)

LEMMA 5.5. *Flow requirement F_1 is satisfiable in B.*

Proof. By assumption, G is 2-edge-connected, so there exists a pair of edge-disjoint paths in G from v_0 to v_ℓ. Each path must cross B, and the union of these two paths intersected with B forms a two-unit flow satisfying F_1. □

LEMMA 5.6. *At least one of F_2 or F_3 is satisfiable in B.*

Proof. Let F_1 be satisfied by a 2-unit flow. Then the flow can be partitioned into two edge-disjoint paths, each connecting a source with a sink. If the paths connect v_0 with v_ℓ and v_0' with v_ℓ', then F_3 is also satisfiable. If the paths connect v_0 with v_ℓ' and v_0' with v_ℓ, then F_2 is also satisfiable. □

LEMMA 5.7. *If some flow requirement F_i is not satisfiable by a flow in B, then B consists of the subgraph induced by a single class C_1.*

Proof. By Lemma 5.6, we can without loss of generality let the unsatisfiable flow requirement be F_2. If $\ell > 1$, this flow requirement would be satisfied by finding one path in the subgraph induced by C_1 connecting v_0 and v_0', and a path in the subgraph induced by C_ℓ connecting v_ℓ and v_ℓ', both of which exist by Lemma 5.3. □

LEMMA 5.8. *When part* (iii) *of rule* (T2′) *is applied to a graph B in which the flow requirement F_2 is not satisfiable by any flow, the resulting graph B' consists of Y together with two vertices u and u', with edges v_0u, uv_1, uu', $v_0'u'$, and $u'v_1'$.*

Proof. Since B' is a contraction of a tree, it is itself a tree. Since F_2 is unsatisfiable, B contains a bridge edge e between $\{v_0, v_1\}$ and $\{v_0', v_1'\}$ by the max-flow min-cut theorem [3]. This edge e must be in T. Construct a tree T' by contracting out all degree-one black vertices in T. Then B' remains a contraction of T'. Since e is on a path between two vertices of Y, it is not contracted in forming T'. On either side of e, T' consists of paths connecting v_0 with v_1, and v_0' with v_1'. Further, note that all vertices in Y must be leaves in T' since they have degree one in B and their degree does not increase in forming T'. The only compressed tree possible with four leaves and a bridge separating the two pairs of leaves is the one described in the lemma. □

LEMMA 5.9. *The graph B' resulting from rule* (T2′) *is a certificate of k-edge-*

connectivity for B.

Proof. We show that for every flow requirement F on terminals in Y, F is satisfiable by a flow in B if and only if it is satisfiable in B'. Requirements with more than two units of flow are never satisfiable in either graph. One-unit requirements are satisfiable in B by Lemma 5.3, and in B' since B' is clearly connected. Thus we need only worry about requirements F_1, F_2, and F_3.

If all three of the requirements F_i are satisfiable by flows in B, then either $\ell > 1$ or B consists of a single well-connected component C_1. In either case parts (i) or (ii) of rule (T2′) contract B to a star $K_{1,4}$ in which all three collections remain satisfiable.

If only two of the three requirements are satisfiable, then by Lemma 5.7, B consists of the subgraph induced by the single component C_1 which must not be well connected. By Lemma 5.6, we can assume without loss of generality that requirement F_2 is not satisfiable by a flow in B. Then by Lemma 5.8, B' consists of a tree with four leaves and a bridge, containing edge-disjoint paths from v_0 to v_1 and v_0' to v_1'; in this graph as in B, F_1 and F_3 are satisfiable and F_2 is not satisfiable. □

LEMMA 5.10. *Rule* (T2) *is equivalent to rule* (T2′).

Proof. The fact that B' is a certificate is shown in Lemma 5.9. It can be shown that it is the minimum certificate for B by noting that any certificate must contain a spanning tree with at least as many vertices as are in B'; we omit the details, as they are not necessary for the overall correctness of our connectivity algorithm. □

Next, we analyze the size of the cactus tree for G' and show that the graph obtained at the end of this compression is a solution to Problem 5.2. Recall that the meaning of our rules in the cactus tree is the following. Rule (T1) takes as input a black node that is contained in only one cycle and deletes it, while rule (T2) compresses a chain of black nodes in the cactus tree. The following lemmas show that the graph obtained at the end of this compression is a solution to Problem 5.2.

LEMMA 5.11. *Let G_2 be the graph obtained from a 2-edge-connected graph G_0 by repeated applications of rules* (T1) *and* (T2)*, until no further rule can be applied. Then there are $O(|X_2|)$ 3-edge-connected components in G_2, and its cactus tree contains $O(|X_2|)$ nodes and edges.*

Proof. Since rules (T1) and (T2) can be described in terms of the cactus tree, and each node of the cactus tree corresponds to a 3-edge-connected class (and thus component), we refer to nodes of the cactus tree as components, and show that when no rule can be applied any more, we are left with a cactus tree that contains $O(|X_2|)$ nodes and edges.

We observe that the cactus tree can be represented by a tree. We form a black or red node for every component in the cactus tree, and a blue node for every cycle in the cactus tree. A node representing a component is adjacent to a node representing a cycle if and only if the cycle contains that component.

Because of rule (T1), a black component must be shared by more than one cycle in the cactus tree. Therefore, all leaves of the tree are red, and there are at most $|X_2| + 1$ leaves.

Next, we examine the degree-two nodes in the tree. Form maximal chains of black and blue degree-two nodes. Each such chain is terminated either by a high-degree node or by a red node; therefore, as in any tree, there can be at most $2|X_2| - 1$ chains. Each chain can consist of at most one black node and two blue nodes by rule (T2), so there are at most $2|X_2| - 1$ black nodes of degree two and at most $4|X_2| - 2$ blue nodes of degree two.

Finally, as in any tree, there are at most two fewer nodes of degrees higher than

two than there are leaves, so there are at most $|X_2| - 1$ such nodes.

In total we find at most $3|X_2| - 2$ black nodes representing black components of the cactus tree, and at most $5|X_2| - 3$ blue nodes representing cycles in the cactus tree. Any cactus tree with k components has at most $2k - 2$ edges, so there are at most $8|X_2| - 4$ edges in the cactus tree. ∎

LEMMA 5.12. *Let $\widehat{G}$ be obtained from G_0 by repeatedly applying rules* (T1) *and* (T2). *Let H be given with $V(G_0) \cap V(H) \subseteq X_2$. Any two vertices of $X_2 \cup V(H) \cup \{t_2\}$ are k-edge-connected in $\widehat{G} \cup H$ if and only if they are k-edge-connected in $G_0 \cup H$, $k \geq 2$.*

Proof. By transitivity of certificates, we need only show that each step produces a certificate for the previous graph. Steps involving rule (T1) yield a split graph with respect to the 2-edge-cut $\{e_1, e_2\}$, and Lemma 4.5 shows that this produces a certificate of k-edge-connectivity. Steps involving rule (T2) yield a certificate by definition. ∎

Lemma 5.12 implies the following corollary.

COROLLARY 5.2. *Let $\widehat{G}$ be obtained from G_0 by repeatedly applying rules* (T1) *and* (T2). *For every $k \geq 2$, $\widehat{G}$ is a local certificate of k-edge-connectivity for X_2 in G_0.*

LEMMA 5.13. *Let $\widehat{G}$ be obtained from G_0 by applying rule* (T1) *or* (T2). *Then $\widehat{G}$ is a global certificate of k-edge-connectivity for X_2 in G_0, $k \geq 2$.*

Proof. Let H be given with $V(G_0) \cap V(H) \subseteq X_2$. Rules (T1) and (T2) can only increase the connectivity of $G_0 \cup H$, and thus $\lambda(\widehat{G} \cup H) \geq \lambda(G_0 \cup H)$. Hence, it remains to show that any k-edge-cut (S, T) in $G_0 \cup H$ corresponds to an edge-cut in $\widehat{G} \cup H$ of cardinality at most k.

If both S and T contain vertices in $V(H) \cup X_2 \cup \{t_2\}$, a corresponding edge-cut can be found by Lemma 5.12. Otherwise assume without loss of generality that T contains only black vertices of G_0. Then all edges of cut (S, T) are in G_0. Let (S', T') be the minimum edge-cut separating X_2 from t_2 in G_0. Then $(S' \cup V(H), T')$ has edge cardinality at most that of (S, T), and since t_2 was colored red, a corresponding edge-cut exists in $\widehat{G} \cup H$ by Lemma 5.12. ∎

5.3. Compressing a 3-edge-connected graph. In this section we describe our solution to Problem 5.3. Since it relies heavily on the notion of cactus tree, we first list some properties of a cactus tree of a 3-edge-connected graph, referring the interested reader to [4, 28] for the full details. It might be helpful to refer to Figure 2 while we discuss these properties.

Let G_0 be a 3-edge-connected graph, and let $\mathcal{T}(G_0)$ denote its cactus tree. Since 3 is odd, $\mathcal{T}(G_0)$ is an actual tree (and not a tree of edges and cycles). Edges of $\mathcal{T}(G_0)$ correspond to 3-edge-cuts of G_0. Each 4-edge-connected class of G_0 corresponds to a node in $\mathcal{T}(G_0)$, while the converse is not necessarily true. Indeed, there can be nodes that do not correspond to any 4-edge-connected class: the reason for having these nodes is to represent the tree structure of the 3-edge-cuts (see Figure 2). We call these nodes *empty* since they do not contain any vertex of G_0. In what follows, since there is no danger of ambiguity, we will use interchangeably the terms 3-edge-cut of G_0 and edge of $\mathcal{T}(G_0)$, and the terms 4-edge-connected class of G_0 and nonempty node of $\mathcal{T}(G_0)$. Note that an edge $e = (u, v)$ of G_0 might take part in different 3-edge-cuts of G_0. However, all these 3-edge-cuts must form a path in $\mathcal{T}(G_0)$: endpoints of this path are the two nodes corresponding to the 4-edge-connected classes containing u and v. We label each cactus edge with the three edges of the corresponding 3-edge-cut.

We now describe our solution to Problem 5.3. Let G_0 be a 3-edge-connected graph, and let $X_3 \subseteq V(G_0)$ and $Y_3 \subseteq E(G_0)$. Let Z_3 be the set of endpoints of edges in Y_3. We color red the vertices of $X_3 \cup Z_3$ and the edges of Y_3. Note that both the endpoints of a red edge are colored red. We define a 3-edge-cut of G_0 to be an *inter* 3-*edge-cut* if it separates two different red vertices of G_0, and define it to be an *extra* 3-*edge-cut* otherwise. If G_0 has at least one *extra* 3-edge-cut, we pick one such 3-edge-cut and we choose arbitrarily one vertex that is separated from all the red vertices by this 3-edge-cut. We call this vertex the *chosen extra vertex*, and we call the 3-edge-cut the *chosen extra* 3-*edge-cut*. We color the chosen extra vertex red: the total number of red vertices of G_0 is therefore $(|X_3 \cup Z_3| + 1)$. Our computation of a solution for Problem 5.3 consists of the following three phases.

`Phase 1:` Compute the cactus tree $\mathcal{T}(G_0)$ of G_0 (see Figure 4(b)).

`Phase 2:` Compute a new cactus tree $\mathcal{T}'$ by compressing $\mathcal{T}(G_0)$, so that $\mathcal{T}'$ will have size linear in the number of red vertices (see Figure 4(c)).

`Phase 3:` Compute G_3 from $\mathcal{T}'$.

We now give the low-level details of these phases. Phase 1 is simply accomplished by computing the cactus tree of G_0. Let R be the set of red vertices in G_0, and let R_1 and R_2 be any two nonempty sets of red vertices in G_0, $R_1 \cap R_2 = \emptyset$. We say that an edge of $\mathcal{T}(G_0)$ separates R_1 and R_2 if it corresponds to a 3-edge-cut separating R_1 and R_2 in G_0. The following lemma is an immediate consequence of the notion of cactus tree [4].

LEMMA 5.14. *Let R_1 and R_2 be any two nonempty sets of red vertices in G_0, $R_1 \cap R_2 = \emptyset$. The* 3-*edge-cut $\{e_1, e_2, e_3\}$ of G_0 separates R_1 and R_2 if and only if the edge (α, β) labeled with $\{e_1, e_2, e_3\}$ in $\mathcal{T}(G_0)$ separates R_1 and R_2.*

In Phase 2 we use a compression similar to the one used for the MSF (minimum spanning forest) certificate. Given the graph G_0 and its cactus tree $\mathcal{T}(G_0)$, we define the *degree of a* 4-*edge-connected class* of G_0 to be the tree degree of the corresponding (nonempty) node in $\mathcal{T}(G_0)$. Intuitively, the degree of a 4-edge-connected class denotes the number of different 3-edge-cuts that are "incident" to the class. Again, we define a 4-edge-connected class to be *red* if it contains at least one red vertex, and define it to be *black* otherwise. We color red the (nonempty) nodes of $\mathcal{T}(G_0)$ that correspond to red 4-edge-connected classes of G_0 (see Figure 4(b)). Black 4-edge-connected classes of degree one are uninteresting leaves in the cactus tree, and adjacent black nodes of degree two give rise to uninteresting chains in the cactus tree. Our rules to compress $\mathcal{T}(G_0)$ are the following.

(Q1) Let Q be a black cactus node of degree 1. Delete Q and its incident edge from the cactus tree.

(Q2) Let Q be a black cactus node of degree 2. Let e_1 and e_2 be the cactus edges incident to Q, and let Q_1 and Q_2 be the cactus nodes adjacent to Q. Delete Q and replace e_1 and e_2 with an edge e between Q_1 and Q_2. Edge e gets the same label as e_1.

We call $\mathcal{T}'$ the cactus tree obtained after all the rules (Q1) and (Q2) have been applied. Note that $\mathcal{T}'$ contains all the red nodes of $\mathcal{T}(G_0)$ and may contain some black nodes of $\mathcal{T}(G_0)$. However, because of (Q1) and (Q2), the total size of $\mathcal{T}'$ is linear in the number of red nodes. Note that edges of $\mathcal{T}'$ are also edges of $\mathcal{T}(G_0)$, and therefore correspond to 3-edge-cuts of G_0. Again, given two nonempty disjoint sets of red vertices R_1 and R_2, we say that an edge of $\mathcal{T}'$ separates R_1 and R_2 if it corresponds to a 3-edge-cut separating R_1 and R_2 in G_0. As the following lemma shows, $\mathcal{T}'$ has the property of preserving 3-edge-cuts separating any two sets of red

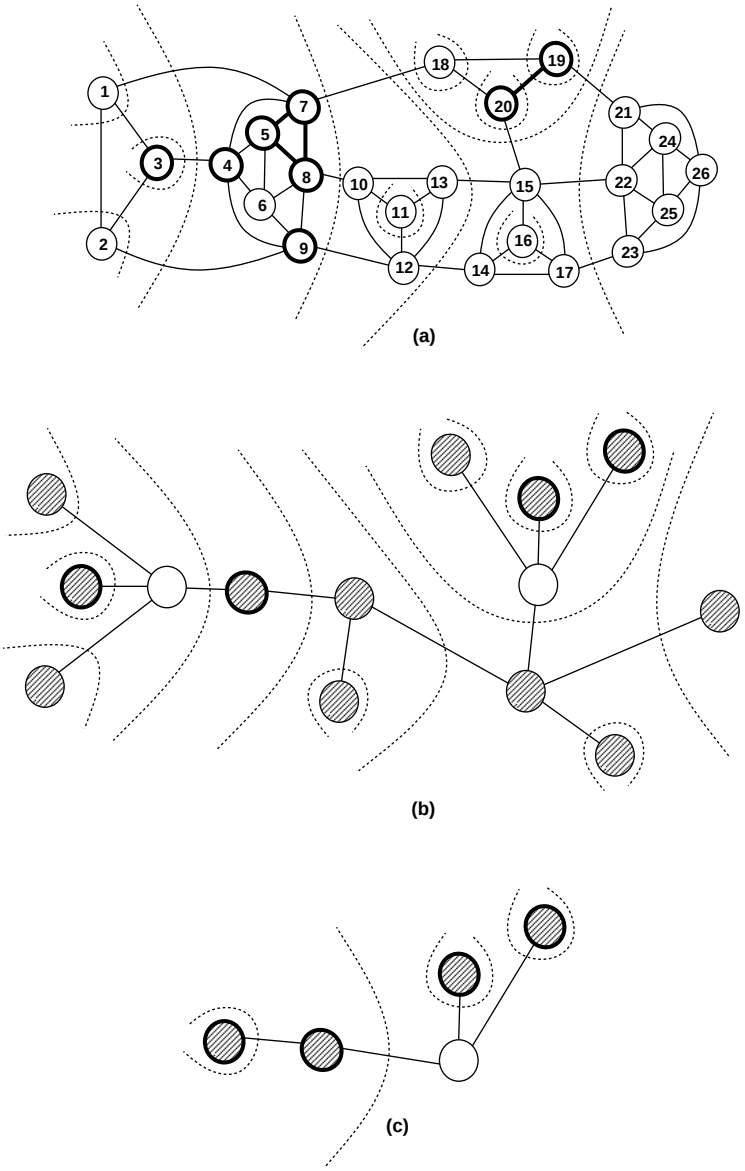

FIG. 4. *Compressing a 3-edge-connected graph G_0.* (a) *The original graph G_0: red vertices ($\{3,4,5,7,8,9,19,20\}$) and red edges ($\{(5,7),(5,8),(7,8),(19,20)\}$) are shown in bold, 3-edge-cuts are dashed.* (b) *The cactus tree $\mathcal{T}(G_0)$: red 4-edge-connected classes are shown in bold.* (c) *The compressed cactus tree $\mathcal{T}'$ obtained from $\mathcal{T}(G_0)$.*

vertices in G_0.

LEMMA 5.15. *Let R_1 and R_2 be any two nonempty sets of red vertices in G_0, $R_1 \cap R_2 \neq \emptyset$. There is an edge (α, β) in $\mathcal{T}(G_0)$ separating R_1 and R_2 if and only if there is an edge (α', β') in $\mathcal{T}'$ separating R_1 and R_2.*

Proof. To prove the lemma, we show that rules (Q1) and (Q2) maintain the following invariant. There is an edge (α, β) separating R_1 and R_2 before the rule is

applied if and only if there is an edge (α', β') separating R_1 and R_2 after the rule is applied.

If rule (Q1) is applied, Q is a black node. Since the edge incident to Q cannot separate red vertices, the invariant must hold. If rule (Q2) is applied, Q is a black node. Consequently, e_1 and e_2 separate exactly the same set of red vertices. But then the edge e inserted by rule (Q2) still separates the same set of red vertices previously separated by e_1 and e_2. Hence, the invariant still holds. □

Now, we describe our implementation of Phase 3, namely, how to compute from $\mathcal{T}'$ the graph G_3 that is a solution to Problem 5.3. By Lemmas 5.14 and 5.15, we know that, given any two sets R_1 and R_2 in G_0, they can be separated by a 3-edge-cut of G_0 if and only if they can be separated by an edge of $\mathcal{T}'$. In Phase 3, we build a graph G_3 that contains the red vertices and red edges of G_0, and has all the 3-edge-cuts corresponding to edges of $\mathcal{T}'$. We will use this property to prove that any two sets of red vertices R_1 and R_2 can be separated by a 3-edge-cut in G_0 if and only if they can be separated by a 3-edge-cut in G_3.

We show how to obtain G_3. For each edge (α', β') of $\mathcal{T}'$, we do the following. Let $\{e_1, e_2, e_3\}$ be the label of (α', β') (corresponding to the 3-edge-cut $\{e_1, e_2, e_3\}$ of G_0): we mark the edges e_1, e_2, and e_3 and their endpoints in G_0. In other words, all the edges that are in a 3-edge-cut corresponding to an edge of $\mathcal{T}'$ are *marked*. Next, we delete all the marked edges from G_0, and denote by G_0^1, G_0^2, ..., G_0^p, $p \geq 1$, the connected components left (see Figure 5(a)). The edges of G_0^i, $1 \leq i \leq p$, are referred to as *unmarked*.

Our graph G_3 will keep all the marked edges and replace each G_0^i with a smaller graph that preserves 3- and 4-edge-connectivity between the red vertices. We compute this smaller graph as follows. We denote the red and marked vertices of G_0^i *interesting*. We force 4-edge-connectedness between any two interesting vertices in G_0^i by replacing G_0^i with a smaller graph that contains all the interesting vertices and the red edges originally in G_0^i and that is 4-edge-connected. We call this graph $\mathcal{C}(G_0^i)$. Note that this might change the edge connectivity inside G_0^i, since it may change the number of edge-disjoint paths inside G_0^i. Namely, two vertices x and y of G_0^i may be ℓ-edge-connected, $\ell \geq 4$ in G_0, and ℓ'-edge-connected, $\ell' \geq 4$, $\ell' \neq \ell$, in the new graph obtained after replacing G_0^i with $\mathcal{C}(G_0^i)$. However, as we will show, this is not a problem, since we are interested in certificates for 3- and 4-edge-connectivity only, and not for higher edge connectivity. We make all the interesting vertices of G_0^i 4-edge-connected in the new graph by compressing the unmarked edges as follows. We first compute the minimal subgraph S_0^i of G_0^i that is connected and contains all the red edges and the interesting vertices in G_0^i (see Figure 5(b)). Note that S_0^i is not necessarily a tree, since it might contain cycles: however, because of the minimality of S_0^i, the possible cycles of S_0^i can have only red edges. We collapse each red cycle in a single node, and then compress the tree obtained, using as interesting vertices the collapsed cycles, the red vertices and the marked vertices. The compression of the unmarked edges left in S_0^i is the same as used in the MSF algorithm: we compress uninteresting branches and uninteresting chains of degree-two vertices (see Figure 5(c)). Next, we expand the red cycles back, and finally, we quadruplicate each unmarked edge left in the compressed graph, to force 4-edge-connectivity. We call the graph obtained $\mathcal{C}(G_0^i)$, and we call G_3 the graph obtained after replacing G_0^i with $\mathcal{C}(G_0^i)$, $1 \leq i \leq p$ (see Figure 5(d)).

Note that G_3 is obtained from G_0 by means of a suitable sequence of the following operations:

(1) delete unmarked edges inside a component G_0^i; and

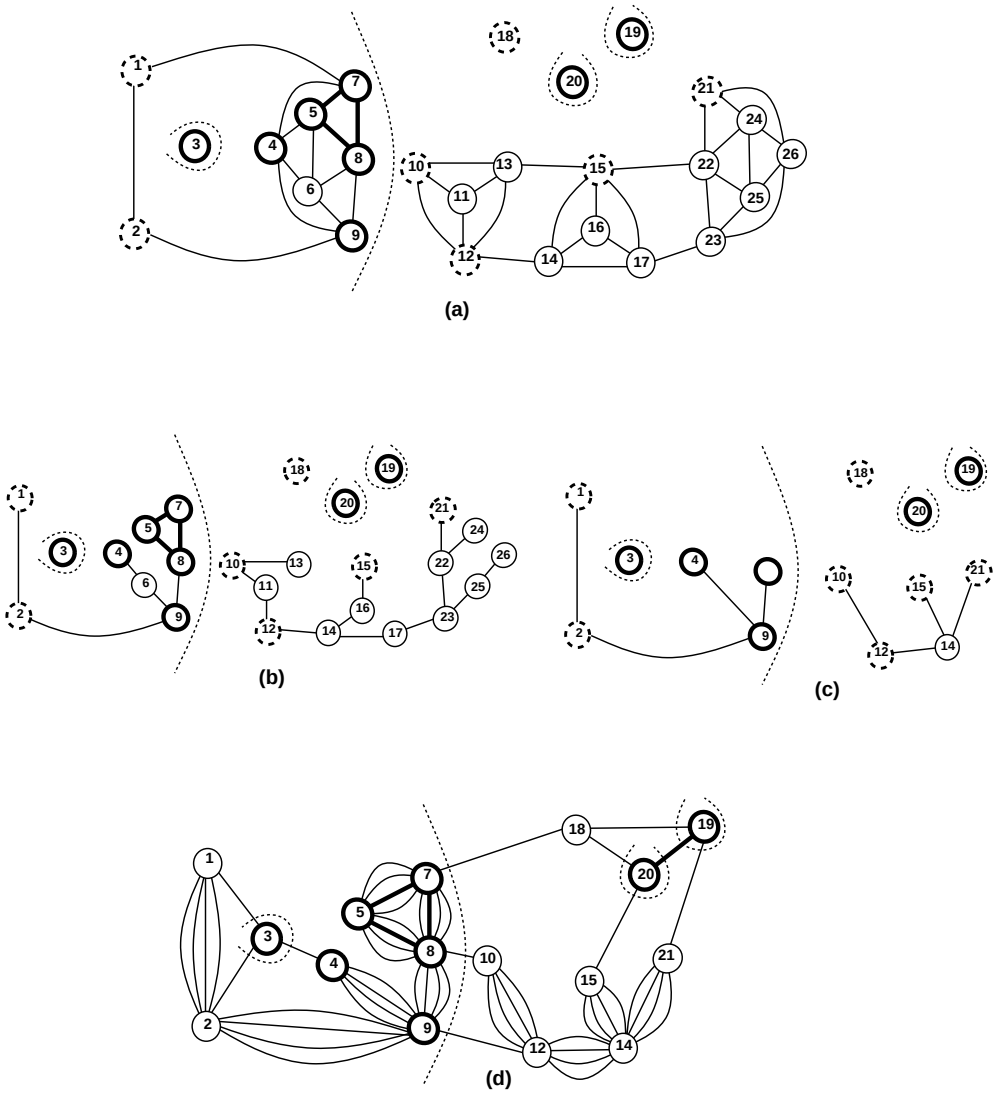

FIG. 5. *Compressing G_0; 3-edge-cuts corresponding to edges of $\mathcal{T}'$ are always shown dashed.* (a) *The connected components G_0^i, $1 \le i \le p$, obtained after the removal of 3-edge-cuts in $\mathcal{T}'$. Marked (non-red) vertices are shown dashed.* (b) *The minimal subgraphs S_0^i, $1 \le i \le p$.* (c) *The graphs obtained after compressing S_0^i, $1 \le i \le p$: the red cycle containing vertices* 5, 7, *and* 8 *has been collapsed into a single node.* (d) *The graph G_3 obtained from G_0 by replacing G_0^i with $\mathcal{C}(G_0^i)$, $1 \le i \le p$. The red cycle has been expanded.*

(2) contract unmarked edges; and
(3) quadruplicate unmarked edges.

Conversely, G_0 can be recomputed from G_3 by means of a suitable sequence of the following operations:

(4) delete multiple unmarked edges;
(5) expand unmarked edges;

(6) insert new unmarked edges inside a component $\mathcal{C}(G_0^i)$.

We now prove that G_3 is a solution to Problem 5.3.

LEMMA 5.16. *G_3 is 3-edge-connected, and $X_3 \subseteq V(G_3)$ and $Y_3 \subseteq E(G_3)$.*

Proof. We first prove that G_3 is 3-edge-connected. Assume by contradiction that the minimum edge-cut γ of G_3 is of cardinality ℓ, $\ell \leq 2$. Recall that G_3 consists of marked edges and unmarked edges. Since each unmarked edge is quadruplicated in G_3, its endpoints are 4-edge-connected. This implies that no unmarked edge can be in γ, and therefore, γ consists of marked edges only. Due to the minimality of γ, deleting the edges of γ disconnects G_3 into two graphs: say G_3' and G_3''. Since γ contains only marked edges, and each $\mathcal{C}(G_0^i)$ is connected, each $\mathcal{C}(G_0^i)$ is contained in either G_3' or G_3''. Recall that G_0 can be obtained from G_3 by means of operations of type (4), (5), and (6) above. Each such operation modifies only the graphs $\mathcal{C}(G_0^i)$ by deleting multiple edges, expanding unmarked edges, and inserting new unmarked edges. Marked edges will be unaffected by these operations. This implies that all these operations will be local to the graphs $\mathcal{C}(G_0^i)$, and therefore will still keep the vertices in G_3' and in G_3'' disconnected. As a result, γ is an ℓ-edge-cut in G_0. This is clearly a contradiction, since $\ell \leq 2$ and G_0 is 3-edge-connected. Thus, there cannot be an ℓ-edge-cut, $\ell \leq 2$, in G_3, and therefore G_3 must be 3-edge-connected.

We now prove that G_3 contains all the red vertices and edges of G_0. Since red vertices are kept in each $\mathcal{C}(G_0^i)$, we have that $X_3 \subseteq V(G_3)$. As for red edges, recall that the edges of G_0 are partitioned into marked and unmarked. Each $\mathcal{C}(G_0^i)$ preserves all the red edges in G_0^i: this shows that all the unmarked red edges are in G_3. Since G_3 preserves all the marked edges, it will preserve also the marked red edges. This shows that $Y_3 \subseteq E(G_3)$. ∎

Before proving the other properties that make G_3 a solution to Problem 5.3, we need some technical lemmas.

LEMMA 5.17. *Let R_1 and R_2 be any two nonempty sets of red vertices in G_0, $R_1 \cap R_2 = \emptyset$. There is a 3-edge-cut in G_0 separating R_1 and R_2 if and only if there is a 3-edge-cut in G_3 separating R_1 and R_2.*

Proof. Assume that there is a 3-edge-cut $\{e_1, e_2, e_3\}$ separating R_1 and R_2 in G_0. By Lemmas 5.14 and 5.15 there must be an edge (α', β') in $\mathcal{T}'$ separating R_1 and R_2. Let $\{e_1', e_2', e_3'\}$ be the label of (α', β'). We claim that $\{e_1', e_2', e_3'\}$ is a 3-edge-cut of G_3 separating R_1 and R_2. Note that, as a consequence of our computation of $\mathcal{T}'$, $\{e_1', e_2', e_3'\}$ must have been the label of one edge of $\mathcal{T}(G_0)$. By definition of cactus tree, this implies that $\{e_1', e_2', e_3'\}$ is a 3-edge-cut of G_0. Note that it is not necessarily the case that $\{e_1, e_2, e_3\} = \{e_1', e_2', e_3'\}$. Both $\{e_1, e_2, e_3\}$ and $\{e_1', e_2', e_3'\}$ are 3-edge-cuts separating R_1 and R_2 in G_0, and $\{e_1', e_2', e_3'\}$ is kept in $\mathcal{T}'$ (and therefore in G_3).

Denote by G_0' and G_0'' the graphs obtained from G_0 after removing e_1', e_2', and e_3', and without loss of generality, assume that $R_1 \subseteq V(G_0')$ and $R_2 \subseteq V(G_0'')$. Note that $\{e_1', e_2', e_3'\}$ is a 3-edge-cut corresponding to an edge of $\mathcal{T}'$. As a result, the edges e_1', e_2', and e_3' are marked edges, and each G_0^i is contained in either G_0' or G_0''. Recall that G_3 is obtained from G_0 by means of operations (1)–(3) above, which are local to the graphs G_0^i and therefore will still keep G_0' and G_0'' disconnected. Since $R_1 \subseteq V(G_0')$ and $R_2 \subseteq V(G_0'')$, this implies that $\{e_1', e_2', e_3'\}$ is a 3-edge-cut separating R_1 and R_2 in G_3.

Assume now that there is a 3-edge-cut $\{e_1, e_2, e_3\}$ separating R_1 and R_2 in G_3. Note that no unmarked edge can be in a 3-edge-cut, since each unmarked edge left after the compression of S_0^i is quadruplicated, therefore making its endpoints 4-edge-connected. As a result, e_1, e_2, and e_3 must all be marked edges. This implies that

e_1, e_2 and e_3 are all edges of G_0.

Since by Lemma 5.16 G_3 is 3-edge-connected, $\{e_1, e_2, e_3\}$ is a minimum edge-cut in G_3, and therefore the removal of e_1, e_2, and e_3 splits G_3 into two graphs, say G_3' and G_3''. Without loss of generality assume that $R_1 \subseteq V(G_3')$ and $R_2 \subseteq V(G_3'')$. Recall that G_0 can be obtained from G_3 by means of operations (4)–(6) above, which still keep G_3' and G_3'' disconnected. Since $R_1 \subseteq V(G_3')$ and $R_2 \subseteq V(G_3'')$, this implies that $\{e_1, e_2, e_3\}$ is a 3-edge-cut separating R_1 and R_2 in G_0. □

LEMMA 5.18. *Let γ be a 3-edge-cut of G_3, separating V' and V'', with $V', V'' \subseteq V(G_3)$. Then γ is a 3-edge-cut of G_0, separating V' and V'' in G_0.*

Proof. Let G_3' and G_3'' be the two graphs obtained after the deletion of γ from G_3, with $V' = V(G_3')$ and $V'' = V(G_3'')$. Recall that G_0 can be obtained from G_3 by means of operations of types (4), (5), and (6). None of these operations adds a path between V' and V'', and therefore γ is a 3-edge-cut of G_0, separating V' and V''. □

LEMMA 5.19. *G_3 has $O(|X_3 \cup Z_3|)$ vertices and edges.*

Proof. As said before, there are exactly $(|X_3 \cup Z_3| + 1)$ red vertices in G_0. Recall that a 4-edge-connected class Q_j of G_0 is red if it contains at least one red vertex. Let $r_j \geq 1$ be the number of red vertices contained in a red 4-edge-connected class Q_j, and let ρ be the total number of red 4-edge-connected classes of G_0. Since any two 4-edge-connected classes are disjoint, we have

$$\sum_{j=1}^{\rho} r_j = |X_3 \cup Z_3| + 1$$

and

$$\rho \leq |X_3 \cup Z_3| + 1.$$

Let $\mathcal{T}(G_0)$ be the cactus tree of G_0. We color red a node of $\mathcal{T}(G_0)$ only if it corresponds to a red 4-edge-connected class of G_0. Hence, there are exactly ρ red nodes in $\mathcal{T}(G_0)$. Let $\mathcal{T}'$ be the compressed cactus tree. Because of rules (Q1) and (Q2), $\mathcal{T}'$ has no black leaves and no black chains of degree-two nodes. Consequently, $\mathcal{T}'$ has $O(\rho)$ nodes and edges. Since there are at most three marked edges in G_0 for each edge in $\mathcal{T}'$, the total number of marked edges and vertices in G_0 will be $O(\rho)$. For $1 \leq i \leq p$, let ρ_i be the total number of marked vertices in G_0^i, and let σ_i be the total number of red vertices in G_0^i. Note that

$$\sum_{i=1}^{p} (\rho_i + \sigma_i) = O(\rho + |X_3 \cup Z_3|) = O(|X_3 \cup Z_3|).$$

Since each $\mathcal{C}(G_i)$ has size $O(\rho_i + \sigma_i)$, and there are $O(\rho)$ marked edges in G_3, the lemma follows. □

LEMMA 5.20. *Let H be a graph such that $V(H) \cap V(G_0) \subseteq X_3 \cup Z_3$. If $\lambda(G_0 \cup H) = \ell$, $\ell \leq 3$, then $\lambda(G_3 \cup H) \leq \ell$.*

Proof. Assume that $\lambda(G_0 \cup H) = \ell \leq 3$, and let γ be a minimum edge-cut of $G_0 \cup H$, with $|\gamma| = \ell$. Let $\gamma_{G_0} = \gamma \cap E(G_0)$ and $\gamma_H = \gamma \cap E(H)$ be, respectively, the edges of γ in G_0 and in H. Due to the minimality of γ, if $\gamma_{G_0} \neq \emptyset$, γ_{G_0} must be an edge-cut in G_0. Similarly, if $\gamma_H \neq \emptyset$, γ_H must be an edge-cut in H. In other words, denote by $G_0' \cup H'$ and $G_0'' \cup H''$ the two graphs obtained from $G_0 \cup H$ after deleting the edges of γ, with $G_0', G_0'' \subseteq G_0$, and $H', H'' \subseteq H$: γ_{G_0} splits G_0 into G_0'

and G_0'', while γ_H splits H into H' and H''. If $\gamma_{G_0} = \emptyset$, then γ uses no edges of G_0, and therefore it does not split G_0: in this case we assume that $G_0' = G_0$ and $G_0'' = \emptyset$. Since γ_{G_0} is an edge-cut of G_0, and G_0 is 3-edge-connected, either $\gamma_{G_0} = \emptyset$ or $|\gamma_{G_0}| \geq 3$. Since $|\gamma| \leq 3$, we are left with only two possibilities: either

(a) $\gamma_{G_0} = \emptyset$ (and therefore $\gamma = \gamma_H$), or
(b) $|\gamma_{G_0}| = 3$ and $\gamma_H = \emptyset$ (and therefore $\gamma = \gamma_{G_0}$ and $\ell = 3$).

In case (a), since $\gamma_{G_0} = \emptyset$, $G_0 = G_0'$. Since $\gamma = \gamma_H$, no path between H' and H'' can go through G_0. Since G_0 is 3-edge-connected, and therefore connected, this implies that either H' or H'' is not connected to G_0: without loss of generality, assume that $V(H') \cap V(G_0) = \emptyset$. Then $\gamma = \gamma_H$ splits $G_0 \cup H$ into $G_0 \cup H''$ and H'. Since $V(H) \cap V(G_0) = V(H) \cap V(G_3)$, we also have that $V(H') \cap V(G_3) = \emptyset$, and therefore $\gamma = \gamma_H$ splits $G_3 \cup H$ into $G_3 \cup H''$ and H'. Thus, $\lambda(G_3 \cup H) \leq \ell$, and the lemma holds in case (a).

Assume now that we are in case (b) and $\gamma = \gamma_{G_0}$ is a 3-edge-cut in $G_0 \cup H$. Since $\ell = 3$, we have to prove that $\lambda(G_3 \cup H) \leq 3$. To do this, we distinguish two subcases.

(b1) γ_{G_0} is separating two nonempty sets of red vertices, say R_1 and R_2, in G_0, or
(b2) no two red vertices are separated by γ_{G_0}.

Assume we are in case (b1). Since $\gamma_H = \emptyset$, and γ_{G_0} is a 3-edge-cut of $G_0 \cup H$ separating R_1 and R_2, there is no path in H between R_1 and R_2. As a consequence of $R_1, R_2 \neq \emptyset$, by Lemma 5.17 there is a 3-edge-cut γ' separating R_1 and R_2 in G_3. Since γ' separates R_1 and R_2 in G_3, with $R_1, R_2 \neq \emptyset$, and there is no path in H between R_1 and R_2, γ' is a 3-edge-cut of $G_3 \cup H$. If we are in case (b2), $\gamma = \gamma_{G_0}$ is a 3-edge-cut of G_0 that does not separate red vertices. Since all the vertices in $X_3 \cup Z_3$ are red, this implies that γ is an *extra* 3-edge-cut. But then there is a chosen extra 3-edge-cut $\widehat{\gamma}$ in G_0. Let v_0 be the chosen extra vertex: $\widehat{\gamma}$ separates $\widehat{R_1} = X_3 \cup Z_3$ from $\widehat{R_2} = \{v_0\}$, and v_0 is colored red. By Lemma 5.17, there is a 3-edge-cut $\widehat{\gamma}'$ separating $X_3 \cup Z_3$ and $\{v_0\}$ in G_3. Since $V(H) \cap V(G_0) \subseteq X_3 \cup Z_3$, and $v_0 \notin (X_3 \cup Z_3)$, there cannot be a path in H between $\widehat{R_1} = X_3 \cup Z_3$ and $\widehat{R_2} = \{v_0\}$. This implies that $\widehat{\gamma}'$ separates $X_3 \cup Z_3$ and v_0 in $G_3 \cup H$, and therefore $\widehat{\gamma}'$ is a 3-edge-cut of $G_3 \cup H$. In summary, in both cases (b1) and (b2), there is a 3-edge-cut in $G_3 \cup H$. Then, $\lambda(G_3 \cup H) \leq 3$, and the lemma also holds in case (b), since $\ell = 3$. □

LEMMA 5.21. *Let H be a graph such that $V(H) \cap V(G_0) \subseteq X_3 \cup Z_3$. If $\lambda(G_3 \cup H) = \ell \leq 3$, then $\lambda(G_0 \cup H) \leq \ell$.*

Proof. We use an argument similar to the one used in the proof of Lemma 5.20. Assume that $\lambda(G_3 \cup H) = \ell \leq 3$, and let δ be a minimum edge-cut of $G_3 \cup H$, with $|\delta| = \ell$. Let $\delta_{G_3} = \delta \cap E(G_3)$ and $\delta_H = \delta \cap E(H)$ be the edges of δ in G_3 and in H. Due to the minimality of δ, if $\delta_{G_3} \neq \emptyset$, δ_{G_3} must be an edge-cut in G_3. Similarly, if $\delta_H \neq \emptyset$, δ_H must be an edge-cut in H. Since by Lemma 5.16, G_3 is 3-edge-connected, either $\delta_{G_3} = \emptyset$ or $|\delta_{G_3}| \geq 3$. As in the proof of Lemma 5.20, $|\delta| \leq 3$ leaves only two possibilities: either (a) $\delta_{G_3} = \emptyset$ or (b) $|\delta_{G_3}| = 3$, $\delta_H = \emptyset$, and $\ell = 3$. In case (a), the same proof previously used for case (a) of Lemma 5.20 shows that $\delta = \delta_H$ is an ℓ-edge-cut in $G_0 \cup H$ too. If we are in case (b), $\delta_H = \emptyset$, and $\delta = \delta_{G_3}$. Let V_1 and V_2 be the two sets of vertices separated by δ in G_3. Because of Lemma 5.18, δ is a 3-edge-cut separating V_1 and V_2 in G_0, which implies that all the paths between V_1 and V_2 in G_0 go through δ. Since $\delta_H = \emptyset$, there is no path in H between V_1 and V_2. The latter two statements imply that all the paths between V_1 and V_2 in $G_0 \cup H$ go through δ. Thus, δ is a 3-edge-cut of $G_0 \cup H$ too. □

LEMMA 5.22. *For $2 \leq k \leq 4$, G_3 is a compressed global certificate of k-edge-connectivity for $(X_3 \cup Z_3)$ in G_0.*

Proof. Let H be any graph with $V(H) \cap V(G_0) \subseteq X_3 \cup Z_3$. By Lemmas 5.20 and 5.21, $\lambda(G_0 \cup H) = \ell \leq 3$ if and only if $\lambda(G_3 \cup H) = \ell \leq 3$. This implies that $\lambda(G_0 \cup H) > 3$ if and only if $\lambda(G_3 \cup H) > 3$. Hence, G_3 is a global certificate of k-edge-connectivity for $(X_3 \cup Z_3)$ in G_0, $2 \leq k \leq 4$. This certificate is compressed because of Lemma 5.19. ∎

LEMMA 5.23. *Let H be given with $V(G_0) \cap V(H) \subseteq X_3 \cup Z_3$, and let $u \in X_3 \cup Z_3 \cup V(H)$. For any vertex $v \in V(G_0)$, all the paths between u and v in $G_0 \cup H$ must contain at least one red vertex. Similarly, for any vertex $w \in V(G_3)$, all the paths between u and w in $G_3 \cup H$ must contain at least one red vertex.*

Proof. Recall that all the vertices in $X_3 \cup Z_3$ are colored red. If $u \in X_3 \cup Z_3$, u is itself a red vertex, and therefore the lemma is trivially true. Assume now that $u \in (V(H) - (X_3 \cup Z_3))$. Since $V(G_0) \cap V(H) \subseteq X_3 \cup Z_3$, G_0 and H share only red vertices, and therefore each path between a vertex in H and a vertex in G_0 must contain at least one red vertex. The same argument applies to G_3. ∎

LEMMA 5.24. *For $2 \leq k \leq 4$, G_3 is a local certificate of k-edge-connectivity for $X_3 \cup Z_3$ in G_0.*

Proof. Let H be given with $V(G_0) \cap V(H) \subseteq X_3 \cup Z_3$, and let x and y be any two vertices of $X_3 \cup Z_3 \cup V(H)$. To prove the lemma, we basically follow the same ideas used for proving Lemma 5.22, but this time we consider edge-cuts that separate x and y instead. Note that since $x, y \in X_3 \cup Z_3 \cup V(H)$, x and y are in both $G_0 \cup H$ and $G_3 \cup H$. We prove the following two properties, which are the analogs of Lemmas 5.20 and 5.21.

(i) If $\lambda_{x,y}(G_0 \cup H) = \ell \leq 3$, then $\lambda_{x,y}(G_3 \cup H) \leq \ell$.
(ii) If $\lambda_{x,y}(G_3 \cup H) = \ell \leq 3$, then $\lambda_{x,y}(G_0 \cup H) \leq \ell$.

Properties (i) and (ii) imply that $\lambda_{x,y}(G_0 \cup H) = \ell \leq 3$ if and only if $\lambda_{x,y}(G_3 \cup H) = \ell \leq 3$. Note that any two vertices whose edge connectivity is not ℓ, $\ell \leq 3$, are at least 4-edge-connected. Hence, the lemma will follow from (i) and (ii).

We first prove (i). If $\lambda_{x,y}(G_0 \cup H) = \ell \leq 3$, then there is a minimum edge-cut $\gamma(x, y)$ separating x and y in $G_0 \cup H$ such that $|\gamma(x, y)| = \ell \leq 3$. Denote by $G_0' \cup H'$ and $G_0'' \cup H''$ the two graphs obtained from $G_0 \cup H$ after deleting the edges of $\gamma(x, y)$, with $G_0', G_0'' \subseteq G_0$, and $H', H'' \subseteq H$. Without loss of generality, assume that x is in $G_0' \cup H'$ and y is in $G_0'' \cup H''$. Let $\gamma_{G_0}(x, y) = \gamma(x, y) \cap E(G_0)$ and $\gamma_H(x, y) = \gamma(x, y) \cap E(H)$ be, respectively, the edges of $\gamma(x, y)$ in G_0 and in H. Due to the minimality of $\gamma(x, y)$, if $\gamma_{G_0}(x, y) \neq \emptyset$, $\gamma_{G_0}(x, y)$ must be an edge-cut of G_0 (separating G_0' and G_0''). If $\gamma_{G_0}(x, y) = \emptyset$, then $\gamma(x, y)$ uses no edges of G_0, and therefore it does not split G_0: in this case we assume that $G_0' = G_0$ and $G_0'' = \emptyset$. Similarly, if $\gamma_H \neq \emptyset$, $\gamma_H(x, y)$ must be an edge-cut of H (separating H' and H'').

Since $\gamma_{G_0}(x, y)$ is an edge-cut of G_0, and G_0 is 3-edge-connected, either $\gamma_{G_0}(x, y) = \emptyset$ or $|\gamma_{G_0}(x, y)| \geq 3$. Since $|\gamma(x, y)| \leq 3$, we are left with only two possibilities:

(a) $\gamma_{G_0}(x, y) = \emptyset$ (and therefore $\gamma(x, y) = \gamma_H(x, y)$);
(b) $|\gamma_{G_0}(x, y)| = 3$ and $\gamma_H(x, y) = \emptyset$ (and therefore $\gamma(x, y) = \gamma_{G_0}(x, y)$).

Assume we are in case (a). Since $\gamma_{G_0}(x, y) = \emptyset$, $G_0 = G_0'$ and $\gamma_H(x, y)$ splits $G_0 \cup H$ into $G_0 \cup H''$ and H'. Due to the fact that $\gamma_H(x, y)$ separates x and y, one of these vertices must be in H', and the other must be in $G_0 \cup H''$. Since $V(G_3) \subseteq V(G_0)$, we have that $V(H') \cap V(G_3) = \emptyset$. Thus, $\gamma_H(x, y)$ splits $G_3 \cup H$ into $G_3 \cup H''$ and H', and therefore it separates x and y in $G_3 \cup H$ too. This yields (i) for this case.

Assume now that we are in case (b). Since $\gamma(x, y) = \gamma_{G_0}(x, y)$ is a 3-edge-cut separating x and y in $G_0 \cup H$, it splits G_0 into G_0' and G_0'', which are both non-empty. Assume that x is in the same side as G_0' and y is in the same side as G_0''.

Let R' and R'' be the sets of red vertices, respectively, in G'_0 and in G''_0. Recall that $V(H) \cap V(G_3) \subseteq X_3 \cup Z_3$, and vertices of $X_3 \cup Z_3$ are colored red. Because of Lemma 5.23, there is a red vertex (of R') in each path between x and a vertex in G'_0, and there is a red vertex (of R'') in each path between y and a vertex in G''_0. This shows that $R', R'' \neq \emptyset$, and therefore by Lemma 5.17, there is a 3-edge-cut $\widehat{\gamma}$ separating R' and R'' in G_3. Again, because of Lemma 5.23, any path between x and y that goes through G_3 must contain at least one vertex in R' and one vertex in R''. Since R' and R'' are separated by $\widehat{\gamma}$ in G_3, any such path between x and y must contain at least one edge of $\widehat{\gamma}$. As a consequence of $\gamma_H(x, y) = \emptyset$, no path between x and y can go through H. Then, every path between x and y in $G_3 \cup H$ must go through $\widehat{\gamma}$, thus giving (i).

We now turn to (ii). Assume that the minimum edge-cut $\delta(x, y)$ separating x and y in $G_3 \cup H$ is of cardinality $|\delta(x, y)| = \ell \leq 3$. Let $\delta_{G_3}(x, y) = \delta(x, y) \cap E(G_3)$ and $\delta_H(x, y) = \delta(x, y) \cap E(H)$ be the edges of $\delta(x, y)$ in G_3 and in H. Due to the minimality of $\delta(x, y)$, if $\delta_{G_3}(x, y) \neq \emptyset$, $\delta_{G_3}(x, y)$ must be an edge-cut in $G_3(x, y)$. Similarly, if $\delta_H(x, y) \neq \emptyset$, $\delta_H(x, y)$ must be an edge-cut in H. Since G_3 is 3-edge-connected, either $\delta_{G_3}(x, y) = \emptyset$ or $|\delta_{G_3}(x, y)| \geq 3$. Once again, we have two possibilities: either (a) $\delta_{G_3}(x, y) = \emptyset$ or (b) $|\delta_{G_3}(x, y)| = 3$ and $\delta_H(x, y) = \emptyset$. In case (a), the same argument used for case (a) of (i) shows that $\delta(x, y) = \delta_H(x, y)$ is an ℓ-edge-cut separating x and y in $G_0 \cup H$ too, and therefore (ii) holds. If we are in case (b), $\delta_H(x, y) = \emptyset$, and $\delta(x, y) = \delta_{G_3}(x, y)$, $|\delta_{G_3}(x, y)| = 3$. Let R' and R'' be the red vertices separated by $\delta(x, y)$ in G_3. Exactly as in (i), any path between x and y that goes through G_3 must contain at least one (red) vertex in R' and one (red) vertex in R''. As before, this implies two things. First, by Lemma 5.17, there is a 3-edge-cut $\widehat{\delta}$ separating R' and R'' in G_0. Second, any path between x and y in G_0 must contain at least one edge of $\widehat{\delta}$. As a consequence of $\gamma_H(x, y) = \emptyset$, no path between x and y can go through H. Then, every path between x and y in $G_0 \cup H$ must go through $\widehat{\delta}$. Thus, $\widehat{\delta}$ is a 3-edge-cut separating x and y in $G_0 \cup H$. Since $\ell = 3$ in case (b), this proves (ii). □

LEMMA 5.25. *G_3 preserves planarity.*

Proof. Let H be any graph such that $V(H) \cap V(G_0) \subseteq X_3 \cup Z_3$. $G_3 \cup H$ can be obtained from $G_0 \cup H$ by means of operations (1), (2), and (3), which consist of deletion of edges, contraction of edges, and insertion of parallel edges. Since all these operations preserve planarity, if $G_0 \cup H$ is planar, then $G_3 \cup H$ is planar. Thus, G_3 preserves planarity according to Definition 3.5. □

Lemmas 5.16, 5.22, 5.24, and 5.25 prove that G_3 is a solution to Problem 5.3.

5.4. Compressed certificates for 3- and 4-edge-connectivity. In this section, we combine the results obtained in sections 5.1, 5.2, and 5.3 to derive compressed full certificates for 3- and 4-edge-connectivity. Let $G = (V, E)$ be a planar connected graph, and let X be a set of interesting vertices in G. Let H be given, with $V(G) \cap V(H) \subseteq X$. Our algorithm for finding compressed full certificates consists of the following steps.

Step 1 (*decreasing the number of* 2*-edge-connected components*). Set $X_1 = X$, $G_0 = G$, and compute a solution G_1 to Problem 5.1 as shown in section 5.1.

Step 2 (*decreasing the number of* 3*-edge-connected components*). Let N_1 be the set of endpoints of bridges left in G_1 at the end of Step 1. Because of the previous step, there are $O(|X|)$ bridges in G_1 and therefore $|N_1| = O(|X|)$. For each 2-edge-connected component B left in G_1 do the following: set $X_2(B) = (X_1 \cup N_1) \cap V(B)$, $G_0(B) = B$, and compute a solution $G_2(B)$ to Problem 5.2 as shown in section 5.2.

Let $X_2 = \sum_B X_2(B)$. Note that $|X_2| = \sum_B |X_2(B)| = |X_1 \cup N_1| = O(|X|)$, so this compression uses $O(|X|)$ interesting vertices overall. Denote by G_2 the graph obtained from G_1 by replacing each 2-edge-connected component B with $G_2(B)$. Since each $G_2(B)$ is a solution to Problem 5.2, $G_2(B)$ has $O(|X_2(B)|)$ 3-edge-connected components. Hence, the overall number of 3-edge-connected components left in G_2 will be $\sum_B O(|X_2(B)|) = O(|X|)$.

Step 3 (*final compression*). Let N_2 be the set of endpoints of 2-edge-cuts left in G_2 at the end of Step 2. Since the total number of endpoints of 2-edge-cuts is linear in the number of 3-edge-connected components, because of the previous step, $|N_2| = O(|X|)$. Let T be a 3-edge-connected component of G_2: recall that T is obtained by means of splits (as defined in section 4.1), and it contains virtual edges corresponding to 2-edge-cuts. Let $M_2(T)$ be the set of virtual edges in T. For each 3-edge-connected component T left in G_2 do the following: set $X_3(T) = (X_2 \cup N_2) \cap V(T)$, $G_0(T) = T$, $Y_3(T) = M_2(T)$, and compute a solution $G_3(T)$ to Problem 5.3 as shown in section 5.3. Let $X_3 = \sum_T X_3(T)$ and $M_2 = \sum_T M_2(T)$ be, respectively, the total number of red vertices and red edges. Note that $|X_3| = \sum_T |X_3(T)| = |X_2 \cup N_2| = O(|X|)$ and $|M_2| = \sum_T |M_2(T)| \leq \sum_T |N_2 \cap V(T)| \leq \sum_T |X_3(T)| = O(|X|)$, so again the compression uses $O(|X|)$ interesting vertices overall. Then merge back the compressed 3-edge-connected components along their original 2-edge-cuts. This is well defined, since all the virtual edges, and hence the endpoints of the original 2-edge-cuts, are colored red and therefore preserved in the graphs $G_3(T)$. Denote by G_3 the graph obtained from G_2 in this way.

We now prove that G_3 is a planarity-preserving compressed full certificate of 3- and 4-edge-connectivity for X in G.

LEMMA 5.26. *Let $G = (V, E)$ be an undirected planar graph with a set $X \subseteq V(G)$. Let G_3 be the graph defined at the end of Step* 3 *above. Then G_3 is a planarity-preserving compressed full certificate for X in G with respect to* 3- *and* 4-*edge-connectivity.*

Proof. Let G_1 be the graph obtained after Step 1. Since G_1 is a solution to Problem 5.1, then for every $k \geq 2$, G_1 is a planarity-preserving full certificate of k-edge-connectivity for X in G and has $O(|X|)$ 2-edge-connected components.

Let G_2 be the graph obtained from G_1 by replacing each 2-edge-connected component B with $G_2(B)$, where each $G_2(B)$ is a solution to Problem 5.2 with interesting vertices $X_2(B)$ as described in Step 2. We claim that for every $k \geq 2$, G_2 is a planarity-preserving compressed full certificate for k-edge-connectivity of X in G. Since each $G_2(B)$ is planarity-preserving, as shown in section 5.2, and G_2 is obtained by only adding bridges between the graphs $G_2(B)$, G_2 will be planarity-preserving too. The fact that G_2 is compressed follows easily from repeated applications of Lemma 5.11. It remains to show that G_2 is indeed a certificate for X in G. To prove this, fix a particular 2-edge-connected component B of G_1. Let $X_2(B)$ be the interesting vertices of B as defined in Step 2, and let $G_2^{(1)}$ be the graph obtained after replacing B with $G_2(B)$. By Lemma 5.13 and Corollary 5.2, for every $k \geq 2$, $G_2(B)$ is a full certificate for k-edge-connectivity of $X_2(B)$ in B. By Lemma 3.2 applied with $C' = G_2(B)$, $X' = X_2(B)$, $G' = B$, $C'' = G'' = G_1 - B$, and $X'' = V(G_1 - B)$, we have that for every $k \geq 2$, $G_2^{(1)}$ is a full certificate for k-edge-connectivity of $X_2(B) \cup V(G_1 - B)$ in G_1. Since $X \cup X_2(B) \subseteq X_2(B) \cup V(G_1 - B)$, by Lemma 3.3 we have that for every $k \geq 2$, $G_2^{(1)}$ is a full certificate for k-edge-connectivity of $X \cup X_2(B)$ in G_1. Repeating this argument for each 2-edge-connected component B of G_1 yields that for every $k \geq 2$, G_2 is a full certificate for k-edge-connectivity of X_2 in G_1. Since G_1 is a full

certificate of k-edge-connectivity for X in G, and $X \subseteq X_2$, by Lemma 3.1 we have that G_2 is a full certificate of k-edge-connectivity for X in G.

Let G_3 be the graph obtained at the end of Step 3. We claim that G_3 is a planarity-preserving compressed full certificate for 3- and 4-edge-connectivity of X in G. By Lemma 5.25, each $G_3(T)$, which is a solution to Problem 5.3, is planar. Recall that G_3 is obtained by splitting G_2, replacing each 3-edge-connected component T with $G_3(T)$, and by merging back the compressed 3-edge-connected components $G_3(T)$. Since splits and merges preserve planarity, G_3 will be planarity-preserving. The fact that G_3 is compressed follows from repeated applications of Lemma 5.19. To show that G_3 is a certificate of 3- and 4-edge-connectivity for X in G, we proceed as follows. Fix a particular 3-edge-connected component T of G_2, and let $B(T)$ be the 2-edge-connected component containing T, whose interesting vertices (defined in step 2) are in $X_2(B)$. Let $X_3(T)$ be the interesting vertices of T as defined in Step 3, and let $G_3^{(1)}$ be the graph obtained from G_2 after replacing T with $G_3(T)$. By Lemmas 5.22 and 5.24, for $2 \le k \le 4$, $G_3(T)$ is a full certificate for k-edge-connectivity of $X_3(T)$ in T. Let $B(T)^{(1)}$ be the 2-edge-component of $G_3^{(1)}$ containing $G_3(T)$. By Theorem 4.2 applied to the 2-edge-connected graph $B(T)$, we have that for $2 \le k \le 4$, $B(T)^{(1)}$ is a full certificate for k-edge-connectivity of $X_2(B)$ in $B(T)$. Applying Lemma 3.2 as before yields that for $2 \le k \le 4$, $G_3^{(1)}$ is a full certificate for k-edge-connectivity of $X_2(B) \cup V(G_2 - B(T))$ in G_2. Again, by Lemma 3.3, we have that for $2 \le k \le 4$, $G_3^{(1)}$ is a full certificate for k-edge-connectivity of $X \cup X_2(B)$ in G_2. Repeating this argument for each 3-edge-connected component T of G_2 yields that for $2 \le k \le 4$, G_3 is a full certificate for k-edge-connectivity of X in G_2. Since we have already proved that, for any $k \ge 2$, G_2 is a full certificate of k-edge-connectivity for X in G, by Lemma 3.1 we have that G_3 is a full certificate of k-edge-connectivity for X in G, $2 \le k \le 4$. □

THEOREM 5.1. *We can maintain a planar graph subject to insertions and deletions that preserve planarity, and allow testing the* 3- *and* 4*-edge-connectivity of the graph in* $O(n^{1/2})$ *time per update, or test whether two vertices are* 3- *or* 4*-edge-connected, in* $O(n^{1/2})$ *time per update or query.*

Proof. Lemma 5.26 shows that planarity-preserving compressed full certificates exist, so we can use Lemma 3.4 to find such certificates in linear time. We then apply Theorem 3.4 with $T(n) = Q(n) = O(n)$. □

6. Vertex connectivity. As another application of our basic sparsification technique, we describe an algorithm for 2- and 3-vertex-connectivity.

THEOREM 6.1. *We can maintain a planar graph, subject to insertions and deletions that preserve planarity, and allow queries that test the* 2- *or* 3*-vertex-connectivity of the graph, or test whether two vertices belong to the same* 2- *or* 3*-vertex-connected component, in* $O(n^{1/2})$ *amortized time per update or query.*

Proof. Galil, Italiano, and Sarnak [21] show that compressed certificates for 2- and 3-vertex-connectivity can be found in linear time. It can be verified that their certificates comply with our Definition 3.3. Using their compressed certificates in our separator tree gives $O(n^{1/2})$ amortized time per update by Theorem 3.2. □

We remark that the same $O(n^{1/2})$ bound can be achieved for the problem of maintaining minimum spanning forests and for local connectivity. This does not improve the $O(n^{1/2})$ bounds that can be achieved using the algorithms for general graphs [9], however. In the companion paper [11], we achieve better $O(\log^2 n)$ bounds for these problems.

7. Conclusions and open problems. We have introduced a new and general technique for designing dynamic planar graph algorithms. This technique is based upon sparsification, compressed certificates, and balanced separator trees, and improves many known bounds. In the companion paper [11], we have showed how this technique produces fast, fully dynamic algorithms for minimum spanning forests, for 2-edge-connectivity on planar graphs, and for dynamic planarity testing. In this paper we have applied this technique to 2-vertex-, 3-vertex-, 3-edge-, and 4-edge-connectivity. For edge connectivity, we have developed certificates which may be interesting on their own. There are a number of related and perhaps interesting questions.

The algorithms described in [11] exploit a stability property in their certificates to support polylogarithmic time updates in planar graphs. For the problems tackled in this paper, we have not been able to apply stable sparsification, and our bounds are $O(n^{1/2})$. Is it possible to exploit stability and to achieve polylogarithmic bounds for these problems too?

Furthermore, are there compressed certificates for other problems? For higher edge connectivity, for instance, the cactus tree gets more complicated (see, for instance, [6]) and makes our way of computing compressed certificates for edge connectivity difficult to generalize. Are there compressed certificates for edge connectivity which are not based on cactus trees?

Finally, can we exploit known partially dynamic algorithms to speed up the insertion times in our bounds? This would be particularly appealing, since there are very fast, partially dynamic algorithms already available in the literature for edge and vertex connectivity [6, 20, 27, 29, 30, 36].

Acknowledgments. We are deeply indebted to the anonymous referees, whose thorough reading of the paper lead to a substantial improvement in its presentation.

A DOWNWARD COLLAPSE WITHIN THE POLYNOMIAL HIERARCHY*

EDITH HEMASPAANDRA†, LANE A. HEMASPAANDRA‡, AND HARALD HEMPEL§

Abstract. Downward collapse (also known as upward separation) refers to cases where the equality of two larger classes implies the equality of two smaller classes. We provide an unqualified downward collapse result completely within the polynomial hierarchy. In particular, we prove that, for $k > 2$, if $\mathrm{P}^{\Sigma_k^p[1]} = \mathrm{P}^{\Sigma_k^p[2]}$ then $\Sigma_k^p = \Pi_k^p = \mathrm{PH}$. We extend this to obtain a more general downward collapse result.

Key words. computational complexity theory, easy-hard arguments, downward collapse, polynomial hierarchy

1. Introduction.

The theory of NP-completeness does not resolve the issue of whether P and NP are equal. However, it does unify the issues of whether thousands of natural problems—the NP-complete problems—have deterministic polynomial-time algorithms. The study of downward collapse is similar in spirit. By proving downward collapses, we seek to tie together central open issues regarding the computing power of complexity classes. For example, the main result of this paper shows that (for $k > 2$) the issue of whether the kth level of the polynomial hierarchy is closed under complementation is identical to the issue of whether two queries to this level give more power than one query to this level.

Informally, downward collapse (equivalent terms are "downward translation of equality" and "upward separation") refers to cases in which the collapse of larger classes implies the collapse of smaller classes (for background, see, e.g., [All91, AW90]). For example, $\mathrm{NP}^{\mathrm{NP}} = \mathrm{coNP}^{\mathrm{NP}} \Rightarrow \mathrm{NP} = \mathrm{coNP}$ would be a (shocking and inherently nonrelativizing [Ko89]) downward collapse, the "downward" part referring to the well-known fact that $\mathrm{NP} \cup \mathrm{coNP} \subseteq \mathrm{NP}^{\mathrm{NP}} \cap \mathrm{coNP}^{\mathrm{NP}}$.

Downward collapse results are extremely rare, but there are some results in the literature that do have the general flavor of downward collapse. Cases where the collapse of larger classes forces sparse sets (but perhaps not nonsparse sets) to fall out of smaller classes were found by Hartmanis, Immerman, and Sewelson ([HIS85], see also [Boo74]) and by others (e.g., Rao, Rothe, and Watanabe [RRW94], but in contrast see also [HJ95]). Existential cases have long been implicitly known (i.e., theorems such as "if PH = PSPACE then $(\exists k)\,[\mathrm{PH} = \Sigma_k^p]$"—note that here one can prove nothing about what value k might have). Regarding probabilistic classes, Ko [Ko82] proved that "if NP $\subseteq$ BPP then NP = R," and Babai, Fortnow, Nisan, and Wigderson [BFNW93] proved the striking result that "if EH = E then P = BPP."

Hemaspaandra, Rothe, and Wechsung have given an example involving degenerate certificate schemes [HRW], and examples due to Allender [All86, section 5] and Hartmanis and Yesha [HY84, section 4] are known regarding circuit-related classes.[1]

We provide an unqualified downward collapse result that is not restricted to sparse or tally sets, whose conclusion does not contain a variable that is not specified in its hypothesis, and that deals with classes whose *ex ante* containments[2] are clear (and plausibly strict). Namely, as is standard, let $\mathrm{P}^{\mathcal{C}[j]}$ denote the class of languages computable by P machines making at most j queries to some set from $\mathcal{C}$. We prove that, for each $k > 2$, it holds that

$$\mathrm{P}^{\Sigma_k^p[1]} = \mathrm{P}^{\Sigma_k^p[2]} \Rightarrow \Sigma_k^p = \Pi_k^p = \mathrm{PH}.$$

(As just mentioned in footnote 2, the classes in the hypothesis clearly have the property that they contain both Σ_k^p and Π_k^p.) The best previously known results from the assumption $\mathrm{P}^{\Sigma_k^p[1]} = \mathrm{P}^{\Sigma_k^p[2]}$ collapse the polynomial hierarchy only to a level that contains Σ_{k+1}^p and Π_{k+1}^p [CK96, BCO93].

Our proof actually establishes a $\Sigma_k^p = \Pi_k^p$ collapse from a hypothesis that is even weaker than $\mathrm{P}^{\Sigma_k^p[1]} = \mathrm{P}^{\Sigma_k^p[2]}$. Namely, we prove that, for $i < j < k$ and $i < k-2$, if one query each (in parallel) to the ith and kth levels of the polynomial hierarchy equals one query each (in parallel) to the jth and kth levels of the polynomial hierarchy, then $\Sigma_k^p = \Pi_k^p = \mathrm{PH}$.

In the final section of the paper, we generalize from 1-versus-2 queries to m-versus-$(m+1)$ queries. In particular, we show that our main result is in fact a reflection of an even more general downward collapse: if the truth-table hierarchy over Σ_k^p collapses to its mth level, then the boolean hierarchy over Σ_k^p collapses one level further than one would expect.

2. Simple case. Our proof works by extracting advice internally and algorithmically, while holding down the number of quantifiers needed, within the framework of a so-called "easy-hard" argument. Easy-hard arguments were introduced by Kadin [Kad88] and were further used by Chang and Kadin ([CK96]; see also [Cha91]) and Beigel, Chang, and Ogiwara [BCO93] (we follow the approach of Beigel, Chang, and Ogiwara).

THEOREM 2.1. *For each $k > 2$ it holds that*

$$\mathrm{P}^{\Sigma_k^p[1]} = \mathrm{P}^{\Sigma_k^p[2]} \Rightarrow \Sigma_k^p = \Pi_k^p = \mathrm{PH}.$$

Theorem 2.1 follows immediately[3] from Theorem 2.4 below, which states that, for $i < j < k$ and $i < k-2$, if one query each to the ith and kth levels of the polynomial

[1] Note that we are not claiming that all the above examples from the literature are totally unqualified downward collapse results, but rather we are merely stating that they have the general flavor of downward collapse. In some cases, the results mentioned above do not fully witness what one might hope for from the notion of "downward." Ideally, downward collapse results would be truly "downward" in the sense that they would be of the form "if $\mathcal{A} = \mathcal{B}$ then $\mathcal{C} = \mathcal{D}$," where the classes are such that (a) $\mathcal{A} \cap \mathcal{B} \supseteq \mathcal{C} \cup \mathcal{D}$ is a well-known result and (b) it is not currently known that $\mathcal{A} \cap \mathcal{B} = \mathcal{C} \cup \mathcal{D}$. The downward collapses proven in this paper do have this strong "downward" form.

[2] For example, in the case of Theorem 2.1, $\Sigma_k^p \cup \Pi_k^p \subseteq \mathrm{P}^{\Sigma_k^p[1]} \cap \mathrm{P}^{\Sigma_k^p[2]}$ is well known to be true (and most researchers suspect that the inclusion is strict).

[3] In particular, taking $i = 0$ and $j = k-1$ in Theorem 2.4 yields a statement that itself clearly implies Theorem 2.1.

hierarchy equals one query each to the jth and kth levels of the polynomial hierarchy, then $\Sigma_k^p = \Pi_k^p = \mathrm{PH}$.

DPTM will refer to deterministic polynomial-time oracle Turing machines, whose polynomial time upper bounds are clearly clocked and are independent of their oracles. We will also use the following definitions.

DEFINITION 2.2.

1. *Let $M^{(A,B)}$ denote DPTM M making, simultaneously (i.e., in a truth-table fashion), at most one query to oracle A and at most one query to oracle B, and let*

$$\mathrm{P}^{(\mathcal{C},\mathcal{D})} = \{L \subseteq \Sigma^* \mid (\exists C \in \mathcal{C})(\exists D \in \mathcal{D})(\exists \text{DPTM } M)[L = L(M^{(C,D)})]\}.$$

2. $A\tilde{\Delta}B = \{\langle x, y\rangle \mid x \in A \Leftrightarrow y \notin B\}$ (*see* [BCO93]).

LEMMA 2.3. *Let $0 \le i < k$, let $L_{\mathrm{P}^{\Sigma_i^p[1]}}$ be any set $\le_{\mathrm{m}}^p$-complete for $\mathrm{P}^{\Sigma_i^p[1]}$, and let $L_{\Sigma_k^p}$ be any language $\le_{\mathrm{m}}^p$-complete for Σ_k^p. Then $L_{\mathrm{P}^{\Sigma_i^p[1]}}\tilde{\Delta}L_{\Sigma_k^p}$ is $\le_{\mathrm{m}}^p$-complete for $\mathrm{P}^{(\Sigma_i^p,\Sigma_k^p)}$.*

Proof. Clearly $L_{\mathrm{P}^{\Sigma_i^p[1]}}\tilde{\Delta}L_{\Sigma_k^p}$ is in $\mathrm{P}^{(\Sigma_i^p,\Sigma_k^p)}$. Regarding $\le_{\mathrm{m}}^p$-hardness for $\mathrm{P}^{(\Sigma_i^p,\Sigma_k^p)}$, let $L \in \mathrm{P}^{(\Sigma_i^p,\Sigma_k^p)}$ via transducer M, Σ_i^p set A, and Σ_k^p set B. Without loss of generality, on each input x, M asks exactly one question a_x to A and one question b_x to B. Define sets D and E as follows:

$D = \{x \mid M^{(A,B)}$ accepts x if a_x is answered correctly and b_x is answered "no"$\}$.

$E = \{x \mid b_x \in B$ and the (one-variable) truth-table with respect to b_x of $M^{(A,B)}$ on input x induced by the correct answer to a_x is neither "always accept" nor "always reject"$\}$.

Note that $D \in \mathrm{P}^{\Sigma_i^p[1]}$, and that $E \in \Sigma_k^p$, since $i < k$. But $L \le_{\mathrm{m}}^p D\tilde{\Delta}E$ via the reduction $f(x) = \langle x, x\rangle$. So clearly $L \le_{\mathrm{m}}^p L_{\mathrm{P}^{\Sigma_i^p[1]}}\tilde{\Delta}L_{\Sigma_k^p}$, via the reduction $\widehat{f}(x) = \langle f'(x), f''(x)\rangle$, where f' and f'' are, respectively, reductions from D to $L_{\mathrm{P}^{\Sigma_i^p[1]}}$ and from E to $L_{\Sigma_k^p}$. □

Theorem 2.4 contains the following two technical advances. First, it internally extracts information in a way that saves a quantifier. (In contrast, the earliest easy-hard arguments in the literature merely ensure that $\Sigma_k^p \subseteq \Pi_k^p/\mathrm{poly}$ and from that infer a weak polynomial hierarchy collapse. Even the interesting recent strengthenings of the argument [BCO93] still, under the hypothesis of Theorem 2.4, conclude only a collapse of the polynomial hierarchy to a level a bit worse than Σ_{k+1}^p.) The second advance is that previous easy-hard arguments seek to determine whether there exists a hard string for a length or not. Then they use the fact that if there is not a hard string, all strings (at the length) are easy. In contrast, we *never* search for a hard string; rather, we use the fact that the input itself (which we do not have to search for as, after all, it is our input) is either easy or hard. So we check whether the input is easy, and if so we can use it as an easy string, and if not, it must be a hard string so we can use it that way. This innovation is important in that it allows Theorem 2.1 to apply for all $k > 2$—as opposed to merely applying for all $k > 3$, which is what we would get without this innovation. (Following a referee's suggestion, we mention that during a first traversal the reader may wish to consider just the $i = 0$ and $j = 1$ special case of Theorem 2.4 and its proof, as this provides a restricted version that is easier to read.)

THEOREM 2.4. *Let $0 \le i < j < k$ and $i < k - 2$. If $\mathrm{P}^{(\Sigma_i^p,\Sigma_k^p)} = \mathrm{P}^{(\Sigma_j^p,\Sigma_k^p)}$ then $\Sigma_k^p = \Pi_k^p = \mathrm{PH}$.*

Proof. Suppose $\mathrm{P}^{(\Sigma_i^p,\Sigma_k^p)} = \mathrm{P}^{(\Sigma_j^p,\Sigma_k^p)}$. Let $L_{\mathrm{P}^{\Sigma_i^p[1]}}$, $L_{\mathrm{P}^{\Sigma_{i+1}^p[1]}}$, and $L_{\Sigma_k^p}$ be $\leq_{\mathrm{m}}^p$-complete for $\mathrm{P}^{\Sigma_i^p[1]}$, $\mathrm{P}^{\Sigma_{i+1}^p[1]}$, and Σ_k^p, respectively; such sets exist. From Lemma 2.3 it follows that $L_{\mathrm{P}^{\Sigma_i^p[1]}}\tilde{\Delta}L_{\Sigma_k^p}$ is $\leq_{\mathrm{m}}^p$-complete for $\mathrm{P}^{(\Sigma_i^p,\Sigma_k^p)}$. Since (as $i<j$) $L_{\mathrm{P}^{\Sigma_{i+1}^p[1]}}\tilde{\Delta}L_{\Sigma_k^p} \in \mathrm{P}^{(\Sigma_j^p,\Sigma_k^p)}$, and by assumption $\mathrm{P}^{(\Sigma_j^p,\Sigma_k^p)} = \mathrm{P}^{(\Sigma_i^p,\Sigma_k^p)}$, there exists a polynomial-time many-one reduction h from $L_{\mathrm{P}^{\Sigma_{i+1}^p[1]}}\tilde{\Delta}L_{\Sigma_k^p}$ to $L_{\mathrm{P}^{\Sigma_i^p[1]}}\tilde{\Delta}L_{\Sigma_k^p}$. So, for all $x_1, x_2 \in \Sigma^*$: if $h(\langle x_1, x_2\rangle) = \langle y_1, y_2\rangle$, then $(x_1 \in L_{\mathrm{P}^{\Sigma_{i+1}^p[1]}} \Leftrightarrow x_2 \notin L_{\Sigma_k^p})$ if and only if $(y_1 \in L_{\mathrm{P}^{\Sigma_i^p[1]}} \Leftrightarrow y_2 \notin L_{\Sigma_k^p})$. Equivalently, for all $x_1, x_2 \in \Sigma^*$, the following fact holds.

Fact 1.
If $h(\langle x_1, x_2\rangle) = \langle y_1, y_2\rangle$,
then

$(x_1 \in L_{\mathrm{P}^{\Sigma_{i+1}^p[1]}} \Leftrightarrow x_2 \in L_{\Sigma_k^p})$ if and only if $(y_1 \in L_{\mathrm{P}^{\Sigma_i^p[1]}} \Leftrightarrow y_2 \in L_{\Sigma_k^p})$.

We can use h to recognize some of $\overline{L_{\Sigma_k^p}}$ by a Σ_k^p algorithm. The definitions of easy and hard used in this paper follow the easy and hard concepts used by Kadin [Kad88], Chang and Kadin ([CK96]; see also [Cha91]), and Beigel, Chang, and Ogiwara [BCO93], modified as needed for our goals. In particular, we say that a string x is *easy for length* n if there exists a string x_1 such that $|x_1| \leq n$ and $(x_1 \in L_{\mathrm{P}^{\Sigma_{i+1}^p[1]}} \Leftrightarrow y_1 \notin L_{\mathrm{P}^{\Sigma_i^p[1]}})$, where $h(\langle x_1, x\rangle) = \langle y_1, y_2\rangle$.

Let p be a fixed polynomial, which will be exactly specified later in the proof. We have the following Σ_k^p algorithm to test whether $x \in \overline{L_{\Sigma_k^p}}$ in the case that (our input) x is an easy string for $p(|x|)$. On input x, guess x_1 with $|x_1| \leq p(|x|)$, let $h(\langle x_1, x\rangle) = \langle y_1, y_2\rangle$, and accept if and only if $(x_1 \in L_{\mathrm{P}^{\Sigma_{i+1}^p[1]}} \Leftrightarrow y_1 \notin L_{\mathrm{P}^{\Sigma_i^p[1]}})$ and $y_2 \in L_{\Sigma_k^p}$. In light of Fact 1 above, it is clear that this is correct.

We say that x is *hard for length* n if $|x| \leq n$ and x is not easy for length n, i.e., if $|x| \leq n$ and for all x_1 with $|x_1| \leq n$ it holds that $x_1 \in L_{\mathrm{P}^{\Sigma_{i+1}^p[1]}} \Leftrightarrow y_1 \in L_{\mathrm{P}^{\Sigma_i^p[1]}}$, where $h(\langle x_1, x\rangle) = \langle y_1, y_2\rangle$.

If x is a hard string for length n, then x induces a many-one reduction from $(L_{\mathrm{P}^{\Sigma_{i+1}^p[1]}})^{\leq n}$ to $L_{\mathrm{P}^{\Sigma_i^p[1]}}$; namely, $f(x_1) = y_1$, where $h(\langle x_1, x\rangle) = \langle y_1, y_2\rangle$. Note that f is computable in time polynomial in $\max(n, |x_1|)$.

We can use hard strings to obtain a Σ_k^p algorithm for $\overline{L_{\Sigma_k^p}}$. Let M be a Π_{k-i-1}^p machine such that M with oracle $L_{\mathrm{P}^{\Sigma_{i+1}^p[1]}}$ recognizes $\overline{L_{\Sigma_k^p}}$. Let the run-time of M be bounded by polynomial p, which without loss of generality satisfies $(\forall \widehat{m} \geq 0)[p(\widehat{m}+1) > p(\widehat{m}) > 0]$ (as promised above, we have now specified p). Then

$$\left(\overline{L_{\Sigma_k^p}}\right)^{=n} = (L\left(M^{\left(L_{\mathrm{P}^{\Sigma_{i+1}^p[1]}}\right)^{\leq p(n)}}\right))^{=n}.$$

If there exists a hard string for length $p(n)$, then this hard string induces a reduction from $(L_{\mathrm{P}^{\Sigma_{i+1}^p[1]}})^{\leq p(n)}$ to $L_{\mathrm{P}^{\Sigma_i^p[1]}}$. Thus, with any hard string for length $p(n)$ in hand, call it w_n, $\widehat{M}$ with oracle $L_{\mathrm{P}^{\Sigma_i^p[1]}}$ recognizes $\overline{L_{\Sigma_k^p}}$ for strings of length n, where $\widehat{M}$ is the machine that simulates M but replaces each query q by the first component of $h(\langle q, w_n\rangle)$. It follows that if there exists a hard string for length $p(n)$, then this string induces a Π_{k-1}^p algorithm for $(\overline{L_{\Sigma_k^p}})^{=n}$ and therefore certainly a Σ_k^p algorithm for $(\overline{L_{\Sigma_k^p}})^{=n}$.

However, now we have an $\mathrm{NP}^{\Sigma_{k-1}^p} = \Sigma_k^p$ algorithm for $\overline{L_{\Sigma_k^p}}$: on input x, the NP base machine of $\mathrm{NP}^{\Sigma_{k-1}^p}$ executes the following algorithm.

1. Using its Σ_{k-1}^p oracle, it deterministically determines whether the input x is an easy string for length $p(|x|)$. This can be done, as checking whether the input is an easy string for length $p(|x|)$ can be done by one query to Σ_{i+2}^p, and $i+2 \leq k-1$ by our $i < k-2$ hypothesis.
2. If the previous step determined that the input is not an easy string, then the input must be a hard string for length $p(|x|)$. So simulate the Σ_k^p algorithm induced by this hard string (i.e., the input x itself) on input x (via our NP machine itself simulating the base level of the Σ_k^p algorithm and using the NP machine's oracle to simulate the oracle queries made by the base level NP machine of the Σ_k^p algorithm being simulated).
3. If the first step determined that the input x is easy for length $p(|x|)$, then our NP machine simulates (using itself and its oracle) the Σ_k^p algorithm for easy strings on input x.

We need one brief technical comment. The Σ_{k-1}^p oracle in the above algorithm is being used for a number of different sets. However, as Σ_{k-1}^p is closed under disjoint union, this presents no problem as we can use the disjoint union of the sets, while modifying the queries so they address the appropriate part of the disjoint union.

Since $\overline{L_{\Sigma_k^p}}$ is complete for Π_k^p, it follows that $\Sigma_k^p = \Pi_k^p = \mathrm{PH}$. □

We conclude this section with three remarks. First, if one is fond of the truth-table version of bounded query hierarchies, one can certainly replace the hypothesis of Theorem 2.1 with $\mathrm{P}_{1\text{-tt}}^{\Sigma_k^p} = \mathrm{P}_{2\text{-tt}}^{\Sigma_k^p}$ (both as this is an equivalent hypothesis and as it in any case clearly follows from Theorem 2.4). Indeed, one can equally well replace the hypothesis of Theorem 2.1 with the even weaker-looking hypothesis[4] $\mathrm{P}^{\Sigma_k^p[1]} = \mathrm{DIFF}_2(\Sigma_k^p)$ (as this hypothesis is also in fact equivalent to the hypothesis of Theorem 2.1—just note that if $\mathrm{P}^{\Sigma_k^p[1]} = \mathrm{DIFF}_2(\Sigma_k^p)$ then $\mathrm{DIFF}_2(\Sigma_k^p)$ is closed under complementation and thus equals the boolean hierarchy over Σ_k^p, see [CGH+88], and so in particular we then have $\mathrm{P}^{\Sigma_k^p[1]} = \mathrm{DIFF}_2(\Sigma_k^p) = \mathrm{P}^{\Sigma_k^p[2]}$).

Of course, the two equivalences just mentioned—$\mathrm{P}^{\Sigma_k^p[1]} = \mathrm{P}^{\Sigma_k^p[2]} \Leftrightarrow \mathrm{P}_{1\text{-tt}}^{\Sigma_k^p} = \mathrm{P}_{2\text{-tt}}^{\Sigma_k^p} \Leftrightarrow \mathrm{P}^{\Sigma_k^p[1]} = \mathrm{DIFF}_2(\Sigma_k^p)$—are well known. However, Theorem 2.4 is sufficiently strong that it creates an equivalence that is quite new and somewhat surprising. We state it below as Corollary 2.6.

THEOREM 2.5. *For each $k > 2$ it holds that*

$$\mathrm{P}^{\Sigma_k^p[1]} = \mathrm{DIFF}_2(\Sigma_k^p) \cap \mathrm{coDIFF}_2(\Sigma_k^p) \Rightarrow \Sigma_k^p = \Pi_k^p = \mathrm{PH}.$$

Proof. Let $A \triangle B =_{\mathrm{def}} (A - B) \cup (B - A)$. Recalling that $k > 2$, it is not hard to see that $\mathrm{P}^{(\mathrm{NP},\Sigma_k^p)} \subseteq \mathrm{DIFF}_2(\Sigma_k^p)$. In particular, this holds due to Lemma 2.3, in light of the facts that (i) $\mathrm{DIFF}_2(\Sigma_k^p) = \{L \mid (\exists L_1 \in \Sigma_k^p)(\exists L_2 \in \Sigma_k^p)[L = L_1 \triangle L_2]\}$ (due to Köbler, Schöning, and Wagner [KSW87]—see the discussion just before Theorem 3.7) and (ii) $A \tilde{\Delta} B = \{\langle x, y\rangle \mid x \in A\} \triangle \{\langle x, y\rangle \mid y \in B\}$. So, since $\mathrm{P}^{(\mathrm{NP},\Sigma_k^p)}$ is closed under complementation, we have $\mathrm{P}^{\Sigma_k^p[1]} \subseteq \mathrm{P}^{(\mathrm{NP},\Sigma_k^p)} \subseteq \mathrm{DIFF}_2(\Sigma_k^p) \cap \mathrm{coDIFF}_2(\Sigma_k^p)$. However, this says, under the hypothesis of the theorem, that $\mathrm{P}^{\Sigma_k^p[1]} = \mathrm{P}^{(\mathrm{NP},\Sigma_k^p)}$, which itself, by Theorem 2.4, implies that $\Sigma_k^p = \Pi_k^p = \mathrm{PH}$. □

[4] Where $\mathrm{DIFF}_2(\mathcal{C}) =_{\mathrm{def}} \{L \mid (\exists L_1 \in \mathcal{C})(\exists L_2 \in \mathcal{C})[L = L_1 - L_2]\}$, and $\mathrm{co}\mathcal{C} =_{\mathrm{def}} \{L \mid \overline{L} \in \mathcal{C}\}$ (see Definition 3.1 for background).

COROLLARY 2.6. *For each $k > 2$ it holds that*

$$\mathrm{P}^{\Sigma_k^p[1]} = \mathrm{DIFF}_2(\Sigma_k^p) \cap \mathrm{coDIFF}_2(\Sigma_k^p) \Leftrightarrow \mathrm{P}^{\Sigma_k^p[1]} = \mathrm{DIFF}_2(\Sigma_k^p).$$

Our second remark is that Theorem 2.1 implies that, for $k > 2$, if the bounded query hierarchy over Σ_k^p collapses to its $\mathrm{P}^{\Sigma_k^p[1]}$ level, then the bounded query hierarchy over Σ_k^p equals the polynomial hierarchy (this provides a partial affirmative answer to the issue of whether, when a bounded query hierarchy collapses, the polynomial hierarchy necessarily collapses to it; see [HRZ95, Problem 4]).

Third, in Lemma 2.3 and Theorem 2.4 we speak of classes of the form $\mathrm{P}^{(\Sigma_i^p, \Sigma_j^p)}$, $i \neq j$. It would be very natural to reason as follows: "$\mathrm{P}^{(\Sigma_i^p, \Sigma_j^p)}$, $i \neq j$, must equal $\mathrm{P}^{\Sigma^p_{\max(i,j)}[1]}$, as $\Sigma^p_{\max(i,j)}$ can easily solve any $\Sigma^p_{\min(i,j)}$ query 'strongly' using the $\Sigma^p_{\max(i,j)-1}$ oracle of its base NP machine and thus the hypothesis of Theorem 2.4 is trivially satisfied and so you in fact are claiming to prove, unconditionally, that $\mathrm{PH} = \Sigma_3^p$." This reasoning, though tempting, is wrong for the following somewhat subtle reason. Though it is true that, for example, $\mathrm{NP}^{\Sigma_q^p}$ can solve any Σ_q^p query and then can tackle any Σ^p_{q+1} query, it does not follow that $\mathrm{P}^{(\Sigma^p_{q+1}, \Sigma^p_q)} = \mathrm{P}^{\Sigma^p_{q+1}[1]}$. The problem is that the answer to the Σ_q^p query may *change the truth-table* the P transducer uses to evaluate the answer of the Σ^p_{q+1} query.

We mention that Buhrman and Fortnow [BF96], building on and extending our proof technique, have very recently obtained the $k = 2$ analogue of Theorem 2.1. They also prove that there are relativized worlds in which the $k = 1$ analogue of Theorem 2.1 fails. On the other hand, if one changes Theorem 2.1's left-hand-side classes to function classes, then the $k = 1$ analogue of the resulting claim does hold due to Krentel (see [Kre88, Theorem 4.2]): $\mathrm{FP}^{\mathrm{NP}[1]} = \mathrm{FP}^{\mathrm{NP}[2]} \Rightarrow \mathrm{P} = \mathrm{PH}$. Also, very recent work of Hemaspaandra, Hemaspaandra, and Hempel [HHH97], building on and extending the techniques of the present paper and those of Buhrman and Fortnow [BF96], has established the $k = 2$ analogue of Theorem 3.2.

3. General case. We now generalize the results of section 2 to the case of m-truth-table reductions. Though the results of this section are stronger than those of section 2, the proofs are somewhat more involved, and thus we suggest the reader first read section 2.

For clarity, we now describe the two key differences between the proofs in this section and those of section 2. (1) The completeness claims of section 2 were simpler. Here, we now need Lemma 3.5, which extends [BCO93, Lemma 8] with the trick of splitting a truth-table along a simple query's dimension in such a way that the induced one-dimension-lower truth-tables cause no problems. (2) The proof of Theorem 3.6 is quite analogous to the proof of Theorem 2.4, except (i) it is a bit harder to understand as one continuously has to parse the deeply nested set differences caused by the fact that we are now working in the difference hierarchy and (ii) the "input is an easy string" simulation is changed to account for a new problem, namely, that in the boolean hierarchy one models each language by a *collection* of machines (mimicking the nested difference structure of boolean hierarchy languages) and thus it is hard to ensure that these machines, when guessing an object, necessarily guess the same object (we solve this coordination problem by forcing them to each guess a lexicographically extreme object, and we argue that this can be accomplished within the computational power available).

The difference hierarchy was introduced by Cai et al. [CGH$^+$88, CGH$^+$89] and is defined below. Cai et al. studied the case $\mathcal{C} = \mathrm{NP}$, but a number of other cases have since been studied [BJY90, BCO93, HR97].

DEFINITION 3.1. *Let $\mathcal{C}$ be any complexity class.*

1. $\mathrm{DIFF}_1(\mathcal{C}) = \mathcal{C}$.
2. *For any $k \geq 1$,* $\mathrm{DIFF}_{k+1}(\mathcal{C}) = \{L \mid (\exists L_1 \in \mathcal{C})(\exists L_2 \in \mathrm{DIFF}_k(\mathcal{C}))[L = L_1 - L_2]\}$.
3. *For any $k \geq 1$,* $\mathrm{coDIFF}_k(\mathcal{C}) = \{L \mid \overline{L} \in \mathrm{DIFF}_k(\mathcal{C})\}$.

Note in particular that

$$\mathrm{DIFF}_m(\Sigma_k^p) \cup \mathrm{coDIFF}_m(\Sigma_k^p) \subseteq \mathrm{P}_{m\text{-tt}}^{\Sigma_k^p} \subseteq \mathrm{DIFF}_{m+1}(\Sigma_k^p) \cap \mathrm{coDIFF}_{m+1}(\Sigma_k^p).$$

THEOREM 3.2. *For each $m > 0$ and each $k > 2$ it holds that*

$$\mathrm{P}_{m\text{-tt}}^{\Sigma_k^p} = \mathrm{P}_{m+1\text{-tt}}^{\Sigma_k^p} \Rightarrow \mathrm{DIFF}_m(\Sigma_k^p) = \mathrm{coDIFF}_m(\Sigma_k^p).$$

Theorem 2.1 is the $m = 1$ case of Theorem 3.2 (except the former is stated in terms of Turing access). Theorem 3.2 follows immediately from Theorem 3.6 below, which states that, for $i < j < k$ and $i < k-2$, if one query to the ith and m queries to the kth levels of the polynomial hierarchy equals one query to the jth and m queries to the kth levels of the polynomial hierarchy, then $\mathrm{DIFF}_m(\Sigma_k^p) = \mathrm{coDIFF}_m(\Sigma_k^p)$. Note, of course, that the conclusion of Theorem 3.2 implies a collapse of the polynomial hierarchy. In particular, via [BCO93, Theorem 10], Theorem 3.2 implies that, for each $m \geq 0$ and each $k > 2$, it holds that if $\mathrm{P}_{m\text{-tt}}^{\Sigma_k^p} = \mathrm{P}_{m+1\text{-tt}}^{\Sigma_k^p}$ then the polynomial hierarchy can be solved by a P machine that makes $m-1$ truth-table queries to Σ_{k+1}^p and that in addition is allowed unbounded queries to Σ_k^p. This polynomial hierarchy collapse is about one level lower in the difference hierarchy over Σ_{k+1}^p than one could conclude from previous papers, in particular, from Beigel, Chang, and Ogiwara. That is, in light of Theorem 3.2, we have the following corollary, given here in a form that corrects a misstatement in an earlier version of this paper. (In fact, one can claim a slightly stronger collapse; see [HHH] for full details.)

COROLLARY 3.3. *For each $m \geq 0$ and each $k > 2$ it holds that* $\mathrm{P}_{m\text{-tt}}^{\Sigma_k^p} = \mathrm{P}_{m+1\text{-tt}}^{\Sigma_k^p} \Rightarrow \mathrm{PH} = \mathrm{P}_{1,m-1\text{-tt}}^{(\Delta_{k+1}^p, \Sigma_{k+1}^p)}$.

The following definition will be useful.

DEFINITION 3.4. *Let $M_{a,b\text{-tt}}^{(A,B)}$ denote DPTM M making, simultaneously (i.e., all $a+b$ queries are made at the same time, in the standard truth-table fashion), at most a queries to oracle A and at most b queries to oracle B, and let*

$$\mathrm{P}_{a,b\text{-tt}}^{(\mathcal{C},\mathcal{D})} = \{L \subseteq \Sigma^* \mid (\exists C \in \mathcal{C})(\exists D \in \mathcal{D})(\exists \text{DPTM } M)[L = L(M_{a,b\text{-tt}}^{(C,D)})]\}.$$

LEMMA 3.5. *Let $m > 0$, let $0 \leq i < k$, let $L_{\mathrm{P}^{\Sigma_i^p[1]}}$ be any set $\leq_{\mathrm{m}}^p$-complete for $\mathrm{P}^{\Sigma_i^p[1]}$, and let $L_{\mathrm{DIFF}_m(\Sigma_k^p)}$ be any language $\leq_{\mathrm{m}}^p$-complete for $\mathrm{DIFF}_m(\Sigma_k^p)$. Then $L_{\mathrm{P}^{\Sigma_i^p[1]}} \tilde{\Delta} L_{\mathrm{DIFF}_m(\Sigma_k^p)}$ is $\leq_{\mathrm{m}}^p$-complete for $\mathrm{P}_{1,m\text{-tt}}^{(\Sigma_i^p, \Sigma_k^p)}$.*

Lemma 3.5 does not require proof, as it is a use of the standard mind-change technique, and is analogous to [BCO93, Lemma 8], with one key twist that we now discuss. Assume, without loss of generality, that we focus on $\mathrm{P}_{1,m\text{-tt}}^{(\Sigma_i^p, \Sigma_k^p)}$ machines that always make exactly $m+1$ queries. Regarding any such machine accepting a set complete for the class $\mathrm{P}_{1,m\text{-tt}}^{(\Sigma_i^p, \Sigma_k^p)}$ of Lemma 3.5, we have on each input a truth-table with $m+1$ variables. Note that if one knows the answer to the one Σ_i^p query, then this induces a truth-table on m variables; however, note also that the two m-variable truth-tables (one corresponding to a "yes" answer to the Σ_i^p query and the other to

a "no" answer) may differ sharply. Regarding $L_{\mathrm{P}^{\Sigma_i^p[1]}}\tilde{\Delta}L_{\mathrm{DIFF}_m(\Sigma_k^p)}$, we use $L_{\mathrm{P}^{\Sigma_i^p[1]}}$ to determine whether the m-variable truth-table induced by the true answer to the one Σ_i^p query accepts or not when all the Σ_k^p queries get the answer no. This use is analogous to [BCO93, Lemma 8]. The new twist is the action of the $L_{\mathrm{DIFF}_m(\Sigma_k^p)}$ part of $L_{\mathrm{P}^{\Sigma_i^p[1]}}\tilde{\Delta}L_{\mathrm{DIFF}_m(\Sigma_k^p)}$. We use this, just as in [BCO93, Lemma 8], to find whether or not we are in an odd mind-change region *but now with respect to the m-variable truth-table induced by the true answer to the one Σ_i^p query*. Crucially, this still is a $\mathrm{DIFF}_m(\Sigma_k^p)$ issue as, since $i < k$, a Σ_k^p machine can first on its own (by its base NP machine making one deterministic query to its Σ_{k-1}^p oracle) determine the true answer to the one Σ_i^p query, and thus the machine can easily determine which of the two m-variable truth-table cases it is in, and thus it plays its standard part in determining if the mind-change region of the m true answers to the Σ_k^p queries falls in an odd mind-change region *with respect to the correct m-variable truth-table*.

THEOREM 3.6. *Let $m > 0$, $0 \le i < j < k$, and $i < k-2$. If $\mathrm{P}_{1,m\text{-tt}}^{(\Sigma_i^p,\Sigma_k^p)} = \mathrm{P}_{1,m\text{-tt}}^{(\Sigma_j^p,\Sigma_k^p)}$ then $\mathrm{DIFF}_m(\Sigma_k^p) = \mathrm{coDIFF}_m(\Sigma_k^p)$.*

Proof. Suppose $\mathrm{P}_{1,m\text{-tt}}^{(\Sigma_i^p,\Sigma_k^p)} = \mathrm{P}_{1,m\text{-tt}}^{(\Sigma_j^p,\Sigma_k^p)}$. Let $L_{\mathrm{P}^{\Sigma_i^p[1]}}$, $L_{\mathrm{P}^{\Sigma_{i+1}^p[1]}}$, and $L_{\mathrm{DIFF}_m(\Sigma_k^p)}$ be $\le_{\mathrm{m}}^p$-complete for $\mathrm{P}^{\Sigma_i^p[1]}$, $\mathrm{P}^{\Sigma_{i+1}^p[1]}$, and $\mathrm{DIFF}_m(\Sigma_k^p)$, respectively; such languages exist, e.g., via the standard canonical complete set constructions using enumerations of clocked machines. From Lemma 3.5 it follows that $L_{\mathrm{P}^{\Sigma_i^p[1]}}\tilde{\Delta}L_{\mathrm{DIFF}_m(\Sigma_k^p)}$ is $\le_{\mathrm{m}}^p$-complete for $\mathrm{P}_{1,m\text{-tt}}^{(\Sigma_i^p,\Sigma_k^p)}$. Since (as $i < j$) $L_{\mathrm{P}^{\Sigma_{i+1}^p[1]}}\tilde{\Delta}L_{\mathrm{DIFF}_m(\Sigma_k^p)} \in \mathrm{P}_{1,m\text{-tt}}^{(\Sigma_j^p,\Sigma_k^p)}$, and by assumption $\mathrm{P}_{1,m\text{-tt}}^{(\Sigma_j^p,\Sigma_k^p)} = \mathrm{P}_{1,m\text{-tt}}^{(\Sigma_i^p,\Sigma_k^p)}$, there exists a polynomial-time many-one reduction h from $L_{\mathrm{P}^{\Sigma_{i+1}^p[1]}}\tilde{\Delta}L_{\mathrm{DIFF}_m(\Sigma_k^p)}$ to $L_{\mathrm{P}^{\Sigma_i^p[1]}}\tilde{\Delta}L_{\mathrm{DIFF}_m(\Sigma_k^p)}$. So, for all $x_1, x_2 \in \Sigma^*$,

if $h(\langle x_1, x_2\rangle) = \langle y_1, y_2\rangle$,
then

$(x_1 \in L_{\mathrm{P}^{\Sigma_{i+1}^p[1]}} \Leftrightarrow x_2 \in L_{\mathrm{DIFF}_m(\Sigma_k^p)})$ if and only if $(y_1 \in L_{\mathrm{P}^{\Sigma_i^p[1]}} \Leftrightarrow y_2 \in L_{\mathrm{DIFF}_m(\Sigma_k^p)})$.

We can use h to recognize some of $\overline{L_{\mathrm{DIFF}_m(\Sigma_k^p)}}$ by a $\mathrm{DIFF}_m(\Sigma_k^p)$ algorithm. In particular, we say that a string x is *easy for length n* if there exists a string x_1 such that $|x_1| \le n$ and $(x_1 \in L_{\mathrm{P}^{\Sigma_{i+1}^p[1]}} \Leftrightarrow y_1 \notin L_{\mathrm{P}^{\Sigma_i^p[1]}})$, where $h(\langle x_1, x\rangle) = \langle y_1, y_2\rangle$.

Let p be a fixed polynomial, which will be exactly specified later in the proof. We have the following algorithm to test whether $x \in \overline{L_{\mathrm{DIFF}_m(\Sigma_k^p)}}$ in the case that (our input) x is an easy string for $p(|x|)$. On input x, guess x_1 with $|x_1| \le p(|x|)$, let $h(\langle x_1, x\rangle) = \langle y_1, y_2\rangle$, and accept if and only if $(x_1 \in L_{\mathrm{P}^{\Sigma_{i+1}^p[1]}} \Leftrightarrow y_1 \notin L_{\mathrm{P}^{\Sigma_i^p[1]}})$ and $y_2 \in L_{\mathrm{DIFF}_m(\Sigma_k^p)}$. This algorithm is not necessarily a $\mathrm{DIFF}_m(\Sigma_k^p)$ algorithm, but it does inspire the following $\mathrm{DIFF}_m(\Sigma_k^p)$ algorithm to test whether $x \in \overline{L_{\mathrm{DIFF}_m(\Sigma_k^p)}}$ in the case that x is an easy string for $p(|x|)$. Let $L_1, L_2, \ldots, L_m$ be languages in Σ_k^p such that $L_{\mathrm{DIFF}_m(\Sigma_k^p)} = L_1 - (L_2 - (L_3 - \cdots (L_{m-1} - L_m)\cdots))$. Then $x \in \overline{L_{\mathrm{DIFF}_m(\Sigma_k^p)}}$ if and only if $x \in L_1' - (L_2' - (L_3' - \cdots (L_{m-1}' - L_m')\cdots))$, where L_r' is computed as follows: on input x, guess x_1 with $|x_1| \le p(|x|)$, let $h(\langle x_1, x\rangle) = \langle y_1, y_2\rangle$, and accept if and only if (a) $(x_1 \in L_{\mathrm{P}^{\Sigma_{i+1}^p[1]}} \Leftrightarrow y_1 \notin L_{\mathrm{P}^{\Sigma_i^p[1]}})$, (b) $(\forall z <_{lex} x_1)[z \in L_{\mathrm{P}^{\Sigma_{i+1}^p[1]}} \Leftrightarrow w_1 \in L_{\mathrm{P}^{\Sigma_i^p[1]}}]$, where $h(\langle z, x\rangle) = \langle w_1, w_2\rangle$, and (c) $y_2 \in L_r$.

Since $i + 2 < k$, $L_r' \in \Sigma_k^p$, and thus our algorithm is in $\mathrm{DIFF}_m(\Sigma_k^p)$. Note that condition (b) has no analogue in the proof of Theorem 2.4. We need this extra condition here as otherwise the different L_r' might latch onto *different* strings x_1 and this would cause unpredictable behavior (as different x_1's would create different y_2's).

We say that x is *hard for length* n if $|x| \leq n$ and x is not easy for length n, i.e., if $|x| \leq n$ and for all x_1 with $|x_1| \leq n$ it holds that $x_1 \in L_{\mathrm{P}^{\Sigma_{i+1}^p[1]}} \Leftrightarrow y_1 \in L_{\mathrm{P}^{\Sigma_i^p[1]}}$, where $h(\langle x_1, x\rangle) = \langle y_1, y_2\rangle$.

If x is a hard string for length n, then x induces a many-one reduction from $(L_{\mathrm{P}^{\Sigma_{i+1}^p[1]}})^{\leq n}$ to $L_{\mathrm{P}^{\Sigma_i^p[1]}}$, namely, $f(x_1) = y_1$, where $h(\langle x_1, x\rangle) = \langle y_1, y_2\rangle$. Note that f is computable in time polynomial in $\max(n, |x_1|)$.

We can use hard strings to obtain a $\mathrm{DIFF}_m(\Sigma_{k-1}^p)$ algorithm for $L_{\mathrm{DIFF}_m(\Sigma_k^p)}$ and thus (since $\mathrm{DIFF}_m(\Sigma_{k-1}^p) \subseteq \mathrm{P}^{\Sigma_{k-1}^p} \subseteq \Sigma_k^p \cap \Pi_k^p$) certainly a $\mathrm{DIFF}_m(\Sigma_k^p)$ algorithm for $\overline{L_{\mathrm{DIFF}_m(\Sigma_k^p)}}$. Again, let $L_1, L_2, \ldots, L_m$ be languages in Σ_k^p such that $L_{\mathrm{DIFF}_m(\Sigma_k^p)} = L_1 - (L_2 - (L_3 - \cdots (L_{m-1} - L_m)\cdots))$. For all $1 \leq r \leq m$, let M_r be a Σ_{k-i-1}^p machine such that $L_r = L(M_r^Y)$, where $Y = L_{\mathrm{P}^{\Sigma_{i+1}^p[1]}}$. Let the run-time of all M_r's be bounded by polynomial p, which without loss of generality satisfies $(\forall \widehat{m} \geq 0)[p(\widehat{m}+1) > p(\widehat{m}) > 0]$ (as promised above, we have now specified p). Then for all $1 \leq r \leq m$,

$$(L_r)^{=n} = (L(M_r^{(Y^{\leq p(n)})}))^{=n},$$

where $Y = L_{\mathrm{P}^{\Sigma_{i+1}^p[1]}}$. If there exists a hard string for length $p(n)$, then this hard string induces a reduction from $(L_{\mathrm{P}^{\Sigma_{i+1}^p[1]}})^{\leq p(n)}$ to $L_{\mathrm{P}^{\Sigma_i^p[1]}}$. Thus, with any hard string for length $p(n)$ in hand, call it w_n, $\widehat{M_r}$ with oracle $L_{\mathrm{P}^{\Sigma_i^p[1]}}$ recognizes L_r for strings of length n, where $\widehat{M_r}$ is the machine that simulates M_r but replaces each query q by the first component of $h(\langle q, w_n\rangle)$. It follows that if there exists a hard string for length $p(n)$, then this string induces a $\mathrm{DIFF}_m(\Sigma_{k-1}^p)$ algorithm for $(L_{\mathrm{DIFF}_m(\Sigma_k^p)})^{=n}$, and therefore certainly a $\mathrm{DIFF}_m(\Sigma_k^p)$ algorithm for $(\overline{L_{\mathrm{DIFF}_m(\Sigma_k^p)}})^{=n}$. It follows that there exist m Σ_k^p sets, say, $\widehat{L_r}$ for $1 \leq r \leq m$, such that the following holds: for all x, if x (functioning as $w_{|x|}$ above) is a hard string for length $p(|x|)$, then $x \in \overline{L_{\mathrm{DIFF}_m(\Sigma_k^p)}}$ if and only if $x \in \widehat{L_1} - (\widehat{L_2} - (\widehat{L_3} - \cdots (\widehat{L_{m-1}} - \widehat{L_m})\cdots))$.

However, now we have an outright $\mathrm{DIFF}_m(\Sigma_k^p)$ algorithm for $\overline{L_{\mathrm{DIFF}_m(\Sigma_k^p)}}$: for $1 \leq r \leq m$ define an $\mathrm{NP}^{\Sigma_{k-1}^p}$ machine N_r as follows: on input x, the NP base machine of N_r executes the following algorithm.

1. Using its Σ_{k-1}^p oracle, it deterministically determines whether the input x is an easy string for length $p(|x|)$. This can be done, as checking whether the input is an easy string for length $p(|x|)$ can be done by one query to Σ_{i+2}^p, and $i+2 \leq k-1$ by our $i < k-2$ hypothesis.
2. If the previous step determined that the input is not an easy string, then the input must be a hard string for length $p(|x|)$. So simulate the Σ_k^p algorithm for $\widehat{L_r}$ induced by this hard string (i.e., the input x itself) on input x (via our NP machine itself simulating the base level of the Σ_k^p algorithm and using the NP machine's oracle to simulate the oracle queries made by the base level NP machine of the Σ_k^p algorithm being simulated).
3. If the first step determined that the input x is easy for length $p(|x|)$, then our NP machine simulates (using itself and its oracle) the Σ_k^p algorithm for L_r' on input x.

It follows that for all x, $x \in \overline{L_{\mathrm{DIFF}_m(\Sigma_k^p)}}$ if and only if $x \in L(N_1) - (L(N_2) - (L(N_3) - \cdots (L(N_{m-1}) - L(N_m))\cdots))$. Since $\overline{L_{\mathrm{DIFF}_m(\Sigma_k^p)}}$ is complete for $\mathrm{coDIFF}_m(\Sigma_k^p)$, it follows that $\mathrm{DIFF}_m(\Sigma_k^p) = \mathrm{coDIFF}_m(\Sigma_k^p)$. □

Finally, we note that we have analogues of Theorem 2.5 and Corollary 2.6. The proof is analogous to that of Theorem 2.5; one just uses $\mathrm{P}_{1,m\text{-tt}}^{(\mathrm{NP},\Sigma_k^p)}$ in the way $\mathrm{P}^{(\mathrm{NP},\Sigma_k^p)}$ was used in that proof and again invokes the relation between the difference and symmetric difference hierarchies (namely, that $\mathrm{DIFF}_j(\Sigma_k^p)$ is exactly the class of sets L that for some $L_1, \ldots, L_j \in \Sigma_k^p$ satisfy $L = L_1 \triangle \cdots \triangle L_j$; this well-known equality is due to [KSW87, section 3] in light of the standard equalities regarding boolean hierarchies (see [CGH+88, section 2.1]); although both [KSW87] and [CGH+88] focus mostly on the $k = 1$ case, it is standard [Wec85, BBJ+89] that the equalities in fact hold for any class closed under union and intersection and containing $\emptyset$ and Σ^*).

THEOREM 3.7. *Let $m \geq 0$ and $k > 2$. If $\mathrm{P}_{m\text{-tt}}^{\Sigma_k^p} = \mathrm{DIFF}_{m+1}(\Sigma_k^p) \cap \mathrm{coDIFF}_{m+1}(\Sigma_k^p)$ then $\mathrm{DIFF}_m(\Sigma_k^p) = \mathrm{coDIFF}_m(\Sigma_k^p)$.*

COROLLARY 3.8. *For each $k > 2$ and $m \geq 0$, it holds that*

$$\mathrm{P}_{m\text{-tt}}^{\Sigma_k^p} = \mathrm{DIFF}_{m+1}(\Sigma_k^p) \cap \mathrm{coDIFF}_{m+1}(\Sigma_k^p) \Leftrightarrow \mathrm{P}_{m\text{-tt}}^{\Sigma_k^p} = \mathrm{DIFF}_{m+1}(\Sigma_k^p).$$

GENERICITY, RANDOMNESS, AND POLYNOMIAL-TIME APPROXIMATIONS*

YONGGE WANG†

Abstract. Polynomial-time safe and unsafe approximations for intractable sets were introduced by Meyer and Paterson [Technical Report TM-126, Laboratory for Computer Science, MIT, Cambridge, MA, 1979] and Yesha [*SIAM J. Comput.*, 12 (1983), pp. 411–425], respectively. The question of which sets have optimal safe and unsafe approximations has been investigated extensively. Duris and Rolim [*Lecture Notes in Comput. Sci.* 841, Springer-Verlag, Berlin, New York, 1994, pp. 38–51] and Ambos-Spies [*Proc. 22nd ICALP*, Springer-Verlag, Berlin, New York, 1995, pp. 384–392] showed that the existence of optimal polynomial-time approximations for the safe and unsafe cases is independent. Using the law of the iterated logarithm for p-random sequences (which has been recently proven in [*Proc. 11th Conf. Computational Complexity*, IEEE Computer Society Press, Piscataway, NJ, 1996, pp. 180–189]), we extend this observation by showing that both the class of polynomial-time Δ-levelable sets and the class of sets which have optimal polynomial-time unsafe approximations have p-measure 0. Hence typical sets in $\mathbf{E}$ (in the sense of p-measure) do not have optimal polynomial-time unsafe approximations. We will also establish the relationship between resource bounded genericity concepts and the polynomial-time safe and unsafe approximation concepts.

Key words. computational complexity, resource bounded genericity, resource bounded randomness, approximation

1. Introduction.

The notion of polynomial-time safe approximations was introduced by Meyer and Paterson in [13] (see also [8]). A safe approximation algorithm for a set A is a polynomial-time algorithm M that on each input x outputs either 1 (accept), 0 (reject), or ? (I do not know) such that all inputs accepted by M are members of A and no member of A is rejected by M. An approximation algorithm is optimal if no other polynomial-time algorithm correctly decides infinitely many more inputs, that is to say, outputs infinitely many more correct 1s or 0s. In Orponen, Russo, and Schöning [14], the existence of optimal approximations was phrased in terms of $\mathbf{P}$-levelability: a recursive set A is $\mathbf{P}$-levelable if for any deterministic Turing machine M accepting A and for any polynomial p there is another machine M' accepting A and a polynomial p' such that for infinitely many elements x of A, M does not accept x within $p(|x|)$ steps while M' accepts x within $p'(|x|)$ steps. It is easy to show that A has an optimal polynomial-time safe approximation if and only if neither A nor $\bar{A}$ is $\mathbf{P}$-levelable.

The notion of polynomial-time unsafe approximations was introduced by Yesha in [19]: an unsafe approximation algorithm for a set A is just a standard polynomial-time bounded deterministic Turing machine M with outputs 1 and 0. Note that, different from the polynomial-time safe approximations, here we are allowed to make errors, and we study the amount of inputs on which M are correct. Duris and Rolim [6] further investigated unsafe approximations and introduced a levelability concept, Δ-levelability, which implies the nonexistence of optimal polynomial-time unsafe approximations. They showed that complete sets for $\mathbf{E}$ are Δ-levelable and there exists

an intractable set in **E** which has an optimal safe approximation but no optimal unsafe approximation. But they did not succeed in producing an intractable set with optimal unsafe approximations. Ambos-Spies [1] defined a concept of weak Δ-levelability and showed that there exists an intractable set in **E** which is not weakly Δ-levelable (hence it has an optimal unsafe approximation).

Like resource-bounded randomness concepts, different kinds of resource-bounded genericity concepts were introduced by Ambos-Spies [2], Ambos-Spies, Fleischhack, and Huwig [3], Fenner [7], and Lutz [9]. It has been proved that resource-bounded generic sets are useful in providing a coherent picture of complexity classes. These sets embody the method of diagonalization construction; that is, requirements which can always be satisfied by finite extensions are automatically satisfied by generic sets.

It was shown in Ambos-Spies, Neis, and Terwijn [4] that the generic sets of Ambos-Spies are **P**-immune, and that the class of sets which have optimal safe approximations is large in the sense of resource-bounded Ambos-Spies category. Mayordomo [11] has shown that the class of **P**-immune sets is neither meager nor comeager both in the sense of resource-bounded Lutz category and in the sense of resource-bounded Fenner category. We extend this result by showing that the class of sets which have optimal safe approximations is neither meager nor comeager both in the sense of resource-bounded Lutz category and in the sense of resource-bounded Fenner category. Moreover, we will show the following relations between unsafe approximations and resource-bounded categories.

1. The class of weakly Δ-levelable sets is neither meager nor comeager in the sense of resource-bounded Ambos-Spies category [4].
2. The class of weakly Δ-levelable sets is comeager (is therefore large) in the sense of resource-bounded general Ambos-Spies [2], Fenner [7], and Lutz [9] categories.
3. The class of Δ-levelable sets is neither meager nor comeager in the sense of resource-bounded general Ambos-Spies [2], Fenner [7], and Lutz [9] categories.

In the last section, we will show the relationship between polynomial-time approximations and p-measure. Mayordomo [12] has shown that the class of **P**-bi-immune sets has p-measure 1. It follows that the class of sets which have optimal polynomial-time safe approximations has p-measure 1. Using the law of the iterated logarithm for p-random sequences which we have proved in Wang [16, 17], we will show that the following hold.

1. The class of Δ-levelable sets has p-measure 0.
2. The class of sets which have optimal polynomial-time unsafe approximations have p-measure 0. That is, the class of weakly Δ-levelable sets has p-measure 1.
3. p-Random sets are weakly Δ-levelable but not Δ-levelable.

Hence typical sets in the sense of resource-bounded measure do not have optimal polynomial-time unsafe approximations.

It should be noted that the above results show that the class of weakly Δ-levelable sets is large both in the sense of the different notions of resource-bounded category and in the sense of resource-bounded measure. That is to say, typical sets in $\mathbf{E}_2$ (in the sense of resource-bounded category or in the sense of resource-bounded measure) are weakly Δ-levelable.

In contrast to the results in this paper, we have recently shown (in [18]) the following results.

1. There is a p-stochastic set $A \in \mathbf{E}_2$ which is Δ-levelable.

2. There is a p-stochastic set $A \in \mathbf{E}_2$ which has an optimal unsafe approximation.

2. Definitions. N and $Q(Q^+)$ are the set of natural numbers and the set of (nonnegative) rational numbers, respectively. $\Sigma = \{0,1\}$ is the binary alphabet, Σ^* is the set of (finite) binary strings, Σ^n is the set of binary strings of length n, and Σ^∞ is the set of infinite binary sequences. The length of a string x is denoted by $|x|$. $<$ is the length-lexicographical ordering on Σ^*, and z_n $(n \geq 0)$ is the nth string under this ordering. λ is the empty string. For strings $x, y \in \Sigma^*$, xy is the concatenation of x and y, $x \sqsubseteq y$ denotes that x is an initial segment of y. For a sequence $x \in \Sigma^* \cup \Sigma^\infty$ and an integer number $n \geq -1$, $x[0..n]$ denotes the initial segment of length $n+1$ of x ($x[0..n] = x$ if $|x| \leq n+1$) and $x[i]$ denotes the ith bit of x, i.e., $x[0..n] = x[0] \cdots x[n]$. Lowercase letters $\ldots, k, l, m, n, \ldots, x, y, z$ from the middle and the end of the alphabet will denote numbers and strings, respectively. The letter b is reserved for elements of Σ, and lowercase Greek letters $\xi, \eta, \ldots$ denote infinite sequences from Σ^∞.

A subset of Σ^* is called a language, a problem, or simply a set. Capital letters are used to denote subsets of Σ^* and boldface capital letters are used to denote subsets of Σ^∞. The cardinality of a language A is denoted by $\|A\|$. We identify a language A with its characteristic function, i.e., $x \in A$ if and only if $A(x) = 1$. The characteristic sequence of a language A is the infinite sequence $A(z_0)A(z_1)A(z_2)\cdots$. We freely identify a language with its characteristic sequence and the class of all languages with the set Σ^∞. For a language $A \subseteq \Sigma^*$ and a string $z_n \in \Sigma^*$, $A\restriction z_n = A(z_0)\cdots A(z_{n-1}) \in \Sigma^*$. For languages A and B, $\bar{A} = \Sigma^* - A$ is the complement of A, $A\Delta B = (A - B) \cup (B - A)$ is the symmetric difference of A and B; $A \subseteq B$ (resp., $A \subset B$) denotes that A is a subset of B (resp., $A \subseteq B$ and $B \not\subseteq A$). For a number n, $A^{=n} = \{x \in A : |x| = n\}$ and $A^{\leq n} = \{x \in A : |x| \leq n\}$.

We fix a standard polynomial-time computable and invertible pairing function $\lambda x, y\langle x, y\rangle$ on Σ^* such that, for every string x, there is a real $\alpha(x) > 0$ satisfying

$$\|\Sigma^{[x]} \cap \Sigma^n\| \geq \alpha(x) \cdot 2^n \text{ for almost all } n,$$

where $\Sigma^{[x]} = \{\langle x, y\rangle : y \in \Sigma^*\}$ and $\Sigma^{[\leq x]} = \{\langle x', y\rangle : x' \leq x \ \&\ y \in \Sigma^*\}$. We will use $\mathbf{P}$, $\mathbf{E}$, and $\mathbf{E}_2$ to denote the complexity classes $DTIME(poly)$, $DTIME(2^{linear})$, and $DTIME(2^{poly})$, respectively. Finally, we fix a recursive enumeration $\{P_e : e \geq 0\}$ of $\mathbf{P}$ such that $P_e(x)$ can be computed in $O(2^{|x|+e})$ steps (uniformly in e and x).

We define a *finite function* to be a partial function from Σ^* to Σ whose domain is finite. For a finite function σ and a string $x \in \Sigma^*$, we write $\sigma(x) \downarrow$ if $x \in dom(\sigma)$, and $\sigma(x) \uparrow$ otherwise. For two finite functions σ, τ, we say σ and τ are compatible if $\sigma(x) = \tau(x)$ for all $x \in dom(\sigma) \cap dom(\tau)$. The concatenation $\sigma\tau$ of two finite functions σ and τ is defined as $\sigma\tau = \sigma \cup \{(z_{n_\sigma+i+1}, b) : z_i \in dom(\tau) \ \&\ \tau(z_i) = b\}$, where $n_\sigma = \max\{n : z_n \in dom(\sigma)\}$ and $n_\sigma = -1$ for $\sigma = \lambda$. For a set A and a string x, we identify the characteristic string $A\restriction x$ with the finite function $\{(y, A(y)) : y < x\}$. For a finite function σ and a set A, σ is extended by A if for all $x \in dom(\sigma)$, $\sigma(x) = A(x)$.

3. Genericity versus polynomial-time safe approximations. In this section, we summarize some known results on the relationship between the different notions of resource-bounded genericity and the notion of polynomial-time safe approximations.

We first introduce some concepts of resource-bounded genericity.

DEFINITION 3.1. *A partial function f from Σ^* to $\{\sigma : \sigma$ is a finite function $\}$ is* dense along *a set A if there are infinitely many strings x such that $f(A\restriction x)$ is defined.*

A set A meets *f if, for some x, the finite function $(A\upharpoonright x)f(A\upharpoonright x)$ is extended by A. Otherwise, A* avoids *f.*

DEFINITION 3.2. *A class $\mathbf{C}$ of sets is* nowhere dense *via f if f is dense along all sets in $\mathbf{C}$ and for every set $A \in \mathbf{C}$, A avoids f.*

DEFINITION 3.3. *Let $\mathbf{F}$ be a class of (partial) functions from Σ^* to $\{\sigma : \sigma$ is a finite function$\}$. A class $\mathbf{C}$ of sets is* $\mathbf{F}$-meager *if there exists a function $f \in \mathbf{F}$ such that $\mathbf{C} = \cup_{i\in N}\mathbf{C}_i$ and $\mathbf{C}_i$ is nowhere dense via $f_i(x) = f(\langle i, x\rangle)$. A class $\mathbf{C}$ of sets is* $\mathbf{F}$-comeager *if $\bar{\mathbf{C}}$ is $\mathbf{F}$-meager.*

DEFINITION 3.4. *A set G is* $\mathbf{F}$-generic *if G is an element of all $\mathbf{F}$-comeager classes.*

LEMMA 3.5 (see [2, 7, 9]). *A set G is $\mathbf{F}$-generic if and only if G meets all functions $f \in \mathbf{F}$ which are dense along G.*

For a class $\mathbf{F}$ of functions, each function $f \in \mathbf{F}$ can be considered as a finitary property $\mathcal{P}$ of sets. If $f(A\upharpoonright x)$ is defined, then all sets extending $(A\upharpoonright x)f(A\upharpoonright x)$ have the property $\mathcal{P}$. So a set A has the property $\mathcal{P}$ if and only if A meets f. f is dense along A if and only if in a construction of A along the ordering $<$, where at stage s of the construction we decide whether or not the string z_s belongs to A, there are infinitely many stages s such that by appropriately defining $A(z_s)$ we can ensure that A has the property $\mathcal{P}$ (that is to say, for some string x, $(A\upharpoonright x)f(A\upharpoonright x)$ is extended by A).

For different function classes $\mathbf{F}$, we have different notions of $\mathbf{F}$-genericity. In this paper, we will concentrate on the following four kinds of function classes which have been investigated by Ambos-Spies [2], Amos-Spies, Neis, and Terwijn [4], Fenner [7], and Lutz [9], respectively. $\mathbf{F}_1$ is the class of polynomial-time computable partial functions from Σ^* to Σ; $\mathbf{F}_2$ is the class of polynomial-time computable partial functions from Σ^* to $\{\sigma : \sigma$ is a finite function$\}$; $\mathbf{F}_3$ is the class of polynomial-time computable total functions from Σ^* to $\{\sigma : \sigma$ is a finite function$\}$; and $\mathbf{F}_4$ is the class of polynomial-time computable total functions from Σ^* to Σ^*.

DEFINITION 3.6.

1. (*See Ambos-Spies, Neis, and Terwijn* [4].) *A set G is* A-generic *if G is $\mathbf{F}_1$-generic.*
2. (*See Ambos-Spies* [2].) *A set G is* general A-generic *if G is $\mathbf{F}_2$-generic.*
3. (*See Fenner* [7].) *A set G is* F-generic *if G is $\mathbf{F}_3$-generic.*
4. (*See Lutz* [9].) *A set G is* L-generic *if G is $\mathbf{F}_4$-generic.*

Obviously, we have the following implications.

THEOREM 3.7.

1. *If a set G is general A-generic, then G is A-generic, F-generic, and L-generic.*
2. *If a set G is F-generic, then G is L-generic.*

Proof. The proof is straightforward. □

In this paper, we will also study the following n^k-time ($k > 1$) bounded genericity concepts. A set G is Ambos-Spies n^k-generic (resp., general Ambos-Spies n^k-generic, Fenner n^k-generic, Lutz n^k-generic) if and only if G meets all n^k-time computable functions $f \in \mathbf{F}_1$ (resp., $\mathbf{F}_2$, $\mathbf{F}_3$, $\mathbf{F}_4$) which are dense along G.

THEOREM 3.8 (see Ambos-Spies [2]). *A class $\mathbf{C}$ of sets is meager in the sense of Ambos-Spies category (resp., general Ambos-Spies category, Fenner category, Lutz Category) if and only if there exists a number $k \in N$ such that there is no Ambos-Spies n^k-generic (resp., general Ambos-Spies n^k-generic, Lutz n^k-generic, Fenner n^k-generic) set in $\mathbf{C}$.*

As an example, we show that Ambos-Spies n-generic sets are $\mathbf{P}$-immune.

THEOREM 3.9 (see Ambos-Spies, Neis, Terwijn [4]). *Let G be an Ambos-Spies n-generic set. Then G is* $\mathbf{P}$*-immune.*

Proof. For a contradiction assume that $A \in \mathbf{P}$ is an infinite subset of G. Then the function $f : \Sigma^* \to \Sigma$ defined by

$$f(x) = \begin{cases} 0 & z_{|x|} \in A, \\ \uparrow & z_{|x|} \notin A \end{cases}$$

is computable in time n and is dense along G. So, by the Ambos-Spies n-genericity of G, G meets f. By the definition of f, this implies that there exists some string $z_i \in A$ such that $z_i \notin G$, a contradiction. □

It has been shown (see Mayordomo [12]) that neither F-genericity nor L-genericity implies $\mathbf{P}$-immunity or non-$\mathbf{P}$-immunity.

A *partial* set A is defined by a partial characteristic function $f : \Sigma^* \to \Sigma$. A partial set A is polynomial-time computable if $dom(A) \in \mathbf{P}$ and its partial characteristic function is computable in polynomial time.

DEFINITION 3.10 (see Meyer and Paterson [13]). *A* polynomial-time safe approximation *of a set A is a polynomial-time computable partial set Q which is consistent with A, that is to say, for every string $x \in dom(Q)$, $A(x) = Q(x)$. The approximation Q is* optimal *if, for every polynomial-time safe approximation Q' of A, $dom(Q') - dom(Q)$ is finite.*

DEFINITION 3.11 (see Orponen, Russo, and Schöning [14]). *A set A is* $\mathbf{P}$-levelable *if, for any subset $B \in \mathbf{P}$ of A, there is another subset $B' \in \mathbf{P}$ of A such that $\|B' - B\| = \infty$.*

LEMMA 3.12 (see Orponen, Russo, and Schöning [14]). *A set A possesses an optimal polynomial-time safe approximation if and only if neither A nor $\bar{A}$ is* $\mathbf{P}$*-levelable.*

Proof. The proof is straightforward. □

LEMMA 3.13. *If a set A is* $\mathbf{P}$*-immune, then A is not* $\mathbf{P}$*-levelable.*

Proof. The proof is straightforward. □

THEOREM 3.14 (see Ambos-Spies [2]). *Let G be an Ambos-Spies n-generic set. Then neither G nor $\bar{G}$ is* $\mathbf{P}$*-levelable. That is to say, G has an optimal polynomial-time safe approximation.*

Proof. This follows from Theorem 3.9. □

Theorem 3.14 shows that the class of $\mathbf{P}$-levelable sets is "small" in the sense of resource-bounded (general) Ambos-Spies category.

COROLLARY 3.15. *The class of* $\mathbf{P}$*-levelable sets is meager in the sense of resource-bounded (general) Ambos-Spies category.*

Now we show that the class of $\mathbf{P}$-levelable sets is neither meager nor comeager in the sense of resource-bounded Fenner category and Lutz category.

THEOREM 3.16.

1. *There exists a set G in $\mathbf{E}_2$ which is both F-generic and* $\mathbf{P}$*-levelable.*
2. *There exists a set G in $\mathbf{E}_2$ which is F-generic but not* $\mathbf{P}$*-levelable.*

Proof. 1. Let $\delta(0) = 0, \delta(n+1) = 2^{2^{\delta(n)}}$, $I_1 = \{x : \delta(2n) \leq |x| < \delta(2n+1), n \in N\}$, $I_2 = \Sigma^* - I_1$, and $\{f_i : i \in N\}$ be an enumeration of $\mathbf{F}_3$ such that $f_i(x)$ can be computed uniformly in time $2^{\log^k(|x|+i)}$ for some $k \in N$.

In the following, we construct a set G in stages which is both F-generic and $\mathbf{P}$-levelable. In the construction we will ensure that

$$G \cap \Sigma^{[e]} \cap I_1 =^* \Sigma^{[e]} \cap I_1$$

for $e \geq 0$. Hence $G \cap \Sigma^{[e]} \cap I_1 \in \mathbf{P}$ for $e \geq 0$. In order to ensure that G is $\mathbf{P}$-levelable, it suffices to satisfy for all $e \geq 0$ the following requirements:

$L_e : P_e \subseteq G \cap I_1 \Rightarrow P_e \subseteq^* \Sigma^{[\leq e]} \cap I_1$.

To show that the requirements $L_e (e \geq 0)$ ensure that G is $\mathbf{P}$-levelable (fix a subset $C \in \mathbf{P}$ of G) we have to define a subset $C' \in \mathbf{P}$ of G such that $C' - C$ is infinite. Fix e such that $P_e = C \cap I_1$. Then, by the requirement L_e, $C \cap I_1 \subseteq^* \Sigma^{[\leq e]} \cap I_1$. So, for $C' = G \cap \Sigma^{[e+1]} \cap I_1$, $C' \in \mathbf{P}$ and C' is infinite. Since $C' \cap C = \emptyset$, C' has the required property.

The strategy for meeting a requirement L_e is as follows: if there is a string $x \in (I_1 \cap P_e) - \Sigma^{[\leq e]}$, then we let $G(x) = 0$ to refute the hypothesis of the requirement L_e (so L_e is trivially met). To ensure that G is F-generic, it suffices to meet for all $e \geq 0$ the following requirements:

G_e: There exists a string x such that G extends $(G\restriction x)f_e(G\restriction x)$.

Because the set I_1 is used to satisfy L_e, we will use I_2 to satisfy G_e. The strategy for meeting a requirement G_e is as follows: for some string $x \in I_2$, let G extend $(G\restriction x)f_e(G\restriction x)$.

Define a priority ordering of the requirements by letting $R_{2n} = G_n$ and $R_{2n+1} = L_n$. Now we give the construction of G formally.

Stage s.

If $G(z_s)$ has been defined before stage s, then go to stage $s + 1$.

A requirement L_e *requires* attention if

1. $e < s$.
2. $z_s \in P_e \cap \Sigma^{[>e]} \cap I_1$.
3. For all $y < z_s$, if $y \in P_e$ then $y \in G \cap I_1$.

A requirement G_e *requires* attention if $e < s$, G_e has not received attention yet, and $x \in I_2$ for all $z_s \leq x \leq z_t$ where z_t is the greatest element in $dom((G\restriction z_s)f_e(G\restriction z_s))$.

Fix the minimal n such that R_n requires attention. If there is no such n, then let $G(z_s) = 1$. Otherwise, we say that R_n *receives* attention. Moreover, if $R_n = L_e$ then let $G(z_s) = 0$. If $R_n = G_e$ then let $G\restriction z_{t+1} = fill_1((G\restriction z_s)f_e(G\restriction z_s), t)$, where z_t is the greatest element in $dom((G\restriction z_s)f_e(G\restriction z_s))$ and for a finite function σ and a number k, $fill_1(\sigma, k) = \sigma \cup \{(x, 1) : x \leq z_k \ \& \ x \notin dom(\sigma)\}$.

This completes the construction of G.

It is easy to verify that the set G constructed above is both $\mathbf{P}$-levelable and F-generic; the details are omitted here.

2. For a general A-generic set G, by Theorem 3.9, G is $\mathbf{P}$-immune. By Theorem 3.7, G is F-generic. Hence, G is F-generic but not $\mathbf{P}$-levelable. □

COROLLARY 3.17. *The class of* $\mathbf{P}$*-levelable sets is neither meager nor comeager in the sense of resource-bounded Fenner category and Lutz category.*

Proof. This follows from Theorem 3.16. □

4. Genericity versus polynomial-time unsafe approximations.

DEFINITION 4.1 (see Duris and Rolim [6] and Yesha [19]). *A* polynomial-time unsafe approximation *of a set A is a set $B \in \mathbf{P}$. The set $A\Delta B$ is called the* error *set of the approximation. Let f be an unbounded function on the natural numbers. A set A is* Δ-levelable with density f *if, for any set $B \in \mathbf{P}$, there is another set $B' \in \mathbf{P}$ such that*

$$\|(A\Delta B)\restriction z_n\| - \|(A\Delta B')\restriction z_n\| \geq f(n)$$

for almost all $n \in N$. A set A is Δ-levelable *if A is Δ-levelable with density f such that* $\lim_{n\to\infty} f(n) = \infty$.

Note that, in Definition 4.1, the density function f is independent of the choice of $B \in \mathbf{P}$.

DEFINITION 4.2 (see Ambos-Spies [1]). *A polynomial-time unsafe approximation B of a set A is* optimal *if, for any approximation $B' \in \mathbf{P}$ of A,*

$$\exists k \in N\ \forall n \in N\ (\|(A\Delta B)\restriction z_n\| < \|(A\Delta B')\restriction z_n\| + k).$$

A set A is weakly Δ-levelable *if, for any polynomial-time unsafe approximation B of A, there is another polynomial-time unsafe approximation B' of A such that*

$$\forall k \in N\ \exists n \in N\ (\|(A\Delta B)\restriction z_n\| > \|(A\Delta B')\restriction z_n\| + k).$$

It should be noted that our above definitions are a little different from the original definitions of Ambos-Spies [1], Duris and Rolim [6], and Yesha [19]. In the original definitions, they considered the errors on strings up to certain length (i.e., $\|(A\Delta B)^{\leq n}\|$) instead of errors on strings up to z_n (i.e., $\|(A\Delta B)\restriction z_n\|$). But it is easy to check that all our results except Theorem 5.14 in this paper hold for the original definitions also.

LEMMA 4.3 (see Ambos-Spies [1]).

1. *A set A is weakly Δ-levelable if and only if A does not have an optimal polynomial time unsafe approximation.*
2. *If a set A is Δ-levelable then it is weakly Δ-levelable.*

LEMMA 4.4. *Let A, B be two sets such that A is Δ-levelable with linear density and $A\Delta B$ is sparse. Then B is Δ-levelable with linear density.*

Proof. Let p be the polynomial such that, for all n, $\|(A\Delta B)^{\leq n}\| \leq p(n)$, and assume that A is Δ-levelable with density αn ($\alpha > 0$). Then there is a real number $\beta > 0$ such that, for large enough n, $\alpha n - 2p(1 + [\log n]) > \beta n$. We will show that B is Δ-levelable with density βn.

Now, given any set $C \in \mathbf{P}$, by Δ-levelability of A, choose $D \in \mathbf{P}$ such that

$$\|(A\Delta C)\restriction z_n\| > \|(A\Delta D)\restriction z_n\| + \alpha n$$

for almost all n. Then

$$\begin{aligned}
\|(B\Delta C)\restriction z_n\| &\geq \|(A\Delta C)\restriction z_n\| - p(1 + [\log n]) \\
&> \|(A\Delta D)\restriction z_n\| + \alpha n - p(1 + [\log n]) \\
&\geq \|(B\Delta D)\restriction z_n\| + \alpha n - 2p(1 + [\log n]) \\
&> \|(B\Delta D)\restriction z_n\| + \beta n
\end{aligned}$$

for almost all n. Hence, B is Δ-levelable with density βn. □

THEOREM 4.5.

1. *There exists a set G in $\mathbf{E}_2$ which is both A-generic and Δ-levelable.*
2. *There exists a set G in $\mathbf{E}_2$ which is A-generic but not weakly Δ-levelable.*

Proof. 1. Duris and Rolim [6] constructed a set A in $\mathbf{E}$ which is Δ-levelable with linear density and, in [4], Ambos-Spies, Neis, and Terwijn showed that, for any set $B \in \mathbf{E}$, there is an A-generic set B' in $\mathbf{E}_2$ such that $B\Delta B'$ is sparse. So, for any set A which is Δ-levelable with linear density, there is an A-generic set G in $\mathbf{E}_2$ such that $A\Delta G$ is sparse. It follows from Lemma 4.4 that G is Δ-levelable with linear density.

2. Ambos-Spies [1, Theorem 3.3] constructed a **P**-bi-immune set in **E** which is not weakly Δ-levelable. In his proof, he used the requirements

$BI_{2e} : P_e \subseteq G \Rightarrow P_e$ is finite,

$BI_{2e+1} : P_e \subseteq \bar{G} \Rightarrow P_e$ is finite,

to ensure that the constructed set G is **P**-bi-immune. In order to guarantee that G is not weakly Δ-levelable, he used the requirements

$$R : \forall e \in N\ \forall n \in N\ (\|(G\Delta B)\restriction z_n\| \leq \|(G\Delta P_e)\restriction z_n\| + e + 1)$$

to ensure that $B = \cup_{i\geq 0}\Sigma^{[2i]}$ will be an optimal unsafe approximation of G. If we change the requirements BI_{2e} and BI_{2e+1} to the requirements

R_e : if $f_e \in \mathbf{F}_1$ is dense along G, then G meets f_e,

then a routine modification of the finite injury argument in the proof of Ambos-Spies [1, Theorem 3.3] can be used to construct an A-generic set G in $\mathbf{E}_2$ which is not weakly Δ-levelable. The details are omitted here. □

COROLLARY 4.6. *The class of (weakly) Δ-levelable sets is neither meager nor comeager in the sense of resource-bounded Ambos-Spies category.*

Corollary 4.6 shows that the class of weakly Δ-levelable sets is neither large nor small in the sense of resource-bounded Ambos-Spies category. However, as we will show next, it is large in the sense of resource-bounded general Ambos-Spies category, resource-bounded Fenner category, and resource-bounded Lutz category.

THEOREM 4.7. *Let G be a Lutz n^3-generic set. Then G is weakly Δ-levelable.*

Proof. Let $B \in \mathbf{P}$. We show that $\bar{B}$ witnesses that the unsafe approximation B of G is not optimal. For any string x, define $f(x) = y$, where $|y| = |x|^2$ and $y[j] = 0$ if and only if $z_{|x|+j} \in B$. Obviously, f is computable in time n^3. Since G is Lutz n^3-generic, G meets f infinitely often. Hence, for any k and n_0, there exists $n > n_0$ such that $n^2 - 2n > k$ and, for all strings x with $z_n \leq x < z_{n^2}$, $x \in G$ if and only if $x \in \bar{B}$. Hence

$$\begin{aligned} \|(G\Delta B)\restriction z_{n^2}\| &\geq n^2 - n \\ &> n + k \\ &\geq \|(G\Delta\bar{B})\restriction z_{n^2}\| + k, \end{aligned}$$

which implies that G is weakly Δ-levelable. □

COROLLARY 4.8. *The class of weakly Δ-levelable sets is comeager in the sense of resource-bounded Lutz, Fenner, and general Ambos-Spies categories.*

Proof. This follows from Theorems 3.7, 3.8, and 4.7. □

Now we show that the class of Δ-levelable sets is neither meager nor comeager in the sense of all these resource-bounded categories we have discussed above.

THEOREM 4.9. *There exists a set G in $\mathbf{E}_2$ which is both general A-generic and Δ-levelable.*

Proof. Let $\delta(0) = 0, \delta(n+1) = 2^{2^{\delta(n)}}$. For each set $P_e \in \mathbf{P}$, let $P_{g(e)}$ be defined in such a way that

$$P_{g(e)}(x) = \begin{cases} 1 - P_e(x) & \text{if } x = 0^{\delta(<e,n>)} \text{ for some } n \in N, \\ P_e(x) & \text{otherwise.} \end{cases}$$

In the following we construct a general A-generic set G which is Δ-levelable by keeping $P_{g(e)}$ to witness that the unsafe approximation P_e of G is not optimal. Let

$\{f_i : i \in N\}$ be an enumeration of all functions in $\mathbf{F}_2$ such that $f_i(x)$ can be computed uniformly in time $2^{\log^k(|x|+i)}$ for some $k \in N$.

The set G is constructed in stages. To ensure that G is general A-generic, it suffices to meet for all $e \in N$ the following requirements:

G_e : if f_e is dense along G, then G meets f_e.

To ensure that G is Δ-levelable, it suffices to meet for all $e, k \in N$ the following requirements, as shown at the end of the proof:

$L_{\langle e,k\rangle} : \exists n_1 \in N\ \forall n > n_1\ (\|(G\Delta P_e)\restriction z_n\| > \|(G\Delta P_{g(e)})\restriction z_n\| + k)$.

The strategy for meeting a requirement G_e is as follows: at stage s, if G_e has not been satisfied yet and $f_e(G\restriction z_s)$ is defined, then let G extend $(G\restriction z_s)f_e(G\restriction z_s)$. But this action may injure the satisfaction of some requirements $L_{\langle i,k\rangle}$ and G_m. The conflict is solved by delaying the action until it will not injure the satisfaction of the requirements $L_{\langle i,k\rangle}$ and G_m which have higher priority than G_e.

The strategy for meeting a requirement $L_{\langle e,k\rangle}$ is as follows: at stage s, if $L_{\langle e,k\rangle}$ has not been satisfied yet and $P_e(z_s) \neq P_{g(e)}(z_s)$, then let $G(z_s) = P_{g(e)}(z_s)$. When a requirement G_e becomes satisfied at some stage, it is satisfied forever, so $L_{\langle e,k\rangle}$ can only be injured finitely often and then it will have a chance to become satisfied forever.

Stage s.

In this stage, we define the value of $G(z_s)$.

A requirement G_n *requires* attention if

1. $n < s$.
2. G_n has not been satisfied yet.
3. There exists $t \leq s$ such that
   A. $f_n(G\restriction z_t)$ is defined.
   B. $G\restriction z_s$ is consistent with $(G\restriction z_t)f_n(G\restriction z_t)$.
   C. For all $e, k \in N$ such that $\langle e,k\rangle < n$, there is at most one $\langle e,m\rangle \in N$ such that $0^{\delta(\langle e,m\rangle)} \in dom((G\restriction z_t)f_n(G\restriction z_t))$.
   D. For all $e, k \in N$ such that $\langle e,k\rangle < n$,

$$\|(G\Delta P_e)\restriction z_s\| - \|(G\Delta P_{g(e)})\restriction z_s\| > k + n. \tag{1}$$

Fix the minimal m such that G_m requires attention, and fix the minimal t in the above item 3 corresponding to the requirement G_m. If there is no such m, then let $G(z_s) = 1 - P_e(z_s)$ if $z_s = 0^{\delta(\langle e,n\rangle)}$ for some $e, n \in N$, and let $G(z_s) = 0$ otherwise. Otherwise we say that G_m *receives* attention. Moreover, let

$$G(z_s) = \begin{cases} ((G\restriction z_t)f_m(G\restriction z_t))(z_s) & \text{if } z_s \in dom((G\restriction z_t)f_m(G\restriction z_t)), \\ 1 - P_e(z_s) & \text{if } z_s \notin dom((G\restriction z_t)f_m(G\restriction z_t)) \ \&\ z_s = 0^{\delta(\langle e,n\rangle)} \\ & \text{for some } e, n, \\ 0 & \text{otherwise.} \end{cases}$$

This completes the construction.

We show that all requirements are met by proving a sequence of claims.

Claim 1. *Every requirement G_n requires attention at most finitely often.*

Proof. The proof is by induction. Fix n and assume that the claim is correct for all numbers less than n. Then there is a stage s_0 such that no requirement G_m with $m < n$ requires attention after stage s_0. So G_n receives attention at any stage $s > s_0$

at which it requires attention. Hence it is immediate from the construction that G_n requires attention at most finitely often. □

CLAIM 2. *Given $n_0 \in N$, if no requirement $G_n (n < n_0)$ requires attention after stage s_0 and G_{n_0} requires attention at stage s_0, then for all $\langle e, k\rangle < n_0$ and $s > s_0$,*

$$\|(G\Delta P_e)\upharpoonright z_s\| - \|(G\Delta P_{g(e)})\upharpoonright z_s\| > k + n_0 - 1.$$

Proof. The proof is straightforward from the construction. □

CLAIM 3. *Every requirement G_n is met.*

Proof. For a contradiction, fix the minimal n such that G_n is not met. Then f_n is dense along G. We have to show that G_n requires attention infinitely often which is contrary to Claim 1. Since $\|P_e\Delta P_{g(e)}\| = \infty$ for all $e \in N$, by the construction and Claim 2, there will be a stage s_0 such that at all stages $s > s_0$, (1) holds for all $e, k \in N$ such that $\langle e, k\rangle < n$. Hence G_n requires attention at each stage $s > s_0$ at which $f_n(G\upharpoonright z_s)$ is defined. □

CLAIM 4. *Every requirement $L_{\langle e,k\rangle}$ is met.*

Proof. This follows from Claims 2 and 3. □

Now we show that G is both A-generic and Δ-levelable. G is A-generic since all requirements G_n are met. For $\langle e, k\rangle \in N$, let $n_{\langle e,k\rangle}$ be the least number s_0 such that for all $s > s_0$,

$$\|(G\Delta P_e)\upharpoonright z_s\| > \|(G\Delta P_{g(e)})\upharpoonright z_s\| + k$$

and let $f(n)$ be the biggest k such that

$$\forall e \leq k\ (n \geq n_{\langle e,k\rangle}).$$

Then $\lim_{n\to\infty} f(n) = \infty$ and, for all $e \in N$,

$$\|(G\Delta P_e)\upharpoonright z_n\| \geq \|(G\Delta P_{g(e)})\upharpoonright z_n\| + f(n) \text{ a.e.}$$

That is to say, G is Δ-levelable with density f. □

THEOREM 4.10. *There exists a set G in $\mathbf{E}_2$ which is general A-generic but not Δ-levelable.*

Proof. As in the previous proof, a set G is constructed in stages. To ensure that G is general A-generic, it suffices to meet for all $e \in N$ the following requirements:

G_e : if f_e is dense along G, then G meets f_e.

Fix a set $B \in \mathbf{P}$. Then the requirements

$$NL_{\langle e,k\rangle} : P_e\Delta B \text{ infinite } \Rightarrow \exists n\ (\|(G\Delta P_e)\upharpoonright z_n\| - \|(G\Delta B)\upharpoonright z_n\| \geq k)$$

will ensure that B witnesses the failure of Δ-levelability of G.

To meet the requirements G_e, we use the strategy in Theorem 4.9. The strategy for meeting a requirement $NL_{\langle e,k\rangle}$ is as follows: at stage s such that $P_e(z_s) \neq B(z_s)$ and $\|(G\Delta P_e)\upharpoonright z_n\| - \|(G\Delta B)\upharpoonright z_n\| < k$ for all $n < s$, let $G(z_s) = B(z_s)$. If $P_e \neq^* B$, this action can be repeated over and over again. Hence $\|G\Delta P_e\|$ is growing more quickly than $\|G\Delta B\|$, and eventually the requirement $NL_{\langle e,k\rangle}$ is met at some sufficiently large stage.

Define a priority ordering of the requirements by letting $R_{2n} = G_n$ and $R_{2\langle e,k\rangle+1} = NL_{\langle e,k\rangle}$. We now describe the construction of G formally.

Stage s.

In this stage, we define the value of $G(z_s)$.

A requirement $NL_{\langle e,k\rangle}$ *requires* attention if $\langle e, k\rangle < s$ and

1. $P_e(z_s) \neq B(z_s)$.
2. $\|(G\Delta P_e)\restriction z_n\| - \|(G\Delta B)\restriction z_n\| < k$ for all $n < s$.

A requirement G_n *requires* attention if

1. $n < s$.
2. G_n has not been satisfied yet.
3. There exists $t \leq s$ such that
   - **A.** $f_n(G\restriction z_t)$ is defined.
   - **B.** $G\restriction z_s$ is consistent with $(G\restriction z_t)f_n(G\restriction z_t)$.
   - **C.** There is no $e, k \in N$ such that
     - **(1).** $\langle e, k\rangle < n$.
     - **(2).** $\forall u < s$ $(\|(G\Delta P_e)\restriction z_u\| - \|(G\Delta B)\restriction z_u\| < k)$.
     - **(3).** There exists $y \in dom((G\restriction z_t)f_n(G\restriction z_t)) - dom(G\restriction z_s)$ such that $P_e(y) \neq B(y)$.

Fix the minimal m such that R_m requires attention. If there is no such m, let $G(z_s) = B(z_s)$. Otherwise we say that R_m *receives* attention. Moreover, if $R_m = NL_{\langle e,k\rangle}$ then let $G(z_s) = B(z_s)$. If $R_m = G_n$ then fix the least t in the above item 3 corresponding to the requirement G_m. Let $G(z_s) = ((G\restriction z_t)f_m(G\restriction z_t))(z_s)$ if $z_s \in dom((G\restriction z_t)f_m(G\restriction z_t))$ and let $G(z_s) = B(z_s)$ otherwise.

This completes the construction of G.

It suffices to show that all requirements are met. Note that, by definition of requiring attention, R_m is met if and only if R_m requires attention at most finitely often. So, for a contradiction, fix the minimal m such that R_m requires attention infinitely often. By minimality of m, fix a stage s_0 such that no requirement $R_{m'}$ with $m' < m$ requires attention after stage s_0. Then R_m receives attention at any stage $s > s_0$ at which R_m requires attention. Now, we first assume that $R_m = G_n$. Then at some stage $s > s_0$, G_n receives attention and becomes satisfied forever. Finally assume that $R_m = NL_{\langle e,k\rangle}$. Then $B\Delta P_e$ is infinite and, at all stages $s > s_0$ such that $B(z_s) \neq P_e(z_s)$, the requirement $NL_{\langle e,k\rangle}$ receives attention; hence $G(z_s) = B(z_s)$. Since, for all other stages s with $s > s_0$, $B(z_s) = P_e(z_s)$, $G\Delta P_e$ grows more rapidly than $G\Delta B$; hence

$$\lim_n(\|(G\Delta P_e)\restriction z_n\| - \|(G\Delta B)\restriction z_n\|) = \infty$$

and $NL_{\langle e,k\rangle}$ is met contrary to assumption. □

COROLLARY 4.11. *The class of Δ-levelable sets is neither meager nor comeager in the sense of resource-bounded (general) Ambos-Spies, Lutz, and Fenner categories.*

Proof. The proof follows from Theorems 3.7, 4.9, and 4.10. □

5. Resource-bounded randomness versus polynomial-time approximations. We first introduce a fragment of Lutz's effective measure theory which will be sufficient for our investigation.

DEFINITION 5.1. *A* martingale *is a function $F : \Sigma^* \to R^+$ such that, for all $x \in \Sigma^*$,*

$$F(x) = \frac{F(x1) + F(x0)}{2}.$$

A martingale F succeeds *on a sequence $\xi \in \Sigma^\infty$ if $\limsup_n F(\xi[0..n-1]) = \infty$. $S^\infty[F]$ denotes the set of sequences on which the martingale F succeeds.*

DEFINITION 5.2 (see Lutz [10]). *A set $\mathbf{C}$ of infinite sequences has* p-measure 0 *($\mu_p(\mathbf{C}) = 0$) if there is a polynomial-time computable martingale $F : \Sigma^* \to Q^+$ which*

succeeds on every sequence in $\mathbf{C}$. *The set* $\mathbf{C}$ *has* p-measure 1 ($\mu_p(\mathbf{C}) = 1$) *if* $\mu_p(\bar{\mathbf{C}}) = 0$ *for the complement* $\bar{\mathbf{C}} = \{\xi \in \Sigma^\infty : \xi \notin \mathbf{C}\}$ *of* $\mathbf{C}$.

DEFINITION 5.3 (see Lutz [10]). *A sequence* ξ *is* n^k-random *if, for every* n^k*-time computable martingale* F, $\limsup_n F(\xi[0..n-1]) < \infty$; *that is to say,* F *does not succeed on* ξ. *A sequence* ξ *is* p-random *if* ξ *is* n^k*-random for all* $k \in N$.

The following theorem is straightforward from the definition.

THEOREM 5.4. *A set* $\mathbf{C}$ *of infinite sequences has* p-measure 0 *if and only if there exists a number* $k \in N$ *such that there is no* n^k*-random sequences in* $\mathbf{C}$.

Proof. See, e.g., [16]. □

The relation between p-measure and the class of $\mathbf{P}$-levelable sets is characterized by the following theorem.

THEOREM 5.5 (see Mayordomo [11]). *The class of* $\mathbf{P}$*-bi-immune sets has* p*-measure* 1.

COROLLARY 5.6. *The class of* $\mathbf{P}$*-levelable sets has* p*-measure* 0.

COROLLARY 5.7. *The class of sets which possesses optimal polynomial-time safe approximations has* p*-measure* 1.

COROLLARY 5.8. *For each* p*-random set* A, A *has an optimal polynomial-time safe approximation.*

Now we turn our attention to the relations between the p-randomness concept and the concept of polynomial-time unsafe approximations. In our following proof, we will use the law of the iterated logarithm for p-random sequences.

DEFINITION 5.9. *A sequence* $\xi \in \Sigma^\infty$ *satisfies the law of the iterated logarithm if*

$$\limsup_{n\to\infty} \frac{2\sum_{i=0}^{n-1} \xi[i] - n}{\sqrt{2n \ln\ln n}} = 1$$

and

$$\liminf_{n\to\infty} \frac{2\sum_{i=0}^{n-1} \xi[i] - n}{\sqrt{2n \ln\ln n}} = -1.$$

THEOREM 5.10 (see Wang [17]). *There exists a number* $k \in N$ *such that every* n^k*-random sequence satisfies the law of the iterated logarithm.*

For the sake of convenience, we will identify a set with its characteristic sequence. The symmetric difference of two sets can be characterized by the parity function on sequences.

DEFINITION 5.11.

1. *The parity function* $\oplus : \Sigma \times \Sigma \to \Sigma$ *on bits is defined by*

$$b_1 \oplus b_2 = \begin{cases} 0 & \text{if } b_1 = b_2, \\ 1 & \text{otherwise,} \end{cases}$$

   where $b_1, b_2 \in \Sigma$.
2. *The parity function* $\oplus : \Sigma^\infty \times \Sigma^\infty \to \Sigma^\infty$ *on sequences is defined by* $(\xi \oplus \eta)[n] = \xi[n] \oplus \eta[n]$.
3. *The parity function* $\oplus : \Sigma^* \times \{f : f \text{ is a partial function from } \Sigma^* \text{ to } \Sigma\} \to \Sigma^*$ *on strings and functions is defined by* $x \oplus f = b_0 \cdots b_{|x|-1}$, *where* $b_i = x[i] \oplus f(x[0..i-1])$ *if* $f(x[0..i-1])$ *is defined and* $b_i = \lambda$ *otherwise.*
4. *The parity function* $\oplus : \Sigma^\infty \times \{f : f \text{ is a partial function from } \Sigma^* \text{ to } \Sigma\} \to \Sigma^* \cup \Sigma^\infty$ *on sequences and functions is defined by* $\xi \oplus f = b_0 b_1 \cdots$ *where* $b_i = \xi[i] \oplus f(\xi[0..i-1])$ *if* $f(\xi[0..i-1])$ *is defined and* $b_i = \lambda$ *otherwise.*

The intuitive meaning of $\xi \oplus f$ is as follows: Given a sequence ξ and a number $n \in N$ such that $f(\xi[0..n-1])$ is defined, we use f to predict the value of $\xi[n]$ from the first n bits $\xi[0..n-1]$. If the prediction is successful, then output 0, else output 1. And $\xi \oplus f$ is the output sequence.

We first explain a useful technique which is similar to the invariance property of p-random sequences.

LEMMA 5.12. *Let $\xi \in \Sigma^\infty$ be n^k-random and $f : \Sigma^* \to \Sigma$ be a partial function computable in time n^k such that $\xi \oplus f$ is an infinite sequence. Then $\xi \oplus f$ is n^{k-1}-random.*

Proof. For a contradiction assume that $\xi \oplus f$ is not n^{k-1}-random and let $F : \Sigma^* \to Q^+$ be an n^{k-1}-martingale that succeeds on $\xi \oplus f$. Define $F' : \Sigma^* \to Q^+$ by letting $F'(x) = F(x \oplus f)$ for all $x \in \Sigma^*$. It is a routine to check that F' is an n^k-martingale. Moreover, since F succeeds on $\xi \oplus f$, F' succeeds on ξ, which is a contradiction with the hypothesis that ξ is n^k-random. □

LEMMA 5.13. *Let k be the number in Theorem 5.10, and let $A, B, C \subseteq \Sigma^*$ be three sets such that the following conditions hold.*

1. $B, C \in \mathbf{P}$.
2. $\|B \Delta C\| = \infty$.
3. *There exists $c \in N$ such that, for almost all n,*

$$\|(A \Delta C)\restriction z_n\| - \|(A \Delta B)\restriction z_n\| \geq -c. \tag{2}$$

Then A is not n^{k+1}-random.

Proof. Let α, β, and γ be the characteristic sequences of A, B, and C, respectively.

By Lemma 5.12, it suffices to define an n^2-time computable partial function $f : \Sigma^* \to \Sigma$ such that $\alpha \oplus f$ is an infinite sequence which is not n^k-random. Define the function f by

$$f(x) = \begin{cases} \beta[|x|] & \text{if } \beta[|x|] \neq \gamma[|x|], \\ \text{undefined} & \text{if } \beta[|x|] = \gamma[|x|]. \end{cases}$$

Then f is n^2-time computable and, since $\|B \Delta C\| = \infty$, $\alpha \oplus f$ is an infinite sequence. In order to show that $\alpha \oplus f$ is not n^k-random, we show that $\alpha \oplus f$ does not satisfy the law of the iterated logarithm.

We first show that, for all $n \in N^+$, the following equation holds:

$$\sum_{i=0}^{n-1} (\alpha \oplus \gamma)[i] - \sum_{i=0}^{n-1} (\alpha \oplus \beta)[i] = l_n - 2 \sum_{i=0}^{l_n - 1} (\alpha \oplus f)[i], \tag{3}$$

where $l_n = |\alpha[0..n-1] \oplus f|$.

Let

$$a(n) = \|\{i < n : \alpha[i] \neq \gamma[i] = \beta[i]\}\|,$$

$$b(n) = \|\{i < n : \alpha[i] \neq \gamma[i] \neq \beta[i]\}\|,$$

$$c(n) = \|\{i < n : \alpha[i] = \gamma[i] \neq \beta[i]\}\|,$$

$$d(n) = \|\{i < n : \alpha[i] = \gamma[i] = \beta[i]\}\|.$$

Then

$$\begin{aligned}\textstyle\sum_{i=0}^{n-1}(\alpha\oplus\gamma)[i] &= a(n)+b(n),\\ \textstyle\sum_{i=0}^{n-1}(\alpha\oplus\beta)[i] &= a(n)+c(n),\\ l_n &= b(n)+c(n),\\ \textstyle\sum_{i=0}^{l_n-1}(\alpha\oplus f)[i] &= c(n).\end{aligned}$$

Obviously, this implies (3).

The condition (2) is equivalent to

$$\sum_{i=0}^{n-1}(\alpha\oplus\gamma)[i]-\sum_{i=0}^{n-1}(\alpha\oplus\beta)[i]\geq -c.$$

So, by (3),

$$l_n-2\sum_{i=0}^{l_n-1}(\alpha\oplus f)[i]\geq -c \tag{4}$$

for almost all n, where $l_n=|\alpha[0..n-1]\oplus f|$. By (4),

$$\liminf_{n\to\infty}\frac{n-2\sum_{i=0}^{n-1}(\alpha\oplus f)[i]}{\sqrt{2n\ln\ln n}}\geq 0.$$

Hence, by Theorem 5.10, $\alpha\oplus f$ is not n^k-random. This completes the proof. □

Now we are ready to prove our main theorems of this section.

THEOREM 5.14. *The class of Δ-levelable sets has p-measure 0.*

Proof. Let A be a Δ-levelable set. Then there is a function $f(n)\geq 0$ satisfying $\lim_{n\to\infty}f(n)=\infty$ and polynomial-time computable sets B,C such that for all n,

$$\|(A\Delta C)\upharpoonright z_n\|-\|(A\Delta B)\upharpoonright z_n\|\geq f(n).$$

By Lemma 5.13, A is not n^{k+1}-random, where k is the number in Theorem 5.10. So the theorem follows from Theorem 5.4. □

THEOREM 5.15. *The class of sets which have optimal polynomial-time unsafe approximations has p-measure 0.*

Proof. If A has an optimal polynomial-time unsafe approximation, then there is a polynomial-time computable set B and a number $c\in N$ such that, for all n,

$$\|(A\Delta B)\upharpoonright z_n\|-\|(A\Delta\bar{B})\upharpoonright z_n\|<c;$$

i.e.,

$$\|(A\Delta\bar{B})\upharpoonright z_n\|-\|(A\Delta B)\upharpoonright z_n\|>-c.$$

By Lemma 5.13, A is not n^{k+1}-random, where k is the number in Theorem 5.10. So the theorem follows from Theorem 5.4. □

COROLLARY 5.16. *The class of sets which are weakly Δ-levelable but not Δ-levelable has p-measure 1.*

COROLLARY 5.17. *Every p-random set is weakly Δ-levelable but not Δ-levelable.*

Acknowledgments. I would like to thank Professor Ambos-Spies for many comments on an early version of this paper, and I would like to thank two anonymous referees for their valuable comments on this paper.

UNIVERSAL LIMIT LAWS FOR DEPTHS IN RANDOM TREES*

LUC DEVROYE†

Abstract. Random binary search trees, b-ary search trees, median-of-$(2k+1)$ trees, quadtrees, simplex trees, tries, and digital search trees are special cases of random split trees. For these trees, we offer a universal law of large numbers and a limit law for the depth of the last inserted point, as well as a law of large numbers for the height.

Key words. binary search tree, data structures, expected time analysis, depth of a node, random tree, law of large numbers

AMS subject classifications. 68Q25, 68P05, 60F05, 60C05

Random split trees. We introduce a model for a random tree that is sufficiently general that it encompasses many important families of random trees, such as random binary search trees, random m-ary search trees, random fringe-balanced trees, random median-of-$(2k+1)$ trees, random quadtrees, and random simplex trees. A *skeleton tree* T_b of branch factor b is an infinite rooted position tree, in which each node has b children, numbered 1 through b. A *split tree* (with branch factor $b > 0$, vertex capacity $s > 0$, and of cardinality $n \geq 0$) is a skeleton tree of branch factor b in which n balls are assigned to a collection of vertices, where each vertex may hold up to s balls. Nodes or vertices are denoted by u. $N(u)$ denotes the number of balls in the subtree rooted at u. $C(u)$ denotes the number of balls associated with vertex u. A vertex u is a *leaf* if $C(u) = N(u) > 0$, or equivalently, if $C(u) > 0$ and $N(v) = 0$ for all b children v of u. A node u is *useless* if $N(u) = 0$. Two split trees with the same parameters b, s, n are equivalent if for all their vertices, the $N(u)$'s are identical. The *trimmed split tree* is the (finite) split tree from which all useless nodes are deleted.

We now introduce a *random split tree* with parameters b, s, s_0, s_1, $\mathcal{V}$, and n. The branch factor b, vertex capacity s, and number of balls n are as for split trees. The additional integers s_0 and s_1 are needed to describe the ball distribution process and satisfy the inequalities

$$0 < s,\ 0 \leq s_0 \leq s,\ 0 \leq bs_1 \leq s + 1 - s_0.$$

Finally, $\mathcal{V}$ is a prototype random vector $(V_1, \ldots, V_b)$ of probabilities: $\sum_i V_i = 1; V_i \geq 0$. A random split tree is a skeleton tree T_b in which each vertex u is given an independent copy of $\mathcal{V}$, and in which n balls are distributed in the manner described below over the vertices, where each vertex may hold up to s balls. The distribution is done in an incremental fashion, as described below. Initially, there are no balls, so every node has a ball count $C(u) = 0$. Adding a ball to a tree rooted at u proceeds as follows. Let $(V_1, \ldots, V_b)$ be the probability vector associated with u.

A. If u is not a leaf (so that $C(u) = s_0$), choose child i with probability V_i, increment $N(u)$ by 1, and recursively add the ball to the subtree rooted at child i.

*Received by the editors March 31, 1995; accepted for publication (in revised form) April 3, 1997; published electronically July 7, 1998. The research of the author was sponsored by NSERC grant A3456 and by FCAR grant 90-ER-0291.

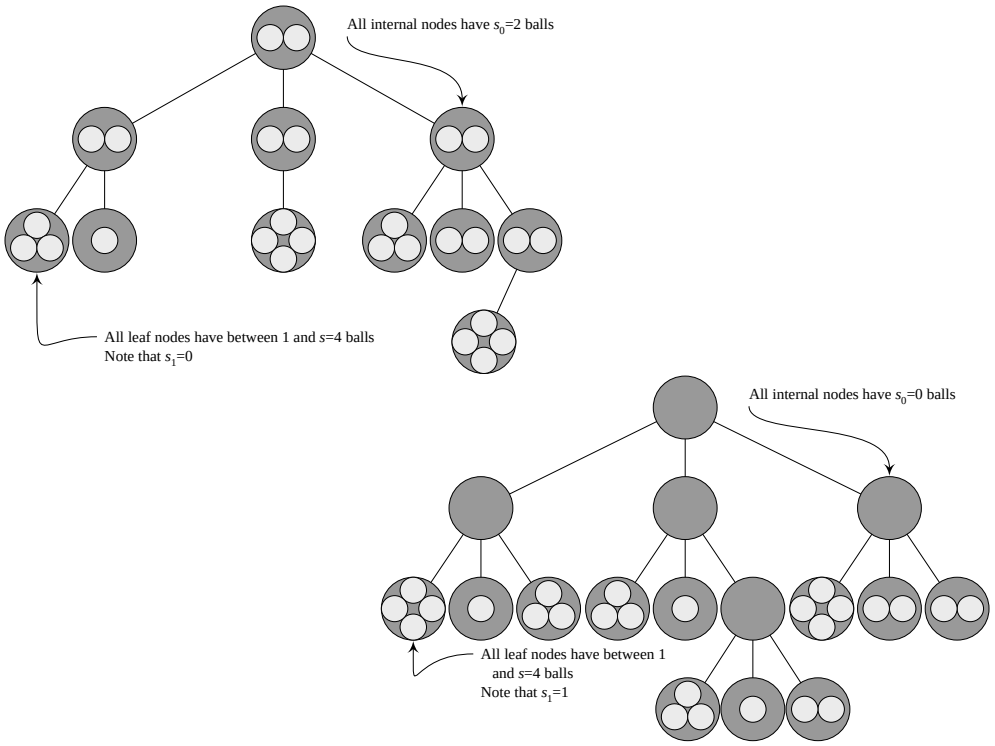

FIG. 1. *A* random trimmed split tree *with parameters b, s, s_0, s_1, $\mathcal{V}$, and n is a random split tree with parameters b, s, s_0, s_1, $\mathcal{V}$, and n from which we eliminate all useless nodes. Note that there is in general no simple relationship between the number of vertices and the number of balls (or points). The ball distribution method described above has several advantages, first and foremost among them the direct relationship with several species of trees that occur as natural data structures. The parameters s, s_0, s_1 add sufficient flexibility. We will see that all trees with fixed finite values of these parameters have the same asymptotic behavior for various shape parameters. When we refer to a random split tree, it is understood that we mean a random trimmed split tree.*

B. If u is a leaf but $C(u) = N(u) < s$ (where s is the capacity of a vertex introduced in the previous paragraph), then add the ball to u and stop. $C(u)$ and $N(u)$ are both incremented by 1.

C. If u is a leaf but $C(u) = N(u) = s$, there is no room for the ball at u. In that case, we set $N(u) = s+1$ and $C(u) = s_0$. We place $s_0 \le s$ randomly selected balls at u, and send $s + 1 - s_0$ balls down to the children of u. This is done as follows. We first give s_1 randomly selected balls to each child and adjust the ball counts for the children. The remaining $s + 1 - s_0 - bs_1$ balls are sent down by choosing a child for each ball independently, according to the probability vector $(V_1, \ldots, V_b)$, and applying the procedure "add a ball" to the tree rooted at the selected child. Note that this may have to be repeated several times if $s_0 = 0$, but only once if $s_0 > 0$ (because no child will reach the capacity s).

Note that every nonleaf node has $C(u) = s_0$ and every leaf has $0 < C(u) \le s$. Two split trees, one with $(s, s_0, s_1) = (4, 2, 0)$ and the other with $(s, s_0, s_1) = (4, 0, 1)$, are shown below.

The depth of a vertex is its distance from the root. The height of a tree is the

maximal depth of any of the leaves. When the $(n+1)$st ball is added to a random split tree of cardinality n (that is, a tree holding n balls), the depth of the vertex reached by the ball is denoted by D_{n+1}. If the leaf is split, the ball ends up, if $s_0 > 0$, at depth D_{n+1} or $D_{n+1}+1$, depending upon which ball we choose to follow in the splitting process. It is therefore convenient to study D_n.

Interestingly, the following property is valid for a tree with n balls rooted at u: if $n \le s$, all balls are in the root node, which is a leaf; if $n > s$, there are s_0 balls in the root node, and the cardinalities $(N_1, \ldots, N_b)$ of the b subtrees of the root are distributed as $(s_1, \ldots, s_1)$ plus a multinomial $(n - s_0 - bs_1, V_1, \ldots, V_b)$ random vector, where $(V_1, \ldots, V_b)$ is associated with u. This property is repeated recursively at every node. Roughly speaking, the subtrees rooted at the children have cardinalities close to $nV_1, \ldots nV_b$.

The behavior of several other parameters is easily deduced from that of D_n. For example, let D'_n be the average depth, i.e., the sum of the depths of the n balls divided by n. The incremental growing process described above shows that, if $s_0 > 0$,

$$\frac{n-an}{n}\mathbf{E}\{D_{an}\} \le \mathbf{E}\{D'_n\} \le \mathbf{E}\{D_n\} + 1$$

for any $a > 0$ such that an is integer. This implies that if $\mathbf{E}\{D_n\} \sim c \log n$ for some constant c, then $\mathbf{E}\{D'_n\} \sim c \log n$. For this reason, we will not investigate D'_n at length.

The purpose of this paper is to point out that within this general setting, the asymptotics—a law of large numbers and a limiting distribution—of D_n are easy to determine. Interestingly, one proof is offered that works for all trees mentioned above.

Throughout this paper, we assume that the components of $(V_1, \ldots, V_b)$ are identically distributed. Note that if they are not, a random permutation $(\sigma_1, \ldots, \sigma_b)$ of $(1, 2, \ldots, b)$ shows that we achieve this goal by taking $(V_{\sigma_1}, \ldots, V_{\sigma_b})$. This random permutation of the children does not affect the depth and height. If V_i has a distribution described by the probability measure μ_i, then the V_{σ_i}'s are identically distributed with common probability measure $(1/b)\sum_j \mu_j$. The latter is called the splitting distribution. A random variable V with the splitting distribution is called a *splitter*. Define $W = V_S$ where, given $(V_1, \ldots, V_b)$, $S = i$ with probability V_i. Observe that $\mathbf{E}V = \mathbf{E}W = 1/b$ in all cases. The law of large numbers and the limit law for D_n depend upon just two parameters,

$$\mu = \mathbf{E}\{\log(1/W)\} = b\mathbf{E}\{V \log(1/V)\}$$

and

$$\sigma^2 = \mathbf{Var}\{\log W\} = b\mathbf{E}\left\{V \log^2 V\right\} - \mu^2.$$

We first state our main results without proof. Then we give a brief discussion of the random trees to which the results apply. The proofs are at the end of the paper.

The main result. For all trees that follow the given model, if H_n denotes the height, that is, the maximal distance between the root and any leaf, we have $H_n = O(\log n)$ in probability. The behavior of H_n is related to that of the moment function

$$m(t) = \mathbf{E}\{V^t\},\ t \ge 0.$$

For later reference, we provide the key properties of this function.

LEMMA 1.

A. *The function m decreases monotonically from $m(0) = 1$ to $\mathbf{P}\{V = 1\}$ as $t \to \infty$.*
B. *m is differentiable for all $t > 0$.*
C. *$\log m$ is convex. In particular, m'/m is increasing on $(0, \infty)$.*
D. *$m(t)^{1/t} \le m(s)^{1/s}$ for $t < s$. Thus, $\log(m(t))/t$ is nondecreasing.*
E. *For $t > 0$, $m'(t) = \mathbf{E}\{V^t \log(V)\}$ and $m''(t) = \mathbf{E}\{V^t \log^2(V)\}$.*
F. *m'/m takes every value between $\mathbf{E}\{\log(V)\}$ (as $t \downarrow 0$) and $\log v_\infty$, where v_∞ is the rightmost point in the support of V.*
G. *The solution of the equation $m'(t)/m(t) = -1/c$ is called $t^* = t^*(c)$. Then t^* is a monotonically increasing function of c, and a solution exists when*

$$-\frac{1}{\mathbf{E}\{\log(V)\}} < c < -\frac{1}{\log v_\infty}.$$

H. *$t^*/c + \log m(t^*)$ decreases in c (or t^*). The value of $t^*/c + \log m(t^*)$ changes from 0 (at $t^* = 0$) to R (possibly $-\infty$) as $t^* \to \infty$, where $R = \lim_{t\to\infty}(\log m(t) - t\, m'(t)/m(t))$.*

THEOREM 1. *Let V be a splitter for a random split tree. Assume that $\mathbf{P}\{V = 1\} = 0$. Then there exists a finite constant c such that*

$$\lim_{n\to\infty} \mathbf{P}\{H_n > c \log n\} = 0.$$

If, additionally, $R < -\log b$, where

$$R = \lim_{t\to\infty} (\log m(t) - t\, m'(t)/m(t)),$$

then the same is true for all $c > \gamma$ and $\gamma \in (0, \infty)$ is a parameter only depending upon b and the distribution of V, and is defined by

$$\gamma = \inf\{c : e^{t^*}(b m(t^*))^c < 1\} = \inf\{c : t^*/c + \log(m(t^*)) < -\log b\},$$

where t^* is the unique solution of $m'(t)/m(t) = -1/c$. (See Lemma 1 below.)

We note that under the conditions of Theorem 1, $H_n/\log n \to \gamma$ in probability. The lower bound that goes with the upper bound of Theorem 1 can be obtained by various methods, and its straightforward proof is not included here (as we focus mainly on depths in this paper). Galton–Watson processes (see Athreya and Ney, 1972) may be used directly (Devroye, 1987). One may also use extrema in branching random walks as exhibited in Devroye (1986b) (see Biggins (1976, 1977), Hammersley (1974), and Kingman (1973) for branching random walks, and see Mahmoud (1992) for further applications). Pittel (1994) points out how one may use the Crump–Mode process in this respect.

THEOREM 2. *Let D_n be the depth of the last node in a random split tree with n nodes and splitter V. If $\mu \neq 0$ and $\mathbf{P}\{V = 1\} = 0$, then*

$$\frac{D_n}{\log n} \to \frac{1}{\mu}$$

and $\mathbf{E}\{D_n\}/\log n$ tends to the same limit. Furthermore, if $\sigma > 0$, then

$$\frac{D_n - (\log n)/\mu}{\sqrt{\sigma^2(\log n)/\mu^3}} \xrightarrow{\mathcal{L}} \mathcal{N}(0, 1),$$

where $\mathcal{N}(0,1)$ *denotes the normal distribution and* $\xrightarrow{\mathcal{L}}$ *denotes convergence in distribution.*

The law of large numbers for D_n does not apply when $\mathbf{E}\{V \log V\} = 0$, i.e., when $\mathbf{P}\{V \in \{0,1\}\} = 1$. This degenerate case is excluded from further consideration. It suffices that V has a density (as in many examples that follow below). For the limit law, we need in addition $\mathbf{Var}\{\log W\} > 0$. This is equivalent to asking that V not be monoatomic. Of all the examples below, only special cases of tries—the symmetric tries and symmetric digital search trees—have a monoatomic splitter V ($V \equiv 1/b$). All other examples satisfy the latter condition.

Some properties of the beta distribution. The beta distribution plays an important role in many important random split trees. We summarize some key properties. Define the beta (a,b) density

$$f(x) = \frac{x^{a-1}(1-x)^{b-1}}{B(a,b)},\ 0 < x < 1,$$

where $a, b > 0$ are parameters and $B(a,b) = \Gamma(a)\Gamma(b)/\Gamma(a+b)$.

LEMMA 2. *If* X *is a beta* (a,b) *random variable, then*

$$\mathbf{E}\{\log(1/X)\} = \psi(a+b) - \psi(a),$$

where $\psi(u) = \Gamma'(u)/\Gamma(u)$ *is the derivative of* $\log\Gamma$ *at* u *(also called the digamma function). Furthermore,*

$$\mathbf{E}\{X \log(1/X)\} = \frac{a}{a+b}(\psi(a+1+b) - \psi(a+1)).$$

Let ψ'*—the trigamma function—be the derivative of* ψ*. Then*

$$\mathbf{E}\{\log^2(X)\} = (\psi(a+b) - \psi(a))^2 + \psi'(a) - \psi'(a+b).$$

Finally,

$$\mathbf{E}\{X \log^2(X)\} = \frac{a}{a+b}\left(\psi(a+1+b) - \psi(a+1)\right)^2 + \frac{a}{a+b}\left(\psi'(a+1) - \psi'(a+1+b)\right).$$

For integrals such as those dealt with in Lemma 2, we refer to Sibuya (1979) or Gradshteyn and Ryzhik (1980, pp. 538, 541). We recall that the digamma function basically behaves like the harmonic numbers (Abramowitz and Stegun, 1970, pp. 258–259): if γ is Euler's constant,

$$\psi(n) = -\gamma + \sum_{k=1}^{n-1} \frac{1}{k} \quad (n \geq 2),\ \psi(1) = -\gamma;$$

$$\psi(z+1) = \psi(z) + \frac{1}{z} = -\gamma + \sum_{n=1}^{\infty} \frac{z}{n(n+z)},\ z > -1.$$

For the trigamma function, we have

$$\psi'(z) = \sum_{n=0}^{\infty} \frac{1}{(z+n)^2}.$$

Also, $\psi'(z) = \psi'(z-1) - 1/(z-1)^2$, and $\psi'(1) = \pi^2/6$.

TABLE 1

Examples: An overview. In Table 1, we list a number of important special cases of random split trees. In this table, $U, U_1, U_2, \ldots$ are independently and identically distributed (i.i.d.) uniform $[0,1]$ random variables. Recall that s is the capacity of a node before it is split, s_0 is the number of balls left in a node after a split, s_1 is the minimum number of balls sent to any subtree, and b is the branch factor.

Table 1 shows that a large variety of trees may be dealt with in one sweep. The fixed parameters s, s_0, and s_1 are irrelevant for first term asymptotics and the law of large numbers for depths and heights. Only the distribution of the splitter V matters.

Nonetheless, many trees cannot be molded into our framework, such as all trees whose depth does not grow logarithmically with n. For example, it is well known that the uniform random binary tree has average depth and height of the order of $\sqrt{n}$ (Flajolet and Odlyzko, 1982; Vitter and Flajolet, 1990). Interestingly, Aldous (1993) has introduced a model that includes many (but not all) of the trees in Table 1 and the uniform random trees, as well as a continuum of trees that link them. Our work was inspired for a great deal by Aldous's paper.

The parameters μ and σ^2 are computed for the trees mentioned above. Most of the limit laws and laws of large numbers are known, but the unified approach of this paper explains things in a stronger way. More details are provided in the nine subsequent subsections, in which each tree is briefly discussed separately. The symbols $\mathcal{H}$ and $\mathcal{H}_2$ are properly defined in the section on tries.

Example 1: *The random binary search tree.* In a random binary search tree with n nodes, the following operation is applied independently and recursively: a random node is chosen from the n nodes at hand, and it is made the root. The nodes with a smaller label travel to the left subtree of the root, and the others, to the right subtree. The size of the left subtree is distributed as $\lfloor nU \rfloor$, where U is uniform $[0,1]$. The size of the right subtree has a similar distribution. Equivalently, attach to each of the balls an independent copy of a uniform $[0,1]$ random variable, to get $U_1, U_2, \ldots, U_n$. Put U_1 in the root and partition the others into left and right subsets by comparison with U_1. Repeating the splitting process at each node creates a random split tree. In a third equivalent representation, that of the random split tree, we may associate with

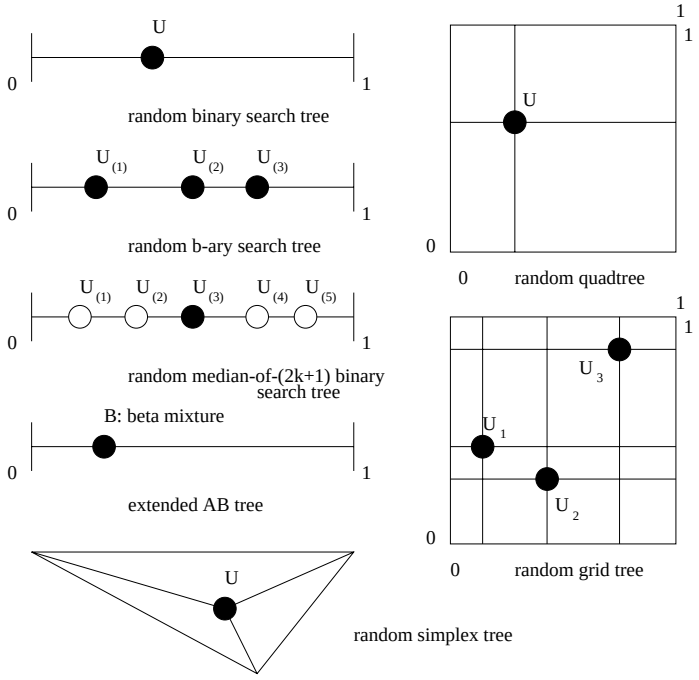

FIG. 2. *Various ways of splitting spaces are shown. All splits are applied recursively. U refers to the uniform distribution, and B, to a mixture of beta distributions.*

TABLE 2

Tree	σ^2	$1/\mu$ (limit of $D_n/\log n$)
Random binary search tree	$1/4$	2
Random b-ary search tree	$\sum_{i=2}^{b} \frac{1}{i^2}$	$\frac{1}{\sum_{i=2}^{b} \frac{1}{i}}$
Random quadtree	$d^2/4$	$2/d$
Random median-of-$(2k+1)$ binary search tree	$\sum_{j=k+2}^{2k+2} \frac{1}{j^2}$	$\frac{1}{\sum_{i=k+2}^{2k+2} \frac{1}{i}}$
Random simplex tree	$\sum_{i=2}^{d+1} \frac{1}{i^2}$	$\frac{1}{\sum_{i=2}^{d+1} \frac{1}{i}}$
AB tree	$\frac{(\psi(2a+1)-\psi(a+1))^2}{+(\psi'(a+1)-\psi'(2a+1))}$	$=\frac{\frac{1}{\psi(2a+1)-\psi(a+1)}}{\sum_{n=1}^{\infty} \frac{a}{(n+a+1)(n+2a+1)}}$
Extended AB tree	$\frac{a}{a+b}(\psi(a+1+b)-\psi(a+1))^2$ $+\frac{a}{a+b}(\psi'(a+1)-\psi'(a+1+b))$ $+\frac{b}{a+b}(\psi(a+1+b)-\psi(b+1))^2$ $+\frac{b}{a+b}(\psi'(b+1)-\psi'(a+1+b))$	$\frac{a+b}{\frac{a(\psi(a+1+b)-\psi(a+1))}{+b(\psi(a+1+b)-\psi(b+1))}}$
b-ary trie	$\mathcal{H}_2-\mathcal{H}^2$	$1/\mathcal{H}$
b-ary digital search tree	$\mathcal{H}_2-\mathcal{H}^2$	$1/\mathcal{H}$
Random m-grid tree	$d\sum_{j=2}^{m+1} \frac{1}{j^2} + d(d-1)\left(\sum_{j=2}^{m+1} \frac{1}{j}\right)^2$	$\frac{1}{d\sum_{i=2}^{m+1} \frac{1}{i}}$

each node an independent random split vector (V_1, V_2) distributed as $(U_1, 1-U_1)$.

It is known that $D_n/\log n \to 2$ in probability (Lynch, 1965; Knuth, 1973; Devroye, 1988). The limit law for D_n was derived by Devroye (1988): $(D_n - 2\log n)/\sqrt{2\log n} \xrightarrow{\mathcal{L}} \mathcal{N}(0,1)$. Robson (1979), Pittel (1984), and Devroye (1986b, 1987) showed that $H_n/\log n \to 4.31107\ldots$ in probability. All of these results are contained in Theorems 1 and 2 as $m(t) = 1/(t+1)$, $\mu = 1/2$, and $\sigma^2 = 1/4$.

An important variant of the binary search tree related to the standard occurs when no balls are stored in internal nodes; so, $s_0 = 0$. This leads to a binary search tree in which all balls are at leaves. This too is a random split tree, and it follows the same limit laws as the ordinary random binary search tree.

Example 2: *The random b-ary search tree.* Let n balls be given and associate with each ball an independent uniform $[0,1]$ random variable. In a random b-ary search tree with n nodes, the following operation is applied independently and recursively: $b-1$ random balls are chosen from the n balls at hand and are associated with the root. The other balls, if there are any, are partitioned into b sets by membership in the intervals induced by the $b-1$ balls. If $(N_1, \ldots, N_b)$ are the number of balls in the intervals (with $\sum_i N_i = n - b + 1$, of course), then this vector is multinomial $(n-b+1, V_1, \ldots, V_b)$, where the V_i's are the lengths of the intervals (or spacings; see Pyke (1965)). The split vector of V_i's is thus distributed as the collection of b spacings induced by $b-1$ i.i.d. uniform $[0,1]$ random variables on $[0,1]$. In particular, $V = V_1$ is distributed as a beta $(1, b-1)$ random variable.

We easily compute $\mu = \sum_{i=2}^{b} 1/i$ and $\sigma^2 = \sum_{i=2}^{b} 1/i^2$. This yields

$$\frac{D_n}{\log n} \to \frac{1}{\sum_{i=2}^{b} \frac{1}{i}} \quad \text{in probability}$$

(a result of Mahmoud and Pittel (1984)) and

$$\frac{D_n - (1/\mu)\log n}{\sqrt{(\sigma^2/\mu^3)\log n}} \xrightarrow{\mathcal{L}} \mathcal{N}(0,1).$$

As an example, if $b = 3$, $\mu = 5/6$, $\sigma^2 = 78/125$, and

$$\frac{D_n - (6/5)\log n}{\sqrt{(78/125)\log n}} \xrightarrow{\mathcal{L}} \mathcal{N}(0,1).$$

We also know that $H_n/\log n \to c$ in probability for a function c of b given in Devroye (1990) and indicated in Theorem 1.

Example 3: *The random quadtree.* The point quadtree in R^d (Finkel and Bentley, 1974; see Samet (1990b) for a survey) generalizes the binary search tree. One ball is put in each node of a tree with branch factor 2^d; each ball has associated with it a d-vector for the point it represents; each subtree of a node corresponds to one of the quadrants formed by considering the ball's d-vector as the new origin. Insertion into point quadtrees is as for binary search trees.

We assume that a random quadtree is constructed on the basis of an i.i.d. sequence drawn from the uniform distribution on $[0,1]^d$. In that case, it is convenient to index the split vector by a bit sequence of length d: $(b_1 \ldots b_d)$. The vector $(V_{00\ldots00}, \ldots, V_{11\ldots11})$ has components that may be written as

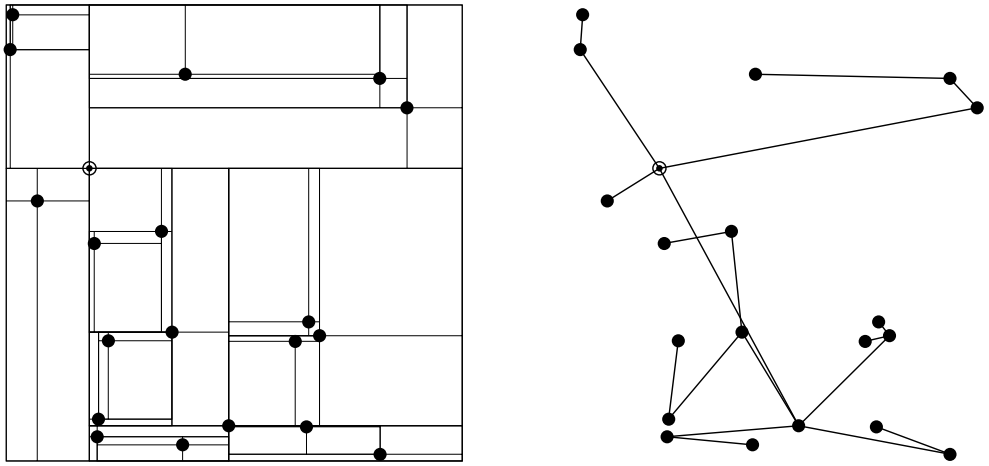

FIG. 3. *At the left, a partition of the plane by a random quadtree is shown. The circled point is the root. It partitions the space into four quadrants, and the splitting rule is recursively applied to each quadrant. At the right, the same points are shown together with the edges in the quadtree.*

$$V_{(b_1 \ldots b_d)} = \prod_{j=1}^{d} U_j^{b_j} (1 - U_j)^{1-b_j},$$

where $(U_1, \ldots, U_d)$ is the point in the node where the split takes place.

The height H_n of a random quadtree is in probability asymptotic to $(c/d) \log n$, where $c = 4.31107\ldots$ is the constant in the height of the random binary search tree (Devroye, 1987). This also follows from Theorem 1 as $m(t) = \mathbf{E}\{V^t\} = 1/(t+1)^d$. Write $V = V_{11\ldots11} = \prod_{j=1}^{d} U_j$. Then it takes just a moment to verify that

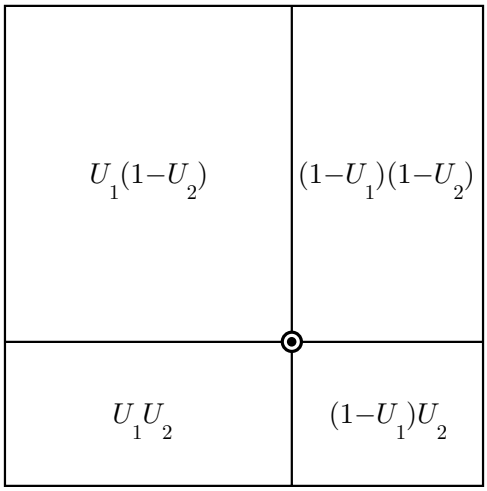

FIG. 4. *The split induced by the root of the quadtree is shown. The random variables U_1, U_2 are i.i.d. uniform $[0,1]$. The areas of the four rectangles are all distributed like products of two independent uniform $[0,1]$ random variables.*

$$\begin{aligned}\mu &= \mathbf{E}\{\log W\} = 2^d \mathbf{E}\{V \log(1/V)\} \\ &= 2^d \sum_{j=1}^{d} \mathbf{E}\left\{\prod_{k=1}^{d} U_k \log(1/U_j)\right\} \\ &= 2^d d\, \mathbf{E}\left\{\prod_{k=2}^{d} U_k\right\} \mathbf{E}\left\{U_1 \log(1/U_1)\right\} \\ &= 2d\, \mathbf{E}\left\{U_1 \log(1/U_1)\right\} \\ &= \frac{d}{2}.\end{aligned}$$

From this, we see that

$$\frac{D_n}{\log n} \to \frac{2}{d} \quad \text{in probability,}$$

a result first noted by Devroye and Laforest (1990). See also Flajolet et al. (1991). The computations of the variance are a bit more tedious. We have

$$\begin{aligned}\sigma^2 + \mu^2 &= 2^d \mathbf{E}\{V \log^2(1/V)\} \\ &= 2^d \mathbf{E}\left\{\prod_{k=1}^{d} U_k \left(\sum_{j=1}^{d} \log(1/U_j)\right)^2\right\} \\ &= 2^d d\, \mathbf{E}\left\{\prod_{k=2}^{d} U_k\right\} \mathbf{E}\left\{U_1 \log^2(1/U_1)\right\} \\ &\quad + 2^d\, d(d-1) \mathbf{E}\left\{\prod_{k=3}^{d} U_k\right\} \mathbf{E}^2\left\{U_1 \log(1/U_1)\right\} \\ &= 2d\, \mathbf{E}\left\{U_1 \log^2(1/U_1)\right\} + 4d(d-1)\mathbf{E}^2\left\{U_1 \log(1/U_1)\right\} \\ &= \frac{d^2}{4} + \frac{d}{4}.\end{aligned}$$

Hence, $\sigma^2 = d/4$. This yields the limit law

$$\frac{D_n - (2/d)\log n}{\sqrt{(2/d^2)\log n}} \xrightarrow{\mathcal{L}} \mathcal{N}(0,1),$$

valid for any $d \geq 1$. This result was obtained via complex analysis by Flajolet and Lafforgue (1994).

Example 4: *The random median-of-*$(2k+1)$ *binary search tree.* Bell (1965) and Walker and Wood (1976) introduced the following method for constructing a binary search tree. Take $2k+1$ points at random from the set of n points on which a total order is defined, where k is integer. The median of these points serves as the root of a binary tree. The remaining points are thrown back into the collection of points and are sent to the subtrees. Following Poblete and Munro (1985), we may look at this tree by considering internal nodes and external nodes, where internal nodes hold one data point and external nodes are bags of capacity $2k$. Insertion proceeds as usual.

As soon as an external node overflows (i.e., when it would grow to size $2k+1$), its bag is split about the median, leaving two new external nodes (bags) of size k each and an internal node holding the median. After the insertion process is completed, we may wish to expand the bags into balanced trees. Using the branching process method of proof (Devroye, 1986b, 1987, 1990; see also Mahmoud, 1992) the almost sure limit of $H_n/\log n$ for all k may be obtained (Devroye, 1993). For another possible proof method, see Pittel (1992). The depth D_n of the last node when the fringe heuristic is used has been studied by the theory of Markov processes or urn models in a series of papers, notably by Poblete and Munro (1985) and Aldous, Flannery, and Palacios (1988). See also Gonnet and Baeza-Yates (1991, p. 109). Poblete and Munro (1985) showed that

$$\frac{D_n}{\log n} \to \frac{1}{\sum_{i=k+2}^{2k+2} \frac{1}{i}}$$

in probability. It should be clear by now that this tree is a random split tree with $s = 2k$, $s_0 = 1$, $s_1 = k$, $b = 2$ and split vector (V_1, V_2) distributed as $(B, 1-B)$, where B is beta $(k+1, k+1)$. That is, B is distributed as the median of $2k+1$ i.i.d. uniform $[0,1]$ random variables. This representation is obtained by associating with each point in the data an independent uniform $[0,1]$ random variable. Clearly,

$$\mu = \sum_{i=k+2}^{2k+2} \frac{1}{i}.$$

Also, if X is beta (a,a) and a is integer-valued, Lemma 2 and the properties of the digamma and trigamma functions imply

$$\begin{aligned}\mathbf{E}\{X\log^2(X)\} &= \frac{1}{2}\left(\psi(2a+1)-\psi(a+1)\right)^2 + \frac{1}{2}\left(\psi'(a+1)-\psi'(2a+1)\right)\\ &= \frac{1}{2}\left(\left(\sum_{j=a+1}^{2a}\frac{1}{j}\right)^2 + \sum_{j=a+1}^{2a}\frac{1}{j^2}\right).\end{aligned}$$

Thus,

$$\sigma^2 = \sum_{j=k+2}^{2k+2}\frac{1}{j^2}.$$

Therefore, we obtain a limit law for all k. As an example, for $k=1$, we obtain $\mu = 1/3 + 1/4 = 7/12$, $\sigma^2 = 1/9 + 1/16 = 25/144$, and thus

$$\frac{D_n - (12/7)\log n}{\sqrt{(300/343)\log n}} \xrightarrow{\mathcal{L}} \mathcal{N}(0,1).$$

We rediscover results for the number of comparisons C_n for median-of-$(2k+1)$ quicksort. As $\mathbf{E}C_n = \mathbf{E}\{nD_n\}$, where D_n is the depth of the nth point when inserted in a median-of-$(2k+1)$ binary search tree holding $n-1$ points. From the above results,

$$\lim_{n\to\infty}\frac{\mathbf{E}C_n}{n\log n} = \frac{1}{\frac{1}{k+2}+\frac{1}{k+3}+\cdots+\frac{1}{2k+2}}.$$

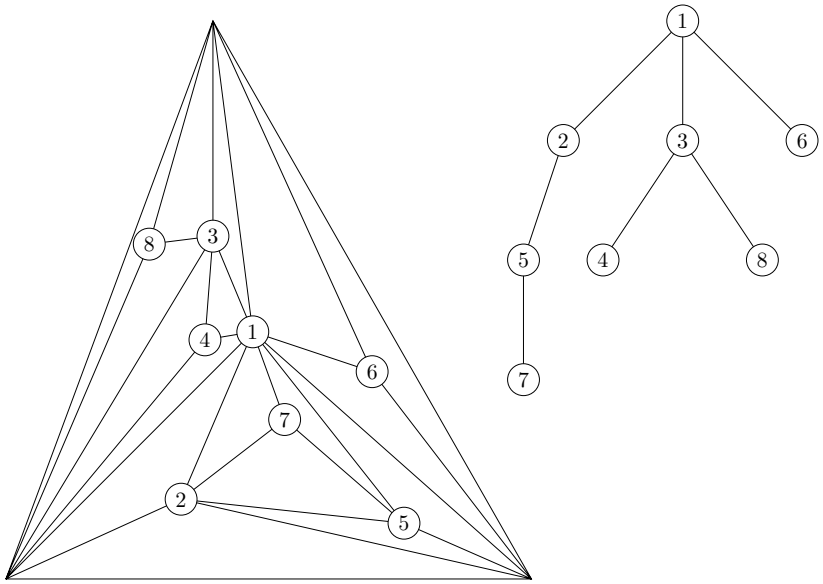

FIG. 5. *A triangle is triangulated by a cloud of random points. The corresponding ternary tree is shown on the right.*

Thus, for median-of-5 quicksort, as $60/47n \log n$, the expected number of comparisons grows. By generating function methodology (Vitter and Flajolet, 1990; Kemp, 1984; Sedgewick, 1983) or via urn models (Aldous, Flannery, and Palacios, 1988), results of this nature are harder to obtain. However, our method does not allow one to compute anything but the main asymptotic term in $\mathbf{E}C_n$.

Example 5: *Random simplex trees.* Triangulating polygons and objects in the plane is an important problem in computational geometry. An $O(n \log n)$ algorithm for triangulating n points was found by Avis and El Gindy (1987). Arkin et al. (1994) obtained a simple fast $O(n \log n)$ expected time algorithm for triangulating any collection of n planar points in general position. We look more specifically at their triangulation and its d-dimensional extension to simplices, and ask what the tree generated by this partitioning looks like if the points are uniformly distributed in the unit simplex. Given are n vectors $X_1, \ldots, X_n$ taking values in a fixed simplex S of $\mathbb{R}^d$. It is assumed that this is an i.i.d. sequence with a uniform distribution on S for the purposes of analysis. X_1 is associated with the root of a $d+1$-ary tree. It splits S into $d+1$ new simplices by connecting X_1 with the $d+1$ vertices of S. Associate with each of these simplices the subset of $X_2, \ldots, X_n$ consisting of those points that fall in the simplex. Each nonempty subset is sent to a child of the root, and the splitting is applied recursively to each child. As every split takes linear time in the number of points processed, it is clear that the expected time is proportional to $n\mathbf{E}D_n$, where D_n is the expected depth of a random node in the tree. The partition consists of $dn+1$ simplices, each associated with an external node of the tree. There are precisely n nodes in the tree and each node contains one point.

If $|S|$ denotes the size of a simplex S, then the following crucial property is valid.

LEMMA 3. *If simplex S is split into $d+1$ simplices $S_1, \ldots, S_{d+1}$ by a point X distributed uniformly in S, then $(|S_1|, \ldots, |S_{d+1}|)$ is jointly distributed as $(|S|V_1, \ldots,$*

$|S|V_{d+1})$, *where* $V_1, \ldots, V_{d+1}$ *are the spacings of* $[0,1]$ *induced by* d *i.i.d. uniform* $[0,1]$ *random variables.*

Proof. It is known that X is distributed as $\sum_{i=1}^{d+1} V_i t_i$, where $t_1, \ldots, t_{d+1}$ are the vertices of S (see Rubinstein (1982), Smith (1984), or Devroye (1986a)). But for a simplex S, we know that

$$|S| = \frac{1}{d!} \det \begin{pmatrix} t_1 & t_2 & t_3 & \cdots & t_{d+1} \\ 1 & 1 & 1 & \cdots & 1 \end{pmatrix}.$$

Apply this formula to S_1 by replacing t_1 by X:

$$\begin{aligned} |S_1| &= \frac{1}{d!} \det \begin{pmatrix} X & t_2 & t_3 & \cdots & t_{d+1} \\ 1 & 1 & 1 & \cdots & 1 \end{pmatrix} \\ &= \frac{1}{d!} \det \begin{pmatrix} \sum_i V_i t_i & t_2 & t_3 & \cdots & t_{d+1} \\ \sum_i V_i & 1 & 1 & \cdots & 1 \end{pmatrix} \\ &= \frac{V_1}{d!} \det \begin{pmatrix} t_1 & t_2 & t_3 & \cdots & t_{d+1} \\ 1 & 1 & 1 & \cdots & 1 \end{pmatrix} \\ &= V_1 |S|. \end{aligned}$$

The statement then follows trivially. □

It is immediate that the random simplex tree is a random split tree with split vector distributed as the spacings defined by d i.i.d. uniform $[0,1]$ random variables on $[0,1]$, $s_0 = 1$, $s = 1$, $s_1 = 0$, and $b = d+1$. Therefore, by Theorem 2, D_n behaves precisely as for the random d+1-ary tree discussed earlier. Thus, $\mu = \sum_{i=2}^{d+1} 1/i$ and $\sigma^2 = \sum_{i=2}^{d+1} 1/i^2$. This yields

$$\frac{D_n}{\log n} \to \frac{1}{\sum_{i=2}^{d+1} \frac{1}{i}} \quad \text{in probability}$$

and

$$\frac{D_n - (1/\mu)\log n}{\sqrt{(\sigma^2/\mu^3)\log n}} \xrightarrow{\mathcal{L}} \mathcal{N}(0,1).$$

As an example, if $d = 2$, then $\mu = 5/6$, $\sigma^2 = 78/125$, and

$$\frac{D_n - (6/5)\log n}{\sqrt{(78/125)\log n}} \xrightarrow{\mathcal{L}} \mathcal{N}(0,1).$$

For $d = 3$, $\mu = 1/2 + 1/3 + 1/4 = 13/12$. Thus, $D_n/\log n \to 12/13$ in probability. We also know that $H_n/\log n \to c$ in probability for a function c of d that may be computed via the recipe described in Theorem 1.

Example 6: *Extended AB trees and simulation.* When generating random trees that resemble botanical trees, a number of mathematical models have been proposed. We refer to Viennot's survey (1990) or the book by Prusinkiewicz and Lindenmayer (1990) for further references. Stripped from geometrical considerations, most trees are binary. The main parameter one needs to control is the height of the tree as a function of the number of nodes. Alternately, one may wish to control the average distance from a node to the root. For this, it is necessary to have a family of random trees in which these parameters can take any large value. In the context of this paper,

if we had a family of splitting trees—a continuum of trees, really—with parameter α and for which $D_n/\log n \to c(\alpha)$ in probability, we would be saved if the domain of values of $c(\alpha)$ would be $(\log 2, \infty)$ as α varies over a given range.

In 1993, Aldous introduced a family of random split trees with $s = 1$, $s_1 = 0$, and $s_0 = 0$. With this set-up, all balls are put in leaves, and internal nodes have no balls. Aldous splits with the aid of $(V, 1-V)$, where V is beta (a, a) for some parameter $a > 0$. By varying a and even extending it beyond its natural range, Aldous creates a one-parameter family that may be used to model certain splitting processes in biology. He also studies the depths of nodes in these trees and obtains laws of large numbers for their heights. We define an AB tree (for *Aldous beta*) in a similar fashion but take $s_0 = s = 1$ and $s_1 = 0$. This change is only cosmetic, as it will not affect any asymptotic result. For $a = 1$, we obtain the random binary search tree. As $a \downarrow 0$, the tree becomes more elongated, and the amount of stretching may be controlled by a. As $a \to \infty$, every split is nearly 50-50, and the height of the tree is in probability asymptotic to $\log_2 n$. The laws of large numbers for depths and heights are essentially those obtained by Aldous for his model.

We feel that a lot is gained by considering two-parameter families for modeling biological phenomena and simulating botanical trees. This may be achieved by extending the AB trees and taking B as an equal mixture of a beta (a, b) and a beta (b, a) density. The splitter V remains symmetric, but as a and b diverge so that $a/(a+b) \to p \in (0, 1)$, we see that in the limit V is p or $1-p$ with equal probability. This creates trees of height about $\log_{1/\min(p,1-p)} n$. The AB trees are obtained at $b = a$. We call this versatile family of trees extended AB trees. We will report on the drawing of realistic-looking trees via extended AB trees elsewhere.

From Lemma 2, the parameters are easily obtained:

$$\mu = \frac{a(\psi(a+1+b) - \psi(a+1)) + b(\psi(a+1+b) - \psi(b+1))}{a+b},$$

and

$$\sigma^2 = \frac{a}{a+b}\left(\psi(a+1+b) - \psi(a+1)\right)^2 + \frac{a}{a+b}\left(\psi'(a+1) - \psi'(a+1+b)\right) + \frac{b}{a+b}\left(\psi(a+1+b) - \psi(b+1)\right)^2 + \frac{b}{a+b}\left(\psi'(b+1) - \psi'(a+1+b)\right).$$

If we set $b = 1$ and a is integer, the limit for $\mathbf{E}D_n/\log n$ is

$$\frac{a+1}{\sum_{i=1}^{a} \frac{1}{i}}.$$

This grows unbounded like $a/\log a$ as $a \to \infty$. As $a \downarrow 0$, the limit is $(a+1)/(a/(a+1) + \psi(a+2) - 1) \sim 1/a$. This grows unbounded as well. In the AB trees, we have $a = b$, and thus,

$$\frac{D_n}{\log n} \to \frac{1}{\psi(2a+1) - \psi(a+1)} = \frac{1}{\sum_{n=1}^{\infty} \frac{a}{(n+a+1)(n+2a+1)}}.$$

This result matches that of Aldous (1993), where the limit is written as an integral. It is easy to verify that as $a \downarrow 0$, the limit is asymptotic to $1/(a(\pi^2/6 - 1))$. At $a = 1$, we have a limit of 2 as in the random binary search tree. As $a \to \infty$, the limit approaches $1/\log 2$, and the splits because nearly all perfectly balanced. The variance is given by

$$\sigma^2 = \left(\psi(2a+1) - \psi(a+1)\right)^2 + \left(\psi'(a+1) - \psi'(2a+1)\right).$$

Finally, consider extended AB trees in which as $a, b \to \infty$, $a = p(a+b)$ with $p \in (0,1)$ fixed. The limit then behaves as

$$\frac{1}{-p\log p - (1-p)\log(1-p)} = \frac{1}{\mathcal{H}(p)},$$

where $\mathcal{H}(p)$ is the entropy of a Bernoulli (p) random variable. Here we rediscover a known property of the entropy $\mathcal{H} = -\sum_i p_i \log(p_i)$ of a discrete distribution $(p_1, p_2, \ldots)$: split a set of size n into subsets of sizes close to $np_1, np_2, np_3, \ldots$. Associate each subset with a child of the root and repeat this process until no further splitting is possible (note that there is no randomness involved in this splitting). If one grabs a random node in the resulting tree, its depth is in probability equal to $(1/\mathcal{H})\log n$. This is exactly like the behavior of random nodes in tries (Fredkin, 1960) in which the symbols have probabilities $p_1, p_2, p_3, \ldots$; see Pittel (1985, 1986) and Szpankowski (1988) and the next section.

Example 7: *Tries and digital search trees.* Tries are b-ary trees for storing infinite strings. Assume that the data consists of n infinite strings of $\{1, \ldots, b\}$-valued symbols, called $X_1, \ldots, X_n$. Each string carves out an infinite path in the infinite complete b-ary tree. For a node u, let $N(u)$ denote the number of strings that pass through node u. Now, eliminate all nodes with $N(u) = 0$ and eliminate all those with $N(u) = 1$ whose parent also has $N(u) = 1$. The resulting tree has n leaves with $N(u) = 1$, and every nonleaf v has $N(v) > 1$. Invented in 1960 by Fredkin, this structure is called a trie. Assume that all the symbols are drawn independently, and that each symbol takes the value i with probability p_i. Define the entropy $\mathcal{H}$ by

$$\mathcal{H} = -\sum_{i=1}^{b} p_i \log p_i,$$

and the second-order entropy by

$$\mathcal{H}_2 = \sum_{i=1}^{b} p_i \log^2 p_i.$$

The trie may be viewed as a random split tree with $s = 1$, $s_0 = s_1 = 0$, in which a node u at which $N(u) = n$ is not split if $n = 1$, and in which a split occurs when $n > 1$; in the latter case, the sizes of the subtrees are distributed jointly as a multinomial $(n, p_1, \ldots, p_b)$ random variable. If V is p_S, where S is uniformly distributed on $\{1, 2, \ldots, b\}$, then

$$b\mathbf{E}\{V \log(1/V)\} = \mathcal{H}.$$

Therefore, from Theorem 2,

$$\frac{D_n}{\log n} \to \frac{1}{\mathcal{H}}.$$

Also,

$$\frac{D_n - \log n/\mathcal{H}}{\sqrt{(\mathcal{H}_2 - \mathcal{H}^2)\log n/\mathcal{H}^3}} \xrightarrow{\mathcal{L}} \mathcal{N}(0,1).$$

The law of large numbers is due to Pittel (1985). The limit law was discovered independently by Jacquet and Régnier (1986) and Pittel (1986). See Szpankowski

(1988) for additional results and references. Our result unifies the analysis of tries and binary search trees. The normal limit law as stated above is not valid if $\mathcal{H}_2 = \mathcal{H}^2$. This occurs if and only if $p_1 = p_2 = \cdots = p_b = 1/b$. In the random split tree, this situation corresponds to a monoatomic distribution for the splitter ($V \equiv 1/b$), which has zero variance.

The digital search tree of Coffman and Eve (1970) is like a trie. It is best described by its incremental construction. It has n nodes, one per string. Nodes are added one by one, starting with X_1 and ending with X_n. The node associated with X_n is the first node u in the infinite path of string X_n that has $N(u) = 0$ before X_n is inserted. This is a random split tree in which a node with $N(u) = n$ spawns subtrees when $n > 1$ of sizes that are jointly distributed as a multinomial $(n-1, p_1, \ldots, p_b)$ random variable. The limit laws given above for tries remain valid here, without change. These were known; see Pittel (1985) for the law of large numbers and Pittel (1986) and Louchard (1987) for the normal limit law. Again, when all p_i's are equal, the normal limit law as stated above is not valid. Another proof method is needed to deal with that situation. Also, Theorem 1 only states that for nondegenerate tries and digital search trees, $H_n = O(\log n)$ in probability. Theorem 1 cannot be used to get a finer result. However, the behavior of the height is well known (Pittel, 1985).

Example 8: *The random grid tree.* The quadtree is easily generalized as follows: consider a collection of m $\mathbb{R}^d$-valued points drawn from the data, and partition the space into $(m+1)^d$ hyperrectangles by the d perpendicular hyperplanes centered at each of the m points. In a quadtree, $m = 1$. This generates a tree, the m-grid tree, with fan-out $(m+1)^d$, and with up to m points per node. If the data consist of n independent random vectors uniformly distributed over $\mathbb{R}^d$, the tree thus constructed becomes a random split tree with split vector $(V_1, \ldots, V_b)$ in which each V_i is distributed as $V = \prod_{j=1}^{d} B_j$, and $B_1, \ldots B_d$ are independent beta $(1, m)$ random variables. While not exactly the same, the random grid tree borrows ideas from the celebrated grid file data structure (Nievergelt, Hinterberger, and Sevcik, 1984; Nievergelt and Hinrichs, 1993). We note the following:

$$\begin{aligned}
\mu &= \mathbf{E}\{\log W\} = (m+1)^d \mathbf{E}\{V \log(1/V)\} \\
&= (m+1)^d \sum_{j=1}^{d} \mathbf{E}\left\{ \prod_{k=1}^{d} B_k \log(1/B_j) \right\} \\
&= (m+1)^d d\, \mathbf{E}\left\{ \prod_{k=2}^{d} B_k \right\} \mathbf{E}\left\{ B_1 \log(1/B_1) \right\} \\
&= (m+1) d\, \mathbf{E}\left\{ B_1 \log(1/B_1) \right\} \\
&= d \sum_{j=2}^{m+1} \frac{1}{j}.
\end{aligned}$$

From this, we see that

$$\frac{D_n}{\log n} \to \frac{1}{d \sum_{j=2}^{m+1} \frac{1}{j}} \quad \text{in probability.}$$

Also,

$$\begin{aligned}
\sigma^2+\mu^2 &= (m+1)^d\mathbf{E}\{V\log^2(1/V)\}\\
&= (m+1)^d\mathbf{E}\left\{\prod_{k=1}^{d}B_k\left(\sum_{j=1}^{d}\log(1/B_j)\right)^2\right\}\\
&= (m+1)^d d\,\mathbf{E}\left\{\prod_{k=2}^{d}B_k\right\}\mathbf{E}\left\{B_1\log^2(1/B_1)\right\}\\
&\quad+(m+1)^d\,2d(d-1)\mathbf{E}\left\{\prod_{k=3}^{d}B_k\right\}\mathbf{E}^2\left\{B_1\log(1/B_1)\right\}\\
&= (m+1)d\,\mathbf{E}\left\{B_1\log^2(1/B_1)\right\}+2(m+1)^2d(d-1)\mathbf{E}^2\left\{B_1\log(1/B_1)\right\}\\
&= d\sum_{j=2}^{m+1}\frac{1}{j^2}+d\left(\sum_{j=2}^{m+1}\frac{1}{j}\right)^2+2d(d-1)\left(\sum_{j=2}^{m+1}\frac{1}{j}\right)^2.
\end{aligned}$$

Hence,

$$\sigma^2 = d\sum_{j=2}^{m+1}\frac{1}{j^2}+d(d-1)\left(\sum_{j=2}^{m+1}\frac{1}{j}\right)^2.$$

This yields the limit law obtained earlier for the quadtree when $m=1$. For $m=2$, we have

$$\frac{D_n-(6/5d)\log n}{\sqrt{\left(\frac{180d-102}{125d^2}\right)\log n}}\xrightarrow{\mathcal{L}}\mathcal{N}(0,1)$$

for any $d\geq 1$. For $d=1$, this coincides with the result obtained earlier for the random 3-ary search tree.

Proof of Theorem 1: *The height.* We show that $\mathbf{P}\{H_n\geq(c+3\epsilon)\log n\}\to 0$ for all $\epsilon>0$ and $c>\gamma$. Define $\delta=s_1$, $k'=\lfloor\epsilon\log n\rfloor$, and $l=k'(\delta+1)$. If n is the number of balls stored in a random split tree, then the cardinalities of the subtrees at distance k from the root are bounded from above by quantities of the form

$$\begin{aligned}
Z_k &\stackrel{\text{def}}{=} \text{binomial}\left(n,\prod_{i=1}^{k}V^{(i)}\right)+\text{binomial}\left(\delta,\prod_{i=2}^{k}V^{(i)}\right)\\
&\quad+\text{binomial}\left(\delta,\prod_{i=3}^{k}V^{(i)}\right)+\cdots+\text{binomial}\left(\delta,V^{(k)}\right)+\delta\\
&\leq \text{binomial}\left(n,\prod_{i=1}^{k}V^{(i)}\right)+\text{binomial}\left(\delta(k-k'+1),\prod_{i=k-k'+1}^{k}V^{(i)}\right)+k'\delta,
\end{aligned}$$

where $V^{(1)},\ldots,V^{(k)}$ is a sequence of i.i.d. random variables distributed as V, and the inequality is in a stochastic sense only. For each of the b^k paths down to a node at distance k, a different sequence is obtained. Thus, by Boole's inequality and the fact that all splitters are identically distributed, we have for integer $k,l>0$,

$$\mathbf{P}\{H_n\geq k+3l\}\leq b^k\mathbf{P}\{Z_k\geq 3l\}.$$

We further argue as follows:

$$\begin{aligned}\mathbf{P}\{Z_k \geq 3l\} \leq & \mathbf{P}\left\{\text{binomial}\left(n, \prod_{i=1}^{k} V^{(i)}\right) \geq l\right\} \\ & + \mathbf{P}\left\{\text{binomial}\left(\delta(k-k'+1), \prod_{i=k-k'+1}^{k} V^{(i)}\right) \geq l\right\} \\ & + \mathbf{P}\left\{k'\delta \geq l\right\}.\end{aligned}$$

The last term is zero by the choice of l. Conditioned on the $V^{(i)}$'s, the first term is easily bounded using Markov's inequality and Chernoff's bounding method. Let $t > 0$ be picked later. Then, if $Z = \prod_{i=1}^{k} V^{(i)}$,

$$\begin{aligned}\mathbf{P}\{\text{binomial}(n, Z) \geq l | Z\} & \leq \mathbf{E}\left\{(1 - Z + Ze^t)^n | Z\right\} e^{-tl} \\ & \leq \mathbf{E}\left\{e^{(e^t-1)nZ} | Z\right\} e^{-tl} \\ & \leq \mathbf{E}\left\{e^{l - nZ + l\log(nZ)} | Z\right\} \quad (\text{take } e^t = l/(nZ)).\end{aligned}$$

Take the expectation with respect to Z. The inequality is then further developed by noting the following: for $z \in (0,1)$ and $t > 0$,

$$\begin{aligned}\mathbf{P}\{\text{binomial}(n, Z) \geq l\} & \leq e^{l - z + l\log(z)} + \mathbf{P}\{nZ > z\} \\ & \leq (ez)^l + (n/z)^t \mathbf{E}\{Z^t\}.\end{aligned}$$

Similarly, for $z' \in (0,1)$, $t' > 0$, and $Z' = \prod_{i=k-k'+1}^{k} V^{(i)}$,

$$\begin{aligned}\mathbf{P}\{\text{binomial}(\delta(k-k'+1), Z') \geq l\} & \leq e^{l - z' + l\log(z')} + \mathbf{P}\{\delta(k-k'+1)Z' > z'\} \\ & \leq (ez')^l + (\delta(k-k'+1)/z')^{t'} \mathbf{E}\{Z'^{t'}\}.\end{aligned}$$

Take $z = z' = b^{-2k/l}/e$ and note that $ze \sim b^{-2c/\epsilon(\delta+1)}$. Then, combining the previous bounds,

$$\begin{aligned}b^k \mathbf{P}\{Z_k \geq 3l\} & \leq 2b^{-k} + b^k (ne)^t b^{2kt/l} m(t)^k + b^k (\delta(k-k'+1)e)^{t'} b^{2kt'/l} m(t')^{k'} \\ & \stackrel{\text{def}}{=} I + II + III,\end{aligned}$$

where $m(t)$ is the tth moment of V. Clearly, $I = o(1)$. Choose t' large enough so that $b\, m(t')^{\epsilon/c} < 1$. This is possible, as $\mathbf{P}\{V = 1\} = 0$ and thus $m(t') \to 0$ as $t' \to \infty$ (Lemma 1). With this choice of t', $III = o(1)$. To treat II, fix t and observe that $II = o(1)$ if

$$b^k n^t m(t)^k \to 0,$$

which occurs if

$$(bm(t))^c e^t < 1 \text{ or, equivalently, } c\log(bm(t)) + t < 0.$$

Here we distinguish between the two statements in the theorem. For the first statement, take t so large that $bm(t) < 1$. Then take c large enough to ensure that $(bm(t))^c e^t < 1$. For the second statement, we must be a bit more careful. The

minimal value of $c\log(bm)+t$ is obtained at the solution $t^*=t^*(c)$ of the equation $m'(t)/m(t)=-1/c$. From Lemma 1, a solution exists when

$$-\frac{1}{\mathbf{E}\{\log(V)\}}<c<-\frac{1}{\log v_\infty}.$$

Replace t by t^* (as we are allowed to choose any positive t) and let $c>\gamma$. As $R<-\log b$, $c\log(bm(t^*))+t^*<0$, and thus $II=o(1)$. This concludes the proof of Theorem 1.

Proof of Theorem 2: *The depth.* The following lemma will be useful for bounding tail probabilities.

LEMMA 4. *If X is binomial (n,Z) (written $B_{n,Z}$) where $Z\in[0,1]$ is a random variable, then for $0<a<n$,*

$$\mathbf{P}\{X\geq a\}\leq\mathbf{P}\{Z>a/(2n)\}+\left(\frac{e}{4}\right)^{a/2}.$$

Similarly,

$$\mathbf{P}\{X\leq a\}\leq\mathbf{P}\{Z<2a/n\}+\left(\frac{2}{e}\right)^{a}.$$

Proof. If X is binomial (n,p), then, for $1>u\geq p$ by Chernoff's bound (Chernoff, 1952; Okamoto, 1958),

$$\mathbf{P}\{X\geq nu\}\leq\left(\left(\frac{p}{u}\right)^u\left(\frac{1-p}{1-u}\right)^{1-u}\right)^n.$$

Interestingly, the same bound applies for $\mathbf{P}\{X\leq nu\}$ if $0<u\leq p$. In particular,

$$\mathbf{P}\{X\geq 2np\}\leq\left(\left(\frac{1}{2}\right)^{2p}\left(\frac{1-p}{1-2p}\right)^{1-2p}\right)^n\leq\left(\left(\frac{1}{2}\right)^{2p}e^p\right)^n=\left(\frac{e}{4}\right)^{np}.$$

Also,

$$\mathbf{P}\{X\leq np/2\}\leq\left((2)^{p/2}\left(1-\frac{p/2}{1-p/2}\right)^{1-p/2}\right)^n\leq\left((2)^{p/2}e^{-p/2}\right)^n=\left(\sqrt{\frac{2}{e}}\right)^{np}.$$

Applying this, we have

$$\begin{aligned}\mathbf{P}\{X>a\}&\leq\mathbf{P}\{Z>a/(2n)\}+\mathbf{P}\{B_{n,a/(2n)}>a\}\\&\leq\mathbf{P}\{Z>a/(2n)\}+\left(\frac{e}{4}\right)^{a/2}.\end{aligned}$$

Similarly, assuming without loss of generality that $n\geq 2$,

$$\begin{aligned}\mathbf{P}\{X\leq a\}&\leq\mathbf{P}\{Z<2a/n\}+\mathbf{P}\{B_{n,2a/n}\leq a\}\\&\leq\mathbf{P}\{Z<2a/n\}+\left(\frac{2}{e}\right)^{a}.\qquad\square\end{aligned}$$

The convergence of $\mathbf{E}\{D_n\}$ follows from the weak convergence,

$$\mathbf{E}\{D_n\}=\int_0^1\mathbf{P}\{D_n>t\}\,dt,$$

and the tail probabilities for $\mathbf{P}\{D_n > t\}$ developed below. The details are omitted.

For the proof of Theorem 2, we consider an infinite random path in the tree, $u_0, u_1, u_2, \ldots$, where u_0 is the root, and given u_i and the split vector $(V_1, \ldots, V_b)$ for u_i, u_{i+1} is the j-child of u_i with probability V_j. Put n balls in the tree as in the construction of a random split tree, and let u^* be the unique leaf on the infinite path. Then D_n is less than or equal to the distance between u^* and the root.

We first show that for all $c > 1/\mu$, $\mathbf{P}\{D_n > c \log n\} \to 0$. Take $k = \lfloor c \log n \rfloor$. Let u_0 be the root, and let u_0, u_1, ... be the path of nodes followed by the inserted point from the root down. We have, if $\beta = (s_0 + 1)k$,

$$[D_n > k + l] \subseteq [N(u_k) > \beta] \cup [H_\beta > l],$$

where H_β is the height of a random split tree with β balls. But

$$\mathbf{P}\{N(u_k) > \beta\} \leq \mathbf{P}\left\{ks_0 + \text{binomial}\left(n, \prod_{i=0}^{k-1} W_i\right) > \beta\right\},$$

where $W_0, W_1, \ldots$ are i.i.d. random variables distributed as $W = V_S$, and $S = i$ with probability V_i. Here we made use of the fact that a binomial (N, p) in which N is binomial (n, q) is distributed as a binomial (n, pq). By Lemma 4, we see that

$$\begin{aligned}
\mathbf{P}\left\{\text{binomial}\left(n, \prod_{i=0}^{k-1} W_i\right) > \beta - ks_0\right\} &\leq \mathbf{P}\left\{\prod_{i=0}^{k-1} W_i > \frac{\beta - ks_0}{2n}\right\} + \left(\frac{e}{4}\right)^{\frac{\beta - ks_0}{2}} \\
&= \mathbf{P}\left\{\sum_{i=0}^{k-1} \log W_i > \log\left(\frac{\beta - ks_0}{2n}\right)\right\} + \left(\frac{e}{4}\right)^{\frac{k}{2}} \\
&= I + II.
\end{aligned}$$

Clearly, $II = o(1)$. Also, $I = o(1)$ by the law of large numbers, as

$$\frac{\sum_{i=0}^{k-1} \log W_i}{k\mathbf{E}\{\log W\}} \to 1$$

almost surely. Recall that $\mu = \mathbf{E}\{\log(1/W)\}$. Also, we used the fact that

$$\liminf_{n\to\infty} \frac{\log\left(\frac{\beta - ks_0}{2n}\right) + k\mu}{k} = -\frac{1}{c} + \mu > 0$$

since $c > 1/\mu$. To wrap up the proof of the first part, we must show that $\mathbf{P}\{H_\beta > l\} \to 0$, where l is our choice. Let us pick $l = \lfloor 2\gamma \log \beta \rfloor = \lfloor 2\gamma \log((s_0 + 1)k) \rfloor$, where $\gamma > 0$ is as in Theorem 1. Then $\mathbf{P}\{H_\beta > l\} \to 0$, because

$$\lim_{n\to\infty} \mathbf{P}\{H_\beta > 2\gamma \log \beta\} = 0.$$

As $l \sim \log \log n$, the first part of the law of large numbers is proved.

Next, we show that for all $c < 1/\mu$, $\mathbf{P}\{D_n < c \log n\} \to 0$. Take $k = \lfloor c \log n \rfloor$. Then, if $N(.)$ refers to the tree with $n - 1$ balls,

$$[D_n < k] \subseteq [N(u_k) = 0].$$

But

$$\mathbf{P}\{N(u_k)=0\} \le \mathbf{P}\left\{-ks + \text{binomial}\left(n-1, \prod_{i=0}^{k-1} W_i\right) \le 0\right\},$$

where $W_0, W_1, \ldots$ are as in the earlier part of this proof. By Lemma 4, we see that

$$\begin{aligned}\mathbf{P}\left\{\text{binomial}\left(n-1, \prod_{i=0}^{k-1} W_i\right) \le ks\right\} &\le \mathbf{P}\left\{\prod_{i=0}^{k-1} W_i \le \frac{2ks}{n-1}\right\} + \left(\frac{2}{e}\right)^{ks} \\ &= \mathbf{P}\left\{\sum_{i=0}^{k-1} \log W_i \le \log\left(\frac{2ks}{n-1}\right)\right\} + \left(\frac{2}{e}\right)^{ks} \\ &= I + II.\end{aligned}$$

Obviously, $II = o(1)$. $I = o(1)$ by the law of large numbers, as

$$\frac{\sum_{i=0}^{k-1} \log W_i}{k\mathbf{E}\{\log W\}} \to 1$$

almost surely and

$$\limsup_{n\to\infty} \frac{\log\left(\frac{2ks}{n}\right) - k\mathbf{E}\{\log W\}}{k} = -\frac{1}{c} - \mathbf{E}\{\log W\} = -\frac{1}{c} + \mu < 0.$$

This concludes the proof of the lower bound for the law of large numbers.

The limit law is obtained by using the same upper and lower bounds introduced in the proof of the law of large numbers. Additionally, we will use the fact that

$$\frac{\sum_{i=0}^{k-1} \log W_i + k\mu}{\sqrt{k\sigma^2}} \xrightarrow{\mathcal{L}} \mathcal{N}(0,1).$$

Consider first the probability $\mathbf{P}\{D_n > k\}$, where $k = \lfloor (1/\mu)\log n + u\sqrt{\log n}\rfloor$ and $u \in \mathbb{R}$. We have, if $\beta = (s_0+1)k$,

$$[D_n > k + l] \subseteq [N(u_k) > \beta] \cup [H_\beta > l],$$

where H_β is the height of a random split tree with β balls. Arguing as in the first part of this proof,

$$\begin{aligned}\mathbf{P}\{N(u_k) > \beta\} &\le \mathbf{P}\left\{\text{binomial}\left(n, \prod_{i=0}^{k-1} W_i\right) > \beta - ks_0\right\} \\ &= \mathbf{P}\left\{\sum_{i=0}^{k-1} \log W_i > \log\left(\frac{\beta - ks_0}{2n}\right)\right\} + \left(\frac{e}{4}\right)^{\frac{k}{2}} \\ &= \mathbf{P}\left\{\frac{\sum_{i=0}^{k-1} \log W_i + k\mu}{\sqrt{k\sigma^2}} > \frac{\log\left(\frac{\beta-ks_0}{2n}\right) + k\mu}{\sqrt{k\sigma^2}}\right\} + o(1) \\ &= \mathbf{P}\left\{\mathcal{N}(0,1) > \frac{\log\left(\frac{\beta-ks_0}{2n}\right) + k\mu}{\sqrt{k\sigma^2}}\right\} + o(1) \\ &= \mathbf{P}\left\{\mathcal{N}(0,1) > \frac{u\mu^{3/2}}{\sigma}\right\} + o(1).\end{aligned}$$

Recall that for $l = \lfloor 2\gamma \log \beta \rfloor = \lfloor 2\gamma \log((s_0+1)k) \rfloor$, we obtain $\mathbf{P}\{H_\beta > l\} \to 0$. As $l \sim \log\log n$, the first part of the limit law is proved:

$$\mathbf{P}\{D_n > k\} \le \mathbf{P}\{N > u\mu^{3/2}/\sigma\} + o(1).$$

Using the arguments for the lower bound, we may prove in a similar fashion that

$$\mathbf{P}\{D_n < k\} \le \mathbf{P}\{N < u\mu^{3/2}/\sigma\} + o(1).$$

Taken together, this proves that

$$\lim_{n\to\infty} \mathbf{P}\{D_n < k\} = \mathbf{P}\{N < u\mu^{3/2}/\sigma\},$$

which was to be shown.

Other possible universal models for random split trees. We could have developed this theory based on other models. In a random split tree, the subtree sizes are multinomial $(n, V_1, \ldots, V_b)$, where $(V_1, \ldots, V_b)$ in turn is a random split vector. This introduces two levels of randomization. A more rigid and perhaps less universal model would fix an integer δ and require that the subtree sizes $N(u_1), \ldots, N(u_b)$ for the children $u_1, \ldots, u_b$ of a node u satisfy:

$$\max_{1\le i\le b} |N(u_i) - nV_i| \le \delta.$$

Some of the trees discussed earlier fall into this framework. For example, in a random binary search tree, it is well known that the left and right subtrees of the root have cardinalities (N_1, N_2) that are jointly distributed as $(\lfloor nU \rfloor, \lfloor n(1-U) \rfloor)$, where U is uniform $[0,1]$ and n is the cardinality of the tree. Setting $(V_1, V_2) = (U, 1-U)$, we thus have $\max_i |N_i - nV_i| \le 1$. Theorems 1 and 2 have straightforward equivalent versions (with the same dependence upon μ, σ^2 and $m(t)$). We should note that for generating extended AB trees for the purpose of simulation, the model of this section is more convenient. Here the split vectors V_1 and $V_2 = 1 - V_1$ are mixtures of beta random variables, but no multinomial sampling is necessary, as we use $(N_1, N_2) = (\lfloor nV_1 \rfloor, \lfloor nV_2 \rfloor)$ to determine subtree sizes at the root of a subtree of cardinality n. This way, each node will receive one ball.

Acknowledgment. I thank Paul Kruszewski and two anonymous referees for great feedback on the manuscript.

AVERAGE-CASE LOWER BOUNDS FOR NOISY BOOLEAN DECISION TREES*

WILLIAM EVANS† AND NICHOLAS PIPPENGER‡

Abstract. We present a new method for deriving lower bounds to the expected number of queries made by noisy decision trees computing Boolean functions. The new method has the feature that expectations are taken with respect to a uniformly distributed random input, as well as with respect to the random noise, thus yielding stronger lower bounds. It also applies to many more functions than do previous results. The method yields a simple proof of the result (previously established by Reischuk and Schmeltz) that almost all Boolean functions of n arguments require $\Omega(n \log n)$ queries, and strengthens this bound from the worst-case over inputs to the average over inputs. The method also yields bounds for specific Boolean functions in terms of their spectra (their Fourier transforms). The simplest instance of this spectral bound yields the result (previously established by Feige, Peleg, Raghavan, and Upfal) that the parity function of n arguments requires $\Omega(n \log n)$ queries and again strengthens this bound from the worst-case over inputs to the average over inputs. In its full generality, the spectral bound applies to the "highly resilient" functions introduced by Chor, Friedman, Goldreich, Hastad, Rudich, and Smolensky, and it yields nonlinear lower bounds whenever the resiliency is asymptotic to the number of arguments.

1. Introduction.

We shall deal in this paper with dynamic decision trees for computing Boolean functions. A *dynamic decision tree* is a binary tree in which each internal node N is labelled with an argument index $\alpha(N) \in \{1, \ldots, n\}$, each child M of an internal node N is labelled with a Boolean value $\beta(M) \in \{0, 1\}$ that might be assumed by this argument (with siblings being labelled with distinct values), and each leaf L is labelled with a Boolean function value $\phi(L) \in \{0, 1\}$. Such a dynamic decision tree computes a Boolean function f of n Boolean arguments $x_1, \ldots, x_n$ in an obvious way: start at the root; when at an internal node N, query the argument $x_{\alpha(N)}$ and proceed to the child M of N such that $\beta(M) = x_{\alpha(N)}$; when at a leaf L, announce the function value $f(x_1, \ldots, x_n) = \phi(L)$. For such a dynamic decision tree, we may speak of the *worst-case cost* (the maximum over argument values of the depth of the leaf that announces the function value) or the *average-case cost* (the average with a uniform distribution over argument values of the depth of the leaf that announces the function value).

We shall be interested in the situation in which dynamic decision trees are noisy, that is, in which each internal node independently passes control to the incorrect child (that is, the child M of the internal node N such that $\beta(M) = \neg x_{\alpha(N)}$) with some fixed probability $0 < \varepsilon < 1/2$. We shall say that such a tree (ε, δ)-computes a

Boolean function f if, for all $x_1, \ldots, x_n \in \{0,1\}$, the probability that control reaches an incorrectly labelled leaf (that is, a leaf L labelled $\phi(L) = \neg f(x_1, \ldots, x_n)$) is at most $\delta < 1/2$. For such a noisy dynamic decision tree, we may again speak of the worst-case or average-case cost (where we may maximize or average over argument values but always average over noise).

An alternative to the error model we have adopted is to assume that errors occur with probability at most ε, rather than exactly ε. This alternative model gives stronger upper bounds. Our interest in this paper is in lower bounds, for which the model we have adopted gives stronger results.

To describe the history of our results, we shall need to refer to two additional computational models. The first of these is the *static decision tree*, which we may regard as a dynamic decision tree in which the argument queried by an internal node does not depend on the outcomes of previous queries (and thus depends only on the depth of the node in the tree), and in which all leaves appear at the same depth. The cost in this case is simply the common depth C of the leaves. It is not hard to see that we may ignore the tree structure, and simply focus on the number of queries C_i to each argument x_i. We then have $C_1 + \cdots + C_n = C$. Furthermore, we may ignore the sequence of answers to the queries to a given argument and focus on the number D_i of affirmative answers among answers to the C_i queries to x_i. We then have $0 \leq D_i \leq C_i$ for $1 \leq i \leq n$. While a noisy static decision tree might announce distinct function values for the same values of $D_1, \ldots, D_n$, it is not hard to see that these announcements can be replaced by a consistent announcement $\phi(D_1, \ldots, D_n)$, without increasing the probability of an incorrect announcement in any situation. Thus we may describe a static decision tree by specifying the numbers $C_1, \ldots, C_n$ and the labelling $\phi(D_1, \ldots, D_n)$ for $0 \leq D_1 \leq C_1, \ldots, 0 \leq D_n \leq C_n$.

Our final computational model is the *circuit with noisy gates*. We shall not describe this model in detail but merely remark that a lower bound to static decision tree cost yields a lower bound to the size (number of gates) of a circuit with noisy gates.

Work on reliable computation in the presence of noise was begun by von Neumann [14], who argued (although he did not give a rigorous proof) that a computation that can be performed by a noiseless network with L gates could be reliably performed by a noisy network with $O(L \log L)$ gates. Dobrushin and Ortyukov [4] provided a rigorous proof of this result, and [3] claimed the following matching lower bound: a noisy network that reliably computes a function f must have $\Omega(S \log S)$ gates, where S is the *sensitivity* of f (the maximum over inputs $x_1, \ldots, x_n$ of the number of indices i such that $f(x_1, \ldots, x_{i-1}, \neg x_i, x_{i+1}, \ldots, x_n) \neq f(x_1, \ldots, x_n)$). Since there are many functions (for example, the disjunction, conjunction, or parity of n arguments) that have sensitivity $S = n$ and can be computed by noiseless networks with $O(n)$ gates, this result shows that the logarithmic ratio of noisy to noiseless gates is necessary for certain functions.

There are, however, several errors in the proof of the lower bound of Dobrushin and Ortyukov [3]. These were pointed out by Pippenger, Stamoulis, and Tsitsiklis [16], who gave a proof of the weaker result that a noisy network that reliably computes the parity function of n arguments must have $\Omega(n \log n)$ gates. The full strength of the lower bound in terms of sensitivity was regained by Gál [9] (see also Gács and Gál [10]) and by Reischuk and Schmeltz [17]. An important consequence of this stronger result is that a noisy network that reliably computes the disjunction (or conjunction) of n arguments must have $\Omega(n \log n)$ gates. All of these lower bound

arguments apply to static decision trees as well as to circuits. For noisy static decision trees, lower bounds of $\Omega(n \log n)$ are best possible, since any Boolean function of n arguments can be computed by a noisy static decision tree with $O(n \log n)$ queries (with $2\log(n/\delta) \,/\, \log\bigl(1/4\varepsilon(1-\varepsilon)\bigr) = O(\log n)$ queries, it is possible to determine a single argument with error probability at most δ/n).

Noisy dynamic decision trees were considered by Feige et al. [6, 7], who showed that there are noisy dynamic decision trees that reliably compute the disjunction or conjunction of n arguments with $O(n)$ queries. Since we have seen that noisy static decision trees require $\Omega(n \log n)$ queries, this exhibits a clear separation between the two models. For noisy dynamic decision trees, Feige et al. [6, 7] showed that $\Omega(n \log n)$ queries are needed to compute the parity or majority of n arguments, and Reischuk and Schmeltz [17] showed that $\Omega(n \log n)$ queries are needed for almost all Boolean functions of n arguments. (This last result contrasts with results of Muller [13] and Pippenger [15] for circuits, to the effect that for almost all Boolean functions of n arguments, $\Omega(2^n/n)$ noiseless gates are necessary and $O(2^n/n)$ noisy gates are sufficient.) The lower bound proofs of both Feige et al. and of Reischuk and Schmeltz depend on locating particular sets of inputs that are difficult for a dynamic decision tree, and thus they yield lower bounds for the worst-case over inputs but not for the average-case over inputs (and clearly no proof that applied to disjunction or conjunction could give a nontrivial lower bound for the average over inputs).

The present paper gives a new method of establishing lower bounds for noisy dynamic decision trees. The gist of the method is to argue that for certain Boolean functions there cannot be even one leaf in the decision tree that has both a small depth and a small probability of error (conditional on control reaching the leaf). The Boolean functions to which the method applies are difficult to compute for all inputs rather than just for certain inputs. This implies that lower bounds established by the method apply to the average case over inputs rather than just the worst case. (It also implies of course that the method is powerless to deal with functions such as disjunction, conjunction, and majority that have inputs such as $x_1 = \cdots x_n = 1$, $x_1 = \cdots x_n = 0$, or both for which it is easy to reliably determine the function value.) These strengths and weaknesses of our new method are embodied in a new complexity measure for Boolean functions, which we call "noisy leaf complexity." In section 2 we shall define noisy leaf complexity and relate it to noisy dynamic decision tree complexity described above.

Our method considers the situation in which control has arrived at a leaf L. Arrival at L conditions the uniform prior distribution on the input x to a posterior distribution. Our method is based on the fact that, if the depth of L is small, this posterior distribution must be spread over a large range of possible input values. In section 3 we shall calculate this posterior distribution and derive quantitative versions of the assertion that it is spread over a large range.

Section 4 deals with random Boolean functions and establishes a lower bound of the form $\Omega(n \log n)$ for the noisy leaf complexity of "almost all" Boolean functions of n arguments. Specifically, we show that if L is a leaf of cost

$$C \le n \log_E(n/2) - n \log_E \log\bigl(2n^2/(1-2\delta)^2\bigr),$$

where $E = (1-\varepsilon)/\varepsilon$, then the probability is at most $2e^{-n^2}$ that L has error probability (conditional on arrival at L) at most δ for a random Boolean function of n arguments. This strengthens (from the worst-case over inputs to the average-case over inputs) the lower bound of Reischuk and Schmeltz [17].

Section 5 establishes a lower bound of the form $\Omega(n \log n)$ for the noisy leaf complexity of the parity function of n arguments. Specifically, we show that if a leaf with cost C has conditional error probability at most δ for the parity function of n arguments, then

$$C \geq n \log_E n - n \log_E \log\bigl(1/(1-2\delta)\bigr),$$

where $E = (1-\varepsilon)/\varepsilon$. This strengthens (from the worst-case over inputs to the average-case over inputs) the lower bound of Feige et al. [6, 7] for the parity function. The proof of our lower bound uses the Fourier transform of the parity function, which has a particularly simple form. Other examples of the use of the Fourier transform to derive lower bounds to the computational complexity of Boolean functions are given by Brandman, Orlitsky, and Hennessy [1] (noiseless decision trees) and by Linial, Mansour, and Nisan [12] (bounded-depth circuits). It would be possible to rephrase this proof so as not to refer to the Fourier transform. Indeed, Fourier analysis on finite groups such as the Boolean n-cube is tantamount to linear algebra in finite-dimensional vector spaces. Fourier analysis lends this linear algebra a certain suggestive terminology, however, that provides a vivid intuition to guide the manipulations. This intuition was valuable in discovering the more general results of section 6.

A general class of Boolean functions to which our method applies is the class of "highly resilient" functions. If a Boolean function is significantly "biased" (that is, if it assumes the values 0 and 1 with significantly unequal probabilities under the uniform input distribution), then even a leaf at depth 0 can announce the function value with a probability of output error significantly less than $1/2$. This suggests we focus our attention on "unbiased" functions, which assume the values 0 and 1 each with probability $1/2$. Extending this reasoning, we see that if a Boolean function can be significantly biased by substituting constants for a small number of arguments, then a leaf with small depth can achieve a probability of output error significantly less than $1/2$. This suggests we focus our attention on functions that are unbiased and which remain unbiased even when constants are substituted for some number t of arguments. Such functions are called "t-resilient" by Chor et al. [2]. Though defined combinatorially, the highly resilient functions have natural characterizations in terms of their "spectra," either in the sense of their Fourier transforms or in the sense of the eigenvalues of the adjacency matrix of the Boolean hypercube. These characterizations are discussed by Friedman [8].

Section 6 establishes a lower bound for the noisy leaf complexity of t-resilient Boolean functions. Specifically, we show that if f is t-resilient and a leaf with cost C has conditional error probability at most δ for f, then

$$C \geq (t+1) \log_E \frac{t+1}{\frac{n}{2} H\left(\frac{t+1}{n}\right) + \log \frac{1}{1-2\delta}},$$

where $E = (1-\varepsilon)/\varepsilon$, and $H(\eta) = -\eta \log \eta - (1-\eta)\log(1-\eta)$ for $0 < \eta < 1$, extended by continuity to $H(0) = H(1) = 0$. The most resilient function of n arguments is the parity function, which is $(n-1)$-resilient. Thus we recover the lower bound of section 5 in this special case. There are, however, many highly resilient functions that are not parity functions. For these functions, our method yields a nonlinear lower bound whenever $t \sim n$, that is, whenever the resiliency is asymptotic to the number of arguments.

2. Noisy leaf complexity. Let f be a Boolean function of n arguments $x_1, \ldots, x_n$. Let T be a decision tree and let L be a leaf of T. By the *cost* of L we shall mean the number of queries along the path from the root of T to L. Suppose now that the input x is chosen at random with the uniform distribution (with each possible input having probability 2^{-n}). Suppose further that the tree T is applied to the input x with query error probability $\varepsilon > 0$ at each internal node. We shall say that L is (ε, δ)-*good* for f if the probability $\Pr(\phi(L) = \neg f(x) \mid L)$ of output error at L, conditional on control reaching L, is at most $\delta < 1/2$. It is clear that whether or not a leaf L is (ε, δ)-good for f depends only on the numbers $C_1, \ldots, C_n$ of queries to the arguments $x_1, \ldots, x_n$, and on the numbers $D_1, \ldots, D_n$ of affirmative responses to these queries, and not on the rest of T. By the (ε, δ)-*leaf complexity* of a Boolean function f, we shall mean the smallest possible cost of a leaf that is (ε, δ)-good for f.

PROPOSITION 2.1. *Suppose that the noisy dynamic decision tree T (ε, δ)-computes the Boolean function f with expected cost C averaged over both inputs and noise. Let δ' be such that $\delta < \delta' < 1/2$. Then f has (ε, δ')-leaf complexity at most $C' = C/(1 - \delta/\delta')$.*

Proof. Let the input x be chosen with the uniform distribution. For each leaf L in T, let $p_L = \Pr(L)$ denote the probability that control reaches L, let $\delta_L = \Pr(\phi(L) = \neg f(x) \mid L)$ denote the probability of error conditional on control reaching L, and let C_L denote the cost of L. Let A denote the set of leaves L such that $\delta_L > \delta'$. If A is nonempty we have

$$\delta' \sum_{L \in A} p_L < \sum_{L \in A} p_L \delta_L \leq \sum_{L} p_L \delta_L = \delta,$$

and if A is empty we have

$$\delta' \sum_{L \in A} p_L = 0 < \delta,$$

so in any case we have

$$\sum_{L \in A} p_L < \delta/\delta'.$$

Let B denote the set of leaves L such that $C_L > C'$. If B is nonempty we have

$$C' \sum_{L \in B} p_L < \sum_{L \in B} p_L C_L \leq \sum_{L} p_L C_L = C,$$

and if B is empty we have

$$C' \sum_{L \in B} p_L = 0 < C,$$

so in any case we have

$$\sum_{L \in B} p_L < C/C'.$$

These inequalities yield

$$\sum_{L \notin A \cup B} p_L > 1 - \delta/\delta' - C/C' = 0.$$

Thus with positive probability control arrives at a leaf L such that $\delta_L \leq \delta'$ and $C_L \leq C'$, which shows that the (ε, δ')-leaf complexity of f is at most C'. □

3. The posterior distribution. Suppose that we choose an input x at random with a uniform distribution: $\Pr(x) = 2^{-n}$. Then suppose that we apply a noisy dynamic decision tree T with query error probability $\varepsilon > 0$ and arrive at a leaf L. We shall calculate the posterior probability distribution on x, given arrival at L: $\Pr(x \mid L)$.

Suppose that along the path from the root of T to L the input x_i is queried C_i times, with D_i affirmative responses (and thus $C_i - D_i$ negative responses). The event of arrival at L is the conjunction of n events $L_1, \ldots, L_n$, where L_i specifies a particular sequence of responses of the C_i queries to x_i. The prior distribution of x_i is $\Pr_i(x_i) = 1/2$. The conditional probability $\Pr_i(L_i \mid x_i)$ of L_i given x_i is

$$\Pr_i(L_i \mid 0) = \varepsilon^{D_i}(1-\varepsilon)^{C_i - D_i},$$
$$\Pr_i(L_i \mid 1) = \varepsilon^{C_i - D_i}(1-\varepsilon)^{D_i},$$

and thus

$$\Pr(L_i) = \frac{\varepsilon^{D_i}(1-\varepsilon)^{C_i - D_i} + \varepsilon^{C_i - D_i}(1-\varepsilon)^{D_i}}{2}.$$

Thus the posterior distribution $\Pr_i(x_i \mid L_i)$ of x_i, conditioned on L_i, is

$$\Pr_i(0 \mid L_i) = \frac{\varepsilon^{D_i}(1-\varepsilon)^{C_i - D_i}}{\varepsilon^{D_i}(1-\varepsilon)^{C_i - D_i} + \varepsilon^{C_i - D_i}(1-\varepsilon)^{D_i}}, \tag{3.1}$$

$$\Pr_i(1 \mid L_i) = \frac{\varepsilon^{C_i - D_i}(1-\varepsilon)^{D_i}}{\varepsilon^{D_i}(1-\varepsilon)^{C_i - D_i} + \varepsilon^{C_i - D_i}(1-\varepsilon)^{D_i}}. \tag{3.2}$$

Finally, since the x_i and the responses to the queries given the x_i are all independent, we have

$$\Pr(x \mid L) = \prod_{1 \le i \le n} \Pr_i(x_i \mid L_i). \tag{3.3}$$

Formulas (3.1), (3.2), and (3.3) give the desired posterior distribution of x.

It will be convenient to have bounds for $\Pr_i(x_i \mid L_i)$ that are independent of D_i. If we divide the numerator and denominator of (3.1) by the numerator, we obtain

$$\Pr_i(0 \mid L_i) = \frac{1}{1 + E^{2D_i - C_i}},$$

where $E = (1-\varepsilon)/\varepsilon$ (and $E > 1$, since $\varepsilon < 1/2$). The right-hand side is maximized when $D_i = 0$, so we have

$$\Pr_i(0 \mid L_i) \le \frac{1}{1 + E^{-C_i}}.$$

Similar reasoning from (3.2) yields an expression that is maximized when $D_i = C_i$, resulting in the same bound for $\Pr_i(1 \mid L_i)$. Thus if we set $P_i = \max\{\Pr_i(0 \mid L_i), \Pr_i(1 \mid L_i)\}$, we have

$$\begin{aligned} P_i &\le \frac{1}{1 + E^{-C_i}} \\ &= \frac{E^{C_i}}{E^{C_i} + 1} \\ &= 1 - \frac{1}{E^{C_i} + 1} \\ &\le 1 - \frac{1}{2E^{C_i}}. \end{aligned} \tag{3.4}$$

This is the desired bound.

4. Random Boolean functions. Throughout this section, f will denote a random Boolean function of n arguments, for which $f(x)$ is equally likely to be 0 or 1, independently for each value of x. Our strategy will be to consider a leaf L of small depth and bound the probability that L is (ε,δ)-good for f. Our main result is the following.

THEOREM 4.1. *Let L be a leaf of cost*

$$C \le n\log_E(n/2) - n\log_E\log\bigl(2n^2/(1-2\delta)^2\bigr),$$

where $E = (1-\varepsilon)/\varepsilon$. Then L is (ε,δ)-good for a random Boolean function of n arguments with probability at most $2e^{-n^2}$.

This result easily yields a lower bound for the noisy leaf complexity of almost all Boolean functions.

COROLLARY 4.2. *For all sufficiently large n (depending on $E = (1-\varepsilon)/\varepsilon > 1$ and $\delta < 1/2$), the fraction of all Boolean functions of n arguments having (ε,δ)-leaf complexity at most $(n/2)\log_E(n/2)$ is at most $2e^{-n^2/2}$.*

Proof. For all sufficiently large n, we have

$$C = (n/2)\log_E(n/2) \le n\log_E(n/2) - n\log_E\log\bigl(2n^2/(1-2\delta)^2\bigr),$$

so we may apply Theorem 4.1 to any leaf of cost at most C. But such a leaf is determined by specifying (1) which of the n arguments is queried at each of the C queries and (2) the response (affirmative or negative) to each query. Thus there are at most $(2n)^C$ leaves, and thus the probability that some leaf is (ε,δ)-good for f is at most $2e^{-n^2}(2n)^{(n/2)\log_E(n/2)}$. For sufficiently large n, this bound is at most $2e^{-n^2/2}$. □

It will be convenient to work not only with the Boolean function f but also with the rescaled real-valued function $F(x) = 1 - 2f(x)$, which is equally likely to be $+1$ or -1, independently for each value of x. Similarly, it will be convenient to work not only with the probability of error δ_L associated with a leaf L but also with the *correlation* $\xi_L = 1 - 2\delta_L$ between the rescaled label $\Phi(L) = 1 - 2\phi(L)$ of L and the rescaled function $F(x)$. If $\delta_L \le \delta < 1/2$, then $\xi_L \ge 1-2\delta > 0$. Thus if L is (ε,δ)-good for f we have

$$1 - 2\delta \le \xi_L = \mathrm{Ex}_x\bigl(\Phi(L)F(x)\bigr) = \Phi(L)\sum_x \Pr(x \mid L)F(x).$$

Since $\Phi(L) = \pm 1$, this implies

$$1 - 2\delta \le \left|\sum_x \Pr(x \mid L)F(x)\right|. \tag{4.1}$$

The terms $\Pr(x \mid L)F(x)$ are independent random variables that assume the values $\pm\Pr(x \mid L)$ each with probability 1/2. Thus, to estimate the probability that (4.1) holds, it will suffice to use an estimate for the probability of large deviations for sums of independent, but not necessarily identically distributed, random variables. The following result of Hoeffding [11, Theorem 2] suits our purpose.

PROPOSITION 4.3 (see [11]). *If A_x are independent random variables with mean 0 and range $|A_x| \le \Delta_x$, then*

$$\Pr\left(\sum_x A_x \ge T\right) \le \exp(-T^2/2S),$$

where

$$S = \sum_x \Delta_x^2.$$

Since the random variables $\Pr(x \mid L)F(x)$ are distributed symmetrically about 0, the probability that (4.1) holds is just twice the probability that

$$1 - 2\delta \le \sum_x \Pr(x \mid L)F(x) \tag{4.2}$$

holds. We can bound this using Proposition 4.3 by taking $A_x = \Pr(x \mid L)F(x)$, so that $\Delta_x = \Pr(x \mid L)$, and $T = 1 - 2\delta$. Thus we seek an estimate for

$$S = \sum_x \Pr(x \mid L)^2.$$

We observe that by virtue of (3.3) we have

$$S = \sum_x \Pr(x \mid L)^2 = \prod_{1 \le i \le n} \left(\Pr_i(0 \mid L_i)^2 + \Pr_i(1 \mid L_i)^2\right).$$

Since

$$u^2 + (1-u)^2 = 1 - 2u(1-u) \le \max\{u, 1-u\},$$

we have

$$S \le \prod_{1 \le i \le n} P_i,$$

with $P_i = \max\{\Pr_i(0 \mid L_i), \Pr_i(1 \mid L_i)\}$ as defined in section 3. Using (3.4) we have

$$S \le \prod_{1 \le i \le n} \left(1 - \frac{1}{2E^{C_i}}\right).$$

Since $1 - u \le \exp(-u)$, we have

$$\begin{aligned} S &\le \prod_{1 \le i \le n} \exp\left(-\frac{1}{2}E^{-C_i}\right) \\ &= \exp\left(-\frac{1}{2}\sum_{1 \le i \le n} E^{-C_i}\right). \end{aligned}$$

Since $E^u = \exp_E u$ is a convex function of u, we have

$$\begin{aligned} S &\le \exp\left(-\frac{n}{2}\exp_E\left(-\frac{1}{n}\sum_{1 \le i \le n} C_i\right)\right) \\ &= \exp\left(-\exp_E\left(\log_E \frac{n}{2} - \frac{C}{n}\right)\right). \end{aligned}$$

Thus if

$$C \le n\log_E(n/2) - n\log_E\log\left(2n^2/(1-2\delta)^2\right),$$

we have $S \le (1-2\delta)^2/2n^2$. Proposition 4.3 then implies that (4.2) holds with probability at most e^{-n^2}, so (4.1) holds with probability at most $2e^{-n^2}$. This completes the proof of Theorem 4.1.

5. The parity function. In this section we shall derive a lower bound for the (ε, δ)-leaf complexity of the parity function:

$$f(x_1, \ldots, x_n) = x_1 + \cdots + x_n \pmod 2.$$

Our result is the following.

THEOREM 5.1. *If the leaf L with cost C is (ε, δ)-good for the parity function f of n arguments, then*

$$C \geq n \log_E n - n \log_E \log\bigl(1/(1-2\delta)\bigr),$$

where $E = (1-\varepsilon)/\varepsilon$.

The proof of this theorem depends on the notion of the Fourier transform of a Boolean function. This notion has already been applied to the computational complexity of Boolean functions by circuits (see Linial, Mansour, and Nisan [12]) and noiseless dynamic decision trees (see Brandman, Orlitsky, and Hennessy [1]), but the present paper appears to mark its debut for the complexity of noisy computation.

Let $F : \mathbf{B}^n \to \mathbf{R}$ be a real-valued function of n Boolean arguments. By the *Fourier transform* of F we shall mean the function $\hat{F} : \mathbf{B}^n \to \mathbf{R}$ defined by

$$\hat{F}(y) = \frac{1}{\sqrt{2^n}} \sum_x (-1)^{x \cdot y} F(x),$$

where $x \cdot y = \sum_{1 \leq j \leq n} x_j y_j$ denotes the inner product of x and y. (The factor $(-1)^{x \cdot y}$ is the specialization of the usual Fourier kernel $e^{2\pi i x \cdot y/m}$ to $m = 2$.) The normalization factor $1/\sqrt{2^n}$ has been chosen to make the transform an involution: we have

$$\begin{aligned}
\hat{\hat{F}}(z) &= \frac{1}{\sqrt{2^n}} \sum_y (-1)^{y \cdot z} \hat{F}(y) \\
&= \frac{1}{\sqrt{2^n}} \sum_y (-1)^{y \cdot z} \frac{1}{\sqrt{2^n}} \sum_x (-1)^{x \cdot y} F(x) \\
&= \frac{1}{2^n} \sum_x F(x) \sum_y (-1)^{x \cdot y + y \cdot z} \\
&= F(z),
\end{aligned}$$

since

$$\sum_y (-1)^{x \cdot y + y \cdot z} = \begin{cases} 2^n & \text{if } x = z, \\ 0 & \text{otherwise.} \end{cases}$$

(The general Fourier transform is not an involution, but rather has period four, and the effect of applying the transform twice is to reverse the function by negating its argument. But in $\mathbf{B}$, regarded as an additive group of order two, every element is its own negative, so each function is its own reversal.)

The key result we shall need is the Parseval identity

$$\sum_y \hat{F}(y)\, \hat{G}(y) = \sum_y F(y)\, G(y),$$

which says that the Fourier transform is an isometry of the Hilbert space $\mathbf{R}^{\mathbf{B}^n}$. This follows from a calculation similar to the one above:

$$\begin{aligned}\sum_y \hat{F}(y)\,\hat{G}(y) &= \sum_y \frac{1}{\sqrt{2^n}} \sum_x (-1)^{x\cdot y} F(x) \frac{1}{\sqrt{2^n}} \sum_z (-1)^{z\cdot y} G(z) \\ &= \frac{1}{2^n} \sum_x \sum_z F(x)\,G(z) \sum_y (-1)^{x\cdot y + z\cdot y} \\ &= \sum_x F(x)\,G(x).\end{aligned}$$

For the proof of Theorem 5.1, we take $F(x) = 1 - 2f(x)$ to be the rescaled parity function. As in the preceding section, we have

$$1 - 2\delta \le \left| \sum_x \Pr(x \mid L) F(x) \right|.$$

Setting $G(x) = \Pr(x \mid L)$ and applying the Parseval identity, we have

$$1 - 2\delta \le \left| \sum_y \hat{G}(y) \hat{F}(y) \right|. \tag{5.1}$$

For F the rescaled parity function, a simple calculation yields $\hat{F}$:

$$\hat{F}(y) = \begin{cases} \sqrt{2^n} & \text{if } y = (1, \ldots, 1), \\ 0 & \text{otherwise.} \end{cases}$$

Substituting this formula into (5.1) yields

$$1 - 2\delta \le \sqrt{2^n}\ \ |\hat{G}(1, \ldots, 1)|.$$

From the definitions of G and $\hat{G}$, this reduces to

$$1 - 2\delta \le \left| \sum_x (-1)^{|x|} \Pr(x \mid L) \right|, \tag{5.2}$$

where $|y| = \sum_{1 \le i \le n} y_i$ denotes the number of i such that $y_i = 1$.

To estimate the right-hand side of (5.2), we observe that

$$\begin{aligned}\sum_x (-1)^{|x|} \Pr(x \mid L) &= \prod_{1 \le i \le n} \big(\Pr_i(0 \mid L_i) - \Pr_i(1 \mid L_i) \big) \\ &= \prod_{1 \le i \le n} \big(1 - 2\Pr_i(1 \mid L_i) \big).\end{aligned}$$

Since

$$|1 - 2u| = 2 \max\{u, 1 - u\} - 1,$$

we have

$$\begin{aligned}1 - 2\delta &\le \left| \sum_x (-1)^{|x|} \Pr(x \mid L) \right| \\ &= \prod_{1 \le i \le n} (2P_i - 1),\end{aligned}$$

with $P_i = \max\{\Pr_i(0 \mid L_i), \Pr_i(1 \mid L_i)\}$ as defined in section 3. Using (3.4) we have

$$1 - 2\delta \leq \prod_{1 \leq i \leq n} \left(1 - \frac{1}{E^{C_i}}\right).$$

Since $1 - u \leq \exp -u$, we have

$$\begin{aligned} 1 - 2\delta &\leq \prod_{1 \leq i \leq n} \exp\left(-E^{-C_i}\right) \\ &= \exp\left(-\sum_{1 \leq i \leq n} E^{-C_i}\right). \end{aligned}$$

Since $E^u = \exp_E u$ is a convex function of u, we have

$$\begin{aligned} 1 - 2\delta &\leq \exp\left(-n \exp_E\left(-\frac{1}{n} \sum_{1 \leq i \leq n} C_i\right)\right) \\ &= \exp\left(-\exp_E\left(\log_E n - \frac{C}{n}\right)\right). \end{aligned}$$

Thus we obtain

$$C \geq n \log_E n - n \log_E \log\bigl(1/(1 - 2\delta)\bigr).$$

This completes the proof of Theorem 5.1.

6. Resilient Boolean functions. A Boolean function f of n arguments is *unbiased* if

$$\sum_x F(x) = 0,$$

where $F(x) = 1 - 2f(x)$ is the rescaled real-valued function as in the preceding section, and the sum is over all 2^n values of x. Thus a function is unbiased if it assumes the values 0 and 1 for equal numbers of inputs.

A Boolean function f is *t-resilient* if every function obtained from f by substituting constants for at most t arguments is an unbiased function of the remaining arguments. Thus a function is 0-resilient if and only if it is unbiased. Our main result in this section is the following.

THEOREM 6.1. *If f is t-resilient and the leaf L with cost C is (ε, δ)-good for f, then*

$$C \geq (t+1) \log_E \frac{t+1}{\frac{n}{2} H\left(\frac{t+1}{n}\right) + \log \frac{1}{1-2\delta}},$$

where $E = (1 - \varepsilon)/\varepsilon$, and $H(\eta) = -\eta \log \eta - (1 - \eta) \log(1 - \eta)$ for $0 < \eta < 1$, extended by continuity to $H(0) = H(1) = 0$.

The projection functions, of the form $f(x_1, \ldots, x_n) = x_i$, are 0-resilient but not 1-resilient. The parity functions, of the form $f(x_1, \ldots, x_n) = x_1 + \cdots + x_n + c \pmod 2$, are $(n-1)$-resilient, which is the maximum possible for a function of n arguments.

Theorem 5.1 applies to many other functions however. If g and h are t-resilient functions of k arguments, then

$$f(x_1,\dots,x_{k+1}) = \begin{cases} g(x_1,\dots,x_k) & \text{if } x_{k+1}=0,\\ h(x_1,\dots,x_k) & \text{if } x_{k+1}=1, \end{cases}$$

defines a t-resilient function of $k+1$ arguments. Since there are two distinct t-resilient parity functions of $t+1$ arguments, and this scheme allows us to square the number of functions by adding one argument, we conclude that there are at least $2^{2^{n-t-1}}$ t-resilient functions of n arguments.

Our proof of Theorem 5.1 will exploit a characterization of resilient functions in terms of their Fourier transforms. Friedman [8] has observed that this characterization is implicit in the work of Chor et al. [2], although the terminology of Fourier transforms is not used there.

PROPOSITION 6.2 (see [2]). *Let $\hat{F}$ be the Fourier transform of $F(x) = 1 - 2f(x)$ for some Boolean function f of n arguments. Then for $t \geq 0$, f is t-resilient if and only if $\hat{F}(y) = 0$ for all y such that $|y| \leq t$.*

In particular, a function f is unbiased if and only if $\hat{F}(0,\dots,0) = 0$, and the parity functions are the only functions for which $\hat{F}(y) = 0$ for all y except $y = (1,\dots,1)$.

We shall also need the following standard estimate for sums of binomial coefficients.

LEMMA 6.3. *If $l \geq n/2$, then*

$$\sum_{k\geq l} \binom{n}{k} \leq \exp\bigl(nH\bigl(l/n\bigr)\bigr).$$

Proof. For $\xi \geq 1$ we have

$$\sum_{k\geq l} \binom{n}{k} \leq \xi^{-l} \sum_{k} \binom{n}{k} \xi^k = \xi^{-l}(1+\xi)^n.$$

Taking $\xi = l/(n-l)$, so that $\xi \geq 1$ follows from $l \geq n/2$, we obtain

$$\sum_{k\geq l} \binom{n}{k} \leq \frac{n^n}{l^l (n-l)^{n-l}} = \exp\bigl(nH(l/n)\bigr),$$

as claimed. □

As in the preceding, section we have

$$1 - 2\delta \leq \left| \sum_y \hat{G}(y)\hat{F}(y) \right|, \tag{6.1}$$

where $\hat{G}$ is the Fourier transform of $G(x) = \Pr(x \mid L)$. Since f is t-resilient, we have $\hat{F}(y) = 0$ for $|y| \leq t$, and thus we have

$$1 - 2\delta \leq \sum_{\substack{y\\ |y|\geq t+1}} |\hat{G}(y)||\hat{F}(y)|.$$

Using Cauchy's inequality we obtain

$$(1-2\delta)^2 \leq \left(\sum_{\substack{y\\ |y|\geq t+1}} \hat{G}(y)^2 \right) \left(\sum_{\substack{y\\ |y|\geq t+1}} \hat{F}(y)^2 \right). \tag{6.2}$$

Since $F(x) = \pm 1$, Parseval's identity yields

$$\sum_{\substack{y \\ |y| \geq t+1}} \hat{F}(y)^2 \leq \sum_y \hat{F}(y)^2 = \sum_x F(x)^2 = 2^n.$$

Thus from (6.2) we obtain

$$(1-2\delta)^2 \leq \left(\sum_{\substack{y \\ |y| \geq t+1}} \hat{G}(y)^2 \right) 2^n. \tag{6.3}$$

We have

$$\begin{aligned} \sum_{\substack{y \\ |y| \geq t+1}} \hat{G}(y)^2 &\leq \left(\max_{\substack{y \\ |y| \geq t+1}} \hat{G}(y)^2 \right) \left(\sum_{\substack{y \\ |y| \geq t+1}} 1 \right) \\ &\leq \left(\max_{\substack{y \\ |y| \geq t+1}} \hat{G}(y)^2 \right) \left(\sum_{k \geq t+1} \binom{n}{k} \right) \\ &\leq \left(\max_{\substack{y \\ |y| \geq t+1}} \hat{G}(y)^2 \right) \exp\left(nH\left(\frac{t+1}{n} \right) \right). \end{aligned}$$

Thus from (6.3) we obtain

$$(1-2\delta)^2 \leq \left(\max_{\substack{y \\ |y| \geq t+1}} \hat{G}(y)^2 \right) \exp\left(nH\left(\frac{t+1}{n} \right) \right) 2^n.$$

We have

$$\hat{G}(y)^2 = \frac{1}{2^n} \left(\sum_x (-1)^{x \cdot y} \Pr(x \mid L) \right)^2.$$

The sum on the right-hand side can be estimated in the same way as the sum in (5.2): if $|y| = k \geq t+1$, the sum factors into a product of k factors, and the final result is

$$\hat{G}(y)^2 \leq \frac{1}{2^n} \exp\left(-2 \exp_E\left(\log_E k - \frac{C}{k} \right) \right),$$

so that

$$\max_{\substack{y \\ |y| \geq t+1}} \hat{G}(y)^2 \leq \frac{1}{2^n} \exp\left(-2 \exp_E\left(\log_E(t+1) - \frac{C}{t+1} \right) \right).$$

Thus from (6.3) we obtain

$$(1-2\delta)^2 \leq \exp\left(-2 \exp_E\left(\log_E(t+1) - \frac{C}{t+1} \right) \right) \exp\left(nH\left(\frac{t+1}{n} \right) \right).$$

This yields

$$C \geq (t+1) \log_E \frac{t+1}{\frac{n}{2} H\left(\frac{t+1}{n} \right) + \log \frac{1}{1-2\delta}},$$

which completes the proof of Theorem 6.1.

COMPETITIVE ALGORITHMS FOR LAYERED GRAPH TRAVERSAL*

AMOS FIAT†, DEAN P. FOSTER‡, HOWARD KARLOFF§, YUVAL RABANI¶, YIFTACH RAVID‖, AND SUNDAR VISHWANATHAN**

Abstract. A layered graph is a connected graph whose vertices are partitioned into sets $L_0 = \{s\}, L_1, L_2, ...$, and whose edges, which have nonnegative integral weights, run between consecutive layers. Its width is $\max\{|L_i|\}$. In the on-line layered graph traversal problem, a searcher starts at s in a layered graph of unknown width and tries to reach a target vertex t; however, the vertices in layer i and the edges between layers $i-1$ and i are only revealed when the searcher reaches layer $i-1$.

We give upper and lower bounds on the competitive ratio of layered graph traversal algorithms. We give a deterministic on-line algorithm which is $O(9^w)$-competitive on width-w graphs and prove that for no w can a deterministic on-line algorithm have a competitive ratio better than 2^{w-2} on width-w graphs. We prove that for all w, $w/2$ is a lower bound on the competitive ratio of any randomized on-line layered graph traversal algorithm. For traversing layered graphs consisting of w disjoint paths tied together at a common source, we give a randomized on-line algorithm with a competitive ratio of $O(\log w)$ and prove that this is optimal up to a constant factor.

1. Introduction.

Finding the shortest path in a graph from a source to a target is a well-studied problem. Dijkstra's algorithm [Dij] appeared in 1959. Other algorithms can be found in [Bel, Flo, FF, AMOT].

Baeza-Yates, Culberson, and Rawlins [BCR] and Papadimitriou and Yannakakis [PY] consider a large family of shortest path problems that operate with incomplete information. They describe algorithms that start at a source, search for the target, and learn about the environment as they progress. The complexity measure associated with such an algorithm is the ratio of the total distance traversed by the algorithm to the length of the shortest source–target path. Related work on exploring graphs with incomplete information is considered in [DP].

This measure is closely related to the concept of *competitive analysis*, introduced by Sleator and Tarjan [ST], which gives a worst case complexity measure for on-line algorithms. An *on-line algorithm* is an algorithm which must deal with a sequence of events, responding to events in real time without knowing what the future holds. The *competitive ratio* of an on-line algorithm A is defined as the supremum, over all sequences of events σ, and all possible (on- or off-line) algorithms ADV, of the ratio between the cost associated with A to deal with σ and the cost associated with ADV to deal with σ. We say that A is c-competitive if this supremum is at most c. (In some of the on-line literature, especially that dealing with paging and the k-server problem, from the cost of A on σ a constant additive term is subtracted, before dividing by the cost of ADV on σ. Where ambiguity might arise, we shall say that A is *strictly* c-competitive, meaning that the definition without an additive term is used.)

The *layered graph traversal problem* was introduced in [PY] and generalizes work of [BCR]. A *layered graph* is a connected graph in which the vertices are partitioned into sets $L_0 = \{s\}, L_1, L_2, L_3, ...$ and all edges run between L_{i-1} and L_i for some i. Each edge has a nonnegative integral weight. Vertex s is known as the *source*. Let $w = \max\{|L_i|\}$; w is called the *width* of the graph. An on-line layered graph traversal algorithm starts at the source and, without knowing w, moves along the edges of the graph, paying a cost equal to the weight of the edge traversed. Its goal is to reach the vertex t in the last layer known as the "target"; which vertex is the target is not revealed until the searcher occupies a vertex in the last layer.

Edges can be traversed in either direction, but the on-line algorithm pays whenever it crosses the edge. The edges between L_{i-1} and L_i, and their lengths, become known only when a node in L_{i-1} is reached.

We define the competitive ratio of a layered graph traversal algorithm to be the worst case ratio between the total distance traveled by the on-line algorithm and the length of the shortest source–target path. (If the algorithm is randomized, we use the expected distance it travels.) The competitive ratio of a layered graph traversal algorithm is given as a function of the width w.

A layered graph is said to consist of w *disjoint paths* if it is formed from w paths which are vertex disjoint except that each contains the common source. [BCR] gave optimal deterministic algorithms for all w with a competitive ratio which is asymptotic to $2ew$.

For arbitrary layered graphs, [PY] gave an optimal algorithm for width 2, with a competitive ratio of 9. It follows from [BCR] that $1 + 2w(1 + \frac{1}{w-1})^{w-1} \sim 2ew$ is a lower bound on the competitive ratio. Prior to this paper no other bounds were known.

Section 2 proves that general layered graphs of width w weighted with arbitrary nonnegative integers are no more difficult to traverse than width-w layered *trees* whose weights are $0-1$. Notice that if we know a lower bound on the smallest nonzero weight of an edge, then we can express the weights as multiples of this lower bound and round to the closest integer, thereby converting the problem with arbitrary nonnegative weights to one with integer weights. The competitive ratio is affected by at most a constant factor due to this conversion. This factor can be made arbitrarily close to one by taking the lower bound arbitrarily close to zero.

In sections 3 and 4 we give upper and lower bounds, exponential in w, on the competitive ratio for deterministic layered graph traversal.

- Section 3 gives an algorithm which attains a competitive ratio of $O(9^w)$ on layered graphs of width w. This algorithm does not need to know w in

advance and automatically adjusts itself to deal with the real width on hand.
- Section 4 proves that for all w, 2^{w-2} is a lower bound on the competitive ratio of any deterministic on-line layered graph traversal algorithm.

Thus arbitrary layered graphs are much harder to traverse than those consisting of disjoint paths.

Randomized on-line algorithms are addressed in several papers including [BLS, RS, CDRS, FKLMSY, BBKTW, KRR]. An oblivious adversary is one who constructs the sequence of events in advance and deals with the sequence optimally. For this adversary model [BLS] and [FKLMSY] give examples where randomization can improve the competitive ratio exponentially. This adversary models a world in which the on-line algorithm's actions do not themselves influence future events. One can consider a situation where the on-line algorithm's actions have a direct influence on the future. In such cases [BBKTW] showed that randomization cannot improve the competitive ratio more than polynomially. We deal with randomized layered graph traversal algorithms (assuming an oblivious adversary), and present the following results.

- Section 5 gives a randomized on-line algorithm for the disjoint path traversal problem. The competitive ratio is $O(\log w)$. We also show that this is optimal up to a constant factor. This is an exponential improvement over the bound for deterministic algorithms. This result immediately gives a randomized min operator [FRR] for on-line k-server algorithms: given a set of w possibly conflicting on-line strategies, a new on-line strategy can be devised which is no worse than $O(\log w)$ times the best of these strategies on every input.
- Section 6 gives a lower bound of $w/2$ on the competitive ratio of any randomized traversal algorithm for general layered graphs.

The problem of traversing layered graphs generalizes numerous on-line problems. For instance, metrical task systems (see [BLS]) can be modeled as layered graphs where layers represent tasks, and in each layer there is a node for each possible state. The k-server problem (see [MMS]), viewed in the servers' configuration space, is the problem of traversing the layered graph of permitted configurations for each request. Unfortunately, the width of this graph depends on the cardinality of the metric space, and not just on the number of servers, so layered graph techniques are inadequate for producing solutions to the k-server problem directly. However, the algorithm given in [BCR] for traversing layered graphs consisting of disjoint paths was used by [FRR] in their construction of competitive k-server algorithms.

As an additional example of the power of layered graph traversal as a tool for designing on-line algorithms, consider the problem of metrical service systems, suggested by [CL]. A single server moving among points of a metric space is presented with requests. Each request is a set of at most w points. One of these points is then selected by the on-line algorithm, and the server is moved to that point; the cost is the distance moved. [CL] gave a competitive metrical service system algorithm for uniform metric spaces and deterministic and randomized algorithms for all metric spaces for the case of $w = 2$. Note that the k-server problem can be reduced to the metrical service systems problem in the configuration space. Section 7 shows that the metrical service systems problem with requests of size w (in metric spaces with integral distances) is equivalent to the width-w layered graph traversal problem, when w is known in advance, in that a c_w-competitive algorithm exists for one problem if and only if one exists for the other. Related recent work appears in [FL].

2. Trees are sufficient. We first prove that given a competitive on-line algorithm for traversing width-w layered trees, in which each edge has a $0-1$ weight and each nonsource vertex has a neighbor in the previous layer, one can construct an on-line algorithm, with the same competitive ratio, for traversing arbitrary width-w layered graphs.

DEFINITION 1. *Let H be any layered graph with source s, and let v be a vertex in H in, say, layer L_j. Define H_v to be a shortest $s-v$ path in H which contains no vertex of $L_{j+1} \cup L_{j+2} \cup L_{j+3} \cup \cdots$ (if such a path exists).*

Let G be a layered graph of width at most w with nonnegative integral edge weights and with source s. We start by proving that an on-line algorithm traversing G can construct, on the fly, a layered tree T with the following properties.

1. A vertex v is in T's ith layer if and only if v is in G's ith layer and G_v exists.
2. For all v, the length of T_v is at most the length of G_v (if G_v exists).
3. Each nonsource vertex in T has exactly one neighbor in the previous layer. (We call such a tree *rooted*.)

Furthermore, any on-line traversal algorithm for T can be simulated on G without increasing the cost.

The tree $T = T(G)$ is defined by induction on the layer index i, starting from a one-node graph ($i = 0$). Let $i > 0$. For every v in G's ith layer L_i for which G_v exists, one vertex and one edge are added to T as follows. Let $u_0 = s$ and let $G_v = \langle u_0, u_1, u_2, \ldots, u_\ell, v\rangle$. Let u_k be the first vertex in G_v which is in layer L_{i-1}. Add to T vertex v and edge (u_k, v) with weight equal to the weight of the portion of G_v between u_k and v.

LEMMA 2. *For all v, the length of T_v is at most the length of G_v.*

Proof. The proof by induction on the index of the layer containing v.

Basis: $i = 0$. Trivial.

Inductive Step: $i > 0$. Assume correctness for $i-1$. Suppose that v is adjacent in T to u_k in T's $i-1$st layer. In path G_v, let a be the length of the prefix from s to u_k and let b be the length of the $u_k - v$ suffix. The length of T_v equals the length of T_{u_k} plus b. By the inductive hypothesis, the length of path T_{u_k} is at most the length of G_{u_k}, which is itself at most a. Therefore, the length of T_v is at most $a + b$, the length of G_v. ∎

Given an algorithm $\mathcal{A}$ to traverse T, we show how to traverse G without increasing the cost. Suppose that $\mathcal{A}$ moves in T from u in layer $i-1$ to v in layer i. The weight of the edge traversed in T is the length of a portion of G_v in G. This portion avoids layers $i+1, i+2, ...$, so the G-traversal algorithm can follow it. Similarly, if $\mathcal{A}$ moves from v in layer i to u in layer $i-1$, the G-traversal algorithm can traverse backward the corresponding portion of G_v.

A layered tree with arbitrary nonnegative integral weights can be converted to a layered tree with $0-1$ weights by inserting additional intermediate layers, on the fly.

3. A deterministic algorithm. Without loss of generality, we may assume that the original problem asks for a traversal algorithm for $0-1$, rooted, layered trees of arbitrary width, each having a target. Instead, for each w we will build a traversal algorithm A_w that maintains the following property. For each $0-1$ rooted tree T of width at most w without a target, for each i, the cost incurred by A_w on T between the start and the time it visits its first layer-i vertex is at most $8 \cdot 9^w$ times the length of a shortest path between s and any vertex of L_i.

We can easily solve the original problem via algorithms $A_1, A_2, ...$ We need only run A_j, starting with $j = 1$, until the width exceeds j, or until we reach some vertex in the same layer as the target. If, including the newly revealed layer, the width is $k > j$, we backtrack to the source and execute procedure A_k, starting at the source, forgetting everything we know about the graph. As soon as we learn that the layer we occupy contains the target, we backtrack to the source and then travel optimally to t. The total cost incurred by this algorithm on a width-w graph whose shortest source−target path is of length d is bounded by

$$d[8 \cdot 9^1 + 8 \cdot 9^2 + \cdots + 8 \cdot 9^w + (8 \cdot 9^w + 1)].$$

This is $O(9^w)$ times the source−target distance.

In order to define algorithms A_w, we need some terminology.

1. We refer to the time just after layer t and the edges from layer $t-1$ to t have been revealed as *time* t. The algorithm must move to a vertex in layer t after time t and before time $t+1$.

2. Vertex v is *active* at time t if it has a descendant in layer t. At time t, vertices in layer t are called *active leaves*.

3. At time t, $SP(v)$ denotes the length of the shortest path from v to a descendant of v in layer t (if v is active at time t).

Now we construct the algorithms. A_1 is the obvious algorithm. A_w for $w > 1$ is constructed from $A_1, A_2, A_3, ..., A_{w-1}$ as follows. Its execution is divided into phases. Within each phase, a vertex r, initially the source, is designated as the root for that entire phase. We will maintain the invariant that every path from the source to an active leaf passes through the root r. The searcher occupies r at the start of the phase. Furthermore, an integer d is fixed for the entire duration of the phase.

To start a phase, we let $d = SP(r)$. If $d = 0$, the searcher moves along length-0 edges from r, visiting all descendents of r at distance 0 from r (using, say DFS), then returning back to r, all at no cost.

At this point, $d = SP(r) \geq 1$ is fixed for the phase, and the searcher occupies r. If y is a descendant of x, let $d(x, y)$ denote the length of the unique $x - y$ path. At all times, let $S = \{s | s$ is an active descendant of r, $d(r, s) = d$, s's parent u satisfies $d(r, u) = d - 1$, and $SP(s) < d\}$. (A function of time, S may change many times within a phase to reflect its definition; however, d is defined once at the beginning of a phase and remains constant.) Because some active leaf is at distance exactly d from r at the start of a phase, $S \neq \emptyset$ at that time. Because the active leaf descendants of different $s \in S$ are distinct, $|S| \leq w$ always.

Let S_t denote the set S at time t. A phase ends as soon as either (1) there is an $x \in S_t$ such that at time t, x has w active leaf descendants, or (2) $S_t = \emptyset$. If either (1) or (2) occurs, the current phase ends at time $t - 1$, and a new phase, possibly with a new root, begins immediately afterward.

Each phase is divided into subphases. The start of a phase marks the beginning of its first subphase. A new subphase begins at a later time t if S_t is strictly smaller than S_{t-1}. (A phase may end in the middle of a subphase.) At the start of a subphase the searcher occupies the root r. He chooses an arbitrary $s \in S$ and at a cost of d moves from r to s. Where $z = |S|$, if $z = 1$, then the searcher executes procedure A_{w-1} with s as the root, and if $z \geq 2$, he executes procedure $A_{w-(z-1)}$ with s as the root.

When the subphase terminates, the searcher retraces all of his steps within that subphase back to r. This ensures that the searcher occupies r at the beginning of the next subphase.

If a phase terminates because of termination condition (1), i.e., there is an $x \in S_t$ such that the tree rooted at x has w active leaves, then $S_t = \{x\}$. In this case the searcher moves from r to x, a distance of d, and makes x the root for the next phase. If a phase terminates because of termination condition (2), i.e., $S_t = \emptyset$, the root remains the same vertex r. Notice that in this case, $SP(r)$ increased during the phase by at least d, so the next phase will begin with the new d at least double its value in the previous phase. This concludes the definition of A_w.

Analysis.

We state four easily proven facts.

FACT 3. *If $z = |S|$ at the beginning of a subphase which starts at s, then throughout that subphase the width of the subtree rooted at s is at most $w - (z-1)$.*

Proof. At any time during the subphase, each vertex in S has at least one active leaf as a descendant. Since $|S - \{s\}|$ equals $z-1$ during the subphase, s can have at most $w-(z-1)$ active leaf descendants at any time, and therefore the width of the subtree rooted at s cannot exceed $w-(z-1)$. ∎

FACT 4. *Within one phase, algorithm A_{w-1} is executed at most twice. For $i < w-1$, A_i is executed at most once within a phase. An invocation of A_i $(1 \le i \le w-1)$ starting at vertex s terminates with $SP(s) \le d$.*

Proof. For a given z, only one recursive call is made while $|S| = z$. For $z \le 2$, A_w calls A_{w-1}. A_i for $i < w-1$ can be called by A_w only if $z = w - i + 1$. As soon as $SP(s) \ge d$, s is evicted from S and the subphase terminates (if not before). ∎

FACT 5. *If a phase ends because of phase termination condition (1), i.e., there is an $x \in S$ such that the tree rooted at x has w active leaves, then the new root x satisfies $d(source, x) = d(source, r) + d$, and, at the phase end, every source$-$active leaf path passes through x.*

Proof. Since $x \in S$ implies that x is a descendant of r satisfying $d(r,x) = d$, clearly $d(source, x) = d(source, r) + d$. And if the tree rooted at x has w active leaves when a phase ends, the width bound of w implies that from that time onward every source–leaf path contains x. ∎

FACT 6. *If condition (2) triggers the end of a phase, then the length of a shortest path from the source to an active leaf is at least d greater at the end of the phase than at the end of the previous phase.*

Proof. When the phase starts, $SP(r) = d$. If $S = \emptyset$ at the phase end, then every vertex originally in S has been evicted from S. All vertices in S at the beginning of the phase evicted by reason of inactivity are inactive at the end of the phase.

If y is any active leaf at the phase end, on the $r - y$ path there must be a vertex x closest to r such that $d(r,x) = d$. The only possible reason why this active vertex is not in S at the end of the phase is that $SP(x) \ge d$ at the end. Therefore, $d(r,y) = d(r,x) + d(x,y) \ge d + d = 2d$ and $SP(r) \ge 2d$ at the end of the phase. ∎

THEOREM 7. *For each w, for each rooted $0-1$ tree T of width at most w, the cost incurred by A_w on T is at most $8 \cdot 9^w$ times the length of a shortest path from the source to a vertex in the highest-numbered layer.*

Proof. We prove the statement by induction on w. For $w = 1$ the statement is clear.

Let $w > 1$. At the start of a phase rooted at, say, r, the searcher occupies r. It incurs no cost until every path from r to an active leaf has positive cost. Moving from r to the designated s costs d. Within a subphase, let z denote $|S|$ at the beginning of the subphase. If $z \ge 2$, algorithm $A_{w-(z-1)}$ is invoked, and by Fact 3 the width of the tree on which $A_{w-(z-1)}$ is invoked does not exceed $w-(z-1)$ during the subphase. A_{w-1}

is invoked if $z = 1$, but the width cannot exceed $w - 1$ during the subphase—for if it did, the tree rooted at s would have w active leaves and phase termination condition (1) would hold, thereby aborting the current phase (and subphase). Furthermore, within a subphase which starts at s, $SP(s)$ cannot exceed $d - 1$. If it did, s would be evicted from S.

By the inductive hypothesis, if $z > 1$ at the start of the subphase, the cost incurred during this subphase is bounded by d (the cost of moving from r to s), plus $8 \cdot 9^{w-(z-1)}d$, plus the cost of backtracking to s and then to r, a total of at most $d + 2(8 \cdot 9^{w-(z-1)}d) + d$. If instead $z = 1$, the cost is at most $2d + 16 \cdot 9^{w-1}d$. There is an additional cost of d at the end of a phase if we move the root forward.

By Fact 4, the total cost in a phase is at most

$$d + \sum_{z=2}^{w}(2d + 16 \cdot 9^{w-(z-1)}d) + (2d + 16 \cdot 9^{w-1}d)$$

$$= (2w + 1)d + 16d[(9 + 9^2 + 9^3 + \cdots + 9^{w-2} + 9^{w-1}) + 9^{w-1}]$$

$$= (2w + 1)d + 16d\left[\frac{9^w - 9}{8} + 9^{w-1}\right]$$

$$< 2wd + 16d\left[\frac{17}{72} \cdot 9^w\right]$$

$$= d\left[2w + \frac{34}{9} \cdot 9^w\right]$$

$$\leq d\left[\frac{2}{9} \cdot 9^w + \frac{34}{9} \cdot 9^w\right] = 4d \cdot 9^w.$$

Suppose v is of minimum distance from the root among those vertices in the jth and final layer. For the analysis alone, add w dummy children to v via length-0 edges. At time $i+1$, v has w active leaf descendants. Thus either $d = 0$ in the current phase, or one vertex $x \in S$ has w active leaf descendants. Hence either $d = 0$, or a phase ends at time j and x becomes the new root. In either case, we can study the cost incurred during *complete* phases.

At all times, define Φ to be the distance from the source to the current root r. Define Ψ to be the length of a shortest path from the source to an active leaf; $\Psi = \Phi + SP(r)$. In a phase, either Φ increases by d, if (1) terminated the phase, or if (2) ended the phase, Ψ increases by at least d. Thus $\Phi + \Psi$ increases within a phase by at least d, and neither Φ nor Ψ ever decreases. It follows that the cost incurred by A_w to visit some vertex in L_i is at most $4 \cdot 9^w$ times the final value of $\Phi + \Psi$, which is at most twice the final value of Ψ. Therefore, A_w is $8 \cdot 9^w$-competitive. □

4. A lower bound for deterministic algorithms. Fix a competitive deterministic layered graph algorithm A for arbitrary layered graphs. A traces out a path in each layered graph. We construct a layered tree that forces A to perform poorly. Figure 1 illustrates the lower bound construction. The construction is recursive. The

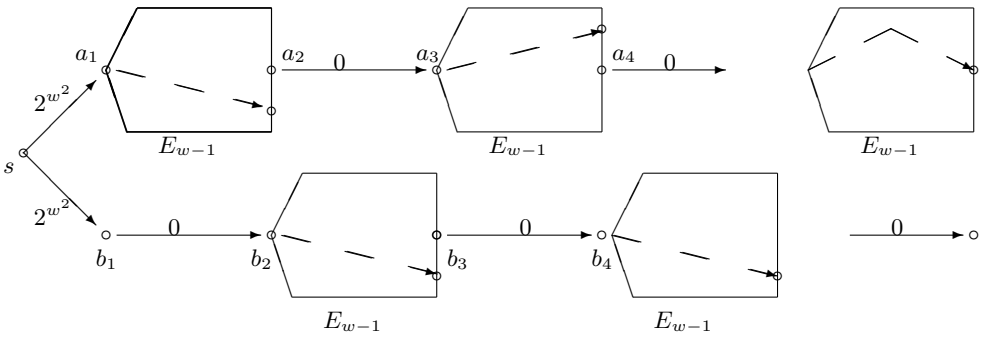

FIG. 1. *Deterministic lower bound.*

idea is that A is forced to move back and forth between the two subtrees attached to the source s, thus incurring a large cost compared with the shortest path to the target.

DEFINITION 8. *Let H be a layered tree. Suppose that $v \in L_{i-1} \neq \emptyset$ is the vertex visited by A at time i.*

1. *Define $T(v)$ to be the minimum $j > i$, if any, such that A visits a nondescendant of v at time j.*

2. *Define $L(v)$ to be the length of a shortest path from v to a descendant of v in layer $T(v)$ (if $T(v)$ and any descendants in layer $T(v)$ exist).*

3. *Define $C(v)$ to be the cost incurred by A from the time when v is first visited until the path traced out by A first exits the subtree rooted at v (if ever). This is exactly the cost incurred by A at times $i+1, i+2, ..., T(v)-1$, plus the portion of the cost incurred at time $T(v)$ attributable to edges in the subgraph rooted at v.*

LEMMA 9. *Let $w \geq 1$. Let H be a layered tree of height i, say, and arbitrary width, with at least two vertices in the ith layer, and let s be the leaf in layer i visited by A. Then there is an infinite rooted tree E_w of width at most w with these properties.*

1. *The root of E_w has $\min\{2, w\}$ children. The edge(s) out of the root are of length 2^{w^2}.*

2. *If E_w is attached to vertex s and an infinite path of length 0 is attached to all other vertices in the ith layer of H, then for this new infinite tree, $L(s)$ exists and $C(s) \geq 2^{w-1}(L(s) - 2^{w^2})$.*

Proof. The proof is by induction on w. Let $w = 1$ and let H be a tree with at least two leaves. If we attach to s an infinite path of edges of length $2^{1^2} = 2$ and attach infinite paths of length 0 to other vertices in the last layer, because A is competitive, $T(s)$ must exist. $C(s) \geq L(s) - 2$. So, clearly, $C(s) \geq 2^{1-1}(L(s) - 2^{1^2})$.

Let $w \geq 2$. Let H be a layered tree and let $s \in L_i$ be visited by A, where $L_{i+1} = \emptyset$ and $|L_i| \geq 2$. Attach to s two children a_1, b_1 via edges of length 2^{w^2}. Add to all other vertices in L_i an edge of length 0.

If A occupies neither a_1 nor b_1 at time $i+1$, then $T(s) = i+1$, $L(s) = 2^{w^2}$, and $C(s) = 0$, so clearly $C(s) \geq 2^{w-1}(L(s) - 2^{w^2})$.

So we may suppose without loss of generality that A visits a_1 at time $i+1$. By induction, there is an infinite tree E_{w-1} of width at most $w-1$ such that if a_1 is extended by E_{w-1} and all other leaves are extended by infinite paths of length 0,

$$C(a_1) \geq 2^{w-2}(L(a_1) - 2^{(w-1)^2}).$$

At time $T(a_1)$, A occupies either a descendant of b_1 or a nondescendant of s. Suppose A occupies a descendant b_2 of b_1. Choose a descendant of a_1 in layer $T(a_1)$ of minimum distance from a_1. Call it a_2. (Such a descendant exists because E_{w-1} is infinite.) "Kill" all other descendants of a_1 in layer $T(a_1)$, i.e., mark them as inactive. They will have no children. Now "truncate" the entire infinite tree to level $T(a_1)$ by removing all vertices in layers $T(a_1)+1, T(a_1)+2, T(a_1)+3, \ldots$.

By the inductive assertion we can find a new infinite tree E'_{w-1} of width at most $w-1$ so that if E'_{w-1} is attached to b_2 and all other vertices in layer $T(a_1)$ (including a_2 but no other descendants of a_1) are extended by 0-length infinite paths, $C(b_2) \geq 2^{w-2}(L(b_2) - 2^{(w-1)^2})$. Now truncate the tree to level $T(b_2)$ by eliminating all vertices in layers $T(b_2)+1, T(b_2)+2, T(b_2)+3, \ldots$. At time $T(b_2)$, A occupies either a descendant a_3 of a_2 or a nondescendant of s. If A occupies a descendant a_3 of a_2 we attach a new infinite tree E''_{w-1} to a_3 and "kill" all descendants of b_2 in layer $T(b_2)$ except for one descendant b_3 of minimum distance from b_2.

This process continues until at some point A visits a nondescendant of s. This must happen eventually, because there is at least one infinite 0-path. Since each stage adds at least 2^{w^2} to A's cost, every competitive algorithm must eventually switch at some time $T(s)$ to a nondescendant of s.

Suppose that the algorithm has constructed $a_1, b_1, a_2, b_2, \ldots, a_k, b_k$ but neither a_{k+1} nor b_{k+1}. Thus A visits either a_k or b_k but exits the subtree rooted at s at time $T(a_k)$ or $T(b_k)$, whichever is defined.

Claim. $C(s)$ increases by at least

$$2^{w^2} + 2^{w-2}(L(a_i) - 2^{(w-1)^2}) \geq 2^{w-2}L(a_i)$$

between the time when A occupies a_i and time $T(a_i)$. Similarly, between the time when A occupies b_i and time $T(b_i)$, $C(s)$ increases by at least

$$2^{w^2} + 2^{w-2}(L(b_i) - 2^{(w-1)^2}) \geq 2^{w-2}L(b_i).$$

Proof of Claim. In moving from a_i to a nondescendant of a_i, A incurs a cost of at least 2^{w^2} on the edges out of s. On the edges in the subtree rooted at a_i, A incurs a cost of

$$C(a_i) \geq 2^{w-2}(L(a_i) - 2^{(w-1)^2})$$

by the inductive case of the theorem. The proof of the second statement is similar.

But if

$$\alpha = L(a_1) + L(a_3) + L(a_5) + \cdots$$

and

$$\beta = L(b_2) + L(b_4) + L(b_6) + \cdots,$$

then

$$L(s) = 2^{w^2} + \min\{\alpha, \beta\}.$$

Thus $C(s) \geq 2^{w-2}(\alpha+\beta) \geq 2^{w-1}\min\{\alpha,\beta\} = 2^{w-1}(L(s) - 2^{w^2})$. Now make the tree infinite, as required, by attaching infinite length-0 paths to each leaf in the final layer. □

Now we prove a lower bound of 2^{w-2} on the competitive ratio.

THEOREM 10. *If A is a layered graph traversal algorithm, then its competitive ratio on width-w graphs is at least 2^{w-2}.*

Proof. We may assume $w \geq 2$. Let s be a source with two children a_1 and b_1 via edges of length 2^{w^2}. Suppose A moves from s to a_1. As in Lemma 9, we can attach to a_1 an infinite tree E_{w-1} of width at most $w-1$ such that $C(a_1) \geq 2^{w-2}(L(a_1) - 2^{(w-1)^2})$ if b_1 is extended by an infinite path of length 0. At time $T(a_1)$, A occupies a descendant b_2 of b_1. Truncate the tree to height $T(a_1)$. Let a_2 be a descendant of a_1 in layer $T(a_1)$, of minimum distance from a_1. All descendants of a_1 in layer $T(a_1)$, other than a_2, will have no children. Now attach to b_2 an infinite tree E'_{w-1}, as in Lemma 9, and to a_2 attach an infinite length-0 path

$$C(b_2) \geq 2^{w-2}(L(b_2) - 2^{(w-1)^2}).$$

At time $T(b_2)$, A occupies a descendant a_3 of a_2. Truncate the tree to height $T(b_2)$. Let b_3 be a descendant of b_2 in layer $T(b_2)$, of minimum distance from b_2. All descendants of b_2 in layer $T(b_2)$, other than b_3, will get no children.

Repeat this process *ad infinitum*. Each pair of additions increases the length of the shortest root−active-leaf path by at least $2^{(w-1)^2}$. Eventually we reach a situation in which we have constructed $a_1, b_1, a_2, b_2, ..., a_k, b_k$ so that if

$$\alpha = L(a_1) + L(a_3) + L(a_5) + \cdots$$

and

$$\beta = L(b_2) + L(b_4) + L(b_6) + \cdots,$$

then $\min\{\alpha, \beta\} \geq 2^{w^2}$. By the claim embedded in the proof of Lemma 9, by that time A's cost is at least

$$2^{w-2}(\alpha + \beta) \geq 2^{w-1} \min\{\alpha, \beta\}.$$

The adversary's cost is

$$2^{w^2} + \min\{\alpha, \beta\} \leq 2 \min\{\alpha, \beta\}.$$

Therefore the competitive ratio is at least

$$\frac{2^{w-1} \min\{\alpha, \beta\}}{2 \min\{\alpha, \beta\}} = 2^{w-2}. \qquad \square$$

5. Disjoint paths. Let L be a layered graph which consists of a set of disjoint paths except that they share the common source. Each edge has a $0-1$ length.

We define the algorithm in phases. At the beginning, while some path has length 0, the algorithm simply chooses such a path and follows it until, if ever, its length increases. It then switches to another path of length 0, and follows that one until its length increases. This continues until all paths have positive length. Then the first phase begins.

In the kth phase ($k = 1, 2, ...$), the length of the shortest path from the source to the current layer lies in the interval $I_k = [2^{k-1}, 2^k)$. At the start of phase k the algorithm chooses a path randomly and uniformly from among those paths of length in I_k running from the source to the current layer. It then backtracks through the

source to the current layer on the chosen path, incurring a cost of at most $2 \cdot 2^k$ in the process.

Whatever path the algorithm is following in phase k, it blindly continues to follow that path until its length reaches 2^k. Whenever the length of the current path reaches 2^k, the algorithm replaces it by a path chosen randomly from those paths of length less than 2^k—if any exist—backtracking through the source and incurring a cost of at most $2 \cdot 2^k$ in the process. A new phase begins and k is incremented as soon as every path has length at least 2^k.

Analysis.

Our initial backtracking cost at the start of a phase is at most $2 \cdot 2^k$. If E_w is an upper bound on the expected number of times the algorithm switches paths within any phase, then the expected cost within phase k is at most $2^{k+1}+E_w 2^{k+1} = 2^{k+1}(1+E_w)$. Let ℓ denote the number of phases. Our total expected cost is bounded above by $(1+E_w)\sum_{k=1}^{\ell} 2^{k+1} < (1+E_w)2^{\ell+2}$. The adversary's cost is at least $2^{\ell-1}$, giving us a competitive ratio bounded by $8+8E_w$. We show that we can take $E_w = H_w = 1+\frac{1}{2}+\frac{1}{3}+\cdots+\frac{1}{w} \sim \ln w$.

We now describe a probabilistic game which models the path selection process in a phase. Let S be a set of size n. There are two players A and B. Initially B randomly and uniformly picks one element, hiding his choice from A. At each step A chooses one element of S and removes it from S. Whenever A discards the element selected by B, B pays A \$1 and B uniformly at random picks a new item (if S is still nonempty).

We prove that the expected cost F_n incurred by B is exactly H_n. Clearly, $F_1 = 1$, and for $n \geq 2$, F_n satisfies

$$F_n = \frac{1}{n}(1+F_{n-1}) + \frac{1}{n}(1+F_{n-2}) + \frac{1}{n}(1+F_{n-3}) + \cdots + \frac{1}{n}(1+F_1) + \frac{1}{n}(1+0).$$

This recurrence and the fact that $F_1 = 1$ imply that $F_n = H_n$ for all n since

$$F_n = 1 + \frac{1}{n}(F_1 + F_2 + F_3 + \cdots + F_{n-1}).$$

Thus

$$nF_n = n + (F_1 + F_2 + \cdots + F_{n-1})$$

and

$$(n-1)F_{n-1} = (n-1) + (F_1 + F_2 + \cdots + F_{n-2}),$$

if $n \geq 3$, so

$$nF_n - (n-1)F_{n-1} = 1 + F_{n-1}.$$

Therefore, for $n \geq 3$, $n(F_n - F_{n-1}) = 1$ and $F_n = F_{n-1} + 1/n$. Since $F_2 = 3/2$, it follows that $F_n = H_n$ for all n.

The connection between the experiment and layered graph traversal.

A corresponds to the adversary and B corresponds to the algorithm. Each element in the set is associated with a path in the layered graph of length less than 2^k at the beginning of the kth phase. A discards an element from the set when the length of the corresponding path reaches 2^k. He pays \$1 every time this happens. The expected

number of times B backtracks is at most the expected cost to B of the game above. Thus we may take $E_w = H_w$. We have proven the following theorem.

THEOREM 11. *The competitive ratio of the randomized algorithm above for traversing disjoint paths is at most* $8 + 8H_w$.

A lower bound.

THEOREM 12. *Let w and M be any positive integers. For any randomized on-line algorithm A for traversing disjoint paths of width at most w, there is a width-w layered graph for which the length of the shortest source−target path is M, but on which A's expected cost is at least $M(2H_w - 1)$.*

Proof. Each path in the width-w layered graph begins with M unit-cost edges. For a layered graph that begins this way, at time M there is at least one layer-M vertex which is occupied by the searcher with probability at least $1/w$. We give that vertex no children, but to every other layer-M vertex we give a child via a length-0 edge. At time $M + 1$, at least one of the $w - 1$ layer-$(M + 1)$ vertices is occupied by the searcher with probability at least $1/(w - 1)$. We add a length-0 edge to layer $M + 2$ from every layer-$(M + 1)$ vertex but that one. That one dies. We repeat this process for layers $M+2, M+3, ..., M+(w-1)$; in layer $M+i$ there are exactly $w-i$ vertices, $i = 0, 1, 2, ..., w-1$. The unique vertex in layer $M+w-1$ is the target. The expected cost incurred by A is bounded below by M plus $2M$ times the sum, over each leaf in the graph other than the target, of the probability that A visits that leaf. This sum of probabilities is $\frac{1}{w} + \frac{1}{w-1} + \frac{1}{w-2} + \cdots + \frac{1}{2} = H_w - 1$. The total expected cost is hence at least $M(1 + 2(H_w - 1)) = (2H_w - 1)M$. □

6. A randomized lower bound. Now we return to general layered graphs. Fix an integer $m \geq 2$. Let $r_w = w(1 - 1/m)$ for all w.

By induction on w, we construct for each w a probability distribution $\mathcal{G}(w)$ on a finite family of layered graphs of width w. Every graph drawn from $\mathcal{G}(w)$ has a designated vertex as the root and another as the target; the target is the unique vertex in the final layer. From the inductive construction it will be easy to verify that the following quantities depend only on w and m:

- the length L_w of the shortest root−target path in the graph,
- the sum S_w of the edge lengths,
- the number F_w of layers, excluding L_0 (the layer containing the source).

Let $E_w = 2S_wF_w$. It is clear that this is an upper bound on the distance traversed by any algorithm when it traverses any layered graph drawn from $\mathcal{G}(w)$.

Now we construct the probability distributions. See Figure 2.

Basis: $w = 1$. With probability 1 we draw a single edge (s, t) of length 1 with s the root and t the target.

Inductive Step: $w > 1$. We start with a vertex designated as the root, say s. To s we attach two edges $(s, u_1), (s, l_1)$ of length $(1/2)E_{w-1}$ each. We now construct the graph in stages. For stage 1 we draw a copy H_1 from $\mathcal{G}(w - 1)$ and attach it to u_1 (i.e., make u_1 the root of this copy). The target of H_1 we call u_2. H_1 has F_{w-1} layers of nonsource vertices in it. For these F_{w-1} layers we extend l_1 by a path of F_{w-1} length-0 edges ending at l_2. For stage 2, we extend l_2 by independently drawing a graph H_2 from $\mathcal{G}(w - 1)$, and we extend u_2 by a path of F_{w-1} length-0 edges. We continue this pattern for $N = N_w = mr_{w-1}E_{w-1}$ stages (N is an even integer). In the ith stage, for i odd, we independently select a graph H_i as in stage 1, and for i even, we choose H_i independently as in stage 2. In the last layer we have vertices

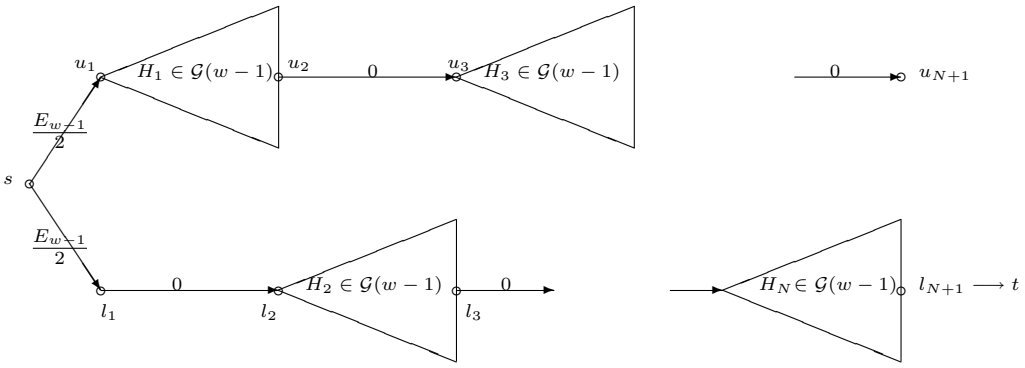

FIG. 2. *Randomized lower bound.*

u_{N+1} and l_{N+1}. We toss a coin and equiprobably choose one. It gets a child, the target, via a length-0 edge; the other gets none. This completes the construction.

LEMMA 13. *For all positive integers w, for all deterministic algorithms A_w designed to traverse graphs drawn from $\mathcal{G}(w)$, the expected cost of A_w to traverse a graph drawn randomly from $\mathcal{G}(w)$ is at least $r_w L_w$.*

Proof. The proof is by induction on w. The $w = 1$ case is trivial.

Let $w \geq 2$. Choose a deterministic algorithm A_w for graphs drawn from $\mathcal{G}(w)$.

Within this proof, we imagine that the random graph H is generated "on the fly"; i.e., only when the searcher reaches either u_i or l_i, for i odd, are the two graphs for stages i and $i+1$ drawn from $\mathcal{G}(w-1)$, and only then are stages i and $i+1$ of H built. This makes no difference, since A_w is on-line and its behavior cannot depend on the future.

Pick an odd $i < N$. At the end of stage $i-1$, the searcher occupies either u_i or l_i. Let J be a graph having $i-1$ stages that induces the searcher to occupy u_i at the end of stage $i-1$ (if possible). Now define an algorithm A_{w-1} (dependent on J) for traversing graphs drawn from $\mathcal{G}(w-1)$, as follows. A_{w-1} mimics A_w in the graph drawn from $\mathcal{G}(w-1)$ in the F_{w-1} layers succeeding u_i, until, if ever, A_w backtracks through s to a nondescendant of u_i. At this point, A_{w-1} blindly marches ahead in a naive way, until u_{i+1} is reached.

The cost of backtracking through s is so large that the cost incurred by A_w in the $2F_{w-1}$ layers succeeding u_i, given that the first $i-1$ stages equal J, is at least the cost of A_{w-1} on those same layers. The inductive hypothesis now implies that the expected cost of A_w in the $2F_{w-1}$ layers succeeding u_i, given J, is at least $r_{w-1}L_{w-1}$.

Now choose an $i-1$-stage graph J', if possible, so that A_w occupies l_i at the end of stage $i-1$. A similar argument implies that the conditional expected cost incurred by A_w in the $2F_{w-1}$ layers succeeding l_i, given that the first $i-1$ stages of H equal J', is at least $r_{w-1}L_{w-1}$. It follows that the (unconditional) expected cost incurred by A_w in progressing from either u_i or l_i to either u_{i+2} or l_{i+2} is at least $r_{w-1}L_{w-1}$.

At the end of stage N, we flip a coin to decide which vertex, u_{N+1} or l_{N+1}, becomes the parent of the target. With probability $1/2$, the searcher must backtrack through s to the target. Thus it incurs an additional expected cost of at least $(1/2)(NL_{w-1} + E_{w-1})$. The total expected cost divided by L_w is at least

$$\begin{aligned}
&\frac{(N/2)r_{w-1}L_{w-1} + (1/2)(NL_{w-1} + E_{w-1})}{(1/2)E_{w-1} + (N/2)L_{w-1}} \\
&= \frac{(N/2)r_{w-1}L_{w-1} + (1/2)r_{w-1}E_{w-1} + (1/2)(NL_{w-1} + E_{w-1}) - (1/2)r_{w-1}E_{w-1}}{(1/2)E_{w-1} + (N/2)L_{w-1}} \\
&= (r_{w-1} + 1) - \frac{(1/2)r_{w-1}E_{w-1}}{(1/2)E_{w-1} + (N/2)L_{w-1}} \\
&\geq (r_{w-1} + 1) - \frac{(1/2)r_{w-1}E_{w-1}}{(N/2)L_{w-1}} \\
&\geq r_{w-1} + 1 - \frac{r_{w-1}E_{w-1}}{N} \\
&= r_{w-1} + (1 - 1/m). \qquad \square
\end{aligned}$$

Now we prove the following theorem.

THEOREM 14. *For every positive integer w, for every randomized algorithm $\mathcal{B}$ for traversing graphs drawn from $\mathcal{G}(w)$, there exists a layered graph K of width at most w such that the ratio of the expected distance traversed by $\mathcal{B}$ to the length of the shortest root−target path in K is at least r_w.*

Proof. The proof follows Yao's observation regarding the minimax principle [Yao]. Choose a randomized algorithm $\mathcal{B}$ and a width w. Lemma 13 implies that the expected cost incurred by every deterministic algorithm $\mathcal{A}$ on a graph drawn randomly from $\mathcal{G}(w)$ is at least $r_w L_w$. However, $\mathcal{B}$ is nothing more than a probability distribution on deterministic algorithms. It follows that the expected cost of $\mathcal{B}$ on a graph drawn randomly from $\mathcal{G}(w)$ is at least $r_w L_w$. It follows that on some graph K assigned positive probability under $\mathcal{G}(w)$, $\mathcal{B}$'s expected cost is at least $r_w L_w$. But the source−target distance in K is L_w. $\square$

7. Metrical service systems. In the following section, w-MSS abbreviates "metrical service systems with requests of size at most w," w-LGT abbreviates "traversal of layered graphs of width at most w," and w-LTT abbreviates "traversal of $0-1$ rooted layered trees of width at most w." (Notice that w-LGT and w-LTT algorithms traverse only graphs of width at most w.)

LEMMA 15. *If A is a c_w-competitive algorithm for w-LGT, then there exist strictly c_w-competitive on-line algorithms for w-MSS in all metric spaces with integral distances.*

Proof. Fix a metric space where the distances are integral. Given a sequence of w-MSS requests, we construct, in an on-line manner, a layered graph. Layer 0 contains a single vertex, which is the starting point of the server. The vertices of layer $i > 0$ are the points of the ith request. For every $i \geq 0$, every vertex of layer i is connected to every vertex of layer $i + 1$ by an edge of weight equal to the distance between the two points. Apply the w-LGT algorithm A to this graph. When A first encounters layer i, it chooses a vertex in that layer to move to. The w-MSS algorithm serves the ith request by moving to that point. $\square$

DEFINITION 16. *Let I be an infinite rooted layered tree in which each vertex has $2w$ children. Let r denote the root of I. Let $\mathcal{M}$ be an infinite metric space whose underlying set is $V(I)$ and in which the distance between u and v is the length of the $u - v$ path in I.*

LEMMA 17. *Let B be a strictly c_w-competitive w-MSS algorithm for the infinite metric space $\mathcal{M}$. Then there exists a c_w-competitive on-line w-LTT algorithm A (and therefore one for w-LGT).*

Proof. Let T be an instance of the w-LTT problem. Let s be the source vertex of T, initially occupied by the searcher. We use B to define algorithm A which traverses T as follows. From the, say, $l_i \leq w$ vertices $v_1^i, v_2^i, ..., v_{l_i}^i$ in the ith layer of T, we construct, on-the-fly, a sequence $p_1^i, p_2^i, ..., p_{l_i}^i$ of l_i vertices of the metric space $\mathcal{M}$ (p_j^i "representing" v_j^i), and then present the set $\{p_1^i, p_2^i, ..., p_{l_i}^i\}$ as a request of $l_i \leq w$ points to B. B will choose one of the points, say, p_j^i, to move to. We stipulate, then, that A moves to v_j^i.

Let us start by defining $v_1^0 := s$, the source vertex of T. Representing v_1^0 is $p_1^0 := r$, the root of I. A starts on the node $p = p_1^0$.

At a generic time, A will occupy some node in, say, layer i of the layered graph. When layer $i+1$ is revealed, we must choose request $i+1$ in $\mathcal{M}$, the response to which tells to which node of layer $i+1$ A should move. This is done as follows. Let the $l_{i+1} \leq w$ nodes of the $i+1$st layer of T be $v_1^{i+1}, v_2^{i+1}, ..., v_{l_{i+1}}^{i+1}$. Look at the edge between a node v_j^{i+1} in the $i+1$st layer and its parent called, say, v_k^i. If the edge between v_j^{i+1} and its parent v_k^i is of weight 0, then we represent v_j^{i+1} by the same node p_k^i that represented its parent: $p_j^{i+1} := p_k^i$. If, on the other hand, the edge from v_j^{i+1} to its parent v_k^i is of weight 1, then we choose a child of p_k^i to represent v_j^{i+1}: we choose, among the $2w$ children of p_k^i, a child which is the root of a subtree in I containing no representative of a vertex in the ith (previous) layer and also containing no representative (so far) of a vertex in layer $i+1$. (Since there are at most $2w$ nodes in layers i and $i+1$, the $2w$ children of p_k^i suffice.) This child is then p_j^{i+1}.

It remains to show that for any two consecutive layers, the distance in T between any pair of vertices contained in those two layers is equal to the distance in I between their representatives. Consider any two consecutive layers numbered i and $i+1$. The proof is by induction on i. The case of $i = 0$ is easy and the proof is omitted. Now consider $i > 0$. Notice that by the inductive hypothesis the claim is true if both vertices in the pair are taken from the ith layer. As we generate the representatives for the vertices in the $i+1$st layer, we check the distances between the representatives and the representatives of vertices in the ith layer, and the distances between their representatives and the representatives already created for vertices in layer $i+1$. Consider a particular vertex v_j^{i+1} of the $i+1$st layer. If the distance to its parent v_k^i in T is 0, then, as described above, we have $p_j^{i+1} = p_k^i$, which is the representative of its parent. Since p_k^i has already been considered in the current step of the induction, the claim trivially holds. If the distance between v_j^{i+1} and v_k^i is 1, the choice of p_j^{i+1} guarantees that its distance to any representative q of a vertex in layer $i+1$ which was already considered in the current step of the induction, or of a vertex in layer i, is exactly the distance between p_k^i and q, plus 1. Thus, the claim holds in this case as well.

Therefore we conclude that at each step, the distance traversed by the w-MSS server is equal to the distance traversed by the w-LTT searcher. We also conclude that the optimal costs for both instances are the same (since an optimal path for one induces a path for the other with the same cost). This completes the proof of the lemma. □

Lemmas 15 and 17 give the following result.

THEOREM 18. *For each w, strictly c_w-competitive, deterministic or randomized algorithms exist for w-MSS for all metric spaces with integral distances if and only if a c_w-competitive, deterministic or randomized algorithm, respectively, exists for w-LGT.*

8. Concluding remarks. An obvious open problem is to close the gap between the upper bound and the lower bound for deterministic and randomized layered graph traversal. Of special interest is the question of designing an efficient randomized traversal algorithm. In an earlier version of this paper, we conjectured that a polynomial upper bound is achievable by the use of randomization. Since then, this conjecture has been proven by Ramesh [Ram], who gives an $O(w^{13})$-competitive randomized algorithm. Ramesh has also reported improvements in the deterministic upper bounds (to $O(w^3 2^w)$) and in the randomized lower bounds (to a nearly quadratic bound). Burley [Bur] recently further improved the deterministic upper bound to $O(w2^w)$ via an algorithm for metrical service systems.

ON MULTIRATE REARRANGEABLE CLOS NETWORKS*

D. Z. DU†, B. GAO‡, F. K. HWANG§, AND J. H. KIM¶

Abstract. In the multirate switching environment each (connection) request is associated with a bandwidth weight. We consider a three-stage Clos network and assume that each link has a capacity of one (after normalization). The network is rearrangeable if for all possible sets of requests such that each input and output link generates a total weight not exceeding one, there always exists a set of paths, one for each request, such that the sum of weights of all paths going through a link does not exceed the link capacity. The question is to determine the minimum number of center switches which guarantees rearrangeability. We obtain a lower bound of $11n/9$ and an upper bound of $41n/16$. We then extend the result for the three-stage Clos network to the multistage Clos network. Finally, we propose the weighted version of the edge-coloring problem, which somehow has escaped the literature, associated with our switching network problem.

1. Introduction.

Let $C(n, m, r)$ denote a symmetric three-stage Clos network satisfying the following conditions.

1. Each of the *input* (first) and *output* (third) stage consists of r $n \times m$ crossbars. The *center* (second) stage consists of m $r \times r$ crossbars.
2. There exists one link between every center switch and every input (output) switch. No link exists between any other pair of switches.

A $C(2, 3, 4)$ is illustrated in Figure 1.

The inlets (outlets) of the input (output) switches are the *inputs (outputs)* of the network. Inputs and outputs are referred to as *external links*, while links between switches are referred to as *internal links*. When $C(n, m, r)$ is used in the multirate environment, each connection is associated with a weight which can be thought of as the bandwidth requirement of that connection. A link can carry any number of connections as long as the *load*, total weight of these connections, does not exceed the link capacity. It is commonly assumed that links have uniform capacity which is normalized to be unity.

A (connection) *request* is a triple (x, y, w) where x is an inlet, y an outlet, and w the weight. A *request frame* is a collection of requests such that the total weight of all requests in the frame involving a fixed inlet or outlet does not exceed unity. To discuss routing it is convenient to assume that all links are directed from left to right. Thus a *path* from an inlet to any outlet always consists of the sequence: an inlet link → an input switch → a link → a center switch → a link → an output switch → an outlet link. Furthermore, since the crossbar is assumed to be nonblocking with fan-in and fan-out properties, a request (x, y, w) is *routable* if and only if there exists a path

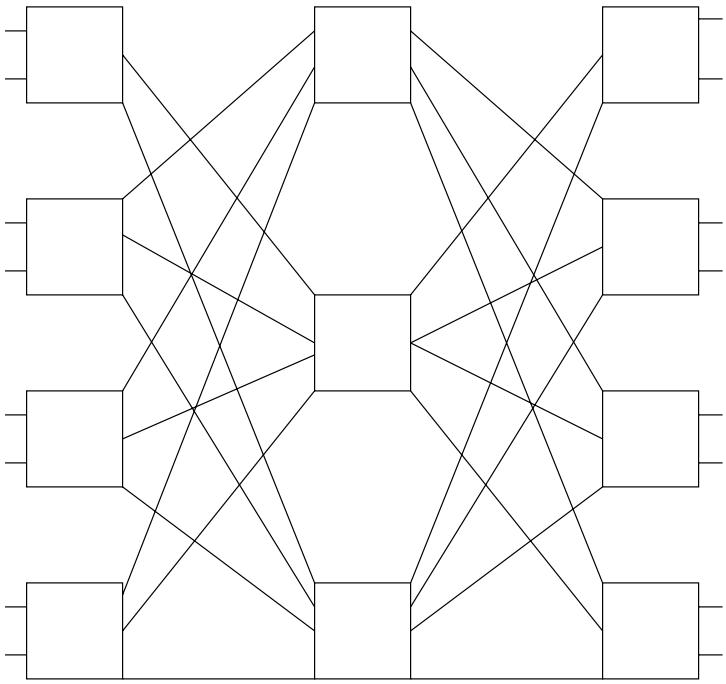

FIG. 1. $C(2,3,4)$.

from x to y such that every link on this path has unused capacity at least $1-w$ before carrying out this request. A request frame is routable if there exists a set of paths, one for each request, such that for every link the sum of weights of all requests going through it does not exceed unity. $C(n,m,r)$ is called *rearrangeable* if every request frame is routable.

Let $M(n,r)$ denote the minimum value of m such that $C(n,m,r)$ is rearrangeable for given n and r. In this paper we prove that $11n/9 \le M(n,r) \le 41n/16$. (Chung and Ross [2] have conjectured that a strictly nonblocking network for the classical circuit switching, hence $C(n,2n-1,r)$, is rearrangeable if the weights belong to a given finite set.) We also describe a weighted edge-coloring problem which is related to the multirate routing problem.

2. When weights are restricted. Let B and b denote the upper and lower bound of the weight of a request. Let $M_{(B,b)}(n,r)$ denote the corresponding $M(n,r)$ when B and b are given. Then $M(n,r)$ can also be interpreted as $M_{(1,0)}(n,r)$. Define a bipartite graph G with the input switches as one part, the output switches as the other part, and an edge with weight w between vertices X and Y for each request (x,y,w) where $x(y)$ is an inlet (outlet) of the switch $X(Y)$. The routing problem for $C(n,m,r)$ can then be formulated as an edge-coloring problem on G where the requirement is that the sum of weights of all edges of the same color at a vertex cannot exceed one. To see this, simply color each center switch with a distinct color and route a request through the switch with the same color.

Melen and Turner [5] gave an elegant routing algorithm, CAP, for the Beneš network. Here we adopt it for $C(n,m,r)$ to prove Lemma 1. Let $d(v)$ denote the degree of v in G.

LEMMA 1. $M_{(B,0)}(n,r) \le \frac{n-B}{1-B}$.

Proof. For each vertex v in G, order its $d(v)$ edges into $q(v) \equiv \lceil d(v)/m \rceil$ groups $g_1(v), \ldots, g_{q(v)}(v)$, where $g_1(v)$ consists of the m heaviest edges, $g_2(v)$ of the next m heaviest edges, and so on ($g_{q(v)}(v)$ may have less than m edges). Let G' be a bipartite graph obtained from G by splitting each vertex v into $q(v)$ vertices $v_1, \ldots, v_{q(v)}$ with edges $g_1(v), \ldots, g_{q(v)}(v)$, respectively. Then the maximum degree of a vertex in G' is upper bounded by m. Hence the edges of G' can be m-colored by the König theorem [3]. Note that an edge-coloring of G' induces an edge-coloring of G. Let $W(v,c)$ denote the set of weights of edges of color c at vertex v. Order the weights in $W(v,c)$ into $w_1(v,c) \ge w_2(v,c) \ge \cdots \ge w_{q(v)}(v,c)$, where $w_{q(v)}(v,c) = 0$ if $w(v,c)$ has only $q(v)-1$ edges. Then

$$w_1(v,c) \le B,\ w_{i+1}(v,c) \le w_i(v,c') \quad \text{for} \quad i = 1, \ldots q-1 \quad \text{and any } c' \ne c\ .$$

Define $w(v,c) = \sum_{i=1}^{q(v)} w_i(v,c)$. Then

$$w(v,c) - B \le w(v,c') \quad \text{for any} \quad c' \ne c\ .$$

Adding the above inequality over the $m-1$ colors other than c, plus the equality

$$w(v,c) - B = w(v,c) - B\ ,$$

we obtain

$$m(w(v,c) - B) \le n - B\ ,$$

or

$$w(v,c) \le \frac{n}{m} + \frac{m-1}{m} B\ .$$

Therefore $w(v,c) \le 1$ will be assured if

$$\frac{n}{m} + \frac{m-1}{m} B \le 1$$

or

$$m \ge \frac{n-B}{1-B}\ . \qquad \square$$

COROLLARY 1. $M_{(1/2,0)}(n,r) \le 2n-1$.

On the other hand, we can also use b to obtain an upper bound of $M_{(1,b)}(n,r)$.

LEMMA 2. $M_{(1,b)}(n,r) \le n\lfloor 1/b \rfloor$.

Proof. Since each inlet (outlet) can appear in at most $\lfloor 1/b \rfloor$ requests, the maximum degree of a vertex in G is upper bounded by $n\lfloor 1/b \rfloor$. Again, by the König theorem, G can be edge-colored in $n\lfloor 1/b \rfloor$ colors. $\square$

Note that Lemma 1 is not very useful when $B \to 1$, and Lemma 2 is not useful when $b \to 0$. Therefore, Lemma 1 and Lemma 2, individually, do not contribute to bounding $M(n,r)$. However, they can be combined to yield the following result.

THEOREM 1. $M(n,r) \le 3n-1$.

Proof. Partition the weights into two groups, those $> 1/2$ and those $\le 1/2$. We route these two groups through two disjoint sets of center switches. The first group has a lower bound $b > 1/2$. By Lemma 2, its routing requires n center switches. The

second group has an upper bound $B = 1/2$. By Corollary 1, its routing requires $2n-1$ center switches. Hence $n + (2n-1) = 3n-1$ center switches suffice. □

With more restrictive bounds, better results can be obtained. For example, Chung and Ross proved that a network which is rearrangeable for the classical circuit switching is multirate rearrangeable if all weights are equal. A corollary of this result is that a network which is strictly nonblocking for the classical circuit switching is multirate rearrangeable if the weights are either 1 or a constant b, $0 < b < 1$. Since $C(n, n, r)$ is rearrangeable and $C(n, 2n-1, r)$ strictly nonblocking [1] for the classical circuit switching, they are multirate rearrangeable when the weights meet the above conditions. We now generalize the results of Chung and Ross under more flexible weight conditions.

THEOREM 2. *A network which is rearrangeable for the classical circuit switching is multirate rearrangeable if all weights are in the interval* $(1/(k+1),\ 1/k]$ *for some positive integer* k.

Proof. Construct a bipartite graph H with the inputs and the outputs as the two parts of vertices, and an edge between u and v if there exists a request between u and v. Since each vertex can have at most k edges, the edges of H can be k-colored. Edges of a given color represent a matching between inputs and outputs. Since the network is assumed to be rearrangeable for the classical circuit switching, it can route any such matching (where each internal link carries at most one path). When we combine the routing of the k colors, then each internal link carries at most k paths, one in each color. Therefore, the load of an internal link is upper bounded by $k(1/k) = 1$. □

COROLLARY 2. *A network which is strictly nonblocking for the classical circuit switching is multirate rearrangeable if all weights not exceeding* $1-b$ *are in the interval* $(1/(k+1),\ 1/k]$, *where* $k = \lfloor 1/b \rfloor$ *for some* $0 < b \le 1/2$.

Proof. Each input (output) can be involved with at most one request with weight exceeding $1-b$. Since the network is strictly nonblocking for the classical circuit switching, it can route all these large weights. Delete these requests from the request frame and delete these paths from the network; the remaining network must still be strictly nonblocking, hence rearrangeable for the remaining inputs and outputs. Apply Theorem 2. □

By k-rate we mean that the set of weights consists of k distinct numbers.

COROLLARY 3. $C(n, kn, r)$ *is* k*-rate rearrangeable.*

Proof. Let $w_1, \ldots, w_k$ denote the k types of rate. Reserve n center switches for each type. □

Let $M^k(n, r)$ denote $M(n, r)$ conditional on k-rate. Clearly, $M^1(n, r) \ge n$, and by Theorem 2, $M^1(n, r) = n$. By stretching an example given by Chung and Ross for $n = 2$, we obtain the following theorem.

THEOREM 3. $M^2(n, r) \ge n + 1$ *for* $r \ge 3$.

Proof. Suppose n colors suffice. Label the inputs (outputs) of the ith input (output) switch by the set $\{(i-1)n+1, \ldots, in\}$. Consider a request frame containing the following requests: $\{(i, i, 1),\ 1 \le i \le 2n-1,\ i \ne n,\ (n, 2n, 1/2),\ (n, 3n, 1/2),\ (2n, 2n+1, 1)\}$. Since the $n-1$ weights $(i, i, 1)$, $1 \le i \le n-1$, must each take a different color, $(n, 2n, 1/2)$ and $(n, 3n, 1/2)$ must take the same color, say blue. Then the n unity weights from the second input switch must have distinct colors other than blue, which is impossible. □

THEOREM 4. $M^3(n, r) \ge 11n/9$ *for* $r \ge 3$.

Proof. Consider a bipartite graph with vertices $(X, Y, Z) \times (U, V)$ and the request frame $\{(X, U, 0.6)^{2n/3},\ (Y, U, 0.4)^{2n/3},\ (Z, U, 0.7)^{n/3},\ (X, V, 0.7)^{n/3},\ (Y, V, 0.7)^{2n/3}\}$,

where the exponent indicates the number of copies of the request in the (multi)set. Note that at vertex Y, the $2n/3$ 0.4-weights can come from $n/3$ inlets each having two-requests.

Consider vertex U and let f denote the proportion of 0.4-weights which are paired with 0.6-weights in coloring. Note that a 0.7-weight cannot be paired with any weight. The number of colors at U is at least $n+(2n/3-fn)/2$, where the latter term denotes the number of colors required by those 0.4-weights paired with each other (but not with the 0.6-weights). Note that none of those fn colors can appear at vertex V, or a conflict would have occurred either at vertex X or vertex Y. Hence at least $n+fn$ colors are required. Therefore

$$M^3(n,r) \geq \max\left\{n + \frac{2n/3 - fn}{2},\ n + fn\right\}$$
$$\geq \max\left\{n + \frac{2n/3 - 2n/9}{2},\ n + 2n/9\right\} = 11n/9\ . \qquad \square$$

3. The general weight case. We first prove a lemma.

LEMMA 3. *Suppose that all weights $> 1/f$, f an integer, are colored by a set C of $c \geq 2n$ colors. Then at most $\lceil (c-2)/f - c + 2n \rceil$ additional colors are needed which, together with C, color all weights $\leq 1/f$.*

Proof. Color the small weights (those $\leq 1/f$) by C until no more coloring is possible. Let S denote the bipartite graph on the uncolored small weights. We prove that the maximum degree of $S \leq c - 2 - (c-2n)f$. Consider vertex u. Let w be the minimum weight at u in S. Suppose w is between vertices u and v. Let $W_j(i)$ denote the weight of all edges in color $j \in C$ at vertex i. Then for each j,

$$W_j(u) + W_j(v) \geq \max\{W_j(u),\ W_j(v)\} > 1 - w\ ,$$

or w would be colored by j. Summing over all j,

$$W(u) + W(v) \equiv \sum_{j \in C} W_j(u) + \sum_{j \in C} W_j(v) > c(1-w)\ .$$

But

$$W(v) \leq n - w\ .$$

Hence

$$W(u) > c(1-w) - (n-w) = c - n - (c-1)w\ .$$

This implies that the total uncolored small weights involving u is at most

$$n - W(u) < (c-1)w - c + 2n\ .$$

But a small weight is lower bounded by w, hence the number of small weights at u is fewer than

$$c - 1 - \frac{c-2n}{w} \leq c - 1 - (c-2n)f \text{ for } c \geq 2n\ .$$

Since u is arbitrary, S has maximum degree $c - 2 - (c-2n)f$, and hence can be $\lceil c - 2 - (c-2n)f \rceil$-colored by the König theorem. But each color has at most one

edge at a vertex and the weight of that edge is at most $1/f$. Hence we can combine any f colors into one and the weight of each color at a vertex is still at most one. Therefore, the number of additional colors required is $\lceil (c-2)/f - c + 2n \rceil$. □

Let $d_G(v)$ denote the degree of a vertex v in G. A *spanning subgraph* of G is a subgraph with the same vertex-set as G (although a vertex can have zero degree). We quote a result from de Werra [6] (also see Lovász [4, p. 56]).

LEMMA 4. *Let G be any bipartite graph and suppose $k \geq 1$. Then G is the union of k edge-disjoint spanning subgraphs $G_1, \ldots, G_k$ such that*

$$\left\lfloor \frac{d_G(v)}{k} \right\rfloor \leq d_{G_i}(v) \leq \left\lceil \frac{d_G(v)}{k} \right\rceil \quad \textit{for each} \quad v \in G \ .$$

The subgraphs are required to be spanning so that the "union" operation is well defined.

THEOREM 5. *$C(n, m, r)$ is rearrangeable if $m \geq \lceil (41n - E_n)/16 \rceil$, where $E_n = 8, 5, 6, 3$ if $n \equiv 0, 1, 2, 3 \pmod 4$.*

Proof. Partition the weights into *large*: $w > 1/2$, *medium*: $1/4 < w \leq 1/2$, and *small*: $0 < w \leq 1/4$. Let $l_i(m_i)$ denote the number of large (medium) weights associated with vertex i. Then $l_i \leq n$ and $m_i \leq l_i + 3(n - l_i)$ since each external link having a large weight can have at most one medium weight, and each other external link can have at most three medium weights. For easier presentation, assume 4 divides n.

Consider the bipartite graph G defined in section 2. Let L denote the subgraph of G consisting of only edges of large weights and M consisting of medium weights. By Lemma 4, $M = M_1 \cup M_2$, where M_1 and M_2 are edge-disjoint spanning subgraphs of M and for $j = 1, 2, d_{M_j}(i) \leq \frac{3n}{2} - l_i$ for all vertices i in M.

Let $L' = L + M_1$. Then vertex i has degree at most $3n/2$ in L'. Hence edges in L' can be $3n/2$-colored. Furthermore, edges in M_2 can also be $3n/2$-colored. But since each edge in M_2 has weight at most $1/2$, we can combine any two colors into one without violating the condition that each color carries a load not exceeding one. In other words, M_2 can be $3n/4$-colored in our sense.

Let C denote the set of colors used in coloring L' and M_2. Then $|C| \leq 3n/2 + 3n/4 = 9n/4$. Add colors to C, if necessary, so that $|C| = 9n/4$. By Lemma 3, the small weights can be colored in at most ($f = 4$)

$$\left\lceil \frac{9n/4 - 2}{4} - (9/4 - 2)n \right\rceil = \left\lceil \frac{5n - 8}{16} \right\rceil$$

additional colors. Hence the total number of colors needed is

$$\frac{9n}{4} + \left\lceil \frac{5n - 8}{16} \right\rceil = \left\lceil \frac{41n - 8}{16} \right\rceil \ .$$

The case in which 4 does not divide n can be derived similarly. □

Note that

$$M(n, r) \geq M^k(n, r) \geq M^{k-1}(n, r) \text{ for } k \geq 2 \ .$$

Hence any lower bounds of $M^k(n, r)$, in particular, those obtained in section 2, are also lower bounds of $M(n, r)$.

4. Extensions. We first note that Theorems 1–5 are independent of r (Theorems 3 and 4 require $r \geq 3$); hence they hold even if the input stage and the output stage have different numbers of switches. Next we consider the case in which the number of inlets per input switch is different from the number of outlets per output switch. Namely, consider the asymmetric 3-stage Clos network $C(n_1, n_2, m, r_1, r_2)$ whose input stage consists of r_1 $n_1 \times m$ crossbars, whose center stage consists of m $r_1 \times r_2$ crossbars, and whose output stage consists of r_2 $m \times n_2$ crossbars. Define $n = \max(n_1, n_2)$. Without loss of generality, assume $n = n_1$. Add $n - n_2$ imaginary outlets to each output switch. Then $C(n_1, n_2, m, r_1, r_2)$ can be treated as $C(n, n, m, r_1, r_2)$, except the imaginary outlets do not appear in the request frame. Thus we have Theorem 6.

THEOREM 6. *$C(n_1, n_2, m, r_1, r_2)$ is multirate rearrangeable if $m \geq \lceil (41n - E_n)/16 \rceil$, where $n = \max\{n_1, n_2\}$.*

With Theorem 4 we can generalize our result on three-stage Clos networks to *multistage Clos networks*. A $(2k + 1)$-stage, $k \geq 2$, Clos network can be obtained from a $(2k - 1)$-stage Clos network by replacing a stage of $p \times q$ crossbars with a $C(n_1, n_2, m, r_1, r_2)$ such that $n_1 r_1 = p$ and $n_2 r_2 = q$.

THEOREM 7. *Suppose that we start with a multirate rearrangeable Clos network and then replace the crossbars only with multirate rearrangeable three-stage Clos networks. Then the resultant network is multirate rearrangeable.*

Note that the external links of the three-stage Clos networks replacing the crossbars are internal links of the multistage Clos network. This explains why we assume that both external and internal links have the same capacity in the three-stage Clos network model.

For applications in which the external links have a capacity larger than the internal link, let k denote the smallest integer not less than the external link capacity. By partitioning each request (x, y, w) into k copies of $(x, y, w/k)$, we can handle each copy by the results obtained for the uniform case. The corresponding results for the nonuniform case are obtained by multiplying by a factor of k.

5. The weighted edge-coloring problem. Let $G = (V, E, W)$ denote a weighted multigraph where each edge e is associated with a weight $w(e) \in W$, $b \leq w(e) \leq B$, and b and B are constants satisfying $0 < b \leq B \leq 1$. The edges are to be colored such that for each vertex v and each color c, the sum of weights of all edges incident to v with color c is at most unity. The problem is to minimize the number of colors. For $b = B = 1$, the weighted edge-coloring problem is reduced to the usual edge-coloring problem. Surprisingly, this very natural extension of the edge-coloring problem seems to have been neglected in the literature.

The notion of maximum degree plays an important role in the edge-coloring problem. In the weighted version, the counterpart is the maximum load of a vertex while the load of a vertex is the sum of weights of all edges incident to it.

The routing problem studied in this paper corresponds to a bipartite weighted edge-coloring problem where the maximum load is n. However, Theorems 1–4 assume some information from the external links which are not in G; i.e., the load of a vertex can be decomposed into n subsets each having a load at most unity. We now give a result on the bipartite weighted edge-coloring problem which does not assume this extraneous condition.

Let $W(n)$ denote the minimum number of colors required in the above bipartite weighted edge-coloring problem.

THEOREM 8. $W(n) \leq \lceil (17n - 5)/6 \rceil$.

Proof. For a given vertex i partition all its weights into l_i large weights: $w > 1/2$, m_i medium weights: $1/2 \geq w > 1/3$, and s_i small weights: $w \leq 1/3$. Let L, M, and S denote the bipartite graphs on the large, medium, and small weights, respectively. Then

$$\frac{l_i}{2} + \frac{m_i}{3} \leq n,$$

or equivalently,

$$m_i \leq 3n - \frac{3l_i}{2} .$$

By Lemma 4, $M = M_1 \cup M_2 \cup M_3$, where the M_i's are edge-disjoint spanning subgraphs of M such that $d_{M_j}(i) \leq \lceil n - l_i/2 \rceil$. Let L' denote the union of L, M_1, and M_2. Then the maximum degree of L' is at most

$$\max_i \left\{ l_i + 2\left(n - \frac{l_i}{2}\right) \right\} = 2n,$$

hence $2n$ colors suffice to color L'.

The maximum degree of M_3 is at most

$$\max_i \left\{ \left\lceil n - \frac{l_i}{2} \right\rceil \right\} \leq n ,$$

hence n colors suffice to color M_3. But since the weight of each edge in M_3 does not exceed $1/2$, we can combine any two colors into one, and the weight of a color at a vertex still does not exceed one. Hence $\lceil \frac{n}{2} \rceil$ colors suffice for M. Adding the colors in L' and M_3, we have

$$2n - 1 + \left\lceil \frac{n}{2} \right\rceil \leq \frac{5n-1}{2} .$$

By Lemma 4 ($f = 3$), at most

$$\left\lceil \frac{(5n-5)/2}{3} - \frac{5n-1}{2} + 2n \right\rceil = \left\lceil \frac{n-1}{3} \right\rceil$$

additional colors are needed. So the total number of colors is at most $\lceil \frac{17n-5}{6} \rceil$. ∎

Next we prove a lower bound of $W(n)$.

THEOREM 9. $W(n) \geq 2n - 1$.

Proof. Let vertex v have $2n-1$ edges of weight $n/(2n-1) > 1/2$. Then all of these $2n-1$ edges must have distinct colors. ∎

FINDING THE CONSTRAINED DELAUNAY TRIANGULATION AND CONSTRAINED VORONOI DIAGRAM OF A SIMPLE POLYGON IN LINEAR TIME*

FRANCIS CHIN† AND CAO AN WANG‡

Abstract. In this paper, we present an $\Theta(n)$ time worst-case deterministic algorithm for finding the constrained Delaunay triangulation and constrained Voronoi diagram of a simple n-sided polygon in the plane. Up to now, only an $O(n \log n)$ worst-case deterministic and an $O(n)$ expected time bound have been shown, leaving an $O(n)$ deterministic solution open to conjecture.

1. Introduction.

Delaunay triangulation and *Voronoi diagram*, duals of one another, are two fundamental geometric constructs in computational geometry. These two geometric constructs for a set of points as well as their variations have been extensively studied [17, 3, 4]. Among these variations, Lee and Lin [15] considered two problems related to *constrained Delaunay triangulation*:[1]

(i) the Delaunay triangulation of a set of points constrained by a set of noncrossing line segments, and
(ii) the Delaunay triangulation of the vertices of a simple polygon constrained by its edges.

They proposed an $O(n^2)$ algorithm for the first problem and an $O(n \log n)$ algorithm for the second one. While the $O(n^2)$ upper bound for the first problem was later improved to $\Theta(n \log n)$ by several researchers [6, 21, 18], the upper bound for the second has remained unchanged and the quest for an improvement has become a recognized open problem [1, 3, 4].

Recently, there have been some results related to this open problem on the Delaunay triangulation of simple polygons. Aggarwal et al. [2] showed that the constrained Delaunay triangulation of a convex polygon can be constructed in linear time. Chazelle [5] presented a linear-time algorithm for finding an "arbitrary" triangulation of a simple polygon. Klein and Lingas showed that the aforementioned open problem for L_1 metrics can be solved in linear time [12], and this problem for the Euclidean metrics can be solved in expected linear time by a randomized algorithm [13]. These efforts all seem to point toward a linear solution to the Delaunay triangulation of simple polygons and support the intuition that the simple polygon problem is easier than the noncrossing line segment problem.

In this paper, we settle this open problem by presenting a deterministic linear-time worst-case algorithm. Our approach follows that of [13]:

[1]Same as *generalized Delaunay triangulation* as defined in [15]

(i) first decomposing the given simple polygon into a set of simpler polygons, called *pseudonormal histograms* (*PNHs*),
(ii) constructing the constrained Delaunay triangulation of each normal histogram (NH), and
(iii) merging the constrained Delaunay triangulations of all these NHs to get the result.

In this three-step process, the first and third steps were shown to be possible in linear time, but the second step was done in expected linear time by a randomized algorithm. Our contribution is to show how this second step can be done in linear worst-case time deterministically.

The organization of the paper is as follows. In section 2, we review some definitions and known facts, which are related to our method. In section 3, we concentrate on how to construct the constrained Delaunay triangulation or constrained Voronoi diagram of a normal histogram in linear time. We conclude the paper in section 4.

2. Preliminaries. In this section,
(i) we define the constrained Delaunay triangulation and its dual, the constrained Voronoi diagram,
(ii) we define PNHs, and
(iii) to put our solution of how to construct the constrained Voronoi diagram of a PNH into perspective, we explain the approach taken to first partition any simple polygon into PNHs and then merge constrained Voronoi diagrams of these pseudodiagrams for the solution of the original polygon.

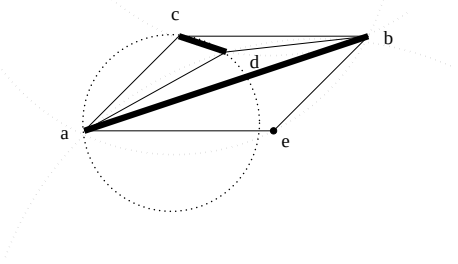
2.1. Constrained Delaunay triangulations and constrained Voronoi diagrams. The *constrained Delaunay triangulation* [15, 6, 21, 18] of a set of noncrossing line segments L, denoted by $CDT(L)$, is a triangulation of the endpoints S of L satisfying the following two conditions:
(i) the edge set of $CDT(L)$ contains L, and
(ii) the line segments in L are treated as obstacles and the interior of the circumcircle of any triangle of $CDT(L)$, say $\Delta ss's''$, does not contain any endpoint in S visible[2] to all vertices s, s', and s''.

Essentially, the constrained Delaunay triangulation is the Delaunay triangulation with the further constraint that the triangulation must contain a set of designated line segments. Figure 1a shows the constrained Delaunay triangulation of two obstacle line segments and a point (a degenerated line segment). In particular, if L forms a nonintersecting chain C, monotone with respect to a horizontal line l, we are only interested in the portion of $CDT(C)$ between C and l. If L forms a simple polygon P, we only consider the portion of $CDT(P)$ internal to P.

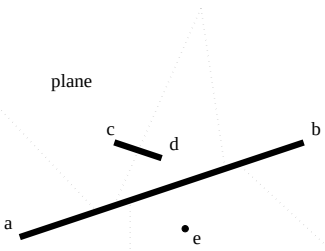
Given a set of line segments L, we can define the Voronoi diagram with respect to L as a partition of the plane into cells, one for each endpoint set S of L, such that a point p belongs to the cell of an endpoint v if and only if v is the closest endpoint visible from p. Figure 1b illustrates the corresponding Voronoi diagram for the set of line segments given in Figure 1a. Unfortunately, this Voronoi diagram is not the complete dual diagram of $CDT(L)$ [3]; i.e., some of the edges in $CDT(L)$ may not have a corresponding edge in this Voronoi diagram.

In [18, 16, 9], the proper dual for the constrained Delaunay triangulation has been defined as the *constrained (or bounded) Voronoi diagram* of L, denoted by $V_c(L)$.

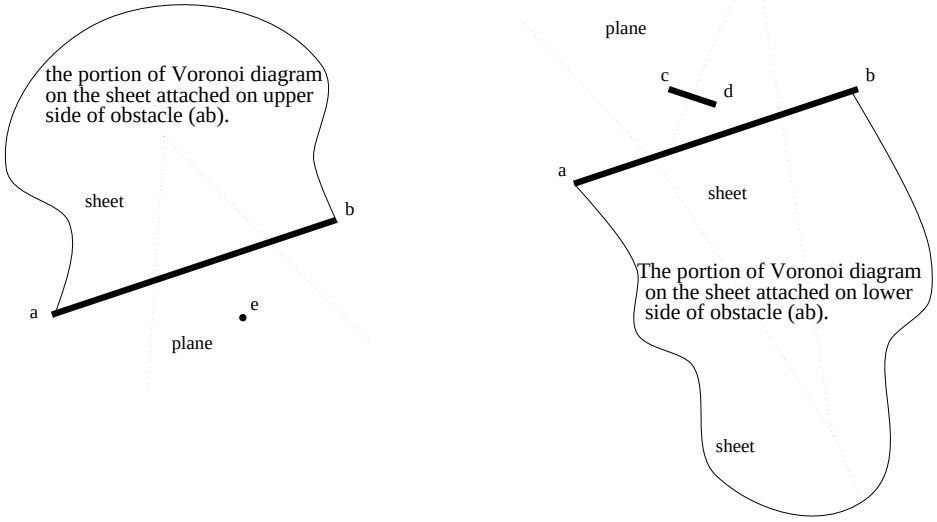
[2]Two points are *visible* to each other if the straight line joining them does not intersect any line segments in L.



(a) the constrained Delaunay triangulation of line segments (ab) and (cd), and point e, (L).



(b) Voronoi diagram w.r.t. L



(c) Constrained Voronoi diagram on 'extended' space.

FIG. 1. *Constrained Delaunay triangulation and constrained Voronoi diagram.*

Imagine two sheets or half-planes attached to each side of the obstacle line segments; for each sheet, there is a well-defined Voronoi diagram that is induced only by the endpoints on the other side of the sheet excluding the obstacle line segment attached to the sheet. The constrained Voronoi diagram extends the standard Voronoi diagram by including the Voronoi diagrams induced by the sheets, i.e., the extended Voronoi diagrams beyond both sides of each line segment in L. Figure 1c gives an example of $V_c(L)$, the Voronoi diagrams on the plane and on the two sheets of the obstacle line segment $\overline{ab}$. Note that the Voronoi diagrams on the two sheets of the obstacle line segment $\overline{cd}$ happened to be the same as the Voronoi diagram on the plane. With this definition of $V_c(L)$, there is a one-to-one duality relationship between edges in $V_c(L)$ and edges in $CDT(L)$. It was further proved in [18, 9] that the dual diagrams, $CDT(L)$ and $V_c(L)$, can be constructed from each other in linear time. For simplicity, we omit the word "constrained" over Voronoi diagrams in this paper as all the Voronoi diagrams are deemed to be constrained unless they are explicitly stated to be standard Voronoi diagrams.

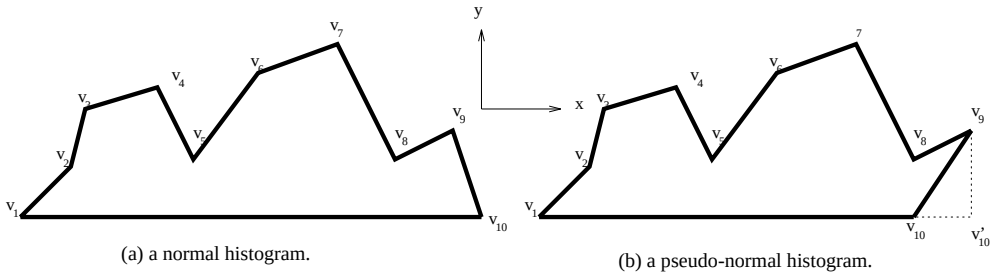


FIG. 2. *NH and PNH.*

2.2. PNHs. A NH [8] is a monotone polygon with respect to one of its edges, called the *bottom edge*, such that all the vertices of the polygon lie on the same side of the line extending the bottom edge (Figure 2a gives an example). A PNH [13] with a bottom edge e is a simple polygon which, by adding at most one right-angle triangle flush with e, can be transformed into a NH whose bottom edge is the extension of e by the colinear edge of the triangle. Intuitively, a PNH can be viewed as a NH missing one of its bottom corners; i.e., a PNH can be transformed into a NH by adding a right-angle triangle at its bottom[3] (Figure 2b).

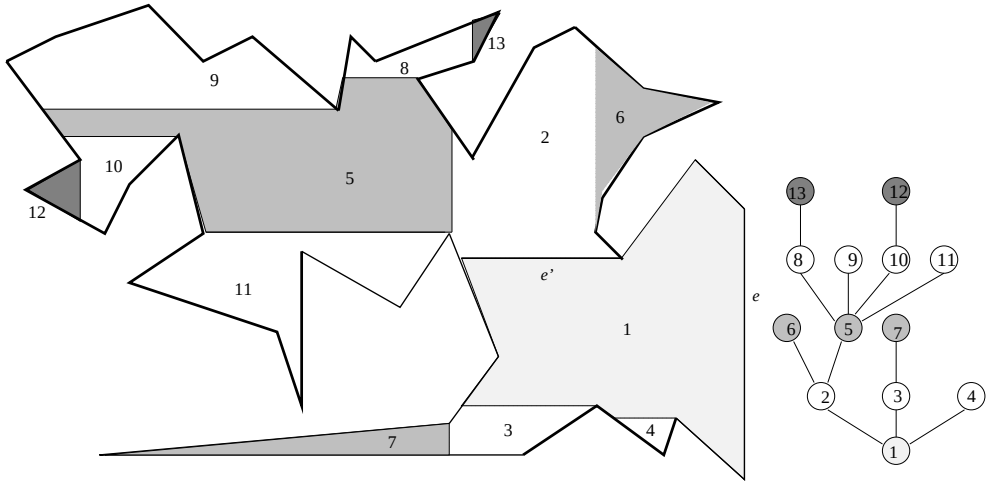

FIG. 3. *A decomposition of P into a tree of PNHs.*

2.3. Decomposition of a simple polygon into PNHs. Figure 3 illustrates how a polygon P is decomposed into 13 PNHs. PNH_1 is associated with the vertical bottom edge e missing its upper bottom corner; PNH_2, associated with the horizontal bottom edge e', is missing its left bottom corner, etc.

A simple polygon P with n vertices can be decomposed into PNHs in $O(n)$ time according to [13] when provided with what are known as the *horizontal* and *vertical visibility maps* of P (Figure 4), which in turn can be obtained in linear time according to [5]. A *diagonal* of P is a line segment joining two vertices of P and lying entirely inside P, while a *chord* of P is a line segment which

[3]Our definition of PNH is different from that given in [13], in which a PNH might be missing both bottom corners. Following the same approach as given in [13], decomposition of a simple polygon into PNHs is also possible with our definition.

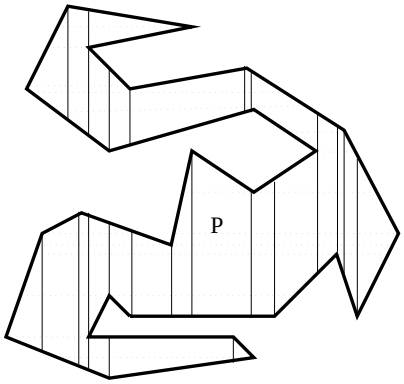

FIG. 4. *Horizontal and vertical visibility maps of simple polygon P.*

(i) lies entirely inside P,
(ii) is parallel to the designated bottom edge, and
(iii) joins a vertex and a boundary point of P (such a boundary point is called a *pseudovertex*).

The *horizontal visibility map* of a simple polygon P is the set of horizontal chords associated with every vertex of P. Note that every vertex of P is associated with at most two chords, and the horizontal visibility map partitions P into a number of horizontal trapezoids (*horizontal trapezoidal decomposition* or *horizontal trapezoidation*). The *vertical visibility map* can be defined similarly.

The decomposition of P into PNHs starts with an arbitrary edge e of P as the bottom edge of the first PNH. The interior of the PNH refers to the part of P that is illuminated by the parallel light emanating into PNH perpendicular to e from its pseudobottom edge $e \cup e_s$, where e_s is the edge (if any) incident to e at an interior angle between 90° and 180°, i.e., the hypotenuse of the missing right-angle triangle. The boundary edges of the PNH that are not edges of P will be the bottom edges in the next step.

The decomposition of P can then be represented by a tree such that each tree node is a PNH and each tree edge represents the adjacency of two PNHs sharing a chord. Consider the example as given in Figure 3: PNH_1, with an edge of P as its bottom edge, is classified as the root. For each edge in PNH_1 which is not an edge of P, we regard it as the bottom edge for a son of PNH_1. PNH_2, PNH_3, and PNH_4 are sons of PNH_1 whose bottom edges are all horizontal, whereas PNH_2 is on one side facing PNH_3 and PNH_4, which are on the other. Similarly, the grandsons of PNH_1 are those with vertical bottom edges adjacent to sons of PNH_1, etc.

2.4. Merging the Voronoi diagrams of PNHs. It has been proved [13] that a Voronoi cell in $V_c(P)$ of a vertex in a PNH would not share any boundary edge with a Voronoi cell of a vertex in another PNH as long as these two vertices are not shared by these two PNHs, and these two PNHs are
(i) at the same depth not facing each other, or
(ii) with their corresponding depths at least two apart.

The Voronoi diagram of a PNH is first merged with the extended Voronoi diagram of its parent, then with those of its sons on one side, and finally with those of the remaining sons on the other. Condition (ii) ensures that the extended Voronoi diagram of its parent will not share any boundary with those of its sons, and thus, only those of

its neighbors (sons and parent) have to be considered in the construction of the part of the Voronoi diagram $V_c(P)$ in a PNH. Condition (i) ensures that merging the Voronoi diagram of a PNH with the extended ones of its sons will trace the bisectors between sites of the PNH at most twice (once for sites on each side) [10, 11, 14, 17, 19]. So, the merging of Voronoi diagrams at each PNH can be done in time linearly proportional to the total size of the PNH and all its sons. Thus, the Voronoi diagram $V_c(P)$ can be obtained in time linearly proportional to the size of P by merging the Voronoi diagram of each PNH together with the extended ones of its neighbors.

In order to find $V_c(P)$ in deterministic linear time, what remains to be solved is the efficient construction of the constrained Voronoi diagram of a PNH. In [13], a randomized algorithm is introduced to find the Voronoi diagram of a NH in expected linear time. The Voronoi diagram of the corresponding PNH can then be obtained by removing the bottom vertex from the Voronoi diagram of this NH, and this can be done in time linearly proportional to the size of the NH. In the next section, we shall concentrate our effort to design a linear-time deterministic algorithm for constructing the Voronoi diagram of a NH.

3. Finding the constrained Voronoi diagram of an NH. Given a normal histogram H with a horizontal bottom edge e, H is decomposed recursively into a tree, say T_I, of smaller normal histograms called *influence normal histograms* (INH), where a node of T_I corresponds to an INH and an edge of T_I indicates an adjacency between two INHs. A formal definition of INH with an algorithmic method of construction will be given in section 3.2. In Figure 5, node 0 (the root INH) is $(v_1, v_3', v_3, v_3'', v_5, v_6, v_7, v_8, v_9,\ v_{10}, v_{12}', v_{12}, v_{13}, v_{13}',\ v_{25}, v_{25}',\ v_{28}, v_{28}', v_{33}, v_{34}, v_{35})$.

Nodes 1–6 form the second level and are sons of node 0.

Node 1 $= (v_3', v_2, v_3)$,
Node 2 $= (v_3, v_4, v_3'')$,
Node 3 $= (v_{12}', v_{11}, v_{12})$,
Node 4 $= (v_{13}, v_{14}, v_{14}', v_{13}')$,
Node 5 $= (v_{25}, v_{26}, v_{27}, v_{25}')$, and
node 6 $= (v_{28}, v_{30}', v_{30}, v_{32}', v_{32}, v_{28}')$.

Nodes 7–9 form the third level with

Node 7 $= (v_{14}, v_{15}, v_{16}, v_{17}, v_{17}',\ v_{19}, v_{20},\ v_{21}, v_{22}, v_{23}, v_{24}, v_{14}')$,
Node 8 $= (v_{30}', v_{29}, v_{30})$,
Node 9 $= (v_{32}', v_{31}, v_{32})$.

Node 10 $= (v_{17}, v_{18}, v_{17}')$ is on the fourth level.

The decomposition ensures that the portion of Voronoi diagram $V_c(H)$ in each INH can only be affected by its own vertices and the vertices of its sons and nothing beyond. In general, the Voronoi cells of $V_c(H)$ associated with vertices of an INH might cross its bottom edge and share edges with Voronoi cells associated with vertices of its parent, but not with those of its brothers or its grandparents. Similarly, the Voronoi cells of an INH would not share any boundary with those of its grandsons. This property implies that, should the Voronoi diagrams of the INHs ($V_c(INH)$) be given, the repeated merging of the Voronoi diagrams of the adjacent INHs can be done in time linearly proportional to the sum of their sizes.

Let $V(p)$ denote the Voronoi cell associated with vertex p in a Voronoi diagram. A point p in a normal histogram H is called an *influence point* if the Voronoi cell $V(p)$ in $V_c(H \cup \{p\})$ will cross H's bottom edge e. The set of influence points is called the *influence region* (IR) with respect to bottom edge e. Consider Figure 5: the IR of H with respect to $\overline{v_1 v_{35}}$ (the bottom edge e) is the region enclosed by $\widehat{v_1 v_5}$, $\overline{v_5 v_6}$, $\overline{v_6 v_7}$, $\overline{v_7 v_8}$, $\overline{v_8 v_9}$, $\overline{v_9 v_{10}}$, $\widehat{v_{10} v_{25}}$, $\widehat{v_{25} v_{28}}$, $\widehat{v_{28} v_{34}}$, $\overline{v_{34} v_{35}}$, and $\overline{v_{35} v_1}$, where $\overline{xy}$ and $\widehat{xy}$ represent,

respectively, the straight line and the arc joining vertices x and y. The *root* (or *root INH*) of T_I is defined as the NH enclosing all influence points of H and consisting of all horizontal trapezoids that intersect the IR. In other words, the root INH would contain all its horizontal chords which will intersect the IR of H, i.e., the *smallest* NH containing IR in the sense that the INH is bound above by the lowest horizontal chords which do not intersect IR. As an example, the root INH is indicated by the unshaded region in Figure 5. Let us now consider the part of H excluding the root INH, which consists of zero or more disjoint polygons. Each polygon is also a NH with a chord as its bottom edge. As given in Figure 5, H is decomposed into a root INH and six other NHs, i.e., the NHs above chords $\overline{v_3'v_3}$, $\overline{v_3v_3''}$, $\overline{v_{12}'v_{12}}$, $\overline{v_{13}v_{13}'}$, $\overline{v_{25}v_{25}'}$, and $\overline{v_{28}v_{28}'}$. For example, the NH above chord $\overline{v_{28}v_{28}'}$ is $(v_{28}, v_{29}, v_{30}, v_{31}, v_{32}, v_{28}')$. The decomposition can be recursively applied to each of these NHs.

Since any node of T_I does not contain the influence points of its parent by the definition of INH, the Voronoi cell associated with a vertex in any node of T_I could not cross the bottom edge of its parent. Thus, the part of $V_c(H)$ within the root can be formed by merging the Voronoi diagram of the root INH with those of its sons. As the Voronoi cells associated with the internal vertices of an INH never share any edges with the Voronoi cells of its brother INH (Theorem 1), the merging can be performed in $O(m_0 + \sum_{i=1}^{s} m_i)$ time, where m_0 is the number of vertices of the root, s is the number of its sons, and m_i is the number of vertices of its ith son.

THEOREM 1. *Let v_1 be a vertex of INH_1 with bottom edge $\overline{u_1w_1}$ and v_2 be a vertex of INH_2 with bottom edge $\overline{u_2w_2}$. Assume that INH_1 and INH_2 are brothers in T_I, $v_1 \neq u_1$, $v_1 \neq w_1$, $v_2 \neq u_2$, and $v_2 \neq w_2$. Then, the Voronoi cell of v_1 will never share any point with the Voronoi cell of v_2.*

Proof. Without loss of generality, assume that $\overline{u_1w_1}$ is on the left-hand side of $\overline{u_2w_2}$; i.e., $u_1 < w_1 \leq u_2 < w_2$ according to their x-coordinates. We show that there does not exist a point p in H

(i) that is equidistant to v_1 and v_2, and
(ii) for which there exists no other vertex in H closer to p than v_1 and v_2.

Assume p exists. Since p is in H, p has to lie directly under $\overline{u_1w_1}$ in order to be closer to v_1 than to u_1 or w_1, i.e., $u_1 < p < w_1$. Similarly, p has to lie directly under $\overline{u_2w_2}$, i.e., $u_2 < p < w_2$. Obviously, p cannot simultaneously satisfy both conditions. □

For example, the Voronoi cell of v_{14} in INH_4 never shares any point with the Voronoi cell of v_{26} or v_{27} in INH_5. Let $M(n)$ denote the merging time for constructing $V_c(H)$ with $\mid H \mid = n$ when provided with the Voronoi diagram of every INH in T_I. Then, we have $M(n) = k(m_0 + \sum_{i=1}^{s} m_i) + \sum_{i=1}^{s} M(n_i)$, where k is a constant and n_i is the number of vertices of the ith subtree. As $n = m_0 + \sum_{i=1}^{s} n_i$, we can show that $M(n) = k(2n - m_0)$ by induction. Thus, the total merging time is $O(n)$. Note that in the above calculation, the pseudovertices are also counted. As n is at most thrice the actual number of vertices of H (as each vertex of H might associate with at most two pseudovertices), the total merging time is still linearly proportional to the actual number of vertices of H.

In the following sections, we shall prove the properties of the IR and the INH which allow us to do efficient merging and identification.

3.1. IR. Let H_V be a subpolygon of NH H, consisting of the bottom edge of H and all those vertices of H with the property that their associated Voronoi cells in $V_c(H)$ cross the bottom edge of H. H_V can also be viewed as the maximum subsequence of the vertices of H having this property. As H is a NH, H_V will also be a

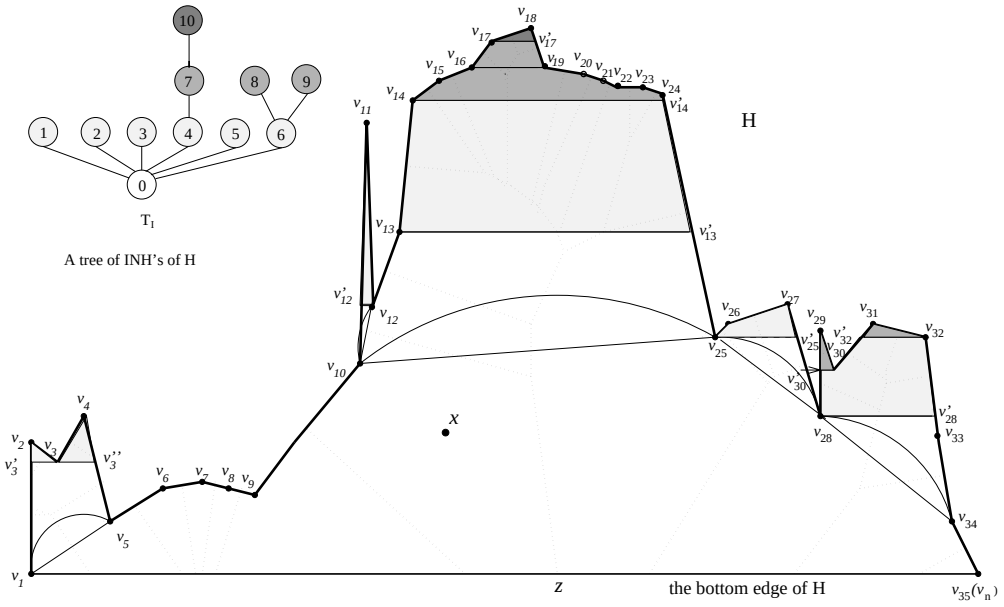

FIG. 5. *Decomposition of H into $INHs$ and T_I.*

NH sharing the same bottom edge as H. Let us consider the example given in Figure 5 again, in which H_V is indicated by the sequence of vertices $(v_1, v_5, v_6, v_7, v_8, v_9, v_{10}, v_{25}, v_{28}, v_{34}, v_{35})$.

LEMMA 1. *All points in H_V are influence points.*

Proof. By the definition of H_V, the bisector of two adjacent vertices (except the two vertices of the bottom edge) of H_V, which forms part of the $V_c(H)$, always crosses the bottom edge of H. In other words, H_V are partitioned by these bisectors into cells, each of which is associated with one of its vertices. These cells resemble the Voronoi cells of $V_c(H)$. In fact, each of these cells in $V_c(H_V)$ always includes its corresponding Voronoi cell in $V_c(H)$. These bisectors also partition the bottom edge into segments according to their closest vertices in H or H_V. It is sufficient to prove this lemma by showing that given any point x in H_V, there always exists a point on the bottom edge which is closer to x than to any vertex in H; i.e., $V(x)$, the Voronoi cell of x, in $V_c(H \cup \{x\})$ would cross the bottom edge. Let x be a point in H_V, in particular, in a Voronoi cell $V(u)$, corresponding to vertex u in $V_c(H_V)$. Furthermore, let the extended line of $\overline{ux}$ intersect the boundary of this Voronoi cell $V(u)$ at y, which may be a point on the bottom edge or a point on a bisector. If y is on the bottom edge, let z be y; otherwise let z be the intersection point of that bisector and the bottom edge. An example is given in Figure 5, where x is in $V(v_{10})$, i.e., $u = v_{10}$. As $\angle uxz > 90°$, z is always closer to x than to u by the triangular property. It is easy to see that z is closer to x than to any other vertices in H, thus z is a point on the bottom edge that belongs to $V(x)$; i.e., $V(x)$ crosses the bottom edge. Hence, x belongs to the IR. □

In general, the IR includes some regions not belonging to H_V. Let b be a boundary edge of H_V. If b is also an edge of H, then b must be an edge of the IR, e.g., $\overline{v_5v_6}$, $\overline{v_6v_7}$, $\overline{v_7v_8}$, etc. in Figure 5. However, if $b = \overline{uw}$ is a diagonal of H, then the IR must include some region of H above b and below the circular arc $\widehat{uw}$, where $\widehat{uw}$ is part of

the semicircle above the bottom edge. (The semicircle is uniquely defined by boundary points u and w and center c, where c is the intersection point of the bottom edge and the perpendicular bisector of u and w.) Let O_{uw} denote the region in H above b (i.e., outside H_V) and below the circular arc $\widehat{uw}$, and let $O_{v_1v_5}$, $O_{v_{10}v_{25}}$, $O_{v_{25}v_{28}}$, and $O_{v_{28}v_{34}}$ be such examples in Figure 5. Then we have the following theorem.

THEOREM 2. *$IR = (\cup_{\overline{uw}\in D} O_{uw}) \cup H_V$, where D is the set of edges of H_V which are diagonals of H.*

Proof. By Lemma 1, we need to prove $IR - H_V = \cup_{\overline{uw}\in D} O_{uw}$ (as $H_V \cap O_{uw} = \phi$). Consider a point p in H, but not in H_V. Then, point p must lie above an edge $\overline{uw}$ of H_V which is a diagonal of H. On one hand, if point $p \in O_{uw}$, then b_{up} and b_{pw} will cross the bottom edge before intersecting each other, where b_{xy} denotes the perpendicular bisector of vertices x and y, and thus p belongs to the IR; i.e., $IR - H_V \supseteq \cup_{\overline{uw}\in D} O_{uw}$. On the other hand, if $p \notin O_{uw}$, then b_{up} and b_{pw} will intersect each other above the bottom edge, and thus p does not belong to the IR; i.e., $IR - H_V \subseteq \cup_{\overline{uw}\in D} O_{uw}$. □

COROLLARY. *Assume a NH H and let $H_V = (v_0, v_1, \ldots, v_n)$. Then the IR with respect to H can be defined by keeping the sequence of vertices of H_V and by replacing all diagonals $\overline{v_iv_{i+1}}$ of H in the sequence of H_V by an arc $\widehat{v_iv_{i+1}}$.* □

3.2. INH. As the root INH is the smallest NH containing the IR, an INH would contain all the edges of the IR, in particular, those edges of H_V (Theorem 2) which are also edges of H (e.g., $\overline{v_5v_6}$, $\overline{v_6v_7}$, $\overline{v_7v_8}$, etc. in Figure 5). As O_{uw} is part of the IR for every $\overline{uw} \in D$ (Theorem 2), the remaining edges of an INH above $\overline{uw}$ would be those chords and edges of H enclosing O_{uw}. Thus, we define H_B *above* $\overline{uw}$ as the smallest NH containing O_{uw}, which consists of edges (or parts of edges) of H and the lowest horizontal chord which do not intersect the IR. For example, as in Figure 5, the H_B's are $(v_1, v_3', v_3, v_3'', v_5)$, $(v_{10}, v_{12}', v_{12}, v_{13}, v_{13}', v_{25})$, $(v_{25}, v_{25}', v_{28})$, and $(v_{28}, v_{28}', v_{33}, v_{34})$.

Now, we can have a precise description of an INH. There are two types of vertices in an INH, the vertices of H_V and the vertices of H_B's, with one H_B for each edge in D. Thus, any vertex in an INH that is not in H_V will be in H_B, and the endpoints of any edge in D will be vertices in both H_V and H_B. In the following, we shall describe the properties of H_B and H_V and show that the Voronoi diagram of an INH can be constructed in linear time.

A *monotonic histogram* is an NH such that if the bottom edge is on the x-axis, then the x-coordinates of the vertices along the boundary are monotonically nondecreasing, and the y-coordinates of the vertices (except the last vertex) along the boundary are monotonically nondecreasing or nonincreasing. A *bitonic histogram* is a composition of two monotone histograms such that the x-coordinates of the vertices along the boundary are monotonically nondecreasing, and the y-coordinates of the vertices along the boundary are first monotonically nondecreasing on one side and then monotonically nonincreasing on the other.

LEMMA 2. *H_B is bitonic.*

Proof. Since H_B is the smallest NH enclosing O_{uw}, all its internal horizontal chords will intersect with O_{uw}; i.e., all vertices of H_B, except possibly the top vertex and its associated pseudovertex (vertices), should be horizontally visible from O_{uw}. As H_B consists of only edges (or parts of edges) and chords of H, all edges of H_B should be monotonically nondecreasing in the x- and y-coordinates on one side and monotonically nondecreasing in the x-coordinate but monotonically nonincreasing in the y-coordinate on the other. Thus, H_B is bitonic. □

LEMMA 3. *The Voronoi diagrams of H_B and H_V can be constructed in linear time.*

Proof. It is shown in [8] that the Voronoi diagram of a monotonic histogram can be constructed in linear time. Because H_B can be partitioned into two monotonic histograms by the vertical line through its highest vertex or edge (Lemma 2), the Voronoi diagrams of two such monotonic polygons can be merged in linear time [20, 13]. Thus, $V_c(H_B)$ can be found in linear time. As far as H_V is concerned, because the vertices on the boundary of H_V are in sorted order according to their x-coordinates (property of the NH), the extended Voronoi diagram below the bottom edge can be found in linear time [2]. Since all the Voronoi cells in H_V must cross the bottom edge, the Voronoi diagram of H_V can be constructed in linear time from its extended Voronoi diagram below the bottom edge. □

Note that in the construction of the Voronoi diagrams of H_B and H_V, all the pseudovertices are ignored. Thus, the resulting Voronoi diagrams do not contain any Voronoi cell of pseudovertices. This approach is different from that proposed in [13], which requires the removal of the Voronoi cells of pseudovertices.

The following lemma shows that the Voronoi diagrams of two H_B's cannot affect each other.

LEMMA 4. *Assume an INH with its attached H_B's, and let x and y be two vertices not belonging to H_V but in two different H_B's. Then the Voronoi cells, $V(x)$ and $V(y)$, cannot share any point in $V_c(H_V)$.*

Proof. As x and y are vertices in two different H_B's but not in H_V, x and y must be separated by some vertex z in H_V. By the definition of H_V, the Voronoi cell $V(z)$ must cross the bottom edge. Thus, $V(x)$ cannot share any point with $V(y)$ above the bottom edge. □

THEOREM 3. *The Voronoi diagram of an INH can be constructed in time linearly proportional to its size.*

Proof. By Lemma 3, the Voronoi diagrams of H_V and H_B's can be constructed in time linearly proportional to their sizes. Since each H_B shares an edge with H_V, the Voronoi diagrams of each H_B and H_V can be merged in time proportional to the number of Voronoi edges shared by them [20, 13]. As different H_B's do not interfere with each other (Lemma 4), the total merging time is linearly proportional to the number of Voronoi edges shared by H_B's and H_V, i.e., the size of the INH. □

3.3. Region identification. In this section, we shall present an algorithm which identifies the INH in a NH in time linearly proportional to the size of the INH. Chazelle's linear-time algorithm [5] is first applied to the NH to obtain its horizontal visibility map (Figure 6). By the property of a normal histogram, H can be further represented by a *partition tree* T_P, in which each tree node represents a chord in the map and each tree edge represents the adjacency of two chords. Let $n(v)$ denote the chord(s) associated with vertex v of H. If there are two chords in $n(v)$, $n^L(v)$ and $n^R(v)$ denote the left chord and right chord, respectively. With this partition tree T_P, the INH to be identified can be represented as a rooted subtree of T_P.[4] For example, the INH indicated by the shaded area can be represented by the rooted subtree as marked in Figure 6. The algorithm to identify the INH is based on tree traversal. In order to achieve linear time complexity, only those tree nodes relevant to the INH will be traversed. Thus, one of the key steps in the tree traversal is the pruning condition, i.e., under what conditions the traversal of a subtree can be terminated. The other key step is the identification of the vertices of H_V so that we can partition the INH

[4] A rooted subtree of T has the property that the root of T is also the root of the subtree.

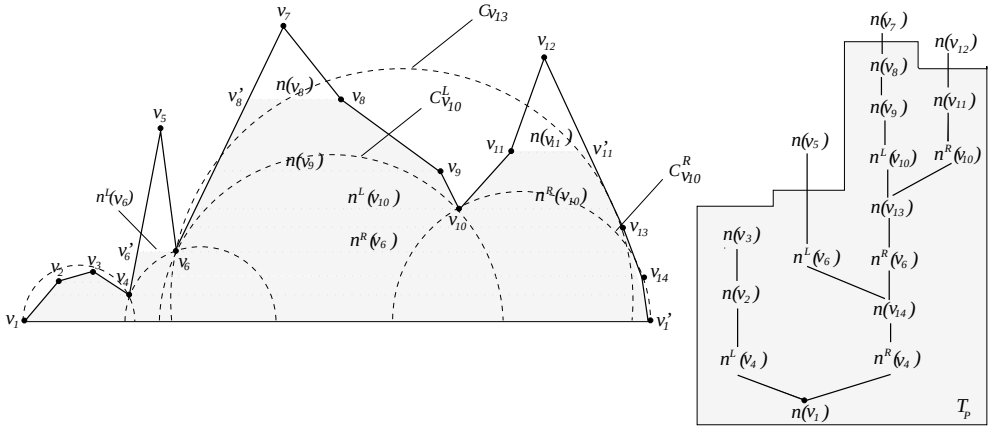

FIG. 6. *An INH and its tree* T_P.

into H_B's and H_V for further constructing of Voronoi diagrams, as described in the previous section.

The following lemma gives a necessary and sufficient condition for a vertex v of H to be a vertex of H_V. Based on Theorem 2 and the definition of H_B, we can ensure that a visited vertex, that is not a vertex of H_V, will be a vertex of H_B.

LEMMA 5. *For any vertex v of H, v is a vertex of H_V if and only if v can be touched by a circle centered at the bottom edge and empty of other vertices of H.*

Proof. The center of such a circle is a point closer to vertex v than to other vertices of H. As Voronoi cells are simply connected, the Voronoi cell $V(v)$ will intersect or cross the bottom edge. The lemma follows directly from the definition of H_V. □

Without loss of generality, assume the parent of $n(v)$ intersects the IR and $n(v)$ is being visited on the traversal of T_P. Based on Lemma 5, vertex v is tested and classified into one of the following three types: (i) a vertex in H_V, (ii) a vertex in H_B (if not in H_V), or (iii) a potential vertex.

A *potential vertex* is such a vertex that can be touched by a circle centered at the bottom edge and empty of any vertices of H *on or below* $n(v)$; i.e., the Voronoi cell of a potential vertex would extend across the bottom edge if no vertex above $n(v)$ will affect this Voronoi cell. However, since we have not examined any vertex above $n(v)$ yet, we cannot rule out the possibility that v is in H_B.

Assume that all circles in the following discussion will be centered at the bottom edge. Let C_v denote the largest circle that crosses chord $n(v)$ and whose interior does not contain any vertex on or below $n(v)$. If vertex v is associated with two chords, then C_v^L and C_v^R denote such circles that cross $n^L(v)$ and $n^R(v)$, respectively. Let us first study some properties of C_v, which can be used to determine the IR above $n(v)$ by considering only the histogram studied so far, i.e., the histogram below $n(v)$ (note that C_v^L and C_v^R also have these properties).

LEMMA 6. *If C_v exists, then*

(i) *C_v must touch vertices to the left and right of its centers, or is centered at a nonvertex endpoint of the bottom edge, i.e., pseudovertex, and*

(ii) *if v is the left (right) endpoint of $n(v)$, then the center of C_v must be to the right (left) of v.*

Proof. (i) If C_v exists, then C_v is unique. This is because, by the x-monotonic property of H, there is no vertex below the bottom edge (e) and between the intervals

of $n(v)$; i.e., the largest circle centered at e cannot be bounded by such vertices. Then, either the largest circle centered at e must touch only one vertex above e and hence will be centered at the (nonvertex) endpoint of e, or this circle must touch two or more vertices above e on both sides of its center. In either case, this largest circle is the C_v if it crosses $n(v)$. (ii) By contradiction, assume that the center of C_v is to the left of v, which is the left endpoint of $n(v)$; then C_v would not cross $n(v)$ and cannot exist. □

The following lemma will give a sufficient condition for a vertex to be in H_V.

LEMMA 7.

(i) *If both C_v^L and C_v^R exist, then vertex v must be in H_V.*

(ii) *If C_v^L (C_v^R) does not exist, then the traversal of the subtree above $n^L(v)$ ($n^R(v)$) is terminated.*

Proof. (i) The existence of both C_v^L and C_v^R implies the existence of an empty circle with center at the bottom edge and lying entirely below $n(v)$. Thus v must be in H_V by Lemma 5. (ii) Since there does not exist any vertex above $n^L(v)$ that can affect the IR, the tree traversal can be terminated. □

Let us consider an example as given in Figure 6 to show how these properties can be applied to classify v. Initially C_{v_1} is the circle that touches v_1 and is centered at v_1'. The next vertex to be visited is v_4. Since both $C_{v_4}^L$ and $C_{v_4}^R$ exist, v_4 is in H_V (Lemma 7). When the tree traversal of T_P at $n^R(v_4)$ is continued, vertices v_{14}, v_6, and v_{13} will be visited and classified as potential vertices.

In order to construct C_v for each v during the tree traversal T_P, the potential vertices previously identified are kept in two stacks, L and R. Except possibly for their bottom vertices, L contains the "left" potential vertices (i.e., left endpoints of the corresponding chords) while R contains the "right" ones. For example, after v_6 and v_{13} are visited, L and R contain $[v_4, v_6)$ and $(v_{13}, v_{14}]$, respectively, with v_6 and v_{13} being their top vertices. The following lemma gives the properties of stacks L and R.

LEMMA 8. *With respect to the histogram on or below the chord $n(v)$ studied so far,* (i) *stacks L and R contain the vertices whose Voronoi cells cross the bottom edge in order, and* (ii) *the largest empty circle C_v is determined by the top vertex of L and the top vertex of R.*

Proof. (i) First, we have to show that the y-coordinates of the vertices in L are monotonically increasing while those in R are monotonically decreasing. Without loss of generality, assume the contrary, that L contains a vertex v whose y-coordinate is lower than that of its precedent vertex t. Then it is impossible for t to be the left endpoint of a chord. As the vertices in L and R are potential vertices visited according to their y-coordinates, their Voronoi cells must cross the bottom edge in order.

(ii) As L and R contain the "left" and "right" potential vertices (i.e., left and right endpoints of the chords), the largest circle C_v must touch the top vertices of L and R, which are the rightmost left endpoint and the leftmost right endpoints, respectively. □

We shall describe the construction of $C_{v'}$ and the tree traversal algorithm of T_P. Assume v' is the next vertex to be visited after v.

Case 1. $n(v')$ does not exist or does not intersect C_v; the tree traversal is terminated/pruned at $n(v')$ and all vertices in L and R become vertices in H_V. Subtrees rooted at such $n(v')$ (if they exist) are pruned because their corresponding INHs do not contain the IR. The pruned subtrees represent smaller NHs needed to be processed recursively.

For example, in Figure 6, the tree traversal is terminated at $n(v_8)$ and $n(v_{11})$ as they do not intersect C_{v_9} and $C^R_{v_{10}}$, respectively. Vertex v_6, previously in L, becomes a vertex in H_V. In Figure 5 the pruned portion $(v_{28}, v_{29}, v_{30}, v_{31}, v_{32}, v_{28'})$ is an NH with $\overline{v_{28}v_{28'}}$ (the pruned chord) as the bottom edge to be processed recursively.

Case 2. $n(v')$ intersects C_v; the tree traversal will continue to visit $n(v')$'s son(s).

(a) v' is outside C_v (i.e., $b_{uv'}$ and $b_{v'w}$ intersect each other above the bottom edge where u and w are top vertices of L and R, respectively). $- v'$ will not be in H_V and must be in H_B; stacks L and R remain unchanged. Vertex v_9 in Figure 6 is such an example.

(b) v' is inside C_v (i.e., $b_{uv'}$ and $b_{v'w}$ cross the bottom edge before intersecting each other), and $- v'$ may be closer to some point of the bottom edge than vertices in L and R. The Voronoi cell of v' crosses the bottom edge and may crowd out the Voronoi cells of some vertices in L and R. If the largest circle determined by the next-to-top vertex of L and v' does not contain the top vertex of L (i.e., $b_{u'u}$ intersects $b_{uv'}$ above the bottom edge where u' is the next-to-top vertex of L), then pop the top vertex of L and assign it as a vertex in H_B. Vertices of L are popped until its top vertex remains in L; Lemma 8 guarantees that all vertices beneath also remain in L. Stack R is handled similarly. For example, in Figure 6, v_{13} is popped when v_{10} is visited.

  (i) If either $C^L_{v'}$ or $C^R_{v'}$ exists but not both, v' is pushed onto stack $L(R)$ if v' is the left (right) endpoint of that chord. The tree traversal is continued at $n(v')$ using the new empty circle $C_{v'}$, new stack $L(R)$, and old stack $R(L)$. Vertices v_6 and v_{13} are such examples which are pushed onto their corresponding stacks L and R when $n(v_6)$ and $n(v_{13})$ are visited.

  (ii) If both $C^L_{v'}$ and $C^R_{v'}$ exist, v' must be a vertex in H_V by Lemma 7. The tree traversal will continue at $n^L(v')$, where $C^L_{v'}$, old stack L, and new stack R' containing v' alone will be used for further vertex classification. Similarly, the traversal at $n^R(v')$ will use $C^R_{v'}$, old stack R, and a new stack L' containing only v'. Vertex v_{10} in Figure 6 is such an example.

For visualizing the above algorithm, Figure 7 gives a walk-through of the example in Figure 6.

3.4. Complexity analysis. Our method for constructing the constrained Voronoi diagram of a simple polygon P mainly relies on the efficiency of the identification of the INHs from an NH. Since the identification for different INHs is executed recursively, we shall only consider the root INH of an NH.

As described previously, when we traverse tree T_P of an NH to identify an INH, we visit each vertex of the INH exactly once. Those vertices which have not been visited in the traversal of T_P cannot belong to the root INH. Therefore, we only need to show that each visited vertex is tested in constant time in order to classify it as a vertex in H_V or in H_B.

Let us consider a vertex v. In the test, v can be classified into one of the following three types: (i) $v \epsilon H_V$, (ii) $v \epsilon H_B$, and (iii) v is a potential vertex.

For type (i), v is stored in the list of vertices representing H_V.

For type (ii), v is stored in the list of vertices corresponding to a particular H_B and vertex v will never be tested again. Note that each vertex in H_V or potential vertex is associated with a separate list H_B of vertices. If the potential vertex, separating the two lists of vertices corresponding to two H_B's, has been determined to be in H_B, then these two lists of vertices will be concatenated together.

For type (iii), v is stored in the left or right stack and could be repeatedly tested

Initially $L = [v_1)$, $R = (\ \ ]$, $H_V = (v_1)$
visiting v_4: insert v_4 into H_V $\quad / * case2b(ii) * /$
left chord $n^L(v_4)$, $L = [v_1)$, $R = (v_4]$
visiting v_2: chord $n(v_2)$, $L = [v_1, v_2)$, $R = (v_4]$ $\quad / * case2b(i) * /$
visiting v_3: traversal terminated, insert v_2, v_3 into H_V $\quad / * case1 * /$
right chord $n^R(v_4)$, $L = [v_4)$, $R = (\ \ ]$
visiting v_{14}: chord $n(v_{14})$, $L = [v_4)$, $R = (v_{14}]$ $\quad / * case2b(i) * /$
visiting v_6: $\quad / * case2b(i) * /$
left chord $n^L(v_6)$, traversal pruned, process NH above $n^L(v_6)$ recursively
$/ * case1 * /$
right chord $n^R(v_6)$, $L = [v_4, v_6)$, $R = (v_{14}]$
visiting v_{13}: chord $n(v_{13})$, $L = [v_4, v_6)$, $R = (v_{13}, v_{14}]$ $\quad / * case2b(i) * /$
visiting v_{10}: insert v_{10} in H_V $\quad / * case2b(ii) * /$
left chord $n^L(v_{10})$, $L = [v_4, v_6)$, $R = (v_{10}]$
visiting v_9: $H_B(-, v_{10}) = (v_9, v_{10})$ $\quad / * case2a * /$

process NH above $n(v_{11})$ recursively
Finally $H_V = (v_1, v_2, v_3, v_4, v_6, v_{10}, v_{14})$

FIG. 7. *Walk-through of the example in Figure* 6.

when the descendants of v are visited. However, once vertex v is identified to be a vertex in H_V or H_B, v will never be tested again. Thus, we can argue that the time for visiting a vertex is constant when amortized over a sequence of tests. To see this, our analysis assumes that one unit credit should have been assigned to each potential vertex in L and R. For each vertex v of H in the bottom-up sweep of T_P, two unit credits of work are needed for each test: one for carrying the test itself, i.e., either assigning v as a vertex in H_V, H_B or a potential vertex in L or R; the other unit credit is assigned to the vertex should it be identified as a potential vertex. The test on a vertex in L or R to determine whether or not it has to be reassigned to H_B or H_V will be paid by the unit credit associated with the vertex. This either happens once for the checked vertex (which is accounted to it) or this test stops at a vertex which still cannot be reassigned and the test stop condition is accounted to the vertex again.

It is not difficult to see that linked lists can be used to keep track of the vertices in H_V and H_B's. In particular, insertion and concatenation operations on H_V and H_B's can be executed in constant time. The time complexity analysis for the construction of Voronoi diagrams of INH, NH, and P is obvious, as described in the previous sections. We shall conclude the above analysis by the following theorem.

THEOREM 4. *$CDT(P)$ can be found in $\Theta(|\ P\ |)$ time for simple polygon P.*

4. Concluding remarks. In this paper, we presented a deterministic algorithm for finding the constrained Delaunay triangulation of a simple polygon with n sides in $\Theta(n)$ time in the worst case. This may be one of the few linear-time algorithms for nonarbitrary triangulation of a simple polygon.

In the definition of Delaunay triangulation, we can check whether a triangulation is Delaunay by studying vertices within local proximity. It should not be surprising that the Delaunay triangulation and the constrained Voronoi diagram of a simple polygon can be done in linear time after being given Chazelle's horizontal visibility map, which links vertices within proximity together. The horizontal visibility maps are helpful to decompose the polygon into components such that the "divide and conquer" approach can be applied. However, if the decomposition of the polygon into components is not carefully done, "interaction" of the Voronoi diagrams of the components may be more than linear (even quadratic time). From Theorem 1, the partition of the polygon into components by chords has the advantage that the Voronoi diagrams of the components at the same level would not interact with each other; i.e., horizontal interaction can be reduced. Moreover, because of the property of H_V, interaction of Voronoi diagrams of components at different levels can also be confined; i.e., vertical interaction can be eliminated.

With our linear-time algorithm, the following related problems can also be solved efficiently:

(1) all nearest (mutual visible) neighbors of the vertices of a simple polygon [13],

(2) a shortest diagonal of a simple polygon [13],

(3) a largest inscribing circle of vertices of a simple polygon [12],

(4) the nearest vertex from a query point [13],

(5) finding $DT(S)$ if the Euclidean minimum spanning tree for a point set S is given [1],

(6) finding standard Voronoi diagram for S' if the Voronoi diagram of a point set S is known [1], where $S' \subset S$.

By treating edges and vertices of a single polygon as sites for the Voronoi diagram, we can apply ideas similar to those given in this paper to find the medial axis of a simple polygon in linear time [7].

Acknowledgment. The authors would like to thank Bethany Chan, Siu-Wing Cheng, and the anonymous referees for their patience in reading the first draft of this paper and their comments in improving the readability of the paper.

RECONSTRUCTING ALGEBRAIC FUNCTIONS FROM MIXED DATA*

SIGAL AR†, RICHARD J. LIPTON†, RONITT RUBINFELD‡, AND MADHU SUDAN§

Abstract. We consider a variant of the traditional task of explicitly reconstructing algebraic functions from black box representations. In the traditional setting for such problems, one is given access to an unknown function f that is represented by a black box, or an oracle, which can be queried for the value of f at any input. Given a guarantee that this unknown function f is some nice algebraic function, say a polynomial in its input of degree bound d, the goal of the reconstruction problem is to explicitly determine the coefficients of the unknown polynomial. All work on polynomial interpolation, especially sparse ones, are or may be presented in such a setting. The work of Kaltofen and Trager [*Computing with polynomials given by black boxes for their evaluations: Greatest common divisors, factorization, separation of numerators and denominators*, in Proc. 29th Ann. IEEE Symp. on Foundations of Computer Science, 1988, pp. 296–305], for instance, highlights the utility of this setting, by performing numerous manipulations on polynomials presented as black boxes.

The variant considered in this paper differs from the traditional setting in that our black boxes represent several algebraic functions $f_1, \ldots, f_k$, where at each input x, the box arbitrarily chooses a subset of $f_1(x), \ldots, f_k(x)$ to output and we do not know which subset it outputs. We show how to reconstruct the functions $f_1, \ldots, f_k$ from the black box, provided the black box outputs according to these functions "often." This allows us to *group* the sample points into sets, such that for each set, all outputs to points in the set are from the same algebraic function. Our methods are robust in the presence of a small fraction of arbitrary errors in the black box.

Our model and techniques can be applied in the areas of computer vision, machine learning, curve fitting and polynomial approximation, self-correcting programs, and bivariate polynomial factorization.

1. Introduction.

Suppose you are given a large set of points in the plane and you are told that an overwhelming majority of these points lie on one of k different algebraic curves of some specified degree bound D (but you are not told anything else about the curves). Given the parameters k and D, your task is to determine or "reconstruct" these algebraic curves, or alternatively, to *group* the points into sets, each of which is on the same degree D curve. Related versions of this problem may also be of interest, such as extensions to higher dimensions, and a setting where instead of the points being given in advance, one is allowed to make queries of the form "what

is the value of one of the curves at point x?" (The answer to such a query will not specify which of the k curves was used to compute the value.)

Solutions to this fundamental problem have applications to:

- the grouping problem in computer vision,
- computational learning theory,
- curve fitting over discrete domains,
- simple algorithms for polynomial factorization,
- self-correcting programs.

Computer vision. Consider a computer vision system for a robot that picks parts out of a bin. The input to the system contains an intensity map of the scene. The robot can distinguish between the parts by extracting edges from the image. Current edge detection algorithms use discretized differential operators to extract edges (e.g., [30], [10]). These algorithms produce output consisting of a bit map, where for every image point (x, y), the bit value of the point, $e(x, y)$, is set to 1 if and only if this point lies on an edge. For many vision applications it is then desired to connect between neighboring points to achieve a more compact representation of the edge map. This problem, known as "the grouping problem," is complicated by the fact that the parts are cluttered, they may be nonconvex, and they may contain holes. No polynomial time algorithm has been found for this problem.

Under the assumption that the edges of the parts are given by piecewise algebraic curves, and that the edge detection process produces results which are free of precision error, our algorithm transforms edge maps into piecewise polynomial curves in polynomial time. The second assumption is unrealistic in real computer vision applications. However, we feel that it suggests an interesting approach which should be studied further.

Computational learning theory. Our mechanism can be used to extend some well-known results on learning boolean functions to the setting of learning real-valued functions. Here is a specific instance of such a situation: in the study of economics, the price–demand curve is often considered to be well described by an algebraic function (e.g., $f(x) = c/x$ or $f(x) = -a \cdot x + b$). However, it is also the case that this curve may change [23]. In particular, there may be several unknown price–demand curves which apply in various situations: one may correspond to the behavior found when the country is at war, a second may apply after a stock market crash, and a third behavior may be found after a change in the tax structure. Some of the factors that determine which curve applies may be obvious, but others may occur because of more subtle reasons. The task of learning the price–demand relationship may be decomposed into the two subtasks of first determining the unknown curves, and then learning what determines the move from one curve to another. Our algorithm gives a solution for the first task.

We consider the Valiant model of PAC learning [36], in which a concept is learnable if there is an efficient algorithm that is able to find a good approximation to the concept on the basis of sample data. In general, our results imply that any function on input x and boolean attributes $(y_1, \ldots, y_m)$ which uses $(y_1, \ldots, y_m)$ to select f_i from a set of polynomial functions $f_1, \ldots, f_k$ and then computes and outputs $f_i(x)$ can be learned, as long as the selector function can be learned.

For example, a *polynomial-valued decision list* given by a list of terms (conjuncts of literals) $(D_1, \ldots, D_k)$ over boolean variables $y_1, \ldots, y_n$, and a list of univariate polynomials $(f_1, \ldots, f_{k+1})$ in a real variable x, represents a real-valued function f as follows:

$$f(x, y_1, \ldots, y_n) = f_i(x),$$

where i is the least index such that $D_i(y_1, \ldots, y_n)$ is true.

If the terms are restricted to being conjunctions of at most c literals, we call it a *polynomial-valued c-decision list*. This is an extension of the *boolean decision list* model defined by Rivest in [32], where the polynomials f_i are restricted to being the constants 0 or 1.

In [32], Rivest shows that the class of boolean c-decision lists is learnable in polynomial time. Using our techniques, in combination with Rivest's algorithm, we can extend this result to show that the class of polynomial-valued c-decision lists can be learned in polynomial time. The only technical point that needs to be made is as follows: Rivest gives an algorithm for producing a decision list that is consistent with the random examples and then argues using an Occam argument (see Blumer et al. [8]) that any hypothesis that is consistent with the labels of the random examples is a good hypothesis (i.e., computes a function that is usually equal to the target function). Our techniques in combination with Rivest's algorithm yield a consistent hypothesis, but since our hypothesis is not a boolean function, we must use the work of Haussler [22] to see that a consistent hypothesis is a good hypothesis.

Independent of our work, Blum and Chalasani [6] also consider a model of learning from examples where the examples may be classified according to one of several different concepts. In their model an adversary controls the decision of which concept would be used to classify the next example. Under this model they study the task of learning boolean-valued concepts such as k-term DNFs and probabilistic decision lists.

Curve fitting problems over discrete domains. A typical curve fitting problem takes the following form: given a set of points $\{(x_1, y_1), \ldots, (x_m, y_m)\}$ on the plane, give a simple curve that "fits" the given points. Depending on the exact specification of the "fit," the problem takes on different flavors: for instance, if the curve is to pass close to all the points, then this becomes a *uniform approximation* problem (see text by Rivlin [33]), while if the curve is supposed to pass through *most* of the points, then it resembles problems from coding theory. Here, we consider a problem that unifies the above two instances over *discrete domains*. For example, given a set of m points, with integer coordinates, we show in section 4.1 how to find a polynomial with integer coefficients that is Δ-close to all but an ϵ fraction of the points (if such a polynomial exists), where ϵ need only be less than $1/2$ (provided m is larger than $\frac{(4\Delta+1)d}{1-2\epsilon}$).

Reducing bivariate factoring to univariate factoring. In [4] Berlekamp gave a randomized polynomial time algorithm for factoring univariate polynomials over finite fields. Kaltofen [24] and Grigoriev and Chistov [18] show that the problem of bivariate factoring can also be solved in polynomial time by a reduction to univariate factoring, using somewhat deep methods from algebra. Our techniques in section 4.2 give a simple method to reduce the problem of factoring bivariate polynomials to that of factoring univariate polynomials over finite fields in the special case when the bivariate polynomial splits into factors which are monic and of constant degree in one of the variables. Though the results are not new, nor as strong as existing results, the methods are much simpler than those used to obtain the previously known results.

Self-correcting programs. One motivation for this work comes from the area of self-correcting programs introduced independently in [7] and [28]. For many functions, one can take programs that are known to be correct on *most* inputs and apply a simple transformation to produce a program that is correct with high probability on *each* input. But how bad can a program be and still allow for such a transformation?

There is previous work addressing this question when the functions in question are polynomials (see, for example, [28], [13], [14]). When the program is not known to be correct on most inputs, the definition of self-correction needs to be modified, since the program can toggle between two seemingly correct functions. Our methods give self-correctors that work when the error of the program is such that it answers according to one of a small number of other algebraic functions. An algebraic decision tree may contain a small number of branches, in which all subtrees are intended to compute the same function but are computed separately for purposes of efficiency. The algebraic decision tree program might err in some of the subtrees and compute the wrong algebraic function. Our self-correctors output a small number of candidates for the correct function.

One particular situation where this is useful is in the computation of the permanent of a matrix, over a finite field. Results of Cai and Hemachandra [9], when used in combination with our results, imply that if there is an efficient program which computes the permanent correctly on a nonnegligible fraction of the input and computes one of a small number of other algebraic functions on the rest of the inputs, then the permanent can be computed efficiently everywhere.

1.1. The *k*-algebraic black box model. We consider the following black box reconstruction problem, which is general enough to model all of the aforementioned problems. We think of the black box as "containing" k functions, $f_1, \ldots, f_k$, where f_i is an "algebraically well-behaved" function. For instance, each f_i could be a polynomial of degree at most d, and on every input x the black box outputs $f_i(x)$ for some $i \in [k]$. (Here and throughout this paper, the notation $[k]$ stands for the set of integers $\{1, \ldots, k\}$.) Relating to the problem discussed in the first paragraph of the introduction, this corresponds to the case where for every value of an x-coordinate there is at least one point that has that value. We now present this definition formally, starting with the standard black box model ($k = 1$).

DEFINITION 1. *A* black box B *is an oracle representing a function from a finite domain* $\mathcal{D}$ *to a range* $\mathcal{R}$.

There are two kinds of domains that will be of interest to us. One is a finite subset H of a (potentially infinite) field F. The second is an n-dimensional vector space over a finite field F. In both cases the range will be the field F.

Previous research on black box reconstruction focused on the following: assuming that B is one of a special class of functions (for example, that B is a degree d polynomial), determine an explicit representation of B. In our model, there may be more than one output that is valid for each input. More specifically, we give the following definition.

DEFINITION 2. *A black box* B *mapping a finite subset* H *of a field* F *to* F *is a* (k, d)-polynomial black box *if there exist polynomials* $f_1, \ldots, f_k : F \to F$ *of degree at most* d *such that for every input* $x \in H$, *there exists* $i \in \{1, \ldots, k\}$, *such that* $B(x) = f_i(x)$. *In such a case, we say that the functions* $f_1, \ldots, f_k$ *describe the black box* B.

Our first *black box reconstruction problem* is:

> Given a (k, d)-polynomial black box B, find a set of functions $f_1, \ldots, f_k$ that describe B.

The definition of a (k, d)-polynomial black box can be generalized to situations involving noise as follows.

DEFINITION 3. *For* $\epsilon \in [0, 1]$ *and for a finite subset* H *of a field* F, *a black box* $B : H \to F$ *is an* ϵ-noisy (k, d)-polynomial black box *if there exist polynomials*

$f_1, \ldots, f_k : F \to F$ of degree at most d and a set $S \subset H$, with $|S| \geq (1-\epsilon)|H|$, such that for every input $x \in S$, there exists $i \in \{1, \ldots, k\}$ such that $B(x) = f_i(x)$. In such a case, the functions $f_1, \ldots, f_k$ are said to describe B.

The notion of the reconstruction problem generalizes to the noisy case in the obvious way. We now attempt to generalize the problem to allow the black box to compute other algebraic functions, such as $B(x) = \sqrt{x}$, etc. This part is somewhat more technical, so we now introduce some new terminology.

DEFINITION 4. *For positive integers d_x, d_y and indeterminates x, y, the $\{(d_x, x), (d_y, y)\}$-*weighted degree *of a monomial $x^i y^j$ is $id_x + jd_y$. The $\{(d_x, x), (d_y, y)\}$-weighted degree of a polynomial $Q(x, y)$ is the maximum over all monomials in Q (i.e., the monomials with nonzero coefficients in Q) of their $\{(d_x, x), (d_y, y)\}$-weighted degree.*

We now introduce the notion of an algebraic box and show how it relates to the earlier notion of a polynomial black box.

DEFINITION 5. *For a finite subset H of a field F, a black box $B : H \to F$ is a* (k, d)-algebraic black box *if there exists a polynomial $Q(x, y)$ of $\{(1, x), (d, y)\}$-weighted degree at most kd, such that for every input $x \in H$, the output y of the black box satisfies $Q(x, y) = 0$. In such a case, we say that the polynomial Q describes B.*

For example, if $B(x) = \sqrt{x}$, the polynomial $Q(x, y) = (y^2 - x)$ satisfies the requirement of the definition and describes B. The $\{(1, x), (d, y)\}$-weighted degree of Q is $2d$.

PROPOSITION 6. *If B is a (k, d)-polynomial black box then B is also a (k, d)-algebraic black box.*

Proof. Let B be a (k, d)-polynomial black box and let $f_1, \ldots, f_k$ describe it. Then the polynomial $Q(x, y) \stackrel{\text{def}}{=} \prod_{i=1}^{k} (y - f_i(x))$ describes B and has $\{(1, x), (d, y)\}$-weighted degree at most kd. □

The (k, d)-algebraic black box reconstruction problem is:

> Given a (k, d)-algebraic box B, find the polynomial Q of $\{(1, x), (d, y)\}$-weighted degree at most kd which describes it.

The definition and proposition can be extended easily to the ϵ-noisy case.

All the above definitions generalize to a case where the input is an n-dimensional vector over F and the black box is computing n-variate functions. In particular, we have the following definition.

DEFINITION 7. *For a finite field F, an n-variate black box $B : F^n \to F$ is a* (k, d)-polynomial black box *if there exist polynomials $f_1, \ldots, f_k : F^n \to F$ of total degree at most d such that for every input $(x_1, \ldots, x_n) \in F^n$ there exists $i \in \{1, \ldots, k\}$ such that $B(x_1, \ldots, x_n) = f_i(x_1, \ldots, x_n)$.*

DEFINITION 8. *For a finite field F, an n-variate black box $B : F^n \to F$ is a* (k, d)-algebraic black box *if there exists a polynomial $Q(x_1, \ldots, x_n, y)$ of $\{(1, x_1), \ldots, (1, x_n), (d, y)\}$-weighted degree at most kd such that for every input $(x_1, \ldots, x_n) \in F^n$, the output y of the black box satisfies $Q(x_1, \ldots, x_n, y) = 0$.*

Again the reconstruction problems are defined correspondingly. In this paper we attempt to solve all such reconstruction problems. Notice that this problem is not well defined if there exist multiple solutions, say Q and $\tilde{Q}$, such that both Q and $\tilde{Q}$ describe the black box. Much of the work is done in establishing conditions under which any $\tilde{Q}$ that describes the black box gives a meaningful answer.

1.2. Previous work and our results. The setting where the black box represents a *single* polynomial or rational function, without noise, is the classic interpolation problem and is well studied. Efficient algorithms for sparse multivariate polyno-

mial interpolation are given by Zippel [40, 41], Grigoriev, Karpinski, and Singer [21], Ben-Or [2] and Ben-Or and Tiwari [3], and for sparse rational functions by Grigoriev and Karpinski GK and Grigoriev, Karpinski, and Singer [20].

The case where the black box represents a single function with some noise has also been studied previously. Welch and Berlekamp [39, 5] (see also [14]) show how to reconstruct a univariate polynomial from a $(\frac{1}{2} - \delta)$-noisy $(1, d)$-polynomial black box and Coppersmith [11], Gemmell et al. [13], and Gemmell and Sudan [14] show how to do the same for multivariate polynomials. All the above-mentioned results require, however, that the field size be at least polynomially large in $\frac{d}{\delta}$. The conditions are required to ensure that there is a *unique* degree d polynomial describing the black box on a $\frac{1}{2} + \delta$ fraction of the inputs. Reconstructing functions from a black box representing more than one function, or when the function it represents is not guaranteed to be unique, seems to be a relatively unexplored subject. The works of Goldreich and Levin [15] and Kushilevitz and Mansour [26] are the only exceptions we know of. Both papers study the reconstruction of n-variate linear functions (i.e., homogenous polynomials of degree 1) from a $\frac{1}{2} - \delta$-noisy black box over GF(2). In this case, there can be up to $O(\frac{1}{\delta}^2)$ polynomials representing the black box and they reconstruct all such polynomials.

The main result in this paper is an algorithm for reconstructing algebraic functions describing noisy algebraic black boxes, which works when the black box satisfies certain conditions. To see why the result needs to have some conditions on the black box, consider the following example. Suppose the black box is described by the polynomial $(x^2 + y^2 - 1)(x + y - 1)$. But suppose that for every x the black box always outputs a y from the unit circle (and never according to the line $x + y - 1 = 0$). Then clearly the reconstruction algorithm has no information to reconstruct the line $x + y - 1$. The condition imposed on the black box essentially addresses this issue. We describe the result for univariate ϵ-noisy (k, d)-polynomial black boxes. We present a randomized algorithm which takes as input a parameter $p > \epsilon$ and with high probability outputs a list of all polynomials f_i which describe the black box on more than p fraction of the input, provided $(p - \epsilon)|H| > kd$. (This condition amounts to saying that the black box must output according to f_i sufficiently often.) The running time of the algorithm is a polynomial in k, d, and $\frac{1}{(p-\epsilon)}$. This result is presented along with generalizations to univariate noisy algebraic black boxes in section 2.

To reconstruct a univariate polynomial, we sample the black box on a small set of inputs and construct a bivariate polynomial $\tilde{Q}(x, y)$ which is zero at *all* the sample points. Then we use bivariate polynomial factorization to find a factor of the form $(y - f(x))$. If it exists, $f(x)$ then becomes our candidate for output. We show that if the number of points (x, y) such that $y = f(x)$ is large in the sample we chose, then $y - f(x)$ has to be a factor of any $\tilde{Q}$ which all the sample points satisfy.

Our results do not generalize immediately to multivariate polynomials. Among other factors, one problem is that an n-variate polynomial of degree d has $\binom{n+d}{d}$ coefficients, which is exponential in n (or d). This seems to make the problem inherently hard to solve in time polynomial in n and d. However, we bypass this, once again using the idea of black boxes. Instead of trying to reconstruct the multivariate polynomial explicitly (i.e., by determining all its coefficients), we allow the reconstruction algorithm to reconstruct the polynomial implicitly, i.e., by constructing a black box which computes the multivariate polynomial. If the polynomial turns out to be sparse then we can now use any sparse interpolation algorithm from [3, 20, 21, 40] to reconstruct an explicit representation of the polynomials in time polynomial in n, d and the

number of nonzero coefficients. On the other hand, by using the techniques of [25] we can also continue to manipulate the black boxes as they are for whatever purposes.[1]

We now describe our result for reconstructing multivariate polynomials. We present a randomized algorithm which takes as input a parameter p and with high probability reconstructs probabilistic black boxes for all the polynomials $f_1, \ldots, f_k$ describing a noisy (k, d)-black box over a finite field F, provided the noisy (k, d)-black black box satisfies the following conditions. (1) Every polynomial is represented on at least a p fraction of the inputs (i.e., for every i, $\Pr_{\hat{x} \in F^n}[B(\hat{x}) = f_i(\hat{x})] \geq p$). (2) The finite field F over which the black box works is sufficiently large ($|F|$ should be polynomially large in $k, d, \frac{1}{(p-\epsilon)}$). The running time of the algorithm is polynomial in k, d, and $\frac{1}{(p-\epsilon)}$. The main technique employed here is a randomized reduction from the multivariate to the univariate case. We note that the solution obtained here for the multivariate case differs in several aspects from the solution for the univariate case. First, this algorithm does not extend to the case of finite subsets of infinite fields. Second, it needs to make sure that all the polynomials are well represented in the black box. The latter aspect is a significant weakness, and getting around this is an open question.

Subsequent work. One of the main questions left open by this paper is the problem of reconstructing all degree d polynomials that agree with an arbitrary black box on ϵ fraction of the inputs. Some recent work has addressed this question. Goldreich, Rubinfeld, and Sudan [16] give an algorithm to (explicitly) reconstruct all n-variate degree d polynomials agreeing with a black box over F on an ϵ fraction of the inputs, provided $\epsilon \geq 2\sqrt{d/|F|}$. Their algorithm runs in time $O((n, \frac{1}{\epsilon})^{\mathrm{poly}(d)})$, which is exponential in d. Their algorithm generalizes the earlier mentioned solution of Goldreich and Levin [15]. For the case of univariate polynomials, Sudan [35] has given a polynomial time algorithm which can find all degree d polynomials agreeing with a black box on ϵ fraction of the domain, provided $\epsilon \geq 2\sqrt{d/|F|}$. The main contribution in [35] is a simple observation which shows that m input/output pairs from any black box can be thought of as the output of a $(O(\sqrt{m}), 1)$-algebraic black box. Using this observation, Lemma 18 of this paper is applied to reconstruct all polynomials of low degree which describe the black box on an ϵ fraction of the inputs. Finding a similar solution for the multivariate cases remains open (some cases are addressed by [35], but the problem is not completely resolved). A second question that is left open is the task of solving the (k, d)-polynomial black box problem over the reals, where the points are not provided to infinite precision. This is the true problem underlying the application to computer vision. While the ideas in this paper do not immediately apply to this question, some variants (in particular, the variant employed in [35]) seem promising and deserve to be investigated further

In other related work, Rubinfeld and Zippel [34] have employed the black box reconstruction problem and build on the techniques presented in this paper to present a modular approach to the polynomial factorization problem. While the application presented in this paper (in section 4.2) is to a restricted subclass of the bivariate factorization problem, the work of [34] finds an application to the general multivariate factorization problem.

[1] The idea of manipulating multivariate polynomials and rational functions represented by black boxes was proposed by Kaltofen and Trager in [25]. They show that it is possible to factor and compute gcd's for polynomials given by such a representation and to separate the numerator from the denominator of rational functions given by such a representation.

1.3. Organization. The rest of this paper is organized as follows. In section 2, we describe our results for univariate polynomials, rational functions, and other algebraic functions. In section 3, we consider extensions of the reconstruction problem to the case of multivariate polynomials. Finally, in section 4, we describe several applications of our work.

2. Univariate black boxes. In this section we consider the univariate reconstruction problem for (noisy) (k, d)-polynomial and algebraic black boxes. We describe the general format of our results with the example of a (k, d)-polynomial black box described by $f_1, \ldots, f_k$. We present a solution in the form of an algorithm which takes m input/output pairs $\{(x_1, y_1), \ldots, (x_m, y_m)\}$ of the black box and attempts to reconstruct the polynomials $f_1, \ldots, f_k$ from this set of input/output pairs. In order to reconstruct a small set of polynomials which includes a specific polynomial f_i, the algorithm (obviously) needs to find sufficiently many points (x_j, y_j) such that $y_j = f_i(x_j)$ ($d + 1$ such points are needed). We present complementary bounds, showing that if the number of points on f_i is sufficiently large, then the output is guaranteed to include f_i. We then show how some simple sampling of the black box (either by exhaustively sampling all points from the domain H or by picking a random sample of x_j's chosen independently and uniformly at random from H) yields a collection of input/output pairs which satisfies the required condition, provided H is large enough and the fraction of inputs on which B's output is described by f_i is large enough.

2.1. An intermediate model. As a first step towards solving the algebraic reconstruction problem, we consider the case where the black box outputs *all* of $f_1(x), \ldots, f_k(x)$ on any input x. We refer to this as a (k, d)-*total polynomial black box*. These are output in arbitrary order, which is not necessarily the same for each x. We further assume that there are no errors in the output. Thus the reconstruction problem we wish to solve may be stated formally as follows.

Given: Positive integers k and d, a field F, and a black box $B = (B_1, \ldots, B_k)$, where $B_i : F \to F$ with the property that there exist polynomials $f_1, \ldots f_k$ of degree at most d over F, such that for every $x \in F$, the multisets $\{B_1(x), \ldots, B_k(x)\}$ and $\{f_1(x), \ldots, f_k(x)\}$ are identical.

Problem: Find $f_1, \ldots, f_k$.

We reduce the problem of extracting the polynomials to that of bivariate polynomial factorization. The main idea underlying this reduction is the following: on input x, if the (k, d)-total polynomial black box outputs $\{y_1, \ldots, y_k\}$, we know that $\forall j \in [k]$, $\exists i \in [k]$ such that $y_j = f_i(x)$. Therefore, each input/output pair $(x; y_1, \ldots, y_k)$ of the black box satisfies the relation:

$$\sum_j \prod_i (y_j - f_i(x)) = 0.$$

Our aim will be to construct a related polynomial which will enable us to recover the f_i's.

Consider the functions $\sigma_j : F \mapsto F$, $j \in [k]$ defined as

$$\sigma_j(x) \stackrel{\text{def}}{=} \sum_{S \subset [k], |S| = j} \prod_{i \in S} f_i(x)$$

(these are the *primitive symmetric* functions of $f_1, \ldots, f_k$).

Observe that $\sigma_j(x)$ can be evaluated at any input x using the given (k,d)-total polynomial black box, using the identity

$$\sigma_j(x) = \sum_{S \subset [k], |S|=j} \prod_{i \in S} B_i(x).$$

Furthermore this computation can be performed in time in $O(k \log k \log\log k)$ using a fast Fourier transform (see survey article by von zur Gathen [12, pp. 320–321]). Observe further that σ_j is a polynomial of degree at most jd. Hence evaluating it at $jd+1$ points suffices to find all the coefficients of this polynomial (if the black box outputs every $f_i(x)$ for every x).

Now consider the following bivariate polynomial, in x and a new indeterminate y:

$$Q(x,y) \stackrel{\text{def}}{=} y^k - \sigma_1(x)y^{k-1} + \cdots + (-1)^k \sigma_k(x).$$

From the explicit representation of the σ_i's, we can also compute an explicit representation of Q. But now notice that Q can equivalently be written as:

$$Q(x,y) = \prod_{i=1}^{k} (y - f_i(x)).$$

(The equivalence follows from the definition of the σ_j's.) Therefore, to recover the f_i's, all we have to do is find the factors of the bivariate polynomial Q. Bivariate factorization can be done efficiently over the rationals [18, 24, 29] and can be done efficiently (probabilistically) over finite fields [17, 24].

We now summarize our algorithm. The input to the algorithm is $kd+1$ distinct elements $\{x_1, \ldots, x_{kd+1}\}$ from the the field F, and a set $\{y_{1,j}, \ldots, y_{k,j}\}$ for every $j \in [kd+1]$ representing the output of the black box B on input x_j.

1. Evaluate $\sigma_j(x_i)$ for every $j \in [k]$ and every $i \in [kd+1]$.
2. Interpolate for the coefficients of $\sigma_j(x)$ and let $\sigma_{j,l}$ be the coefficient of x^l in σ_j.
3. Let $Q(x,y)$ be the polynomial $\sum_{j=0}^{k} \sum_{l=0}^{jd} (-1)^j \sigma_{j,l} x^l y^{k-j}$.
4. Factor Q into its irreducible factors. This will yield $Q(x,y) = \prod_{i=1}^{k} (y - g_i(x))$.
5. Output the polynomials $g_1, \ldots, g_k$.

The arguments leading to this algorithm prove its correctness and we have the following lemma.

LEMMA 9. *Let $\{(x_j; (y_{j,1}, \ldots, y_{j,k}))\}_{j=1}^{kd+1}$ be the input/output pairs of a (k,d) total polynomial black box B over a field F on $kd+1$ distinct inputs. Then there exists a randomized algorithm whose running time is polynomial in k, d which explicitly reconstructs the set of polynomials $\{f_1, \ldots, f_k\}$ which describe B.*

Since the only condition on the x_j's is that they be distinct, it is easy to get a total polynomial reconstruction algorithm from the above lemma and thus we get the following theorem.

THEOREM 10. *Let $f_1, \ldots, f_k$ be degree d polynomials over $\mathcal{Q}$ (the rationals) or a finite field F of cardinality at least $kd+1$. Given a black box B which on input x outputs the multiset $\{f_1(x), \ldots, f_k(x)\}$ (in arbitrary order), there exists an algorithm which queries the black box on $kd+1$ distinct inputs and reconstructs the polynomials that describe the black box. The algorithm is deterministic when the polynomials are over $\mathcal{Q}$ and probabilistic when the polynomials are over some finite field.*

2.2. (k, d)-polynomial black boxes. We now build on the methods of the previous section to reconstruct information from a (k, d)-polynomial black box which outputs the value of *one* of k univariate polynomials $f_1, \ldots, f_k$, on every input. Our method extends immediately to two more general cases:

1. (k, d)-algebraic black boxes,
2. noisy (polynomial and algebraic) black boxes.

The generalizations are dealt with in the next section.

The problem we wish to solve is formally stated as follows.

Given: Positive integers k and d, a field F, a finite set $H \subseteq F$, and a black box $B : H \to F$ with the property that there exist polynomials $f_1, \ldots f_k$ of degree at most d over F, such that for every $x \in H$, $B(x) \in \{f_1(x), \ldots, f_k(x)\}$.

Problem: Find $f_1, \ldots, f_k$.

Our solution for this problem is based on the solution of the previous subsection. The critical observation is that the polynomial Q produced by the algorithm of the previous section always satisfied the property $Q(x, y) = 0$ for any input x to the black box and where y is any element of the output set of the black box on input x. We will try to construct a polynomial Q in two variables as in the previous section, satisfying the property that if $y = B(x)$ is the output of the black box on input x, then $Q(x, y) = 0$. However, we will not be able to construct the polynomials $\sigma_i(x)$ as in the previous case. Hence, we will abandon that part of the algorithm and directly try to find any polynomial $\tilde{Q}$ such that $\tilde{Q}(x, y) = 0$ on all the sampled points. We will then use the factors of this polynomial to determine the f_i's as in the previous section. Thus our algorithm is summarized as follows.

The input to the algorithm is m distinct pairs of elements $\{(x_1, y_1), \ldots, (x_m, y_m)\}$.

1. Interpolate to find a set of coefficients $\tilde{q}_{lj}$ of the polynomial

$$\tilde{Q}(x, y) = \sum_{l=0}^{k} \sum_{j=0}^{dl} \tilde{q}_{lj} y^{k-l} x^j$$

   that satisfies $\tilde{Q} \not\equiv 0$ and $\tilde{Q}(x_i, y_i) = 0$ for $i \in [m]$.
2. Factor the polynomial $\tilde{Q}$ and if it has any factors of the form $(y - g(x))$, output g as a candidate polynomial.

Notes. The important step above is step 1, which involves finding a nontrivial solution to a homogenous linear system. First we need to make sure this system has at least *one* solution. This is easy since $Q(x, y) = \prod_i (y - f_i(x))$ is such a solution. However, the solution in such a step need not necessarily be unique and we will simply find *any* solution to this system and show that it suffices, under certain conditions, for step 2. In what follows, we shall examine the conditions under which the output will include a certain polynomial f_i.

LEMMA 11. *For a set $\{(x_j, y_j) | j \in [m]\}$ of m distinct pairs from $F \times F$, if $\tilde{Q}$ is a bivariate polynomial of $\{(1, x), (d, y)\}$-weighted degree kd satisfying*

$$\forall\ j \in [m],\ \tilde{Q}(x_j, y_j) = 0$$

and f is a univariate polynomial of degree d satisfying

$$|\{j | f(x_j) = y_j\}| > kd,$$

then the polynomial $(y - f(x))$ divides the polynomial $\tilde{Q}(x, y)$.

Proof. Let $S \stackrel{\text{def}}{=} \{j | f(x_j) = y_j\}$. Notice that for distinct $j_1, j_2 \in S$, $x_{j_1} \neq x_{j_2}$, or else the pairs $(x_{j_1}, f(x_{j_1}))$ and $(x_{j_2}, f(x_{j_2}))$ are not distinct.

Consider the univariate polynomial $\tilde{Q}_f(x) \equiv \tilde{Q}(x, f(x))$. For all indices $j \in S$ we have that $\tilde{Q}(x_j) = 0$. Furthermore, $\tilde{Q}_f(x)$ is a polynomial of degree at most kd in x. Hence if $\tilde{Q}_f$ is zero at $|S| > kd$ places, then it must be identically zero, implying that $(y - f(x))|\tilde{Q}(x, y)$. □

The lemma above guarantees that under certain circumstances, the factors of $\tilde{Q}(x, y)$ do give useful information about the f_i's. The effect is summarized in the following lemma.

LEMMA 12. *Let $\{(x_1, y_1), \ldots, (x_m, y_m)\}$ be m distinct pairs of elements which are the input/output pairs of a (k, d)-polynomial black box B described by polynomials $f_1, \ldots, f_k$. If there exists an $i \in [k]$ such that $|\{j | y_j = f_i(x_j)\}| > kd$, then a set of at most k polynomials $\{g_1, \ldots, g_k\}$ that includes f_i can be found in time polynomial in m, k, and d.*

Remark. Notice that Lemma 12 is a strict strengthening of Lemma 9.

To finish the analysis of the algorithm we need to determine how to sample the black box B so as to get enough points according to f_i. Let $p_i \stackrel{\text{def}}{=} \Pr_{x \in H}[B(x) = f_i(x)]$ and $\delta > 0$ be the confidence parameter. Let $M = \frac{4}{p_i}(kd + \ln \frac{2}{\delta})$. The strategy for picking the points $\{(x_1, y_1), \ldots, (x_m, y_m)\}$ depends on $|H|$. If $|H| \geq \frac{2}{\delta}\binom{M}{2}$, then we let $m = M$ and pick m elements $x_1, \ldots, x_m$ independently and uniformly at random from H. Lemma 35 in the appendix (shown using a simple combination of Chernoff bounds and the "birthday problem analysis") shows that the sampled points are all distinct and satisfy $|\{j : B(x_j) = f_i(x_j)\}| > kd$ with probability at least $1 - \delta$. Thus in this case we will use $\{(x_1, B(x_1)), \ldots, (x_m, B(x_m))\}$ as the input to the algorithm described above. If, on the other hand, $|H|$ is not large enough, then we will simply sample every point in H (i.e., the input set will be $\{(x, B(x)) | x \in H\}$), implying in particular that $m = |H|$, and in this case the algorithm described above will include f_i as part of its output provided $p_i|H| > kd$. Notice that in both cases the running time of the algorithm is polynomial in M, which is in turn bounded by some polynomial in $k, d, \frac{1}{p_i}, \frac{1}{\delta}$. Furthermore, by choosing $\delta' = \delta/k$ and a threshold parameter p and running the algorithm above with confidence parameter δ', we find that the algorithm above recovers, with confidence $1 - \delta$, every polynomial f_i, such that $p_i \geq p$. The running time is still a polynomial in $k, d, \frac{1}{p}, \frac{1}{\delta}$. This yields the following theorem.

THEOREM 13. *Let B be a (k, d)-polynomial black box, mapping a finite domain H to a field F, described by polynomials $f_1, \ldots, f_k$. For $i \in [k]$, let $p_i \stackrel{\text{def}}{=} \Pr_{x \in H}[B(x) = f_i(x)]$. There exists an algorithm which takes as input a confidence parameter $\delta > 0$ and a threshold $p > 0$, runs in time $\text{poly}(k, d, \frac{1}{p}, \frac{1}{\delta})$ and makes calls to the black box B, and with probability at least $1 - \delta$ reconstructs a list of at most k polynomials which includes all polynomials f_i such that $p_i \geq p$, provided $p > \frac{kd}{|H|}$.*

2.3. (k, d)-algebraic black boxes. The algorithm of section 2.2 extends immediately to the case of algebraic black boxes. Here, by definition, the input/output pair of the black box, (x, y), satisfies an algebraic relation of the form $Q(x, y) = 0$. We can attempt to find a polynomial $\tilde{Q}$ which satisfies $\tilde{Q}(x, y) = 0$ for all the sampled points by interpolation (step 3 in the algorithm of section 2.2).

As in the previous section, it will not be possible to guarantee that the output we produce will be exactly Q. For instance, if $Q(x, y) = (x^2 + y^2 - 1)(x + y - 1)$, but all the points actually come from the unit circle, then the algorithm has no information to

point to the line $x+y-1=0$. Thus, as in the previous section, we will only attempt to find those parts of the curve that describe significant portions of output of the black box. More precisely, if $Q(x,y)$ factors into irreducible factors $Q_1(x,y),\ldots,Q_l(x,y)$ and we know that many points satisfy, say, $Q_1(x_j,y_j)=0$, then we would like Q_1 to be one of the outputs of the algorithm.

The proof that this is indeed the case is slightly more complicated than in the previous subsection. We will use a version of Bezout's theorem ([38, Theorem 3.1]). Essentially, Bezout's theorem states that two algebraic curves in the plane cannot intersect in infinitely many points, unless they are identical. The theorem gives an explicit bound on the number of points where two curves of degree d_1 and d_2 may meet. Bezout's bound is slightly weaker than the one we wish to prove for the case of (k,d)-algebraic black boxes, so we prove our lemma from first principles.

Before going on to the next lemma we review a couple of standard definitions from algebra (cf. [38]).

DEFINITION 14. *Given univariate polynomials* $P(y)=\sum_{i=0}^{d_1}\alpha_i y^i$ *and* $Q(y)=\sum_{j=0}^{d_2}\beta_j y^j$ *over some domain* F*, let* $M(P,Q)$ *be the* $(d_1+d_2)\times(d_1+d_2)$ *matrix given as follows:*

$$M(P,Q)=\begin{bmatrix}
\alpha_0 & \alpha_1 & \cdots & \alpha_{d_1-1} & \alpha_{d_1} & 0 & \cdots & 0 & 0 & 0 & \cdots & 0\\
0 & \alpha_0 & \cdots & \alpha_{d_1-2} & \alpha_{d_1-1} & \alpha_{d_1} & \cdots & 0 & 0 & 0 & \cdots & 0\\
\vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \ddots & \vdots\\
0 & 0 & \cdots & 0 & 0 & 0 & \cdots & \alpha_0 & \alpha_1 & \alpha_2 & \cdots & \alpha_{d_1}\\
\beta_0 & \beta_1 & \cdots & \beta_{d_1-1} & \beta_{d_1} & \beta_{d_1+1} & \cdots & \beta_{d_2-1} & \beta_{d_2} & 0 & \cdots & 0\\
0 & \beta_0 & \cdots & \beta_{d_1-2} & \beta_{d_1-1} & \beta_{d_1} & \cdots & \beta_{d_2-2} & \beta_{d_2-1} & \beta_{d_2} & \cdots & 0\\
\vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \ddots & \vdots\\
0 & 0 & \cdots & \beta_0 & \beta_1 & \beta_2 & \cdots & \beta_{d_2-d_1} & \beta_{d_2-d_1+1} & \beta_{d_2-d_1+2} & \cdots & \beta_{d_2}
\end{bmatrix}.$$

The resultant *of the polynomials* P *and* Q*, denoted* $\mathrm{Res}(P,Q)$*, is the determinant of* $M(P,Q)$*. For multivariate polynomials* $P(x_1,\ldots,x_n;y)$ *and* $Q(x_1,\ldots,x_n,y)$ *their resultant with respect to* y *is defined similarly by viewing* P,Q *as polynomials in* y *with coefficients from the ring of polynomials in* $x_1,\ldots,x_n$*. We define the matrix* $M_y(P,Q)$ *as above and its determinant is the resultant* $\mathrm{Res}_y(P,Q)$*.*

LEMMA 15. *For a set of points* $\{(x_1,y_1),\ldots,(x_m,y_m)\}$*, with the* x_j*'s being distinct, if* $\tilde{Q}(x,y)$ *and* $Q_1(x,y)$ *are polynomials of* $\{(1,x),(d,y)\}$*-weighted degree at most* kd *and* $k_1 d$*, respectively, satisfying the properties* (1) $\forall\ j\in[m]$, $\tilde{Q}(x_j,y_j)=0$ *and* (2) $|\{j|Q_1(x_j,y_j)=0\}|>kk_1d$*, then the polynomials* $Q_1(x,y)$ *and* $\tilde{Q}(x,y)$ *share a nonconstant common factor.*

Proof. Consider the resultant $R_y(x)$ of the polynomials $\tilde{Q}(x,y)$ and $Q_1(x,y)$ with respect to y. Observe that the resultant is a polynomial in x. The following claim bounds the degree of this polynomial.

CLAIM 16. $R_y(x)$ *is a polynomial of degree at most* k_1kd*.*

Proof. The determinant of the matrix $M_y(\tilde{Q},Q_1)$ is given by

$$\sum_{\pi}\prod_{i=1}^{k+k_1}\mathrm{sign}(\pi)(M_y(\tilde{Q},Q_1))_{i\pi(i)},$$

where π ranges over all permutations from $[k+k_1]$ to $[k+k_1]$ and $\mathrm{sign}(\pi)$ denotes the sign of the permutation. We will examine every permutation $\pi:[k+k_1]\to[k+k_1]$

and show that the degree of the term $\prod_{i=1}^{k+k_1}(M_y(\tilde{Q},Q_1))_{i\pi(i)}$ (viewed as a polynomial in x) is at most kk_1d. This will suffice to show that the determinant is a polynomial of degree at most kk_1d.

Let d_{ij} denote the degree of the entry $(M_y(\tilde{Q},Q_1))_{ij}$. Observe that, by the definition of the resultant, $d_{ij} \leq (i+k-j)d$ for $i \leq k_1$ and $d_{ij} \leq (i-j)d$ for $i \geq k_1$. (Here we consider the polynomial 0 as having degree $-\infty$.) Thus the degree of the term $\prod_{i=1}^{k+k_1}(M_y(\tilde{Q},Q_1))_{i\pi(i)}$ is given by

$$\begin{aligned}\sum_{i=1}^{k+k_1} d_{i\pi(i)} &= \sum_{i=1}^{k_1} d_{i\pi(i)} + \sum_{i=k_1+1}^{k+k_1} d_{i\pi(i)} \\ &\leq \sum_{i=1}^{k_1}(i+k-\pi(i))d + \sum_{i=k_1+1}^{k+k_1}(i-\pi(i))d \\ &= \sum_{i=1}^{k+k_1} id - \sum_{i=1}^{k+k_1}\pi(i)d \;+\; kk_1d \\ &= kk_1d.\end{aligned}$$

This concludes the proof. □

It is well known that the resultant of two polynomials is zero if and only if the polynomials share a common factor (cf. [38, Chapter 1, Theorem 9.3]). We will show that $R_y(x)$ is identically zero, and this will suffice to prove the lemma. We show this part in the next claim by showing that $R_y(x)$ has more zeroes than the upper bound on its degree.

CLAIM 17. *For every j such that $\tilde{Q}(x_j,y_j) = Q_1(x_j,y_j) = 0$, $R_y(x_j) = 0$.*

Proof. Fix x_j and consider the polynomials $\tilde{q}(y) = \tilde{Q}(x_j,y)$ and $q_1(y) = Q_1(x_j,y)$. Now $R_y(x_j)$ gives the resultant of the polynomials $\tilde{q}(y)$ and $q_1(y)$. Now we know that $\tilde{q}(y_j) = q_1(y_j) = 0$, implying that $(y-y_j)$ is a common factor of $\tilde{q}$ and q_1. Therefore, the resultant of $\tilde{q}$ and q_1 must be zero, implying $R_y(x_j) = 0$. □

Since the above holds for any factor Q_i of Q, we have the following lemma.

LEMMA 18. *Let B be a (k,d)-algebraic black box described by a bivariate polynomial Q with no repeated nonconstant factors. Let $Q_1,\ldots,Q_l$ be the irreducible factors of Q of $\{(1,x),(d,y)\}$-weighted degree $k_1d,\ldots,k_ld$, respectively. Given m pairs of elements $\{(x_1,y_1),\ldots,(x_m,y_m)\}$ which are the input/output pairs of B on m distinct inputs, if there exists an $i \in [k]$ such that $|\{j|Q_i(x_j,y_j) = 0\}| > k_ikd$, then a set of at most k polynomials $\{\tilde{Q}_1,\ldots,\tilde{Q}_k\}$ that includes Q_i can be found in time polynomial in m, k, and d.*

Remark. For a set of pairs $\{(x_1,y_1),\ldots,(x_m,y_m)\}$, with distinct x_j's, Lemma 18 is a strengthening of Lemma 12. Unfortunately, the proof as shown above does not extend to the case where the pairs are distinct, but the x_j are not. Due to this limitation, Lemma 18 does not even cover the case of Lemma 9.

Once again, using a sampling method similar to that used for Theorem 13, we get the following theorem.

THEOREM 19. *Let B be a (k,d)-algebraic black box described by a polynomial Q with distinct irreducible factors $Q_1,\ldots,Q_l$ such that the $\{(1,x),(d,y)\}$-weighted degree of Q is at most kd and that of Q_i is at most k_id. Further, let $p_i = \Pr_{x\in H}[Q_i(x,B(x)) = 0]$. There exists a randomized algorithm which takes as input a confidence parameter $\delta > 0$ and a threshold $p > 0$, runs in time* $\mathrm{poly}(k,d,\frac{1}{p},\frac{1}{\delta})$, *makes calls to the*

black box B, and with probability at least $1-\delta$ reconstructs a list of at most k bivariate polynomials which includes every polynomial Q_i such that $p_i/k_i \geq p$, provided $p|H| > kd$.

2.4. ϵ-noisy black boxes. Finally we extend the reconstruction algorithms of the previous section to the case when the black boxes are allowed to output noise on an ϵ fraction of the inputs from H. As usual, the basic algorithm will be to find a polynomial $\tilde{Q}(x,y)$ which is zero on all the input-output pairs of the black box. However, we will have to do something about the noisy points which do not lie on any nice algebraic curve. We adapt an algorithm of Welch and Berlekamp [39, 5] (see also [14]) to handle this situation.

Say we sample the black box B in m points $x_1,\ldots,x_m$ and the black box outputs $y_1,\ldots,y_m$ according to some (unknown) polynomial Q in all but m' locations. Say that these locations are given by $E=\{j|Q(x_j,B(x_j))\neq 0\}$. We use the fact that there exists a nonzero polynomial $W(x)$ of degree at most m' which is zero when $x=x_j$ for $j\in E$. Indeed $W(x)=\prod_{j\in E}(x-x_j)$ is such a polynomial. Let $Q^*(x,y)=Q(x,y)\cdot W(x)$. Then $Q^*(x_j,y_j)$ is zero for all $j\in[m]$. Thus we can modify the algorithm of the previous section to try to find Q^*. This algorithm is summarized as follows.

The input to the algorithms is m pairs of elements $\{(x_1,y_1),\ldots,(x_m,y_m)\}$ with distinct x_j's.

1. Interpolate to find a set of coefficients q_{lj} of the polynomial

$$\tilde{Q}(x,y)=\sum_{l=0}^{k}\sum_{j=0}^{dl+m'} q_{lj}y^{k-l}x^j$$

   that satisfies $\tilde{Q}(x_i,y_i)=0$ for $i\in[m]$. /* The parameter m' will be specified later. */
2. Factor the polynomial $\tilde{Q}$ and output all its irreducible factors.

Let $Q_1(x,y),\ldots,Q_l(x,y)$ be the irreducible factors of the unknown polynomial $Q^*(x,y)$ describing the black box B. We focus on the factor Q_1. Let the $\{(1,x),(d,y)\}$-weighted degree of Q_1 be k_1d. The following two lemmas essentially show that if the fraction of points (x_i,y_i) for which $Q_1(x_i,y_i)=0$ is sufficiently larger than k_1 times the fraction of noise, then we can reconstruct the polynomial Q_1.

LEMMA 20. *For a set of points $\{(x_j,y_j)|j\in[m]\}$, if $\tilde{Q}(x,y)$ and $Q_1(x,y)$ are polynomials of $\{(1,x),(d,y)\}$-weighted degree at most $kd+m'$ and k_1d, respectively, satisfying the properties (1) $\forall\ j\in[m]$, $\tilde{Q}(x_j,y_j)=0$ and (2) $|\{j|Q_1(x_j,y_j)=0\}|>k_1(kd+m')$, then the polynomials $Q_1(x,y)$ and $\tilde{Q}(x,y)$ share a nonconstant common factor.*

Proof. The proof is a straightforward modification of the proof of Lemma 15. The only change is in Claim 16, where the bound on the degree of the resultant $\mathrm{Res}_y(\tilde{Q},Q_1)$ goes up to $k_1(kd+m')$, because the degree of the nonzero entries in the first k_1 columns goes up by m'. □

LEMMA 21. *Let B be a (k,d)-algebraic black box described by a bivariate polynomial Q with no repeated nonconstant factors. Let $Q_1,\ldots,Q_l$ be the irreducible factors of Q of at most $\{(1,x),(d,y)\}$-weighted degree $k_1d,\ldots,k_ld$, respectively. Given $m'\leq m$ and m pairs $\{(x_1,y_1),\ldots,(x_m,y_m)\}$, which are the input/output pairs of B on distinct inputs, if there exists an $i\in[k]$ such that $|\{j|Q_i(x_j,y_j)=0\}|>k_i(m'+kd)$ and $|\{j|Q(x_j,y_j)\neq 0\}|\leq m'$, then a set of at most k bivariate polynomials that includes Q_i can be found in time polynomial in m, k, and d.*

Lemma 36 of the appendix ensures that if $M = \frac{k_i kd}{p-k_i\epsilon} + \frac{16}{(p-k_i\epsilon)^2}\ln\frac{3}{\delta}$ and $|H| \geq \frac{3}{\delta}\binom{M}{2}$, then a sample of M elements $\{x_1, \ldots, x_M\}$ chosen independently and uniformly at random from F satisfies the following three properties.

1. The x_j's have no repeated elements.
2. There are (strictly) less than $((\epsilon + p_i/k_i)/2)M - kd/2$ values of j such that $Q(x_j, B(x_j)) \neq 0$.
3. There are at least $((p_i+k_i\epsilon)/2)M+k_ikd/2$ values of j such that $Q_i(x_j, B(x_j)) = 0$.

Thus if $|H| \geq \frac{3}{\delta}\binom{M}{2}$, then we randomly choose $m = M$ points from H and use $\{(x_1, B(x_1)), \ldots, (x_m, B(x_m))\}$ and $m' = ((\epsilon + p_i/k_i)/2)M - kd/2 - 1$ as input to the algorithm described above. If, on the other hand, H is small, then we use all $\{(x, B(x))|x \in H\}$ as the input set and use $m' = \epsilon|H|$ as input to our algorithm. In the latter case, Q_i is guaranteed to be part of the output if $(p_i - k_i\epsilon)|H| > kk_id$. This yields the following theorem.

THEOREM 22. *Let B be an ϵ-noisy (k, d)-algebraic black box described by a polynomial Q with no repeated nonconstant factors. Further, let $Q_1, \ldots, Q_l$ be the (distinct) irreducible factors of Q and let $p_i \stackrel{\text{def}}{=} \Pr_{x\in H}[Q_i(x, B(x)) = 0]$. There exists an algorithm which takes as input $\delta, p > 0$, runs in time $\text{poly}(k, d, \frac{1}{p-\epsilon}, \frac{1}{\delta})$, and with probability at least $1 - \delta$ reconstructs a list of at most k bivariate polynomials which includes every Q_i such that $p_i/k_i \geq p$, provided $(p - \epsilon)|H| > kd$.*

3. Multivariate black boxes. In this section, we extend Theorem 22 to multivariate polynomial black boxes over finite fields. The methods of section 2, i.e., those based on trying to find the coefficients of polynomials simultaneously, do not seem to extend directly to the general multivariate case. This is due to the possibly large *explicit* representation of the function extracted from the black box, which makes it inefficient to work with. Instead, we use techniques of pairwise independent sampling to reduce the problem to a univariate situation and then apply Theorem 22 to the new univariate problem. We start by summarizing the problem.

Given: An n-variate ϵ-noisy (k, d)-polynomial black box $B : F^n \to F$. That is, there exist n-variate polynomials $f_1, \ldots, f_k$ of total degree at most d such that

$$\Pr_{\hat{x}\in F^n}[\exists i \in [k] \text{ s.t. } B(\hat{x}) = f_i(\hat{x})] \geq 1 - \epsilon,$$

and furthermore, each f_i is well represented in B; i.e.,

$$\forall\ i \in [k] \Pr_{\hat{x}\in F^n}[B(\hat{x}) = f_i(\hat{x})] \geq p > \epsilon.$$

Problem: Construct k black boxes computing the functions $f_1, \ldots, f_k$.

Notice that we have changed the problem from that of the previous section in several ways. First, we no longer ask for an explicit representation of f_i, but allow for implicit representations. This is a strengthening of the problem, since explicit representations may be much longer than implicit ones, and thus allow a reconstruction algorithm much more time than we do. For instance, if the reconstructed function is a sparse multivariate polynomial, then we can use any of the sparse multivariate polynomial interpolation algorithms given in [3, 20, 21, 40] to recover explicit representations of the reconstructed functions, in running time which is polynomial in the number of nonzero coefficients rather than the total number of possible coefficients. A second change from the problem of the previous section is that we expect all the

polynomials $f_1, \ldots, f_k$ to be well represented in the black box B. This is a weakening of the problem, and we do not know how to get around it.

The outline of the method we use to solve the above problem is as follows. Consider first the slightly simpler problem: given B and an input $\hat{b} \in F^n$, find the multiset $\{f_1(\hat{b}), \ldots, f_k(\hat{b})\}$. This we solve by a reduction to a univariate version of the reconstruction problem. Now a solution to this problem does not immediately suffice to yield a solution to the n-variate reconstruction problem as described above. This is because the solution produces a multiset of values $\{y_1, \ldots, y_k\}$ for which we do not know which y_j corresponds to f_i. We want the black boxes to always output according to the same polynomial consistently.

In order to solve this problem, we introduce the notion of a *reference point* $\hat{r} \in F^n$, which will have the property that the value of the k different polynomials will be all distinct on this point. We will then use a more general reduction to the univariate problem which will allow us to reconstruct a set of pairs $\{(y_1, z_1), \ldots, (y_k, z_k)\} = \{(f_1(\hat{b}), f_1(\hat{r})), \ldots, (f_k(\hat{b}), f_k(\hat{r}))\}$. This, along with the property of the reference point, allows us to order the points consistently for all inputs $\hat{b}$. We now go into the details.

3.1. Reference points. The following definition of a reference point is motivated by the above discussion. We wish to consider the polynomial $Q(x_1, \ldots, x_n; y) = \prod_{i=1}^{k}(y - f_i(x_1, \ldots, x_n))$, and want to ensure that at the reference point $\hat{r}$, $f_i(r_1, \ldots, r_n) \neq f_j(r_1, \ldots, r_n)$, whenever $i \neq j$. One way to test for this is to see if the polynomial $p(y) \stackrel{\text{def}}{=} Q(r_1, \ldots, r_n; y)$ has any repeated nonconstant factors. This will be our definition of a reference point. Note that this definition is general enough to apply also to polynomials Q which do not factor linearly in y.

DEFINITION 23. *For a multivariate polynomial $Q(x_1, \ldots, x_n; y)$ that has no nonconstant repeated factors, a* reference point *is an element $\hat{r} = (r_1, \ldots, r_n)$ of F^n such that the univariate polynomial $p(y) \stackrel{\text{def}}{=} Q(r_1, \ldots, r_n; y)$ has no repeated nonconstant factors.*

The next lemma will show that a random point is likely to be a reference point for any given polynomial Q, provided the field size is large compared to the degree of the polynomial Q. We will need one more notion which is standard in algebra.

DEFINITION 24. *The discriminant of a univariate polynomial $Q(y)$, denoted Δ, is $\mathrm{Res}(Q, Q')$ where Q' is the derivative of Q with respect to y. The discriminant of a multivariate polynomial $Q(x_1, \ldots, x_n; y)$ with respect to y, denoted $\Delta(x_1, \ldots, x_n)$, is defined to be $\mathrm{Res}_y(Q, Q')$ where Q' is the derivative of Q with respect to y. (Formally, the derivative of a monomial $q_i y^i$ is $(q_i + \cdots + q_i)y^{i-1}$, where the summation is of i q_i's. The derivative of a polynomial is simply the sum of the derivatives of the monomials in it.)*

The above definition is motivated by the following well-known fact: a polynomial p (over any unique factorization domain) has repeated nonconstant factors if and only if it shares a common factor with its derivative (cf. [27, Theorem 1.68]). From the well-known fact about resultants, this extends to saying that a polynomial has repeated nonconstant factors if and only if its discriminant is zero.

LEMMA 25. *For a polynomial $Q(x_1, \ldots, x_n; y)$ of $\{(1, x_1), \ldots, (1, x_n), (d, y)\}$-weighted degree at most kd with no repeated nonconstant factors, a random point $\hat{r} \in F^n$ is a reference point with probability at least $1 - \frac{k(k-1)d}{|F|}$.*

Proof. Let $\Delta(x_1, \ldots, x_n)$ be the discriminant of Q with respect to y. Notice that Q' is a polynomial of $\{(1, x_1), \ldots, (1, x_n), (d, y)\}$-weighted degree at most $(k-1)d$.

Thus, as in Claim 16, we can show that $\Delta(x_1, \ldots, x_n)$ is a polynomial in $x_1, \ldots, x_n$ of degree at most $k(k-1)d$. Since Q has no repeated factors, $\Delta(x_1, \ldots, x_n)$ is not identically zero. Thus for a random point $\hat{r} \in F^n$, the probability that $\Delta(\hat{r}) = 0$ is at most $k(k-1)d/|F|$. But observe that $\Delta(\hat{r})$ is the discriminant of the univariate polynomial $p(y) \stackrel{\text{def}}{=} Q(r_1, \ldots, r_n, y)$, and if $\Delta(\hat{r}) \neq 0$, then $\hat{r}$ is a reference point. □

3.2. Reduction to the univariate case. We now consider the case where we are given a black box B, described by polynomials $f_1, \ldots, f_k$, and two points $\hat{a}, \hat{b} \in F^n$, and we wish to find a set of k pairs $\{(y_1, z_1), \ldots, (y_k, z_k)\}$ such that for every $i \in [k]$, there exists some $j \in [k]$ such that $(y_j, z_j) = (f_i(\hat{a}), f_i(\hat{b}))$. We solve this problem by creating a univariate reconstruction problem and then using Theorem 22 to solve this problem. This reduction builds upon a method of [14], which in turn builds upon earlier work of [1, 13].

We create a univariate "subdomain," more precisely, a function $D : F \to F^n$, such that the image of the domain, $\text{Im}(D) \stackrel{\text{def}}{=} \{D(t) | t \in F\}$, satisfies the following properties.

1. $\hat{a}$ and $\hat{b}$ are contained in $\text{Im}(D)$.
2. The restriction of a polynomial $\tilde{Q}(x_1, \ldots, x_n, y)$ of $\{(1, x_1), \ldots, (1, x_n), (d, y)\}$-weighted degree kd to $\text{Im}(D)$, i.e., the function $\tilde{Q}^D(t, y) \stackrel{\text{def}}{=} \tilde{Q}(D(t), y)$, is a bivariate polynomial of $\{(1, t), (3d, y)\}$-weighted degree $3kd$.
3. $\text{Im}(D)$ resembles a randomly and independently chosen sample of F^n of size $|F|$. In particular, with high probability, the fraction of points from $\text{Im}(D)$ where the black box responds with $f(x_1, \ldots, x_n)$ is very close to the fraction of points from F^n where the black box responds with f.

For a finite field F, with $|F| > 3$, $D = (D_1, \ldots, D_n)$, where $D_i : F \to F$ is constructed by picking vectors $\hat{c} = (c_1, \ldots, c_n)$ and $\hat{d} = (d_1, \ldots, d_n)$ at random from F^n and setting $D_i(t) = a_i + c_i t + d_i t^2 + (b_i - c_i - d_i - a_i)t^3$ for $i \in [n]$. By construction, it is immediately clear that the "subdomain" D satisfies properties (1) and (2) listed above. The following lemma shows that it also satisfies property (3) above.

LEMMA 26. *For sets $S_1, \ldots, S_k, E \subset F^n$, let $p_i \stackrel{\text{def}}{=} |S_i|/|F^n|$ and $\epsilon \stackrel{\text{def}}{=} |E|/|F^n|$ and let $\gamma > 0$. Then*

$$\Pr_{\hat{c},\hat{d}}[\exists i \in [k] \text{ s.t. } |\text{Im}(D) \cap S_i|/|F| \leq p_i - \gamma/2 \text{ or } |\text{Im}(D) \cap E|/|F| \geq \epsilon + \gamma/2] \leq \frac{k+1}{\gamma^2(|F|-2)}.$$

Proof. Observe that the set of points $\{D(t) | t \in F \setminus \{0, 1\}\}$ constitutes a pairwise independent sample of points chosen uniformly at random from F^n. The lemma now follows from a standard application of Chebyshev bounds. □

Thus we obtain the following algorithm (tuned for confidence parameter $\delta = 1/3$). The algorithm is given a threshold p.

1. Pick $\hat{c}, \hat{d}$ at random from F^n.
2. Let $D(t) = (D_1(t), \ldots, D_n(t))$ be given by $D_i(t) = a_i + c_i t + d_i t^2 + (b_i - a_i - c_i - d_i)t^3$, and let $B' : H \to F$ be the black box given by $B'(t) = B(D(t))$, where $H = F - \{0, 1\}$.
3. Reconstruct all univariate polynomials $g_1, \ldots, g_k$ of degree at most $3d$ describing B', for threshold p and confidence $1 - 1/6$.

4. Output $\{(g_1(0), g_1(1)), \ldots, (g_k(0), g_k(1))\}$.

Let $\gamma = \sqrt{\frac{6(k+1)}{(|F|-2)}}$. By Lemma 26 we know that the above algorithm finds a univariate domain D, s.t. at most an $\epsilon + \gamma/2$ fraction of the points on the domain are "noisy" and every polynomial is represented on at least a $p_i - \gamma/2$ fraction of the domain, with probability at least $1-1/6$. Thus if $p_i \geq p$ for every i, and $(p-\epsilon-\gamma)(|F|-2) > 3kd$, then the univariate reconstruction algorithm is guaranteed to find all the f_i's, with probability at least $1 - 1/6$. The condition on $|F|$ above can be simplified (somewhat) to $(p-\epsilon)|F| > 3kd + \sqrt{6(k+1)|F|} + 2$, and under this condition the algorithm above returns $\{(f_1(0), f_1(1)), \ldots, (f_k(0), f_k(1))\}$ correctly with probability at least $2/3$. Notice that by repeating $\log \frac{1}{\delta}$ times and outputting the majority answer (i.e., the set that is output most often), we can boost the confidence up to $1 - \delta$, for any $\delta > 0$. This yields the following lemma.

LEMMA 27. *Given an ϵ-noisy n-variate polynomial black box B described by polynomials $f_1, \ldots, f_k$ of degree d, s.t.*

$$\forall i \in [k], \Pr_{\hat{x} \in F^n} [B(\hat{x}) = f_i(\hat{x})] \geq p > \epsilon,$$

there exists a randomized algorithm that takes as input $\delta, p > 0$ and $\hat{a}, \hat{b} \in F^n$, runs in time $\mathrm{poly}(n, k, d, \frac{1}{(p-\epsilon)}, \log \frac{1}{\delta})$, *and outputs the set of k ordered pairs $\{(f_1(\hat{a}), f_1(\hat{b})), \ldots, (f_k(\hat{a}), f_k(\hat{b}))\}$ with probability at least $1 - \delta$ provided $(p-\epsilon)|F| > 3kd + 2 + \sqrt{6(k+1)|F|}$.*

3.3. Putting it together. We are now ready to describe the algorithm for solving the multivariate reconstruction problem. The algorithm has a preprocessing stage where it sets up k black boxes, and a query processing stage where it is given a query point $\hat{a} \in F^n$ and the black boxes compute $f_i(\hat{a})$.

Preprocessing Stage: Given: Oracle access to a black box B described by polynomials $f_1, \ldots, f_k$. Parameters k, ϵ, p, and δ.

Step 1: Pick $\hat{r}$ at random and $\hat{b}$ at random.

Step 2: Reconstruct, with confidence $1 - \delta$, the set $\{(f_1(\hat{r}), f_1(\hat{b})), \ldots, (f_k(\hat{r}), f_k(\hat{b}))\}$ using the algorithm of section 3.2.

Step 3: If the multiset $\{f_1(\hat{r}), \ldots, f_k(\hat{r})\}$ has two identical values, then output "failure". Else pass the reference point $\hat{r}$ and the values $f_1(\hat{r}), \ldots, f_k(\hat{r})$ to the Query Processing Stage.

Query Processing Stage: Given: Oracle access to a black box B, $\hat{b} \in F^n$, and parameters k, d, p, and δ. Additionally, reference point $\hat{r}$ and values $v_1, \ldots, v_k$ passed on by the Preprocessing Stage.

Step 1: Reconstruct with confidence δ the set $\{(f_1(\hat{r}), f_1(\hat{b})), \ldots, (f_k(\hat{r}), f_k(\hat{b}))\}$ using the algorithm of section 3.2.

Step 2: If the set $\{f_1(\hat{r}), \ldots, f_k(\hat{r})\}$ equals the set $\{v_1, \ldots, v_k\}$ then reorder the indices so that $f_i(\hat{r}) = v_i$ for every $i \in [k]$. If the sets are not identical, then report "failure".

Step 3: For every $i \in [k]$, the black box B_i outputs $f_i(b)$.

This yields the following theorem.

THEOREM 28. *Let B be an ϵ-noisy n-variate (k, d)-polynomial black box s.t.*

$$\Pr_{\hat{x} \in F^n} [\exists i \in [k], \text{ s.t. } B(\hat{x}) = f_i(\hat{x})] \geq 1 - \epsilon$$

$$\text{and } \forall i \in [k] \Pr_{\hat{x} \in F^n} [B(\hat{x}) = f_i(\hat{x})] \geq p > \epsilon.$$

Then, if $(p-\epsilon)|F| > 3kd+2+\sqrt{6(k+1)|F|}$, *there exists a randomized algorithm that takes as input a confidence parameter* δ *and with probability* $1-\delta$ *produces* k *black boxes* B_j *such that for every* $i \in [k]$ *there exists* $j \in [k]$ *s.t. for every input* $\hat{b} \in F^n$, *the black box* B_j *computes* $f_i(\hat{b})$ *with probability* $1-\delta$.

4. Applications. In this section, we describe the application of our techniques to curve fitting and bivariate polynomial factorization.

4.1. Curve fitting problems over discrete domains. In this subsection, we study the curve fitting problem over discrete domains. Given a set of m points, with integer coordinates, we show how to find a polynomial with integer coefficients that is Δ-close to all but an ϵ fraction of the points (if such a polynomial exists), where ϵ need only be less than $1/2$ (provided m is larger than $\frac{(4\Delta+1)d}{1-2\epsilon}$). Over Z_p (or over the integers) the problem can be formulated as follows.

Given: m pairs of points, $\{(x_1, y_1), \ldots, (x_m, y_m)\}$ and ϵ, such that there exists a polynomial f, of degree at most d, such that for all but ϵm values of j in $[m]$

$$\exists i \in [-\Delta, \Delta] \text{ s.t. } y_j = f(x_j) + i$$

Problem: Find such an f.

Consider $f_i(x) \stackrel{\text{def}}{=} f(x) + i$, where $i \in [-\Delta, \Delta]$. Notice that all but an ϵ fraction of the points are described by the polynomial f_i's. Thus the above problem could be thought of as a reconstruction problem for an ϵ-noisy $(2\Delta+1, d)$-polynomial black box reconstruction problem. Lemma 21 can now be applied to this set of points to get the following result.

CLAIM 29. *If there exists an* i *such that the number of points for which* $y = f_i(x)$ *is strictly more than* $\epsilon m + kd$, *then we can find a small set of polynomials which includes* f_i.

The weakness of the above procedure is that it can only be guaranteed to succeed if ϵ is smaller than $\frac{1}{2\Delta+2}$, since only then can we guarantee the existence of an i such that the polynomial $f_i(x)$ is represented more often than the noise in the input set. We now present a variation of the above method which gets around this weakness and solves the curve fitting problem for strictly positive values of ϵ (independent of Δ) and in fact works for ϵ arbitrarily close to $1/2$.

The idea is that we can artificially decrease the influence of the *bad* points. To do this, we look at the following set of points: $\{(x_1^i, y_1^i), \ldots, (x_m^i, y_m^i)\}_{i=-\Delta}^{\Delta}$, where $x_j^i = x_j$ and $y_j^i = y_j - \Delta + i$. (From each point in the original sample, we generate $2\Delta+1$ points, by adding and subtracting up to Δ to the y coordinate of each point.) We show that these points represent the output of a (k, d)-algebraic black box for $k = \epsilon m + (4\Delta+1)d$.

Observe that the following conditions hold for the $(2\Delta+1)m$ points constructed above.

- There exists a polynomial $Q(x, y)$ of $\{(1, x), (d, y)\}$-weighted degree at most $\epsilon m + (4\Delta+1)d$ such that $Q(x, y) = 0$ for all the points. This is the polynomial: $Q(x, y) = W(x) \cdot \Pi_{i=-2\Delta}^{2\Delta} (y - f_i(x))$, where $f_i(x) = f(x) + i$ and $W(x)$ is the polynomial satisfying $W(x_j) = 0$ if $f_i(x_j) \neq y_j$ for any $i \in [-\Delta, \Delta]$. (Notice that the degree of W is ϵm.)
- At least $(1-\epsilon)m$ of the points satisfy $y = f(x)$. This is because for every point in the original (x_j, y_j) such that y_j is within Δ of $f(x_j)$ (and there were $(1-\epsilon)m$ such points), one of the new (x_j^i, y_j^i) pairs satisfies $y_j^i = f(x_j^i)$.

LEMMA 30. *Given m points $\{(x_1, y_1), \ldots, (x_m, y_m)\}$, integer d, and $\epsilon < \frac{1}{2}$, there exists a polynomial time algorithm that can find all polynomials f of degree d such that f is Δ-close to all but an ϵ fraction of the points (x_j, y_j), provided $m > \frac{(4\Delta+1)d}{1-2\epsilon}$.*

Proof. Find a polynomial $\tilde{Q}(x, y)$ such that $\tilde{Q}(x, y) = 0$ for all the points $\{(x_j^i, y_j^i)\}_{j=1, i=-\Delta}^{m, \Delta}$ such that the degree of $\tilde{Q}$ is at most $\epsilon m + (4\Delta + 1)d$. If $\epsilon m + (4\Delta + 1)d < (1 - \epsilon)m$, then by Lemma 11 we know that for every candidate function f which forms an (ϵ, Δ) fit on the given points, $(y - f(x))$ divides $\tilde{Q}$. Thus factoring $\tilde{Q}$ will give us all the candidates. ∎

4.2. Reducing bivariate factoring to univariate factoring. In section 2.1, we saw how to reduce the problem of reconstructing total polynomial black boxes to the problem of factoring bivariate polynomials. In the specific case of univariate polynomial black boxes over finite fields, we will also reduce the reconstruction problem to that of factoring univariate polynomials into their irreducible factors. As an interesting consequence, we describe a simple way of reducing the problem of factoring special bivariate polynomials over finite fields to the problem of factoring univariate polynomials.

We first show how to reduce the reconstruction problem to that of factoring univariate polynomials. Suppose we have a black box which on input x outputs the (unordered) set $\{f_1(x), \ldots, f_k(x)\}$, where the f_i's are univariate polynomials, each of degree at most d. Sampling from the black box and interpolating, we can find the polynomial $f(x) = \prod_{i=1}^{k} f_i(x)$ explicitly (in terms of its coefficients). If somehow we could guarantee that at least one of the f_i's is irreducible, we could factor t to find f_i. Such a guarantee is not available, but we simulate it via randomization.

Let $\alpha(x) \in F[x]$ be a random degree d polynomial. We can convert the given set of sample points so that on each input x we have the (still unordered) set $\{g_1(x), \ldots, g_k(x)$: $g_i(x) = f_i(x) + \alpha(x)\}$. Each of the polynomials g_i is a random degree d polynomial (but they are not necessarily independent). We then use the fact that random polynomials over finite fields have a reasonable chance of being irreducible.

LEMMA 31 ([27, p. 84]). *The probability $P_q(d)$ that a random polynomial of degree d is irreducible over F_q is at least $\frac{1}{d}(1 - \frac{1}{q-1})$.*

We can thus interpolate (after sampling at $kd + 1$ points) and explicitly compute $g(x) = \prod_{i=1}^{k} g_i(x)$. We factor g into irreducible factors $r_1, \cdots, r_l$. For each factor r_j of g, we verify whether or not $r_j - \alpha$ is a candidate for one of the f_i's by checking that it evaluates to one of the outputs of the black box B on all the sampled points. By Lemma 31 we know that with nonnegligible probability g_i is irreducible and if this happens, we find g_i as one of the factors of g (i.e., as one of the r_j's). Subtracting α from g_i gives us f_i, which will pass the candidacy verification.

LEMMA 32. *If a degree d polynomial p agrees with one of the outputs of the black box on $kd + 1$ different x's, then p agrees with one of the outputs of the black box on all x's.*

Proof. If p agrees with one of the outputs of the black box on $kd + 1$ different x's, then by the pigeonhole principle there is a polynomial f_i which agrees with p on at least $d + 1$ different x's. Thus $p \equiv f_i$. ∎

Thus, no r_j which is not equal to one of the g_i's will pass the candidacy verification. By repeating this procedure enough times and outputting all the candidates, we can reconstruct all the polynomials $\{f_1, \ldots, f_k\}$. Straightforward analysis shows that the expected number of times that we need to repeat the process (choose random α) is $O(k/P_q(d))$. Refining the analysis, we can show that $O(\ln k/P_q(d))$ times suffice.

From the above, we get the following algorithm for finding the monic linear factors of a bivariate polynomial $Q(x, y)$.

```
program Simple Factor
repeat O( ln k/P_q(d) ) times
   pick a random degree d polynomial
         α(x) over F
   factor Q(x, α(x))
   for every factor g(x) of Q(x, α(x))
      if (y + g(x) − α(x)) divides Q(x, y)
         output (y + g(x) − α(x))
end
```

CLAIM 33. *Given a bivariate polynomial $Q(x, y)$, over a finite field F, of total degree at most kd, the algorithm* **Simple Factor** *finds all the linear and monic factors of $Q(x, y)$.*

We next extend this mechanism and apply the reconstruction mechanism of section 2.2 to the problem of finding the factors of $Q(x, y)$ which are monic and of constant degree in y. Our mechanism tries to isolate some factor $A(x, y)$ of $Q(x, y)$ of the form

$$A(x, y) = y^c + a_{c-1}(x)y^{c-1} + \cdots + a_0(x),$$

where the a_i's are polynomials in x of degree at most d (and c is a constant).

Let $Q(x, y)$ be a polynomial of $\{(1, x), (d, y)\}$-weighted degree kd. For each $i \in [c]$ we construct a program P_i which is supposed to be a (K, d)-algebraic box for a_i, for some $K \leq 2ikd\binom{k}{c}$. We then use our reconstruction procedure (Theorem 22) to produce, for each $i \in [c]$, a list of at most K polynomials which contains a_i. This, in turn, gives a set of at most K^c polynomials in x and y which contains $A(x, y)$. $A(x, y)$ can be isolated from this set by exhaustive search. The running time of this algorithm is thus some polynomial in $(kd)^{c^2}$.

The program P_i for a_i works as follows on input x_1.

- P_i constructs the polynomial $Q_{x_1}(y) \equiv Q(x_1, y)$ (which is a polynomial in y) and factors Q_{x_1}.
- Let S be the set of factors of Q_{x_1}. (S contains polynomials in y.)
- Let S^c be the set of polynomials of degree c obtained by taking products of polynomials in S.
- P_i picks a random polynomial f in S^c and outputs the coefficient of y^i in f.

We now show that P_i is a $(2ikd\binom{k}{c}, d)$-algebraic black box described by some polynomial $Q^*(x, y)$ such that $y - a_i(x)$ divides $Q^*(x, y)$. Let $Q(x, y) = q_k(x)y^k + q_{k-1}y^{k-1} + \cdots + q_0(x)$. Over the algebraic closure of the quotient ring of polynomials in x, $Q(x, y)$ factors into linear factors in y; let this factorization be

$$Q(x, y) = q_k(x)(y - b_1(x))(y - b_2(x)) \cdots (y - b_k(x)).$$

(The $b_i(x)$ are some functions of x, but not necessarily polynomials.) For $T \subset [k]$, $|T| = c$, let $\sigma_{T,i}(x) \stackrel{\text{def}}{=} \sum_{S \subset T, |S|=i} \prod_{l \in S} b_l(x)$. Notice that the function $a_i(x)$ that we are interested in is actually $\sigma_{T,i}(x)$ for some T. Notice further that the output of the program P_i is always $\sigma_{T,i}(x)$ for some T (though this T is some arbitrary subset of $[k]$). Thus the input/output pairs (x, y) of the program P_i always satisfy $\prod_{T \subset [k], |T|=c}(y - \sigma_{T,i}(x)) = 0$. Unfortunately, $\sigma_{T,i}(x)$ need not be a polynomial in x. So we are not done

yet. We will show that $Q^*(x,y) \stackrel{\text{def}}{=} (q_k(x,y)^N) \prod_{T \subset [k], |T|=c} (y - \sigma_{T,i}(x))$ is actually a polynomial in x and y of $\{(1,x),(d,y)\}$-weighted degree at most Ki, where $N = i\binom{k}{c}$. To see this, consider the coefficient of y^j in $Q^*(x,y)$. This is $q_k(x)^N$ times some polynomial in $b_1(x), \ldots, b_k(x)$, denoted $g_j(b_1(x), \ldots, b_k(x))$. By the definition of Q^*, we notice that g_j is a symmetric polynomial in $b_1(x), \ldots, b_k(x)$ of degree at most $i\binom{k}{c}$. We now invoke the "fundamental theorem of symmetric polynomials" [27, pp. 29–30], which states that a symmetric polynomial of degree D in variables $z_1, \ldots, z_k$ can be expressed as a polynomial of degree at most D in the *primitive* symmetric functions in $z_1, \ldots, z_k$. In our case this translates into saying that there exists some polynomial $\tilde{g}_j$ of degree at most N s.t. $g_j(b_1(x), \ldots, b_k(x)) = \tilde{g}_j(\frac{q_{k-1}(x)}{q_k(x)}, \ldots, \frac{q_0(x)}{q_k(x)})$ (since the primitive symmetric functions in $b_1(x), \ldots, b_k(x)$ are actually $\frac{q_{k-1}(x)}{q_k(x)}, \ldots, \frac{q_0(x)}{q_k(x)}$). Thus we find that the coefficient of y^j in $Q^*(x,y)$ is a polynomial in x of degree at most $ikd\binom{k}{c}$. The claimed bound on the degree of Q^* now follows easily.

Thus we get the following lemma.

LEMMA 34. *Given a polynomial $Q(x,y)$ of $\{(1,x),(d,y)\}$-weighted degree kd, there is an algorithm that runs in time polynomial in $(kd)^{c^2}$ which finds all factors of Q that are monic and of degree c in y.*

Appendix A.

LEMMA 35. *Given $S \subset H$, with $|S|/|H| = p$, if $|H| \geq \frac{2}{\delta}\binom{M}{2}$, and $M \geq \frac{2}{p}(kd + \ln \frac{2}{\delta})$, then the probability that M points $x_1, \ldots, x_M$ chosen uniformly at random from H turn out to be distinct and satisfy $|\{j | x_j \in S\}| \geq kd$ is at least $1 - \delta$.*

Proof. First observe that for a given $i \neq j$, the probability that $x_i = x_j$ is exactly $1/|H|$. Thus the probability that there exists i, j s.t. $x_i = x_j$ is at most $\binom{M}{2}/|H| \leq \delta/2$.

Now, for the second part, we use Chernoff bounds (in particular, we use a bound from [31, Theorem 4.2]). Let X denote the number of elements j s.t. $x_j \in S$. Let $\mu = Mp$ denote the expected value of X. Then $\Pr[X \leq K] \leq \exp(-(\mu - K)^2/2\mu)$. Plugging in the values of $\mu = 2(kd + \ln \frac{2}{\delta})$ and $K = kd$ and simplifying, we find that $\exp(-(\mu - K)^2/2\mu) \leq \delta/2$.

Thus the probability that either of the above two events happens is bounded by at most δ as desired. ∎

LEMMA 36. *Given $S, E \subset H$, with $|S|/|H| = p$ and $|E|/|H| = \epsilon$ if $|H| \geq \frac{3}{\delta}\binom{M}{2}$, and $M \geq \frac{k_1 kd}{p - k_1\epsilon} + \frac{16}{(p-k_1\epsilon)^2} \ln \frac{3}{\delta}$, then the probability that M points $x_1, \ldots, x_M$ chosen uniformly at random from H turn out to be distinct and satisfy $|\{j | x_j \in S\}| > M(p + k_1\epsilon)/2 + k_1 kd/2$ and $|\{j | x_j \in E\}| < M(p/k_1 + \epsilon)/2 - kd/2$ is at least $1 - \delta$.*

Proof. First we argue as above that the probability that the x_j's are not distinct is at most $\delta/3$.

Now for the second part we again use Chernoff bounds (this time we use the bounds from [31, Theorems 4.2 and 4.3]). Let X denote the number of elements j s.t. $x_j \in S$. The above-mentioned bounds translate to show that the probability that the number of points from S is less than $Mp - \lambda\sqrt{Mp}$ is at most $\exp(-\lambda^2/2)$. Similarly, the probability that the number of points from E turns out to be more than $M\epsilon + \lambda\sqrt{M\epsilon}$ is bounded by at most $\exp(-\lambda^2/4)$. Each of these probabilities is at most $\delta/3$ if we choose $\lambda = 2\sqrt{\ln \frac{3}{\delta}}$. The lemma now follows from the fact that for the chosen value of M, we have that $M\epsilon + \lambda\sqrt{M} < M(p/k_1 + \epsilon)/2 - kd/2$ and $Mp + \lambda\sqrt{M} > M(p + k_1\epsilon)/2 + k_1 kd/2$. ∎

Acknowledgments. We are very grateful to Avi Wigderson for asking a question that started us down this line of research and for helpful discussions. We are very grateful to Umesh Vazirani for his enthusiasm, his valuable opinions and suggestions, and the time that he spent with us discussing this work. We thank Ronen Basri, Oded Goldreich, and Mike Kearns for their comments on the writeup of this paper. We thank Joel Friedman for technical discussions about questions related to the topics of this paper. We also thank the anonymous referees for their extensive reports and for catching many blatant as well as subtle errors from an earlier version of this paper.

OPTIMAL BROADCAST WITH PARTIAL KNOWLEDGE*

BARUCH AWERBUCH†, ISRAEL CIDON‡, SHAY KUTTEN§, YISHAY MANSOUR¶, AND DAVID PELEG‖

Abstract. This work is concerned with the problem of broadcasting a large message efficiently when each processor has partial prior knowledge about the contents of the broadcast message. The partial information held by the processors might be out of date or otherwise erroneous, and consequently, different processors may hold conflicting information. Tight bounds are established for broadcast under such conditions, and applications of the broadcast protocol to other distributed computing problems are discussed.

Key words. distributed algorithms, topology update, error correcting code, universal hash, self stabilization

1. Introduction.

1.1. Motivation. Many tasks in distributed computing deal with concurrently maintaining the "view" of a common object in many separate sites of a distributed system. This object may be the topology of a communication network (in which case the view is a description of the underlying network graph), or certain resources held at the system sites (in which case the view is an inventory listing the resources held at each site), or even a general database. The objects considered here are dynamic in nature, and are subject to occasional changes (e.g., a link fails, a resource unit is consumed or released, a database record is modified). It is thus necessary to have an efficient mechanism for maintaining consistent and updated views of the object at the different sites.

One obvious algorithm for maintaining updated views of a distributed object is the *full broadcast* algorithm. This algorithm is based on initiating a broadcast of the entire view of the object whenever a change occurs. Due to the possibility of message pipelining, the time complexity of this algorithm is relatively low. On the other hand, this algorithm might be very wasteful in communication, since the object may be rather large.

Consequently, it is clear that a successful consistency maintenance strategy should strive to utilize the fact that the processors already have a correct picture of "most"

of the object and need to be informed of relatively few changes. Viewed from this angle, the problem can be thought of as having to broadcast the entire view of the object, while taking advantage of prior partial knowledge available to the processors of the system.

On the other extreme there is the *incremental update* strategy, in which only "necessary" information is transmitted. This strategy is at the heart of the algorithms suggested for handling the topology update problem [ACK90, MRR80, SG89, BGJ$^+$85]. Unfortunately, it is not obvious how to employ information pipelining with this method, as demonstrated in the sequel. This increases the time complexity.

The purpose of this work is to study the problem of updating a distributed database, under minimal assumptions. That is, we do not assume any initial coordination and allow only a small amount of space. Under such conditions, we look for efficient solutions to the problem with respect to communication and time overheads. In this setting, it turns out that the main bottleneck of the database update problem can be characterized as a fairly simple "communication complexity" problem, called *broadcast with partial knowledge*.

1.2. The model and the problem. The *broadcast with partial knowledge* problem can be formulated as follows. Consider an asynchronous communication network, consisting of $n+1$ processors, $p_0, \ldots, p_n$; each processor p_i has an m-bit *local input* w_i, and processor p_0 is distinguished as the *broadcaster*. In a correct solution to the problem all the processors write in their local output the value of the broadcaster's input, $w = w_0$.

Without loss of generality we assume that the network is arranged in a line. That is, each processor p_i (for $1 < i < n$) is connected only to p_{i-1} and p_{i+1}. The algorithm can be easily adapted to be executed on trees, rather than on a line (which is the "worst-case" tree) as described here. Thus, in an arbitrary topology network, performing the algorithm on a shortest-path tree yields optimal message and time complexities. (Our results are expressed in terms of n, as well as of other parameters; in the case of general networks n is replaced by the diameter of the network.)

This formulation of the problem can be interpreted as follows. The input w_i is stored at processor p_i and describes the local representation of the object at processor p_i. The correct description of the object is $w = w_0$, held by the broadcaster. The local descriptions w_i may differ from the correct one as a result of changes in the object. In particular, every two processors may have different descriptions due to different messages they got from the broadcaster in the past, as a result of message losses, topology changes, and the asynchronous nature of the network. Our goal is to inform all the processors throughout the network about the correct view of the object w, and to use the processor's local inputs given to each processor in order to minimize the time and communication complexities.

In this paper, we provide a randomized solution for the hardest version of this problem, in which each processor only knows its own input, and has no information regarding inputs of other processors. A weaker version of the problem is based on making the rather strong "neighbor knowledge" assumption, namely, assuming that each processor correctly knows the inputs of all its neighbors, in addition to its own. This assumption is justified in [ACK90], where it is shown that neighbor knowledge comes for free in the context of database and topology update protocols. Even for this weaker problem, none of the previously known solutions are efficient in *both* communication and time. (Following the original version of the current paper [ACK$^+$91], a deterministic algorithm was given for the weaker problem [AS91]. The complexity

of that algorithm is larger than that of the randomized algorithm presented here by a polylogarithmic factor.)

In order to quantify the possibility of exploiting local knowledge, we first introduce a new measure that captures the level of "information" of the knowledge held by each processor. Let the *discrepancy* δ_i of the input w_i held by processor p_i be the number of bits in which w_i, the local description at p_i, differs from the broadcaster's input w, which is the correct description of the object. Define also the *total discrepancy* $\Delta = \sum_i \delta_i$, the *average discrepancy* $\delta_{av} = \Delta/n$, and the *maximum discrepancy* $\delta_{max} = \max_i\{\delta_i\}$.

Our goal is to study the relationships between these discrepancies and the complexity of broadcast algorithms, following the intuition that the complexity of broadcast protocols should be proportional to discrepancy of processors' inputs; i.e., if the views of most processors are "almost correct," then the overhead of the protocol should be small. We therefore express the communication and time complexities of our solution as a function of m, n, and δ_{av}. The complexities are measured in the bit complexity model.

1.3. Basic solutions. The first obvious solution to the *broadcast with partial knowledge* problem is the aforementioned *full broadcast* protocol, which is wasteful in communication, i.e., requires $\Omega(nm)$ bits. On the other hand it is rather fast, since the broadcast can be done in a pipelined fashion and thus can terminate in $O(n + m)$ time. Thus, one would like to improve on this algorithm with respect to communication complexity, aiming towards reducing this complexity to be close to the total discrepancy Δ, while maintaining near-optimal time complexity.

The *incremental update* strategy proposed in [ACK90] poses an alternative approach. It can be applied only under the strong assumption of "neighbor knowledge," where each node is assumed to "know" the value of the database at its neighbor. The essence of this strategy is that a processor with "correct" view transmits to its neighbor a "correction" list, which contains all the positions where the neighbor's input is erroneous. When the neighbor receives all the corrections, it can assume that the rest of its input is correct and start using it for correcting its own neighbors who are further away from the source. In this algorithm, a "correction wave" propagates through the network from the source, until all nodes are corrected. Note that there is almost no pipelining possible in this algorithm as described above, since a node can start transmitting only after it is done with the receiving. Even in the simple case of a path network the protocol may require $\Omega(\Delta)$ time. As mentioned above, in the follow-up paper [AS91] the complexity of this strategy (for the "neighbor knowledge" variant of the problem) was improved significantly (although still not matching the lower bound), using a very sophisticated partitioning of the information and a recursive implementation.

1.4. Our results. In this paper, we provide an efficient randomized solution to the broadcast with partial knowledge problem. It has success probability at least $1 - \epsilon$, and uses $O(\Delta \log m + n \log \frac{n}{\epsilon})$ communication and $O(n + m)$ time, where ϵ is a parameter to the algorithm. Note that in all cases, we allow the inputs stored at the various processors to differ in arbitrary ways, subject to the discrepancy constraints.

Our upper bounds are derived using linear codes. Such codes were used before in constructing distributed algorithms for solving various problems. Metzner [Met84] uses Reed–Solomon and random codes to achieve efficient retransmission protocols in a complete network. Ben-Or, Goldwasser, and Wigderson [BOGW88] use Bose–Chaudhuri Hocquenghem (BCH) codes to guarantee privacy in a malicious environ-

ment. Rabin [Rab89] uses codes to achieve a reliable fault-tolerant routing with a low overhead. Another closely related concept is that of source coding with side information [SW73].

Using simple arguments from information theory and communication complexity theory, we are able to show that our upper bounds are almost tight. We argue that when the average discrepancy is δ_{max}, the communication complexity is at least $\Omega(\Delta \log(\frac{m}{\delta_{max}}))$ and the time complexity is at least $\Omega(n+\delta_{max} \log(\frac{m}{\delta_{max}}))$. We also argue that in the case when no information is known about the discrepancies, any deterministic protocol would send $\Omega(nm)$ bits, even if there are *no* discrepancies at all.

The comparison of our protocols, previous results, and the lower bounds is given in Table 1.

1.5. Applications. One application of our work is to the classical network problem of topology update. This task is at the heart of many practical network protocols [MRR80, BGJ$^+$85, ACG$^+$90]. The problem can be formulated as follows. Initially, each processor is aware of the status of its adjacent links, i.e., whether each link is up or down, but is unaware of the status of other links. The purpose of the protocol is to supply each processor with this global link status information.

The topology update algorithm of [ACK90] is based on the *incremental update* strategy. The possibility of recurring network partitions and reconnections significantly complicates implementation of this strategy. Nevertheless, the resulting broadcast procedure is efficient in terms of communication (although not in time) and leads to essentially communication-optimal topology update protocols [ACK90].

A consequence of [ACK90] that is most significant for our purposes is the observation that it is possible to relate the complexities of the problem of broadcasting with partial knowledge to those of topology update, effectively reducing the former problem to the latter. Namely, given *any* solution for the broadcast with partial knowledge problem, one can construct a topology update protocol with lower or equal overheads in both communication and time.

Table 2 summarizes the complexities of protocols to the topology update task obtained by applying various broadcast with partial knowledge algorithms (with V, E denoting the number of vertices and edges in the network, respectively).

It is worth pointing out that our complexity results are presented in the bit com-

plexity model, whereas the results in [ACK90] are presented in the message complexity model which charges only one complexity unit for a message of size $O(\log n)$ bits.

Our algorithm may also be applicable for dealing with the issue of self-stabilization [Dij74, AKY90, KP90, APV91]. The self-stabilization approach is directed at dealing with intermittent faults that may change the memory contents of nodes and cause inconsistency between the local states of nodes. Dijkstra's example [Dij74] is that of a token passing system, where it is required that exactly one of the nodes holds a *token* at any given time. The faults may cause an illegal situation in which no node holds a token (each "assumes" that some other has it) or alternatively, that several nodes hold a token. Overcoming such faults requires the nodes to continuously check the states of their neighbors and possibly to correct them when necessary. It is conceivable that the faults cause only partial changes in memory, so our algorithm can be used to mend the situation. Note that in this context, it is essential that we do not make the "neighbor knowledge" assumption.

1.6. Organization of the paper. The rest of the paper is structured as follows. In section 2 we review for later use some necessary material concerning universal hash functions and coding theory. In section 3, we present our upper bound (algorithm BPart). Finally, lower bounds on the problem are established in section 4.

2. Preliminaries.

2.1. Universal hash functions. Universal hash functions have found many interesting applications since their introduction by Wegman and Carter [WC79]. A family of functions $\mathcal{F} = \{h : A \to B\}$ is called a *universal hash function* if for any $a_1 \neq a_2 \in A$ and $b_1, b_2 \in B$ the following holds:

$$\text{Prob}[h(a_1) = b_1 \text{ and } h(a_2) = b_2] = \frac{1}{|B|^2},$$

where the probability is taken over the possible choices of h, which is randomly and uniformly chosen from $\mathcal{F}$.

There are many families of simple universal hash functions. One example can be constructed as follows. Let p be a prime and let $B = Z_p$. (Note $|B| = p$.) Then

$$H = \{h_{\alpha,\beta}(x) = (\alpha x + \beta) \bmod p \mid \alpha, \beta \in Z_p\}$$

is a family of universal hash functions.

In the above example the encoding of a hash function requires only two elements from Z_p, and also p; therefore we can describe such a hash function using only $O(\log |B|)$ bits. (Note that the encoding of h does not depend on A.) Later, when using a universal hash function, it is assumed that it can be represented with $O(\log |B|)$ bits.

Another way to view the parameters is the following. We are interested in a family of universal hash functions $\mathcal{F}_\epsilon$ that has the following property: given any two distinct elements, the probability that a random hash function $h \in \mathcal{F}_\epsilon$ maps them to the same point is bounded by ϵ. From the properties of the universal hash function this occurs with probability $1/|B|$. Therefore, choosing $\epsilon = 1/|B|$, we conclude that there is a family of hash functions $\mathcal{F}_\epsilon$ whose encoding size is $O(\log \frac{1}{\epsilon})$.

2.2. Information theoretic background. The tools developed later on are based on some basic results from coding theory. A code $C_{m,d} : \{0,1\}^m \mapsto \{0,1\}^{m+r}$ is a mapping that transforms an input word $w \in \{0,1\}^m$ into a codeword $C_{m,d}(w) =$

$\hat{w} \in \{0,1\}^{m+r}$. The codes considered in this paper are standard "check bit" codes; namely, the resulting codeword $\hat{w}$ is assumed to be of the form $\hat{w} = w\|\rho$, where $\rho \in \{0,1\}^r$ is a "trail" of r check bits concatenated to the input word w, called the *syndrome*. Denote by the check bit syndrome that the code $C_{m,d}$ attaches to a word w by $C^*_{m,d}(w)$. The lengths of the entire codeword and the check bit syndrome are denoted in the sequel by $|C_{m,d}(w)|$ and $|C^*_{m,d}(w)|$, respectively.

A code $C_{m,d}$ is said to be *d-correcting* if the original word w can be correctly decoded from any word z that differs from the codeword $C_{m,d}(w)$ in no more than d places.

The following theorem states the properties possessed by the code necessary for our purposes.

THEOREM 2.1. *For any m and $d \leq m/3$, there exists a check-bit code $C_{m,d}$ with the following properties.*

1. *The check bit syndrome is of length $|C^*_{m,d}(w)| = O(d \log m)$.*
2. *The code $C_{m,d}$ is d-correcting.*
3. *The encoding and decoding operations ($C_{m,d}$ and $C^{-1}_{m,d}$, respectively) require time polynomial in m and d.*

In order to show the theorem, we can slightly modify BCH codes, so they will have all the above properties. It is well known that the decoding and encoding of BCH codes can be accomplished in polynomial time and that the length of the check bit syndrome is $O(d \log m)$. The only property that we need to comment about is the use of arbitrary m. The code words in BCH codes are of length $2^k - 1$. We simply have to extend our input (e.g., by padding zeros) to the appropriate size. When encoding, we first extend the input $w \in \{0,1\}^m$ to $2^k - 1 - |C^*_{m,d}(w)|$ bits and then perform the encoding. After the decoding, the padding bits will be removed.

All codes $C_{m,d}$ referred to later on in the paper are meant to be check bit codes that satisfy the properties in Theorem 2.1. The subscripts m, d are omitted whenever m and d are clear from the context.

3. Upper bounds. We develop our solution in a modular fashion via a number of steps. The first step is a simple deterministic algorithm named MAXIMUM, presented in section 3.1, which is based on the assumption that the maximum discrepancy δ_{max} is known to the broadcaster. Next, section 3.2 presents the algorithm AVERAGE, which assumes only knowledge of the average discrepancy. Then, in section 3.3 it is shown that the assumptions about knowledge of the discrepancy can be eliminated at the cost of increasing the time complexity by a factor of $\log \delta_{av}$. Finally, in section 3.4 it is shown that the algorithm can be condensed, so that its time complexity becomes optimal again.

3.1. Algorithm MAXIMUM. This section handles broadcast in the case where the maximum discrepancy δ_{max} is known and presents a straightforward broadcasting algorithm MAXIMUM, which assumes that the broadcaster "knows" δ_{max}. The algorithm requires $O(n\delta_{max} \log m)$ communication and $O(n + \delta_{max} \log m)$ time.

We should note that this algorithm is not efficient, since the maximum discrepancy can be very far from the average discrepancy. This algorithm is presented in order to be used in the next section as a subroutine.

For simplicity, it is assumed that the network is a simple path; namely, the $n+1$ processors $p_0, \ldots, p_n$ are arranged on a line, with a bidirectional link connecting processor p_i to processor p_{i+1} for every $0 \leq i < n$. Note that this does not restrict generality in any way, since the path is the worst topology for broadcast, and moreover, there exists an easy transformation from every other network to a path network by

using a depth-first tour [Eve79].

Algorithm MAXIMUM works as follows: the *broadcaster* encodes the broadcast message w using the code $C = C_{m,\delta_{max}}$. (Note that this code C is fixed and known to all other processors.) The broadcaster broadcasts only the check bit syndrome $C^*(w)$. The broadcasting proceeds in full pipelining. That is, each processor p_i for $i < n$ that receives the first bit of $C^*(w)$ immediately forwards it to processor p_{i+1}, without waiting for the entire value of $C^*(w)$.

Once a processor p_i has received the complete message $\rho = C^*(w)$, it concatenates it to its own input w_i, thus obtaining a complete (but possibly corrupted) codeword $\hat{w}_i = w_i \| \rho$ and decodes this codeword by computing $o_i = C^{-1}(\hat{w}_i)$, which is taken to be the output.

LEMMA 3.1. *If the input w_i of processor p_i is different from w in at most δ_{max} places, then $o_i = w$.*

Proof. Consider the word o_i output by processor p_i. As $\delta_i \leq \delta_{max}$, it follows that $\hat{w}_i = w_i \| \rho$ differs from $\hat{w} = w \| \rho$ in at most δ_{max} places. Since the code C is δ_{max}-correcting, it follows that $o_i = C^{-1}(\hat{w}_i) = C^{-1}(\hat{w}) = w$. ∎

LEMMA 3.2. *The time complexity of algorithm* MAXIMUM *is $n + O(\delta_{max} \cdot \log m)$.*

Proof. The algorithm broadcasts the message $\rho = C^*(w)$ in full pipelining. Hence the first bit of ρ reaches the last processor, p_n, by time n, and the entire message reaches p_n by time $n + |C^*(w)|$. The lemma follows since $|C^*(w)| = O(\delta_{max} \cdot \log m)$. ∎

LEMMA 3.3. *The communication complexity of algorithm* MAXIMUM *is $O(n \cdot \delta_{max} \log m)$.*

Proof. The message $C^*(w)$ traverses each edge exactly once. Therefore, the communication complexity is $n \cdot |C^*(w)| = n \cdot O(\delta_{max} \cdot \log m)$. ∎

We complete the description by noting that both the time and communication complexities can be improved for large δ_{max}. Specifically, if $\delta_{max} \log m > m$, then a full broadcast of the information is more efficient (namely, send w to all the processors). Therefore we have the following theorem.

THEOREM 3.4. *Given the value of δ_{max}, there is a deterministic algorithm for performing broadcast with partial information that requires $n + O(\min\{m, \delta_{max} \cdot \log m\})$ time and has communication complexity $O(n \cdot \min\{m, \delta_{max} \cdot \log m\})$.*

A similar result holds when the broadcaster knows only an upper bound d on the discrepancies, where the same complexities hold except with d replacing δ_{max}. When the upper bound is "accurate," namely, $d = O(\delta_{max})$, the complexities remain the same.

Note that the communication complexity of this algorithm is not good when there are differences between the discrepancies of nodes. For example, consider the case in which one has a high discrepancy. This forces the algorithm to send a long check bit syndrome also to the other nodes on the way, although they have low discrepancies. The algorithm of the next section manages to fix this problem, even though it relies on a weaker assumption.

3.2. Algorithm AVERAGE**.** In this section we replace the assumption of a known δ_{max} with the assumption that only the average discrepancy δ_{av} is known. Note that no assumptions are made about how the discrepancies are distributed. In particular, it may be that some processors have large discrepancies while others have the correct value. For simplicity of notation, we assume throughout the section that $\delta_{av} \geq 1$, or $\Delta \geq n$.

The broadcast algorithm AVERAGE presented in this section is randomized; i.e., it

guarantees the correctness of the output of each processor with high probability. The communication complexity of algorithm AVERAGE depends linearly on the average discrepancy δ_{av}, while its time complexity is still linear in m. Both complexities apply to the worst-case scenario.

We begin with a high level description of algorithm AVERAGE. The algorithm works in phases and invokes algorithm MAXIMUM of section 3.1 at each phase. At every phase of the execution, each processor can be in one of two states, denoted $\mathcal{K}$ and $\mathcal{R}$. Initially, only the broadcaster is in state $\mathcal{K}$, while the other processors are in state $\mathcal{R}$. Intuitively, a processor p_i switches from state $\mathcal{R}$ to state $\mathcal{K}$ when it concludes that its current guess for w is equal to the "real" broadcast word w.

The phases are designed to handle processors with increasingly large discrepancies. More specifically, let us classify the processors into classes $C_1, \ldots, C_\mu$, $\mu = \lceil \log(\frac{m}{\delta_{av} \log m}) \rceil$, where the class C_l contains all processors p_i whose discrepancy δ_i falls in the range $2^{l-1}\delta_{av} < \delta_i \leq \min\{m, 2^l \delta_{av}\}$ for $2 \leq l \leq \mu - 1$, $\delta_i \leq 2\delta_{av}$ for $l = 1$, and the rest in C_μ (i.e., $\delta_i \geq \frac{m}{\log m}$). Then each phase $l \geq 0$ is responsible for informing the processors in class C_l. This is done by letting the processors in state $\mathcal{K}$ broadcast to the other processors.

Note that the $\mathcal{K}$ and $\mathcal{R}$ states reflect, in a sense, only the processors' "state of mind," and not necessarily the true situation. It might happen that a processor switches prematurely to state $\mathcal{K}$, erroneously believing it holds the true value of the input w. Such an error might subsequently propagate to neighboring processors as well. Our analysis will show that this happens only with low probability.

By a simple counting argument, the fraction of processors whose discrepancy satisfies $\delta_i \geq k\delta_{av}$ is bounded from above by $\frac{1}{k}$ for every $k \geq 1$. The first phase attempts to correct the inputs of processors from C_1, while in general, the lth phase attempts to correct the processors in C_l. By the previous argument, at least half of the processors are in C_1, and furthermore, $\sum_{j=l}^{\mu} |C_j| \leq \frac{n}{2^l}$. Assuming that all the processors that shifted from $\mathcal{R}$ to $\mathcal{K}$ had the correct value, then after the lth phase, at most $\frac{n}{2^l}$ processors are in state $\mathcal{R}$.

Let us now describe the structure of a phase l in more detail. At the beginning of phase l, the current states of the processors induce a conceptual partition of the line network into consecutive intervals $I_1, \ldots, I_t$, with each interval $I = (p_i, p_{i+1}, \ldots)$ containing one or more processors, such that the first processor p_i is in state $\mathcal{K}$ and the rest of the processors (if any) are in state $\mathcal{R}$.

The algorithm maintains the property that each processor knows its state, as well as the state of its two neighbors, hence each processor knows its relative role in its interval, as either a "head" of the interval, an intermediate processor, or a "tail" (i.e., the last processor of the interval).

Suppose that processor p_i is in state $\mathcal{K}$ at the beginning of phase $l < \mu$ and is the "head" of some interval I. If the processor p_{i+1} is also in state $\mathcal{K}$, then the interval I contains only p_i, and thus p_i has finished its part in the algorithm. Otherwise, interval I contains at least one processor in state $\mathcal{R}$. In this case, processor p_i is assigned the role of the *broadcaster* with respect to its interval in phase l. More specifically, it needs to reveal its value to all processors of class C_l in its interval I. Hopefully, this results in the further partition of interval I into subintervals for the next phase.

Processor p_i performs this task by using algorithm MAXIMUM of section 3.1, with parameter $d_l = 2^l \delta_{av}$. To be more specific, if p_i's interval I contains other processors (i.e., processor p_{i+1} is in state $\mathcal{R}$) then p_i computes $C^*_{m,d_l}(o_i)$ and sends it to p_{i+1}. (In case $l = \mu$, processor p_i sends o_i.) As we shall see, with high probability, $o_i = w$

for any processor i that is in state $\mathcal{K}$. Therefore, later in this informal description we substitute $C^*_{m,d_l}(w)$ for $C^*_{m,d_l}(o_i)$. Consider that any intermediate processor p_j (in state $\mathcal{R}$) in interval I that receives a message simply forwards the message (using pipelining). The tail processor of the interval (i.e., the one whose successor is in state $\mathcal{K}$) does nothing.

It remains to explain when a processor decides to change its state from $\mathcal{R}$ to $\mathcal{K}$. This task requires an *initialization* phase, in which the broadcaster chooses a random universal hash function $h \in \mathcal{F}_{\epsilon/n\mu}$ and sends both the description of h and the hashed value of the broadcast message, i.e., the pair

$$\mathcal{H}(w) = \langle h, h(w) \rangle,$$

to all processors. Since the description of h requires $O(\log \frac{n\mu}{\epsilon})$ bits, the size of the message is $O(\log \frac{n\mu}{\epsilon}) = O(\log \log m + \log \frac{n}{\epsilon})$. The pair $\mathcal{H}(w)$ will later serve each processor to test whether its new computed value of w is correct.

Specifically, as said above, in phase $l < \mu$ each processor p_j in state $\mathcal{R}$ receives $\rho_l = C^*_{m,d_l}(w)$. It concatenates it to w_j and computes

$$g_j(l) = C^{-1}_{m,d_l}(w_j C^*_{m,d_l}(w)),$$

which is its "guess" for w. It then tests whether $h(g_j(l)) = h(w)$.

In case of equality, the processor deduces that its current guess is correct. It then changes its state from $\mathcal{R}$ to $\mathcal{K}$ and sets its output to be $o_j = g_j(l)$. At the last phase, $l = \mu$, when a processor p_j receives value o_i from some processor p_i, then p_j sets $o_j = o_i$. The algorithm ends after phase μ.

LEMMA 3.5. *The probability that some processor produces an incorrect output is bounded from above by* ϵ.

Proof. Let $\mathcal{E}_j(l)$ denote the event that processor p_j outputs an incorrect value at phase l, given that all the outputs at earlier phases were correct. This event implies that $g_j(l) \neq w$, but $h(g_j(l)) = h(w)$. However, the hash function h was chosen so as to guarantee that this probability is at most $\frac{\epsilon}{n\mu}$. Summing over all possible bad events $\mathcal{E}_j(l)$, it follows that the probability that some processor ends with an incorrect output is bounded by ϵ.

Another possible failure is that a processor stays in state $\mathcal{R}$. However, recall that in this case some other processor has to output an incorrect value before. ∎

Now, we analyze the communication and time complexities of the protocol. We first show that if no node mistakenly outputs an incorrect value, then both time and communication complexities are small.

LEMMA 3.6. *Assuming that no processor outputs an incorrect value, the time complexity of algorithm* AVERAGE *is* $O(n + m + \log \frac{1}{\epsilon})$.

Proof. The initialization phase involves sending a message $\mathcal{H}(w)$ containing the pair $\langle h, h(w) \rangle$, which is of size $O(\log \log m + \log \frac{n}{\epsilon})$ bits, to all n processors. This phase therefore requires time $O(n + \log \log m + \log \frac{n}{\epsilon})$. It remains to analyze the time required for the main phases.

Assuming that at the start of phase l all the processors in state $\mathcal{K}$ have the correct value, the number of processors in state $\mathcal{R}$ at the end of the phase is at most $n/2^l$. This follows from the fact that at phase l the algorithm corrects the input values of all processors whose discrepancy is at most $d_l = 2^l \delta_{av}$. Since the average discrepancy is δ_{av}, the number of processors with a larger discrepancy is at most $n/2^l$.

The time required for completing a phase l is clearly bounded from above by the number of processors in state $\mathcal{R}$ plus the size of the message sent in this phase,

i.e., $n/2^l + \min\{m, d_l \log m\}$. The first term is clearly bounded by n, and the second obtains its maximum at the last phase and is therefore bounded by $O(m)$.

Hence the time complexity is $O(n + m + \log \frac{1}{\epsilon})$. □

LEMMA 3.7. *Assuming that no processor outputs an incorrect value, the communication complexity of algorithm* AVERAGE *is* $O(\Delta \log m + n \log \frac{n}{\epsilon})$.

Proof. Again, the initialization phase requires sending a message of size $O(\log \log m + \log \frac{n}{\epsilon})$, which contributes $O(n(\log \log m + \log \frac{n}{\epsilon})) \leq O(\Delta \log m + n \log \frac{n}{\epsilon})$ to the communication complexity.

Let us now concentrate on the main phases. Consider a processor p_i with discrepancy δ_i. We count the number of bits that p_i *receives* during the entire execution. After phase $\mu_i = \lceil \log(\delta_i/\delta_{av}) \rceil$, assuming that all the processors in state $\mathcal{K}$ have the correct value, p_i should already be in state $\mathcal{K}$, and from then on it never receives messages. At each phase l prior to phase μ_i, processor p_i gets a message $C^*_{m,d_l}(w)$ of size $O(d_l \log m)$ bits. Therefore, the number of bits received by p_i throughout the execution is bounded by

$$\sum_{l=1}^{\mu_i} O(d_l \log m) = O(2^{\mu_i} \delta_{av} \log m) = O(\delta_i \log m).$$

Summing over all processors, the contribution of the main phases is bounded by

$$\sum_{i=1}^{n} O(\delta_i \log m) = O(\Delta \log m).$$

Consequently, the communication complexity of the entire algorithm is $O(\Delta \log m + n \log \frac{n}{\epsilon})$. □

Note that ϵ can always be chosen so as to make the failure probability polynomially small in m, without degrading the time or communication complexities of the algorithm. Consequently we have the following theorem.

THEOREM 3.8. *Given an average discrepancy* δ_{av} *and* $0 < \epsilon < 1$, *algorithm* AVERAGE *solves the broadcast with partial knowledge problem correctly with probability* $1 - \epsilon$. *In the case when the solution is correct, the time complexity is* $O(n + m + \log \frac{1}{\epsilon})$ *and the communication complexity is* $O(\delta_{av} \cdot n \cdot \log m + n \log \frac{n}{\epsilon})$ *bits.*

In case algorithm AVERAGE fails and the output is incorrect, we can guarantee only trivial bounds on the time and communication complexities of the algorithm. These bounds are derived from bounding the number of phases by $\log m$, and the number of bits in a message by m. This gives worst-case bounds of $O((n + m) \log m)$ time and $O(nm)$ communication. However, ϵ can be selected so as to equate the expected complexity (over all executions) with the high probability complexity (i.e., over the executions that have a correct output). Consequently we have the following corollary.

COROLLARY 3.9. *Algorithm* AVERAGE *has expected time complexity* $O(n + m)$ *and expected communication complexity of* $O(\Delta \log m + n \log nm)$ *bits.*

3.3. Unknown discrepancy. In the case when δ_{av} is not known in advance, we can solve the problem by initiating algorithm AVERAGE with a guessed average discrepancy $\hat{\delta}_{av} = 1$. Call this algorithm UNKNOWN. In such a case, in the $\log \delta_{av}$ first phases of algorithm AVERAGE, it may happen that no processor changes to $\mathcal{K}$. The communication complexity essentially remains the same, since the additional $O(\delta_{av} \cdot n) = O(\Delta)$ bits are absorbed in the previous bound. However, the time complexity does increase in this case by an additive factor of $O(n \log \delta_{av})$.

THEOREM 3.10. *Given* $0 < \epsilon < 1$, *algorithm* UNKNOWN *solves the broadcast with partial knowledge problem correctly with probability* $1-\epsilon$. *In the case when the solution is correct, the time complexity is* $O(n \log \delta_{av} + m + \log \frac{1}{\epsilon})$ *and the communication complexity is* $O(\Delta \log m + n \log \frac{n}{\epsilon})$ *bits.*

In a similar way to the previous section, we can bound the expected complexities by choosing ϵ appropriately.

COROLLARY 3.11. *Algorithm* UNKNOWN *has expected time complexity* $O(n \log \delta_{av} + m)$ *and expected communication complexity of* $O(\Delta \log m + n \log nm)$ *bits.*

3.4. Optimal time complexity. Intuitively, the main reason that the time in the previous subsection is not optimal is the fact that there can be "time spaces" between the phases. In this section we describe a simulation of algorithm UNKNOWN in which the information transmitted is fully pipelined. For the sake of clarity we describe the whole algorithm below.

Algorithm BPART**.** We assume that $\Delta \log m < mn$. If this assumption does not hold, then the algorithm might fail, at which time full broadcast can be engaged, since the maximum complexity must be paid in any case.

The algorithm requires an initialization phase similar to the one of algorithm AVERAGE, in which a random universal hash function $h \in \mathcal{F}_{\epsilon/n\mu}$ is chosen and the pair $\mathcal{H}(w)$ is sent to all processors.

The main part of the algorithm proceed as follows. Set $\mu = \log m - \log \log m$. The source transmits the syndromes of the encodings $w(i) = \mathcal{C}_{m,2^i}(w)$ of its vector w in all codes $\mathcal{C}^*_{m,2^i}$ of all levels $0 \le i \le \mu$, one after another. Hence the sequence transmitted by the source is of the form

$$\xi(w) = \langle w(0), w(1), \ldots, w(\mu), w \rangle.$$

Essentially, this information is to be forwarded along the line to all processors. Observe that a naive implementation of this would require communication complexity nm and time $m + n$. The communication complexity is minimized by stopping the flood of bits into a node p_j once this node is able to correctly decode the entire source's vector ξ (with high probability), i.e., to produce an output o_j such that $h(w) = h(o_j)$. This is done in the same way as in algorithm UNKNOWN, as described below.

During the main part of the algorithm, each processor p_j on the line does the following. It initially enters state $\mathcal{R}$, intuitively signifying the fact that its data may be outdated. It then receives the sequence $\xi(o_{j-1})$ from its predecessor p_{j-1}, constructs its own output o_j and sequence $\xi(o_j)$, and sends this sequence to its successor. The incoming sequence is received and processed entry by entry, as long as p_j is in state $\mathcal{R}$.

Each arriving entry $o_{j-1}(i) = \mathcal{C}^*_{m,2^i}(o_{j-1})$, $0 \le i \le \mu$, is processed as follows. First, the entry is stored as $o_j(i)$ and forwarded to p_{j+1}. In addition, p_j concatenates $o_{j-1}(i)$ to w_j and computes its "guess" for w,

$$g_j(i) = C^{-1}_{m,2^i}(w_j \cdot C^*_{m,2^i}(o_{j-1})).$$

It then tests whether $h(g_j(i)) = h(w)$.

In case of equality, the processor does the following. First, it changes its state from $\mathcal{R}$ to $\mathcal{K}$ and informs its predecessor p_{j-1} to stop sending the rest of the sequence $\xi(o_{j-1})$. Next, it sets its output to be $o_j = g_j(i)$ and computes the rest of the sequence $\xi(o_j)$ locally (in order to be able to continue sending it to its successor on the line).

Note that p_j may fail in its tests in all stages $i \leq \mu$. In this case, it will receive the entire sequence $\xi(o_{j-1})$ from its predecessor, including o_{j-1} in its last entry, and adopt this value for o_j.

Let us now bound the probability of failure.

LEMMA 3.12. *The probability that some processor produces an incorrect output is bounded from above by ϵ.*

Proof. The proof proceeds in the same way as that of Lemma 3.5, except that we define $\mathcal{E}_j(i)$ to be the event that processor p_j outputs an incorrect value after getting $o_{j-1}(i)$, while the output of every processor p_l to the left of p_j (i.e., such that $l < j$) that made its decision after receiving (all or some of) the syndromes $o_{l-1}(k)$ for $0 \leq k \leq i$ is correct. □

Finally, we analyze the communication and time complexities of the protocol.

THEOREM 3.13. *Assuming that no processor outputs an incorrect value, the communication complexity of algorithm* BPART *is $O(\Delta \log m + n \log \frac{n}{\epsilon})$.*

Proof. The proof is similar to that of Lemma 3.7. In particular, the initialization message $\mathcal{H}(w)$ requires sending $O(\log \frac{n\mu}{\epsilon}) = O(\log \log m + \log \frac{n}{\epsilon})$ bits. As for the ξ messages, nodes with more than $\frac{m}{\log m}$ errors receive at most $O(m)$ bits, and there can be at most $\delta_{av} \log m$ such nodes. Otherwise, a node p_j that has less than 2^i errors will decode the original message correctly (with high probability) after receiving $\mathcal{C}_{m,2^i}(o_{j-1})$, i.e., after receiving $O(2^i \cdot \log m)$ bits. □

THEOREM 3.14. *Assuming that no processor outputs an incorrect value, the time complexity of algorithm* BPART *is $O(n + \log \frac{n}{\epsilon} + \min\{m, \Delta \log m\})$.*

Proof. The upper bound follows from the fact that all the data from the source (including both the $\mathcal{H}(w)$ and the ξ messages) is sent along the line in full pipelining, and the combined length of the vector broadcast is $O(\log \frac{n}{\epsilon} + \min\{m, \Delta \log m\})$. □

As before, we bound the expected complexities by choosing ϵ appropriately.

COROLLARY 3.15. *Algorithm* BPART *has expected time complexity $O(n+m)$ and expected communication complexity $O(\Delta \log m + n \log nm)$.*

4. Lower bounds. In this section we establish some simple lower bounds that show that our construction is optimal. The first bound concerns the communication complexity of broadcast algorithms assuming maximum discrepancy $d = \delta_{max}$. Assume that all processors but the broadcaster have as input the all-zero vector, while the broadcast message is a vector containing exactly d ones, that is chosen arbitrarily from among all $\binom{m}{d}$ possible vectors, with all choices being equally likely. This implies that the entropy of the source (the broadcaster) is $\log \binom{m}{d}$. The entropy is clearly a lower bound on the number of bits each processor has to receive. Therefore, we have the following bound.

THEOREM 4.1. *The communication complexity of any broadcast algorithm is at least*

$$n \log \binom{m}{\delta_{max}} = \Omega\left(n\delta_{max} \log\left(\frac{m}{\delta_{max}}\right)\right).$$

The bound on the time required for broadcast is derived by considering the communication lower bound above and the last processor, and noticing that it cannot receive any information before time n. Therefore, we have the following theorem.

THEOREM 4.2. *The time complexity of any broadcast algorithm is at least*

$$n + \log \binom{m}{\delta_{max}} = \Omega\left(n + \delta_{max} \log\left(\frac{m}{\delta_{max}}\right)\right).$$

The next theorem establishes the limitations of the derandomization of the algorithm when the average discrepancy is δ_{av}, and it is not known in advance. Consider a simpler task, in which every processor has to decide whether its input equals the broadcast message or not. This is a well-studied problem in communication complexity theory, where lower bounds for the number of bit exchanges required of solving the equality problem are known. For the case of $n = 2$, Yao showed a lower bound of $\Omega(m)$ for deterministic algorithms [Yao79], and Tiwari extended it to a line of processors and showed an $\Omega(nm)$ lower bound [Tiw84]. This bound holds in particular when all the inputs are equal, in which case $\delta_{av} = 0$. This implies the following lower bound.

THEOREM 4.3. *For any deterministic or randomized Las-Vegas-type algorithm that has to work for an arbitrary δ_{av}, there is an input whose discrepancy is zero (i.e. $\delta_{av} = 0$), and the algorithm requires $\Omega(nm)$ communication complexity on this input.*

5. Conclusion. We have shown that one can take advantage of prior knowledge of the recipient in order to save in communication, while still keeping the time optimal in the worst case. It may be interesting to find out whether more efficient solutions can be derived for special cases. For example, it often happens that faults are related. Consequently, it may be likely that the set of bits in which w at some recipient disagrees with w_0 at the source, forms clusters, rather than being distributed arbitrarily in w. It may be interesting to devise an algorithm that performs better in such a case. A technique for finding regions of disagreements appears in [Met91].

There may be other interesting special cases. One such case is when later (and more updated) versions of a document are longer (or shorter) than previous versions. Our algorithm can solve this case by "padding" the shorter vector, but this seems to lead to an inefficient solution.

PRIMAL-DUAL RNC APPROXIMATION ALGORITHMS FOR SET COVER AND COVERING INTEGER PROGRAMS*

SRIDHAR RAJAGOPALAN† AND VIJAY V. VAZIRANI‡

Abstract. We build on the classical greedy sequential set cover algorithm, in the spirit of the primal-dual schema, to obtain simple parallel approximation algorithms for the set cover problem and its generalizations. Our algorithms use randomization, and our randomized voting lemmas may be of independent interest. Fast parallel approximation algorithms were known before for set cover, though not for the generalizations considered in this paper.

Key words. algorithms, set cover, primal-dual, parallel, approximation, voting lemmas

1. Introduction.

Given a universe $\mathcal{U}$, containing n elements, and a collection, $\mathcal{S} \doteq \{S_i : S_i \subseteq \mathcal{U}\}$, of subsets of the universe, the *set cover* problem asks for the smallest subcollection $\mathcal{C} \subseteq \mathcal{S}$ that covers all the n elements in $\mathcal{U}$ (i.e., $\bigcup_{S\in\mathcal{C}} S = \mathcal{U}$). In a more general setting, one can associate a cost, c_S, with each set $S \in \mathcal{S}$ and ask for the minimum cost subcollection which covers all of the elements.[1] We will use m to denote $|\mathcal{S}|$.

Set multicover and *multiset multicover* are successive natural generalizations of the set cover problem. In both problems, each element e has an integer coverage requirement r_e, which specifies how many times e has to be covered. In the case of multiset multicover, element e occurs in a set S with arbitrary multiplicity, denoted $m(S, e)$. Setting $r_e = 1$ and choosing $m(S, e)$ from $\{0, 1\}$ to denote whether S contains e gives back the set cover problem.

The most general problems we address here are *covering integer programs*. These are integer programs that have the following form:

$$\text{MIN } \mathbf{c}\cdot\mathbf{x}, \text{ s.t. } M\mathbf{x} \geq \mathbf{r}, \mathbf{x} \in \bar{\wedge}^+;$$

the vectors $\mathbf{c}$ and $\mathbf{r}$ and the matrix M are all nonnegative rational numbers.

Because of its generality, wide applicability, and clean combinatorial structure, the set cover problem occupies a central place in the theory of algorithms and approximations. Set cover was one of the problems shown to be NP-complete in Karp's seminal paper [Ka72]. Soon after this, the natural greedy algorithm, which repeatedly adds the set that contains the largest number of uncovered elements to the cover, was shown to be an H_n factor approximation algorithm for this problem ($H_n = 1 + 1/2 + \ldots + 1/n$) by Johnson [Jo74] and Lovasz [Lo75]. This result was extended to the minimum cost case by Chvatal [Ch79]. Lovasz establishes a slightly stronger statement, namely, that the ratio of the greedy solution to the optimum fractional solution is at most

[1] Here it is to be understood that the cost of a subcollection $\mathcal{C}$ is $\sum_{S\in\mathcal{C}} c_S$.

H_n. Consequently, the *integrality gap*, the ratio of the optimum integral solution to the optimum fractional one, is at most H_n. An approximation ratio of $O(\log n)$ for this problem has been shown to be essentially tight by Lund and Yannakakis [LY93].[2] More recently, Feige [Fe96] has shown that approximation ratios better than $\ln n$ are unlikely.

The first parallel algorithm for approximating set cover is due to Berger, Rompel, and Shor [BRS89], who found an RNC^5 algorithm with an approximation guarantee of $O(\log n)$. Further, this algorithm can be derandomized to obtain an NC^7 algorithm with the same approximation guarantee. Luby and Nisan [LN93], building on the work of Plotkin, Shmoys, and Tardos [PST91] have obtained a $(1+\epsilon)$ factor (for any constant $\epsilon > 0$), NC^3 approximation algorithm for covering and packing linear programs. Since the integrality gap for set cover is H_n, the Luby–Nisan algorithm approximates the cost of the optimal set cover to within a $(1+\epsilon)H_n$ factor. Furthermore (as noted by Luby and Nisan), in the case of set cover, by using a randomized rounding technique (see [Ra88]), fractional solutions can be rounded to integral solutions at most $O(\log n)$ times their value.

This paper describes a new RNC^3, $O(\log n)$ approximation algorithm for the set cover problem. This algorithm extends naturally to RNC^4 algorithms for the various extensions of set cover each achieving an approximation guarantee of $O(\log n)$. In addition, the approximation guarantee that we obtain in the case of covering integer programs is better than the best known sequential guarantee, due to Dobson [Do82].

2. A closer look at set cover. We begin by taking a closer look at the greedy algorithm for set cover. In the minimum cost case, the greedy algorithm chooses the set that covers new elements at the lowest average cost. More precisely, let $U(S)$ denote the set of yet uncovered elements in S. The greedy algorithm repeatedly adds the set $\operatorname{argmin}_S \left\{ \frac{c_S}{|U(S)|} \right\}$ to the set cover.

Choose $\text{cost}(e)$ to be the cost of covering e by the greedy algorithm. Thus, if S is the first set to cover e and $U(S) = k$ before S was added to the cover, then $\text{cost}(e) \doteq c_S/k$. Let e_i be the ith last element to be covered. Let OPT denote the optimum set cover as well as its cost.

We now observe that $\text{cost}(e_i) \leq \text{OPT}/i$ because there is a collection of sets, namely OPT, which covers all i elements $\{e_1, \ldots, e_i\}$. Thus, there is a set S such that $c_S \leq \text{OPT}/i|U(S)|$. Since e_i is the element of smallest cost among $\{e_1 \cdots e_i\}$, $\text{cost}(e_i) \leq \text{OPT}/i$. Therefore, the cost of the cover obtained by the greedy algorithm is at most $\sum_i \text{cost}(e_i) \leq \text{OPT} \sum_i \frac{1}{i} = \text{OPT}H_n$, which provides the approximation guarantee.

The simple proof given above can be viewed in the more general and powerful framework of linear programming and duality theory. One can state the set cover problem as an integer program:

$$\textbf{IP}: \quad \begin{array}{ll} \text{MIN} & \sum_S c_S x_S \\ \text{s.t.} & \sum_{S \ni e} x_S \geq 1, \\ & x_S \in \{0,1\}. \end{array}$$

By relaxing the integrality condition on $\mathbf{x}$, we obtain a linear program which has the

[2] More precisely, Lund and Yannakakis establish that there is a constant c such that unless $\tilde{\text{P}} = \tilde{\text{NP}}$, set cover cannot be approximated to a ratio smaller than $c \log n$.

following form and dual:

$$\begin{array}{lll} \textbf{LP}: & & \textbf{DP}: \\ \text{MIN} & \sum_S c_S x_S & \text{MAX} \quad \sum_e y_e \\ \text{s.t.} & \sum_{S \ni e} x_S \geq 1, & \text{s.t.} \quad \sum_{e \in S} y_e \leq c_S, \\ & x_S \geq 0; & \qquad y_e \geq 0. \end{array}$$

The primal linear program is a covering problem and the dual is a packing problem. We will now reanalyze the greedy algorithm in this context. Define value(e) of an uncovered element as

$$\text{value}(e) \doteq \min_{S \ni e} \frac{c_S}{|U(S)|}.$$

The "value" of an element is a nondecreasing function of time in that it gets bigger as more and more elements get covered and therefore each $U(S)$ gets smaller. The greedy algorithm guarantees that cost(e) = value(e) at the moment e is covered.

Now consider any set $S \in \mathcal{S}$. Let $e_i \in S$ be the ith last element of S to be covered by the greedy algorithm. Then, clearly, $\text{cost}(e_i) = \text{value}(e_i) \leq c_S/i$ at the moment of coverage. Thus, we establish the following inequality for each set S:

$$\sum_{e \in S} \text{cost}(e) \leq \left(1 + \frac{1}{2} + \cdots + \frac{1}{|S|}\right) c_S.$$

Alternately, if k is the size of the largest set $S \in \mathcal{S}$, then the assignment $y_e = \frac{\text{cost}(e)}{H_k}$ is dual feasible. The dual value for this assignment to $\mathbf{y}$ is $\mathbf{DP} = \sum_e y_e = \frac{1}{H_k} \sum_e \text{cost}(e) = \frac{1}{H_k}$greedy cost. Due to the duality theorem of linear programming, $\mathbf{DP}$ is a lower bound on the value of OPT. Thus, the greedy algorithm approximates the value of set cover to within a factor of H_k.

3. The key ideas behind our parallel algorithm. The greedy algorithm chooses a set to add to the set cover for which $\sum_{e \in S} \text{value}(e) = c_S$. One of the key ideas in this paper is to find a suitable relaxation of this set selection criterion which guarantees that rapid progress is made but does not degrade the approximation guarantee significantly. This is by no means a new notion. Indeed, it has been used in the context of set cover earlier [BRS89]. However, the way in which the relaxation is made and the resulting parallel algorithms are different from the choices made in [BRS89].

In our algorithm we identify cost-effective sets by choosing those that satisfy the inequality

$$\sum_{e \in U(S)} \text{value}(e) \geq \frac{c_S}{2}.$$

This criterion can be distinguished from the greedy criterion in that elements with different values contribute to the desirability of any set. This weighted mixing of diverse elements and the consequent better use of the dual variables, value(e), appears to lend power to our criterion.

Our relaxed criterion guarantees rapid progress. To see this, consider $\alpha \doteq \min_e \text{value}(e)$. Then, any set for which $\frac{c_S}{|U(S)|} \in [\alpha, 2\alpha]$ qualifies to be picked. Thus, after each iteration, the value of α doubles. This and a preprocessing step will enable us

to show rapid progress for our algorithm. However, an algorithm based solely on this relaxed criterion will not approximate set cover well, as exhibited by Example 3.0.1.

EXAMPLE 3.0.1. Let $\mathcal{U} = \{1, 2, \ldots, n\}$. Let $\mathcal{S}$ be the $\binom{n}{2}$ sets of size 2 derived from $\mathcal{U}$. The cost of each set is 1. The optimal cover consists of $\frac{n}{2}$ sets. However, the relaxed criterion chooses all the sets. □

We now address the approximation guarantee. We will be able to assign costs to each element, denoted cost(e), such that the cost of the set cover is at most $\sum_e \text{cost}(e)$. Further, we will establish that at the moment of coverage, cost(e) $\leq \mu$value(e) for each element e and a suitably chosen constant μ. If, for any algorithm, it is possible to choose element costs such that these conditions are satisfied, then we will say that the algorithm has the *parsimonious accounting* property with parameter μ. It is evident from the analysis of the greedy algorithm detailed earlier that the parsimonious accounting property with parameter μ suffices to establish an approximation guarantee of μH_k where k is the cardinality of the largest set in $\mathcal{S}$.

These observations motivate a straightforward method of relaxing the set selection criterion which, however, fails to achieve our stated goal, namely, fast parallel execution. The relaxation and an instance exhibiting its shortcomings are detailed by Example 3.0.2 below.

EXAMPLE 3.0.2. Number the sets arbitrarily. In each iteration, each uncovered element votes for the lowest numbered set that covers it at the least average cost. Any set with more than $\frac{U(S)}{2}$ votes adds itself to the set cover. It is easily verified that this algorithm has the parsimonious accounting property with parameter $\mu = 2$. However, the algorithm can be forced to execute $\Theta(n)$ iterations on the following input: let $\mathcal{U} = \{u_i, v_j : 1 \leq i, j \leq n\}$. Choose $\mathcal{S} = \{U_i, V_j : 1 \leq i, j \leq n-1\}$, where $U_i = \{u_i, u_{i+1}, v_{i+1}\}$ and $V_j = \{v_j, u_{j+1}, v_{j+1}\}$. Finally, choose the set costs to satisfy $c_{U_{i-1}} > c_{U_i} = c_{V_i} > c_{U_{i+1}}$ for ech i. □

The solution we propose finds a compromise between the two strategies detailed above to achieve both objectives, namely, rapid progress as well as good approximation. The critical extra ingredient used in making this possible is the introduction of randomization into the process.

The primal-dual scheme provides a general framework in which we can search for good and fast approximation algorithms for otherwise intractable problems. In the typical case, the hard problem is formulated as an integer program which is then relaxed to obtain a linear program and its dual. In this context, the algorithm starts with a primal, integral infeasible solution and a feasible, suboptimal dual solution. The algorithm proceeds by iteratively improving the feasibility of the primal and the optimality of the dual while maintaining primal integrality until the primal solution becomes feasible. On termination, the obtained primal integral feasible solution is compared directly with the feasible dual solution to give the approximation guarantee. The framework leaves sufficient room to use the combinatorial structure of the problem at hand: in designing the algorithm for the iterative improvement steps and in carrying out the proof of the approximation guarantee.

The greedy algorithm for set cover can be viewed as an instance in the above paradigm. At any intermediate stage of the algorithm let $y_e = \frac{\text{cost}(e)}{H_n}$ if e has been covered and $\frac{\text{value}(e)}{H_n}$ otherwise. Then, by the arguments presented in section 2, $\mathbf{y}$ is feasible for **DP**. The currently picked sets constitute the primal solution.

4. The parallel set cover algorithm. Our proposed algorithm for set cover is described in Figure 1. The preprocessing step is done once at the inception of

PARALLEL SETCOV

Preprocess.

Iteration:

For each uncovered element e, compute value(e).

For each set S: include S in $\mathcal{L}$ if

(•) $\sum_{e \in U(S)} \text{value}(e) \geq \frac{c_s}{2}$.

Phase:

(a) Permute $\mathcal{L}$ at random.

(b) Each uncovered element e votes for first set S (in the random order) such that $e \in S$.

(c) If $\sum_{e \text{ votes } S} \text{value}(e) \geq \frac{c_S}{16}$, S is added to the set cover.

(d) If any set fails to satisfy (•), it is deleted from $\mathcal{L}$.

Repeat until $\mathcal{L}$ is empty.

Iterate until all elements are covered.

FIG. 1. *The parallel set cover algorithm.*

the computation and is a technical step which we will explicitly establish in the next section. The purpose of this step is to reduce the range of values of c_S to one wherein the largest and smallest values are at most a polynomial factor from each other.

Notice that value(e) is computed only at the beginning of an iteration and is not updated at the inception of each phase.

4.1. Analysis of PARALLEL SETCOV. We now present an analysis of the proposed algorithm. We will first consider the approximation guarantee and then the running time. The content of the preprocessing step will be defined with the analysis of the running time.

4.1.1. Approximation guarantee. The algorithm PARALLEL SETCOV satisfies the parsimonious accounting property with $\mu = 16$. If we choose $\text{cost}(e) = 16\text{value}(e)$ if e votes for S and S is added to the set cover in the same phase, then it is easily verified that $\sum_e \text{cost}(e) \geq$ cost of cover.

4.1.2. Running time. We will now establish that PARALLEL SETCOV is in RNC^3. In order to do this, we will establish the following three assertions.

1. The algorithm executes $O(\log n)$ iterations.
2. With high probability, $(1 - o(1))$, every iteration terminates after $O(\log nm)$ phases.
3. Each of the steps in Figure 1 can be executed in time $\log nmR$, where R is the length of the largest set cost in bits.

These three assertions imply that PARALLEL SETCOV is in RNC^3. Indeed, it follows that PARALLEL SETCOV runs in $(\log n)(\log nm)(\log nmR)$ time on any standard PRAM or circuit model with access to coins.

The third assertion follows from the parallel complexity of integer arithmetic and parallel prefix computations. The details of these operations can be found in a number of standard texts on parallel computation (see [Le92], for instance).

In order to prove the first assertion, we have to detail the preprocessing step. Define $\beta = \max_e \min_{S \ni e} c_S$. Then, $\beta \leq$ cost of optimal cover $\leq n\beta$. The first inequality is because any cover has to pick some set that contains e^*, the maximizing element for β. The second inequality holds because for any arbitrary element e, there is a set of cost at most β containing e. Thus, there is a cover comprising of all these sets of cost at most $n\beta$.

Thus, any set S such that $c_S \geq n\beta$ could not possibly be in the optimum cover. The preprocessing step eliminates all such sets from consideration. Further, if for any element e there is a set S containing it with cost less than $\frac{\beta}{n}$, then we will add S to the set cover immediately. Since there are at most n elements, at most n sets can be added in this manner. These can all be added in parallel and the total cost incurred is at most an additional β. Since β is a lower bound on the cost of the set cover, the additional cost is subsumed in the approximation.

Thus, we can assume that for each set surviving the preprocessing stage, $c_S \in [\frac{\beta}{n}, n\beta]$. This consequence of the preprocessing stage is a key ingredient in establishing the following lemma.

LEMMA 4.1.1. PARALLEL SETCOV *requires at most* $O(\log n)$ *iterations.*

Proof. Define $\alpha \doteq \min_e \text{value}(e)$. At any point in the current iteration, consider a set S that has not yet been included in the set cover and such that $c_S \leq 2\alpha|U(S)|$. Then, by the definition of α,

$$\sum_{e \in U(S)} \text{value}(e) \geq |U(S)|\alpha \geq \frac{c_S}{2}.$$

Thus S satisfies ($\bullet$) and must have satisfied it at the inception of the iteration. Thus $S \in \mathcal{L}$. However, at the end of an iteration, $\mathcal{L}$ is empty. Thus for every remaining S, $c_S \geq 2\alpha|U(S)|$, or alternately, $\frac{c_S}{|U(S)|} \geq 2\alpha$. This ensures that in the next iteration, α increases by a factor of 2. Since α is at least $\frac{\beta}{n^2}$ and is at most $n\beta$, there can be no more than $\log n^3 = 3 \log n$ iterations. □

We will now show that the number of phases in every iteration is small with high probability. To this end, we will show the following lemma.

LEMMA 4.1.2. *Consider a fixed iteration, i. The probability that the number of phases in iteration i exceeds $O(\log nm)$ is smaller than $\frac{1}{n^2}$.*

Proof. We will focus our attention only on those sets that are in $\mathcal{L}$. Thus, the precondition $\sum_{e \in U(S)} \text{value}(e) \geq \frac{c_S}{2}$ is imposed on all sets that participate in this proof unless otherwise specified. The proof of this lemma is made via a potential function argument. The potential function is $\Phi \doteq \sum_{S \in \mathcal{L}} |U(S)|$. In other words, it is the number of uncovered element-set pairs in $\mathcal{L}$. In what follows, we will show that Φ decreases by a constant fraction (in expectation) after each phase. Since the initial value of Φ is at most nm, the lemma will follow from standard arguments.

Define the *degree* $\deg(e)$ of an element as

$$\deg(e) \doteq |\{S \in \mathcal{L} : S \ni e\}|.$$

Call a set-element pair $(S, e), e \in U(S)$ *good* if $\deg(e) \geq \deg(f)$ for at least three quarters of the elements in $U(S)$.

Let $e, f \in U(S)$ such that $\deg(e) \geq \deg(f)$. Let N_e, N_f, and N_b be the number of sets that contain e but not f, f but not e, and both e and f, respectively. Thus, $\text{prob}(e \text{ votes } S) = \frac{1}{N_e + N_b}$. The probability that both e and f vote for S is exactly the

probability that S is the first among $N_e + N_f + N_b$ sets which is exactly $\frac{1}{N_e+N_f+N_b}$. Since $\deg(e) \geq \deg(f)$ implies that $N_e \geq N_f$ we have

$$\text{prob}\,[f \text{ votes } S \mid e \text{ votes } S] = \frac{\text{prob}\,[e \text{ and } f \text{ vote } S]}{\text{prob}\,[e \text{ votes } S]} \geq \frac{N_e + N_b}{N_e + N_b + N_f} > \frac{1}{2}.$$

The statement above provides the heart of the proof, since it implies that if (S, e) is good, then S should get a lot of votes if e votes for S. Thus, under this condition, S should show a tendency to get added to the set cover. We shall now make this formal.

Noting that for any $f \in U(S)$, $\text{value}(f) \leq \frac{c_S}{|U(S)|}$, we see that for any good (S, e), $\sum_{f \in U(S), \deg(f) > \deg(e)} \leq \frac{c_S}{4}$. Since S satisfies $(\bullet)$, we obtain

$$\sum_{f \in U(S), \deg(f) \leq \deg(e)} \text{value}(f) \geq \frac{c_S}{2} - \frac{c_S}{4} = \frac{c_S}{4}.$$

The conditional probability statement above allows us to infer that if (S, e) is good and e votes for S, then the expected value of $\sum_{f \in U(S), f \text{ votes } S} \text{value}(f)$ is at least $\frac{c_S}{8}$. An application of Markov's inequality will show that the probability that S is picked is at least $\frac{1}{15}$.

We will ascribe the decrease in Φ when an element e votes for a set S and S is subsequently added to the set cover, to the set-element pair (S, e). The decrease in Φ that will then be ascribed to (S, e) is $\deg(e)$, since Φ decreases by 1 for each set containing e. Since e voted for only one set, any decrease in Φ is ascribed to only one (S, e) pair. Thus, the expected decrease in Φ, denoted $\Delta\Phi$, is at least

$$\begin{aligned}
E(\Delta\Phi) &\geq \sum_{(S,e): e \in U(S)} \text{prob}(e \text{ voted for } S,\ S \text{ was picked}) \cdot \deg(e) \\
&\geq \sum_{(S,\,e) \text{ good}} \Big(\text{prob}(e \text{ voted for } S) \times \text{prob}(S \text{ was picked} \mid e \text{ voted for } S) \times \deg(e)\Big) \\
&\geq \sum_{(S,\,e) \text{ good}} \frac{1}{\deg(e)} \frac{1}{15} \deg(e) \\
&= \frac{1}{15}(\text{number of good } (S, e) \text{ pairs}).
\end{aligned}$$

Finally since at least a quarter of all relevant (S, e) pairs are good, we observe that $E(\Delta\Phi) \geq \frac{1}{60}\Phi$. We recall the following fact from probability theory.

Fact 4.1.3. Let $\{X_t\}$ be a sequence of integer-valued and nonnegative random variables such that $E(X_t - X_{t+1} | X_t = x) \geq cx$ for some constant c. Let $Y \doteq \min_k\{X_k = 0\}$. Then, $\text{prob}(Y > O(\log(pX_0))) \leq p$. Here the asymptotic notation hides the dependence on $\frac{1}{c}$ which is linear. □

Notice that we have just established that the evolution of Φ satisfies the preconditions that allow us to apply Fact 4.1.3. Therefore, choosing $p = \frac{1}{n^2}$, we have our lemma. □

THEOREM 4.1. PARALLEL SETCOV *finds a cover which is at most* $16H_n$ *times the optimal set cover. Further, the total running time is* $O(\log n \cdot \log nm \cdot \log nmR)$ *with probability* $1 - \frac{1}{n}$.

Comment. The constant 16 can be improved to $2(1+\epsilon)$ for any $\epsilon > 0$. This is done by changing the number $\frac{c_S}{16}$ in step (c) to $\frac{c_S}{2(1+\epsilon)}$ and the quantity in the definition of $(\bullet)$ to $c_S(1-\epsilon^2)$. □

Comment. The conditional statement is a correlation inequality which we feel should be of independent interest. Generalizing this correlation inequality will be a central issue in our analysis of parallel algorithms for the generalizations of set cover. □

5. Set multicover and multiset multicover. The set multicover problem is a natural generalization of the set cover problem. In this generalization, each element e is associated with a coverage requirement, r_e, which indicates the depth to which e must be covered by any feasible cover. Thus, the set multicover problem can be formulated as an integer program as follows: MIN $\sum_S c_S x_S$ subject to $\sum_{S \ni e} x_S \geq r_e$ and $x_S \in \{0,1\}$.

Multiset multicover is the generalization where, in addition to the coverage requirement, each element e appears in any set S with a multiplicity $m(S,e)$. Thus, the integer program is MIN $\sum_S c_S x_S$ subject to $\sum m(S,e)x_S \geq r_e$ and $x_S \in \{0,1\}$.

On relaxing the integrality requirement on x_S we obtain the following linear program and dual in the case of multiset multicover.

LP :		**DP** :	
MIN	$\sum_S c_S x_S$	MAX	$\sum_e r_e y_e - \sum_S z_S$
s.t.	$\sum_S m(S,e)x_S \geq r_e$,	s.t.	$\sum_e m(S,e)y_e - z_S \leq c_S$,
	$-x_S \geq -1$,		$z_S \geq 0$,
	$x_S \geq 0$;		$y_e \geq 0$.

In the case of set multicover, $m(S,e)$ is simply the indicator function that takes a value of 1 if $e \in S$ and 0 otherwise. The interesting feature here is the need to explicitly limit the value of x_S to at most 1 and the associated appearance of the dual variables z_S. Notice that in the set cover problem the limit of 1 on the value of x_S was implicit.

In the following discussion, we shall largely restrict our attention to the more general case of multiset multicover. In some places, it is possible to obtain slightly stronger results in the case of set multicover. We will indicate these at appropriate points in the text.

5.1. Greedy algorithms. There is a natural greedy sequential algorithm for multiset multicover. Like the set cover algorithm, this algorithm works by repeatedly picking sets until all the coverage requirements are met. At an intermediate stage of this process, let $r(e)$ be the residual requirement of e. Thus, $r(e)$ is initially r_e and is decremented by $m(S,e)$ each time a set S is added to the cover. Define $a(S,e) \doteq \min\{m(S,e), r(e)\}$ and the set of alive elements in S, $A(S)$ to be the multiset containing exactly $a(S,e)$ copies of any element e if S is not already in the set cover, and the empty set if it is. The greedy algorithm repeatedly adds a set minimizing $\frac{c_S}{|A(S)|}$ to the set cover.

We will extend this notation to multisets in general. Thus, we will denote $|A(S)| \doteq \sum_e a(S,e)$. Let $k = \max_S \sum_e m(S,e)$. Let K denote $\sum_e r_e$. Dobson [Do82] shows that this natural extension of the greedy algorithm to set multicover achieves an approximation ratio of H_K. However, he does this by comparing the cost of the multicover obtained directly to the optimum integral solution of the set multicover problem. In what follows, we will establish an approximation ratio of H_k by comparing

the greedy solution to the best possible fractional multicover. Since we can always restrict $m(S,e)$ to at most r_e, $k \leq K$. Thus, this represents a slight improvement over Dobson's result.[3]

When a set S is picked, its cost c_S is ascribed equally to each tuple (e,i) where S covers e for the ith time. Here, i ranges from 1 to r_e. We will say S covers (e,i), in short, to describe this case. Obviously, the cost assigned to each tuple is exactly $\text{cost}(e,i) = \frac{c_S}{|A(S)|}$. Now, we choose $y_e = \frac{\max_i\{\text{cost}(e,i)\}}{H_k} = \frac{\text{cost}(e,r_e)}{H_k}$. If a set S is not picked, let $z_S = 0$, and otherwise let

$$z_S = \frac{\sum_{(e,i) \text{ covered by } S} (\text{cost}(e,r_e) - \text{cost}(e,i))}{H_k}.$$

The value of this dual assignment is easily verified to be the cost of the greedy multicover divided by H_k.

LEMMA 5.1.1. $\mathbf{y}, \mathbf{z}$ *is dual feasible.*

Proof. First, trivially, both $\mathbf{y}$ and $\mathbf{z}$ are nonnegative. Consider for any S,

$$\begin{aligned}
&\left(\sum_e m(S,e)y_e\right) - z_S \\
&\quad = \frac{1}{H_k}\left(\sum_e m(S,e)\text{cost}(e,r_e) - \sum_{(e,i) \text{ covered by } S} (\text{cost}(e,r_e) - \text{cost}(e,i))\right) \\
&\quad = \frac{1}{H_k}\left(\sum_{(e,i) \text{ covered by } S} \text{cost}(e,i) + \sum_{e \in S, \text{ not covered by } S} \text{cost}(e,r_e)\right).
\end{aligned}$$

We want to view a multiset S as a set which contains $m(S,e)$ copies of element e. Notice that there is a term in the right-hand side of the above expression corresponding to each element copy S. Thus, there are $m(S,e)$ terms corresponding to e. Let us arrange the element copies in S in the reverse order in which they were covered, for instance, if $m(S,e) = 10$ and $m(S,f) = 5$, and suppose $r(e)$ fell to 9 before $r(f)$ fell to 4 before $r(e)$ fell to 8. Then, the ninth copy of e precedes the fifth copy of f which precedes the tenth copy of e in this reverse ordering. Notice that the term corresponding to the jth element in this ordering is at most $\frac{c_S}{j}$. Thus, we have

$$\left(\sum_e m(S,e)y_e\right) - z_S \leq \frac{1}{H_k}\left(\sum_{i=1}^{k} \frac{1}{i}\right) c_S.$$

In other words, the dual constraint corresponding to S is satisfied. Thus, we establish the feasibility of $\mathbf{y}$, $\mathbf{z}$ for the dual problem. □

The consequence of the above arguments is the following theorem.

THEOREM 5.1. *The extended greedy algorithm finds a multiset multicover within an H_k factor of* $\mathbf{LP}^*$.

[3]Recall that in the case of set cover, the approximation factor is logarithmic in the size of the largest set and not just in n, the size of the universe. Similarly, in this case, the ratio is logarithmic in k, which is the "local size," as opposed to K, the "global size" of the problem.

PARALLEL MULTMULTCOV
Set $r(e) = r_e$ for each e.
Iteration:
For each element e, compute value$(e) = \min_{S \ni e} \frac{c_S}{|A(S)|}$.
For each set S: include S in $\mathcal{L}$ if
(•) $\sum_e a(S,e)\text{value}(e) \geq \frac{c_s}{2}$.
Phase:
Initialization:
(a) Permute $\mathcal{L}$ at random.
(b) Each element e votes for first $r(e)$ copies of itself in the random ordering of $\mathcal{L}$.
(c) If $\sum_{e \text{ votes } S} \text{value}(e) \geq \frac{c_S}{128}$, S is added to the set cover.
(d) Decrement $r(e)$ appropriately. Adjust $a(S,e)$ as required. Delete sets that are picked or fail to satisfy (•) from $\mathcal{L}$.
Repeat until $\mathcal{L}$ is empty.
Iterate until all elements are covered.

FIG. 2. *The parallel multiset multicover algorithm.*

5.2. Parsimonious accounting. More pertinently, the proof implies that the parsimonious accounting principle ensures approximation in the case of multiset multicover as well. By this we mean the following. Define the dynamic quantity value$(e) = \min\{\frac{c_S}{|A(S)|}\}$. Then, as long as we can assign costs cost(e,i) where i ranges from 1 to r_e such that

1. cost$(e,i) \leq \mu$value(e) at the moment that the set S covering (e,i) is picked,
2. $\sum_{(e,i)} \text{cost}(e,i) \geq$ cost of cover,

then the algorithm approximates the value of the multiset multicover to within μH_k. Here k is the largest set size, i.e., $\max_S \sum_e m(S,e)$. We note that in the case of set multicover, k is at most n, and thus we would have an H_n approximation. Moreover, in many instances, k could be substantially smaller than n.

5.3. Parallel algorithms and analysis. We now outline parallel algorithms for multiset multicover. The parallel multiset multicover algorithm is essentially the same as the set cover algorithm except that with each element we associate a dynamic variable, $r(e)$, initially r_e, which tracks the residual requirement of e. After a random permutation of the candidate sets $\mathcal{L}$ is chosen, each element votes for the first $r(e)$ copies of itself in the sequence.[4] The algorithm is detailed in Figure 2. Notice that we can assume without loss of generality that $r(e) \leq \deg(e)$.

5.4. Analysis. It is easy to see that the algorithm satisfies that parsimonious accounting property with $\mu = 128$. This establishes the approximation ratio.

The number of iterations is bounded by $O(\log mnk)$. As earlier, we will denote the cost of the optimum multiset multicover by $\mathbf{IP}^*$. The proof follows exactly along the lines of the proof for the set cover case. The only change required for proving this is in the definition of the crude estimator β: let $S_1, S_2 \cdots S_m$ be the sets arranged in

[4]For example, $r(e)$ is 4 and $m(S_1,e) = 2$, $a(S_2,e) = 3$, and $a(S_3,e) = 2$. Let the permutation be $S_1 < S_2 < S_3$. Then, e votes for S_1 twice and S_2 twice, casting a total of four votes. If the total number of copies of e in the candidate sets is less than $r(e)$, then e votes for them all.

increasing order of cost. Let β_e be the cost of the set containing the r_eth copy of e, and let $\beta = \max_e \beta_e$. Then, $\beta \leq \mathbf{IP}^* \leq mn\beta$. As before, we can restrict attention to the sets such that $c_S \in [\beta/m, mn\beta]$. Again, it can be easily established that $\min_e \text{value}(e)$ increases by a constant factor after each iteration. Since value(e) for any element is at least β/mnk and at most $mn\beta$, there can be only $O(\log mnk)$ iterations.

Notice that for the special case of set multicover, k is at most n. Thus, the bound is $\log mn$ iterations.

5.4.1. Phases in an iteration. The number of phases required in an iteration is at most $O(\log^2 nm)$. This is established by extending the corresponding lemma for set cover. However, the extension is non-trivial and we shall need some machinery to do this.

First we restrict our attention to the sets in $\mathcal{L}$, i.e., sets that satisfy (•). In the following discussion, we will denote the copies of element e in the set S by $e^{(i)}$. Here, i ranges from 1 to $a(S, e)$. We say that $e^{(i)}$ votes for S if $e^{(i)}$ is among the first $r(e)$ copies of e in the random ordering of $\mathcal{L}$.

We will now introduce some notation that will simplify our analysis. We denote by $r(e, i) \doteq r(e) - i + 1$. We denote by $\deg(e, i) \doteq \sum_{S \in \mathcal{L}} \min\{a(S, e), r(e, i)\}$. Notice that from the definitions, it follows that $r(e) = r(e, 1)$ and $\deg(e) = \deg(e, 1)$. The second since $a(S, e)$ is at most $r(e)$. In general, it is tricky to get a handle on the probability that $e^{(i)}$ obtains a vote for S. However, we shall now show the following lemma which says that the quantity $\frac{r(e,i)}{\deg(e,i)}$ approximates this quantity quite nicely.

LEMMA 5.4.1.

$$\frac{1}{2}\frac{r(e,i)}{\deg(e,i)} \leq \text{prob}(e^{(i)} \textit{ votes } S) \leq 4\frac{r(e,i)}{\deg(e,i)}.$$

Proof. The proof has two parts. The first establishes the upper bound, and the second, the lower bound. For the upper bound we notice that with each permutation of the sets such that $e^{(i)}$ votes S, we can associate at least $\frac{\deg(e,i)}{2r(e,i)} - 2$ permutations such that (e, i) does not vote for S. In order to make this association, consider the notion of a "rotation," exhibited by Figure 3. This figure is to be interpreted as

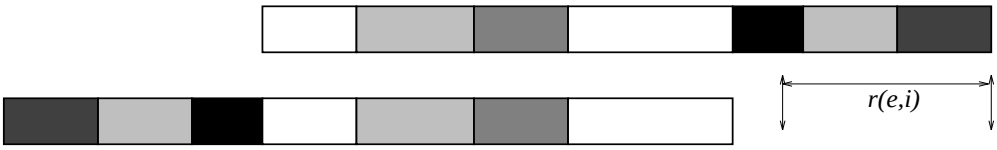

FIG. 3. *The top bar shows a permutation of $\mathcal{L}$, and the bottom, a rotated permutation.*

follows: the figure shows two permutations of $\mathcal{L}$. These two permutations differ by a "rotation." The shaded rectangles representing each permutation represent the various sets in $\mathcal{L}$. The length of these rectangles correspond to their contributions to $\deg(e, i)$. Thus, the total length of the set of rectangles representing any permutation of $\mathcal{L}$ is exactly $\deg(e, i)$.

A rotation is made by extracting from the end of the permutation a minimum number of sets such that they contribute at least $r(e, i)$ towards $\deg(e, i)$ and then placing them in reversed order in the front of the permutation (as shown).

It is easily verified that a rotation is reversible; i.e., it is possible to "unrotate" any rotated permutation to the original permutation. This is most easily seen by turning

Figure 3 upside down. More formally, the unrotation is performed by reversing the sequence, rotating, and then reversing again.

It is also easily verified that for any configuration such that $e^{(i)}$ votes S, it is possible to rotate at least $\frac{\deg(e,i)}{2r(e,i)} - 2$ times such that for each rotated configuration, $e^{(i)}$ does not vote S. This is because the maximum contribution of any set towards $\deg(e,i)$ is $r(e,i)$. Thus, we have associated with each voting permutation at least $\frac{\deg(e,i)}{2r(e,i)} - 2$ nonvoting permutations. Thus, the probability that $e^{(i)}$ votes for S is at most $(\frac{\deg(e,i)}{2r(e,i)} - 1)^{-1} = \frac{2r(e,i)}{\deg(e,i)-2r(e,i)}$. It can be seen via some simple algebraic manipulations that this implies that $\text{prob}(e^{(i)} \text{ votes } S) \leq \frac{4r(e,i)}{\deg(e,i)}$.[5]

For the second part, we need to do some simple analysis. Let us imagine that we permute $\mathcal{L}$ by choosing at random $X_T \in [0,1]$ for each set T and then sorting $\mathcal{L}$ in increasing order of X_T. Notice that we do not need to do this algorithmically; we introduce this just as a means to get a handle on the probability that interests us. Define $Y(x) \doteq \sum_{X_T<x} \min\{a(T,e), r(e,i)\}$. Then, it is easily verified that the events ($e^{(i)}$ votes S) and ($Y(X_S) \leq r(e,i)$) are equivalent. Since for any x, $E(Y(x)) = x\deg(e,i)$, we have by Markov's inequality,

$$\text{prob}(e^{(i)} \text{ votes } S \mid X_S = x) \geq 1 - \text{prob}(Y(x) \geq r(e,i) | X_S = x) \geq 1 - \frac{\deg(e,i)}{r(e,i)}x.$$

Let $\theta \in [0,1]$; then

$$\text{prob}(e^{(i)} \text{ votes } S) \geq \int_0^\theta \text{prob}(e^{(i)} \text{ votes } S \mid X_S = x)dx \geq \theta - \frac{\theta^2}{2}\frac{\deg(e,i)}{r(e,i)}.$$

Choosing $\theta = \frac{r(e,i)}{\deg(e,i)}$ completes the proof, since by our assumption (which, as we pointed out, can be made without loss of generality) that $r(e) \leq \deg(e)$, this fraction is smaller than 1. Otherwise, the lemma is trivial. □

LEMMA 5.4.2. *Let* $e^{(i)}, f^{(j)} \in S$. *Then*

$$\text{prob}\left(e^{(i)} \textit{ and } f^{(j)} \textit{ vote } S\right) \geq \frac{1}{2}\left(\frac{1}{\frac{\deg(e,i)}{r(e,i)} + \frac{\deg(f,j)}{r(f,j)}}\right).$$

Proof. The proof of this lemma is very similar to the proof of Lemma 5.4.1.

$$\begin{aligned}
&\text{prob}\,(e \text{ and } f \text{ vote } S)\\
&= \int_0^1 \text{prob}\,(e \text{ and } f \text{ vote } S | X_S = x)\,dx\\
&\geq \int_0^\theta \text{prob}\,(e \text{ and } f \text{ vote } S | X_S = x)\,dx, \quad \theta \in [0,1],\\
&\geq \int_0^\theta 1 - \text{prob}\,(e \text{ does not vote } S | X_S = x) - \text{prob}\,(f \text{ does not vote } S | X_S = x)\,dx.
\end{aligned} \tag{1}$$

[5] To see this, we consider two cases. If $\deg(e,i) \leq 4r(e,i)$, then the conclusion is trivial. Otherwise, it is easy to see that $\frac{2r(e,i)}{\deg(e,i)-2r(e,i)} \leq 4\frac{r(e,i)}{\deg(e,i)}$ by crossmultiplication

Define $Y_e(x)$ and $Y_f(x)$ as in the previous lemma,

$$\text{prob}(e^{(i)} \text{ does not vote for } S \mid X_S = x) \leq \frac{x \cdot \deg(e,i)}{r(e,i)},$$

and do similarly for $f^{(j)}$. Substituting these values back into (1), we obtain

$$\text{prob}(e^{(i)} \text{ and } f^{(j)} \text{ vote for } S) \geq \theta - \left(\frac{\deg(e,i)}{r(e,i)} + \frac{\deg(f,j)}{r(f,j)}\right) \cdot \frac{\theta^2}{2}.$$

Choosing the value of θ to maximize the right-hand side, we get[6]

$$\text{prob}\left(e^{(i)} \text{ and } f^{(j)} \text{ vote } S\right) \geq \frac{1}{2}\left(\frac{1}{\frac{\deg(e,i)}{r(e,i)} + \frac{\deg(f,j)}{r(f,j)}}\right). \qquad \square$$

LEMMA 5.4.3. *Let* $e^{(i)}, f^{(j)} \in S$ *such that* $\frac{r(e,i)}{\deg(e,i)} \leq \frac{r(f,j)}{\deg(f,j)}$.

$$\text{prob}(f^{(j)} \textit{ votes } S \mid e^{(i)} \textit{ votes } S) \geq \frac{1}{8}.$$

Proof. The proof is immediate from the previous two lemmas. $\square$

Remark. In the case of set multicover, the first of the two lemmas implying Lemma 5.4.3 is trivial. Indeed, since $a(S,e)$ is either 0 or 1, we can immediately infer that $\text{prob}(e \text{ votes } S) = \frac{r(e)}{\deg(e)}$. The second lemma (with i and j both set to 1) immediately implies the corresponding version of Lemma 5.4.3 with a bound of $\frac{1}{4}$. $\square$

Say that a set-element pair $(S, e^{(i)})$ is *good* if $\frac{\deg(e,i)}{r(e,i)} \geq \frac{\deg(f,j)}{r(f,j)}$ for at least three quarters of the elements $f^{(j)} \in S$. Then, as in the case of set cover, Lemma 5.4.3 implies that if $(S, e^{(i)})$ is good

$$\text{prob}\left(S \text{ is picked} \mid e^{(i)} \text{ votes for } S\right) \geq p,$$

where $p > 0$. The potential function we use is

$$\Phi \doteq \sum_e \deg(e) H_{r(e)} = \sum_e \deg(e) \sum_{i=1}^{r(e)} \frac{1}{r(e,i)}.$$

Initially, $\Phi \leq mn \log r$, where r is the largest requirement. The expected decrease in Φ ascribable to a good set-element pair $(S, e^{(i)})$, denoted $\Delta\Phi_{(S,e^{(i)})}$, is at least

$$\begin{aligned} E(\Delta\Phi_{(S,e^{(i)})}) &\geq \text{prob}(e^{(i)} \text{ voted for } S) \times \text{prob}(S \text{ was picked} \mid e \text{ voted for } S) \frac{\deg(e)}{r(e,i)} \\ &\geq \frac{r(e,i)}{\deg(e,i)} \frac{p}{2} \frac{\deg(e)}{r(e,i)} \\ &\geq \frac{p}{2}. \end{aligned}$$

[6] Again, the assumption that $r(e) \leq \deg(e)$ implies that our choice of θ is at most 1.

The first inequality is from the definition of Φ, the second is due to Lemmas 5.4.1 and 5.4.3, and the last is due to $\deg(e) \geq \deg(e, i)$. Since a constant fraction of all $(S, e^{(i)})$ are good, $\mathrm{E}\Delta\Phi \geq O(\frac{\Phi}{\log r})$, where r is the largest requirement value. From Fact 4.1.3, we know that the total number of phases is at most $O(\log r(\log mn + \log\log r))$.

THEOREM 5.2. PARALLEL MULTMULTCOV *approximates multiset multicover to within* $128H_n$*, using a linear number of processors and running in time* $O(\log^4 mnr)$.

COROLLARY 5.4.4. *If the number in step* (c) *of Figure* 2 *were changed to* $\frac{c_S}{32}$*, and the algorithm were run on an instance of set multicover, then it would be a* RNC^4 *algorithm approximating set multicover to within* $32H_n$.

Proof. The proof follows from the remark following Lemma 5.4.3. □

6. Covering integer programs. Covering integer programs are integer programs of the following form:

$$\textbf{CIP}: \quad \begin{array}{ll} \text{MIN} & \sum_S c_S x_S \\ \text{s.t. } \forall e & \sum_S M(S,e) x_S \geq r_e, \\ & x_S \in \bar{\wedge}^+. \end{array}$$

Here, $\bar{\wedge}^+$ are the nonnegative integers. The vectors $\mathbf{c}$ and $\mathbf{r}$ and the matrix M are all composed of nonnegative (rational) numbers. At this stage, the notion of a "set" does not have any meaning, however, we continue to use this notation simply to maintain consistency with the previous discussion. For the purpose of the subsequent discussion, the reader should keep in mind that S varies over one set of indices, and e, over the other. Without loss of generality, we may assume that $M(S, e) \leq R_e$.

What we present here is a scaling and rounding trick. The goal is to reduce to an instance of multiset multicover with polynomially bounded (and integral) element multiplicities and requirements. Moreover, in making this reduction, there should be no significant degradation in the approximation factor.

LEMMA 6.0.5. *There is an* NC^1 *reduction from covering integer programs to multiset multicover with element multiplicities and requirements at most* $O(n^2)$ *such that the cost of the fractional optimal (i.e., the cost of the LP relaxation) goes up by at most a constant factor.*

Proof. Essentially, we need to reduce the element requirements to a polynomial range and ensure that the requirements and multiplicities are integral. Then, replicating sets to the extent of the largest element requirement, we would get an instance of multiset multicover. We will achieve this as follows: we will obtain a (crude) approximation to the fractional optimal within a polynomial factor, and then we will ensure that the costs of sets are in a polynomial range around this estimate. Also, we will set all element requirements at a fixed polynomial and set the multiplicities accordingly. At this point, rounding down the multiplicities will change the fractional optimal by only a constant factor.

Let $\beta_e = R_e \cdot \min_S \frac{c_S}{M(S,e)}$ and $\beta = \max_e \beta_e$. Clearly, $\beta \leq \mathbf{CLP}^* \leq n\beta$, where $\mathbf{CLP}^*$ is the cost of the optimal solution to the LP relaxation of **CIP**. If a set S has large cost, i.e., $c_S > n\beta$, then S will not be used by the fractional optimal, and we will eliminate it from consideration. So, for the remaining sets, $c_S \leq n\beta$. Define $\alpha_S = \lceil \frac{\beta}{nc_S} \rceil$. We will clump together α_S copies of S (i.e., $M(S, e) \leftarrow M(S, e)\alpha_S$, $c_S \leftarrow c_S\alpha_S$). The cost of the set so created is at least $\frac{\beta}{n}$. Additionally, the fractional optimum is not affected by this scaling (though the same cannot be said of the integral optimal). Thus, we can assume that for each S, $c_S \in [\frac{\beta}{n}, n\beta]$.

If any element is covered to its requirement by a set of cost less than $\frac{\beta}{n}$, cover the element using that set and eliminate the element from consideration. The cost incurred in the process is at most β for all elements so covered, and this is subsumed in the constant factor. Notice that as a result of this step, the multiplicity of an element in a set will still be less than its requirements. The reason we require α_S to be integral is that we need to map back solutions from the reduced problem to the original problem. Henceforth, we can assume that the costs satisfy $c_S \in [\frac{\beta}{n}, n\beta]$. Next, we will fix the requirement of each element to be $2n^2$, and we will set the multiplicities appropriately, $m'(S,e) = \frac{M(S,e)}{r_e} \cdot 2n^2$. Since this is just multiplying each inequality by a constant, this will not change the (both fractional and integral) optimal solution or value.

Finally, we will round down the multiplicities, $m(S,e) = \lfloor m'(S,e) \rfloor$. We will show that this will increase the fractional optimal by a factor of at most 4. The same cannot be said for the integral optimum. This is the reason why we needed to compare the solution obtained by our approximation algorithms for multiset multicover to the fractional optimum.

Consider an optimal fractional solution to the problem with multiplicities $m'(S,e)$. Since the cost of this solution is at most $n\beta$, and the c_S is at least $\frac{\beta}{n}$, $\sum_S x_S \leq n^2$. Consider an element e, and let $\mathcal{S}$ be the collection of all sets S such that $m'(S,e) < 1$. Then, the total coverage of e due to sets in $\mathcal{S}$ is at most n^2. Therefore, the total coverage of e due to the remaining sets is at least n^2. Since for each of these sets, $m(S,e) \geq \frac{1}{2} m'(S,e)$, if we multiply each x_S by 4, element e will be covered to the extent of at least $2n^2$ in the rounded-down problem. The lemma follows. □

Notice that the reduction in Lemma 6.0.5 is such that a feasible solution to the instance of the multiset multicover problem can be mapped back to a feasible solution of the original problem without increasing the cost. Hence we get the following theorem.

THEOREM 6.1. *There is an $O(\log n)$ factor RNC^4 approximation algorithm for covering integer programs requiring $O(n^2 \#(A))$ processors, where $\#(A)$ is the number of nonzero entries in A.*

Since, in the reduction, all element requirements are set to $O(n^2)$, we obtain the processor bound stated above. Further, since we are comparing the performance of our algorithm with the fractional optimal, it follows that the integrality gap for covering integer programs, in which element multiplicities are bounded by requirements, is bounded by $O(\log n)$. It is easy to see that if multiplicities are not bounded by requirements, the integrality gap can be arbitrarily high.

The previous best (sequential) approximation guarantee for covering integer programs was $H_{nmax(A)}$, where $\max(A)$ is the largest entry in A, assuming that the smallest one is 1 [Do82]. Moreover, in that result, the performance of the algorithm given was compared to the integral optimal.

Notice that the multiset multicover problem with the restriction that each set can be picked at most once is not a covering integer program, since we will have negative coefficients. This raises the question of whether there is a larger class than covering integer programs for which we can achieve (even sequentially) an $O(\log n)$ approximation factor.

Acknowledgments. We thank the referees. Their comments greatly improved the presentation of the paper.

OPTIMAL CONSTRUCTION OF EDGE-DISJOINT PATHS IN RANDOM GRAPHS*

ANDREI Z. BRODER†, ALAN M. FRIEZE‡, STEPHEN SUEN§, AND ELI UPFAL¶

Abstract. Given a graph $G = (V, E)$ with n vertices, m edges, and a family of κ pairs of vertices in V, we are interested in finding for each pair (a_i, b_i) a path connecting a_i to b_i such that the set of κ paths so found is edge disjoint. (For arbitrary graphs the problem is $\mathcal{NP}$-complete, although it is in $\mathcal{P}$ if κ is fixed.)

We present a polynomial time randomized algorithm for finding the optimal number of edge disjoint paths (up to constant factors) in the random graph $G_{n,m}$ for all edge densities above the connectivity threshold. (The graph is chosen first; then an adversary chooses the pairs of endpoints.) Our results give the first tight bounds for the edge-disjoint paths problem for any nontrivial class of graphs.

1. Introduction.

Given a graph $G = (V, E)$ with n vertices, m edges, and a set of κ pairs of vertices in V, we are interested in finding for each pair (a_i, b_i) a path connecting a_i to b_i such that the set of κ paths so found is edge disjoint.

For arbitrary graphs the related decision problem is $\mathcal{NP}$-complete, although it is in $\mathcal{P}$ if κ is fixed (Robertson and Seymour [16]). Nevertheless, this negative result can be circumvented for certain classes of graphs. Peleg and Upfal [15] presented a polynomial time algorithm for the case where G is a (sufficiently strong) bounded degree expander graph, and $\kappa \leq n^{\epsilon}$ for a small constant ϵ that depends on the expansion property of the graph. (A precise upper bound for ϵ was not computed, but it is clearly less that 1/3.) This result has recently been improved by Broder, Frieze, and Upfal [8]: G still has to be a (sufficiently strong) bounded degree expander but κ can now grow as fast as $n/(\ln n)^{\theta}$, where θ depends only on the expansion properties of the input graph but is at least 7.

For the vertex-disjoint paths problem Kleinberg and Tardos [13] come within an $O(\log n)$ factor of the maximum possible κ for a class of planar graphs. In random graphs Shamir and Upfal have shown in [17] that any set of up to $O(\sqrt{n})$ pairs can be connected via vertex-disjoint paths; similar results using efficient flow techniques

were also obtained by Hochbaum [12]. These results were proved for graphs with $m \geq Kn \log n$ random edges, where K is a sufficiently large constant.

Let D be the median distance between pairs of vertices in G. Clearly it is not possible to connect more than $O(m/D)$ pairs of vertices by edge-disjoint paths for all choices of pairs, since some choice would require more edges than all the edges available. In the case of bounded degree expanders, this absolute upper bound on κ is $O(n/\log n)$. The results mentioned above use only a vanishing fraction of the set of edges of the graph and thus are far from reaching this upper bound. In contrast, in this work we show that for the basic models of random graphs, $G_{n,m}$ and $G_{n,p}$, the absolute upper bound is achievable within a constant factor, and we present an algorithm that constructs the required paths in polynomial time.

As usual, let $G_{n,p}$ denote a random graph with vertex set $\{1, 2, \ldots, n\} = [n]$ in which each possible edge is included independently with probability p, and let $G_{n,m}$ denote a random graph also with vertex set $[n]$ and exactly m edges, all sets of m edges having equal probability. The degree of a vertex v is denoted by $d_G(v)$.

Our main result is formulated in the following theorem.

THEOREM 1. *Let $m = m(n)$ be such that $d = 2m/n \geq (1 + o(1)) \ln n$. Then as $n \longrightarrow \infty$ with probability $1 - o(1)$, the graph $G_{n,m}$ has the following property: there exist positive constants α and β such that for all sets of pairs of vertices $\{(a_i, b_i) \mid i = 1, \ldots, \kappa\}$ satisfying*

(i) $\kappa = \lceil \alpha m \ln d / \ln n \rceil$,

(ii) *for each vertex v, $|\{i : a_i = v\}| + |\{i : b_i = v\}| \leq \min\{d_G(v), \beta d\}$,*

there exist edge-disjoint paths in G, joining a_i to b_i, for each $i = 1, 2, \ldots, \kappa$. Furthermore, there is an $O(nm^2)$ time randomized algorithm for constructing these paths.

A similar result holds for $G_{n,p}$, with $d = np$ and $\kappa = \lceil \alpha n^2 p \ln d / (2 \ln n) \rceil$.

This result is the best possible up to constant factors. For (i) note that the distance between most pairs of vertices in G is $\Omega(\log n / \log d)$, and thus with m edges we can connect at most $O(m \log d / \log n)$ pairs. For (ii) note that a vertex v can be the endpoint of at most $d_G(v)$ different paths. Furthermore suppose that $d \geq n^\gamma$ for some constant $\gamma > 0$ so that $\kappa \geq \lceil \alpha \gamma n d / 2 \rceil$. Let $\epsilon = \alpha\gamma/3$, $A = [\epsilon n]$, and $B = [n] \setminus A$. Now with probability $1 - o(1)$ there are less than $(1 + o(1))\epsilon(1 - \epsilon)nd$ edges between A and B in $G_{n,m}$. However, almost all vertices of A have degree $(1 + o(1))d$ and if for these vertices we ask for $(1 - \epsilon/2)d$ edge-disjoint paths to vertices in B then the number of paths required is at most $(1 + o(1))\epsilon(1 - \epsilon/2)nd < \kappa$, but, without further restrictions, this many paths would require at least $(1 - o(1))\epsilon(1 - \epsilon/2)nd > (1 + o(1))\epsilon(1 - \epsilon)nd$ edges between A and B, which is more than what is available. This justifies an upper bound of $1 - \epsilon/2$ for β of Theorem 1.

We note that we have proved similar optimal results for the vertex-disjoint paths problem in random graphs [7].

The construction of $n/(\ln n)^\theta$ edge-disjoint paths on expander graphs that was described in [8] was achieved through the use of the Lovász local lemma [9]. Sets of possible paths were constructed for each pair, and the local lemma was applied to prove that there is a global choice of one path per set such that all the choices are edge disjoint. However, this approach can only be used when the total number of edges in the final set of disjoint paths is a vanishing fraction of the number of edges in the graph; inherently, it does not lead to optimal bounds.

Here we address the problem in a different way. After a randomization phase, similar to the one in [8], the disjoint paths are constructed one after the other, and all the edges seen during the construction are deleted from the graph. The paths

connecting each pair are chosen through a "random walk" type process. The crux of the analysis is to show that after a number of pairs have already been connected, the remaining graph is sufficiently connected to continue with this process. To prove that, we use a good estimate on the eigenvalues of the intermediate graphs generated by the algorithm. (Since we cannot throw logarithmic factors at our trouble spots, the proofs are rather intricate, although the algorithm itself is quite simple.) Eventually the number of pairs not yet connected becomes small enough that we can use [8] directly.

The disjoint paths problem has numerous algorithmic applications. One that has received increased attention in recent years is in the context of communication networks. The only efficient way to transmit high volume communication, such as in multimedia applications, is through disjoint paths that are dedicated to one pair of processors for the duration of the communication. To efficiently utilize the network one needs a very simple algorithm that with minimum overhead constructs a large number of edge-disjoint paths between a given set of requests. The algorithm we study is simple and easy to implement (after eliminating some steps that are needed only for the proof) and thus suggests some possibly good practical heuristics.

In section 3 we present a very brief overview of the algorithm. The details of the algorithm are exposed in section 4. The remainder of the paper gives the analysis.

2. Preliminaries. The paper contains a number of unspecified constants of which α and β above are the first. Exact values could be given, but it is easier for us *and the reader* if we simply give the relations between them. New constants will be introduced as $C_0, C_1, \ldots$ without further comment. Furthermore, specific constants have been chosen for convenience, we made no attempt to optimize them, and, in general, we only claim that inequalities dependent on n hold for n sufficiently large.

For a graph $G = (V, E)$ we use $\delta(G)$ and $\Delta(G)$ to denote the smallest and largest degrees, respectively. For a set $S \subseteq V$ we define its neighbor set, $N(S, G)$, as

$$N(S, G) = \{v \in V \setminus S : \exists w \in S \text{ such that } \{v, w\} \in E\}.$$

For $S \subseteq V$, we use $G[S]$ to denote the subgraph of G induced by S.

The *Chernoff bounds* on the tails of the binomial $\text{bin}(n, \theta)$ that we use are

$$\mathbf{Pr}(\text{Bin}(n, \theta) \leq (1 - \epsilon)n\theta) \leq e^{-\epsilon^2 n\theta/2}, \tag{1}$$

$$\mathbf{Pr}(\text{Bin}(n, \theta) \geq (1 + \epsilon)n\theta) \leq e^{-\epsilon^2 n\theta/3}, \tag{2}$$

valid for $0 \leq \epsilon \leq 1$.

3. Overview of the algorithm. Our algorithm divides naturally into the five phases sketched below.

Phase 1. Partition G into five edge-disjoint graphs $G_i = (V_i, E_i)$, $1 \leq i \leq 5$. Phase 2 will use only the graph G_1; Phase 3 will use only the graph G_2; Phase 4 will use only the graph G_3; and Phase 5 will use only the graphs G_4 and G_5. The partition is such that $V_1 = V$ but $V_2 = V_3 = V_4 = V_5 \subseteq V$ with $|V_2| = n - o(n)$.

Phase 2. Choose a random multiset $Z = \{z_1, \ldots, z_{2\kappa}\}$ of 2κ points in V_2. Connect the endpoints $\{(a_i, b_i) \mid i = 1, \ldots, \kappa\}$ to the newly chosen points in an arbitrary manner via edge-disjoint paths in G_1 using a flow algorithm. Let $\tilde{a}_i$ (resp., $\tilde{b}_i$) be the vertex connected to a_i (resp., b_i). The original problem is now reduced to finding edge-disjoint paths from $\tilde{a}_i$ to $\tilde{b}_i$ for each i. (This randomization was used in [8] and has its roots in Valiant's routing algorithm [19].)

Phase 3. For each $z \in Z$ in turn, we do a random walk of length $\tau = \lceil C_0 \ln n / \ln d \rceil$ in G_2, starting at z. We remove the edges of the jth walk before embarking on the $j+1$st. This keeps the paths constructed edge disjoint. The terminating endpoint of the walk starting at $\tilde{a}_i$ (resp., $\tilde{b}_i$) will be denoted by $\hat{a}_i$ (resp., $\hat{b}_i$) for $1 \le i \le \kappa$. The analysis below shows that in almost every $G_{n,p}$, the (multi)set of vertices $\hat{a}_1, \ldots, \hat{a}_\kappa, \hat{b}_1, \ldots, \hat{b}_\kappa$ is *not too far* from being independently, uniformly distributed.

Phase 4. For each i in turn, we repeatedly do a certain type of random walk in G_3 starting from $\hat{a}_i$ until one of these walks ends at $\hat{b}_i$. We keep the last walk as our path from $\hat{a}_i$ to $\hat{b}_i$ and remove from G_3 all edges seen in these walks. (The analysis below promises that this process will succeed whp[1] for most i.) Not every pair $(\hat{a}_i, \hat{b}_i)$ will be successfully connected in this phase, but the final path for each pair that succeeds is the concatenation of the paths from a_i to $\tilde{a}_i$, and from b_i to $\tilde{b}_i$ found in Phase 2, the paths from $\tilde{a}_i$ to $\hat{a}_i$ and $\tilde{b}_i$ to $\hat{b}_i$ found in Phase 3, and the path from $\hat{a}_i$ to $\hat{b}_i$ found here.

Phase 5. At the end of Phase 4, whp, there will be at most $n^{1-\epsilon}$ pairs $(\hat{a}_i, \hat{b}_i)$, for a constant $\epsilon > 0$, which have not been joined by paths. We use the algorithm of [8] to join them by edge-disjoint paths, using only the edges of G_4 and G_5, and then construct the final paths as above.

To prove Theorem 1 it suffices to show that for almost every $G_{n,p}$,

(i) Phases 1 and 2 will succeed for *all* choices of $a_1, \ldots, b_\kappa$ and *almost every* choice of $z_1, \ldots, z_{2\kappa}$;

(ii) Phases 3, 4, and 5 are successful for *almost every* choice of $z_1, \ldots, z_{2\kappa}$ and *any* mapping $\{\tilde{a}_1, \ldots, \tilde{a}_\kappa, \tilde{b}_1, \ldots, \tilde{b}_k\} \leftrightarrow \{z_1, \ldots, z_{2\kappa}\}$.

Note that to prove these facts we have to consider only one experiment; namely, choose $G_{n,p}$ or $G_{n,m}$ at random and then $z_1, \ldots, z_{2\kappa}$ at random. From this we can deduce that almost every $G_{n,p}$ or $G_{n,m}$ is such that for *all* choices of $a_1, \ldots, b_\kappa$ and almost every choice of $z_1, \ldots, z_{2\kappa}$, we can find edge-disjoint paths $a_i - \tilde{a}_i - \hat{a}_i - \hat{b}_i - \tilde{b}_i - b_i$ for $1 \le i \le \kappa$.

4. Description of the algorithm. The input to our algorithm is a random graph $G_{n,p}$ and a set of pairs of vertices $\{(a_i, b_i) \mid i = 1, \ldots, \kappa\}$ satisfying the premises of Theorem 1. The output is a set of κ edge-disjoint paths, $P_1, \ldots, P_\kappa$ such that P_i connects a_i to b_i.

4.1. Phase 1. We start by partitioning G into five edge-disjoint graphs $G_i = (V_i, E_i)$ for $1 \le i \le 5$. Phase 2 will use only G_1; Phase 3 will use only G_2; Phase 4 will use only G_3; Phase 5 will use only G_4 and G_5. The partition is such that $V_1 = V$ but $V_2 = V_3 = V_4 = V_5 \subseteq V$ with $|V_1| = n - o(n)$.

In this construction, we use the notion of a k-core. The k-core of a graph H is the largest $S \subseteq V(H)$ which induces a subgraph of minimum degree at least k. It is unique and can be found by repeatedly removing vertices of degree less than k until what remains is empty or has minimum degree k.

The algorithm Split depicted in Figure 1 starts by constructing preliminary versions of these graphs, denoted G_i' for $1 \le i \le 5$. Then edges and vertices are deleted from $G_2', \ldots, G_5'$ in order to achieve certain minimum degree properties.

We will show later (Lemma 2) that whp this algorithm terminates with $|K| = n - o(n)$. Note that Split ensures that the following hold.

(i) The final graphs G_i, $2 \le i \le 5$ have the same vertex set K.

[1] In this paper, an event $\mathcal{E}_n$ is said to occur whp (with high probability) if $\mathbf{Pr}(\mathcal{E}_n) = 1 - o(n^{-9/10})$ as $n \longrightarrow \infty$. For reasons explained in section 7, the usual $1 - o(1)$ does not suffice here.

```
1.  algorithm SPLIT
2.  begin
3.      Divide E into E'_i, 1 ≤ i ≤ 5 by placing each edge of E
            independently with probability 5/6 in E'_1, and with
            probability 1/24 into each of E'_i for 2 ≤ i ≤ 5.
4.      For 1 ≤ i ≤ 5 set G'_i ← (V, E'_i)
5.      K ← ⌊d/2⌋-core of G'_1
6.      For 2 ≤ i ≤ 5 set G_i ← (K, E'_i ∩ (K × K))
7.      while ∃v ∈ K such that min{d_{G_i}(v) : 2 ≤ i ≤ 5} < d/30 do
8.          For 2 ≤ i ≤ 5 remove v and its adjacent edges from
                G_i.
9.          K ← K \ {v}

13. end SPLIT
```

FIG. 1. *Algorithm* SPLIT.

(ii) Every $v \in K$ has degree at least $\lfloor d/2 \rfloor$ in G_1 and at least $\lfloor d/30 \rfloor$ in each of G_i, $2 \le i \le 5$.

(iii) If $v \in V \setminus K$ then $d_{G_1}(v) = d_G(v)$.

4.2. Phase 2. Choose $z_1, z_2, \ldots, z_{2\kappa} \in V_2$ uniformly and randomly with replacement. Let Z denote the multiset $\{z_1, z_2, \ldots, z_{2\kappa}\}$. We are going to replace the problem of finding paths from a_i to b_i by that of finding paths from $\tilde{a}_i$ to $\tilde{b}_i$, where $\{\tilde{a}_1, \tilde{b}_1, \tilde{a}_2, \tilde{b}_2, \ldots, \tilde{a}_\kappa, \tilde{b}_\kappa\} = Z$ as multisets. Let A denote the multiset $\{a_1, b_1, a_2, b_2, \ldots, a_\kappa, b_\kappa\}$.

We connect A to Z via edge-disjoint paths in the graph G_1 using network flow techniques. We construct a network as follows.

(i) Each undirected edge of G_1 gets capacity 1.

(ii) Each member of A becomes a source and each member of Z becomes a sink.

(iii) If a vertex occurs r times in A then it becomes a source with supply r, and if a vertex occurs s times in Z, then it becomes a sink with demand s.

Then we find a flow from A to Z that satisfies all demands. Since the maximum flow has integer values, it decomposes naturally into $|A|$ edge-disjoint paths (together perhaps with some cycles). If a path joins a_i to $z \in Z$, then we let $\tilde{a}_i = z$. Similarly, if a path joins b_i to $z \in Z$, then we let $\tilde{b}_i = z$.

Thus Phase 2 finds edge-disjoint paths $P_i^{(1)}$ from a_i to $\tilde{a}_i$ and $P_i^{(5)}$ from $\tilde{b}_i$ to b_i, $1 \le i \le \kappa$, where the vertices $\tilde{a}_1, \tilde{b}_1, \tilde{a}_2, \tilde{b}_2, \ldots, \tilde{a}_\kappa, \tilde{b}_\kappa \in V_2$ are chosen uniformly at random with replacement. (Some of these paths may of course be single vertices.) On the other hand there may be some difficult conditioning involved in the pairing of $\tilde{a}_i$ with $\tilde{b}_i$, $1 \le i \le \kappa$. We deal with this in Phase 3.

4.3. Phase 3. We construct paths $P_i^{(2)}$, $P_i^{(4)}$ in G_2 with start vertices $\tilde{a}_i, \tilde{b}_i$, respectively, for $1 \le i \le \kappa$. Each path is constructed by simulating a random walk

of length $\tau = \lceil C_0 \ln n / \ln d \rceil$ from each start point. The endpoints of $P_i^{(2)}$, $P_i^{(4)}$ are $\hat{a}_i, \hat{b}_i$, respectively. The edges of a walk are deleted from G_2 before the next one starts. This keeps the paths edge disjoint. We construct these walks with start points Z in the *random* order $z_1, z_2, \ldots, z_{2\kappa}$. (This random order is helpful in the proof of (21) below.) W_i denotes the walk started at z_i; it ends at $\hat{z}_i$. Γ_i denotes the state of G_2 after the edges of $W_1, W_2, \ldots, W_{i-1}$ have been deleted.

A *random walk* on an undirected graph (or multigraph) $G = (V, E)$ is a Markov chain $\{X_t\}$ on V associated with a particle that moves from vertex to vertex according to the following rule: the probability of a transition from vertex v of degree d_v to a vertex w is $1/d_v$ if $\{v, w\} \in E$ and 0 otherwise. (For multigraphs, each edge out of a vertex is an equally likely exit; loops are counted as two exits.) Its stationary distribution, denoted by π or $\pi(G)$, is given by $\pi_v = d_v/(2|E|)$. A trajectory W of length τ is a sequence of vertices $[w_0, w_1, \ldots, w_\tau]$ such that $\{w_t, w_{t+1}\} \in E$ for $1 \le t < \tau$. The Markov chain induces a probability distribution on trajectories in the usual way. We use $P_G^{(\tau)}(a, b)$ to denote the probability that a random walk in G of length τ starting at a terminates at b.

4.4. Phase 4. The problem now is to find edge-disjoint paths $P_i^{(3)}$ joining $\hat{a}_i$ to $\hat{b}_i$ for $1 \le i \le \kappa$. We use only the edges of G_3 to avoid conflict with paths already chosen in $G_1 \cup G_2$. Thus eventually we can take P_i to be the path (after removing cycles if necessary) that joins a_i to $\tilde{a}_i$ via $P_i^{(1)}$, $\tilde{a}_i$ to $\hat{a}_i$ via $P_i^{(2)}$, $\hat{a}_i$ to $\hat{b}_i$ via $P_i^{(3)}$, $\hat{b}_i$ to $\tilde{b}_i$ via $P_i^{(4)}$, and $\tilde{b}_i$ to b_i via $P_i^{(5)}$. (Actually, this will only be true for *most* i. If $d = O(\ln n)$ then a fifth phase may be necessary to find paths for some indices i.)

The paths $P_i^{(3)}$ are again found by simulating a random walk. The reader might expect us to choose a random walk from those with endpoints $\hat{a}_i, \hat{b}_i$. The main problem with this is that the distribution of $\hat{b}_i$ may be significantly different from the steady state distribution of a walk from $\hat{a}_i$ in G_3. If we choose a walk in this manner then deleting it will condition the graph in a way that is complex to analyze, especially as we have to repeat the procedure κ times.

We overcome this by choosing a set of random walks and use rejection sampling to make the final walk have the correct distribution. There is still the complication that the $\hat{b}_i$ are chosen before we do the walks. This leads to the subroutine WALK described next. See Figure 2. WALK$(\hat{a}_i, \hat{b}_i, \hat{\Gamma}_i, \Gamma_j, z_j)$ generates a series of random walks of length τ in $\hat{\Gamma}_i$ starting from $\hat{a}_i$. The graph $\hat{\Gamma}_i$ is such that $\hat{\Gamma}_i \subseteq G_3$ with $V(\hat{\Gamma}_i) = V(G_3) = V(\Gamma_j)$, and j is defined by $z_j \equiv \tilde{b}_i$. The last walk generated ends at $\hat{b}_i$ which, by the construction used in the previous phase, has the distribution

$$\hat{p}_v = P_{\Gamma_j}^{(\tau)}(z_j, v).$$

The somewhat strange method used to generate these walks will be further explained in section 7.

We maintain an array of counters, $S[v]$, for $v \in V_3$, initially all 0. The counter $S[v]$ shows how many times v was used as a start point of a walk. No vertex is allowed to be the start of more than $d/120$ walks; thus there is a chance (in fact, only when $d = O(\ln n)$) that for some pairs of vertices Phase 4 will not connect them. The indices of these pairs are kept in a set L and considered in the last phase.

The distributions p_v and $\hat{p}_v$ can be computed in $O(nm\tau)$ time by computing powers of the transition matrix, after which a random walk can be found in $O(n\tau)$ time. (For details see [8].) The analysis will show that in the range of interest whp s

subroutine WALK($\hat{a}_i, \hat{b}_i, \hat{\Gamma}_i, \Gamma_j, z_j$)
begin
/* By construction, $z_j = \tilde{b}_i$. */
$p_v \leftarrow P^{(\tau)}_{\hat{\Gamma}_i}(\hat{a}_i, v)$ for $v \in V_3$
$\hat{p}_v \leftarrow P^{(\tau)}_{\Gamma_j}(z_j, v)$ for $v \in V_2$ (the distribution of $\hat{b}_i$)
$p_{\min} \leftarrow \min\{p_v : v \in V_3\}$
$\hat{p}_{\max} \leftarrow \max\{\hat{p}_v : v \in V_2\}$
Choose r from the geometric distribution with probability of success $s = p_{\min}/\hat{p}_{\max}$
if $S[\hat{a}_i] + r \geq d/120$ **then**
    $L \leftarrow L \cup \{i\}$
    exit WALK
else
    $S[\hat{a}_i] \leftarrow S[\hat{a}_i] + r$
fi
for k **from** 1 **to** $r - 1$ **do**
    Choose x_k according to $\mathbf{Pr}(x_k = v) = (p_v - \hat{p}_v p_{\min}/\hat{p}_{\max})/(1 - s)$
od
$x_r \leftarrow \hat{b}_i$
for k **from** 1 **to** r **do**
    Pick a walk $\hat{W}_k$ of length τ in $\hat{\Gamma}_i$ according to the distribution on trajectories, conditioned on start point $= \hat{a}_i$ and endpoint $= x_k$
od
output $\hat{W}_1, \hat{W}_2, \ldots, \hat{W}_r$
end WALK

FIG. 2. *Algorithm* WALK.

is bounded away from zero by a constant; hence the expected total running time of WALK is $O(nm\tau)$.

The complete algorithm for Phase 4, GENPATHS, is depicted in Figure 3. The expected running time of GENPATHS is $O(\kappa nm\tau) = O(nm^2)$.

4.5. Phase 5. Use (a slight modification of) the algorithm of [8] to find edge-disjoint paths in $G_4 \cup G_5$ from $\hat{a}_i$ to $\hat{b}_i$ for $i \in L$.

5. Analysis of Phase 1. In Lemmas 2, 3, and 4 we calculate with $G_{n,p}$ and deduce the result for $G_{n,m}$ via

$$\mathbf{Pr}(G_{n,m} \in \mathcal{P}) \leq O(n^{1/2})\, \mathbf{Pr}(G_{n,p} \in \mathcal{P})$$

for any graph property $\mathcal{P}$, assuming $m = \binom{n}{2} p \geq n$.

FIG. 3. *Algorithm* GenPaths.

Our immediate task regarding this phase is to prove Lemma 1.

LEMMA 2. *With high probability, the vertex set* $K = V_i$, $2 \le i \le 5$ *satisfies*

$$|K| = n - o(n).$$

Proof. Let K_0 denote the value of K immediately prior to the execution of the while loop of Split; that is, K_0 is the $\lfloor d/2 \rfloor$ core of G_1'. The final K is the largest subset S of K_0 for which $\delta(G_i'[S]) \ge d/30$, $2 \le i \le 5$.

Let $A_1 = \{v \in V : d_{G_1'}(v) \le 2d/3\}$ and $A_i = \{v \in V_i : d_{G_i'}(v) \le d/27,\ 2 \le i \le 5\}$. Let $A = \bigcup_{i=1}^{5} A_i$. We show that whp

(i) $|A| = o(n)$,

(ii) $v \in V \setminus A$ implies that v has at most 50,000 G-neighbors in A.

It follows from (ii) and the definition of A that for d sufficiently large $K \supseteq V \setminus A$ and then (i) implies the lemma.

We start from the fact that for any $k \ge 1$,

$$\mathbf{Pr}(|A_1| \ge k) \le \binom{n}{k} \mathbf{Pr}(\mathrm{Bin}(n-k, 5p/6) \le 2d/3)^k.$$

Putting $k = k_1 = \lceil n^{61/62} \rceil$ and using (1) with $\epsilon = 1/5$, we obtain

$$\mathbf{Pr}(|A_1| \ge k_1) \le \left(\frac{ne}{k_1}\right)^{k_1} e^{-k_1 d/61} = \left(\frac{ne^{1-d/61}}{k_1}\right)^{k_1} = o(n^{-2}). \tag{3}$$

Also, for any fixed $k \ge 300$,

$$\begin{aligned} &\mathbf{Pr}(\exists v \in V : |N(v, G_{n,p}) \cap A_1| \ge k) \\ &\qquad \le n\binom{n}{k} p^k \mathbf{Pr}(\mathrm{Bin}(n-k-1, 5p/6) \le 2d/3)^k \\ &\qquad \le n d^k e^{-kd/61} = o(n^{-2}). \end{aligned} \tag{4}$$

Similarly, for any $k \geq 1$ and $i \geq 2$,

$$\mathbf{Pr}(|A_i| \geq k) \leq \binom{n}{k} \mathbf{Pr}(\mathrm{Bin}(n-k, p/24) \leq d/27)^k.$$

Now putting $k = k_2 = \lceil n^{3999/4000} \rceil$ and using (1) with $\epsilon = 1/9$, we obtain

$$\mathbf{Pr}(|A_i| \geq k_2) \leq \left(\frac{ne}{k_2}\right)^{k_2} e^{-k_2 d/3900} = \left(\frac{ne^{1-d/3900}}{k_2}\right)^{k_2} = o(n^{-2}), \tag{5}$$

and for any fixed $k \geq 12000$,

$$\begin{aligned} &\mathbf{Pr}(\exists v \in V : |N(v, G_{n,p}) \cap A_i| \geq k) \\ &\qquad \leq n\binom{n}{k} p^k \, \mathbf{Pr}(\mathrm{Bin}(n-k-1, p/24) \leq d/27)^k \\ &\qquad \leq n d^k e^{-kd/3900} = o(n^{-2}). \end{aligned} \tag{6}$$

From (3) and (5) we conclude that whp $A = o(n)$, and from (4) and (6) we conclude that whp no vertex in G has more than 50,000 neighbors in A. □

6. Analysis of Phase 2. In this section we show that if our input graph $G = (V, E)$ is $G_{n,p}$, then whp, after we run SPLIT, we can find in G_1 edge-disjoint paths from a_i to $\tilde{a}_i$ and b_i to $\tilde{b}_i$ for $1 \leq i \leq \kappa$ for *any* choice for $a_1, \ldots, b_\kappa$ consistent with the premises of Theorem 1 and for *almost every* choice for $\tilde{a}_1, \ldots, \tilde{b}_\kappa$.

Let A and Z be as defined in section 4.2. For $v \in V$, let $\alpha(v)$ be the multiplicity of $v \in A$ and $\xi(v)$ be the multiplicity of $v \in Z$. For $S \subseteq V$, let $\alpha(S) = \sum_{v \in S} \alpha(v)$ and $\xi(S) = \sum_{v \in S} \xi(v)$. For sets $S, T \subseteq V$, let $e_{G_1}(S, T)$ denote the number of edges of G_1 with an endpoint in S and the other endpoint in T. It suffices to prove that

$$e_{G_1}(S, \bar{S}) \geq \alpha(S) - \xi(S) \qquad \forall S \subseteq V. \tag{7}$$

We can then apply a theorem of Gale [11] (or see Bondy and Murty [6, Theorem 11.8]) to deduce the existence of the required flow in G_1 for the successful run of Phase 2. (We must of course demonstrate (7) for all A satisfying the premises of Theorem 1 and almost all Z.)

We next prove three lemmas instrumental in proving Lemma 6 below.

LEMMA 3. *With high probability, for any $v \in V_2$,*

$$\xi(v) \leq \beta d_{G_1}(v). \tag{8}$$

Proof. Observe that $\xi(v)$ has the distribution $\mathrm{Bin}(2\kappa, |V_2|^{-1})$. Thus

$$\begin{aligned} \mathbf{Pr}(\xi(v) > \beta d_{G_1}(v)) &\leq \binom{2\kappa}{\beta d/2} |V_2|^{-\beta d/2} \leq \left(\frac{4e\kappa}{\beta d} \cdot \frac{1+o(1)}{n}\right)^{\beta d/2} \\ &\leq \left(\frac{12\alpha \ln d}{\beta \ln n}\right)^{\beta d/2} = o(n^{-3}), \end{aligned}$$

provided that

$$\alpha \leq \beta e^{-6/\beta}/12. \tag{9}$$ □

LEMMA 4. (a) *G_1 has the following property whp: if $S \subseteq V$ and $n_0 = ne^{-d/10} \le |S| \le n/2$ then $e_{G_1}(S, \bar{S}) \ge d|S|/5$.*

(b) *$G_{n,p}$ has the following property whp: if $S \subseteq V$ and $|S| \le n_0$ then $e_G(S,S) \le 2|S|$.*

Proof. (a) Note that G_1' is distributed as $G_{n,5p/6}$ and $G_1' \subseteq G_1$. But

$$\begin{aligned}
&\mathbf{Pr}(G_{n,5p/6} \text{ does not satisfy property (a)}) \\
&\quad \le \sum_{k=n_0}^{n/2} \binom{n}{k} \mathbf{Pr}(\mathrm{Bin}(k(n-k), 5p/6) \le kd/5) \\
&\quad \le \sum_{k=n_0}^{n/2} \binom{n}{k} \mathbf{Pr}\left(\mathrm{Bin}(k(n-k), 5p/6) \le \frac{1}{2}k(n-k)\frac{5}{6}p\right) \\
&\quad \le \sum_{k=n_0}^{n/2} \left(\frac{ne}{k}\right)^k \exp\left(-\frac{5}{48}k(n-k)p\right) = o(n^{-2}).
\end{aligned}$$

(b) Note that property (b) holds trivially for $|S| \le 5$ or $d \ge 10 \ln n$, which implies $n_0 \le 1$. Assume $d \le 10 \ln n$ and $|S| \ge 6$. Thus

$$\begin{aligned}
&\mathbf{Pr}(G_{n,p} \text{ does not satisfy property (b)}) \\
&\quad \le \sum_{k=6}^{n_0} \binom{n}{k} \binom{k(k-1)/2}{2k} p^{2k} \le \sum_{k=6}^{n_0} \left(\frac{ne}{k}\right)^k \left(\frac{k^2 ep}{2k}\right)^{2k} = o(n^{-2}). \qquad \square
\end{aligned}$$

LEMMA 5. *Let $I = \{v \in V : d_{G_1}(v) \le 2\beta d\}$. Then whp no two (distinct) vertices in I are within distance of two or less in G_1.*

Proof. Observe first that $I = \emptyset$ if $d \ge C \ln n$ for C sufficiently large. We can thus assume that $d = O(\log n)$ for the rest of the proof of this lemma. If $v \in I$ then either $d_G(v) \le 2\beta d$ or $d_{G_1}(v) \ne d_G(v)$. The latter cannot be true, since it implies that $v \in V_2$, and then $d_{G_1}(v) \ge \lfloor d/2 \rfloor$. Thus

$$\mathbf{Pr}(I \text{ contains an edge}) \le n^2 p \left(\sum_{k=0}^{2\beta d} \binom{n-2}{k} p^k (1-p)^{n-k}\right)^2.$$

But

$$\begin{aligned}
&\sum_{k=0}^{2\beta d} \binom{n-2}{k} p^k (1-p)^{n-k} \\
&\qquad = O\left(\binom{n}{2\beta d} p^{2\beta d}(1-p)^n\right) = O\left(\left(\frac{e}{2\beta}\right)^{2\beta d} e^{-d}\right) = O(n^{-.99}),
\end{aligned}$$

provided that

$$2\beta(1 - \ln 2\beta) \le 1/100. \tag{10}$$

Thus

$$\mathbf{Pr}(I \text{ contains an edge}) = o(n^{-9/10}).$$

A similar calculation deals with the case of a path of length two joining two vertices of I.

The rather tedious calculation for $G_{n,m}$ is left to the interested reader—see [5] for details of a similar calculation. □

Now inequality (7) will follow easily from Lemma 5.

LEMMA 6. *Define for every* $v \in V$

$$\theta(v) = \min\{d_{G_1}(v), \beta d\}.$$

Then whp for every $S \subseteq V$ *satisfying* $1 \le |S| \le n/2$,

$$e_{G_1}(S, \bar{S}) \ge \theta(S), \tag{11}$$

where $\bar{S} = V \setminus S$ *and* $\theta(S) = \sum_{v \in S} \theta(v)$.

Proof. Since $\beta < 1/5$, Lemma 4(a) implies that for $S \subseteq V$ satisfying $n_0 \le |S| \le n/2$,

$$e_{G_1}(S, \bar{S}) \ge d|S|/5 \ge \theta(S).$$

Suppose next that $|S| \le n_0$. Let

$$I_1 = \{v \in V : d_{G_1}(v) \le 2\beta d\},$$
$$I_2 = \{v \in V : 2\beta d < d_{G_1}(v)\}.$$

Let $S_i = S \cap I_i$ for $i = 1, 2$. Then

$$e_{G_1}(S, \bar{S}) = e_{G_1}(S_1, \bar{S}_1) + e_{G_1}(S_2, \bar{S}_2) - 2e_{G_1}(S_2, S_1).$$

But by Lemma 5 $G_1[S_1]$ has no edges, so that

$$e_{G_1}(S_1, \bar{S}_1) \ge \theta(S_1) \qquad \text{whp},$$

and using Lemma 4(b),

$$e_{G_1}(S_2, \bar{S}_2) \ge (2\beta d - 4)|S_2| \qquad \text{whp},$$

and since Lemma 5 implies that whp no vertex in S_2 is adjacent to two or more vertices in S_1, we have also

$$e_{G_1}(S_2, S_1) \le |S_2| \qquad \text{whp}.$$

It thus follows that whp

$$e_{G_1}(S, \bar{S}) \ge \theta(S_1) + (2\beta d - 6)\,|S_2| \ge \theta(S),$$

where the last inequality holds for sufficiently large n so that $\beta d > 6$. This shows (11). □

We now show that Lemma 5 implies equation (7). First note that condition (ii) in Theorem 1 implies $\alpha(v) \le \theta(v)$ for all $v \in V$.

Second observe that SPLIT guarantees that for $v \in Z$, $\theta(v) = \beta d$, assuming that $\beta < 1/2$, since $Z \subseteq V_2$ and every $v \in V_2$ has degree at least $\lfloor d/2 \rfloor$ in G_1. Thus

$$\mathbf{Pr}(\exists v \in V \text{ such that } \xi(v) > \theta(v) \mid |V_2|)$$
$$\le |V_2| 2 \binom{\kappa}{\beta d} |V_2|^{-\beta d} \le 2n \left(\frac{(1 + o(1))e\alpha m \ln d}{n\beta d \ln n} \right)^{\beta d} = o(n^{-2}),$$

provided that α is sufficiently small. We can thus assume that whp $\xi(v) \le \theta(v)$ for all $v \in V$.

To complete the proof of equation (7), note first that for $|S| \le n/2$, by Lemma 6,

$$e_{G_1}(S, \bar{S}) \ge \theta(S) \ge \alpha(S) \ge \alpha(S) - \xi(S);$$

and for $|S| \ge n/2$,

$$e_{G_1}(S, \bar{S}) = e_{G_1}(\bar{S}, S) \ge \theta(\bar{S}) \ge \xi(\bar{S}) \ge \xi(\bar{S}) - \alpha(\bar{S}) = \alpha(S) - \xi(S).$$

7. Analysis of Phase 3. If a vertex $v \in V_2$ has degree $d_v^{(i)}$ in Γ_i, then the steady state probability of a random walk in Γ_i being at v is

$$\pi_v^{(i)} = \frac{d_v^{(i)}}{\sum_{w \in V_2} d_w^{(i)}}.$$

The main thrust of our analysis is to show that the joint distribution of the $\hat{z}_i$ is close to that of independent samples from $\pi^{(i)}$ for $1 \le i \le 2\kappa$; that is, whp for $v \in V_2$ and $1 \le i \le 2\kappa$,

$$\mathbf{Pr}(\hat{z}_i = v \mid \Gamma_i,\ \hat{z}_j,\ j \ne i) = (1 + o(1))\pi_v^{(i)}. \tag{12}$$

In this case, when we come to join $\hat{a}_i$ to $\hat{b}_i$ then we can argue that $\hat{b}_i$ is (essentially) independent of $\hat{a}_i$. It is difficult to argue this for $\tilde{a}_i, \tilde{b}_i$ since they have been "chosen" as pairs by a flow algorithm. This is why we need Phase 3.

Let $\mathcal{E}_0$ denote the intersection of the events previously shown to hold whp. Let $P^{(i)}$ denote the transition probability matrix of a random walk on Γ_i. Let $\lambda^{(i)}$ be the second largest eigenvalue of $P^{(i)}$. We will prove Theorem 2 later.

THEOREM 7. *For $1 \le i \le \kappa$ let $\mathcal{E}_i$ be the event that*

(a) *the maximum degree $\Delta^{(i)}$ in Γ_i satisfies*

$$\Delta^{(i)} \le C_1 d; \tag{13}$$

and

(b) *the minimum degree $\delta^{(i)}$ in Γ_i satisfies*

$$\delta^{(i)} \ge d/C_2. \tag{14}$$

If $d \le n^{1/10}$ then there exists a constant $\gamma = \gamma(C_1, C_2) > 0$ such that if $\mathcal{F}_i$ denotes the event that

$$\lambda^{(i)} \le \gamma/\sqrt{d} \tag{15}$$

and $\mathcal{U}_i = \mathcal{F}_i \cap \mathcal{E}_i \cap \cdots \cap \mathcal{F}_1 \cap \mathcal{E}_1 \cap \mathcal{E}_0$, then

$$\mathbf{Pr}(\mathcal{F}_i \mid \mathcal{E}_i, \mathcal{U}_{i-1}) = \mathbf{Pr}(\mathcal{F}_i \mid \mathcal{E}_i) = 1 - O(n^{-3}). \tag{16}$$

Proof. See section 10. □

The reader will notice the bound $d \le n^{1/10}$ in the theorem above. If $d > n^{1/10}$ we can randomly split the edge set of G into $r = \lceil 2d/n^{1/10} \rceil$ subsets $E_1, E_2, \ldots, E_r$, each of size roughly $m' = m/r$. We can similarly split the set of κ pairs into r roughly

equal sets K_i. We can then use the graph $G_i = (V, E_i)$ to find paths for the pairs in K_i. Every vertex of every G_i will have degree roughly d/r whp. Hence since

$$\frac{\kappa}{r} \le \alpha m' \frac{\ln n}{\ln d},$$

we can apply Theorem 1 to each G_i, which implies that we succeed whp on each K_i, and thus we will succeed overall[2] with probability $1 - o(1)$. Therefore, without loss of generality, we can assume from now on that $d \le n^{1/10}$.

We now return to the analysis of Phase 3. We start by assuming that

$$\mathcal{E}_i \text{ and } \mathcal{F}_i \text{ hold for every } i. \tag{17}$$

It is well known that the second eigenvalue determines the rate of convergence of a Markov chain to its steady state. An explicit form of this result was obtained by Sinclair and Jerrum [18]: if $P^{(t)}_{\Gamma_i}(u, v)$ denotes the probability that a random walk of length t in Γ_i that starts at u will end at v, then assuming $\mathcal{E}_i$ we have

$$|P^{(t)}_{\Gamma_i}(u,v) - \pi^{(i)}_v| \le \left(\lambda^{(i)}\right)^t \sqrt{\frac{\pi^{(i)}_v}{\pi^{(i)}_u}} \le \left(\lambda^{(i)}\right)^t \sqrt{C_1 C_2} \le \frac{\gamma(C_1, C_2)^t}{d^{t/2}} \sqrt{C_1 C_2}. \tag{18}$$

Since in the algorithm we take $t = \tau = \lceil C_0 \ln n / \ln d \rceil$, this implies (12).

We now proceed to show that the assumption (17) is indeed correct whp. We take $C_1 = 5$ and $C_2 = 60$. Since Γ_i is a subgraph of $G_{n,p}$, inequality (13) holds for all i whp, and since $\Gamma_1 = G_2$ and by construction $\delta(G_2) \ge d/30$, inequality (14) holds for Γ_1; thus $\mathcal{E}_1$ holds. Applying Theorem 7, we see that $\mathcal{F}_1$ holds whp. We continue by showing inductively that for $i \ge 0$,

$$\mathbf{Pr}(\mathcal{U}_i \mid \mathcal{E}_0) = 1 - O(in^{-3}).$$

Since

$$\mathbf{Pr}(\mathcal{U}_{i+1} \mid \mathcal{U}_i) = \frac{\mathbf{Pr}(\mathcal{U}_{i+1})}{\mathbf{Pr}(\mathcal{U}_i)} = \mathbf{Pr}(\mathcal{F}_{i+1} \mid \mathcal{E}_{i+1}, \mathcal{U}_i)\, \mathbf{Pr}(\mathcal{E}_{i+1} \mid \mathcal{U}_i),$$

and

$$\mathbf{Pr}(\mathcal{U}_{i+1} \mid \mathcal{E}_0) = \mathbf{Pr}(\mathcal{U}_{i+1} \mid \mathcal{U}_i)\, \mathbf{Pr}(\mathcal{U}_i \mid \mathcal{E}_0),$$

and given Theorem 7, we only need to prove that

$$\mathbf{Pr}(\mathcal{E}_{i+1} \mid \mathcal{U}_i) = 1 - O(n^{-3}), \tag{19}$$

which reduces to proving that given $\mathcal{U}_i$, the removal of the walks $W_1, \ldots, W_i$ from G_2 does not reduce the degree of any vertex to less than $d/60$.

Now assume $\mathcal{U}_i$. Consider the walk W_i on Γ_i. For $v \in V_2$, let $Z_{i,v}$ denote the number of edges incident with v that are covered by W_i, and let $N_{i,v}$ be the number of visits to v during W_i. Let $q_k = \mathbf{Pr}(N_{i,v} = k \mid \mathcal{U}_i)$ for $k \ge 1$. We claim that independently of $W_1, W_2, \ldots, W_{i-1}$, there exist constants C_3 and C_4 so that

$$q_k \le \frac{C_4 C_3^{k-1} \ln n}{d^{k-1} n \ln d}. \tag{20}$$

[2]This is the reason for our definition of whp. The number r of subgraphs G_i is $O(n^{9/10})$ and we succeed with probability $1 - o(n^{-9/10})$ on each.

To prove (20) for $k = 1$, fix Γ_i, and let $h_v(t)$ be the probability that the walk is at v at time t. Then

$$h_v(0) = 1/|V_2| \le C_1 C_2 \pi_v^{(i)} \tag{21}$$

since the walk starts from z_i which is a vertex chosen uniformly at random in $|V_2|$. (The last inequality follows assuming that $\mathcal{U}_i$ occurs, and thus $\mathcal{E}_i$ occurs.)

We next show inductively that for all $v \in V_2$, we have $h_v(t) \le C_1 C_2 \pi_v^{(i)}$. This follows from stationarity equations and

$$h_v(t+1) = \sum_{w \in N(v:\Gamma_i)} \frac{h_w(t)}{d_w^{(i)}} \le C_1 C_2 \pi_v^{(i)}. \tag{22}$$

Hence since $\tau = \lceil C_0 \ln n / \ln d \rceil$ and $\pi_v^{(i)} \le C_1 C_2 / n$, there is a constant C_4 so that

$$q_1 \le \sum_{t=0}^{\tau} h_v(t) \le \frac{C_4 \ln n}{n \ln d}.$$

We next prove (20) for $k \ge 2$. Fix Γ_i and for vertex v let ρ_v be the probability that a random walk of length τ from v ever returns to v. Since a return to v requires at least two steps, we obtain from equation (18) that there exists a constant C_3 such that

$$\rho_v \le \tau \pi_v^{(i)} + \sqrt{C_1 C_2} \sum_{t \ge 2} \frac{\gamma(C_1, C_2)^t}{d^{t/2}} \le \frac{C_3}{d}. \tag{23}$$

This gives (20) since

$$q_k \le (\rho_v)^{k-1} \sum_{t=1}^{\tau} h_v(t).$$

We now show that (20) implies (19). First (20) implies that for any constant c,

$$\mathbf{E}(e^{2cN_{i,v}} \mid \mathcal{U}_i, W_1, \ldots, W_{i-1}) \le 1 + \sum_{k \ge 1} e^{2ck} \frac{C_4 C_3^{k-1} \ln n}{d^{k-1} n \ln d} \le 1 + \frac{2C_4 e^{2c} \ln n}{n \ln d}.$$

Clearly $Z_{i,v} \le 2N_{i,v}$. Thus for any constant $c > 0$ and any $t > 0$,

$$\begin{aligned}
&\mathbf{Pr}\left(\sum_{j=1}^{i} Z_{j,v} \ge t \;\middle|\; \mathcal{U}_i \right) \\
&\quad \le e^{-ct}\, \mathbf{E}\left(\exp\left(2c \sum_{j=1}^{i} N_{j,v} \right) \;\middle|\; \mathcal{U}_i \right) \\
&\quad \le e^{-ct} \left(1 + \frac{2C_4 e^{2c} \ln n}{n \ln d} \right) \mathbf{E}\left(\exp\left(2c \sum_{j=1}^{i-1} N_{j,v} \right) \;\middle|\; \mathcal{U}_i \right) \\
&\quad \le e^{-ct} \exp\left(\frac{2C_4 e^{2c} \ln n}{n \ln d} \right) \mathbf{E}\left(\exp\left(2c \sum_{j=1}^{i-1} N_{j,v} \right) \;\middle|\; \mathcal{U}_{i-1} \right) \frac{\mathbf{Pr}(\mathcal{U}_{i-1})}{\mathbf{Pr}(\mathcal{U}_i)}
\end{aligned}$$

$$\le \exp\left(-ct + i\frac{2C_4e^{2c}\ln n}{n\ln d}\right)\frac{1}{\mathbf{Pr}(\mathcal{U}_i)}$$
$$\le \exp\left(-ct + 2\kappa\frac{2C_4e^{2c}\ln n}{n\ln d}\right)(1+O(in^{-3}))$$
$$\le 2\exp(-ct + 4\alpha C_4e^{2c}d).$$

Taking $t = d/60$, $c = 240$, and $\alpha \le (4C_4e^{480})^{-1}$, we obtain that

$$\mathbf{Pr}\left(\sum_{j=1}^{i} Z_{j,v} \ge \frac{d}{60} \,\middle|\, \mathcal{U}_i\right) \le 2n^{-3},$$

and since the minimum degree in G_2 is at least $d/30$, this proves (19). (Recall that $C_2 = 60$.)

8. Analysis of Phase 4. We start by discussing the subroutine WALK. Consider a modification of WALK depicted in Figure 4.

```
1.   subroutine WALK1(â_i, Γ̂_i, Γ_j, z_j)
2.   begin
3.   /* By construction, z_j = b̃_i. */
4.   p_v ← P^(τ)_{Γ̂_i}(â_i, v) for v ∈ V(Γ̂_i)
5.   p̂_v ← P^(τ)_{Γ_j}(z_j, v) for v ∈ V(Γ̂_i) (the distribution of b̂_i)
6.   p_min ← min{p_v : v ∈ V(Γ̂_i)}
7.   p̂_max ← max{p̂_v : v ∈ V(Γ̂_i)}
8.   r̄ ← 0
9.   forever do
10.      r̄ ← r̄ + 1
11.      S[â_i] ← S[â_i] + 1
12.      if S[â_i] ≥ d/120 then
13.          L ← L ∪ {i}
14.          exit WALK1
15.      fi
16.      Pick a walk W̄_r̄ of length τ according to the distribution on
             trajectories, conditioned on start point = â_i
17.      Let x̄_r̄ be the terminal vertex of W̄_r̄
18.      With probability p̂_{x̄_r̄} p_min/(p_{x̄_r̄} p̂_max) accept W̄_r̄ and
             exitloop
19.  od
20.  output W̄_1, W̄_2, ..., W̄_r̄
21.  end WALK1
```

FIG. 4. *Algorithm* WALK1.

LEMMA 8. *In* WALK1, $\bar{x}_{\bar{r}}$ *is chosen according to the distribution* $\hat{p}$.

Proof. The probability s that a walk is accepted at the last step in the loop is given by

$$s = \sum_{v \in V(G)} p_v \frac{\hat{p}_v p_{\min}}{p_v \hat{p}_{\max}} = \frac{p_{\min}}{\hat{p}_{\max}}. \tag{24}$$

(Observe that $\hat{p}_{\max} \geq 1/|V(G)| \geq p_{\min}$.) Thus if S_0 is the value of $S[\hat{a}_i]$ at the start of WALK1 and $k_0 = d/120 - S_0$, then

$$\mathbf{Pr}(\bar{x}_{\bar{r}} = v \mid \text{step 14 is not executed}) = \frac{1}{1-(1-s)^{k_0}} \sum_{k=0}^{k_0-1} (1-s)^k p_v \frac{\hat{p}_v p_{\min}}{p_v \hat{p}_{\max}} = \hat{p}_v. \tag{25}$$

Also, $\mathbf{Pr}$(step 14 is executed) is equal to $(1-s)^{k_0}$ in both procedures. □

Hence $\bar{W}_{\bar{r}}$ is a random walk to a vertex chosen with distribution $\hat{p}$. Furthermore, since the minimum degree of any graph in which a walk is constructed is at least $d/60$ and the maximum degree is at most $5d$, we find

$$s \geq \frac{1}{300} \stackrel{\text{def}}{=} \sigma \tag{26}$$

and therefore the expected number of generated walks is constant.

There is a minor problem in that we want to choose the endpoints before we do the walks. This leads to the algorithm WALK described before. We now turn to its analysis.

LEMMA 9. *Suppose that* $\hat{b}_i$ *is chosen from* $V(G)$ *with distribution* $\hat{p}$. *Then the set of walks* $\bar{W}_1, \ldots, \bar{W}_{\bar{r}}$ *in* WALK1$(\hat{a}_i, G, \Gamma_j, z_j)$ *and the set of walks* $\hat{W}_1, \ldots, \hat{W}_r$ *in* WALK$(\hat{a}_i, \hat{b}_i, G, \Gamma_j, z_j)$ *have the same distribution.*

Proof. Note first from the proof of Lemma 8 that $\bar{r}$ and r have the same truncated geometric distribution. Also we have from Lemma 8 that $\bar{x}_{\bar{r}}$ and $x_r = \hat{b}_i$ have the same distribution. Consider next that for $v_1, v_2, \ldots, v_i \in V(G)$,

$$\begin{aligned}
&\mathbf{Pr}(\bar{x}_1 = v_1, \ldots, \bar{x}_i = v_i \text{ and } \bar{r} > i) \\
&\qquad = \prod_{j=1}^{i} \left(\left(1 - \frac{\hat{p}_{v_j} p_{\min}}{p_{v_j} \hat{p}_{\max}} \right) p_{v_j} \right) = \prod_{j=1}^{i} \left(p_{v_j} - \frac{\hat{p}_{v_j} p_{\min}}{\hat{p}_{\max}} \right) \\
&\qquad = (1-s)^i \prod_{j=1}^{i} \left(\frac{p_{v_j} - \hat{p}_{v_j} p_{\min}/\hat{p}_{\max}}{1-s} \right) \\
&\qquad = \mathbf{Pr}(x_1 = v_1, \ldots, x_i = v_i \text{ and } r > i).
\end{aligned}$$

Thus $\bar{x}_1, \bar{x}_2, \ldots, \bar{x}_{\bar{r}}$ and $x_1, x_2, \ldots, x_r$ have the same distribution. Finally, the lemma follows from the fact that the distribution of $\bar{W}_j$ conditional on $\bar{x}_j = v$ is clearly equal to that of $\hat{W}_j$ conditional on $x_j = v$. □

The net effect of GENPATHS is to run WALK κ times. In light of Theorem 7 we only need show that the minimum degree in G_3 is not made too small by the deletion of paths generated by WALK. This requires a slightly more complicated analysis than for Phase 3. The main problem in extending the analysis of Phase 3 is that we cannot argue now that (21) holds independently of previous walks. Each execution of WALK

(or, equivalently, WALK1) involves a set of walks with the same starting point. The initial vertex of each set is chosen nearly randomly, but it is the same for each walk.

For the purpose of the analysis we relate to WALK1. Fix $v \in V_3$ and $1 \le i \le \kappa$ and let $\bar{W}_1, \bar{W}_2, \ldots, \bar{W}_r$ denote the walks made while trying to connect $\hat{a}_i$ to $\hat{b}_i$. We shall refer to these walks as the ith *bundle*, B_i. We shall follow closely the line of proof used in the analysis of Phase 3, with all the events now referring to $\hat{\Gamma}_i$ rather than Γ_i. As before, the proof reduces to showing that given $\mathcal{U}_i$, the removal of the bundles $B_1, \ldots, B_i$ from G_3 does not reduce the degree of any vertex in G_3 to less than $d/60$.

The stationary distribution on $\hat{\Gamma}_i$ is denoted $\hat{\pi}^i$.

LEMMA 10. *Assuming $\mathcal{U}_i$, the probability that a fixed vertex v is visited by bundle i is less than*

$$\frac{C_5 \ln n}{n \ln d}.$$

Proof. Assume for a moment that the probability of a walk being accepted is decreased to exactly σ (see (26)). This can only increase the number of visits to v, but the number of walks is now independent of the start point. For every walk in the bundle we can show via (20) and (21) applied to $\hat{\Gamma}_i$ that the expected number of visits to v is less than $C_1 C_2 \tau \hat{\pi}_v^{(i)}$; thus the expected total number of visits is less than

$$\frac{C_1 C_2}{\sigma} \tau \hat{\pi}_v^{(i)} = \frac{C_5 \ln n}{n \ln d}. \qquad \square$$

LEMMA 11. *Assume $\mathcal{U}_i$ and consider a random walk of length τ in $\hat{\Gamma}_i$ starting from vertex v. Then*

(a) *the probability that the walk returns k times to v is less than $(C_3/d)^k$;*

(b) *for any vertex $u \ne v$, the probability that u is visited k times is less than $(C_3/d)^k$.*

Proof. As before let ρ_v be the probability that a random walk of length τ from v ever returns to v. From (23) applied to $\hat{\Gamma}_i$,

$$\rho_v \le \frac{C_3}{d}.$$

For part (a) notice that the probability of k returns to v is bounded by

$$\sum_{t=2}^{\tau} \left(\hat{\pi}_v^{(i)} + \frac{\gamma (C_1, C_2)^t}{d^{t/2}} \right) \rho_v^{k-1} \le \left(\frac{C_3}{d} \right)^k.$$

For part (b) the probability of k visits to u is bounded by

$$\frac{C_2}{d} \rho_u^{k-1} + \sum_{t=2}^{\tau} \left(\hat{\pi}_u^{(i)} + \frac{\gamma (C_1, C_2)^t}{d^{t/2}} \right) \rho_u^{k-1} \le \left(\frac{C_3}{d} \right)^k.$$

(The first term deals with the case when u is a neighbor of v.) $\square$

We are ready now to evaluate the number of visits to a fixed vertex v. For this goal we will distinguish between *free* visits and *start* visits. If $v = \hat{a}_i$, then v undergoes $|B_i|$ visits as the start point of all the walks in the bundle. All other visits to v are free visits. In particular a return visit to $\hat{a}_i$ is a free visit.

Analogously to the analysis of Phase 3, let $N_{i,v}$ be the number of *free* visits to v during B_i and let $q_k = \mathbf{Pr}(N_{i,v} = k \mid \mathcal{U}_i)$ for $k \geq 1$. We claim that independently of $B_1, B_2, \ldots, B_{i-1}$, there exists a constant C_6 so that

$$q_k \leq \frac{C_5 C_6^{k-1} \ln n}{d^{k-1} n \ln d}. \tag{27}$$

To simplify notation view the r walks in bundle B_i as a single walk X_t that restarts from $\hat{a}_i$ every τ steps. Let $h_v(t)$ be the probability that this walk is at v at time t. Then

$$q_k \leq \sum_{1 \leq t \leq \tau} h_v(t)\, \mathbf{Pr}(k-1 \text{ free visits to } v \text{ after } t \mid \hat{a}_i, X_t = v).$$

Now given r, the number of walks in bundle B_i, the $k-1$ free visits to v can be distributed among the r walks in at most $\binom{k+r-2}{r-1}$ ways. So in view of Lemma 11 we have

$$\mathbf{Pr}(k-1 \text{ free visits to } v \text{ after } t \mid \hat{a}_i, X_t = v, r) \leq \binom{k+r-2}{r-1} \left(\frac{C_3}{d}\right)^{k-1}.$$

From Lemma 10

$$\sum_{1 \leq t \leq \tau} h_v(t) \leq \frac{C_5 \ln n}{n \ln d},$$

and using equation (26) we finally obtain that

$$q_k \leq \frac{C_5 \ln n}{n \ln d} \sum_{1 \leq r \leq \infty} \binom{k+r-2}{r-1} \left(\frac{C_3}{d}\right)^{k-1} \sigma (1-\sigma)^{r-1} = \frac{C_5 \ln n}{n \ln d} \left(\frac{C_3}{\sigma d}\right)^{k-1},$$

which proves (27). From here we can proceed exactly as in the analysis of Phase 3 to show that the decrease in degree due to free visits is no more than $d/120$ whp, provided that α is small enough. By construction the reduction in degree due to start visits is at most $d/120$, so that the total reduction in degree during Phase 4 is at most $d/60$ as required. It remains to show that not too many pairs are deferred to Phase 5.

9. Analysis of Phase 5. We start by bounding the number of pairs not connected in Phase 4. Recall that a pair $\hat{a}_i, \hat{b}_i$ is not connected iff the total number of walks started from $\hat{a}_i$ would have exceeded $d/120$.

Fix $v \in V_3$. From equation (22) and the discussion that follows it, we have that for every i

$$\mathbf{Pr}(\hat{a}_i = v) \leq \frac{C_1^2 C_2^2}{n} \stackrel{\text{def}}{=} p.$$

Thus in view of (26) the number of starts from v is dominated by a random variable with the following probability generating function:

$$\sum_i \binom{\kappa}{i} p^i (1-p)^i \frac{\sigma x}{1 - x(1-\sigma)} = \left(\frac{\sigma p x}{1 - x(1-\sigma)} + 1 - p\right)^{\kappa}.$$

In general, given a probability generating function $f(x)$ for the random variable $X \geq 0$, and an integer $a \geq 1$ we have

$$\mathbf{Pr}(X \geq a) \leq \frac{f(x)}{x^a}, \qquad \rho > x \geq 1,$$

where ρ is the radius of convergence of f. So let X be the random variable that counts starts from v. Choosing

$$x = \frac{2+\sigma}{2+\sigma-\sigma^2} = 1 + \frac{\sigma^2}{2+\sigma-\sigma^2},$$

we obtain that

$$\begin{aligned}\mathbf{Pr}\left(X \geq \frac{d}{120}\right) &\leq \left(1+\frac{\sigma p}{2}\right)^{\kappa}\left(1+\frac{\sigma^2}{2+\sigma-\sigma^2}\right)^{-d/120} \\ &\leq \exp\left(\frac{\sigma p}{2}\kappa - \frac{\sigma^2}{3}\frac{d}{120}\right) \\ &= \exp\left(\frac{C_1^2 C_2^2 \sigma\alpha n d \ln d}{2n\ln n} - \frac{\sigma^2 d}{360}\right) \leq \exp\left(-\frac{\sigma^2 d}{400}\right)\end{aligned}$$

for α small enough.

At the end of Phase 4 we will be left with a set L of indices of pairs $(\hat{a}_i, \hat{b}_i)$ for which Phase 4 failed to find a path. The discussion above shows that $|L|$ is dominated in distribution by $\mathrm{Bin}(n, \exp(-\sigma^2 d/500))$, so whp $L = \emptyset$ if $d \geq 1000\sigma^{-2}\log n$ and otherwise $|L| \leq n^{1-\epsilon}$ for a *constant* $\epsilon > 0$. So assume that $d = O(\log n)$.

We join the pairs in L using a modification of the algorithm of [8]. That algorithm starts by splitting the edges of an expander graph to form two disjoint expanding subgraphs. This is unnecessary here as G_4 and G_5 will suffice for the two expander graphs; namely, G_4 can be used for the flow phase of [8] and then G_5 can be used for the random walks phase of [8]. The algorithm is capable of joining $\Omega(n/(\ln n)^c)$ pairs for some constant $c > 0$, provided the graph in the flow phase has edge expansion at least 1 and the second eigenvalue of the graph used in the random walks phase has a second eigenvalue bounded away from 1. Here whp we have fewer than $n^{1-\epsilon}$ pairs, the graph G_4 has an edge expansion $\Omega(\ln n)$, and the graph G_5 has a second eigenvalue of size $O(1/\sqrt{\ln n})$. So from this point of view there is room to spare.

On the other hand [8] only deals with the case where the required path endpoints are distinct. We will replace the flow phase of [8] with the following procedure. Suppose $v \in V_3$ is required to be an endpoint $\lambda(v)$ times. We have

$$\sum_{v \in V_3} \lambda(v) = 2|L| \leq 2n^{1-\epsilon}.$$

Furthermore, $\lambda(v)$ is dominated in distribution by $\mathrm{Bin}(\kappa, (1+o(1))n)$; hence $\mathbf{E}(\lambda(v)) = O(d\log d/\log n) = O(\log\log n)$ and whp

$$\lambda(v) \leq C_7 \log n/\log\log n \qquad \text{for all } v \in V_3.$$

We start Phase 5 by constructing for each $v \in V$ and $1 \leq i \leq \lambda(v)$ a set of $2/\epsilon$ random walks of length τ with start point v. We delete the edges of previous walks before beginning the next walk. The analysis of Phase 3 shows that we will succeed

in constructing these walks whp, since in Phase 3 the average number of walks per start point was $O(d \log d/logn)$ and the maximum was βd while the corresponding numbers are now $o(1)$ and $O(d/\log d)$.

The probability that k such walks all end at the endpoints already visited is bounded by

$$\binom{4\epsilon^{-1}|L|}{k} O(n^{-k}) = O(n^{-\epsilon k}),$$

so whp for each v and i at least one of the $2/\epsilon$ random walks ends up at a previously unvisited point. Thus we can associate with each $v \in V_3$ a set of $\lambda(v)$ endpoints of walks started from v, and all these sets are disjoint. From here we can continue with the second phase of [8] on G_5.

It only remains to prove Theorem 7.

10. Proof of Theorem 7. Now it is not too difficult to verify that the second eigenvalue of the walk on Γ_1 is not too large. There is however a technical problem in the fact that we are deleting the edges of a random graph by a process that conditions the distribution. We overcome this by considering graphs with a fixed degree sequence and consequently the configuration model of multigraphs. (We need now only consider $G_{n,m}$. To handle $G_{n,p}$ we simply condition on the number of edges being close to the expected number.)

10.1. Configuration model. The graphs G_i, $2 \le i \le 5$ will be random given their degree sequences. This is because the executions of lines 5 and 8 of SPLIT (Figure 1) do not condition the remaining graphs, once we are given their degree sequences. This idea has been used several times previously; see, for example, Bollobàs, Fenner, and Frieze [5].

The simplest model for graphs with a fixed degree sequence is the *configuration model* of Bollobás [3], which is a probabilistic interpretation of the counting formula of Bender and Canfield [2]. Let $\mathbf{d} = \{d_1, d_2, \ldots, d_\nu\}$ denote a degree sequence, $D_i = \{1, \ldots, d_i\} \times \{i\}$ for $1 \le i \le \nu$ and $D = \cup_{i=1}^{\nu} D_i$. Let $\Omega = \Omega(D)$ be the set of partitions of D into pairs. If $F \in \Omega$ then the multigraph $M = M(F)$ is defined as follows: $V(M) = [\nu]$ and there is an edge $\{i, j\}$ for every pair in F of the form $\{(x, i), (y, j)\}$ (for some x and y). It is unfortunate that we have to introduce multigraphs, but the salient properties of M are as follows in Lemma 10.

LEMMA 12. (a) *If M is simple, then it is equally likely to be any simple graph with degree sequence* $\mathbf{d}$.

(b) $\mathbf{Pr}(M \text{ is simple}) = \exp\{-O(\mu^2/\nu^2)\}$ *where $\mu = |D|/2$ is the number of edges in M; hence $2\mu/\nu$ is the average degree of M.*

We consider the probability space of multigraphs $M(F, \phi)$ where F is chosen randomly from Ω. We are interested in the case where

$$\delta = \min \mathbf{d} \ge d/C_2,$$
$$\Delta = \max \mathbf{d} \le C_1 d.$$

It will be useful to think of F as being constructed sequentially by the algorithm CONSTRUCT depicted in Figure 5.

It is important to observe that for any $t > 0$, $F \setminus F_t$ is a random member of $\Omega(R_t)$.

An important consequence of the above observation is that if we start with $M = M(F)$, then the multigraph obtained by removing from M the edges of a random

```
1.   algorithm CONSTRUCT
2.   begin
3.       F_0 ← ∅; R_0 ← W
4.       for t = 1 to m* do
5.           Choose u_t ∈ R_{t−1} arbitrarily
6.           Choose v_t randomly from R_{t−1} \ {u_t}
7.           F_t ← F_{t−1} ∪ {{u_t, v_t}}; R_t ← R_{t−1} \ {u_t, v_t}
8.       od
9.   output F
10.  end CONSTRUCT
```

FIG. 5. *Algorithm* CONSTRUCT.

walk W remains random. Indeed, we may imagine CONSTRUCT as performed in parallel with our walk W. Suppose our walk makes a transition from a vertex x, and the current value of R_t in CONSTRUCT is R. The transition from x is equivalent to choosing a random member $u = u_t$ of D_x. If $u \in R$, then we perform one step of CONSTRUCT and pair u with a point $v = v_t \in R \setminus \{u\}$. If $v \in D_y$ for some y, then the walk makes a transition from x to y. If $u \notin R$ then v is the point already paired with u. Thus since $F \setminus F_t$ is random, we see that removing from M the edges of a random walk results in a multigraph from a *random* configuration.

10.2. Random walks on configurations. We only discuss G_3 since the situation for G_2 is identical. Suppose G_3 has degree sequence $\mathbf{d}' = (d'_1, d'_2, \dots, d'_\nu)$, where $\nu = n(1-o(1))$. As observed, G_3 is random given its degree sequence. In our analysis, we want to consider G_3 as of the form $M(F)$ conditional on it being simple.

Each of the κ iterations deletes some pairs from F. Suppose $F^{(i)}$ denotes the remaining pairs at the start of iteration i and $D^{(i)} = \bigcup F^{(i)}$. If we ignore the condition that $M(F)$ is simple, then $F^{(i)}$ is a random member of $\Omega(D^{(i)})$. This requires a little justification. Our algorithm produces paths by choosing $\hat{a}_1, \hat{a}_2, \dots, \hat{a}_\kappa$ and $\hat{b}_1, \hat{b}_2, \dots, \hat{b}_\kappa$ at random and by applying WALK. As observed in Lemma 9, this is equivalent to just applying WALK1 a number of times. By our arguments of the previous section, deleting edges in the walks produced by WALK1 leaves a random configuration.

Thus we may imagine that initially we have a multigraph M_1. Then for $i \geq 2$ we apply GENPATHS to M_{i-1} and eventually produce M_i in which case M_i is a multigraph from a random configuration (when its degree sequence is given).

All that remains now is to show that (15) holds with suitably high probability for M_i, $i \geq 1$, conditioned on it being simple.

10.3. Eigenvalues. We will prove (15) by imitating the proof of Kahn and Szemerédi [10].

Let $\mathbf{d} = d_1, d_2, \dots, d_n$ be a degree sequence with maximum $\Delta = o(n^{1/2})$ and minimum $\delta > 0$ such that $\Delta/\delta < \theta$ for some constant θ. (Strictly speaking we should be concerned with $\mathbf{d} = d_1, d_2, \dots, d_\nu$, but $\nu = n - o(n)$ whp and n is "friendlier.") Let $M = M(F)$ be the multigraph on $[n]$ formed from a random configuration $F \in \Omega(\mathbf{d})$. Use e_{uv} to denote the number of edges joining vertices u and v. Consider the Markov

chain of a random walk on M. The transition matrix of the chain is

$$P_{uv} = \frac{e_{uv}}{d_u}.$$

Note that since the Markov chain is reversible, all eigenvalues of P are real and the largest eigenvalue of P equals 1. The eigenvalues are denoted by

$$1 = \lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_n.$$

We need to show that conditional on M being simple with probability $1 - O(n^{-3})$,

$$\rho^* = \max\{|\lambda_2|, |\lambda_n|\} \leq \gamma/\sqrt{d}, \tag{28}$$

where $d = \sum_{i=1}^{n} d_i/n$ and $\gamma = \gamma(\theta)$.

LEMMA 13. *Let A be the matrix*

$$A_{uv} = \frac{e_{uv}}{d_u d_v},$$

and let

$$\rho_1 = \max\left\{|y^t A y| : \sum_u y_u = 0, \sum_u y_u^2 = 1\right\}.$$

Then $\rho^* \leq \Delta\rho_1$.

Proof. Let Q be the matrix

$$Q_{uv} = \frac{e_{uv}}{d_u^{1/2} d_v^{1/2}}.$$

Note that Q and P are similar; that is, $Q = DPD^{-1}$ where D is a diagonal matrix with diagonal elements $d_1^{1/2}, \ldots, d_n^{1/2}$ and so (λ, v) is an eigenvalue–eigenvector pair of P iff (λ, Dv) is an eigenvalue–eigenvector pair of Q. Since the largest eigenvalue of Q is 1 with eigenvector $(d_1^{1/2}, d_2^{1/2}, \ldots, d_n^{1/2})$, the Rayleigh quotient principle gives that

$$\rho^* = \max\left\{\frac{|\sum_{u,v} x_u Q_{uv} x_v|}{\sum_u x_u^2} \;\middle|\; \sum_u x_u d_u^{1/2} = 0\right\}.$$

Since

$$\sum_{u,v} x_u Q_{uv} x_v = \sum_{u,v} x_u d_u^{1/2} A_{uv} x_v d_v^{1/2}$$

and

$$\sum_u x_u^2 \geq \frac{1}{\Delta} \sum_u x_u^2 d_u,$$

we have, on putting $y_u = x_u d_u^{1/2}$,

$$\rho^* \leq \Delta \max\left\{|y^t A y| \;\middle|\; \sum_u y_u = 0, \sum_u y_u^2 = 1\right\} = \Delta\rho_1. \qquad \square$$

Following Kahn and Szemerédi, choose a real $\epsilon \in (0,1)$ (eventually ϵ will be fixed in equation (38)), and let

$$T = \left\{ x \in \left(\frac{\epsilon}{n^{1/2}}\boldsymbol{Z}\right)^n \;\middle|\; \sum_u x_u = 0, \sum_u x_u^2 \le 1 \right\},$$

where $\boldsymbol{Z}$ denotes the set of integers. Then by considering the total volume of cubes of side $\epsilon/\sqrt{n}$ which have their centers in T, we see that

$$\begin{aligned} |T| &\le \left(\frac{n^{1/2}}{\epsilon}\right)^n \boldsymbol{V}\mathrm{ol}\left(\left\{ x \in \boldsymbol{R}^n \;\middle|\; \sum_u x_u^2 \le \left(1+\frac{\epsilon}{2}\right) \right\} \right) \\ &= \left(\frac{(2+\epsilon)n^{1/2}}{2\epsilon}\right)^n \frac{\pi^{n/2}}{\Gamma(n/2+1)} \le \left(\frac{(2+\epsilon)n^{1/2}}{2\epsilon}\right)^n \frac{\pi^{n/2}e^{n/2}}{(n/2)^{n/2}\sqrt{\pi n}} \\ &\le \left(\frac{(2+\epsilon)\sqrt{2\pi e}}{2\epsilon}\right)^n. \end{aligned} \tag{29}$$

LEMMA 14. *Let ρ_1 be defined as in Lemma 13. We claim that*

$$\rho_1 \le (1-\epsilon)^{-2}\rho,$$

where

$$\rho = \max\{ |x^t A y| \mid x, y \in T \}.$$

Proof. Let $S = \{ x \in \boldsymbol{R}^n \mid \sum_u x_u = 0, \sum_u x_u^2 \le 1 \}$. We first show that for every $x \in S$ there is a $y \in T$ such that $x - y \in \epsilon S$ and $\|x - y\| \le \epsilon$. Suppose that for $i = 1, 2, \ldots, n$,

$$x_i = \epsilon m_i n^{-1/2} + f_i, \qquad m_i \in \boldsymbol{Z}, \qquad f_i \in [0, \epsilon n^{-1/2}).$$

Note that since $\sum_u x_u = 0$, we have $\sum_i f_i = \epsilon f n^{-1/2}$, where f is a nonnegative integer less than n. Rearrange subscripts so that $m_i \le m_j$ whenever $i \le j$. Define a vector $y \in \boldsymbol{R}^n$ so that

$$y_u = \begin{cases} \epsilon(m_u+1)n^{-1/2} & \text{if } u \le f, \\ \epsilon m_u n^{-1/2} & \text{if } u > f. \end{cases}$$

Then we have

(a) $\displaystyle\sum_u y_u = \sum_u x_u = 0,$

(b) $\displaystyle\sum_u y_u^2 \le \sum_u x_u^2 \le 1,$

(c) $\|x - y\| \le \epsilon$ (since $|x_u - y_u| \le \epsilon n^{-1/2}$).

Thus y is in T and has the required property. It follows that one can apply the above construction to obtain that for any $x \in S$ there are $x^{(0)}, x^{(1)}, \ldots$ in T such that

$$x = \sum_i \epsilon^i x^{(i)},$$

and therefore for any $x \in S$ there are $x^{(i)} \in T$ such that

$$x^t Ax = \sum_{i=0}^{\infty}\sum_{j=0}^{\infty}\left(x^{(i)}\right)^t Ax^{(j)}\epsilon^{i+j} \le (1-\epsilon)^{-2}\max\{|y^tAz| : y,z \in T\}.$$

The lemma now follows. □

Now write

$$\rho = \max\{|x^tMy| : x, y \in T\}.$$

Our aim is to find a probabilistic upper bound for ρ of order $O(\Delta^{-3/2})$ that will verify (28). This is done by considering the random variables $X = X(x,y) = \sum_{u,v} x_u A_{uv} y_v$, where $x, y \in T$. Note that for any two distinct points in the configuration the probability that the two points are joined by an edge is $1/(2m-1)$, where $2m = \sum_{i=1}^{n} d_i$. Thus for $u \neq v$,

$$\mathbf{E}[e_{uv}] = \frac{d_u d_v}{2m-1}$$

and

$$\mathbf{E}[e_{uu}] = \frac{d_u(d_u-1)}{2(2m-1)}.$$

Fix $x, y \in T$ and define

$$B = \left\{(u,v) \;\middle|\; 0 < |x_u y_v| < \Delta^{1/2}/n\right\}. \tag{30}$$

Let

$$X' = \sum_{(u,v)\in B} x_u A_{uv} y_v \quad \text{and} \quad X'' = \sum_{(u,v)\notin B} x_u A_{uv} y_v,$$

so that $X = X' + X''$.

10.4. Estimating X'. Note that

$$\mathbf{E}[X'] = \sum_{(u,v)\in B}\frac{x_u y_v}{2m-1} + \sum_{(u,u)\in B}\frac{x_u y_u (d_u-1)}{2(2m-1)d_u}.$$

Write S_1 and S_2 for the first and second sums in the above equation. Then

$$|S_2| \le \sum_{(u,u)\in B}\frac{|x_u y_u|(d_u-1)}{2(2m-1)d_u} \le \frac{\Delta^{1/2}}{4m}. \tag{31}$$

For S_1 we follow Lemma 2.4 in [10]. Since $\sum_u x_u = \sum_v y_v = 0$ we have $\sum_{u,v} x_u y_v = 0$ and so

$$\left|\sum_{(u,v)\in B} x_u y_v\right| = \left|\sum_{(u,v)\notin B} x_u y_v\right|.$$

Now

$$\left|\sum_{(u,v)\notin B} x_u y_v\right| \le \sum_{|x_u y_v| \ge \Delta^{1/2}/n}\frac{x_u^2 y_v^2}{|x_u y_v|} \le \frac{n}{\Delta^{1/2}}\sum_{u,v} x_u^2 y_v^2 \le \frac{n}{\Delta^{1/2}}.$$

Hence

$$|\,\mathbf{E}[X']| \le \frac{n}{(2m-1)\Delta^{1/2}} + \frac{\Delta^{1/2}}{4m} = (1+o(1))\frac{n}{2m\Delta^{1/2}}. \tag{32}$$

We next show that X' is concentrated around its mean. For this we need some more notation. Recall that a configuration is a perfect matching F of the set $W = \cup_{i=1}^{n}\{i\}\times[d_i]$. We call the elements in W points and assume that the points in W are ordered lexicographically. For $\alpha \in W$, let $v(\alpha)$ denote the first component of α, and for a pair $e = \{\alpha, \beta\}$ in a configuration with $\alpha < \beta$, we write $t(e)$ for $v(\alpha)$ and $h(e)$ for $v(\beta)$. For real x, define

$$\chi(x) = \begin{cases} x & \text{if } |x| < \Delta^{1/2}/n, \\ 0 & \text{otherwise.} \end{cases}$$

Then

$$X' = \sum_{e\in F}\frac{\chi(x_{t(e)}y_{h(e)})}{d_{t(e)}d_{h(e)}} + \sum_{e\in F}\frac{\chi(x_{h(e)}y_{t(e)})}{d_{t(e)}d_{h(e)}} = X'_a + X'_b, \quad \text{say.} \tag{33}$$

We next write $F = F_1 \cup F_2 \cup F_3$ where

$$\begin{aligned} F_1 &= \{e \in F : |x_{t(e)}| > n^{-1/2}/\epsilon\}, \\ F_2 &= \{e \in F : |y_{h(e)}| > n^{-1/2}/\epsilon, |x_{t(e)}| \le n^{-1/2}/\epsilon\}, \\ F_3 &= \{e \in F : |y_{h(e)}| \le n^{-1/2}/\epsilon, |x_{t(e)}| \le n^{-1/2}/\epsilon\}. \end{aligned}$$

Then let

$$X_i = \sum_{e\in F_i}\frac{\chi(x_{t(e)}y_{h(e)})}{d_{t(e)}d_{h(e)}} \qquad \text{for } i = 1,2,3,$$

so that

$$X'_a = X_1 + X_2 + X_3.$$

Recall that $\Delta/\delta < \theta$, a constant. We claim Lemma 15.

LEMMA 15. *There are constants $B_i = B_i(\theta) > 0$ for $i = 1,2,3$ such that for any $t > 0$,*

$$\mathbf{Pr}(|X_1 - \mathbf{E}[X_1]| \ge t\Delta^{-3/2}) \le 2\exp(-tn + B_1 n), \tag{34}$$

$$\mathbf{Pr}(|X_2 - \mathbf{E}[X_2]| \ge t\Delta^{-3/2}) \le 2\exp(-tn + B_2 n), \tag{35}$$

$$\mathbf{Pr}(|X_3 - \mathbf{E}[X_3]| \ge t\Delta^{-3/2}) \le 2\exp(-tn + B_3 n). \tag{36}$$

Proof. We first prove (34). Assume without loss of generality that $|x_i| \ge |x_{i+1}|$ for all i and let the pairs $\{\alpha_i, \beta_i\}$ for $1 \le i \le m$ that compose F be ordered such that $\alpha_i < \beta_i$ and $\alpha_i < \alpha_{i+1}$. Recall that the order among points is lexicographic; thus $v(\alpha_i) \le v(\alpha_{i+1})$ and $|x_{v(\alpha_i)}| \ge |x_{v(\alpha_{i+1})}|$.

Let $\equiv_k$ be the equivalence relation on Ω such that $F \equiv_k F'$ if and only if the sequences of the first k pairs in F and F' are identical. Write Ω_k for the set of equivalence classes, and $\mathcal{F}_k$ for the corresponding σ-algebra. Define $Y_k = \mathbf{E}[X_1|\mathcal{F}_k]$; that is, Y_k is a function from Ω to $\boldsymbol{R}$ so that $Y_k(F)$ equals the expected value of

X_1 conditional on the first k pairs being exactly equal to the first k pairs in F. Now $Y_0, Y_1, \ldots, Y_m$ is a Doob martingale with $Y_0 = \mathbf{E}[X_1]$ and $Y_m = X_1$. Define $Z_k = Y_k - Y_{k-1}$. Note that as in Lemma 2.7 in [10], if there is $f_k(\zeta)$ such that $Z'_k = \mathbf{E}[\exp(\zeta^2 Z_k^2)|\mathcal{F}_{k-1}] \le f_k(\zeta)$, then for all t and $\zeta > 0$,

$$\mathbf{Pr}(|X_1 - \mathbf{E}[X_1]| \ge t) \le 2e^{-\zeta t} \prod_{k=1}^{m} f_k(\zeta). \tag{37}$$

We next write down the distribution of Z_k. Define

$$\hat{\chi}(x,y) = \begin{cases} xy & \text{if } |xy| < \Delta^{1/2}/n \text{ and } |x| > n^{-1/2}/\epsilon, \\ 0 & \text{otherwise.} \end{cases}$$

For a pair $e = \{\alpha, \beta\}$ in F with $\alpha < \beta$, write

$$q(e) = \frac{\hat{\chi}(x_{v(\alpha)}, y_{v(\beta)})}{d_{v(\alpha)} d_{v(\beta)}}.$$

Then

$$X_1(F) = \sum_{e \in F} q(e).$$

Note that we can express

$$Z_k(F) = \frac{2^{m-k}(m-k)!}{(2m-2k)!} \left\{ \sum_{F' \equiv_k F} X_1(F') - \frac{1}{2m-2k+1} \sum_{F'' \equiv_{k-1} F} X_1(F'') \right\}.$$

Let $\{\alpha, \beta\}$ be the kth pair in F with $\alpha < \beta$ and let J be the set of points contained in the first k pairs in F. For $\eta \notin J - \{\beta\}$ and for $F' \equiv_k F$, we define F'_η as follows. Suppose that η is matched with γ in F'. Write $e = \{\alpha, \beta\}$, $f = \{\eta, \gamma\}$, $e' = \{\alpha, \eta\}$, $f' = \{\gamma, \beta\}$. Then F'_η is defined to be $(F' - \{e, f\}) \cup \{e', f'\}$, giving $F'_\eta \equiv_{k-1} F$ and $F'_\beta = F'$. Note also that $\{\{F'_\eta \mid \eta \notin J - \{\beta\}\} \mid F' \equiv_k F\}$ is a partition of $\{F'' \mid F'' \equiv_{k-1} F\}$. Thus

$$Z_k(F) = \frac{2^{m-k}(m-k)!}{(2m-2k)!} \frac{1}{2m-2k+1} \sum_{F' \equiv_k F} \sum_{\eta \notin J} \left(X_1(F') - X_1(F'_\eta) \right).$$

Also, since

$$X_1(F') - X_1(F'_\eta) = q(e) + q(f) - q(e') - q(f'),$$

we have

$$Z_k(F) = \sum_{\eta \notin J} \sum_{\gamma \notin J, \gamma \ne \eta} \frac{q(\{\alpha,\beta\}) + q(\{\gamma,\eta\}) - q(\{\alpha,\eta\}) - q(\{\gamma,\beta\})}{(2m-2k+1)(2m-2k-1)}.$$

Note that since $\sum x_u^2 \le 1$, there at most $n\epsilon^2$ indices u such that $|x_u| > n^{-1/2}/\epsilon$. Thus $Z_k = 0$ if $k \ge \epsilon^2 \Delta n$; otherwise

$$2m - 2k - 1 \ge 2m - 2\epsilon^2 \Delta n - 1 \ge \delta n$$

if we choose ϵ so that

$$\frac{\epsilon^2\Delta}{\delta} = \frac{1}{3}. \tag{38}$$

Therefore,

$$|Z_k(F)| \le \frac{1}{(\delta n)^2} \sum_{\eta\notin J} \sum_{\gamma\notin J, \gamma\neq\eta} \{|q(\{\alpha,\beta\})| + |q(\{\gamma,\eta\})| + |q(\{\alpha,\eta\})| + |q(\{\gamma,\beta\})|\}.$$

Let

$$y^\alpha = \frac{1}{|x_{v(\alpha)}|} \min\{|yx_{v(\alpha)}|, \Delta^{1/2}/n\},$$

and note that $x_{v(\alpha)} \ge \max\{x_{v(\beta)}, x_{v(\gamma)}, x_{v(\eta)}\}$ and that $|x_{v(\eta)}| \le |x_{v(\alpha)}|$ implies $|x_{v(\eta)}|y^\eta \le |x_{v(\alpha)}|y^\alpha$. Therefore,

$$\begin{aligned}
&|q(\{\alpha,\beta\})| \le \delta^{-2}|x_{v(\alpha)}|y^\alpha_{v(\beta)},\\
&|q(\{\gamma,\eta\})| \le \delta^{-2}(|x_{v(\gamma)}|y^\gamma_{v(\eta)} + |x_{v(\eta)}|y^\eta_{v(\gamma)}) \le \delta^{-2}(|x_{v(\alpha)}|y^\alpha_{v(\eta)} + |x_{v(\alpha)}|y^\alpha_{v(\gamma)}),\\
&|q(\{\alpha,\eta\})| \le \delta^{-2}|x_{v(\alpha)}|y^\alpha_{v(\eta)},\\
&|q(\{\gamma,\beta\})| \le \delta^{-2}(|x_{v(\gamma)}|y^\gamma_{v(\beta)} + |x_{v(\beta)}|y^\beta_{v(\gamma)}) \le \delta^{-2}(|x_{v(\alpha)}|y^\alpha_{v(\beta)} + |x_{v(\alpha)}|y^\alpha_{v(\gamma)}).
\end{aligned}$$

Next observe that since $\sum y_u^2 \le 1$ implies $\sum |y_u| \le n^{1/2}$, we have for example

$$\sum_{\eta\notin J} y^\alpha_{v(\eta)} \le \sum_{\eta\notin J} |y_{v(\eta)}| \le \Delta \sum_{w=1}^{n} |y_w| \le \Delta n^{1/2}.$$

Thus we have

$$|Z_k(F)| \le 4\Delta^2\delta^{-4}|x_{v(\alpha)}|(y^\alpha_{v(\beta)} + n^{-1/2}).$$

Writing $Z'_k = \mathbf{E}[\exp(\zeta^2 Z_k^2)|\mathcal{F}_{k-1}]$, we have

$$Z'_k(F) \le \frac{1}{2m-2k-1} \sum_{\nu\notin J-\{\beta\}} \exp(16\zeta^2\Delta^4\delta^{-8}(x_{v(\alpha)})^2(y^\alpha_{v(\nu)} + n^{-1/2})^2).$$

Take

$$\zeta = \Delta^{3/2}n, \tag{39}$$

which means that the expression

$$\begin{aligned}
&\zeta^2\Delta^4\delta^{-8}(x_{v(\alpha)})^2(y^\alpha_{v(\nu)} + n^{-1/2})^2\\
&\qquad = \zeta^2\Delta^4\delta^{-8}\Big\{(x_{v(\alpha)}y^\alpha_{v(\nu)})^2 + 2(x_{v(\alpha)}y^\alpha_{v(\nu)})x^\alpha_{v(\alpha)}n^{-1/2} + (x_{v(\alpha)})^2 n^{-1}\Big\}
\end{aligned}$$

is bounded by $4\theta^8\epsilon^{-2}$.

(Here we use $x_{v(\alpha)}y^\alpha_{v(\nu)} \le \sqrt{\Delta}/n$ and $y^\alpha_{v(\nu)} \ge \epsilon/\sqrt{n}$ (since $y_{v(\nu)} \neq 0$) to get $x_{v(\alpha)} \le \sqrt{\Delta}/(\epsilon\sqrt{n})$.)

Hence putting $B = \exp\{64\theta^8\epsilon^{-2}\}$ and using $e^x \le 1 + xe^x$ for $x \ge 0$,

$$\begin{aligned} Z'_k(F) &\le 1 + \frac{B}{2m-2k-1} \sum_{\nu \notin J - \{\beta\}} \zeta^2 \Delta^4 \delta^{-8} (x_{v(\alpha)})^2 (y^\alpha_{v(\nu)} + n^{-1/2})^2 \\ &\le 1 + B\zeta^2\Delta^4\delta^{-9} n^{-1} (x_{v(\alpha)})^2 \sum_\nu (y^2_{v(\nu)} + 2|y_{v(\nu)}| n^{-1/2} + n^{-1}) \\ &\le \exp(4B\zeta^2\Delta^5\delta^{-9} n^{-1} (x_{v(\alpha)})^2). \end{aligned}$$

Writing $r(k) = \lceil k/\Delta \rceil$, we have for any $F \in \Omega$,

$$Z'_k(F) \le \exp(4B\zeta^2\Delta^5\delta^{-9} n^{-1} (x_{r(k)})^2).$$

Thus, using (37), we have

$$\begin{aligned} \mathbf{Pr}(|X_1 - \mathbf{E}[X_1]| \ge t\Delta^{-3/2}) &\le 2e^{-\zeta t\Delta^{-3/2}} \exp\left(\sum_{k=1}^m 4B\zeta^2\Delta^5\delta^{-9} n^{-1} (x_{r(k)})^2 \right) \\ &\le 2\exp\left(-tn + 4B\Delta^8\delta^{-9} n \sum_{k=1}^m (x_{r(k)})^2 \right) \\ &\le 2\exp\left(-tn + 4B\Delta^9\delta^{-9} n \right). \end{aligned} \tag{40}$$

This proves (34).

The proof of (35) is almost identical even though F_2 has a slightly different definition of F_1. We simply reorder F according to $y_{v(\beta)}$ and go through the proof above without using the condition $|x_{v(\alpha)}| \le n^{-1/2}/\epsilon$.

The proof of (36) is much simpler. We use the more usual martingale argument (Alon and Spencer [1], Bollobás [4], McDiarmid [14]); for now if $Y_k = \mathbf{E}(X_3 \mid \mathcal{F}_k)$ then $|Y_k - Y_{k-1}| \le 4/(\epsilon^2 n\delta^2)$. Since we took (in (38)), $\epsilon = 1/\sqrt{3\theta}$, we have

$$\begin{aligned} \mathbf{Pr}(|X_3 - \mathbf{E}[X_3]| \ge t\Delta^{-3/2}) &\le 2\exp\left(\frac{-t^2\epsilon^4 n^2\delta^4}{32\Delta^3 m} \right) \\ &\le 2\exp\left(\frac{-t^2\epsilon^4 n}{32\theta^4} \right) \le 2\exp\left(\frac{-t^2 n}{288\theta^6} \right). \end{aligned}$$

□

Note that the lemma above shows that there is a constant $B > 0$ such that

$$\mathbf{Pr}(|X'_a - \mathbf{E}[X'_a]| \ge t\Delta^{-3/2}) \le 6\exp(-tn + Bn).$$

Clearly the same result holds for the second sum X'_b in (33). Thus we have that for any $\hat{\xi} < \xi \in (0,1)$ there is a $K = K(\theta, \xi) > 0$ such that

$$\mathbf{Pr}(|X' - \mathbf{E}[X']| \ge K\Delta^{-3/2} \mid M \text{ is simple}) \le 2^{O(d^2)} \hat{\xi}^n \le \xi^n. \tag{41}$$

Note that we should multiply the right-hand side of (41) by $\kappa \le n^2$ to account for the probability there exists M_i for which X' is large.

10.5. Estimating X''. In view of (41), it only remains to show that $X'' = O(\Delta^{-3/2})$ with suitably high probability. We shall first prove a preliminary result showing that the random graph G with degree sequence $\mathbf{d}$ is unlikely to have a *dense* subgraph. It will be enough to consider the case $G = G_3$ and argue an immediate implication for its subgraphs.

LEMMA 16. *Let G be chosen randomly from the set $\mathcal{G}(\mathbf{d})$ of simple graphs with vertex set $[n]$ and degree sequence $\mathbf{d}$. For $A, B \subseteq [n]$, let $e(A,B)$ be the number of edges joining a vertex in A to a vertex in B and $\mu(A,B) = \theta|A||B|\Delta/n$, where $\theta > \Delta/\delta$ is sufficiently large. For every constant $K > 0$ there is a constant $C = C(\theta, K)$ such that with probability $1 - o(n^{-K})$ every pair of $A, B \subseteq [n]$, with $|A| \le |B|$, satisfies at least one of the following:*

(i) $e(A,B) \le C\mu(A,B)$,

(ii) $e(A,B)\ln\frac{e(A,B)}{\mu(A,B)} \le C|B|\ln\frac{n}{|B|}$.

Proof. Write $a = |A|$, $b = |B|$, and let d_A and d_B be the sums of degrees in A and in B, respectively. Condition (i) clearly holds *deterministically* if b is at least a constant fraction of n since $e(A,B) \le a\Delta$. Assume then that $a, b \le n/(4\theta)$.

We prove later that for any set of possible edges S, $|S| \le n\Delta/(4\theta) \le n\delta/2$, we have

$$\mathbf{Pr}(G \text{ contains } S) \le \left(\frac{\Delta^2}{m}\right)^{|S|}. \tag{42}$$

Thus the probability that there exists a pair (A,B) with $e(A,B) = t$ is at most

$$\binom{n}{b}\binom{n}{a}\binom{ab}{t}\left(\frac{\Delta^2}{m}\right)^t \le \left(\frac{ne}{b}\right)^{2b}\left(\frac{abe\Delta^2}{mt}\right)^t \le \left(\frac{ne}{b}\right)^{2b}\left(\frac{\mu(A,B)}{t}\right)^t e^t.$$

Now consider a value x that satisfies

$$\begin{aligned} x\ln\left(\frac{x}{\mu(A,B)}\right) &> Cb\ln\left(\frac{n}{b}\right) \ge \frac{1}{2}Cb\ln\left(\frac{en}{b}\right) \\ x &> C\mu(A,B) \\ x &\ge (\ln n)^2. \end{aligned}$$

Then clearly

$$\mathbf{Pr}(\exists A, B:\ e(A,B) = x) \le n^{-\ln n},$$

and therefore

$$\begin{aligned} &\mathbf{Pr}\left(\exists A, B:\ (e(A,B) \ge (\ln n)^2)\ \&\ \neg(\mathrm{i})\ \&\ \neg(\mathrm{ii})\right) \\ &\qquad = \sum_{(\ln n)^2 \le x \le n^2} \mathbf{Pr}\Big(\exists A, B:\ (e(A,B) = x)\ \&\ \neg(\mathrm{i})\ \&\ \neg(\mathrm{ii})\Big) \le n^2 n^{-\ln n}. \end{aligned}$$

It remains to deal with $\mathbf{Pr}\left(\exists A, B:\ (e(A,B) < (\ln n)^2)\ \&\ \neg(\mathrm{i})\ \&\ \neg(\mathrm{ii})\right)$. If $e(A,B) < (\ln n)^2$ and (ii) does not hold then

$$2e(A,B)\ln n > Cb\ln\left(\frac{n}{b}\right) \ge Cb\ln(4\theta) \tag{43}$$

and so $b \le e(A,B)\ln n \le (\ln n)^3$, which in turn, from the first inequality in (43), implies that $e(A,B) > Cb/3$. But the probability that $e(A,B) \ge Cb/3$, for C sufficiently large, and $b \le (\ln n)^3$ can be bounded by

$$\begin{aligned} \binom{n}{b}\binom{n}{a}\sum_{t=Cb/3}^{\Delta(\ln n)^3}\binom{ab}{t}\left(\frac{\Delta^2}{m}\right)^t &\le 2\binom{n}{b}\binom{n}{a}\binom{ab}{Cb/3}\left(\frac{\Delta^2}{m}\right)^{Cb/3} \\ &\le 2\left(\frac{ne}{b}\right)^{2b}\left(\frac{3ea\Delta^2}{Cm}\right)^{Cb/3} \\ &\le 2(n^{2-3C/10}b^{C/3-2})^b. \end{aligned}$$

This yields the conclusion of the lemma.

Proof of (42). Let $S = \{e_1, e_2, \ldots, e_s\}$, $\mathcal{G}_0 = \mathcal{G}(\mathbf{d})$ and $\mathcal{G}_i = \{G \in \mathcal{G}(\mathbf{d}) : G$ contains $\{e_1, e_2, \ldots, e_i\}$ for $1 \le i \le s$. It is sufficient to prove that for $0 \le i < s$,

$$\frac{|\mathcal{G}_{i+1}|}{|\mathcal{G}_i|} \le \frac{\Delta^2}{2m - 2\Delta^2 - 2s} \le \frac{\Delta^2}{m}, \tag{44}$$

where the second inequality follows from our bound on s. To prove the first inequality we consider

$$X = \{(H_1, H_2) : H_1 \in \mathcal{G}_i \setminus \mathcal{G}_{i+1}, H_2 \in \mathcal{G}_{i+1}, H_1 \sim H_2\},$$

where $H_1 \sim H_2$ means that there is some four-cycle with edges $f_1 = e_{i+1}, f_2, f_3, f_4$ such that H_2 is obtained from H_1 by adding f_1, f_3 and deleting f_2, f_4. The first inequality in (44) follows immediately from the following:

(i) a particular $H_1 \in \mathcal{G}_i \setminus \mathcal{G}_{i+1}$ appears in at most Δ^2 pairs of X;

(ii) a particular $H_2 \in \mathcal{G}_{i+1}$ appears in at least $2m - 2\Delta^2 - s$ pairs of X.

Let $e_{i+1} = (x, y)$. For (i) observe that there are at most Δ^2 choices for f_2, f_4—one is incident with x and one is incident with y. For (ii), given $H_2 \in \mathcal{G}_{i+1}$ we chose an *oriented* edge $f_3 = (u, v) \in H_2$ not incident with e_{i+1}. Let $f_2 = (x, u)$ and $f_4 = (y, v)$. At most $2(\Delta - 1)^2$ choices of f_3 are forbidden because at least one of f_2, f_4 are already in H_1 and at most $s - 1$ choices are disallowed because $f_3 \in S$. □

We now explain why it suffices just to consider G_3 (and G_2) for the large pairs and not their subgraphs $\hat{\Gamma}_j$ (and Γ_j). Indeed, if one of the conditions (i) or (ii) hold for G_3 then at least one holds for any of its subgraphs Γ. If condition (i) was true for G_3 then it is true a fortiori for Γ. Similarly, if condition (i) fails, $C \ge 1$, and condition (ii) holds for G_3 then it holds a fortiori for Γ.

LEMMA 17. *Given the assertions in Lemma* 16, $X'' = \sum_{(u,v) \notin B} x_u A_{uv} y_v$, *where* $B = \{(u, v) \mid 0 < |x_u y_v| < \Delta^{1/2}/n\}$, *satisfies*

$$X'' = O(\Delta^{-3/2})$$

for every *pair* $x, y \in T$.

Proof. Given $x \in T$, we write

$$S_i(x) = \{u : \epsilon^{2-i} n^{-1/2} \le |x_u| < \epsilon^{1-i} n^{-1/2}\}, \qquad i \in I,$$

where $I = \{i : S_i(x) \ne \emptyset\}$. Define J and $S_j(y)$ analogously. Also, for $S \subseteq [n]$ and $x \in T$, write

$$(x_S)_u = \begin{cases} x_u & \text{if } u \in S, \\ 0 & \text{otherwise.} \end{cases}$$

Given $x, y \in T$, we write $A_i = S_i(x)$, $B_j = S_j(y)$, $a_i = |A_i|$, $b_j = |B_j|$. Let

$$\mathcal{C} = \{(i, j) \mid i, j > 0,\ \epsilon^{2-i-j} > \sqrt{\Delta},\ a_i \le b_j\},$$
$$\mathcal{C}' = \{(i, j) \mid i, j > 0,\ \epsilon^{2-i-j} > \sqrt{\Delta},\ a_i > b_j\}.$$

Since

$$X'' = \sum_{|x_u y_v| \ge \Delta^{1/2}/n} x_u A_{uv} y_v,$$

it is sufficient to show that

$$\sum_{(i,j)\in\mathcal{C}} (x_{A_i})^t A y_{B_j} = O(\Delta^{-3/2})$$

or, equivalently, if $e_{i,j} = e(A_i, B_j)$,

$$\frac{1}{n}\sum_{(i,j)\in\mathcal{C}} \frac{e_{i,j}}{\epsilon^{i+j}} = O(\sqrt{\Delta}).$$

The sum on $\mathcal{C}'$ follows by symmetry.

Note that since $\sum x_u^2 \le 1$ for $x \in T$, we have

$$\sum_{i\in I} a_i/\epsilon^{2(i-2)} \le n, \qquad \sum_{j\in J} b_j/\epsilon^{2(i-2)} \le n.$$

Next partition $\mathcal{C}$ into $\mathcal{C}_I \cup \mathcal{C}_{II}$, where $\mathcal{C}_x$ is the set of $(i,j) \in \mathcal{C}$ such that $e(A_i, B_i)$ satisfies assertion x in Lemma 16. First, using the definition of $\mathcal{C}$, we have

$$\frac{1}{n}\sum_{(i,j)\in\mathcal{C}_I} \frac{e_{i,j}}{\epsilon^{i+j}} = O\left(\frac{1}{n^2}\sum_{(i,j)\in\mathcal{C}_I} \frac{a_i b_j \Delta}{\epsilon^{i+j}}\right) = O\left(\frac{\Delta}{n^2}\sum_{(i,j)\in\mathcal{C}_I} \frac{a_i b_j}{\epsilon^{2(i+j)}\sqrt{\Delta}}\right) = O(\sqrt{\Delta}).$$

It therefore remains to show

$$\frac{1}{n}\sum_{(i,j)\in\mathcal{C}_{II}} \frac{e_{i,j}}{\epsilon^{i+j}} = O(\sqrt{\Delta}). \tag{45}$$

For $k = 1, \dots, 5$, let $\mathcal{D}_k$ be the set of $(i,j) \in \mathcal{C}_{II}$ satisfying (k) below but not (k') if $k' < k$.

(1) $\epsilon^j \ge \epsilon^i\sqrt{\Delta}$,
(2) $e_{i,j} \le \mu_{i,j}/(\epsilon^{i+j}\sqrt{\Delta})$, where $\mu_{i,j} = \mu(A_i, B_j)$,
(3) $\ln(e_{i,j}/\mu_{i,j}) \ge \frac{1}{4}\ln(n/b_j)$,
(4) $n/b_j \le \epsilon^{-4j}$,
(5) $n/b_j > \epsilon^{-4j}$.

Then equation (45) follows if for $k = 1, \dots, 5$,

$$H_k = \frac{1}{n}\sum_{(i,j)\in\mathcal{D}_k} \frac{e_{i,j}}{\epsilon^{i+j}} = O(\sqrt{\Delta}).$$

Start by noting that since $(i,j) \in \mathcal{C}_{II}$, we have

$$e_{i,j}\ln(e_{i,j}/\mu_{i,j}) \le C b_j \ln(n/b_j). \tag{46}$$

For $k = 1$, from the trivial inequality $e_{i,j} \le a_i\Delta$ we have

$$H_1 \le \frac{1}{n}\sum_i \sum_{j:\epsilon^j \ge \epsilon^i\sqrt{\Delta}} \frac{a_i\Delta}{\epsilon^{i+j}} = O\left(\frac{1}{n}\sum_i \frac{a_i\sqrt{\Delta}}{\epsilon^{2i}}\right) = O(\sqrt{\Delta}).$$

For $k = 2$, we have

$$H_2 \le \frac{1}{n}\sum_{i,j} \frac{\mu_{i,j}}{\sqrt{\Delta}\epsilon^{2(i+j)}} = O\left(\frac{\sqrt{\Delta}}{n^2}\sum_{i,j} \frac{a_i b_j}{\epsilon^{2(i+j)}}\right) = O(\sqrt{\Delta}).$$

For $k = 3$, equation (46) implies that

$$e_{i,j} = O(b_j),$$

and so using $(i,j) \notin \mathcal{D}_1$, that is, $\epsilon^j < \epsilon^i\sqrt{\Delta}$,

$$H_3 = O\Big(\frac{1}{n}\sum_j \sum_{i:\epsilon^i > \epsilon^j/\sqrt{\Delta}} \frac{b_j}{\epsilon^{i+j}}\Big) = O\Big(\frac{1}{n}\sum_j \frac{\sqrt{\Delta}b_j}{\epsilon^{2j}}\Big) = O(\sqrt{\Delta}).$$

For $k = 4$, using $(i,j) \notin \mathcal{D}_3$, we have

$$\frac{e_{i,j}}{\mu_{i,j}} \le \frac{1}{\epsilon^j}.$$

Also, using $(i,j) \notin \mathcal{D}_2$, we have

$$\frac{e_{i,j}}{\mu_{i,j}} \ge \frac{1}{\epsilon^{i+j}\sqrt{\Delta}},$$

thus giving

$$\epsilon^{-i} \le \sqrt{\Delta}.$$

From (46), we also have $e_{i,j} = O(jb_j)$ (using also $e_{i,j} \ge C\mu_{i,j}$). Thus

$$H_4 = O\Big(\frac{1}{n}\sum_j \sum_{i:\epsilon^{-i} \le \sqrt{\Delta}} \frac{jb_j}{\epsilon^{i+j}}\Big) = O\Big(\frac{\sqrt{\Delta}}{n}\sum_j \frac{jb_j}{\epsilon^j}\Big).$$

Since $\sum_{j\in J} b_j/(n\epsilon^{2j}) = O(1)$ we have

$$H_4 = O(\sqrt{\Delta}).$$

For $k = 5$, since $b_j < n\epsilon^{4j}$, we have from (46) that

$$e_{i,j} \le Cn\epsilon^{4j}\ln\epsilon^{-4j} = O(nj\epsilon^{4j}).$$

Also, since $(i,j) \notin \mathcal{D}_1$, we have $\epsilon^j < \epsilon^i\sqrt{\Delta}$; thus

$$H_5 = O\Big(\sum_j \sum_{i:\epsilon^i > \epsilon^j/\sqrt{\Delta}} j\epsilon^{3j-i}\Big) = O\Big(\sqrt{\Delta}\sum_j j\epsilon^{2j}\Big) = O(\sqrt{\Delta}). \qquad \square$$

Observe finally that for future reference we have in fact proven the following lemma.

LEMMA 18. *Let* $\mathbf{d} = d_1, d_2, \ldots, d_n$ *be a degree sequence with maximum degree* $\Delta = o(n^{1/2})$ *and minimum degree* δ *such that* $\Delta/\delta < \theta$ *for some constant* $\theta > 0$. *Let* G *be chosen randomly from the set of* simple *graphs with degree sequence* $\mathbf{d}$. *Let* $0 < c < 1$ *be an arbitrary constant and* $\mathcal{G}$ *be the set of vertex induced subgraphs* H *of* G *which have degree at least* $c\delta$. *Let* $K > 0$ *be an arbitrary constant. Then with probability* $1 - O(n^{-K})$ every *graph* H *in* $\mathcal{G}$ *has a second eigenvalue at most* $\gamma/\sqrt{\Delta}$ *where* $\gamma = \gamma(\theta, c, K)$.

Proof. We can handle "small pairs" by using multigraphs and pass to simple graphs as above. We observe that only the failure probability (41) now needs to be

inflated by $2^{n+O(d^2)}$ and this is handled by making ξ small enough or γ large enough. The case of "large" pairs is handled as before by deducing it from what happens in G. □

There are no lower bounds explicitly stated for δ, but our results are not useful for small minimum degree. It follows from (40) that γ is at least $4\theta^9 \exp\{192\theta^9\}$. Thus say for $\delta \le 10^6$ we will have $\gamma \ge \Delta$ and so the estimate for the second eigenvalue will exceed one, the largest eigenvalue.

Acknowledgment. It is a pleasure to acknowledge the work of the anonymous reviewers. In particular, we would like to thank the referee who pointed out a small gap in the originally submitted version of the paper.

FULLY DYNAMIC ALGORITHMS FOR BIN PACKING: BEING (MOSTLY) MYOPIC HELPS*

ZORAN IVKOVIĆ† AND ERROL L. LLOYD‡

Abstract. The problem of maintaining an approximate solution for *one-dimensional bin packing* when items may arrive and depart dynamically is studied. In accordance with various work on fully dynamic algorithms, and in contrast to prior work on bin packing, it is assumed that the packing may be arbitrarily rearranged to accommodate arriving and departing items. In this context our main result is a *fully dynamic* approximation algorithm for bin packing *MMP* that is $\frac{5}{4}$-competitive and requires $\Theta(\log n)$ time per operation (i.e., for an *Insert* or a *Delete* of an item). This competitive ratio of $\frac{5}{4}$ is nearly as good as that of the best practical off-line algorithms. Our algorithm utilizes the technique (introduced here) whereby the packing of an item is done with a total disregard for already packed items of a smaller size. This *myopic* packing of an item may then cause several smaller items to be repacked (in a similar fashion). With a bit of additional sophistication to avoid certain "bad" cases, the number of items (either individual items or "bundles" of very small items treated as a whole) that needs to be repacked is bounded by a constant.

Key words. bin packing, fully dynamic algorithm

1. Introduction.

In the (one-dimensional) bin packing problem, a list $L = (a_1, a_2, ..., a_n)$ of items of size $size(a_i)$ in the interval (0,1] is given. The goal is to find the minimum k such that all of the items a_i can be packed into k unit-size bins. Bin packing was shown to be *NP*-complete in [15].

For the past quarter century, bin packing has been a central area of research activity in the algorithms and operations research communities (see [3, 7]). Despite its advanced age, bin packing has retained its appeal by being a fertile ground for the study of approximation algorithms (more than a decade ago, bin packing was labeled "the problem that wouldn't go away" [3]). In this paper, we consider *fully dynamic* bin packing, where

- items may arrive and depart from the packing dynamically, and
- items may be moved from bin to bin as the packing is adjusted to accommodate arriving and departing items.

In general, *fully dynamic* algorithms are aimed at situations where the problem instance is changing over time. Fully dynamic algorithms incorporate these incremental changes without any knowledge of the existence and nature of future changes.

Each of the earlier works on *on-line* and *dynamic* bin packing differ from this notion of fully dynamic bin packing in either of two ways: either they do not allow an item to be moved from a bin (of course, this has a predictably bad effect on the achievable quality of the packing), or they restrict themselves to dynamic arrivals of items—there are no departures.

Although most of the existing work on fully dynamic algorithms has been directed toward problems known to be in P, some recent attention has been paid to fully dynamic *approximation* algorithms for problems that are *NP*-complete [9, 16].

In this paper we develop a fully dynamic approximation algorithm for bin packing that is "competitive" with existing off-line algorithms. In this case, being competitive with off-line algorithms means that the quality of the approximation produced by the fully dynamic approximation algorithm should be as good as that produced by the off-line algorithms. Further, the running time per operation (i.e., change) of the fully dynamic algorithm should be as small as possible.

1.1. Bin packing—Existing results. The usual measure of the quality of a solution produced by a bin packing algorithm A is its *competitive ratio* $R(A)$ defined as

$$R(A) = \lim_{n\to\infty} \sup_{OPT(L)=n} \frac{A(L)}{OPT(L)},$$

where $A(L)$ and $OPT(L)$ denote, respectively, the number of bins used for packing of the list L by A and some optimal packing of L. Here, we say that A is $R(A)$-*competitive*.

In the domain of off-line algorithms, the value of R has been successively improved [3, 19, 5, 13, 4]. Indeed, it has been shown that for any value of $R \geq 1$, there is an $\mathcal{O}(n \log n)$-time algorithm with that competitive ratio [14]. Unfortunately, the running times for these algorithms involve exceedingly large constants (actually, these "constants" depend on how close R is to 1). Among algorithms of practical importance, the best result is an $\mathcal{O}(n \log n)$ algorithm for which R is $\frac{71}{60}$ [13].

With respect to on-line bin packing, the problem has been defined strictly in terms of arrivals (*Inserts*)—items never depart from the packing (i.e., there are no *Deletes*). Further, most on-line algorithms have operated under the restriction that each item must be packed into some bin, and it should remain in that bin permanently. In this context, it is shown that for every on-line linear time algorithm A, $R(A) \geq 1.536...$ [3]. Further, the upper bound has been improved over the years to roughly 1.6 [10, 11, 12, 17, 18].

The work reported in [6] focused on a variant of on-line bin packing, again supporting *Inserts* only, in which each item may be moved a constant number of times (from one bin to another). Two algorithms were provided: one with a linear running time (linear in n, the number of *Inserts*, which is also the number of items) and a competitive ratio of 1.5, and one with an $\mathcal{O}(n \log n)$ running time and a competitive ratio of $\frac{4}{3}$.

Another notion that is related to, but distinct from, fully dynamic bin packing is dynamic bin packing of [2], where each item is associated with not only its size, but also with an arrival time and a departure time (interpreted in the natural way). Here, again (and unlike [6]), items cannot be moved once they are assigned to some bin, unless they depart from the system permanently (at their departure time). This variant differs from fully dynamic bin packing in that items are not allowed to be moved once they are assigned to a bin and through the departure time information. It was shown in [2] that for any such algorithm A, $R(A) \geq 2.5$, and that for their dynamic first fit (FF), $2.770 \leq R(FF) \leq 2.898$.

1.2. Competitive ratio and running time for fully dynamic approximation algorithms. In this section we discuss the notions of competitiveness and running time in the context of developing fully dynamic approximation algorithms.

We begin by noting that with respect to the definition of *competitive ratio* there is no need to make a distinction between fully dynamic and off-line algorithms. In each case, these measures reflect the size of the packing produced by the algorithm relative to the size of optimal packing.

With respect to running times, we say that a fully dynamic approximation algorithm B for bin packing has *running time* $\mathcal{O}(f(n))$ if the time taken by B to process a change (an *Insert* or *Delete*) to an instance of n items is $\mathcal{O}(f(n))$. If $\mathcal{O}(f(n))$ is a *worst-case* time bound, then B is *uniform*. If $\mathcal{O}(f(n))$ is an *amortized* time bound, then B is *amortized*.

Our general goal in developing fully dynamic approximation algorithms for bin packing is to design algorithms with competitive ratios close to those of the best off-line algorithms such that the changes are processed quickly. Of particular interest are algorithms that are, in a sense, the best possible relative to the existing off-line methods. For bin packing the best known off-line algorithms require time $\Theta(n \log n)$. Thus, a fully dynamic algorithm that runs in time $\Theta(\log n)$ per operation is, in that sense, the best possible. Indeed, the fully dynamic algorithm *MMP* that we give in this paper runs in precisely this time per operation.

The algorithms that we present process a sequence of *Inserts* (arrivals) and *Deletes* (departures) of items. Further, our algorithm is designed to handle "lookup" queries of the following form:

- *size*—returns in $\mathcal{O}(1)$ time the number of bins in the current packing;
- *packing*—returns a description of the packing in the form of a list of pairs $(x, \mathrm{Bin}(x))$, where $\mathrm{Bin}(x)$ denotes the bin into which an item x is packed, in time linear in the number of items in the current instance.

These queries may be interspersed in the *Insert/Delete* sequence as follows.

1.3. What's to come. The main result of this paper is a fully dynamic algorithm *MMP* that is $\frac{5}{4}$-competitive and requires $\Theta(\log n)$ time per operation. Relative to the best off-line algorithms, *MMP* has a running time that is best possible, and it has a competitive ratio that is nearly the equal of the best practical off-line algorithms. This is a surprising result even in terms of off-line bin packing, since it is the first practical bin packing algorithm that has a competitive ratio of less than $\frac{4}{3}$ that does not rely on packing the items in sorted order (as discussed in section 2, dynamically maintaining a packing based on a sorted list is problematic). That the algorithm is fully dynamic is all the more remarkable.

With the preliminaries concluded, the remainder of the paper is organized as follows. In the next section we review the basic definitions and define two key properties of *MMP* packing: *LLS-maximality* and *M-thoroughness*. We further provide a sketch of *MMP*'s *Insert* and *Delete* operations, and we focus on the techniques *MMP* utilizes to maintain the above properties: *myopic packing*, *bundles*, and *LLS-coalitions*.

In section 3 we describe the (rather complex) data structure, and the details of *MMP*. In section 4 we prove the competitive ratio of $\frac{5}{4}$ and the uniform logarithmic running time per *Insert/Delete* operation. Finally, in section 5 we furnish some concluding remarks.

2. Toward full dynamization of bin packing. Motivated by the notions of competitiveness introduced in the preceding section, a natural approach to the development of fully dynamic bin packing algorithms is to adapt existing methods to work in the fully dynamic situation. Unfortunately, this is easier said than done. The difficulty is that most of the off-line algorithms perform bin packing in two distinct stages. First, there is a *preprocessing stage* in which the items are organized in some

fashion (this reorganization should have a positive effect on the resulting packing). This is followed by a *packing stage* where the actual packing is accomplished. In the off-line situation, this two stage approach is quite natural since the entire list of items is available at the outset. However, in a dynamic environment a two-stage process becomes awkward. Consider, for example, the algorithm first fit decreasing (*FFD*), which is $\frac{11}{9}$-competitive. This algorithm first sorts the items and then packs them in order of decreasing size using the *FF* packing rule.[1] What about a fully dynamic version of *FFD*? There is, of course, no difficulty in maintaining a sorted list of the elements. *But* there is great difficulty in maintaining the packing based on that sorted list, since the insertion (or deletion) of a single item can result in a large number of changes to that packing. It would seem that the packing induced by the sorted list of items is "too specific" to be maintained dynamically, and that perhaps a less specific rule might be of use. Indeed, in this paper we utilize a weaker notion: Johnson's *grouping* [10, 11].

2.1. Some definitions. Before proceeding, we require a few definitions that will be used throughout the remainder of the paper. In particular, for a bin B, $level(B)$ is the sum of the sizes of the items packed in B; $gap(B)$ is $1 - level(B)$, i.e., the amount of empty space in B; and $content(B)$ is the set of items packed in B.

We can assume that the bins are numbered in such a way that every bin has a unique number with the property that, for any two bins, the bin with the lower number is placed "to the left" of the bin with the higher number. In other words, we assume that, for conceptual purposes, the bins are numbered in increasing order from left to right.

Following Johnson's *grouping* [10, 11], we partition the items according to their respective sizes. In particular, an item a is a B-item (big) if $size(a) \in (\frac{1}{2}, 1]$, an L-item (large) if $size(a) \in (\frac{1}{3}, \frac{1}{2}]$, an S-item (small) if $size(a) \in (\frac{1}{4}, \frac{1}{3}]$, a T-item (tiny) if $size(a) \in (\frac{1}{5}, \frac{1}{4}]$, and an M-item (miniscule) if $size(a) \in (0, \frac{1}{5}]$.

Let $\mathcal{B}$, $\mathcal{L}$, $\mathcal{S}$, $\mathcal{T}$, and $\mathcal{M}$ denote the number of B-items, L-items, S-items, T-items, and M-items in L, respectively.

When the meaning is otherwise clear, the fact that a is a B-item (L-item, S-item, T-item, M-item) will be abbreviated as $a \in$ B (L,S,T,M). A bin is a B-bin (L-bin, S-bin, T-bin, M-bin) if its largest item is a B-item (L-item, S-item, T-item, M-item). There are several types of B-bins: bins containing one B-item and one L-item, and no more B-items, L-items, S-items, or T-items will be called bins of type BL; bins of type BST, BS, BTT, BT, and B are defined analogously. Likewise, there are several types of L-bins, several types of S-bins, and several types of T-bins. The possible types of B-bins, L-bins, S-bins, and T-bins are illustrated in Figure 1. Note that we did not take into consideration the M-items: while it is certainly the case that bins may contain M-items, accounting for them will have no substantive effect on the competitive ratio of *MMP*.

By way of preliminaries, we introduce a binary relation of *superiority* over types of bins. First, all of the types of B-bins, L-bins, S-bins, and T-bins are superior to M-bins. Second, we consider non-M-bins. Here the following ordering of relevant types of items is assumed: B $\prec$ L $\prec$ S $\prec$ T $\prec$ Z, where Z denotes a fictitious item of size 0. We imagine that each bin contains, on top of its B-items, L-items, S-items, and T-items (M-items may be present but are being ignored), a fictitious item of type

[1] Informally, bins are ordered from left to right, and an item is packed into the leftmost bin into which it will fit.

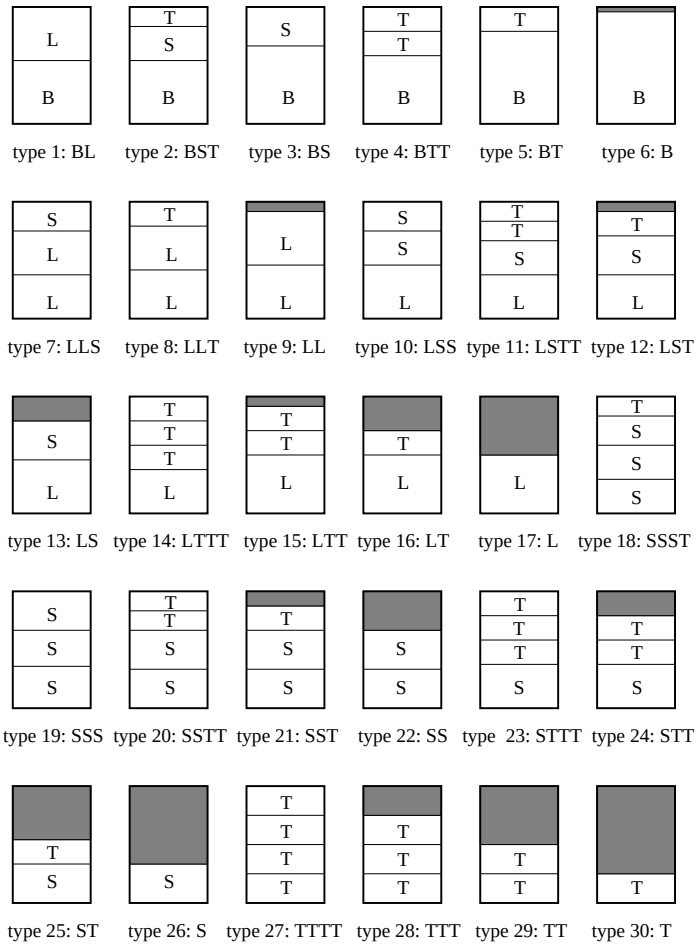

FIG. 1. *Possible types of bins in* MMP.

Z (zero), of size 0. Zero items are introduced solely for technical convenience, as their presence will enable us to impose the desired ordering on the types of bins. Thus, in view of the introduction of Z-items, the types of bins are BLZ, BSTZ, BSZ, ..., TTZ, and TZ. For these types of bins, the relation of superiority is defined as the lexicographical ordering over the types of bins. For example, a bin of type BLZ is superior to a bin of type BSTZ. In the remainder of this paper, we omit Z from the notation describing the types of bins.[2] Finally, we will sometimes find it convenient to refer to these types of bins according to their canonical index in this lexicographical ordering, as depicted in Figure 1: a bin of type 1 is a bin of type BL, a bin of type 2 is a bin of type BST, ..., a bin of type 30 is a bin of type T. We assert naturally that if B_j is superior to B_i, then B_i is *inferior* to B_j.

The *allowed* types of bins in the packings produced by *MMP* are BL, BST, BS, BTT, BT, B, LLS, LLT, LL, SSST, SSS, and TTTT, and, of course, M-bins. This restriction may result in at most six unpacked items: one L-item, two S-items, and

[2]Although Z is omitted, it is needed to ensure that, e.g., BLZ is superior to BZ. The reader should keep in mind that the relation of superiority relies on the presence of Z in each non-M-bin.

three T-items. Clearly, these items could be packed into at most two additional bins (a bin of type LTT and a bin of type SST). *MMP* will utilize the *regular packing*, consisting at all times only of bins of the allowed types, and the *auxiliary storage*, containing the items that are not (currently) packed into a bin from the regular packing.

2.2. LLS-maximality and M-thoroughness. We next define the properties of packings that play a key role for the competitive ratio of *MMP*. We first define the *thoroughness property*. Next, we define the *LLS-maximality property*, a property that is similar to, and (much) stronger than, the thoroughness property. Finally, we define the *M-thoroughness property* aimed at the M-items and their role in the packing. Intuitively, maintaining the LLS-maximality property leads to the competitive ratio of $\frac{5}{4}$ for packings of lists of non-M-items; maintaining LLS-maximality *and* the M-thoroughness property leads to the competitive ratio of $\frac{5}{4}$ for packings of arbitrary lists. We begin with two definitions.

DEFINITION 1. *Let $\mathcal{P}_{B,L,S,T}$ be a set of packings of B-items, L-items, S-items, and T-items such that each packing $P \in \mathcal{P}_{B,L,S,T}$ consists only of the allowed types of bins (BL, BST, BS, BTT, BT, B, LLS, LLT, LL, SSST, SSS, and TTTT), where all of the bins of type BL are to the left of all the non-BL-bins, all of the bins of type BST are to the left of all the non-BL-bins and non-BST-bins, etc.*

DEFINITION 2. *Let a packing $P \in \mathcal{P}_{B,L,S,T}$. Then*

1. *Bins of type BL are thorough in P iff there does not exist a B-item b and an L-item l such that $size(b) + size(l) \leq 1$, and item b is either in a bin of type inferior to BL in the packing P or in the auxiliary storage, and item l is either in a bin of type inferior to BL in the packing P or in the auxiliary storage, i.e., iff it is not possible to pack a B-item from a bin of type inferior to BL or from the auxiliary storage, and an L-item from a bin of type inferior to BL or from the auxiliary storage into a bin.*
2. *Bins of type BST are thorough in P iff there does not exist a bin B of type BS in P, where b and s are the B-item and the S-item packed into B, and a T-item t such that $size(b) + size(s) + size(t) \leq 1$, and the item t is in a bin of type inferior to BST in the packing P or the auxiliary storage.*
3. *Bins of type BS are thorough in P iff there does not exist a B-item b and an S-item s such that $size(b) + size(s) \leq 1$, and the item b is either in a bin of type inferior to BS in the packing P or in the auxiliary storage, and the item s is in a bin of type inferior to BS in the packing P or in the auxiliary storage.*
4. *Bins of type BTT are thorough in P iff there does not exist a bin B of type BT in P, where b and t_1 are the B-item and the T-item packed into B, and a T-item t_2 such that $size(b) + size(t_1) + size(t_2) \leq 1$, and the item t_2 is in a bin of type inferior to BTT in the packing P or in the auxiliary storage.*
5. *Bins of type BT are thorough in P iff there does not exist a B-item b and a T-item t such that $size(b) + size(t) \leq 1$, and the item b is either in a bin of type inferior to BS in the packing P or in the auxiliary storage, and the item t is in a bin of type inferior to BT in the packing P or in the auxiliary storage.*
6. *Bins of type LLS are thorough in P iff there does not exist a bin B of type LLT or LL in P, where l_1 and l_2 are the L-items packed into B, and an S-item s such that $size(l_1) + size(l_2) + size(s) \leq 1$, and the item s is either in a bin of type inferior to LLS in the packing P or in the auxiliary storage.*

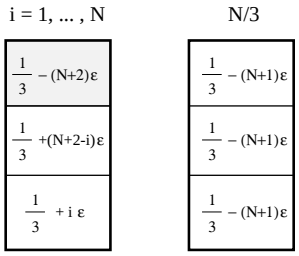

FIG. 2. *An example of a thorough but not LLS-maximal packing. In the packing above, N is an arbitrary integer. The bottom L-item a_1 from the first bin ($i = 1$), $size(a_1) = \frac{1}{3} + \epsilon$, and the top L-item a_2 from the second bin ($i = 2$), $size(a_2) = \frac{1}{3} + N\epsilon$ can fit together with an S-item (all S-items have the size of $\frac{1}{3} - (N+1)\epsilon$). The same is true of the bottom L-item from the second bin ($i = 2$) and the top L-item from the third bin ($i = 3$), ..., the bottom L-item from the $(N-1)$st bin and the top L-item from the Nth bin. Thus, although the packing above is thorough, it is far from LLS-maximal, since many bins of type LLS could be packed from the items in the packing, and all of the items are packed into bins of type inferior to LLS.*

7. *Bins of type LLT are thorough in P iff there does not exist a bin B of type LL in P, where l_1 and l_2 are the L-items packed into B, and a T-item t such that $size(l_1) + size(l_2) + size(t) \leq 1$, and the item t is either in a bin of type inferior to LLT in the packing P or in the auxiliary storage.*
8. *Bins of type SSST are thorough in P iff there does not exist a bin B of type SSS in P, where s_1, s_2, and s_3 are the S-items packed into B, and a T-item t such that $size(s_1) + size(s_2) + size(s_3) + size(t) \leq 1$, and the item t is either in a bin of type inferior to SSST in the packing P or in the auxiliary storage.*

Finally, a packing $P \in \mathcal{P}_{B,L,S,T}$ is thorough iff all of the above types of bins are thorough in P.

LLS-maximality. *MMP* will take some pains to be guaranteed of packing a certain portion of certain L-items and S-items into bins of type LLS (we will call this endeavor "seeking *LLS-coalitions*"). Leading toward this guarantee, we define *LLS-maximality*. LLS-maximality strengthens thoroughness: maintenance of thoroughness does not require LLS-coalitions, and the absence of coalitions leads to a competitive ratio of at least $\frac{4}{3}$ (see the lower bound example for *FFG* in [10]).

DEFINITION 3. *Let a packing $P \in \mathcal{P}_{B,L,S,T}$. Then P is LLS-maximal iff P is thorough and bins of type LLS are LLS-maximal in P; i.e., there does not exist an L-item l_1, another L-item l_2, and an S-item s such that $size(l_1)+size(l_2)+size(s) \leq 1$, and the item l_1 is either in a bin of type inferior to LLS in the packing P or in the auxiliary storage, and the item l_2 is in a bin of type inferior to LLS in the packing P or in the auxiliary storage, and s is in a bin of type inferior to LLS in the packing P or in the auxiliary storage.*

Note that LLS-maximality is a (much) stronger property than thoroughness: there might be packings that are thorough but not maximal. In Figure 2 we give an example, a variant of the lower bound example for *FFG* from [10], of a packing that is thorough but not maximal.

The key factor that distinguishes between thoroughness and LLS-maximality is that when considering whether or not it is possible to pack two L-items and an S-item from bins of type inferior to LLS or the auxiliary storage into a bin, LLS-maximality, unlike thoroughness, does *not* insist that the two L-items must come from the same bin. We note that it can be shown that the maintenance of thoroughness, but not

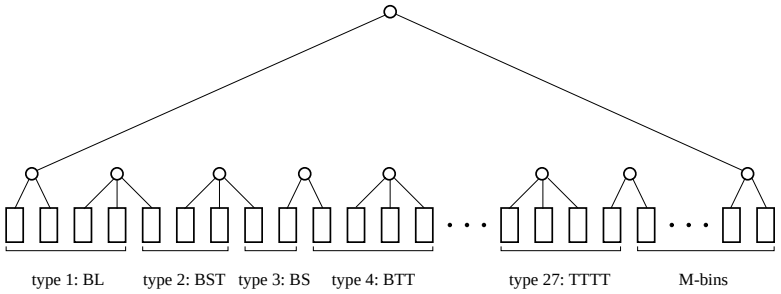

FIG. 3. *A sketch of the* 2-3 *tree of bins in* MMP. *Note that it contains only the allowed types of bins.*

LLS-maximality, leads to a simpler algorithm that also runs in uniform logarithmic time per *Insert/Delete* operation, and is $\frac{4}{3}$–competitive (see [8]).

M-thoroughness. M-thoroughness is the third property we require. It pertains to the role of M-items in the *MMP* packings. Ideally, we would like to be able to develop a method that would enable *MMP* to pack as many M-items into non-M-bins as possible. However, this is not necessary, as it turns out that maintaining M-thoroughness (a much weaker goal), coupled with LLS-maximality, of course, is quite sufficient to guarantee a competitive ratio of $\frac{5}{4}$. Later in this section we show that *MMP* maintains the M-thoroughness property.

DEFINITION 4. *A packing P is M-thorough iff precisely one of the following two conditions is satisfied:*

1. *there are no M-bins in P, or*
2. *there is at least one M-bin in P, and all of the non-M-bins have a level exceeding* $\frac{4}{5}$ *(i.e., a gap less than* $\frac{1}{5}$*), and all of the M-bins, except for possibly the rightmost bin in the packing, also have a level exceeding* $\frac{4}{5}$.

2.3. A sketch of *Insert* and *Delete*. In the next section we describe the data structure of *MMP* in detail. Here we briefly note that all of the bins in the packing will be stored at the leaves of the 2-3 tree of bins, with the bins of type BL placed in the leftmost leaves of the 2-3 tree of bins, with the bins of type BST placed in the leftmost remaining leaves (those not holding bins of type BL) of the 2-3 tree of bins, etc. for all of the other allowed types of bins, and, finally, with the M-bins placed in the rightmost leaves of the 2-3 tree of bins,[3] as depicted in Figure 3.

We now consider, somewhat informally, how to *Insert/Delete* an item. This is done using three major ideas: *myopic packing*, *bundles*, and *LLS-coalitions*.

***Insert* and *Delete* of non-M-items.** We first consider how *MMP Insert*s an item $a \in \mathrm{B} \cup \mathrm{L} \cup \mathrm{S}$. We begin by explaining how *myopic packing* is used to maintain thoroughness. Based on Johnson's grouping [10, 11], when an item a is being packed, a should be more insensitive to previously packed items of "smaller" types than the type of a. Thus, what would a "see" in the bins? Only the items of its own type or of "larger" type. In this sense, a K-item (K is B, L, S, or T) is *myopic* in that it can "see" relatively large items (K-items or larger), and it cannot "see" relatively small ones (smaller than K-items). Based on that view of the packing, a is packed in an *FF*

[3]Recall that the bins are numbered in increasing order from left to right. A numbering of bins that ranges $1, \ldots, MMP(L)$ corresponds to the graph theoretic notion of a preorder numbering of leaves of the 2-3 tree of bins.

fashion (in a's "K or larger" world) using the information stored in the internal nodes and leaves of the 2-3 tree of bins.[4] Let B be the bin into which a was packed. This packing of a results in a forceful eviction of items of smaller types from B, if there are such items at all. The evicted items will be temporarily "set aside" into the auxiliary storage and will eventually be reinserted. Next, an attempt is made to restore the thoroughness of the packing by trying to pack additional items into B, starting from the available items of the largest type that are smaller than K, i.e., the items of the largest type that are smaller than K from the auxiliary storage and from the bins that are inferior to the type of bin the algorithm is trying to reconstruct for B. This effort continues until there are no more available items of that type that can fit with the current bin content. Next, *MMP* continues with the available items (auxiliary storage or inferior bins) of the next largest type, until there are no more available items of that type that would fit into the bin, etc. Here, if an item is taken from some bin, that bin is deleted from the packing, and its contents, except for the item that was taken, are temporarily moved into the auxiliary storage. Upon completing the filling of B and inserting B into the packing, *MMP* reinserts the items from the auxiliary storage into the packing. Their reinsertion may, of course, disturb some other bins and move their contents to the auxiliary storage for later reinsertion. Eventually, all of the items from the auxiliary storage (except perhaps at most one L-item, two S-items, and/or three T-items, of course) are reinserted into the packing, and that packing is thorough.

In addition to thoroughness, *MMP* maintains LLS-maximality. This is done by using LLS-coalitions. To avoid the situation of a list that is thorough but far from LLS-maximal (see Figure 2), an amendment is made to the myopic discipline outlined above. Namely, the insertion of an L-item a is carried out as follows: first, packing a into a B-bin is attempted in a standard myopic fashion. If this attempt fails, a is authorized to try to form an *LLS-coalition* with another L-item and an S-item. The latter two can each be sought in any, and not necessarily the same, bin whose type is inferior to LLS or in the auxiliary storage. If such a coalition is possible, a and the two items are packed into a bin of type LLS, and that bin is inserted into the regular packing. The bins that yielded some or all of these two items need to be deleted, and their remaining content will eventually be reinserted. If the coalition is not possible, the packing of a is completed by resuming the standard myopic steps. Similarly, insertion of an S-item a would involve first packing a into a B-bin in a standard myopic fashion. If this fails, a will seek two L-items coming from any, and not necessarily the same, bins whose type is inferior to LLS or from the auxiliary storage. If two such items are found, an LLS-coalition is formed, and the bin of type LLS is inserted into the regular packing. If not, the packing of a is completed by resuming the standard myopic steps. A careful implementation can guarantee that the added complexity of this *mostly myopic* discipline does not asymptotically add to the running time.

Deletes are implemented as follows: the bin in which a (the item that needs to be deleted) resides is emptied and is deleted. Upon discarding a, the remaining contents of the deleted bin are temporarily moved to the auxiliary storage, from which they are reinserted into the packing as a part of this *Delete* operation.

We show later that *Inserts* and *Deletes* can be carried out in $\Theta(\log n)$ uniform running time, since the number of bins inserted and deleted by an *Insert/Delete*

[4]Note that we do not provide for all the details here. A more detailed description of the data structure and the algorithm *MMP* will be furnished in the coming sections.

operation is bounded by a fixed constant. Intuitively, the discipline of "touching" only the inferior types of bins provides for the desired running time.

Handling M-items. We now consider how *MMP* packs the lists that contain M-items. The goal here is to utilize *bundles* to manipulate many M-items at once within logarithmic uniform running time. At the same time, a proper manipulation of M-items will be important for the M-thoroughness property.

In general, the simplest approach would be to pack the M-items independently of the B-items, L-items, S-items, and T-items by packing them into totally separate bins. This would, however, lead to a competitive ratio greater than $\frac{5}{4}$. Rather, the M-items need to be packed, whenever possible, into non-M-bins. Thus, *MMP* inserts M-items just like any other items, according to their myopic view of the packing (of course, they actually "see" the entire packing). However, the presence of M-items in the packing gives rise to several important considerations.

First, upon insertion of an M-item a into a bin no items will be evicted—M-items are the smallest items! This makes the insertion of an M-item very efficient.

Second, the insertion of B-items, L-items, S-items, and T-items in situations where the input lists contain M-items needs to be examined very carefully. In particular, if the algorithm were to follow only the simple logic of myopic packing, its striving to maintain a thorough packing might require relocation of as many as $\mathcal{O}(n)$ M-items, leading to $\mathcal{O}(n \log n)$ time per *Insert/Delete* operation. This would happen during both insertions and deletions that require relocation of items from the bins of type inferior to that of the bin that is currently being filled. Furthermore, the number of bins that could be inserted and deleted per operation would be huge: it would be possible, for example, to delete as many as $\mathcal{O}(n)$ bins of type BST for the sake of taking a few M-items from each of them and packing those M-items into a single bin of type BL. The disaster does not stop here: each of the items from those many bins of type BST needs to be reinserted, and each reinsertion may again cause an avalanche of deleted bins.

Third, in case the simple myopic discipline is followed, the deletion of an M-item would cause the temporary relocation of B-items, L-items, S-items, T-items, and potentially many M-items into the auxiliary storage. Packing all of these items back into the bins might be very costly: following the same argument as above, $\mathcal{O}(n \log n)$ time might be required to reinsert a single non-M-item, with many inserted and deleted bins.

Thus handling M-items in the same manner as the other items will not do. We solve this apparent difficulty by introducing the technique of *bundling* (see [1]). The idea is that the M-items in each bin (in the auxiliary storage) are collected into *bundles* g_i. All of the bundles in a bin (in the auxiliary storage) have the cumulative size of $\frac{1}{10} < size(g_i) \leq \frac{1}{5}$, except for at most one bundle whose cumulative size is $\leq \frac{1}{10}$. The former kind of bundles is called *closed*, while the latter kind is called *open*.

The purpose of bundles is to allow efficient manipulation of large numbers of M-items at one time: in response to the need to move M-items from a bin to the auxiliary storage, or from the auxiliary storage to a bin, the algorithm will only move entire bundles. During this process, when a bundle is inserted into a bin (or temporarily stored into auxiliary storage), it is first checked to see whether it could be merged with the open bundle, if any, from that bin (or from the auxiliary storage), and, if so, the merging is carried out. While this does not asymptotically increase the running time required for the insertion of an M-item, it drastically decreases the running time of other operations involving M-bundles and makes *MMP* fast ($\Theta(\log n)$ running time per *Insert/Delete* operation).
