A description of the algorithm $\mathbf{apasp}_k$ is given in Figure 2. The algorithm is extremely simple. It starts by decomposing the graph G by invoking algorithm **decompose** of section 2 with the thresholds $s_i=(m/n)^{1-i/k}(\log n)^{i/k}$ for $1\le i<k$. As a result of this decomposition, we get a decreasing sequence of edge sets $E=E_1\supseteq E_2\supseteq\cdots\supseteq E_k$, a sequence of dominating sets $D_1,D_2,\ldots,D_{k-1}$, and $D_k=V$, and an edge set E^*. We will also refer to a decreasing sequence of vertex sets $V=V_1\supseteq V_2\supseteq\cdots\supseteq V_k$, where V_i for $1\le i<k$ is the set of all vertices of G of degree greater than s_i and $V_k=V$. The set E_i for $1\le i\le k$ is then the set of edges that touch a vertex that does *not* belong to V_{i-1}, and the set D_i is a set that dominates V_i through edges of E^*.

Next, algorithm $\mathbf{apasp}_k$ initializes a matrix $\{\hat{\delta}(u,v)\}$ of upper bounds on the distances of the graph by letting $\hat{\delta}(u,v)=1$ if $(u,v)\in E$ and $\hat{\delta}(u,v)=+\infty$ otherwise. Throughout the operation of the algorithm we have $\delta(u,v)\le\hat{\delta}(u,v)$ for every $u,v\in V$,

```
Algorithm apasp_k:

input: An unweighted undirected graph $G = (V, E)$.
output: A matrix $\{\hat{\delta}(u, v)\}_{u,v}$ of estimated distances.

For $i \leftarrow 1$ to $k - 1$ let $s_i \leftarrow (m/n)^{1-i/k}(\log n)^{i/k}$

$(\langle E_1, E_2, \ldots, E_k, E^*\rangle, \langle D_1, D_2, \ldots, D_k\rangle) \leftarrow$ decompose$(G, \langle s_1, s_2, \ldots, s_{k-1}\rangle)$

For every $u, v \in V$ do
    if $(u, v) \in E$ then $\hat{\delta}(u, v) \leftarrow 1$ else $\hat{\delta}(u, v) \leftarrow +\infty$

For $i \leftarrow 1$ to $k$ do
    For every $u \in D_i$ run dijkstra$(\,(V, E_i \cup E^* \cup (\{u\} \times V))\,, \hat{\delta}, u)$
```

FIG. 2. *An $\tilde{O}(n^{2-1/k}m^{1/k})$-time algorithm for computing surplus $2(k-1)$ distances.*

where $\delta(u, v)$ denotes the distance from u to v in the graph G.

Finally, the main part of **apasp**$_k$ is composed of successive calls to Dijkstra's algorithm. At first, Dijkstra's algorithm is run from every vertex of the dominating set D_1, then it is run from every vertex of the dominating set D_2, and so on. Most of these runs are performed, however, on graphs that are much sparser than the original input graph G. The run of Dijkstra's algorithm from a vertex $u \in D_i$ is performed on a graph $G_i(u) = (V, E_i(u))$, where $E_i(u) = E_i \cup E^* \cup (\{u\} \times V)$. The edges of $E_i \cup E^*$ are original edges of the graph and they are attached a weight of 1. The edges of $\{u\} \times V$ are not necessarily edges of the input graph. The weight attached to such an edge (u, v) is $\hat{\delta}(u, v)$, the best upper bound available at the time on the distance from u to v in the graph. Note that a slightly different graph is used in each invocation of Dijkstra's algorithm, even from vertices that belong to the same dominating set.

THEOREM 3.1. *For every $k \geq 2$, the running time of algorithm* **apasp**$_k$ *is $O(kn^{2-1/k}m^{1/k}(\log n)^{1-1/k})$, where n is the number of vertices and m is the number of edges in the input graph $G = (V, E)$, and for every $u, v \in V$ we have $\delta(u, v) \leq \hat{\delta}(u, v) \leq \delta(u, v) + 2(k - 1)$.*

Proof. We start with the complexity analysis of the algorithm. The call to **decompose** takes $O(kn^2)$ time. The initialization of $\hat{\delta}(u, v)$ takes $O(n^2)$ time. Most of the running time of the algorithm is spent in the calls to Dijkstra's algorithm. It is not difficult to see that the total running time of these calls is

$$O\left(\sum_{i=1}^{k} |D_i| \cdot (|E_i| + n)\right) = O\left(\frac{n \log n}{s_1} \cdot m + \sum_{i=2}^{k-2} \frac{n \log n}{s_i} \cdot ns_{i-1} + n \cdot ns_{k-1}\right) .$$

This follows from the fact that $|D_i| = O(n \log n/s_i)$ for $1 \leq i < k$, $|D_k| = |V| = n$, and from the fact that $|E_1| = |E| = m$ and $|E_i| \leq ns_{i-1}$ for $2 \leq i \leq k$. With the choice $s_i = (m/n)^{1-i/k}(\log n)^{i/k}$, each one of the k terms in this expression is equal to $n^{2-1/k}m^{1/k}(\log n)^{1-1/k}$ and the total running time of the algorithm is $O(kn^{2-1/k}m^{1/k}(\log n)^{1-1/k})$, as promised. The running time of the algorithm can also be expressed as $O(kn^2 \log n \cdot ((m \log n)/n)^{1/k})$.

We now examine the accuracy of the algorithm. For every $1 \leq i \leq k$ and $u, v \in V$, let $\delta_i(u, v)$ be the value of $\hat{\delta}(u, v)$ after running **dijkstra** from all the vertices of

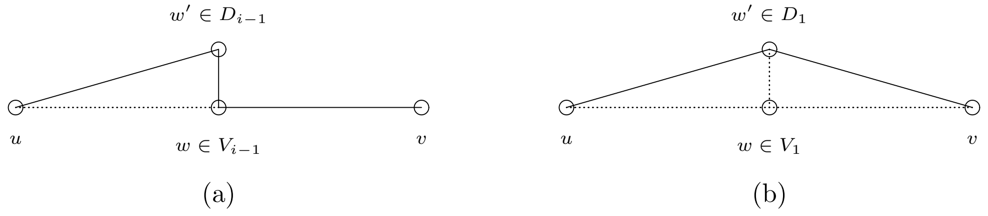

FIG. 3. (a) *Case* 2 *in the proof of Theorem* 3.1. (b) *Case* 1 *in the proof of Theorem* 4.1.

D_i. We now prove by induction on i that if $u \in D_i$ and $v \in V$, then $\delta(u,v) \le \delta_i(u,v) \le \delta(u,v) + 2(i-1)$. Recall that $D_k = V$. For every $u, v \in V$, we get that $\hat{\delta}(u,v) = \delta_k(u,v) \le \delta(u,v) + 2(k-1)$, as required.

Let $G_i(u) = (V, E_i(u))$ be the graph on which Dijkstra's algorithm is run from $u \in D_i$. For $i = 1$, the claim is clear, because for every $u \in D_1$ we have $G_1(u) = G$, and therefore $\delta_1(u,v) = \delta(u,v)$ for every $u \in D_1$ and $v \in V$. Suppose therefore that $i > 1$ and that the claim holds for $i-1$. Let $u \in D_i$ and let $v \in V$. Consider a shortest path p from u to v. We consider two cases.

Case 1. All the edges of p belong to E_i.

Because all the edges of p belong to E_i, they also belong to the graph $G_i(u)$ on which Dijkstra's algorithm is run from u. We get, therefore, that $\delta_i(u,v) = \delta(u,v)$ and we are done.

Case 2. Not all the edges of p belong to E_i.

Because the edges of E_i are edges that touch vertices that are not in V_{i-1}, there must be a vertex from V_{i-1} on the path p. (There must, in fact, be two consecutive vertices from V_{i-1} on the path p but we do not use this fact here.) Let w be the last vertex from V_{i-1} on the path p. Let p' be the subpath of p that connects w and v. Because all the vertices on p', except w, do not belong to V_{i-1}, all the edges of p' belong to E_i. Let $w' \in D_{i-1}$ be such that $(w, w') \in E^*$. The graph $G_i(u)$ contains the edge (w, w') and a weighted edge (u, w') whose weight is $\delta_{i-1}(u, w') = \delta_{i-1}(w', u)$ (see Figure 3(a)). By the induction hypothesis, $\delta_{i-1}(w', u) \le \delta(w', u) + 2(i-2) \le \delta(u,w) + (2i-3)$. As a consequence, we get that

$$\begin{aligned}\delta_i(u,v) &\le \delta_{i-1}(u,w') + \delta(w',w) + \delta(w,v)\\ &\le (\delta(u,w) + (2i-3)) + 1 + \delta(w,v)\\ &\le \delta(u,v) + 2(i-1)\ .\end{aligned}$$

This completes the proof of the theorem. ∎

Although the additive error of the estimated distances produced by $\mathbf{apasp}_k$ increases as k increases, we can show that the *stretch* of the estimated distances produced is always at most 3.

THEOREM 3.2. *For every* $2 \le k = O(\log n)$, *the running time of algorithm* $\mathbf{apasp}_k$ *is* $O(kn^{2-1/k}m^{1/k}(\log n)^{1-1/k})$, *and for every* $u, v \in V$ *we have* $\delta(u,v) \le \hat{\delta}(u,v) \le \min\{\,\delta(u,v) + 2(k-1)\,,\, 3\delta(u,v) - 2\,\}$.

Proof. We only have to show that for every $u, v \in V$ we have $\hat{\delta}(u,v) \le 3\delta(u,v) - 2$. All the rest follows from Theorem 3.1. We start with the following lemma.

LEMMA 3.3. *Let* p *be a path of length* ℓ *between* u *and* v, *where* $u \in D_i$. *If* $\delta_i(u,v) > \ell + 2r$, *then there are at least* $r+1$ *edges on the path* p *that do not belong to* $E_i \cup E^*$.

We prove this Lemma by induction on i. If $i = 1$, then $\delta_1(u, v) = \delta(u, v) \leq \ell$ and there is nothing to prove.

Suppose that the lemma is true for every $j < i$. Let p be a path of length ℓ between $u \in D_i$ and v, and suppose that $\delta_i(u, v) > \ell + 2r$. It follows that not all the edges of p belong to $E_i(u)$. This completes the proof if $r = 0$. Suppose therefore that $r > 0$. Let $e = (w_1, w_2)$ be the last edge on p that does not belong to $E_i(u)$. Let $1 \leq j < i$ be such that $w_2 \in V_j \setminus V_{j-1}$ (where $V_0 = \phi$). Since $w_2 \notin V_{j-1}$, we get that $e \in E_j$. Let $w_2' \in D_j$ such that $(w_2, w_2') \in E^*$. Let ℓ_1 and ℓ_2 be the distances from u to w_2 and from w_2 to v on p. Because $\delta_i(u, v) > \ell + 2r$ on the one hand, and $\delta_i(u, v) \leq \delta_j(w_2', u) + 1 + \ell_2$ on the other, we get that $\delta_j(w_2', u) > (\ell_1 + 1) + 2(r - 1)$. Let p' be the path from w_2' to u composed of the edge (w_2', w_2) and the portion of p from w_2 to u. According to the induction hypothesis, there must be at least r edges on p' that do not belong to $E_j \cup E^*$. Since $(w_2', w_2) \in E^*$, we get that all these r edges must be edges of p. Because $e \in E_j$, we get that e is not one of these edges. Since $e \notin E_i \cup E^*$, we get that there must be at least $r + 1$ edges on p that do not belong to $E_i \cup E^*$, as required. This completes the proof of the lemma.

Proof of Theorem 3.2. A path p of length ℓ may contain at most ℓ edges that do not belong to $E_k \cup E^*$. Thus, if p is a path of length ℓ connecting $u \in D_k$ and v, then it follows from Lemma 3.3 that $\hat{\delta}(u, v) \leq 3\ell$. Note that $D_k = V$. This is almost what we wanted to show, but not quite.

Consider again a path p of length ℓ between two vertices u and v. If at least one of the edges of p belongs to $E_k \cup E^*$, then Lemma 3.3 implies that $\hat{\delta}(u, v) \leq 3\ell - 2$. If the path p is of length one, i.e., $\ell = 1$, then $\hat{\delta}(u, v) = \delta(u, v) = 1 = 3\ell - 2$. Otherwise, we know that $e_1 = (u, u')$ and $e_2 = (v', v)$, the first and last edges on the path p, do not belong to $E_k \cup E^*$. As a consequence, we get that $u, v \in V_{k-1}$. Let $1 \leq j_1 < k$ and $1 \leq j_2 < k$ be such that $u \in V_{j_1} \setminus V_{j_1-1}$ and $v \in V_{j_2} \setminus V_{j_2-1}$ (where again $V_0 = \phi$). Assume, without loss of generality, that $j_2 \leq j_1$. For brevity, let $j = j_2$. Because $u, v \notin V_{j-1}$, we get that $e_1, e_2 \in E_j$. Let $w \in D_j$ such that $(v, w) \in E^*$. Let p' be the path from w to u composed of the edge (w, v) and the path p in reversed order. Since the number of edges on the path p' that do not belong to $E_j \cup E^*$ is at most $\ell - 2$, we get, by Lemma 3.3, that $\delta_j(w, u) \leq (\ell + 1) + 2(\ell - 2) = 3\ell - 3$. Thus, $\delta_k(u, v) \leq \delta_j(w, u) + 1 \leq 3\ell - 2$, as required. ☐

As an immediate corollary, we get that the estimated distances produced by $\mathbf{apasp}_k$ satisfy $\delta(u, v) \leq \hat{\delta}(u, v) \leq (3 - \frac{2}{k})\delta(u, v)$ for every $u, v \in V$. For $k = 2$, the distances are stretched by a factor of at most 2. For $k = 3$, the distances are stretched by a factor of at most 7/3. For any k, the distances are stretched by a factor of at most 3.

By taking $k = \Theta(\log n)$, we get an $\tilde{O}(n^2)$-time algorithm for finding stretch 3 approximate distances. An extension of this algorithm for weighted graphs is presented in [12].

4. Algorithm $\overline{\mathbf{apasp}}_{\boldsymbol{k}}$. In this section we present another family of algorithms, called $\overline{\mathbf{apasp}}_k$, for estimating all the distances in an unweighted and undirected graph with a small additive error. Algorithms from the family $\overline{\mathbf{apasp}}_k$ perform better than algorithms from the family $\mathbf{apasp}_k$ when the input graphs are sufficiently dense. For example, algorithms $\mathbf{apasp}_2$ and $\overline{\mathbf{apasp}}_3$ both produce estimated distances with an additive error of at most 2. Algorithm $\mathbf{apasp}_2$ runs in time $\tilde{O}(n^{3/2}m^{1/2})$ while algorithm $\overline{\mathbf{apasp}}_3$ runs in time $\tilde{O}(n^{7/3})$. Algorithm $\overline{\mathbf{apasp}}_3$ is therefore faster when $m \geq n^{5/3}$. We will show later that algorithm $\overline{\mathbf{apasp}}_k$ for $k > 3$ runs in $\tilde{O}(n^{2+1/k})$ time and produces estimates with an additive error of at most $2(\lfloor k/3 \rfloor + 1)$. Thus, algorithm

```
Algorithm $\overline{\mathbf{apasp}}_k$:

input: An unweighted undirected graph $G = (V, E)$.
output: A matrix $\{\hat{\delta}(u, v)\}_{u,v}$ of estimated distances.

For $i \leftarrow 1$ to $k - 1$ let $s_i \leftarrow n^{1-i/k}(\log n)^{i/k}$

$(\langle E_1, E_2, \ldots, E_k, E^*\rangle, \langle D_1, D_2, \ldots, D_k\rangle) \leftarrow \mathbf{decompose}(G, \langle s_1, s_2, \ldots, s_{k-1}\rangle)$

For every $u, v \in V$ do
    if $(u, v) \in E$ then $\hat{\delta}(u, v) \leftarrow 1$ else $\hat{\delta}(u, v) \leftarrow +\infty$

For $i \leftarrow 1$ to $k$ do
    For every $u \in D_i$ do
        run $\mathbf{dijkstra}(\,(V, E_i \cup E^* \cup (\{u\} \times V) \cup (\cup_{i+j_1+j_2 \le 2k+1} D_{j_1} \times D_{j_2}))\,, \hat{\delta}, u)$
```

FIG. 4. *An $\tilde{O}(n^{2+1/k})$-time algorithm for computing surplus $O(k)$ distances.*

$\overline{\mathbf{apasp}}_5$, for example, runs in $\tilde{O}(n^{11/5})$ time and provides estimated distances with a surplus of at most 4.

Algorithm $\overline{\mathbf{apasp}}_k$, given in Figure 4, is similar to algorithm $\mathbf{apasp}_k$. There are two main differences, however. The first is that the sequence of degree thresholds is this time $s_i = n^{1-i/k}(\log n)^{i/k}$ instead of $s_i = (m/n)^{1-i/k}(\log n)^{i/k}$. The second and more important one is that the edge set $E_i(u)$ of the graph $G_i(u) = (V, E_i(u))$ on which Dijkstra's algorithm is run from u during the ith iteration of the algorithm is now "reacher" than the corresponding set $E_i(u)$ used in $\mathbf{apasp}_k$. The set $E_i(u)$ is now composed of the following components:

$$E_i(u) \;=\; E_i \;\cup\; E^* \;\cup\; (\{u\} \times V) \;\cup\; \left(\bigcup_{i+j_1+j_2 \le 2k+1} D_{j_1} \times D_{j_2} \right).$$

Thus, in addition to edges used by $\mathbf{apasp}_k$, $\overline{\mathbf{apasp}}_k$ also uses edges from the set $D_{j_1} \times D_{j_2}$ for every $1 \le j_1, j_2 \le k$ such that $i + j_1 + j_2 \le 2k + 1$. Note, in particular, that for every $1 \le i \le k$ and every $u \in D_i$, we have

$$(V \times D_1) \cup (D_1 \times V) \subseteq E_i(u)\ .$$

(Recall that $D_k = V$.) As a further example, note that in $\overline{\mathbf{apasp}}_3$ we have

$$E_3(u) \;=\; E_i \;\cup\; E^* \;\cup\; (\{u\} \times V) \;\cup\; (D_1 \times D_3) \;\cup\; (D_2 \times D_2) \;\cup\; (D_3 \times D_1)\ .$$

We begin with the relatively simple analysis of $\overline{\mathbf{apasp}}_3$. The more complicated analysis of $\overline{\mathbf{apasp}}_k$ for $k > 3$ will then follow.

THEOREM 4.1. *Algorithm $\overline{\mathbf{apasp}}_3$ runs in $O(n^{7/3} \log^{2/3} n)$ time, where n is the number of vertices in the input graph $G = (V, E)$, and for every $u, v \in V$ we have $\delta(u, v) \le \hat{\delta}(u, v) \le \delta(u, v) + 2$.*

Proof. The fact that algorithm $\overline{\mathbf{apasp}}_3$ runs in $O(n^{7/3} \log^{2/3} n)$ time will follow from the analysis in the proof of Theorem 4.2. We show here that $\delta(u, v) \le \hat{\delta}(u, v) \le \delta(u, v) + 2$ for every $u, v \in V$.

It is again clear that $\delta(u,v) \le \hat{\delta}(u,v)$ for every $u,v \in V$. It remains to show therefore that $\hat{\delta}(u,v) \le \delta(u,v)+2$ for every $u,v \in V$. Let u and v be two vertices in G. Let p be a shortest path from u to v in G. We consider the following three cases.

Case 1. The shortest path p contains a vertex w from V_1.

Let $w' \in D_1$ such that $(w,w') \in E$ (see Figure 3(b)). (Note that we do not require $(w,w') \in E^*$, although we could.) Since $(V \times D_1) \cup (D_1 \times V) \subseteq E_3(u)$, the edges (u,w') and (w',v) belong to the graph on which Dijkstra's algorithm is run from u. The weights of these edges are $\delta(u,w')$ and $\delta(w',v)$, the distances found by running Dijkstra's algorithm on the original graph G from $w' \in D_1$. Note that $\delta(u,w') \le \delta(u,w)+1$ and $\delta(w',v) \le 1+\delta(w,v)$. By running Dijkstra's algorithm from u, we find therefore that

$$\hat{\delta}(u,v) \le \delta(u,w') + \delta(w',v) \le \delta(u,v)+2.$$

Case 2. The shortest path p contains vertices from V_2 but not from V_1.

This case is very similar to Case 1 in the proof of Theorem 3.1. Let w be the *last* vertex on the path that belongs to V_2. All the edges on the path from w to v touch vertices that do not belong to V_2 and therefore belong to the set E_3 and to the graph $G_3(u)$ on which Dijkstra's algorithm is run from u. Let $w' \in D_2$ be such that $(w,w') \in E^*$. The graph $G_3(u)$ contains weighted edges connecting u to all the vertices of V. It contains in particular a weighted edge (u,w'). The weight of this edge is the distance $\delta_2(u,w')$ between u and w' in the graph $G_2(w') = (V, E_2(w'))$, found by running Dijkstra's algorithm from $w' \in D_2$ on $G_2(w')$. Because all the edges on the path from u to w as well as (w,w') belong to $E_2(w')$, we get that $\delta_2(u,w') \le \delta(u,w)+1$. By running Dijkstra's algorithm from u we find therefore that

$$\hat{\delta}(u,v) \le \delta_2(u,w') + \delta(w',w) + \delta(w,v) \le \delta(u,v)+2.$$

Case 3. The shortest path p does not contain any vertex from V_2.

This shortest path is then contained in (V,E_3), and therefore $\hat{\delta}(u,v) = \delta(u,v)$. ◻

As mentioned above, the edge set $E_3(u)$ for every $u \in V$ contains the edge set $D_2 \times D_2$. A closer look at the proof of Theorem 4.1 reveals that we have not used this fact in the proof. The set $D_2 \times D_2$ plays, however, a central role in the proof of Theorem 6.3.

We now turn to the more complicated analysis of algorithm $\overline{\mathbf{apasp}}_k$ for $k \ge 3$. (The analysis below applies also for $k=2$, but for $k=2$, the bound in Theorem 4.1 is tighter.)

THEOREM 4.2. *For every $k \ge 2$, the running time of algorithm $\overline{\mathbf{apasp}}_k$ is $O(k^2 n^{2+1/k}(\log n)^{1-1/k})$, where n is the number of vertices in the input graph $G = (V,E)$, and for every $u,v \in V$ we have $\delta(u,v) \le \hat{\delta}(u,v) \le \delta(u,v) + 2(\lfloor k/3 \rfloor + 1)$.*

Proof. We start with the complexity analysis. It is easy to see that all the preparatory steps of the algorithm take $\tilde{O}(n^2)$ time. For every $1 \le i \le k$ and for every $u \in D_i$, we then run Dijkstra's algorithm from u on the graph $G_i(u) = (V, E_i(u))$. It is easy to verify that $|E_1| = O(n^2)$, $|E_i(u)| = O(kns_{i-1})$ for $2 \le i \le k$, and that $|D_i| = O(n \log n / s_i)$ for $1 \le i < k$, and $|D_k| = n$. A simple calculation, similar to the one in the beginning of the proof of Theorem 3.1, shows that the total running time of $\overline{\mathbf{apasp}}_k$ is $O(k^2 n^{2+1/k}(\log n)^{1-1/k})$. The running time of the algorithm can also be expressed as $O((kn)^2 \log n \cdot (n/\log n)^{1/k})$.

We now study the accuracy of the distance estimates produced by $\overline{\mathbf{apasp}}_k$. For every $1 \le i \le k$, we let $\delta_i(u,v)$ be the value of $\hat{\delta}(u,v)$ after running **dijkstra** from all the vertices of D_i. We now define recursively the sequence

$$e_{i_1,j,i_2} = \left\{ \begin{array}{cl} 0 & \text{if } \; i_1 \le j \\ 2 & \text{if } \; i_1 + j + i_2 \le 2k+1 \\ e_{i_1-1,j,i_1} + 2 & \text{otherwise} \end{array} \right\}$$

and prove by induction the following claim.

Claim. If $u \in D_{i_1}$ and $v \in D_{i_2}$ are connected by a path p of length ℓ in which the vertex of highest degree belongs to V_j, then $\delta_{i_1}(u,v) \le \ell + e_{i_1,j,i_2}$.

To prove the claim we use essentially the same arguments used in the proofs of Theorems 3.1 and 4.1.

If $i_1 \le j$, then all the edges on the path p are contained in $E_{i_1}(u)$ and therefore $\delta_{i_1}(u,v) \le \ell$, as required.

Suppose now that $i_1 + j + i_2 \le 2k+1$ and that $j < i_1$. This means that $D_j \times D_{i_2} \subseteq E_{i_1}(u)$. Let w be a vertex on p that belongs to V_j. Let ℓ_1 be the distance from u to w on the path p. Let ℓ_2 be the distance from w to v on the path p. Clearly $\ell = \ell_1 + \ell_2$. Let $w' \in D_j$ such that $(w,w') \in E^*$. It is easy to see that $\delta_j(u,w') \le \ell_1 + 1$ and $\delta_j(w',v) \le \ell_2 + 1$. Because $(u,w'),(w',v) \in E_{i_1}(u)$, we get that $\delta_{i_1}(u,v) \le \ell + 2$, as required.

Finally, suppose that $i_1 + j + i_2 > 2k+1$ and that $j < i_1$. Since $j < i_1$, we get that $V_j \subseteq V_{i_1-1}$. Let w be the *last* vertex on p that belongs to V_{i_1-1}. Let $w' \in D_{i_1-1}$ such that $(w,w') \in E^*$. Let ℓ_1 and ℓ_2 be, as before, the distances from u to w and from w to v on p. Consider the path p' composed of the edge (w',w) and the portion of the path p from w to u. The path p' starts at $w' \in D_{i_1-1}$ and ends at $u \in D_{i_1}$, and the vertex of highest degree on it belongs to V_j. The length of p' is $\ell_1 + 1$. By applying the claim inductively to p', we get that $\delta_{i_1-1}(w',u) \le \ell_1 + 1 + e_{i_1-1,j,i_1}$. Because w is the last vertex from v_{i_1-1} on p, all the edges on the portion of p from w to v belong to $E_{i_1}(u)$. The set $E_{i_1}(u)$ also contains the edge $(w',w) \in E^*$ and a weighted edge (u,w') of weight $\delta_{i_1-1}(w',u) = \delta_{i_1-1}(u,w')$. After running **dijkstra** from u on $(V, E_i(u))$, we get $\delta_{i_1}(u,v) \le (\ell_1 + 1 + e_{i_1-1,j,i_1}) + (1 + \ell_2) = \ell + (e_{i_1-1,j,i_1} + 2) = \ell + e_{i_1,j,i_2}$, as required. This completes the proof of the claim.

Now let $e_{i,j} = e_{i,j,i+1}$. It is easy to verify that

$$e_{i,j} = \left\{ \begin{array}{cl} 0 & \text{if } \; i \le j \\ 2 & \text{if } \; 2i + j \le 2k \\ e_{i-1,j} + 2 & \text{otherwise} \end{array} \right\} .$$

It is not difficult to unwind this recursion and get that

$$e_{i,j} = \left\{ \begin{array}{cl} 0 & \text{if } \; i \le j \\ 2 & \text{if } \; 2i + j \le 2k \\ \min\{\, 2(i-j)\, ,\, 2(i - k + \lceil \frac{j}{2} \rceil + 1)\,\} & \text{otherwise} \end{array} \right\} .$$

Finally, we get

$$e_{k,j,k} = \left\{ \begin{array}{cl} 0 & \text{if } \; j = k \\ 2 & \text{if } \; j = 1 \\ e_{k-1,j} + 2 & \text{otherwise} \end{array} \right\} = \left\{ \begin{array}{cl} 0 & \text{if } \; j = k \\ 2 & \text{if } \; j = 1 \\ \min\{\, 2(k-j)\, ,\, 2\lceil \frac{j}{2} \rceil + 2\,\} & \text{otherwise} \end{array} \right\} .$$

It is now not difficult to verify that for every $1 \le j \le k$, we have $e_{k,j,k} \le 2(\lfloor k/3 \rfloor + 1)$. Because $D_k = V$, this completes the proof of the theorem. $\square$

To get an additive error of at most k, where $k > 2$ is even, we can use either algorithm $\mathbf{apasp}_{k/2+1}$, whose running time is $\tilde{O}(n^{2-2/(k+2)}m^{2/(k+2)})$, or algorithm $\overline{\mathbf{apasp}}_{(3k-2)/2}$, whose running time is $\tilde{O}(n^{2+2/(3k-2)})$. The combination of these two algorithms is the algorithm $\mathbf{APASP}_k$ mentioned in the abstract.

We can easily get a randomized version of algorithm $\overline{\mathbf{apasp}}_3$ which has the property that *all* reported distances greater than $n^{2/3}$ are, with high probability, correct. Similarly, we can get a randomized version of $\mathbf{apasp}_2$ for which all reported distances greater than $n^{3/2}/m^{1/2}$ are, with high probability, correct. We use the following simple observation (a similar idea is used by Ullman and Yannakakis [31]).

THEOREM 4.3. *Let $G = (V, E)$ be a weighted directed graph with n vertices and m edges. Let $1 \le s \le n$. There is an $O(n^3 \log n/s)$-time randomized algorithm that finds, with high probability, the exact distance between any pair of vertices connected by a shortest path that uses at least s edges.*

Proof. Let D be a random set of vertices obtained by picking each vertex independently with probability $(c \log n)/s$ for some large enough $c > 0$. The expected size of D is $O(n \log n/s)$. Run Dijkstra's algorithm from each vertex of D in both G and the graph obtained from G by reversing the edges. The complexity of this step is $O(nm \log n/s)$. For every $u \in D$ and $v \in V$, we now know $\delta(u, v)$ and $\delta(v, u)$ exactly. For every pair of vertices $u, v \in V$, let $\hat{\delta}(u, v) = \min_{w \in D}\{\delta(u, w) + \delta(w, v)\}$. The complexity of this step is $O(n^3 \log n/s)$. It is easy to see that $\hat{\delta}(u, v) = \delta(u, v)$ if and only if there is a shortest path between u and v that passes through a vertex of D. If there is a shortest path between u and v of length s, then with high probability, at least one of the vertices on the path will belong to D. Since there are $O(n^2)$ pairs of vertices connected by shortest paths that use at most s edges, and since we can focus on one such path for each pair, we get that, with high probability, each one of these $O(n^2)$ paths will pass through a vertex of D, and the exact distances between all these pairs will be found. ∎

It follows that if the set D_1 in algorithm $\overline{\mathbf{apasp}}_3$ is chosen at random by picking each element with probability $cn^{-2/3} \log n$, then, with high probability, if $\delta(u, v) \ge n^{2/3}$, then $\hat{\delta}(u, v)$ is the exact distance between u and v. Long distances are therefore easier to compute.

5. Boolean matrix multiplication.

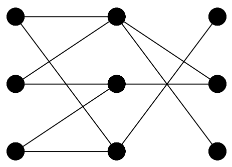
Let A and B be two Boolean $n \times n$ matrices. Construct a graph $G_{A,B} = (V, E)$ with

$$V = \{u_1, \dots, u_n\} \cup \{v_1, \dots, v_n\} \cup \{w_1, \dots, w_n\} ,$$
$$E = \{(u_i, v_k) \mid a_{ik} = 1\} \cup \{(v_k, w_j) \mid b_{kj} = 1\} .$$

The graph corresponding to two 3×3 matrices is depicted in Figure 5. Let $C = A \times B$ (Boolean matrix multiplication). Clearly, $c_{ij} = 1$ if and only if $\delta_G(u_i, w_j) = 2$. Furthermore, because the graph $G_{A,B}$ is bipartite, $c_{ij} = 1$ if and only if $\delta_G(u_i, w_j) \le 3$. As a consequence we get the following result.

THEOREM 5.1. *If all the distances in an undirected n-vertex graph can be approximated with a one-sided additive error of at most 1 in $O(A(n))$ time, then Boolean matrix multiplication can also be performed in $O(A(n))$ time.*

By adding a disjoint path of length $k - 2$ ending at each u_i, we get that, for any *fixed* $k \ge 2$, distinguishing between distance k and $k + 2$ in graphs with n vertices, i.e., deciding for each pair of vertices u, v whether $\delta(u, v) \le k$ or $\delta(u, v) \ge k + 2$ (if $\delta(u, v) = k + 1$, then either decision is fine), is at least as hard as multiplying two Boolean matrices of size $n \times n$. Note, in contrast, that if $k \ge n^{2/3}$, then by



$$\begin{pmatrix}1 & 0 & 1\\ 1 & 1 & 0\\ 0 & 1 & 1\end{pmatrix} \times \begin{pmatrix}0 & 1 & 1\\ 0 & 1 & 0\\ 1 & 0 & 0\end{pmatrix}$$

FIG. 5. *Boolean matrix multiplication.*

Theorem 4.3 we can distinguish, with high probability, between distances k and $k+2$ in graphs with n vertices in $\tilde{O}(n^{7/3})$ time, i.e., faster than the fastest known matrix multiplication algorithm.

Similarly, because any approximation algorithm that finds approximated distances of stretch strictly less than 2 can distinguish between distance 2 and distance 4, getting approximate distances of stretch *less* than 2 between all pairs of vertices is also as hard as Boolean matrix multiplication.

By turning the graph $G_{A,B}$ into a directed graph, where edges are directed to the right, we get that $c_{ij} = 1$ if and only if $\delta_G(u_i, w_j) < \infty$. Approximating distances in *directed* graphs to within any *multiplicative* factor, not necessarily bounded, is therefore as hard as Boolean matrix multiplication. Note that such an approximation is equivalent to the computation of the *transitive closure* of the graph. It is proved in [1] (see Theorems 5.6 and 5.7) that the computation of the transitive closure of a directed graph is equivalent to Boolean matrix multiplication. We end this section with another simple observation.

THEOREM 5.2. *If two $n \times n$ Boolean matrices could be multiplied in $O(M(n))$ time, then for any fixed $\epsilon > 0$, all the distances in an unweighted directed graph on n vertices can be estimated with stretch $1+\epsilon$ in $\tilde{O}(M(n))$ time.*

Proof. Let $G = (V, E)$ be an unweighted directed graph on n vertices. Let A be the adjacency matrix of the graph with self-loops added to all the vertices. Note that $\delta_G(u, v) \le d$ if and only if $(A^d)_{u,v} = 1$. Let $r_i = \lfloor (1+\epsilon)^i \rfloor$ for $1 \le i \le k = \lceil \log_{1+\epsilon} n \rceil$. We compute A^{r_i} for $1 \le i \le k$. We let $\hat{\delta}(u, v) = r_{i+1}$ if and only if $(A^{r_i})_{u,v} = 0$ but $(A^{r_{i+1}})_{u,v} = 1$. It is easy to verify that for every $u, v \in V$ we have $\delta(u, v) \le \hat{\delta}(u, v) \le (1+\epsilon) \cdot \delta(u, v)$, and that the running time of this algorithm is $\tilde{O}(M(n))$. $\square$

6. Distance emulators.

6. Distance emulators. Closely related to the algorithms of sections 3 and 4 is the notion of emulators.

DEFINITION 6.1 (emulators). *Let $G = (V, E)$ be an unweighted undirected graph. A weighted graph $H = (V, F)$ is said to be a k-*emulator *of G if and only if for every $u, v \in V$ we have $\delta_G(u, v) \le \delta_H(u, v) \le \delta_G(u, v) + k$.*

There is a fundamental difference, however, between emulators and the auxiliary graphs used in the algorithms of sections 3 and 4. There, we constructed for each vertex u an auxiliary graph $G_k(u)$ that supplied good approximations to the distances from u to all the vertices of the graph. Here we want a *single* graph that will supply good approximations of *all* distances. Constructing a sparse k-emulator is therefore harder than computing surplus k distances.

The definition of k-emulators is related to the definition of *k-spanners* (Awerbuch [6], Peleg and Schäffer [27]). Let $G = (V, E)$ be a weighted undirected graph. A subgraph $G' = (V, E')$ of G is said to be a k-spanner of G if and only if for every

$u, v \in V$ we have $\delta_{G'}(u,v) \leq k \cdot \delta_G(u,v)$. Since G' is a subgraph of G, we always have $\delta_G(u,v) \leq \delta_{G'}(u,v)$. This definition differs from the definition of emulators in three respects. We require additive error, not multiplicative error. We do not insist on getting a subgraph of the original graph and we allow weighted edges. Althöfer et al. [5] also consider *Steiner spanners* in which vertices and edges may be added to the graph. Steiner spanners are more closely related to emulators. Liestman and Shermer [24] consider *additive spanners*. They are able, however, to obtain sparse additive spanners only for specific graphs such as pyramids, grids, and hypercubes. Additive spanners, unlike emulators, must be subgraphs of the original graph. Emulators may be described as weighted additive Steiner spanners. The definition of k-emulators is also related to the definition of *hop sets* (Cohen [10]).

Implicit in the work of Aingworth et al. [2] is an $\tilde{O}(n^{5/2})$-time algorithm for constructing 2-emulators with $\tilde{O}(n^{3/2})$ edges. We can get the following slightly stronger result.

THEOREM 6.2. *Every unweighted undirected graph $G = (V, E)$ on n vertices can be 2-emulated by a* subgraph *$G' = (V, F)$ with $O(n^{3/2}(\log n)^{1/2})$ edges. Such a subgraph can be constructed in $O(n^2 \log^2 n)$ time.*

Proof. We start by proving the existence of such an emulator. Split the vertices of G into two classes: $V_1 = \{v \in V \mid \deg(v) \geq (n \log n)^{1/2}\}$ and $V_2 = \{v \in V \mid \deg(v) < (n \log n)^{1/2}\}$. Find a set D of size $O((n \log n)^{1/2})$ that dominates V_1 and a set E^* of at most n edges such that for every $u \in V_1$ there exists $v \in D$ such that $(u, v) \in E^*$. From every $v \in D$ perform a BFS and find its distances to all the vertices of the graph. A 2-emulator of G of size $O(n^{3/2}(\log n)^{1/2})$ is then obtained by taking all edges that touch vertices of V_2 and weighted edges between any vertex of D and any vertex of V. Instead of adding these weighted edges, we can simply take a tree of shortest paths rooted at each vertex of D. The total number of edges is still $O(n^{3/2}(\log n)^{1/2})$. It is easy to check that the resulting subgraph is a 2-emulator. The proof is similar to the proofs of Theorems 3.1 and 4.1.

The above construction can be carried out in $O(n^{5/2}(\log n)^{1/2})$ time. The most time-consuming task is running BFS from all the vertices of D. To reduce the running time to $\tilde{O}(n^2)$, we split the vertices into $O(\log n)$ classes instead of just two. (A similar idea is used in [2].) The resulting algorithm $\mathbf{emul}_2$ is given in Figure 6. Note that s_{k-1}, the last degree threshold in $\mathbf{emul}_2$, is about $(n \log n)^{1/2}$.

It is easy to see that the running time of $\mathbf{emul}_2$ is $O(\sum_{i=1}^{k-1} |D_i| \cdot |E_i|) = O(n^2 \log n \cdot \sum_{i=1}^{k-1} s_{i-1}/s_i) = O(n^2 \log^2 n)$, and that the number of edges in the set F produced by $\mathbf{emul}_2$ is $O(|E_k| + n \cdot \sum_{i=1}^{k} |D_i|) = O(n^{3/2}(\log n)^{1/2})$.

All that remains is to show that $G' = (V, F)$ is indeed a 2-emulator of G. Note that $G' = (V, F)$ is a subgraph of $G = (V, E)$. This immediately implies that $\delta_G(u,v) \leq \delta_{G'}(u,v)$ for every $u, v \in V$. We have to show that $\delta_G(u,v) \leq \delta_{G'}(u,v) \leq \delta_G(u,v) + 2$ for every $u, v \in V$. As usual, we consider two different cases.

Case 1. There is a shortest path between u and v in G all of whose edges are contained in E_k.

In this case, $\delta_{G'}(u,v) = \delta_G(u,v)$.

Case 2. Every shortest path between u and v in G contains edges that are not contained in E_k.

Consider a shortest path p between u and v in G. Let w be a vertex of highest degree on p. Let $1 \leq i < k$ be such that $w \in V_i \setminus V_{i-1}$ (where $V_0 = \phi$). Let $w' \in D_i$ be such that $(w, w') \in E$. Because all the vertices on p do not belong to V_{i-1}, we get that all the edges on p as well as the edge (w, w') belong to E_i. The shortest

```
Algorithm emul_2:

input: An unweighted undirected graph $G = (V, E)$.
output: A subgraph 2-emulator $(V, F)$ of $G$.

Let $k \leftarrow \lceil \frac{1}{2} \log_2(n/\log_2 n) \rceil$
For $i \leftarrow 0$ to $k-1$ let $s_i \leftarrow n/2^i$

$(\langle E_1, E_2, \ldots, E_k, E^* \rangle, \langle D_1, D_2, \ldots, D_k \rangle) \leftarrow$ decompose$(G, \langle s_1, s_2, \ldots, s_{k-1} \rangle)$

For $i \leftarrow 1$ to $k-1$ do
For every $u \in D_i$ run bfs$(\,(V, E_i)\,, \hat{\delta}, u)$

The edge set $F$ is composed of $E_k$ and the edges
of all the shortest paths trees found in all the BFS runs.
```

FIG. 6. *An $\tilde{O}(n^2)$-time algorithm for generating a subgraph 2-emulator.*

paths tree constructed by running BFS on (V, E_i) from w' contains therefore a path from w' to u of length at most $\delta_G(u, w) + 1$ and a path from w' to v of length at most $\delta_G(w, v) + 1$. It follows that this shortest paths tree, and therefore $G' = (V, F)$, contains a path from u to v of length at most $\delta_G(u, v) + 2$.

This completes the proof of the theorem. $\square$

A subgraph 2-emulator is also an additive 2-spanner and a multiplicative 3-spanner. In section 7 (Theorem 7.3) we show that weighted graphs also have 3-spanners of size $\tilde{O}(n^{3/2})$. We present there an algorithm whose running time is $\tilde{O}(mn^{1/2})$ for finding such 3-spanners. Because there are bipartite graphs with $\Omega(n^{3/2})$ edges that do not contain cycles of length four [32], this result is tight up to polylogarithmic factors. We can also show the following result.

THEOREM 6.3. *Every unweighted undirected graph $G = (V, E)$ on n vertices has a 4-emulator with $\tilde{O}(n^{4/3})$ edges. Such a graph can be constructed in $\tilde{O}(n^{7/3})$ time.*

Proof. It is not difficult to check that the graph $G_3 = (V, E_3 \cup E^* \cup (D_1 \times V) \cup (D_2 \times D_2) \cup (V \times D_1))$, in the notations of algorithm $\overline{\textbf{apasp}}_3$, is a 4-emulator of $G = (V, E)$. $\square$

It is tempting to claim that k-emulators for $k > 4$ can be similarly obtained by running $\overline{\textbf{apasp}}_k$ with $k > 4$. Unfortunately, this is not true. The fact that all the edges that touch a vertex u are added to the graph on which distances are found from u seems to be crucial there. We cannot do the same with emulators because we are supposed to use the same graph for all sources.

Let e_k be the infimum of all numbers for which each graph on n vertices has a k-emulator with $\tilde{O}(n^{1+e_k})$ edges. We have shown that $e_2 \leq 1/2$ and $e_4 \leq 1/3$. Does $e_k \to 0$ as $k \to \infty$? This remains an intriguing open problem.

We are not able to construct emulators with $o(n^{4/3})$ edges. We can, however, construct 6-emulators with $\tilde{O}(n^{4/3})$ edges in $\tilde{O}(n^2)$ time.

THEOREM 6.4. *Let $G = (V, E)$ be an unweighted undirected graph of n vertices. A 6-emulator of G with $O(n^{4/3}(\log n)^{2/3})$ edges can be constructed in $O(n^2 \log^2 n)$ time.*

Proof. The required 6-emulator is generated by algorithm **emul**$_6$ given in Figure 7. Algorithm **emul**$_6$ is similar to algorithm **emul**$_2$. Note that s_k, the last degree

```
Algorithm emul_6:

input: An unweighted undirected graph $G = (V, E)$.
output: A 6-emulator $(V, F)$ of $G$.

Let $k \leftarrow \lceil \frac{2}{3} \log_2(n/\log_2 n) \rceil$
For $i \leftarrow 0$ to $k-1$ let $s_i \leftarrow n/2^i$

$(\langle E_1, E_2, \ldots, E_k, E^* \rangle, \langle D_1, D_2, \ldots, D_k \rangle) \leftarrow$ decompose$(G, \langle s_1, s_2, \ldots, s_{k-1} \rangle)$

For every $u, v \in V$ do
if $(u, v) \in E$ then $\hat{\delta}(u, v) \leftarrow 1$ else $\hat{\delta}(u, v) \leftarrow +\infty$

For $i \leftarrow 1$ to $k-1$ do
For every $u \in D_i$ run bfs$(\,(V, E_i \cup E^*)\,\hat{\delta}, u)$

Let $F \leftarrow E_k \cup E^* \cup_{i=1}^{k-1} D_i \times D_{k-1}$
The weight of an edge $(u, v) \in F$ is $\hat{\delta}(u, v)$
```

FIG. 7. *An $\tilde{O}(n^2)$-time algorithm for generating a 6-emulator.*

threshold in **emul**$_6$, is about $n^{1/3}(\log n)^{2/3}$.

It is straightforward to verify that **emul**$_6$ runs in $O(n^2 \log^2 n)$ time and that the edge set F is of size $O(n^{4/3}(\log n)^{2/3})$. All that remains is to show that $H = (V, F)$ is a 6-emulator of G. We have to show that for every $u, v \in V$ we have $\delta_G(u, v) \le \delta_H(u, v) \le \delta_G(u, v) + 6$. Let $u, v \in V$. The fact that $\delta_G(u, v) \le \delta_H(u, v)$ is obvious. Let p be a shortest path from u to v in G. We again consider two cases.

Case 1. All the edges of p are contained in E_k.

In this case, $\delta_H(u, v) = \delta_G(u, v)$.

Case 2. The path p contains edges that do not belong to E_k.

The path p must pass through at least two vertices from V_{k-1}. Let w_1 and w_3 be the first and last such vertices on the path (the vertex w_1 may be u and the vertex w_3 may be v). Let w_2 be a vertex with the maximum degree on the path (the vertex w_2 may be one of w_1 and w_3). Let $1 \le i < k$ be such that $w_2 \in V_i \setminus V_{i-1}$. Let $w'_1, w'_3 \in D_{k-1}$ be neighbors of w_1 and w_3 such that $(w_1, w'_1) \in E^*$ and $(w_3, w'_3) \in E^*$. Let $w'_2 \in D_i$ be a neighbor of w_2 such that $(w_2, w'_2) \in E^*$.

Because w_1 and w_3 are the first and last vertices from V_{k-1} on the path, and because $(w_1, w'_1), (w_3, w'_3) \in E^*$, we get that $\delta_H(u, w'_1) \le \delta_G(u, w_1) + 1$ and $\delta_H(w'_3, v) \le \delta_G(w_3, v) + 1$. Since w_2 is a vertex with maximum degree on the shortest path from u to v, the shortest path p and the edges $(w_1, w'_1), (w_2, w'_2), (w_3, w'_3)$ are contained in the graph $G_i = (V, E_i \cup E^*)$. We get, therefore, that $\delta_G(w_1, w_2) = \delta_{G_i}(w_1, w_2)$ and $\delta_G(w_2, w_3) = \delta_{G_i}(w_2, w_3)$ and thus $\delta_{G_i}(w'_1, w'_2) \le \delta_G(w_1, w_2) + 2$ and $\delta_{G_i}(w'_2, w'_3) \le \delta_G(w_2, w_3) + 2$. For every $x \in D_i$ and $y \in D_k$, we have added to F an edge (x, y) whose weight is at most $\delta_{G_i}(x, y)$. We get therefore that $\delta_H(w'_1, w'_2) \le \delta_G(w_1, w_2) + 2$ and $\delta_H(w'_2, w'_3) \le \delta_G(w_2, w_3) + 2$. Combining these bounds we get

$$\begin{aligned}\delta_H(u, v) &\le \delta_H(u, w'_1) + \delta_H(w'_1, w'_2) + \delta_H(w'_2, w'_3) + \delta_H(w'_3, v) \\ &\le (\delta_G(u, w_1) + 1) + (\delta_G(w_1, w_2) + 2) + (\delta_G(w_2, w_3) + 2) + (\delta_G(w_3, v) + 1) \\ &= \delta_G(u, v) + 6.\end{aligned}$$

This completes the proof of the theorem. □

It is easy to see that k-emulators are Steiner $(k{+}1)$-spanners. It follows easily from the arguments of Althöfer et al. [5] and the constructions of Wenger [32] that there are unweighted undirected graphs on n vertices for which every Steiner 3-spanner, and therefore any 2-emulator, must have $\tilde{\Omega}(n^{3/2})$ edges, and there are graphs for which every Steiner 5-spanner, and therefore any 4-emulator, must have $\tilde{\Omega}(n^{4/3})$ edges (where $\tilde{\Omega}(f) = \Omega(f\,/\,\mathrm{polylog}\,n)$).

7. Stretched paths and distances.

In this section we describe algorithms for finding stretched paths in *weighted* graphs. We use the following result which is part of the folklore.

LEMMA 7.1 (truncated Dijkstra). *Let $G = (V, E)$ be a weighted graph on n vertices. Suppose that the adjacency lists of the vertices of G are sorted according to weight. Let $v \in V$ be a vertex of G and let $1 \le s \le n$. Shortest paths from v to s vertices closest to v can be found in $O(s(s + \log n))$ time.*

The set of s vertices returned by the truncated Dijkstra algorithm running from v is not uniquely defined, since there may be many vertices at the same distance from v. All that we require is that if S is the set of vertices returned by the algorithm then for every $u \in S$ and $w \in V \setminus S$ we have $\delta(v, u) \le \delta(v, w)$.

THEOREM 7.2. *Let $G = (V, E)$ be a weighted undirected graph with n vertices and m edges. We can preprocess the graph in $O((m \log n)^{2/3} n)$ time so that given any two vertices $u, v \in V$, we can in $O(1)$ time output an estimated distance $\hat{\delta}(u, v)$ satisfying $\delta(u, v) \le \hat{\delta}(u, v) \le 3{\cdot}\delta(u, v)$.*

Proof. Let $s \ge \log n$ be a parameter to be chosen later. We run the truncated Dijkstra algorithm from every vertex $v \in V$ and find a set $N(v)$ of s vertices closest to v. The time required for finding these sets is $O(ns^2)$. Next, we find a set D of size $d = O(n \log n/s)$ so that for every $v \in V$ there is $u \in D$ such that $u \in N(v)$. Such a set can be found in $O(ns)$ time. For every vertex $v \in V$, we keep a pointer to a vertex $u = P(v)$ such that $u \in D \cap N(v)$. We now run the full Dijkstra algorithm from all the vertices of D. The time required is $O(nm \log n/s)$. We keep a $d \times n$ matrix with the distances from the vertices of D to all the other vertices of the graph. The time used so far is $O(ns^2 + nm \log n/s)$. This is minimized by taking $s = (m \log n)^{1/3}$. The total time is then $O((m \log n)^{2/3} n)$.

Given a pair of vertices u and v, we first check whether $v \in N(u)$. If so, we output the exact distance $\delta(u, v)$ computed during the truncated Dijkstra from u. Otherwise, we let $w = P(u) \in D \cap N(u)$ and we output the estimated distance $\hat{\delta}(u, v) = \delta(u, w) + \delta(w, v)$. The distance $\delta(u, w)$ was found during the truncated Dijkstra from u. The distance $\delta(w, v)$ was found during the full Dijkstra from w.

Clearly $\delta(u, v) \le \hat{\delta}(u, v)$. If $v \in N(u)$, then $\hat{\delta}(u, v) = \delta(u, v)$. If $v \notin N(u)$, then $\delta(u, w) \le \delta(u, v)$ and the estimate $\hat{\delta}(u, v)$ satisfies

$$\begin{aligned}\hat{\delta}(u, v) &= \delta(u, w) + \delta(w, v)\\ &\le \delta(u, w) + (\delta(w, u) + \delta(u, v))\\ &\le 2\delta(u, w) + \delta(u, v) \;\le\; 3\delta(u, v),\end{aligned}$$

as required. □

Using essentially the same algorithm we can get the following result.

THEOREM 7.3. *Every weighted undirected graph $G = (V, E)$ on n vertices has a 3-spanner with $O(n^{3/2}(\log n)^{1/2})$ edges. Such a 3-spanner can be constructed in $\tilde{O}(m(n \log n)^{1/2})$ time.*

Proof. Let s be a parameter to be chosen later. Run the truncated Dijkstra algorithm from every vertex and find for every vertex $v \in V$ a set $N(v)$ of s vertices closest to v. Find a set D of size $O(n \log n/s)$ such that for every $v \in V$, there is a $u \in D \cap N(v)$. We then run a full Dijkstra from every vertex of D. The 3-spanner will be composed of the shortest paths trees found in all the truncated and full runs of Dijkstra's algorithm. The total number of edges will therefore be $O(ns + n^2 \log n/s)$. We choose $s = (n \log n)^{1/2}$. The number of edges in the 3-spanner is then $O(n^{3/2}(\log n)^{1/2})$ and the total running time is $O(ns^2 + nm \log n/s) = O(n^2 \log n + m(n \log n)^{1/2})$. Note that if $m(n \log n)^{1/2} \le n^2 \log n$, then $m \le n^{3/2}(\log n)^{1/2}$ and the original graph is the required 3-spanner. ▯

Cohen and Zwick [12] extend the techniques presented here and obtain, among other things, an $\tilde{O}(n^2)$-time algorithm for finding stretch 3 distances, and an algorithm whose running time is $\tilde{O}(n^{3/2}m^{1/2})$ for finding stretch 2 distances in weighted undirected graphs with n vertices and m edges.

8. Concluding remarks and open problems.

We have shown that surplus 2 estimates of all distances in an unweighted undirected graph on n vertices can be computed in $\tilde{O}(n^{7/3})$ time, i.e., faster than the fastest known matrix multiplication algorithm. Many open problems still remain. We end by mentioning some of them:

1. Is it possible to find surplus 2 estimated distances between all pairs of vertices in a graph on n vertices in $O(n^{7/3-\epsilon})$ time for some $\epsilon > 0$?
2. Is it possible to find surplus k estimated distances between all pairs of vertices in a graph on n vertices, for some fixed constant $k \ge 2$, in $\tilde{O}(n^2)$ time?
3. Do there exist fixed constants $k \ge 2$ and $\epsilon > 0$ such that every graph on n vertices has a k-emulator with $O(n^{4/3-\epsilon})$ edges?
4. Is it possible to find the *exact* distances between all pairs of vertices in an unweighted *directed* graph on n vertices in $\tilde{O}(M(n))$ time, where $M(n)$ is the time needed to multiply two $n \times n$ matrices?

Acknowledgments. We would like to thank Howard Karloff for some helpful discussions, Edith Cohen and David Peleg for some clarifications regarding their papers, and the two anonymous referees whose comments helped improve the presentation of the paper.

IMPROVED DATA STRUCTURES FOR FULLY DYNAMIC BICONNECTIVITY[*]

MONIKA R. HENZINGER[†]

Abstract. We present fully dynamic algorithms for maintaining the biconnected components in general and plane graphs.

A fully dynamic algorithm maintains a graph during a sequence of insertions and deletions of edges or isolated vertices. Let m be the number of edges and n be the number of vertices in a graph. The time per operation of the best deterministic algorithms is $O(\sqrt{n})$ in general graphs and $O(\log n)$ in plane graphs for fully dynamic connectivity and $O(\min\{m^{2/3}, n\})$ in general graphs and $O(\sqrt{n})$ in plane graphs for fully dynamic biconnectivity. We improve the later running times to $O(\sqrt{m \log n})$ in general graphs and $O(\log^2 n)$ in plane graphs. Our algorithm for general graphs can also find the biconnected components of all vertices in time $O(n)$.

Key words. dynamic graph algorithms, biconnectivity, data structures

1. Introduction.

Many computing activities require the recomputation of a solution after a small modification of the input data. Thus algorithms are needed that update an old solution in response to a change in the problem instance. *Dynamic graph algorithms* are data structures that, given an input graph G, maintain the solution of a graph problem in G while G is modified by insertions and deletions of edges.[1] In this paper we study the problem of maintaining the biconnected components (see below) of a graph.

We say that a vertex x is an *articulation point separating* vertex u and vertex v (or that x separates u and v) if the removal of x disconnects u and v. Two vertices are *biconnected* if there is no articulation point separating them. In the same way, an edge e is a *bridge separating* vertex u and vertex v if the removal of e disconnects u and v. Two vertices are 2-*edge connected* if there is no bridge separating them. A *biconnected component* or *block* (resp., 2-*edge connected component*) of a graph is a maximal set of vertices that are biconnected (resp., 2-edge connected). Note that biconnectivity implies 2-edge connectivity but not vice versa.

Given a graph $G = (V, E)$, a *dynamic biconnectivity algorithm* is a data structure that executes an arbitrary sequence of the following operations:

insert(u, v): Insert an edge between node u and node v.
delete(u, v): Delete the edge between node u and node v if it exists.
query(u, v): Returns *yes* if u and v are biconnected, and *no* otherwise.
complete-*block*-*query*: Return for all nodes all the blocks they belong to.

Operations *insert* and *delete* are called *updates*. To compare the asymptotic performance of dynamic graph algorithms, the time per update, called *update time*, and the time per query, called *query time*, are compared. Let m be the number of edges

[1]Insertions or deletions of isolated vertices are usually trivial.

and n be the number of vertices in the graph. Prior to this work, the best update time was $O(\min(m^{2/3}, n))$ [11, 2] with a constant query time. This paper presents an algorithm with $O(\sqrt{m \log n})$ update time and constant query time. Subsequently, the sparsification technique was applied to the algorithm in this paper and its running time was improved to $O(\sqrt{n \log n} \log(m/n))$ [13]. Recently, a data structure that requires only polylogarithmic amortized time per operation was presented [15]. The data structure presented in this paper can answer complete-block-queries in time $O(n)$. This was not mentioned explicitly but can also be done with the data structure in [11, 2].

Additionally, we give an algorithm with $O(\log^2 n)$ update time and $O(\log n)$ query time for planar embedded graphs, under the condition that each insertion maintains the planarity of the embedding. The best previous algorithm took time $O(\sqrt{n})$ per update and $O(\log n)$ per query.

Related work. Frederickson [5] gave the first dynamic graph algorithm for maintaining a minimum spanning tree and the connected components. His algorithm takes time $O(\sqrt{m})$ per update and $O(1)$ per query operation. The first dynamic 2-edge connectivity algorithm by Galil and Italiano [8] took time $O(m^{2/3})$ per update and query operation. It was consequently improved to $O(\sqrt{m})$ per update and $O(\log n)$ per query operation [6]. The sparsification technique of Eppstein et al. [3] and Eppstein, Galil, and Nissenzweig [2] improves the running time of an update operation to $O(\sqrt{n})$. Subsequently, a dynamic connectivity algorithm was given with $O(n^{1/3} \log n)$ update time and $O(1)$ query time [12]. It can also output all nodes connected to a given node in time linear in their number. Very recently, an algorithm with polylogarithmic amortized time per operation was presented [15]. Note that there is a lower bound on the amortized time per operation of $\Omega(\log n / \log \log n)$ for all these problems [7, 16].

The best known dynamic algorithms in plane graphs take time $O(\log n)$ per operation for maintaining connected components by Eppstein et al. [1], $O(\log^2 n)$ for maintaining 2-edge connected components by Hershberger, Rauch, and Suri [14] and Eppstein et al. [4], and $O(\sqrt{n})$ for maintaining biconnected components by Eppstein et al. [4].

Outline of the paper. First (section 2), we study the dynamic biconnectivity problem for *general* graphs. Our basic approach is to partition the graph G into small connected subgraphs called *clusters* (see [5] for a first use of this technique in dynamic graph algorithms). Each biconnectivity query between a vertex u and a vertex v can be decomposed into a query in the cluster of u, a query in the cluster v, and a query between clusters. To test biconnectivity between clusters we use the 2-dimensional topology tree data structure [5] in a novel way and extend the ambivalent data structure [6]. These data structures were used before to test connectivity and 2-edge connectivity.

To test biconnectivity within a cluster we need to know how the vertices outside the cluster are connected with each other. Thus, we build two graphs, called *internal* and *shared* graphs. Each graph contains all vertices and edges inside the cluster C and a *compressed certificate* of $G \setminus C$. A compressed certificate is a graph that has the same connectivity properties as $G \setminus C$, but is not necessarily a minor of $G \setminus C$. This approach is similar to the concept of strong certificates in the sparsification technique: a strong certificate is not necessarily a subgraph of the given graph. The crux in the analysis of the algorithm is that we can show that only an amortized constant number of compressed certificates need "major" updates after an update in G (see Lemma 2.44).

Second (section 3), we study the dynamic biconnectivity problem for *plane* graphs. We use a topology tree approach based on [5].

An earlier version of this paper appeared in [17].

2. General graphs.

Let G be an undirected graph with n vertices and m edges. The *size* $|G|$ of a graph is the total number of its nodes and edges. We assume in the paper that G is connected, which implies $m \geq n-1$. If G is not connected, we build the data structure described below for each connected component and during an update combine two data structures or split a data structure in time $O(\sqrt{m \log n})$.

Let $m/\log^2 n \geq k \geq \sqrt{m}$ be a parameter to be determined later. Note that $m/k \leq k$. We build a data structure for G that we rebuild from scratch every m/k update operations. The operations between two rebuilds form a *phase*. This allows us to limit the necessary maintenance of the data structure within a phase, i.e., the data structure slowly "deteriorates" within a phase.

The data structure consists of the following parts: We map G to a graph G' of degree at most 3 and partition G' into $O(m/k)$ many subgraphs of size $O(k)$, called *clusters*. We keep data structures for (1) the graph of clusters, (2) each cluster (called *cluster graph*), and (3) for special *shared* nodes (called *shared graphs*). We will show how to rebuild these data structures in time $O(m \log n)$ and update them in time $O(\sqrt{m \log n})$ after an edge insertion or deletion in G.

2.1. The graph G' and the relaxed partition of order k.

We want to partition G into about equally sized subgraphs (see the relaxed partition below). For this purpose, we map G to a graph G' of degree at most 3 as in [5]. At each rebuild, G' is created by *expanding* a vertex u of degree $d \geq 4$ by $d-2$ new degree-3 vertices $u'_1, \ldots, u'_{d-2}$ and connecting u'_i and u'_{i+1} by a *dashed* edge, for $1 \leq i \leq d-3$. Every node u of degree at most 3 is represented by one node u'_1 in G'. Every edge (u, v) is replaced by a *solid* edge (u'_i, v'_j), where i and j are the appropriate indices of the edge in the adjacency lists for u and v. We say that the edge (u'_i, u'_{i+1}) *belongs* to u and that every u'_i is a *representative* of u. The vertex u of G is called the *origin* of the vertex u'_i in G', for $1 \leq i \leq d-2$. We denote vertices of G' by variables with prime, like u' or u'_i, and their origin by variables without prime, like u. Thus, at the beginning of a phase the graph G' contains at most $2m$ vertices and at most $3m$ edges. We use $deg(u)$ to denote the degree of a vertex u in G and $num(u)$ to denote the number of representatives of u in G'.

The graph G' is maintained during insertions and deletions of edges as follows: Consider how the representatives of u are updated when an edge (u, v) is inserted. If $num(u)$ is 1 and $deg(u)$ was 3 before the insertion, then add a new vertex u'_2, connect u'_1 and u'_2 by a dashed edge, and make u'_1 and u'_2 each incident to 2 edges incident to u. If $num(u)$ is greater than 1, then one new vertex $u'_{num(u)+1}$ is created and connected by a dashed edge to $u'_{num(u)}$. Thus an edge insertion increases the number of vertices in G' by up to 2 and the number of edges by up to 3. If an edge is deleted, the corresponding edge is removed from G', *but no vertices are deleted from* G'. Thus, within a phase there are at most $2m + 2m/k$ vertices and $3m + 3m/k$ edges in G'.

Data structure: The algorithm keeps the following mapping from G to G' and vice versa:

(G1) Each vertex of G stores a list of its representatives, ordered by index, and pointers to the beginning and the end of this list. Each vertex of G' keeps a pointer to its position in this list, to its origin, and a list of incident edges.

(G2) Each dashed edge of G' stores a pointer to the vertex of G that it belongs to; each solid edge of G' stores a pointer to the edge of G that it represents.

Note that there exists a spanning tree of G' that contains every dashed edge. The algorithm maintains such a spanning tree, denoted by T'. Let T be the corresponding spanning tree in G. We denote by $\pi_{T'}(u', v')$ the path from u' to v' in T'. If the spanning tree is understood, we use $\pi(u', v')$. Let u'_v denote the representative of u with the shortest tree path to a representative of v. Note that every articulation point separating u and v must have a representative that lies on $\pi_{T'}(u'_v, v'_u)$.

Data structure:

(G3) Both T and T' are stored in a degree-k ET-tree data structure [12] and in a dynamic tree data structure [18]. The ET-tree has constant depth.

We build a "balanced" decomposition of G' into subgraphs of size $O(k)$ and maintain data structures based on this decomposition. At the beginning of each phase, the decomposition and data structures are rebuilt from scratch in time $O(m \log n)$, adding an amortized cost of $O(k \log n)$ to each update. The rebuilds significantly simplify the "rebalancing" operations needed to maintain the decomposition balanced during updates.

We next describe the balanced decomposition of G' into *clusters*. A *cluster* is a set of vertices of G' that induces a connected subgraph of T'. If the representatives of a vertex u of G belong to different clusters, u is called a *shared vertex*. An edge is *incident* to a cluster if exactly one of its endpoints is in the cluster. An edge is *internal* if both endpoints are in the cluster. Let (x, y) be a tree edge incident to a cluster C and let $x \in C$. Then x is called a *boundary node* of C. The *tree degree* of a cluster is the number of tree edges incident to the cluster. Let $|C|$ denote the number of nodes in a cluster.

A *relaxed partition of order k* with respect to T' is a partition of the vertices into clusters so that

(C1) each cluster contains at most $k + 2m/k$ vertices of G';
(C2) each cluster has tree degree at most 3;
(C3) each cluster with tree degree 3 has cardinality 1;
(C4) if a cluster contains a shared vertex, then all boundary nodes are representatives of this shared vertex;
(C5) there are $O(m/k)$ many clusters; and
(C6) at the beginning of the phase if a cluster contains a shared vertex s, then every non-tree edge incident to the cluster either is adjacent to a representative of the shared vertex or is incident to another cluster sharing s.

This definition is an extension of [6]. We denote the cluster containing a node u' of G' by $C_{u'}$.

If all representatives of a vertex u of G belong to the same cluster C, we denote C by C_u and say that C *contains* u and u *belongs to* C. For a cluster C, let $V(C)$ denote the set of origins in G of the nodes of G' that (1) either belong to C or (2) are connected to a node in C by a solid tree edge.[2]

Each cluster containing a representative of a shared vertex u is called a cluster *sharing* u or u*-cluster*. Condition (C4) implies that each cluster shares at most one vertex. Together with condition (C5), it follows that there are $O(m/k)$ shared vertices.

[2]The origin of a node s' that is connected by a dashed edge to a node t' in C belongs to $V(C)$ since the origin of s' equals the origin of t', which belongs to $V(C)$ according to (1). Thus set C_T of [11] equals $V(C)$.

Data structure:

(G4) Each cluster keeps (a) a doubly linked list of all its vertices, (b) a doubly linked list of all its incident tree edges, and (c) a pointer to its shared vertex (if it exists).

(G5) Each nonshared vertex of G' keeps a pointer to the cluster it belongs to. Each shared vertex keeps a doubly linked list of all the clusters that share the vertex.

We repeatedly make use of the following fact.

FACT 2.1. *Let G be an n-node graph and let $u_1, \ldots, u_a$ be a set of articulation points that lie on a (simple) path in G. Then $\sum_i deg(u_i) \leq 2n$.*

To guarantee that conditions (C1)–(C4) are maintained within a phase any cluster violating the conditions is split into two clusters (see section 2.2). We show below that all these splits create only $O(m/k)$ new clusters, i.e., condition (C5) is always fulfilled.

2.2. Maintaining a relaxed partition of order k.

To maintain a relaxed partition during updates, we create a more restricted partition at each rebuild, i.e., at the beginning of each phase, and let it gradually "deteriorate" during updates. Specifically, a cluster might be split but two clusters will never be merged. This implies that if a vertex becomes shared at some point in a phase it stays shared until the end of the phase.

A *restricted partition of order k* with respect to T' is a partition of the vertices into clusters so that

(C1′) each cluster has cardinality at most k;
(C2′) each cluster has tree degree ≤ 3;
(C3′) each cluster with tree degree 3 has cardinality 1;
(C4′) if a cluster contains a shared vertex, then all boundary nodes are representatives of this shared vertex;
(C5′) there are $O(m/k)$ clusters; and
(C6′) if a cluster contains a shared vertex s, then every non-tree edge incident to the cluster is either adjacent to the representative of the shared vertex or is incident to another cluster sharing s.

LEMMA 2.2. *A partition fulfilling* (C1′)–(C5′) *can be found in linear time.*

Proof. The algorithm in [6] shows how to find a partition fulfilling (C1′)–(C3′) and (C5′) in time $O(m + n)$.

Enforcing (C4′) *for a cluster in time linear in its size:* Each cluster that does not fulfill (C4′) has tree degree 2. Let x' and y' be the two boundary nodes in the cluster. Since x' and y' represent different shared vertices, the tree path between x' and y' contains at least one solid edge. Splitting the cluster at the solid edge on $\pi(x', y')$ closest to x' and at the solid edge on $\pi(x', y')$ closest to y' creates at most three clusters that fulfill conditions (C1′)–(C4′). Each split takes time linear in the size of the cluster. The lemma follows. □

LEMMA 2.3. *By modifying the spanning tree T' a partition fulfilling* (C1′)–(C5′) *can be modified in time $O(m \log n)$ to additionally fulfill* (C6′).

Proof. We need to enforce that if a cluster contains a shared vertex s, then every non-tree edge incident to the cluster is either adjacent to a representative of the shared vertex or is incident to another cluster sharing s. The main idea of our approach is to make every edge that violates this condition a tree edge, i.e., to remove a subtree of T' connected to the violating edge from the cluster sharing s.

To be precise, mark all vertices in clusters sharing s and test every edge incident to such a vertex whether it is adjacent either to a shared vertex or to a marked vertex. If x' is in an s-cluster and the edge (x', y') does not fulfill the above condition, then determine the representative s' of s that is closest to x' in T' and the tree edge e incident to s' on $\pi(s', x')$. Make e a non-tree edge and make (x', y') a tree edge. Remove the subtree $\tilde{T}$ of $T' \setminus e$ containing x' from the s-cluster and add it to the cluster of y' if the resulting cluster $C_{y'}$ does not violate (C1$'$). Otherwise, create a cluster containing $\tilde{T}$. This increases the tree degree of $C_{y'}$ by 1. Since $C_{y'}$ contains y', a vertex which had an adjacent non-tree edge, it follows from (C3$'$) that $C_{y'}$ has now tree degree at most 3. If it has degree 3 and consists of more than one vertex, $C_{y'}$ is split as follows.

Let v', y', and z' be the three (not necessarily distinct) boundary nodes of $C_{y'}$. There exists a tree degree-3 node w' that belongs to $\pi(v', y')$, $\pi(v', z')$, and $\pi(y', z')$. The algorithm splits $C_{y'}$ at w' by creating a tree degree-3 cluster for w' alone and up to three additional tree degree-2 clusters, namely, if $v' \neq w'$, a cluster containing v', if $y' \neq w'$, a cluster containing y', and if $z' \neq w'$, a cluster containing z'. The new clusters fulfill (C1$'$)–(C3$'$). It is possible that (a) w' was not a shared vertex before the split, but is a shared vertex after the split, and that (b) $C_{y'}$ shared a vertex u' different from w' before the split. If (a) and (b) hold, then one of the new tree degree-2 clusters might violate condition (C4$'$). Split these clusters in the same way as described in the proof of Lemma 2.2, namely, at the solid edge on $\pi(w', u')$ closest to w' and at the solid edge on $\pi(w', u')$ closest to u'. This creates at most three clusters that fulfill conditions (C1$'$)–(C4$'$).

Note that a constant number of clusters was formed from the vertices in $C_{y'}$ and the vertices in $\tilde{T}$ and that there are more than k vertices in $C_{y'}$ and $\tilde{T}$ combined. Thus the total number of clusters when (C6$'$) holds for all clusters is still $O(m/k)$, i.e., (C5$'$) continues to hold.

To implement the above algorithm in time $O(m \log n)$ we use the following data structure to represent T', G', and the current cluster partitioning.

(1) We store a list of clusters and for each cluster we store its boundary vertices, its incident tree edges, and its shared vertex if it exists. For each shared vertex s we keep a list of all s-clusters.

(2) Each vertex of G' stores a doubly linked list of all incident edges, separated by tree and non-tree edges. Each edge points to its two positions in these lists.

(3) We also assume data structure (G1) exists already. This data structure will not be modified by this algorithm.

(4) Each vertex of G stores a bit indicating whether it is shared or not.

(5) We build in linear time a degree-k ET-tree data structure [12]. By removing the tree edges incident to a cluster, determining the size of the resulting spanning tree inside the cluster, and adding the tree edges again this data structure allows us to determine the number of vertices of a cluster in time $O(\log n)$.

(6) We build two dynamic tree data structures [18]. We mark in linear time each edge of T' in one of the dynamic tree data structures (G3) by a weight which is 1 for solid edges and 0 for dashed edges. These data structures are updated in time $O(\log n)$ after each edge insertion or deletion in T'. We use the second dynamic tree data structure to mark or unmark in time $O(\log n)$ all the vertices on an arbitrary path and to determine in time $O(\log n)$ the marked vertex on a (second) path closest to one of the endpoints of the path.

This data structure can be built in time $O(m)$.

The algorithm checks each cluster on the list of clusters to determine whether it has a shared vertex s and, if so, it traverses and marks all vertices in the s-clusters starting at a boundary vertex. This takes time linear in the number of these vertices. Afterward it traverses them a second time and tests in constant time each adjacent non-tree edge whether it is incident to a marked vertex or a representative of a shared vertex. To test whether a vertex u' is the representative of a shared vertex u of G we determine the vertex u of G which u' represents and test the bit at u. This takes constant time.

We next show how to deal efficiently with an edge that violates the condition. Making a tree edge a non-tree edge or vice versa takes time $O(\log n)$. Determining the size of a cluster takes time $O(\log n)$ as discussed above. We still need to show how to determine s', e, w' and the solid tree edges closest to w' and closest to u' on $\pi(w', u')$ in time $O(\log n)$.

Determining s' and e: Mark in the second dynamic tree data structure all the representatives of s using (G1). Root the dynamic tree data structure at a vertex not in an s-cluster, for example, at y', and determine the marked vertex on $\pi(x', y')$ closest to x'. This vertex is s'. Then root the dynamic tree at x' and determine the edge from s' to its parent. This is the edge e. Finally unmark the marked vertices.

Determining w': Mark in the second dynamic tree data structure all the vertices on $\pi(v', z')$. Root the (updated) dynamic tree data structure at v' and determine the marked vertex on $\pi(y', v')$ closest to y'. This vertex is w'. Unmark the marked vertices.

Determining the solid tree edges closest to w' (resp., u') on $\pi(w', u')$: Root the first dynamic tree data structure at u' (resp., w') and determine the edge with weight 1 closest to w' (resp., u'). This is the desired edge.

Thus, for each non-tree edge that violates the condition we spend time $O(\log n)$ to make it a tree edge and to restore conditions (C1)–(C4). Note that if a tree edge becomes a non-tree edge, it stays a non-tree edge since it is adjacent to a shared vertex. Thus the cost of $O(\log n)$ is incurred $O(m)$ times, for a total time of $O(m \log n)$. ∎

We discuss next how to maintain a relaxed partition during updates. We show that an update does not violate condition (C1), (C4), or (C5). Obviously condition (C6) can never be violated since it only has to hold at the beginning of a phase. Condition (C2) or (C3) might be violated but can be restored by splitting a constant number of clusters. Restoring (C3) might lead to a violation of (C4), which can also be restored with an additional constant number of cluster splits.

We use the following *update algorithm for the relaxed partition*: If an insert(u, v) operation replaces u by two nodes, add both to C_u. If only one new representative $u_{num(u)+1}$ is created, add it to the cluster of $u_{num(u)}$ and increment $num(u)$ afterward. A deletion does not remove any vertices.

LEMMA 2.4. *The update algorithm for the relaxed partition does not violate condition* (C1), (C4), *or* (C5). *Conditions* (C2) *and* (C3) *might be violated for the clusters containing the endpoints of the newly inserted edge (in the case of an insertion) or the endpoints of the new tree edge (in the case of a deletion).*

Proof. Condition (C1)*:* An update increases the number of nodes in a cluster by at most two, implying that at the end of the phase each cluster contains at most $k + 2m/k$ nodes. It follows that condition (C1) is never violated.

Condition (C4)*:* Every newly added dashed edge has both endpoints in the same cluster, i.e., it is *not* incident to a cluster. Thus, condition (C4) is not violated.

Condition (C5)*:* A delete(u,v) operation might disconnect the connected component of C_u if $C_u = C_v$, leading to one additional cluster. Since there are m/k updates in a phase, there exist $O(m/k)$ clusters during a phase, i.e., condition (C5) is not violated by the update algorithm.

Conditions (C2) *and* (C3)*: Deletions:* Note first that the deletion of a non-tree edge does not invalidate condition (C2) or (C3) and, thus, does not require any cluster splits. A deletion of a tree edge might make a (solid) non-tree edge into a tree edge, and, if this edge is an intercluster edge, add one new incident tree edge to its endpoint clusters. This might lead to a violation of condition (C2) or (C3) for the clusters incident to the new tree edge. *Insertions:* In the case that G is disconnected, a newly inserted edge might become a tree edge, adding one new (solid) tree edge to at most two clusters. As before, this might lead to a violation of conditions (C2) and (C3) for the clusters incident to the new tree edge. Additionally, an insertion might increase the number of nodes in a tree degree-3 cluster to two, violating condition (C3).

In conclusion, an update violates conditions (C2) and/or (C3) for at most two clusters, namely, the clusters containing the endpoints of the newly inserted edge or of the new tree edge. $\square$

The algorithm first restores condition (C2) and then condition (C3). However, restoring (C3) might lead to the violation of condition (C4). If this happens, condition (C4) is restored after condition (C3).

Restoring condition (C2)*:* If a cluster violates (C2), it has tree degree 4 and consists of exactly two tree degree-3 nodes. Splitting it into two clusters creates two connected 1-node clusters of degree 3, fulfilling conditions (C1)–(C4).

Restoring condition (C3)*:* If a cluster C violates condition (C3), let x', y', and z' be the three (not necessarily distinct) boundary nodes of C. There exists a tree degree-3 node w' that belongs to $\pi(x', y')$, $\pi(x', z')$, and $\pi(y', z')$. The algorithm splits C at w' by creating a tree degree-3 cluster for w' alone and up to three additional tree degree-2 clusters, namely, if $x' \neq w'$, a cluster containing x', if $y' \neq w'$, a cluster containing y', and if $z' \neq w'$, a cluster containing z'. It is possible that (a) w' was not a shared vertex before the split, but is a shared vertex after the split, and that (b) C was incident to up to two dashed edges before the update, i.e., shared a vertex different from w'. If (a) and (b) hold, then one of the new tree degree-2 clusters might violate condition (C4). Splitting these clusters in the same way as in the proof of Lemma 2.2 creates at most three additional tree degree-2 clusters, each fulfilling conditions (C1)–(C4).

Thus, restoring conditions (C1)–(C4) requires creating a constant number of additional clusters after an update operation. Since there are m/k updates in a phase, condition (C5) is fulfilled at any point in a phase.

We summarize this discussion in the following lemma.

Lemma 2.5.

(1) *An insertion does not split any cluster, but restoring the relaxed partition after an insertion might require a constant number of cluster splits, namely, of the clusters that contain the endpoints of the inserted edge.*

(2) *A deletion of a non-tree edge does not require any cluster splits.*

(3) *A deletion of a tree edge might split the cluster containing the endpoints of the deleted edge. Additionally, restoring the relaxed partition after a deletion might require a constant number of cluster splits, namely, of the clusters that contain the endpoints of the new tree edge.*

Testing whether a cluster violates (C2) or (C3) takes constant time; splitting a cluster takes time linear in its size. Thus, it takes time $O(k)$ to update the relaxed partition of order k after each update.

2.3. Queries. Mapping G to G' causes correctness problems: If two nodes u and v are biconnected in G, they are also biconnected in G', but the reverse statement does *not* always hold (see [11] for an example).

The following lemma (an extension of Lemma 2.2 of [11]) relates the biconnectivity properties of G and of G'. To *contract* an edge (u, v) identify u and v and remove (u, v). To *contract* a vertex of G contract all dashed edges in G' belonging to the vertex.

LEMMA 2.6. *Let u and v be two vertices of G.*

(1) *Let G_1 be the graph that results from G' by contracting every vertex on $\pi_T(u, v)$ (excluding u and v). The vertices u and v are biconnected in G iff u'_v and v'_u are biconnected in G_1.*

(2) *Let y be a node on $\pi_T(u, v)$ that does not separate u and v in G. Let G_2 be the graph that results from G' by contracting every vertex on $\pi_T(u, v)$, excluding y, u, and v. The vertices u and v are biconnected in G iff u'_v and v'_u are biconnected in G_2.*

Proof. The graphs G_1, resp., G_2, can be created from G by expanding appropriate vertices. Thus, if u and v are biconnected in G, then u'_v and v'_u are biconnected in G_1, resp., G_2.

For the other direction, assume that u and v are separated by an articulation point x in G. Then x belongs to $\pi_T(u, v)$. It follows that x is represented by one node in G_1, resp., G_2. Assume by contradiction that u'_v and v'_u are biconnected in G_1, resp., G_2, i.e., there exists a path P' between them not containing x. The corresponding path P in G connects u and v and does not contain x, which leads to a contradiction. ∎

Note that the lemma also holds if additional vertices of G_1, resp., G_2, are contracted.

To test the biconnectivity of u and v in G we decompose the problem into subproblems, such that each subproblem is either (a) a biconnectivity query in a graph of size $O(k + m/k)$ or (b) a connectivity query in a graph of size $O(m)$. Subproblems of type (a) can be solved efficiently since $k + m/k$ is chosen to be "small." For subproblems of type (b) we use the existing efficient data structures for maintaining connectivity dynamically. Since no data structure is known that solves both subproblems efficiently, we maintain two different data structures, called *cluster graphs* and *shared graphs.*

To be precise, for each shared vertex s, a *shared graph* is maintained. Given a shared vertex s and two of its tree neighbors x and y, the shared graph of s is used to test in constant time whether s is an articulation point separating x and y. This is equivalent to testing if x and y are disconnected in $G \setminus s$. Thus, we use the dynamic connectivity data structure [12] to maintain the shared graphs.

Recall that $V(C)$ for a cluster C denotes the set of origins in G of the nodes of G' that either (1) belong to C or (2) are connected to a node in C by a solid tree edge. We maintain for C a *cluster graph* which is built to test (in constant time) if any two nodes of $V(C)$ that are not separated by s_C are biconnected in G, where s_C is the shared vertex of C. In particular, the cluster graph can be used to test whether s_C is biconnected with another node in C. To maintain the cluster graphs we use the data structure of [11]. To test if two nodes x and y are biconnected in G, the data structure contracts in G' all vertices on $\pi_T(x, y)$ (and potentially additional vertices).

We describe next how we use these two data structures to answer a biconnectivity query. We use the following lemma.

LEMMA 2.7. *Let u and v be nodes of G and let $(x^{(i)'}, y^{(i)'})$, for $1 \leq i \leq p$, denote* *the solid intercluster tree edges on $\pi_{T'}(u'_v, v'_u)$, in the order of their occurrence. Then u and v are biconnected in G iff*

(Q1) *u and $y^{(1)}$ are biconnected in G,*

(Q2) *$x^{(i)}$ and $y^{(i+1)}$ are biconnected in G, for $1 \le i < p$, and*

(Q3) *$x^{(p)}$ and v are biconnected in G.*

Proof. If u and v are biconnected, then all nodes on $\pi(u, v)$ are pairwise biconnected, and thus (Q1)–(Q3) hold. If u and v are not biconnected, then u and v are separated by an articulation point z. Since z belongs to $\pi_T(u, v)$, either (Q1), (Q2), or (Q3) is violated. This is a contradiction. □

For a query(u, v), let C be the cluster of u'_v. If C shares a vertex, call it s. We test the conditions of the lemma using only a cluster graph if this is possible and using a cluster graph and a suitable shared graph otherwise.

Testing condition (Q1)*:* Condition (Q1) of Lemma 2.7 can be tested using two cluster graphs and the shared graph of s: if s does not lie on $\pi(u, y^{(1)})$, then s does not separate u and $y^{(1)}$, and $y^{(1)}$ belongs to $V(C)$. Thus, we use the cluster graph of C to test whether u and $y^{(1)}$ are biconnected.

If s lies on $\pi(u, y^{(1)})$, then let x_u and y_u be the nodes incident to s on $\pi(u, y^{(1)})$. Let s' be the node representing s closest to $y^{(1)}$ on $\pi(u, y^{(1)})$. Note that s belongs to $V(C)$ and that $y^{(1)}$ belongs to $V(C_{s'})$. Test in the cluster graph of C if u and s are biconnected, test in the cluster graph of $C_{s'}$ if s and $y^{(1)}$ are biconnected, and test in the shared graph of s if x_u and y_u are biconnected. If all tests are successful, u and $y^{(1)}$ are biconnected in G, since the last test guarantees that s does not separate u and $y^{(1)}$ and the first two tests guarantee that no other node of $\pi(u, y^{(1)})$ separates u and $y^{(1)}$.

Testing condition (Q2)*:* If $y^{(i)'}$ and $x^{(i+1)'}$ belong to the same cluster C_i and C_i does not share a vertex, then both, $x^{(i)}$ and $y^{(i+1)}$, belong to $V(C_i)$ and are not separated by a shared vertex of C_i. Thus, condition (Q2) can be tested using the cluster graph of C_i.

We show that otherwise $x^{(i)}$ and $y^{(i+1)}$ are tree neighbors of a shared vertex s_i and the shared graph of s_i can be used to test condition (Q2): either (a) $y^{(i)'}$ and $x^{(i+1)'}$ belong to the same cluster C_i that shares a vertex s_i, or (b) $y^{(i)'}$ and $x^{(i+1)'}$ belong to different clusters. In case (a), C_i is incident to two solid tree edges and one dashed tree edge, i.e., C_i has tree degree 3. By condition (C3) it follows that C_i contains only one node, i.e., $y^{(i)'} = x^{(i+1)'}$, and both are representatives of s_i. It follows that $x^{(i)}$ and $y^{(i+1)}$ are both tree neighbors of s_i. In case (b), all intercluster edges between the cluster of $y^{(i)'}$ and the cluster of $x^{(i+1)'}$ are dashed. By condition (C4) of a relaxed partition, all these dashed edges and also $y^{(i)'}$ and $x^{(i+1)'}$ belong to the same shared vertex s_i. Thus, also in this case $x^{(i)}$ and $y^{(i+1)}$ are tree neighbors of s_i. It follows that the shared graph of s_i can be used to test whether $x^{(i)}$ and $y^{(i+1)}$ are biconnected in G.

Testing condition (Q3)*:* Condition (Q3) is tested analogously to condition (Q1).

Since each test takes constant time, this leads to a query algorithm whose running time is linear in the number of solid intercluster edges on $\pi_{T'}(u'_v, v'_u)$, which is $O(m/k)$. However, we will give in section 2.11 a data structure that allows all these tests to be executed in constant time.

Our next goal is to describe *cluster graphs* and *shared graphs* in detail. Maintaining them requires a third data structure, called *high-level graphs*, which we describe first.

2.4. Overview of high-level graphs. There are two *high-level graphs*, H_1 and H_2. Basically, H_1 is a graph where each cluster is contracted to one node, and H_2 is a copy of H_1 with intercluster dashed edges contracted as well.

To be precise, the graph H_1 contains a node for each cluster of G'. Two nodes C and C' of H_1 are connected by an edge in H_1 iff there is an edge between a vertex of C and a vertex of C'. If there exists an edge between C and C', we call C' the *neighbor* of C. The edge between C and C' in H_1 is a dashed edge iff there is a dashed edge between a vertex of C and a vertex of C'. Otherwise the edge in H_1 is *solid.*

The graph H_2 is the graph H_1 with all dashed edges of H_1 contracted.

We call vertices of H_1 or H_2 *nodes* and refer to vertices of G of G' as *vertices.*

Since each node of H_1 represents exactly one cluster, we will use the terms *node of* H_1 and *cluster* interchangeably. Each node of H_2 represents at least one cluster and it also represents the vertices of G with a representative in these clusters. Note that each vertex of G is represented by a unique node of H_2, while this does not hold for H_1: a shared vertex is represented by more than one node of H_1.

The spanning tree T' of G' induces a spanning tree T_1 on H_1 and T_2 on H_2. We say C' is a *tree neighbor* of C if there is a tree edge between C' and C in H_1. Otherwise C' is a *non-tree neighbor.*

We need the high-level graphs to define and maintain the cluster graphs and the shared graphs. Roughly speaking, a cluster graph tests (under certain conditions) whether two vertices represented by the same node of H_1 are biconnected in G, and a shared graph tests whether two vertices represented by the same node of H_2 are biconnected in G.

When maintaining cluster and shared graphs we make use of the following data structures. Details of some of these data structures are delayed until section 2.7. Let $i = 1, 2$.

(HL1) We store for each node of H_i all the vertices of G' belonging to the node,[3] and we store at each vertex of G' the node of H_i to which the vertex belongs.

(HL2) We keep the following adjacency list representation for H_i (of size $O((m/k)^2) = O(m)$): For each node of H_i we keep the list of all incident neighbors and a list of pointers to all of its positions in the lists of its neighbors. Thus, in constant time an edge between two nodes can be removed from this representation.

(HL3) We maintain a data structure that given two nodes C and C' returns the tree neighbor C'' of C such that C'' lies on $\pi_{T_i}(C, C')$. For H_1 this takes constant time; for H_2 it takes time $O(\log n)$.

(HL4) We store a data structure that implements the following query operations in H_i:

biconnected?(C,C′,C″): Given that nodes C' and C'' are both tree neighbors of a node C, test whether C' and C'' are biconnected in H_i.

blockid?(C,C′): Given that C and C' are tree neighbors in T_i, output the name of the biconnected component of H_i that contains both C and C'.

components?(C): Output the tree neighbors of C in H_i grouped into biconnected components.

Operations *biconnected?* and *blockid?* take constant time, and *components?* takes time linear in the size of the output.

(HL5) We keep a *mapping* h from H_1 to H_2 and a mapping h^{-1} from H_2 to H_1. For each node of H_2 we keep a list of pointers to all the nodes of H_1 whose contraction formed H_1, and for each node of H_1 we keep a pointer back to the corresponding node of H_2.

[3]For H_1 this is already part of (G4) and, of course, does not need to be stored twice.

(HL6) We keep an empty array of size $O(m/k)$ at each node in H_i (needed for various bucket sorts—see sections 2.5 and 2.6).

Note that using (HL3) and (HL4) one can test in constant time whether two neighbors of a node C in H_i are biconnected in H_i.

Recall that after an update operation clusters might be split to restore the relaxed partition.

LEMMA 2.8. *If a cluster C is split while restoring the relaxed partition, then the clusters containing the vertices of C when the relaxed partition is restored form a connected subgraph of H_1.*

Proof. Splitting simply regroups the partitioning of vertices into clusters but does not change the connectivity properties in G. Since the vertices in C form a connected subgraph of G before the split, they also do so after the split. Hence, the clusters containing these vertices form a connected subgraph of H_1. □

Next we need to assign "ancestors" to nodes and edges in H_1 and H_2. This is necessary for our lazy update scheme: if a node is split into two nodes, then the resulting nodes have the same ancestor. However, we cannot afford to update all cluster and shared graphs accordingly. Therefore, we will treat nodes with the same ancestor that fulfills certain additional conditions as one node in some of the cluster and shared graphs.

First we define a unique *ancestor* for each node in H_2. Let C be a node in the current graph H_2. Since clusters are only split, never joined, all nodes represented by C were represented by the same cluster A at the beginning of a phase. This node A is called the *ancestor* of C.

To define ancestors for nodes in H_1, we denote by B_s the cluster that contains $s_{num(s)}$ at the beginning of a phase for each shared vertex s. Note that if a cluster contains only representatives that were created after the last rebuild, then these representatives represent a shared vertex. Consider a cluster C of H_1. If C only contains representatives that were created after the last rebuild, then the ancestor of C is B_s. Otherwise, C has at least one representative that existed at the last rebuild. In this case, the representatives that existed at the last rebuild belonged to the same cluster A at the last rebuild. This node A is called the *ancestor* of C.

LEMMA 2.9. *Let $i = 1$ or 2. Assume a node C of H_i is split into clusters C_1 and C_2. Then C_1 and C_2 have the same ancestor as C.*

Proof. For $i = 2$ this follows immediately from the definition. For $i = 1$, we only give the argument for C_1; the same argument applies to C_2. If C_1 contains representatives that existed at the last rebuild, then these representatives all belonged to the same cluster at the last rebuild. This cluster is also the ancestor of C. Otherwise, C_1 contains only representatives that were created after the last rebuild. In this case the ancestor of C_1 is B_s. We show below inductively that representatives that are created after the last rebuild are added into clusters whose ancestor is B_s. Thus, the ancestor of C is B_s as well.

When a new representative is added for s, it is added to the cluster containing $s_{num(s)}$. We show inductively that the cluster containing $s_{num(s)}$ for the current value of $num(s)$ has B_s as ancestor. The induction goes over the number of representatives of s added to G' after the last rebuild. By the definition of ancestor for clusters with representatives that existed at the last rebuild the claim holds before a new representative was added for s. Consider next the addition of the ith new representative $s_{num(s)+1}$ of s. If the cluster containing $s_{num(s)}$ is not split, then the claim holds inductively. Otherwise two situations can arise: either the cluster C containing $s_{num(s)+1}$

after the split contains only representatives that were created after the last rebuild, or not. In the former case, B_s is the ancestor of C by definition. In the latter case, C contains representatives that belonged to B_s at the last rebuild. Thus, in either case, B_s is the ancestor of C. $\square$

In particular, C_1 and C_2 have the same ancestor and each node has a unique ancestor.

Data structure:

(HL7) We store at each node of H_i its ancestor.

(HL8) We number the edges of H_i in the order in which they were added to H_i with the edges added during a rebuild in arbitrary order.

Recall that at the beginning of each phase a cluster contains at most k vertices of G'. This enables us to prove the following lemma.

LEMMA 2.10. *The total number of vertices of G' in all clusters with the same ancestor is $k + 2m/k$. The total number of edges incident to these vertices is $O(k)$.*

Proof. Let A be a cluster at the beginning of a phase. All nodes of a cluster with ancestor A (in G') that existed at the time of the last rebuild belonged to A at the beginning of the phase. Thus, there are at most k of them. Every other node was created by one of the m/k update operations. Since each update creates at most two new vertices, the bound follows. $\square$

2.5. Cluster graphs. Let C be a cluster. The *cluster graph* $I(C)$ of C is used to test if two vertices u and v of $V(C)$ that are not separated by s_C are biconnected in G. This leads to a first requirement for $I(C)$:

(IC1) *If s_C does not separate u and v, then u and v are biconnected in $I(C)$ iff they are biconnected in G.*

As we see below, an amortized constant number of cluster graphs is rebuilt during each update operation. This leads to a second requirement for $I(C)$:

(IC2) *The graph $I(C)$ has size $O(|C|) = O(k)$.*

Recall that $V(C)$ denotes the set of origins in G of the nodes of G' that (1) either belong to C or (2) are connected to a node in C by a solid tree edge.

We next motivate our definition of $I(C)$ and explain why it can be used only if s_C does not separate the two nodes. Obviously, $I(C)$ has to contain all nodes of $V(C)$ and all edges between the nodes of $V(C)$. Since two nodes of $V(C)$ can be connected by a path in $V(C)$ and additionally by a path that contains nodes of a non-tree neighbor of C, we represent each non-tree neighbor of C by a node in $I(C)$ (called either *b-node* or *c-node*) and we add to $I(C)$ all edges incident to C.

However, three questions remain: (1) If C shares a vertex s_C, let C' be one of the neighbors of C connected to C by a dashed tree edge (belonging to s_C). Should $I(C)$ also contain a node representing C', i.e., should s_C and C' be represented by the same or different nodes in $I(C)$? (2) How is the set of b- and c-nodes connected by edges? (3) How can the graph be maintained efficiently when a neighbor of C is split?

Next we describe our solution to these questions. (1) If s_C and C' are represented by the same node, then two nodes u and v of $V(C)$ that are biconnected in G might not be biconnected in $I(C)$. See Figure 2.1 for an example. On the other side, if $I(C)$ contains a node for s_C and a separate node for C', then two vertices u and v of $V(C)$ that are not biconnected in G can be biconnected in $I(C)$. See Figure 2.2 for an example.

However, by Lemma 2.6 and the fact that in the latter approach all nodes on $\pi_T(u, v)$ except for s_C are contracted, it follows that the latter situation can happen

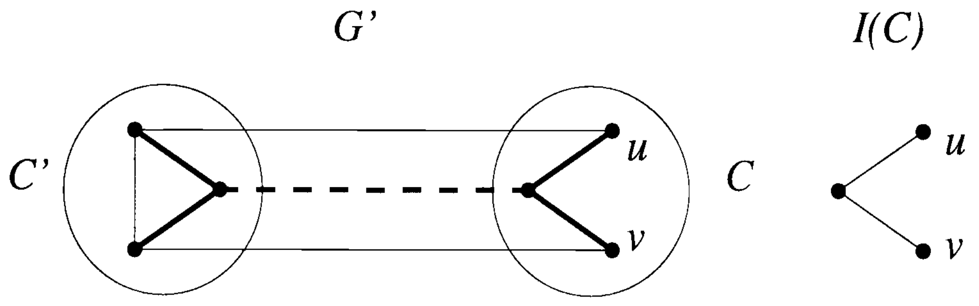

FIG. 2.1. *The graph G' and a potential graph $I(C)$. The graph G' consists of cluster C and C' (represented by circles), both sharing vertex s (represented by two nodes and the dashed line between them). Tree edges are bold or dashed. In $I(C)$, C' and s are collapsed to one node. Nodes u and v are biconnected in G but not in $I(C)$.*

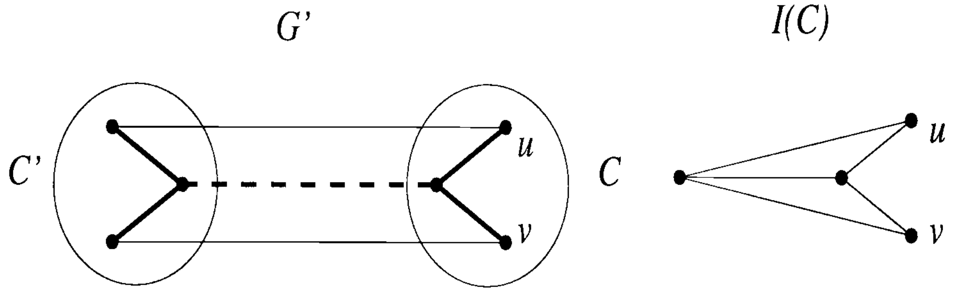

FIG. 2.2. *The graph G' and a potential graph $I(C)$. The graph G' consists of cluster C and C' (represented by circles), both sharing vertex s (represented by two nodes and the dashed line between them). Tree edges are bold or dashed. In $I(C)$, C' and s are represented by two different nodes. Nodes u and v are not biconnected in G' but are biconnected in $I(C)$.*

only if s_C separates u and v in G. Since this case is excluded by (IC1), we represent s_C and C' by separate nodes in $I(C)$.

(2) Let j be the number of neighbors of C. There are at most j b- or c-nodes in $I(C)$. Since G' is a graph of degree at most 3, $j = O(|C|)$. To guarantee that $I(C)$ has size $O(|C|)$, $I(C)$ will contain at most $j-1$ many edges between b- or c-nodes. These edges will be colored and will fulfill the condition that two b- or c-nodes are connected by a path of colored edges iff they are connected in $H_1 \setminus C$.

(3) We will split a node representing a neighbor C' of C only if the two clusters resulting from the split of C' are disconnected in $H_1 \setminus C$. Otherwise, both resulting clusters will be represented by the same c-node in $I(C)$, i.e., a c-node in the cluster graph might represent not just one cluster, but a set of clusters. This leads to the following invariant: *Two neighbors of C are represented by the same node in $I(C)$ or are connected by a colored path iff they are connected in $H_1 \setminus C$.*

Let us now give the exact definition of a *cluster graph* $I(C)$ for a cluster C. Let A be the ancestor of C. The cluster graph contains as nodes

(1) a node, called *a-node*, for each vertex with a representative in C,

(2) one node, called *b-node*, for each neighbor C' of C with ancestor A,

(3) one node, called *c-node*, for each maximal set X of clusters such that (a) every cluster $C' \in X$ is a neighbor of C, (b) all clusters in the set are connected in

$H_1 \setminus C$, (c) all clusters in X have the same ancestor which is different from A, (d) at the creation of C, the set X contains only one cluster, and (e) at each previous point in time since the creation of C all clusters that contain the vertices in $\cup_{C' \in X} C'$ existing at this time are represented by the same c-node in $I(C)$.

Note that for each neighbor C' of C there exists a unique node in $I(C)$ representing C' (and potentially other clusters). Note further that each node of G is represented by at most one node in $I(C)$, except for s_C, which can be represented by an a-node and up to two b- or c-nodes, namely, the tree neighbors of C that share s_C.

The graph $I(C)$ contains the following edges:

(1) All edges between two vertices of G represented by an a-node belong to $I(C)$.

(2) For each edge (u, v) where u is represented by an a-node and v is not, and (u', v') is the corresponding edge in G', there is an edge (u, d) in $I(C)$, where d is the b- or c-node representing $C_{v'}$.

(3) For each tree neighbor C_1 connected to C by a dashed edge there is an edge from the b- or c-node of C_1 to the a-node of s_C.

(4) For each pair C_1 and C_2 of tree neighbors of C there is a *red* edge (d_1, d_2) if C_1 and C_2 are biconnected in H_1, where d_j is the b- or c-node representing C_j, $j = 1, 2$.

(5) For each non-tree neighbor C_1 of C with representative d_1,[4] $I(C)$ contains a *blue* edge (d_1, d_2), where d_2 represents the tree neighbor of C that lies on $\pi_{T_1}(C, C_1)$, if C is an articulation point in H_1 (separating its at most two tree neighbors), and a *blue* edge (d_1, d_3), where d_3 represents an arbitrary tree neighbor of C, otherwise.[5]
Note that $I(C)$ can contain parallel edges. They can be discarded without affecting the correctness.

We show next that the cluster graphs fulfill (IC1) and (IC2).

LEMMA 2.11. *Two neighbors of C are biconnected in H_1 iff either they are represented by the same node in $I(C)$ or their representatives in $I(C)$ are connected by a colored path.*

Proof. We show first that if there is a colored edge between two nodes d_1 and d_2 in $I(C)$, then the clusters that they represent are biconnected in H_1. For red edges this follows immediately from the definition. For a blue edge consider first the case that C is not an articulation point in H_1. In this case all neighbors of C are biconnected in H_1. Since each blue edge connects two neighbors of C, the claim holds. Consider next the case that C separates its tree neighbors C_1 and C_2 in H_1. Note that there are two vertex-disjoint paths in H_1 between C and each of its non-tree neighbors C_1: one path consists of the non-tree edge (C, C_1), and the other path is $\pi_{T_1}(C, C_1)$. Thus C_1 and C's tree neighbor on $\pi_{T_1}(C, C_1)$ are biconnected as well, i.e., the claim holds for each blue edge.

This implies that if the representative of two neighbors of C are connected by a colored path in $I(C)$, then the neighbors of C are biconnected in H_1. If two neighbors are represented by the same node in $I(C)$, then they are biconnected in H_1 by the definition of a c-node.

Next we show that if two neighbors of C are biconnected in H_1 and represented by two different nodes in $I(C)$, then these representatives in $I(C)$ are connected by a colored path. Each non-tree neighbor C_1 is biconnected with the tree neighbor of C

[4]If C has a non-tree neighbor, then C has tree degree at most 2.

[5]Note that C_1 and C are biconnected in H_1. Thus this is equivalent to requiring that for each non-tree neighbor C_1 of C there exists a blue edge (d_1, d_2), where d_2 represents a tree neighbor of C that is biconnected to C_1 in H_1 and d_1 represents C_1.

on $\pi_{T_1}(C, C_1)$ and is connected to this tree neighbor by a colored path (of length at most two). Thus it suffices to show the claim for two tree neighbors of C. But for two tree neighbors the claim holds by definition. ∎

LEMMA 2.12. *Let C be a cluster and let u and v be two nodes of $V(C)$. If s_C does not separate u and v in G, then u and v are biconnected in $I(C)$ iff they are biconnected in G.*

Proof. Assume first that u and v are biconnected in $I(C)$ but are separated by a node x in G. Note that x must belong to $V(C)$. Furthermore, x must be represented by at least two nodes in $I(C)$. However, each node of G is represented by at most one node in $I(C)$, except for s_C. Thus, $x = s_C$, which leads to a contradiction.

Assume next that u and v are biconnected in G, but are separated by a node y in $I(C)$. Since u and v are connected by a tree path whose (internal) nodes all belong to C, no b-node or c-node can separate u and v in $I(C)$. Thus, y must be an a-node.

Consider the path P between u and v in G that does not contain y. Let $\tilde{P}$ be the path created from P by (1) extending P to a path in G', (2) contracting all intracluster edges of P except for the nondashed intracluster edges of C, and (3) by labeling the resulting nodes of $\tilde{P}$ with their clusters of G'.

Every edge of $\tilde{P}$ either is connecting two clusters or is incident to a vertex with a representative in C. We show that $\tilde{P}$ induces a path without y in $I(C)$ connecting u and v. We split $\tilde{P}$ into subpaths. Each subpath either

(1) connects two neighbors of C and does not contain other neighbors of C or vertices with representatives in C, or

(2) is one edge connecting two vertices with representatives in C, or

(3) is a solid edge connecting a vertex with a representative in C with a neighbor of C, or

(4) is a dashed edge connecting a vertex with a representative in C with a neighbor of C.

By Lemma 2.11 the endpoints of the type-(1) subpaths are connected by a colored path in $I(C)$. By definition type-(2), (3), or (4) subpaths are contained in $I(C)$. Thus $\tilde{P}$ induces a path without y from u to v in $I(C)$. Thus we have a contradiction. ∎

LEMMA 2.13. *For each cluster C,*

$$|I(C)| = O(|C|).$$

Proof. Obviously, there are $O(|C|)$ a-nodes and $O(|C|)$ edges incident to them in $I(C)$. Each b-node or c-node in $I(C)$ can be charged to one of the edges that connects the b-node or c-node to a node in C. Thus, there are $O(|C|)$ b- or c-nodes. Since the number of colored edges is linear in the number of b- and c-nodes, it follows that $|I(C)| = O(|C|)$. ∎

We will need the following fact when bounding the time of updates.

LEMMA 2.14. *Let $C_1, \ldots, C_l$ be a set of clusters with the same ancestor. Then*

$$\sum_{i=1}^{l} |I(C_i)| = O(k).$$

Proof. By Lemma 2.13,

$$\sum_{i=1}^{l} |I(C_i)| = \sum_{i=1}^{l} O(|C_i|).$$

Let A be the ancestor of the clusters $C_1, \ldots, C_l$. Recall that either (1) each C_i contains the representative of a vertex and that representative or the (unexpanded) origin of the representative also belonged to A, or (2) C contains only representatives of the shared vertex s of A, all these representatives were created after the last rebuild, and $A = C_s$.

The number of clusters fulfilling (1) is bounded by the number of nodes of G' in A. The total number of clusters fulfilling (2) is bounded by the number of updates since the last rebuild, which is m/k.

Thus,

$$\sum_{i=1}^{l} O(|C_i|) \leq O(|\{v, v \text{ is a node of } G' \text{ in } A\}| + m/k) = O(k). \qquad \square$$

In [11][6] a *cluster data structure* for $I(C)$ is given so that

(1) building the data structure takes time $O(|C|)$, provided that the b-nodes, the c-nodes, and the red and blue edges are given;

(2) changing one or all of the colored edges takes time linear in their total number, provided the new colored edges are given;[7]

(3) testing whether two vertices of $V(C)$ that are not separated by s_C are biconnected in $I(C)$ takes constant time.

We keep as data structure

(CG1) for each cluster C a *cluster data structure* for $I(C)$;

(CG2) for each cluster C the adjacency lists of the graph $I(C)$ with the two occurrences of edges pointing at each other;

(CG3) for each cluster C, a list of pointers to the b- or c-nodes representing C in $I(C)'$ for each neighbor C'; for each b-node in $I(C')$, a pointer back to C, and for each c-node in $I(C')$, a set of pointers to the clusters represented by the c-node.

Note that given the b-nodes and c-nodes of $I(C)$, the red and blue edges of $I(C)$ can be determined in time linear in their number using the data structure (HL3) and (HL4) for H_1. This leads to the following lemma.

LEMMA 2.15. *Let C be a cluster. There exists a cluster data structure for $I(C)$ such that*

(1) *building the data structure takes time $O(|C|)$, provided that the b-nodes and the c-nodes are given;*

(2) *changing one or all of the colored edges takes time linear in their total number, given the b-nodes and c-nodes;*

(3) *testing whether two vertices of $V(C)$ that are not separated by s_C are biconnected in $I(C)$ takes constant time.*

Note: We will use the same data structure and the same update algorithm in section 2.6 for one class of shared graphs. There the same problem has to be solved in

[6]Lemma 4.6 of [11] states the result; section 4.1.2 of [11] describes the data structure. In the notation of [11], $G_3(C)$ is identical to $I(C)$ except that a non-tree neighbor C_1 of C *always* has a blue edge (C_1, C_2) to the tree neighbor C_2 of C that lies on $\pi_{T_1}(C, C_1)$, even if C is not an articulation point. Furthermore, $G_2(C) = G_3(C) \setminus \{\text{red edges}\}$, $C_T = V(C)$, and the *artificial edges* of [11] are identical to the colored edges of $I(C)$.

[7]In [11] changing a red edge actually takes no time during an update: the existence of a red edge is not recorded during an update but is checked during queries (by asking a biconnectivity query in H_1). This is possible, since only one red edge exists in a cluster graph. Since we will use the same data structure also for one class of shared graphs, we treat red edges as blue edges in the data structure of [11].

H_2 instead of H_1. Since nodes in H_2 are not guaranteed to have bounded tree degree, we will not make use of this property of H_1 in our update algorithm.

2.5.1. Updates. We show in this section that it takes amortized time $O(k)$ to update the data structures for all cluster graphs after an edge insertion or deletion in G. The major difficulty is to maintain the b-nodes and c-nodes of each cluster graph. Once it has been determined how they change, it will be quite straightforward to update data structures (CG1)–(CG3). Let C be a cluster. A c-node of $I(C)$ has to be partitioned either (i) because C is split or (ii) because conditions (a) or (b) of a c-node are no longer fulfilled for the c-node. We call the latter kind of update a *split by condition violation (CV-split)* of a c-node. We say a CV-split *occurs* at a node C of H_1 if one of the c-nodes of C is CV-split.

Section 2.8 presents a data structure that given an update operation decides which if any c-nodes have to be CV-split and for each CV-split c-node it returns the set of clusters forming each new c-node. In section 2.9 we show that during m/k update operations CV-splits occur at $O(m/k)$ different nodes of H_1. When a CV-split occurs at a node C of H_1 in a cluster graph, all data structures for the cluster graph of C are rebuilt from scratch in time $O(k)$. Thus the CV-splits add an amortized cost of $O(k)$ to the time per update. We describe below the remaining work that is necessary after an update to maintain the cluster graphs.

Insertion. Let u' and v' be the (potentially newly added) representatives that are incident to the newly inserted edge (u, v). The insertion affects the cluster graphs as follows:

(1) The clusters $C_{u'}$ and $C_{v'}$ might become neighbors because of the edge insertion and they also might be split while rebalancing the relaxed partition. In either case some b-nodes and/or c-nodes in $I(C_{u'})$ and $I(C_{v'})$ change. If this happens the data structures for $I(C_{u'})$ and $I(C_{v'})$ are rebuilt from scratch.

(2) For a cluster C' incident to a split cluster the b-node representing the split cluster might have to be partitioned into a constant number of b-nodes. If this happens the data structures for $I(C')$ are rebuilt from scratch.

(3) Nodes on $\pi_{T_1}(C_{u'}, C_{v'})$ that separated $C_{u'}$ and $C_{v'}$ in H_1 before the insertion no longer separate $C_{u'}$ and $C_{v'}$. For each such node, a suitable red edge is added to the cluster graph, without rebuilding the cluster graph from scratch.

We next discuss each case in detail. (1) If $C_{u'}$ and $C_{v'}$ become neighbors because of the edge insertion, then a new b- or c-node representing $C_{v'}$, resp., $C_{u'}$, has to be added to $I(C_{u'})$, resp., $I(C_{v'})$. Consider the split of a cluster C into a constant number of clusters C_j. Then each c-node in $I(C_j)$ represents only one cluster by part (d) of the definition of a c-node. Thus, for each neighbor of C_j simply test whether it has the same ancestor as C_j. If yes, it is represented by a b-node in $I(C_j)$, otherwise it is represented by a c-node.

(2) We describe next how the changes in the b-nodes of $I(C')$ are determined when cluster C is split into a constant number of nodes C_j. Bucketsort the edges incident to C in lexicographic order of its two endpoints in the updated graph H_1 (using (HL6)). Each neighbor of C with the same ancestor as C that is incident to edges from $l > 1$ different buckets (i.e., new clusters) of its array receives l new b-nodes representing these new clusters, discards the b-node of C, and keeps all the other old b-nodes.

(3) The articulation points on $\pi_{T_1}(C_{u'}, C_{v'})$ are found by testing in constant time each of the clusters on $\pi_{T_1}(C_{u'}, C_{v'})$ using data structure (HL4) for H_1 (before the update). Then a red edge between its tree neighbors on $\pi_{T_1}(C_{u'}, C_{v'})$ is added to each

articulation point.

We next show that this takes total time $O(k)$. In (1) it takes constant time to test whether a b-node or a c-node has to be added for the neighbor of a cluster. Each test takes constant time using (HL7). By Lemma 2.10 there are $O(k)$ many such tests. Building the data structure (CG1) for a constant number of clusters takes time $O(k)$ by Lemma 2.15; building (CG2) and (CG3) takes $O(k)$ as well.

In (2) there are $O(k)$ edges to bucketsort. If each bucket with a count larger than 1 is put in a separate list, then all new b-nodes can be determined in time $O(k)$, and (CG3) can be updated accordingly. By Lemma 2.10 the total size of all the cluster graphs rebuilt in (2) is $O(k)$. Thus building (CG1) and (CG2) for all of them takes total time $O(k)$ by Lemma 2.15.

Each test in (3) takes constant time, and adding the red edge for a former articulation point C' in H_1 takes time linear in the degree of C'. By Fact 2.1 the H_1-degree of all articulation points on $\pi_{T_1}(C_{u'}, C_{v'})$ sums to $O(m/k)$.

Deletion of a non-tree edge. The deletion of a non-tree edge does not change the spanning tree and does not split a cluster (Lemma 2.5). Thus, the deletion of a non-tree edge affects the cluster graph as follows:

(1) The clusters $C_{u'}$ and $C_{v'}$ might no longer be neighbors in H_1. In this case the corresponding b-node or c-node has to be removed from $I(C_{v'})$, resp., $I(C_{u'})$. If this happens the data structures for $I(C_{u'})$ and $I(C_{v'})$ are rebuilt from scratch.

(2) A red edge has to be removed and the blue edges have to be updated in the cluster graph of each new articulation point on $\pi_{T_1}(C_{u'}, C_{v'})$ in the updated graph H_1.

We next discuss each case in detail: in case (1) we simply need to test whether the edge $(C_{u'}, C_{v'})$ was removed from H_1. If so, and if $C_{u'}$ and $C_{v'}$ have the same ancestor, then the corresponding b-nodes are removed from $I(C_{v'})$ and $I(C_{u'})$. Otherwise, we need to test whether the c-node representing $C_{u'}$ in $I(C_{v'})$ represents further clusters. If not, then the c-node is removed. We proceed in the same way for the c-node representing $C_{v'}$ in $I(C_{u'})$.

In case (2) we determine each new articulation point C on $\pi_{T_1}(C_{u'}, C_{v'})$ by testing in constant time each of the clusters on $\pi_{T_1}(C_{u'}, C_{v'})$ using data structure (HL4) for H_1 (after the update). Then we remove all old red and blue edges from $I(C)$. Using (HL3) we determine for each neighbor C' of C the tree neighbor C'' of C such that C'' lies on $\pi_{T_1}(C, C')$, and connect C' by a blue edge with C''. Finally we determine the biconnected components of the tree neighbors of C using a *components?(C)* operation in (HL4) and add the suitable red edges.

We next show that this takes total time $O(k)$. In case (1) testing and rebuilding the data structures takes time $O(k)$ by the same argument as for insertions. In case (2) finding all articulation points takes time $O(m/k)$. Determining the new red and blue edges takes time linear in the degree of each articulation point. By Fact 2.1 the total cost for all articulation points is $O(m/k)$.

Deletion of a tree edge. Let u' and v' be the representatives that are incident to the deleted edge (u, v) and let x' and y' be the representatives that are incident to the new tree edge (x, y), if it exists. By Lemma 2.5, $C_{u'}$, $C_{v'}$, $C_{x'}$, and $C_{y'}$ are the only clusters that might be split.

The cluster graphs are affected as follows: (1) The clusters $C_{u'}$ and $C_{v'}$ might no longer be neighbors in H_1. In this case the corresponding b-node or c-node has to be removed from $I(C_{v'})$, resp., $I(C_{u'})$. If this happens the data structures for $I(C_{u'})$ and $I(C_{v'})$ are rebuilt from scratch.

(2) The clusters $C_{u'}$, $C_{v'}$, $C_{x'}$, and $C_{y'}$ might be split. The data structures (CG1)–(CG3) are rebuilt from scratch for each cluster created by the splits.

(3) For a cluster C' incident to a split cluster the b-node representing the split cluster might have to be partitioned into a constant number of b-nodes. If this happens the data structures for $I(C')$ are rebuilt from scratch.

(4) A red edge has to be removed and the blue edges have to be updated in the cluster graph of each new articulation point on $\pi_{T_1}(C_{x'}, C_{y'})$ in the updated graph H_1.

We implement (1), (2), (3), and (4) as in the cases of edge insertions or deletions of non-tree edges. Thus, the same arguments as above show that all this can be implemented in time $O(k)$.

We summarize the section with the following theorem.

THEOREM 2.16. *The given data structure*

(1) *tests in constant time whether two vertices u and v of $V(C)$ for a cluster C that are not separated by s_C are biconnected in G,*

(2) *can be updated in amortized time $O(k)$ after each update in G, and*

(3) *can be built in time $O(m)$.*

2.6. Shared graphs. We maintain a shared graph $G(s)$ for every shared vertex s. Given a shared vertex s and two of its tree neighbors x and y, the shared graph of s is used to test in constant time whether s is an articulation point separating x and y in G.

Let C_s be the node of H_2 representing s, i.e., it represents the nodes in all s-clusters. Let $\mathcal{V}(C_s) = \{v; v \in G$, and v is represented by $C_s\}$. Shared graphs are used to test whether a pair of two special vertices of G that either are represented by the same node of H_2 or are incident to the same node of H_2 (to be precise, two tree neighbors of s) are biconnected in G. Note that cluster graphs solve this problem in H_1: a cluster graph tests whether two vertices of G that are represented by or are incident to the same node of H_1 are biconnected in G, under the additional condition that no dashed edge is incident to this node of H_1. (For nodes of H_1 that are incident to a dashed edge only a restricted version of the problem is solved.) Since there are no dashed edges in H_2, we simply can define shared graphs analogously to cluster graphs and use the data structure for cluster graphs also for shared graphs. However, it is possible that $|C_s| = \Theta(m)$ and, thus, rebuilding the data structure from scratch can take time $\Theta(m)$.

This leads to the following definition. Let us call a shared vertex s *new* if s became shared by a cluster split after the last rebuild, and let it be called *old* otherwise (i.e., if it became a shared vertex during the last rebuild). Note that if s is new, then $|\mathcal{V}(C_s)| = O(k)$ by Lemma 2.10, and, thus, a solution analogous to cluster graphs is efficient.

For old shared vertices we use a new technique, which exploits the fact that the tree neighbors x and y of s are biconnected iff x and y are connected in $G \setminus s$. Thus, we maintain a "compressed" version of $G \setminus s$ in which we ask *connectivity* queries. The shared graph will be stored in a dynamic connectivity data structure. Note that there are $O(m/k) = O(k)$ many shared vertices, which implies we have to maintain $O(k)$ many shared graphs.

2.6.1. Shared graphs for new shared vertices. Let s be a new shared vertex represented by node C_s in H_2, and let A_s be the ancestor of C_s. The *shared graph* $G(s)$ contains as nodes

(1) a node, called *a-node*, for each vertex in $\mathcal{V}(C_s)$,

(2) one node, called *b-node*, for each neighbor of C_s with ancestor A_s,

(3) one node, called *c-node*, for each maximal set X of nodes of H_2 such that (a) every cluster $C' \in X$ is a neighbor of C_s, (b) all nodes in X are connected in $H_2 \setminus C_s$, (c) all nodes in X have the same ancestor which is different from A_s, (d) at the creation of C_s, the set X contains only one node, and (e) at each previous point in time since the creation of C_s all nodes of H_2 that contain the vertices in $\cup_{C' \in X} C'$ existing at this time are represented by the same c-node in $G(s)$.

Note that for each neighbor C' of C_s there exists a unique node in $G(s)$ representing C' and potentially other clusters.

The graph $G(s)$ contains the following edges:

(1) All edges between two vertices of $\mathcal{V}(C_s)$ belong to $G(s)$.

(2) For each edge (u, v), where u belongs to $\mathcal{V}(C_s)$, v does not belong to $\mathcal{V}(C_s)$, and (u', v') is the corresponding edge in G, there is an edge (u, d), where d is the b- or c-node representing $C_{v'}$ in $G(s)$.

(3) All b- or c-nodes representing tree neighbors of C that are biconnected in H_2 are connected by a tree of *red* edges.

(4) For each non-tree neighbor C_1 of C, $G(s)$ contains a *blue* edge (d_1, d_2), where d_2 represents a tree neighbor of C that is biconnected to C_1 in H_2, and d_1 represents C_1.

Note that for each non-tree neighbor C_1 of C there always exists a tree neighbor of C that is biconnected to C_1 in H_2—the tree neighbor of C that lies on $\pi_{T_2}(C, C_1)$ always is biconnected to C_1.

Since all clusters sharing s have the same ancestor, Lemma 2.10 shows that $|G(s)| = O(k)$.

A tree neighbor of s either belongs to $\mathcal{V}(C_s)$ and is represented by an a-node, or does not belong of $\mathcal{V}(C_s)$ and is represented by a b- or c-node. We need to show the following lemma.

LEMMA 2.17. *Let x and y be two tree neighbors of a new shared vertex s. Then (the representative of) x and y are biconnected in $G(s)$ iff x and y are biconnected in G.*

Proof. Note that $G(s)$ can be created by contracting edges in G. Thus, biconnectivity in $G(s)$ implies biconnectivity in G.

Vertices x and y are connected by a tree path $(u, s), (s, v)$. Thus s is the only node that could be an articulation point separating x and y. Contracting edges not incident to s cannot make s into an articulation point separating x and y. Hence, biconnectivity in G implies biconnectivity in $G(s)$. □

We use the same data structure as for cluster graphs to store shared graphs for new shared vertices. Given the b- and c-nodes the red edges can be found in time linear in their number using the data structure (HL4) for H_2. We determine the blue edges of $G(s)$ by connecting each non-tree neighbor C_1 of a node C to the tree neighbor of C on $\pi_{T_2}(C, C_1)$. Using the data structure (HL3) for H_2 this takes time linear in the number of blue edges times $O(\log n)$. Using the data structure of [11] results in the following lemma.

LEMMA 2.18. *Let s be a shared vertex represented by the node C of H_2. Then there exists a data structure for the shared graph of s such that*

(1) *building the data structure takes time $O(|C_s| + (m/k) \log n)$, provided that the b-nodes and the c-nodes are given;*

(2) *changing one or all of the colored edges in the data structure takes time linear in their total number times $O(\log n)$, given the b-nodes and c-nodes;*

(3) *testing whether two vertices of* $\mathcal{V}(C_s)$ *are biconnected in* $G(s)$ *takes constant time.*

These data structures are updated with the algorithm of section 2.5.1 with H_1 replaced by H_2. Since the test in (HL3) takes time $O(\log n)$, the amortized time per operation is $O(k + (m/k)\log n)$.

2.6.2. Shared graphs for old shared vertices. Let s be an old shared vertex and let C_s be the node of H_2 representing s. We cannot use the data structure of the previous section for the shared graph of s since rebuilding the data structure from scratch would take time $\Omega(|C_s|)$, which might be $\Theta(m)$. Still we use an approach similar to the one in the previous section but avoid rebuilds from scratch for the whole data structure.

We will exploit the following fact: Condition (C6) of a relaxed partition guarantees that at any time in a phase $O(m/k)$ vertices that do not belong to C_s are incident to a vertex of C_s. Only the $O(m/k)$ shared vertices and the $O(m/k)$ endpoints of edges inserted in the phase can be neighbors of a vertex in C_s and not belong to C_s.

The graphs $G(s)$. Let s be an old shared vertex,
(1) let C_s be the node representing s in H_2,
(2) let A_s be the ancestor of C_s in H_2, and
(3) let $\mathcal{V}_s = \{v, v \in G$ and v is represented by a node of H_2 with ancestor $A_s\}$.

Note that at the beginning of a phase $\mathcal{V}_s$ consists exactly of all the vertices in C_s. Later in the phase, the vertices of G in C_s are all contained in $\mathcal{V}_s$, but $\mathcal{V}_s$ can contain additional vertices.

The graph $G(s)$ contains as vertices
(1) a node, called *a-node*, for each vertex in $\mathcal{V}_s$, except for s, and
(2) a node, called *d-node*, for each vertex of G that does not belong to $\mathcal{V}_s$ but is a neighbor of a vertex in $\mathcal{V}_s$.
The graph $G(s)$ contains as edges every edge between two a-nodes or between an a-node and a d-node.

LEMMA 2.19. *Let s be an old shared vertex. The number of d-nodes in $G(s)$ is $O(m/k)$.*

Proof. By condition (C6) of a relaxed partition the number of d-nodes at the beginning of a phase connected to a vertex of $\mathcal{V}_s$ by non-tree edges is $O(m/k)$. Additionally there are $O(m/k)$ tree edges. During the phase only the endpoints of edges inserted during the phase can become neighbors of vertices in $\mathcal{V}_s$. Thus, the lemma follows. ☐

Data structure:

(S1) We store $G(s)$ in a fully dynamic connectivity data structure. This data structure allows us to execute the following operations:
(1) *insert(u,v)/delete(u,v):* Insert or delete the edge (u, v) in time $O(\sqrt{m'})$, where m' is the number of edges in $G(s)$.
(2) *insert(u):* Insert the degree-0 vertex u in time $O(\sqrt{m'})$, where m' is the number of edges in $G(s)$.
(3) *connected?(u,v):* Test whether u and v are connected in constant time.
(4) *component?(u):* Return the connected component of u in constant time.

(S2a) We keep for each connected component of $G(s)$ a list of all the d-nodes that belong to it.

(S2b) We keep for each connected component of $G(s)$ a list of all neighbors of C_s with ancestor A_s whose vertices belong to the connected component. We also store for each node of H_2 its position in the at most one such list to which it belongs.

LEMMA 2.20. *The data structures for $G(s)$ for all old shared vertices s can be built in time linear in its size at the beginning of a phase and can be updated in time $O(\sqrt{m})$ after an edge insertion or deletion in G.*

Proof. At the beginning of a phase the vertices of $G(s)$ are simply the vertices in C_s and their neighbors and are given by (HL1) and (G1). The edges are given by (G1). Building (S1) and (S2a) takes linear time; (S2b) is an empty list.

Each edge insertion or deletion in G affects the data structure for $G(s)$ of at most one old shared vertex s since the sets $\mathcal{V}_s$ are vertex-disjoint for different old shared vertices s. Since the graph $G(s)$ consists of at most m edges, its fully dynamic connectivity data structure can be updated in time $O(\sqrt{m})$.

In case of the deletion of the edge (u', v') we test after the removal of the edge from $G(s)$ whether u' and v' are still connected. If not, we test each d-node in the old connected component of u' and v' whether it is either connected to u' or to v'. In this way we construct the list of d-nodes for the two new connected components of $G(s)$. By Lemma 2.19 this requires $O(m/k)$ tests. In the same way we split the (S2b) list of the old connected component to create the (S2b) lists of the two new connected components and update the corresponding positions at the nodes of H_2.

In case of an edge insertion we insert a new d-node if one of the endpoints of the new edge does not belong to $G(s)$. Then we test whether the endpoints of the edge belonged to the same connected component before the insertion. If they did not, we combine their lists of d-nodes and their lists of neighbors of C_s. Note that these lists were disjoint before the combination since otherwise the two connected components would have shared a vertex.

Additionally we determine for each cluster split by an update operation whether its node in H_2 is split as well and whether a position in an (S2b) list is stored at the node. If so, we update the entry in the (S2b) list accordingly and store the appropriate positions at the new nodes. Since only a constant number of nodes is split by Lemma 2.5, this takes constant time.

Thus, the total time of an update is $O(\sqrt{m})$. ∎

Note that each tree neighbor x of s either belongs to C_s or is represented by a node of H_2 that is a neighbor of C_s. In the latter case we call the neighbor of C_s representing x the *x-neighbor* of C_s. In the former case we determine a node that is a neighbor of C_s and connected to x in $G(s)$ as follows: Using (S1) and (S2b) we can determine in constant time a neighbor of C_s with ancestor A_s that is in the connected component of x. If no such node exists, then using (S1) and (S2a) we can determine in constant time a d-node, and using (HL1) a node of H_2, that is connected to x in $G(s)$ if such a d-node exists. Note that in the latter case the d-node is connected to a node in C_s, i.e., the node of H_2 containing the d-node is a neighbor of C_s, since no node with ancestor A_s belongs to the connected component of x. In either case the determined neighbor of C_s is called an *x-neighbor* of C_s.

The graphs $\tilde{G}(s)$. The intuition for the graph $\tilde{G}(s)$ is as follows: Initially, and whenever $\tilde{G}(s)$ is rebuilt, each neighbor of C_s is represented by a vertex in $\tilde{G}(s)$. If this neighbor is split into two nodes C_1 and C_2 of H_2, then the corresponding vertex of $\tilde{G}(s)$ is updated (and the whole graph $\tilde{G}(s)$ is rebuilt) only if C_1 and C_2 are not connected in $H_2 \setminus C_s$ after the update. If C_1 and C_2 are connected in $H_2 \setminus C_s$ after the update, then the vertex of $\tilde{G}(s)$ is not modified, but represents now both nodes of H_2. This would guarantee that after an edge update we only have to update the graph $\tilde{G}(s)$ of an old shared vertex s if an edge of $G(s)$ was modified (i.e., $\mathcal{V}_s$ contains an endpoint of the updated edge) or the connected components of $H_2 \setminus C_s$ are modified by the update. However, to bound the number of these graphs using the amortization lemma of section 2.9 we need to treat nodes with ancestor A_s in a special way.

We formalize this as follows: The graph $\tilde{G}(s)$ contains as vertices

(1) one node, called *e-node*, for each maximal set X of nodes of $H_2 \setminus C_s$ such that (a) every node in X is a neighbor of C_s, (b) all nodes in X are connected in $H_2 \setminus C_s$, (c) all nodes in X have the same ancestor which is different from A_s, (d) at the creation of C_s, the set X contains only one element, and (e) the vertices in $\cup_{C' \in X} C'$ used to belong to the same node C_{old} of H_2 and since the split of C_{old}, the graph $G(s)$ was not modified and the connected components of $H_2 \setminus C_s$ did not change;

(2) one node, called *b-node*, for each neighbor of C_s with ancestor A_s.

Each vertex in $\tilde{G}(s)$ *represents* the nodes in the set X and thus also the vertices of G contained in these nodes.

The graph $\tilde{G}(s)$ contains the following edges.

(1) All vertices of $\tilde{G}(s)$ that contain vertices that are connected in $G(s)$ are connected by a tree of *yellow* edges in $\tilde{G}(s)$.

(2) All vertices of $\tilde{G}(s)$ whose nodes are connected in $H_2 \setminus C_s$ are connected by a tree of *green* edges in $\tilde{G}(s)$.

Let x be a vertex of $\mathcal{V}_s$ and a tree neighbor of s. Note that by definition all nodes of $\tilde{G}(s)$ representing an x-neighbor are connected in $\tilde{G}(s)$ by yellow edges, i.e., belong to the same connected component of $\tilde{G}(s)$.

Data structure:

(S3) We store $\tilde{G}(s)$ in an adjacency list representation and label each node with its connected component.

(S4) We store for each node C of H_2 an array with one entry per old shared vertex. The array stores for each old shared vertex s the vertex in $\tilde{G}(s)$ that represents C in $\tilde{G}(s)$ if such a vertex exists and *null* otherwise.

The next lemma shows how to use $G(s)$ and $\tilde{G}(s)$ to test whether two neighbors of s are biconnected in G.

LEMMA 2.21. *Two tree neighbors x and y of s are biconnected in G iff*

(1) *either x and y are connected in $G(s)$, or*

(2) *the connected component of the vertices of $\tilde{G}(s)$ representing x-neighbors is identical to the connected component of the vertices of $\tilde{G}(s)$ representing y-neighbors.*

Proof. Each edge in $G(s)$ or $\tilde{G}(s)$ corresponds to a path in G that does not contain s, and each vertex $u \in \mathcal{V}_s \setminus \{s\}$ is either contained in the u-neighbor or connected to every u-neighbor by a path in $G(s)$ that does not contain s. Additionally connectivity of x and y in $G \setminus \{s\}$ implies biconnectivity in G. Thus, if x and y are connected in $G(s)$ or if a vertex of $\tilde{G}(s)$ representing an x-neighbor of C_s is connected with a vertex of $\tilde{G}(s)$ representing a y-neighbor of C_s in $\tilde{G}(s)$, then x and y are biconnected in G.

To show the other direction consider a path P in G that connects x and y and does not contain s. If all vertices of P belong to $\mathcal{V}_s \setminus \{s\}$, then x and y are connected in $G(s)$.

Otherwise, recall that all vertices of $G(s)$ representing an x-neighbor (resp., y-neighbor) form a connected component of $\tilde{G}(s)$. It follows that it suffices to show that one of the vertices of $\tilde{G}(s)$ representing an x-neighbor is connected in $\tilde{G}(s)$ to one of the vertices of $\tilde{G}(s)$ representing a y-neighbor. In this case P contains a d-node d_x that is connected to x by a path in $G(s)$. If the path from x to d_x contains only vertices of C_s (excluding d_x), then let b_x be the vertex of $\tilde{G}(s)$ representing d_x and let u_x be d_x. If the path from x to d_x contains vertices not in C_s, let b_x be the vertex of $\tilde{G}(s)$ representing the first such node u_x on the path. In either case b_x represents an x-neighbor. Define u_y and b_y in the same way.

Consider the subpath P' of P between the u_x and u_y. Partition P' into subpaths such that each subpath is a maximal sequence of edges such that either (a) each edge is incident to a vertex of C_s or (b) no edge is incident to a vertex of C_s. Note that the endpoints of each subpath belong to nodes in H_2 that are neighbors of C_s.

Since P does not contain s, each subpath fulfilling (a) corresponds to a path in $G(s)$. Thus the vertices of $\tilde{G}(s)$ representing the endpoints of the subpath are connected by a path of yellow edges in $\tilde{G}(s)$. Each subpath fulfilling (b) connects the nodes of H_2 containing the endpoints of the subpath by a path in $H_2 \setminus C_s$. Thus the vertices of $\tilde{G}(s)$ representing these nodes of H_2 are connected by a path of green edges in $\tilde{G}(s)$. It follows that b_x is connected to b_y in $\tilde{G}(s)$. □

The first condition is tested in constant time using (S1). To test the second condition we determine the x-neighbor and y-neighbor using (S1), (S2a), (S2b), and (HL1). We determine the vertices of $\tilde{G}(s)$ representing the x-neighbor and the y-neighbor using (S4) and then test their connected components in $\tilde{G}(s)$ using (S3). All this takes constant time.

Let $deg_2(C_s)$ be the degree of C_s in H_2.

LEMMA 2.22. *If only the green edges of* $H_2 \setminus C_s$ *change, then* $\tilde{G}(s)$ *and the data structures* (S3) *and* (S4) *can be updated in time* $O(deg_2(C_s) \log n)$.

Proof. Discard all old green edges. To compute the new green edges, map each neighbor of C_s to a tree neighbor of C_s in H_2 using (HL3) and determine the biconnected component of this tree neighbor using *blockid?*-queries in (HL4) for H_2. Then bucketsort the neighbors according to these biconnected components using (HL6). For each neighbor in a biconnected component determine its vertex in $\tilde{G}(s)$ using (S4) and connect it by a green edge to the vertex in $\tilde{G}(s)$ of the previous neighbor in the same biconnected component. Then compute a spanning forest of the green edges by performing a depth-first search on the graph of green edges, and discard all green edges not in the spanning tree. Finally recompute the connected components of $\tilde{G}(s)$. This takes time $O(\log n)$ per neighbor and constant time per green edge. Since the number of green edges is linear in the number of neighbors, the lemma follows. □

LEMMA 2.23. *Let s be an old shared vertex. At the beginning of a phase or whenever* $G(s)$ *has changed, the graph* $\tilde{G}(s)$ *can be constructed in time* $O((m/k) \log n)$.

Proof. Note first that the size of $\tilde{G}(s)$ is linear in its number of vertices of $\tilde{G}(s)$, which is bounded by $deg_2(C_s)$.

The vertices of $\tilde{G}(s)$ are the neighbors of C_s and are given by (HL2). To determine the yellow edges, process the d-nodes belonging to the same connected component of $G(s)$ as follows. Map each d-node in (S2a) for this connected component to its node in H_2 using (HL1). Append to this list the neighbors of C_s stored in (S2b) for this connected component. Now process each node C in this list as follows: Determine the vertex of $\tilde{G}(s)$ representing C and connect it by a yellow edge to the vertex of $\tilde{G}(s)$ representing the previous node on the list. This takes time linear in the length of the list. Then compute a spanning tree of yellow edges by performing a depth-first search on the graph of yellow edges. Discard the yellow edges that do not belong to the spanning tree. This takes time linear in the number of yellow edges, which is linear in the length of the list. The length of the list is linear in the number of d-nodes in $G(s)$ in the connected component and the length of the (S2b) list for the connected component. By Lemma 2.19 there are $O(m/k)$ many d-nodes in $G(s)$, i.e., in the (S2a) lists for all connected components. Also there are $O(m/k)$ many neighbors, i.e., in the (S2b) lists for all connected components. Thus, the total time for determining all yellow edges in $\tilde{G}(s)$ is $O(m/k)$.

The green edges are computed in time $O((m/k)\log n)$ as in Lemma 2.22. ∎

Lemma 2.24. *Constructing the graphs $\tilde{G}(s)$ for all old shared vertices at the beginning of a phase takes time $O(m \log n)$. Building the data structures* (S3) *and* (S4) *for all s at the beginning of a phase takes time $O(m)$.*

Proof. By Lemma 2.23, constructing one graph $\tilde{G}(s)$ takes time $O((m/k)\log n)$, for a total of $O((m/k)^2 \log n) = O(m \log n)$.

When $\tilde{G}(s)$ is given, then building (S3) for s takes time linear in the size of $\tilde{G}(s)$. To build (S4) we allocate and initialize with *null* all the necessary arrays. This takes time $O((m/k)^2) = O(m)$. Then we process each graph $\tilde{G}(s)$ and set the entry for s in the array of node C of H_2 to the vertex of $\tilde{G}(s)$ representing C if it exists. ∎

Lemma 2.25. *The graphs $\tilde{G}(s)$ and the data structures* (S3) *and* (S4) *for all old shared vertices s can be updated in amortized time $O((m/k)\log n)$ after an edge insertion or deletion in G.*

Proof. We will show that after the insertion or deletion of the edge (u, v) in G the only old shared vertices s for which $\tilde{G}(s)$ has to be updated are the ones (1) where $\mathcal{V}_s$ contains u or v, (2) where a node of H_2 that is split by the update has ancestor A_s, or (3) where C_s is an articulation point on $\pi_{T_2}(C_u, C_v)$ before or after the current update. For type-(3) old shared vertices either (i) a vertex of $\tilde{G}(s)$ has to be split and the green and yellow edges have to be recomputed or (ii) only the green edges have to be updated. If a yellow edge has to be changed without splitting a vertex, then $\mathcal{V}_s$ must contain u or v, i.e., it is a type-(1) old shared vertex.

To guarantee that all graphs that have to be changed are indeed updated we use the following update algorithm:

(1) Rebuild from scratch the graphs $\tilde{G}(s)$ for all old shared vertices s where $\mathcal{V}_s$ contains either u or v (type (1) above), where C_s has the same ancestor as a split node in H_2 (type (2) above), or where a vertex of $\tilde{G}(s)$ is split (type (3(i)) above).

(2) Update the green edges in the graph $\tilde{G}(s)$ for the remaining old shared vertices where C_s is an articulation point on $\pi_{T_2}(C_u, C_v)$ before or after the update (case (3(ii)) above).

To find all type-(2) old shared vertices, we determine for each split node of H_2 its ancestor A using (HL7) and test for each old shared vertex s whether the ancestor of C_s equals A. The old shared vertices for which this test returns true are the type-(2) old shared vertices.

We discuss next how to determine all type-(3(i)) and type-(3(ii)) old shared vertices. There are two kinds of vertices in $\tilde{G}(s)$, e-nodes and b-nodes. If a b-nodes has to be split, then s is also a type-(2) old shared vertex and will be updated correctly. Thus, it suffices to determine all type-(3(i)) old shared vertices s where an e-nodes has to be split. In section 2.8 we give a data structure that determines all e-nodes that have to be split in time $O((m/k)\log n)$. Furthermore, we show in section 2.9 that only an amortized constant number of e-nodes has to be split. We determine all articulation points on $\pi_{T_2}(C_u, C_v)$ using (HL4). This gives all type-(3) old shared vertices. We remove the ones that are of type (2). In the remaining set the ones that contain an e-node that has to be split are the type-(3(i)) but not type-(2) old shared vertices; the rest are the type-(3(ii)) old shared vertices.

Whenever $\tilde{G}(s)$ is rebuilt, we also rebuild (S3) from scratch. The data structure (S4) is updated as follows:

(1) For each new node that is created by a split of an old node during the phase, the array of the old node is copied to create the array for the new node.

(2) For each old shared vertex s where $\tilde{G}(s)$ is rebuilt, the entry of s in the array of every neighbor of C_s is replaced by the vertex representing the neighbor in $\tilde{G}(s)$.

Lemma 2.23 shows that for type-(1), type-(2), and type-(3(i)) old shared vertices the graph $\tilde{G}(s)$ can be constructed in time $O((m/k)\log n)$. Lemma 2.22 shows that for type-(3(ii)) old shared vertices the green edges can be updated in time $O(deg_2(C_s)\log n)$. Determining all old shared vertices s such that a vertex of $\tilde{G}(s)$ has to be split or that $A_s = A$ takes time $O(m/k)$ per split cluster. By Lemma 2.5 there are a constant number of split clusters per update, i.e., the total time spent to determine type-(2) and type-(3(i)) old shared vertices is $O(m/k)$. Determining all articulation points and all type-(3(ii)) old shared vertices takes time $O(m/k)$. Building (S3) takes time $O(deg_2(C_s))$. The first type of update of (S4) creates a new array and takes time $O(m/k)$; the second type takes time $O(deg_2(C_s))$. Thus, updating the graphs $\tilde{G}(s)$ and the data structure (S3) for type-(1), (2), and (3(i)) old shared vertices takes time $(O(m/k)\log n)$ each; updating the graphs $\tilde{G}(s)$ and the data structure (S3) for type-(3(ii)) old shared vertices takes time $O(deg_2(C_s)\log n)$ each.

We show next that there are only an amortized constant number of type-(1), (2), and (3(i)) old shared vertices whose graphs $\tilde{G}(s)$ have to be updated, for a total time of $O((m/k)\log n)$ to update them. There are at most two type-(1) old shared vertices. There is at most one type-(2) old shared vertex per split node C of H_2, since the fact that C has ancestor A_s implies that the vertices of C belong to $\mathcal{V}_s$ and the sets $\mathcal{V}_s$ are disjoint for different old shared nodes. By Lemma 2.43 and Lemma 2.44 there are an amortized constant number of type-(3(i)) old shared vertices, where an e-node has to be split.

By Fact 2.1 the degree of all articulation points on a path in H_2 sums to $O(m/k)$. Thus, $deg_2(C_s)$ for all type-(3(ii)) old shared vertices sums to $O(m/k)$. Hence, updating all graphs $\tilde{G}(s)$ and building (S3) for the type-(3(ii)) old shared vertices takes time $O((m/k)\log n)$. Finally, a new array in (S4) is created for a constant number of new nodes of H_2. Summing all the cost gives a total time of $O((m/k)\log n)$ to update all graphs $\tilde{G}(s)$ and their data structures (S3) and (S4).

We still need to show the above claim about which graphs $\tilde{G}(s)$ have to be changed and how. A graph $\tilde{G}(s)$ has to be updated if (A) a vertex, (B) a yellow edge, or (C) a green edge has to be changed.

(A) If a b-node of $\tilde{G}(s)$ has to be changed, then a node in H_2 with ancestor A_s was split (case (2) above). If an e-node of $\tilde{G}(s)$ has to be changed, then either condition (a), (b), or (c) of an e-node does not hold anymore. If (a) does not hold anymore, then the current update deleted an edge of $G(s)$, i.e., $\mathcal{V}_s$ contains an endpoint of the updated edge (case (1) above). If (b) does not hold anymore, then C_s is an articulation point separating the endpoints of the updated edge before or after the current update (case (3) above). If (c) does not hold, then again either the current update modified an edge of $G(s)$ (case (1) above), or C_s is an articulation point separating the endpoints of the updated edge before or after the current update (case (3) above).

(B) If a yellow edge but no vertex of $\tilde{G}(s)$ has to be changed, then an update occurred in the graph $G(s)$. It follows that $\mathcal{V}_s$ contains at least one of the endpoints of the updated edge (case (1) above).

(C) If a green edge has to be changed, then C_s is an articulation point separating the endpoints of the updated edge before or after the current update (case (3) above).

This completes the proof of the lemma. ◻

We summarize the section with the following theorem.

THEOREM 2.26. *The given data structure*

(1) *tests in constant time whether two tree neighbors x and y of a shared vertex s are biconnected in G,*

(2) *can be updated in amortized time $O((m/k)\log n + \sqrt{m})$ after each update in G, and*

(3) *can be built in time $O(m \log n)$.*

2.7. The high-level graphs. In this section we give the details of the high-level graph data structures and explain how they are updated. For (HL1), (HL2), (HL5), (HL6), and (HL7) the details are given in section 2.4 and it is obvious how to update them in time $O(k)$ per update in G, provided the change in the cluster partition is known. The description in section 2.2 gives an $O(k)$-time algorithm to update the cluster partition. Thus, we concentrate in this section on the details of (HL3) and (HL4).

2.7.1. The data structure (HL3). Consider the graph H_i. Given the two nodes C and C' of H_i we use (HL3) to find the tree neighbor of C on $\pi_{T_i}(C, C')$. For H_2 (HL3) consists of a dynamic tree data structure of T_2. To find the tree neighbor, root T_2 at C' and return the parent of C. Update (HL3) by executing link and cut operations whenever T_2 changes. It takes time $O(\log n)$ to test or update (HL3).

For H_1, (HL3) consists of a degree-k ET-tree data structure of T_1. To find the tree neighbor proceed as follows. For the node C', and the tree neighbors of C, label one of the leaves representing the node with the name of the node. Then traverse the ET-tree from all labeled leaves in lockstep, labeling each internal node with the concatenation of the label of its left child and the label of its right child. At the root the label incident to C''s label is the desired tree neighbor. To update the ET-tree, whenever T_1 changes, split and join the ET-tree accordingly. Since the ET-tree has $O(1)$ depth and C has $O(1)$ tree neighbors, a test takes $O(1)$ time. Each update takes time $O(k)$.

2.7.2. The data structure (HL4). Recall that (HL4) implements the following query operations in H_i:

(1) *biconnected?(C,C′,C″):* Given that nodes C' and C'' are both tree neighbors of a node C test whether C' and C'' are biconnected in H_i.

(2) *blockid?(C,C′):* Given that C and C' are tree neighbors in T_i, output the name of the biconnected component of H_i that contains both C and C'.

(3) *components?(C):* Output the tree neighbors of C in H_i grouped into biconnected components.

As we show below, *biconnected?* and *blockid?* take constant time, and *components?* takes time linear in the size of the output.

We say a node C of H_i is *avoidable on the tree path P* iff C and two of its tree neighbors, called D and D', belong to P and there is an edge in $H_i \setminus C$ between the subtree of $T_i \setminus C$ containing D and the subtree containing D'. Note that if C is avoidable, then C does not separate D and D'. However, if C does not separate D and D' it does not follow that C is avoidable.

To implement (HL4) we build a compressed graph $H_i(C)$ of $H_i \setminus C$ for each node C in H_2. Let C be a node in H_i. The graph $H_i(C)$ contains a node for each tree neighbor of C in H_i. There is an edge between two tree neighbors D and D' of C iff C is avoidable on $\pi_{T_i}(D, D')$.

We keep the following data structures. The second is needed to efficiently maintain the $H_i(C)$.

(HL4-1) For $i = 1, 2$, and for each node C we store $H_i(C)$ in a dynamic connectivity data structure.

(HL4-2) A 2-dimensional topology tree [5] of T and one ambivalent data structure [6] are maintained. They implement the following operations in time $O((m/k) \log n)$:

(1) *insert&return_avoidable(u,v):* Return all nodes on $\pi(C_u, C_v)$ that become avoidable on $\pi(C_u, C_v)$ by the insertion of edge (u, v), where C_u and C_v are the endpoints in H_i of the newly inserted edge.

(2) *delete&return_unavoidable(u,v):* Return all nodes on $\pi(C_u, C_v)$ that become unavoidable on $\pi(C_u, C_v)$ by the deletion of edge (u, v), where C_u and C_v are the endpoints in H_i of the newly deleted edge.

We show how to implement the operations of (HL4) using (HL4-1).

(1) *biconnected?(C,C′,C″)*: Return *connected?(C′, C″)* in $H_i(C)$.

(2) *blockid?(C,C′)*: Return *component?(C′)* in $H_i(C)$.

(3) *components?*: Return all connected components of $H_i(C)$, and for each connected component output all its nodes.

The correctness of this implementation is shown by the following lemma.

LEMMA 2.27. *Two tree neighbors D and D' of C in H_i are biconnected in H_i iff they are connected in $H_i(C)$.*

Proof. If D and D' are connected in $H_i(C)$, then every edge on the path connecting D and D' corresponds to a path in $H_i \setminus C$. Thus they are biconnected in H_i. If D and D' are biconnected in H_i, they are connected by a path in $H_i \setminus C$. Every edge on this path either lies in a subtree of $T_i \setminus C$ or connects two subtrees. The edges connecting two subtrees give a path in $H_i(C)$ connecting D and D'. □

Updates in $H_i(C)$. Consider an insertion of edge (u, v) in G and let C_u and C_v be the nodes in H_i incident to the edge. The graph $H_i(C)$ has to be modified only for the nodes that become avoidable on $\pi(C_u, C_v)$. These nodes can be found with one *insert&return_avoidable* operation in (HL4-2). Let C be such a node. Note that exactly one edge is added to $H_i(C)$, namely, the edge between the tree neighbors of C on $\pi(C_u, C_v)$.

An edge deletion in G is handled analogously.

To analyze the running time recall that the operation in (HL4-2) takes time $O((m/k) \log n)$. The update in a graph $H_i(C)$ takes time $O((deg_T(C))^{1/3} \log deg_T(C))$, where $deg_T(C)$ is the degree of C in T_i. Since $\sum_C deg_T(C) = O(k)$, the cost for updating all $H_i(C)$ is $O(k)$. This shows the following theorem.

THEOREM 2.28. *There exists a data structure that implements the operations biconnected?, blockid?, and components? in time linear in their output. The data structure can be updated in time $O(k + (m/k) \log n)$ after each update operation in G.*

2.7.3. The data structure (HL4-2).

We present now a data structure that implements *insert&return_avoidable* and *delete&return_unavoidable* in time $O((m/k) \log n)$.

We will actually show a slightly more general result: we give a data structure that can be updated in time $O(m/k)$ after each update in G and that can return all avoidable nodes on a tree path P in H_i in time $O((m/k) \log n)$. Obviously this data structure can be used to execute the above operations in time $O((m/k) \log n)$.

In this section we assume that T_1 is rooted at a node R.

The data structure consists of two parts: (1) a 2-*dimensional topology tree* and (2) an *extended ambivalent data structure*. Both are slight variations of data structures defined in [5, 6].

Let $e = (D, C)$ be an edge of T_1. We denote by $ST(D, C)$ the subtree of $T_1 \setminus e$ that contains D. Obviously a node C of H_1 is avoidable on a tree path P iff there exists an edge between $ST(D, C)$ and $ST(D', C)$, where D and D' are the neighbors of C on P. We call a node on P that is not an endpoint of P an *internal* node of P.

The 2-dimensional topology tree and the extended ambivalent data structure are based on H_1, not H_2. Thus, to test avoidability in H_2 we need to reduce it to testing avoidability in H_1. For each path P in T_2, let P_{T_1} denote the corresponding path in T_1 starting, resp., ending, at an arbitrary node of H_1 that maps to the start node, resp., end node, of P. Recall that each node C of H_2 is created by a set of H_1-nodes that are connected by a path of dashed edges. For an internal node C on P, let $C(P_{T_1})$ and $C(P_{T_1})'$ denote the extreme-most nodes of that dashed path on P_{T_1}. We use the following lemma.

LEMMA 2.29. *Let C be a node of H_2 on a tree path P in T_2. Let D, resp., D', be the neighbor of $C(P_{T_1})$, resp., $C(P_{T_1})'$, on P_{T_1} that does not map to C. Then C is avoidable on P iff there is an edge between $ST(D, C(P_{T_1}))$ and $ST(D', C(P_{T_1})')$.*

Proof. Note that the edges incident to the subtree containing $h(D)$, resp., $h(D')$, in $H_2 \setminus C$ are identical to the edges incident to $ST(D, C(P_{T_1}))$, resp., $ST(D', C(P_{T_1})')$. □

As we show below, the 2-dimensional topology tree can test in time $O(m/k)$ whether there is an edge between $ST(D, C(P_{T_1}))$ and $ST(D', C(P_{T_1})')$. We extend the ambivalent data structure of [6] such that it can test in time $O(m/k)$

(1) for all but $O(\log n)$ nodes C of H_2 on a path P of T_2 whether there is an edge between $ST(D, C(P_{T_1}))$ and $ST(D', C(P_{T_1})')$; and

(2) for all but $O(\log n)$ nodes C of H_1 on a path P of T_1 whether there is an edge between $ST(D, C)$ and $ST(D', C)$.

Thus, to test the avoidability on a path P we use the ambivalent data structure to get the avoidability information for all but $O(\log n)$ nodes of P and we use the 2-dimensional topology tree for the remaining nodes.

Note that the term *tree edge* refers to an edge in T, T', or T_i, never to an edge in a topology tree.

The 2-dimensional topology tree. Given a restricted partition of order k we call each cluster of the partition a *level*-0 *cluster* or *basic cluster*. A *level-i cluster* is

(1) the union of two level-$(i-1)$ clusters that are connected by a tree edge such that one of them has tree degree 1 or both have tree degree 2, or

(2) one level-$(i-1)$ cluster if the previous rule does not apply.

A *topology tree* TT is a tree such that each node C at level i corresponds to a level-i cluster. If C is the union of two clusters C_1 and C_2 at level $i-1$, then C_1 and C_2 are the children of C and the tree edge (C_1, C_2) is stored at C. If C consists of one level-$(i-1)$ clusters C at level i, then C_1 is the only child of C in the topology tree. A *rooted topology tree* TT is a topology tree with the additional condition that R is only unioned when no other unions are possible.[8]

A 2-*dimensional topology tree* $2TT$ for TT is a tree that contains a node $C \times D$ at level i for every pair (C, D) of level-i clusters in TT. A level-$(i-1)$ node $C_1 \times D_1$

[8]We will exploit the rootedness in the next section.

is a child of a level-i node $C \times D$ iff C_1 is a child of C and D_1 is a child of D. We call each node in a topology tree or a 2-dimensional topology tree a *topology node*.

We keep TT and $2TT$. We store at every node $C \times D$ of $2TT$ with $C \neq D$ a bit that is set to 1 iff there is a non-tree edge between cluster C and cluster D.

Next we show how to use $2TT$ to test whether an edge exists between $ST(D, C)$ and $ST(D', C')$. Let (D, C) be a tree edge in T_1. The topology nodes *representing* $ST(D, C)$ are the nodes of TT (1) that are children of ancestors of C but are not ancestors of C, and (2) whose leaf descendants in TT belong to $ST(D, C)$. Since TT has depth $O(\log n)$ [5], $ST(D, C)$ is represented by $O(\log n)$ topology nodes.

LEMMA 2.30. *For $D \neq D'$ let (D, C) and (D', C') be edges of T_1 such that D and D' do not belong to $\pi_{T_1}(C, C')$. Let $X_1, \ldots, X_p$ be the topology nodes representing $ST(D, C)$ and let $Y_1, \ldots, Y_q$ be the topology nodes representing $ST(D', C')$ such that X_i and Y_i are level-i topology nodes.*

There is a non-tree edge between $ST(D', C')$ and $ST(D, C)$ iff a bit is set to 1 at a node $X \times Y$ of $2TT$ such that either

(1) *$X = X_i$ for some $1 \leq i \leq p$ and Y is a level-i descendant of a node Y_j for some $1 \leq j \leq q$, or*

(2) *$Y = Y_j$ for some $1 \leq j \leq q$ and X is a level-j descendant of a node X_i for some $1 \leq i \leq p$.*

Proof. Note that $ST(D, C)$ and $ST(D', C')$ are disjoint. It follows that the subtrees of TT rooted at $X_1, X_2, \ldots, X_p$ are disjoint from the subtrees rooted at $Y_1, Y_2, \ldots, Y_q$.

Let (A, B) be the non-tree edge between $ST(D, C)$ and $ST(D', C')$ with $A \in ST(D, C)$ and $B \in ST(D', C')$. Let X_i (Y_j) be the lowest ancestor of A (B) in TT that is a topology node representing $ST(D, C)$ ($ST(D', C')$). If $i \leq j$, there exists a level-i cluster Y which is a descendant of Y_j such that there is an edge between X_i and Y. It follows that the bit stored at $X_i \times Y$ is set to 1. If $j > i$, a symmetric argument applies.

If a bit is set to 1 at a node $X \times Y$ of $2TT$ such that either (1) $X = X_i$ for $1 \leq i \leq p$ and Y is a level-i descendant of a node Y_j for $1 \leq j \leq q$ or (2) $Y = Y_j$ for $1 \leq j \leq q$ and X is a level-j descendant of a node X_i for $1 \leq i \leq p$, then there is an edge between X and Y and, thus, between $ST(D, C)$ and $ST(D', C')$. ∎

Let X_i and Y_j be defined as in the lemma. Let $\mathcal{Y}_i = \{Y | Y$ is a level-i descendant of a topology node Y_j for some $i \leq j \leq q\}$ and let $\mathcal{X}_j$ be defined symmetrically. Note that the subtree in $2TT$ induced by the set of nodes $\{X_i \times Y$, for all $1 \leq i \leq p$, and all $Y \in \mathcal{Y}_i\}$ is isomorphic to a subtree of TT. The same holds with the roles of X and Y reversed. Thus, Lemma 2.29 shows how to check the avoidability of C on a path P by checking the bits of $O(m/k)$ nodes in $2TT$. Finding the topology nodes X_i and Y_i for all i takes time $O(\log n)$. As was shown in [5], $2TT$ can be maintained in time $O(k + m/k)$ after each update operation in G.

LEMMA 2.31. *A 2-dimensional topology tree can test in time $O(m/k)$ whether a node C is avoidable on a path P in a high-level graph H_i. It can be updated in time $O(k)$.*

The extended ambivalent data structure. To determine the avoidability of all but $O(\log n)$ nodes on a path P in H_i, for $i = 1, 2$, we simply extend TT and $2TT$ with additional labels to construct the *extended ambivalent data structure*. We will use two types of avoidability information, one for H_1 and one for H_2. Our approach is to partition T_i into complete paths and to keep avoidability information for each complete path. Then we show that each path P consists of subpaths of $O(\log n)$ complete paths.

Thus, P's avoidability can be determined from the avoidability information of these complete paths. To be precise let $P = \pi_{T_i}(A, B)$ in H_i. Let $P_1 = P$ if $i = 1$, and let $P_1 = P_{T_1}$ if $i = 2$. We partition P_1 at the least common ancestor LCA of its endpoints A_1 and B_1 into the paths $P_A = \pi_{T_1}(A_1, LCA)$ and $P_B = \pi_{T_1}(B_1, LCA)$. Note that both paths are *increasing*, i.e., they consist of a directed path toward the root R of T_1. We show below how to test the avoidability of all but $O(\log n)$ nodes of an increasing path by breaking it into $O(\log n)$ complete paths.

Recall that T_1 is stored in a rooted topology tree TT. Note that T_1 induces a rooted spanning tree TT_j of the nodes at each level j of TT whose root is R. Note further that when given TT, R, and also the least common ancestor between any two basic clusters can be determined in time $O(\log n)$.

We now give the necessary definitions. For a basic cluster X_1 let the graph $G(X_1)$ be (1) the graph induced by the vertices of X_1, if the tree degree of X_1 is 1 or 3, and (2) the graph induced by the vertices of X_1 with all vertices between the two boundary nodes contracted to one vertex, otherwise.

To construct complete paths we first need to introduce partial paths. We define the *partial path* of a basic cluster X_1 to be the (unique) endpoint $x(X_1)$ in $G(X_1)$ of the tree edge incident to X_1. In the following we often identify X_1 and $x(X_1)$. Note that if X_1 shares a vertex s, then the partial path of X_1 consists of s. The *partial path*[9] of a level-i cluster X_1 with $i > 0$ consists of

(1) *Case A:* the partial path of X_2, if X_1 consists of one level-$(i-1)$ cluster X_2,

(2) *Case B:* the concatenation of the partial path of X_2 and of X_3, if X_1 is the union of X_2 and X_3, and neither X_2 nor X_3 has tree degree 3.

(3) *Case C:* the vertex $x(X_3)$ and the two tree edges incident to it that are not incident to X_2 if X_1 is the union of X_2 and X_3, and X_2 has tree degree 1 and X_3 has tree degree 3. In this case the *complete path* of X_1 consists of the partial path of X_2 concatenated with the vertex $x(X_3)$. In all previous cases, the complete path of X_1 is not defined. Note that X_3 is the parent of X_2 in TT_j.

(4) *Case D:* an empty path if X_1 is the union of X_2 and X_3, and X_2 has tree degree 1 and X_3 has tree degree 1. In this case the *complete path* of X_1 consists of the partial path of X_2 and the partial path of X_3.

For every complete path not stored at the root of TT note that one endpoint has tree degree 1, and one has tree degree 3 (namely, the vertex of X_3). The endpoints of the complete path stored at the root of TT either both have tree degree 1 or one has tree degree 1 and one has tree degree 3. We call the endpoint with tree degree 1 the *tail* and the endpoint with tree degree 3 the *head* of the complete path. A tree-degree 3 node belongs to two complete paths; in one it is an internal node and in one it is a head. All other nodes belong to exactly one complete path.

If $x(X_1), \ldots, x(X_p)$ is the sequence of nodes on a partial or complete path P^c, then either $X_1, \ldots, X_p$ is an increasing path in T_1 or $X_1, \ldots, X_j$ and $X_p, X_{p-1}, \ldots, X_j$ are increasing paths, for some $1 < j < p$.

Next we show that P_A and also P_B consist of $O(\log n)$ increasing subpaths of complete paths. We will store avoidability information for the complete paths and use it to test the avoidability of P_A and P_B except for the nodes that are heads in the complete paths. Let $P_1^c, P_2^c, \ldots, P_l^c$ be the complete paths whose intersection with P_A is nonempty such that the head of P_j^c belongs to P_{j+1}^c. Let X_j be the topology node in TT at which P_j^c is stored. Note that all topology nodes whose partial path contains a vertex of P_j^c are true descendants of X_j in TT. Note further that the head

[9]A path is formed by a list of vertices.

of P^c_{j-1} belongs to P^c_j. Thus, X_{j-1} is a true descendant of X_j. Since TT has depth $O(\log n)$ it follows that P_A is contained in the union of $O(\log n)$ complete paths, i.e., $l = O(\log n)$. The same holds for P_B.

We use the algorithm described in the previous section to test the avoidability of LCA on P_A and P_B and for the heads of the complete paths. For all remaining nodes on P_A and P_B we use the extended ambivalent data structure. It consists of further labels for the 2-dimensional topology tree $2TT$ and search trees for the partial and complete paths. The labels and search trees will be oblivious of the rooting of T_1, which is important for the efficiency of rebuilds.

Every node $A \times B$ with $A \neq B$ is labeled with two additional labels *maxcov* and *shared* that are explained later. Each node $A \times A$ of $2TT$ is labeled with a pointer to the partial path and complete path (if it exists) of A. The partial and complete paths are stored in shared search trees as follows:

(1) The partial path of a level-0 cluster X is represented by one node $x(X)$.

(2) In Case A, the search tree of the partial path of X_1 is identical to the search tree of the partial path of X_2.

(3) In Case B, the partial path of X_1 consists of a (root) node pointing to the roots of the search trees of the partial paths of X_2 and X_3.

(4) In Case C, the partial path of X_1 consists of one node. The complete path of X_1 consists of a (root) node pointing to the roots of the search trees of the partial paths of X_2 and X_3.

(5) In Case D, the partial path of X_1 is empty. The complete path of X_1 consists of a (root) node pointing to the roots of the search trees of the partial paths of X_2 and X_3.

Since the topology tree has depth $O(\log n)$, every search tree has depth $O(\log n)$. A vertex v in the balanced search tree of a partial or complete path is labeled with two bits $somecov_i(v)$ for $i = 1, 2$.

Let C be an internal node on the increasing path Q in H_i whose avoidability we have to test. Let D and D' be the neighbors of C on Q such that D is the child and D' is the parent of C in T_i. Lemma 2.37 below shows that

(1) for $i = 1$, if a complete path P^c exists to which $x(D')$, $x(C)$, and $x(D)$ belong, then $somecov_1(v)$ is set to 1 for an ancestor v of $x(C)$ in P^c iff C is avoidable on Q, and

(2) for $i = 2$, let $C_1, \ldots, C_l$ form an increasing subpath of Q_{T_1} with $C_1 = C(Q_{T_1})$ and $C_l = C(Q_{T_1})'$. If a complete path exists to which $x(D')$, $x(D)$, and $x(C_q)$ for all $1 \leq q \leq l$ belong, then for all C_q in P^c, $somecov_2(v_q)$ is set to 1 for an ancestor v_q of $x(C_q)$ in P^c iff C is avoidable on Q.

If no such complete path exists, then some C_q is the head of a complete path and hence C is tested for avoidability using the 2-dimensional topology tree.

Note that P^c is the lowest ancestor of the least common ancestor of C for H_1 (resp., C_1 for H_2) and D in TT that has a complete path. It can be found in time $O(\log n)$.

Thus, if l nodes of an increasing path of H_1 lie on a complete path, we can test their avoidability except for the head of the complete path in time $O(l + \log n)$. Since the nodes of P_A and P_B are contained in $O(\log n)$ complete paths, we can test the avoidability of all nodes on P_A or P_B excluding LCA and the heads in time $O(m/k + \log^2 n) = O(m/k)$ for $k \leq m/\log^2 n$.

LEMMA 2.32. *Given a path P in H_i the extended ambivalent data structure can test the avoidability of all but $O(\log n)$ nodes on P in time $O(m/k)$.*

Let us now define *somecov*, *maxcov*, and *shared* and prove Lemma 2.37. For a cluster A the *projection* of a non-tree edge (u, v) with $u \in A$ and $v \notin A$ onto the partial or complete path P^c of A is the node x on P^c such that the tree path from u to x in $G(A)$ does not contain any other node on P^c.

Recall that every node $A \times B$ with $A \neq B$ is labeled with a constant number of labels: (1) For each tree edge E incident to A, there exists a label $\mathit{maxcov}(A, B, e)$ which is the node with maximum distance from e on the partial path of A that is avoidable because of a non-tree edge between A and B, assuming that the tree edge e incident to A lies on the tree path between A and B. (2) For each shared vertex s of A, there exists a label $\mathit{shared}(A, B, s)$ which is a bit that is set to 1 iff A shares s and there is an edge between A and B whose projections onto the partial path of A and of B are not nodes belonging to s.

Note that for each subpath of a complete path P^c there exist $O(\log n)$ nodes in the search tree of P^c whose leaf descendants form exactly a subpath of P^c. We say we *set the* $\mathit{somecov}_i$ *bits of a subpath* when we set the $\mathit{somecov}_i$ bits of these $O(\log n)$ nodes, excluding the nodes representing the endpoints.

The $\mathit{somecov}_i$ bits in the partial and complete paths are defined bottom-up. No basic cluster has a complete path and the partial path of every basic cluster consists of one node whose *somecov* bit is set to 0. The partial and complete path of a level-$(j+1)$ cluster X_1 is computed with the help of the *maxcov* and *shared* labels at the nodes of $2TT$ as follows. If X_1 has two children let $e = (x, y)$ be the tree edge connecting them.

(1) In Case A, the partial path of X_1 is identical to the partial path of this child.

(2) In Case B, the partial path of X_1 is built by adding a node pointing to the balanced search trees of X_2 and X_3. The $\mathit{somecov}_i$ bits of this node are unset. We set the $\mathit{somecov}_1$ bit to 1 for the path p between $\mathit{maxcov}(X_2, X_3, e)$ and $\mathit{maxcov}(X_3, X_2, e)$. We remove from p all but one representative of the shared vertices of the endpoints of p. This results in a subpath p'. If e is solid or if e is dashed, belonging to the shared vertex s, and $\mathit{shared}(X_2, X_3, s)$ is 1, then we also set the $\mathit{somecov}_2$ bits of p'. If e is dashed and $\mathit{shared}(X_2, X_3, s)$ is 0, then we split p' at the representatives of s and remove all but one representative of s from each of the resulting subpaths. We set the $\mathit{somecov}_2$ bits for these subpaths.

(3) In Case C, the partial path of X_1 consists of a tree of one node whose $\mathit{somecov}_i$ bits are set to 0. The complete path of X_1 consists of the partial path of X_2 unioned with the partial path of X_3 which consists only of the node $x(X_3)$. We describe next which $\mathit{somecov}_i$ bits of this complete path are set. We set the $\mathit{somecov}_1$ bits of the subpath p between $x(X_3)$ and $\mathit{maxcov}(X_2, Y, e)$ for any level-j cluster Y in $TT_j \setminus X_2$. We remove from p all but one representative of the shared vertices of the endpoints of p. We set the $\mathit{somecov}_2$ bits of this subpath.

(4) In Case D, the partial path of X_1 is empty. The complete path of X_1 consists of the partial path of X_2 unioned with the partial path of X_3. We set the $\mathit{somecov}_1$ bits of the subpath p between $\mathit{maxcov}(X_2, X_3, e)$ and $\mathit{maxcov}(X_3, X_2, e)$. We remove from p all but one representative of the shared vertices of the endpoints of p. This results in a subpath p'. If e is solid or if e is dashed, belonging to the shared vertex s, and $\mathit{shared}(X_2, X_3, s)$ is 1, then we also set the $\mathit{somecov}_2$ bits of p'. If e is dashed and $\mathit{shared}(X_2, X_3, s)$ is 0, then we split p' at the representatives of s and remove all but one representative of s from each of the resulting subpaths. We set the $\mathit{somecov}_2$ bits for these subpaths.

Given the *maxcov* and *shared* labels, the above description also is an algorithm to build the partial paths of X_1 from the partial paths of the children of X_1 in time $O(\log n)$ and the complete path of a level-j cluster in time linear in the number of level-j nodes in TT.

Next we show how to use the $somecov_i$ bits to test the avoidability of a node e. We start with the $somecov_1$ bits.

LEMMA 2.33. *Let P^c be a complete path and let D, D', and C be basic clusters such that $x(C), x(D)$, and $x(D')$ belong to P^c. Then $somecov_1(v)$ is set for an ancestor v of $x(C)$ in P^c iff there exists a non-tree edge between $ST(C,D)$ and $ST(C,D')$.*

Proof. Consider the lowest level node X_1 such that the partial or complete path P^x of X_1 contains $x(c), x(D)$, and $x(D')$. Let $j+1$ be the lowest level of X_1 at which a $somecov_1$ bit is set for an ancestor v of $x(C)$. Then X_1 has two children X_2 and X_3 in TT, connected by an edge e in TT_j. Without loss of generality (w.l.o.g.) $x(C)$ is a node of the partial path of X_2. Then $somecov_1(v)$ is set in the path of X_1 because $x(C)$ is an internal node of the subpath of P^x between $maxcov(X_2, X_3, e)$ and the first node of X_3 on P^x. By the definition of $maxcov$ there exists an edge between $ST(C,D)$ and $ST(C,D')$.

Assume next that an edge exists between $ST(C,D)$ and $ST(C,D')$. Let X_1 be the least common ancestor of D and D' in TT and let X_2 and X_3 be its two children. W.l.o.g. the partial path of X_2 contains $x(C)$ and $x(D)$. Since there exists a non-tree edge between X_2 and X_3 whose projection is $x(D)$, $x(C)$ lies between $maxcov(X_2, X_3, e)$ and the first node of X_3 on the partial or complete path P^x of X_1. Thus the $somecov_1$ bit is set for an ancestor of $x(C)$ in the partial or complete path of X_1 and, hence, also in P^c. ∎

Next we discuss under which conditions $somecov_2(v)$ is set for an ancestor v of $x(C)$.

LEMMA 2.34. *Let C be a basic cluster and let P^c be a complete path containing C. If C is not connected in T_1 to its neighbors in P^c by a dashed edge of P^c, then $somecov_2(v)$ is set for an ancestor v of $x(C)$ in P^c iff $somecov_1(v)$ is set.*

Proof. The lemma follows immediately from the definition of $somecov_2$. ∎

LEMMA 2.35. *Let P^c be a complete path and let $C_1, \ldots, C_l$ be basic clusters such that $x(C_1), \ldots, x(C_l)$ forms a maximal subpath of P^c sharing the same vertex s. Let j be the lowest level such that the $somecov_2$ bits are set for an ancestor for every node $x(C_1), \ldots, x(C_l)$. Then all nodes $x(C_1), \ldots, x(C_l)$ belong to the partial or complete path of the same cluster at level j.*

Proof. Let P^c be stored at a level j^* node. The claim obviously holds for level j^*. Assume it does not hold for a level $j < j^*$. Then there exists at least one node $x(C_q)$ that is an endpoint of its partial path on level j and in this partial path there exists an ancestor of $x(C_q)$ whose $somecov_2$ bit is set. Note that $x(C_q)$ was the endpoint of this partial path for every level $\leq j$. Note further that the $somecov_2$ bit is never set to 1 for an ancestor of an endpoint of a partial path. Thus at level j, the $somecov_2$ bit is not set for any ancestor of $x(C_q)$. This is a contradiction. ∎

LEMMA 2.36. *Let P^c be a complete path and let D, D', and $C_1, C_2, \ldots, C_l$ be basic clusters such that $x(D), x(C_1), x(C_2), \ldots, x(C_l), x(D')$ is a subpath of P^c and $x(C_1), x(C_2), \ldots, x(C_l)$ forms a maximal subpath of P^c sharing the same vertex. Then, for all $1 \leq q \leq l$, $somecov_2(v)$ is set for an ancestor v of $x(C_q)$ in P^c iff there exists a non-tree edge between $ST(C_1, D)$ and $ST(C_l, D')$.*

Proof. Let s be the vertex shared by the cluster C_q to which the dashed edges incident to C_q belong. Consider the lowest level $j+1$ at which, for all $1 \leq q \leq l$, $somecov_2(v_q)$ is set for an ancestor v_q of $x(C_q)$. By Lemma 2.35, all $x(C_q)$ belong to the partial or complete path P^x of the same level-$(j+1)$ cluster X_1. Then X_1 has two children X_2 and X_3 connected by an edge e in TT_j. Note that one of the $somecov_2(v_q)$ bits was set while constructing P^x.

If neither X_2 nor X_3 has tree degree 3, a $somecov_2(x(C_q))$ bit was set when constructing the path for X_1 because either (1) $x(D), x(D')$, and all nodes $x(C_q)$ are nodes on the path between $maxcov(X_2, X_3, e)$ and $maxcov(X_3, X_2, e)$, and e does not belong to s, or (2) there exists an edge between X_2 and X_3 whose projections do not belong to s. In either case there exists a non-tree edge between $ST(D, C_1)$ and $ST(C_l, D')$.

If X_2 has tree degree 1 and X_3 has tree degree 3, a $somecov_2(x(C_q))$ bit is set while constructing the path for X_1 only if all nodes $x(C_q)$ are internal nodes on the path between $maxcov(X_2, Y, e)$ and $x(X_3)$ for a level-j cluster Y in $TT_j \setminus X_2$. It follows that there is a non-tree edge between $ST(C_1, D)$ and $ST(C_l, D')$.

Assume next that an edge exists between $ST(C_1, D)$ and $ST(C_l, D')$. Let X_1 be the least common ancestor of D and D' and let X_2 and X_3 be its two children. If neither X_2 nor X_3 has tree degree 3, we consider two cases. If the tree edge e between X_2 and X_3 does not belong to s, the $somecov_2$ bits of the subpath $x(C_1), \ldots, x(C_l)$ including endpoints are set because the tree edge lies between $maxcov(X_2, X_3, e)$ and $maxcov(X_3, X_2, e)$. If e belongs to s, the $somecov_2$ bits of the subpath are set because $shared(X_2, X_3, s)$ is 1.

If X_2 has tree degree 1 and X_3 has tree degree 3, then $x(X_3) = x(D')$ or $x(X_3) = x(D)$, i.e., e is solid. The subpath $x(C_1), \ldots, x(C_l)$ is internal to the path between $maxcov(X_2, Y, e)$ and $x(X_3)$ for some level-j cluster Y in $TT_j \setminus X_2$. Thus, the $somecov_2$ bits of the subpath $x(C_1), \ldots, x(C_l)$ including endpoints are set. ∎

LEMMA 2.37. *Let C be an internal node on the increasing path Q in T_i and let D and D' be the neighbors of C on Q such that D is the child and D' is the parent of C.*

(1) *For $i = 1$, if a complete path P^c exists to which $x(D')$, $x(C)$, and $x(D)$ belong, then $somecov_1(v)$ is set to 1 for an ancestor v of $x(C)$ in P^c iff C is avoidable on Q.*

(2) *For $i = 2$, let $C_1, \ldots, C_l$ form an increasing subpath of Q_{T_1} with $C_1 = C(Q_{T_1})$ and $C_l = C(Q_{T_1})'$. If a complete path exists that contains $x(D')$, $x(D)$, and $x(C_q)$ for all $1 \le q \le l$, then for all C_q in P^c $somecov_2(v_q)$ is set to 1 for an ancestor v_q of $x(C_q)$ iff C is avoidable on Q.*

Proof. Let P^c be C's complete path. We discuss first the case $i = 1$. Lemma 2.33 shows that $somecov_1$ is set for an ancestor of $x(C)$ iff there is a non-tree edge between $ST(C, D)$ and $ST(C, D')$. By the definition of avoidability, the latter holds iff C is avoidable on Q.

Next we discuss the case $i = 2$. Lemma 2.34 shows the claim if $l = 1$. If $l > 1$, then C represents at least two clusters in H_1. Lemma 2.36 shows that for all C_q in P^c $somecov_2(v_q)$ is set to 1 for an ancestor v_q of $x(C_q)$ iff there exists a non-tree edge between $ST(C_1, D)$ and $ST(C_l, D')$. The latter holds iff C is avoidable on Q. ∎

LEMMA 2.38. *The extended ambivalent data structure can determine the avoidability of all but $O(\log n)$ nodes on a path P in H in time $O(m/k)$.*

Updates. Next we show how to maintain the *maxcov* and *shared* values and the partial and complete paths in time $O(k)$ after each update operation in G. First, we discuss the *maxcov* and *shared* values. By definition an update (u, v) operation affects only the $maxcov(X, Y, e)$ and $shared(X, Y, s)$ values iff either X or Y contains either u, v, x, or y, where (x, y) is the new tree edge. Consider the subtree of $2TT$ induced by marking all nodes $A \times B$ such that A and B contain either u, v, x, or y.

Since this subtree forms a structure which is isomorphic to two copies of TT, the total number of affected *maxcov* and *shared* values is $O(m/k)$. As was shown in [6] for the *maxcov* values and as we show below for the *shared* values each such value at an internal node of $2TT$ can be computed in constant time from the values of its children and in time $O(k)$ for a basic cluster. Thus, updating all *maxcov* and all *shared* values takes time $O(k)$.

Lemma 2.39 shows that the only clusters whose partial or complete paths are affected by updates are the ones that are ancestors in TT of the basic cluster containing u, v, x, or y. Thus, the partial and complete paths of at most two clusters at each level have to be updated. We discuss below how to restore the partial and complete paths of the clusters that do not contain u, v, x, or y, but are children of clusters containing u, v, x, or y. The partial path of a cluster C can be computed in time $O(\log n)$ from the partial paths of the children of C and the *shared* and *maxcover* values. The complete path of a cluster C at level j can be computed in time linear in the number of level j nodes in TT from the partial path of the child of C with tree degree 1 and from the *shared* and *maxcover* values. Since TT has depth $O(\log n)$ and size $O(m/k)$, all affected partial and complete paths can be updated in time $O(m/k + \log^2 n) = O(m/k)$ for $k \leq m/\log^2 n$.

Whenever we build the partial or complete path we keep a *back log* that stores for each node X_1 of $2TT$ all the operations that were executed to build the partial or complete path of X_1 from the partial or complete path of its children. Whenever we execute an update operation, we walk top-down in TT and restore the path of the suitable clusters and their children. The partial and complete path of the root of TT are given. Assume inductively the partial and complete path of a node X at level j are restored. Undo the operations in the back log of X to restore the partial and complete paths of the children of X. Then recurse on the suitable child(ren) of X. The same argument as above shows that this takes time $O(m/k)$. Note also that modifications in the back log of one child does not affect the back log of its sibling.

LEMMA 2.39. *An insert(u, v) and a delete(u, v) operation only modifies the balanced tree of partial or complete paths of clusters containing u, v, x, or y, where (x, y) is a new tree edge.*

Proof. A *somecov* bit is set at a node in the balanced tree representing the partial path of a cluster C only if there exists an edge internal to C that covers the corresponding nodes. For a cluster not containing u, v, x, or y neither the partial path nor the non-tree edges internal to the cluster have changed. Thus, the balanced search tree of its partial path does not have to be updated.

Next we discuss complete paths. If a cluster C which has a complete path does not contain u, v, x, or y, then the partial path of its child C' with tree degree 1 and the non-tree edges incident to C' are not affected by the above argument. The modifications to this partial path that create the data structure for the complete path of C depend only on the projection of edges incident to C' onto the partial path of C'. Since the partial path of C' and the non-tree edges incident to C' did not change, the balanced search tree of the complete path of C is not affected by the operation. ∎

We are left with showing how to compute $shared(A_1, B_1, s)$ from the *shared* values of the children of A_1 and B_1 and information stored at their children in constant time. Recall that for each pair of clusters at the same level $shared(A_1, B_1, s)$ is 1 iff A_1 shares s and there is an edge between A_1 and B_1 whose projection onto the partial path of A_1 and onto the partial path of B_1 is not s. If A_1 does not share a vertex s, then $\mathit{shared}(A_1, B_1, s)$ is not defined. Since each basic cluster and each cluster with tree degree 1 or 3 shares at most one vertex and each nonbasic cluster with tree degree 2 shares at most two vertices, at most four $\mathit{shared}(A_1, B_1, .)$ values are defined for every pair of clusters A_1 and B_1. We distinguish cases depending on the number of children of A_1 and of B_1 under the assumption that A_1 shares the vertex s.

Case 1: A_1 and B_1 are basic clusters.

Then $\mathit{shared}(A_1, B_1, s) = 0$, since every edge incident to A_1 is projected onto s when it is projected onto the partial path of A_1.

Case 2: A_1 and B_1 are clusters at level $j > 0$.

Case 2.1: A_1 has one child A_2 and B_1 has one child B_2.

Then $\mathit{shared}(A_1, B_1, s) = \mathit{shared}(A_2, B_2, s)$.

Case 2.2: A_1 has one child A_2 and B_1 has two children B_2 and B_3.

If neither B_2 nor B_3 has tree degree 3, then $\mathit{shared}(A_1, B_1, s) = \mathit{shared}(A_2, B_2, s)$ *or* $\mathit{shared}(A_2, B_3, s)$.

If the tree degree of B_3 is 3 and the tree degree of B_2 is 1, then $\mathit{shared}(A_1, B_1, s) = \mathit{shared}(A_2, B_2, s)$ if B_3 does not share s and 0 if B_3 shares s.

Case 2.3: A_1 has two children A_2 and A_3, A_3 shares s, and B_1 has one child B_2.

W.l.o.g. A_3 is incident to the tree edge incident to A_1. Thus, A_3 has tree degree at least 2. If the tree degree of A_3 is 3, then $\mathit{shared}(A_1, B_1, s) = 0$, since every edge incident to A_1 is projected onto s when it is projected onto the partial path of A_1.

If the tree degree of A_3 is 2, then we distinguish between the cases that A_2 shares s and that A_2 does not share s. If A_2 shares s, then

$$\mathit{shared}(A_1, B_1, s) = \mathit{shared}(A_2, B_2, s),$$

since the projection of every edge incident to A_3 onto the partial path of A_1 is s.

If A_2 does not share s, then we distinguish between the cases that B_2 shares s and that B_2 does not share s. If B_2 shares s, then

$$\mathit{shared}(A_1, B_1, s) = \mathit{shared}(A_3, B_2, s) \mathit{or}\ \mathit{shared}(B_2, A_2, s).$$

(Note that $\mathit{shared}(A_2, B_2, s)$ is not defined in this case, but $\mathit{shared}(B_2, A_2, s)$ is defined.)

If B_2 does not share s, then

$$\mathit{shared}(A_1, B_1, s) = \mathit{shared}(A_3, B_2, s) \mathit{or}\ \mathit{edge}(A_2, B_2),$$

where $\mathit{edge}(A_2, B_2) = 1$ iff there exists an edge between A_2 and B_2 iff $\mathit{maxcov}(A_2, B_2, e)$ (for any tree edge e incident to A_2) is defined.

Case 2.4: A_1 has two children A_2 and A_3 and B_1 has two children B_2 and B_3.

W.l.o.g. A_3 is incident to the tree edge incident to A_1. Thus, A_3 has tree degree at least 2. If the tree degree of A_3 is 3, then $\mathit{shared}(A_1, B_1, s) = 0$, since the projection of every non-tree edge incident to A_1 onto the partial path of A_1 is s.

If the tree degree of A_3 is 2, then we distinguish between the cases that A_2 shares s and that A_2 does not share s. If A_2 shares s, then

$$\mathit{shared}(A_1, B_1, s) = \mathit{shared}(A_2, B_2, s) \mathit{or}\ \mathit{shared}(A_2, B_3, s),$$

since the projection of every non-tree edge incident to A_3 onto the partial path of A_1 is s.

If A_2 does not share s, then we distinguish between the case that (1) B_2 shares s and B_3 does not share s, that (2) B_3 shares s and B_2 does not share s, that (3) both share s, and that (4) both do not share s.

In case (1) (B_2 shares s and B_3 does not share s)

$$\begin{aligned}shared(A_1,B_1,s) = {} & shared(A_3,B_2,s)\, or\; shared(A_3,B_3,s)\, or \\ & shared(B_2,A_2,s)\, or\; edge(A_2,B_3).\end{aligned}$$

(Note that $shared(A_2,B_2,s)$ is not defined in this case, but $shared(B_2,A_2,s)$ is defined.) The case (2) is symmetric to case (1).

In case (3) (B_2 and B_3 share s)

$$\begin{aligned}shared(A_1,B_1,s) = {} & shared(A_3,B_2,s)\, or\; shared(A_3,B_3,s)\, or \\ & shared(B_2,A_2,s)\, or\; shared(B_3,A_2,s).\end{aligned}$$

In case (4) (B_2 and B_3 do not share s)

$$\begin{aligned}&rclshared(A_1,B_1,s) \\ &\quad = shared(A_3,B_2,s)\, or\; shared(A_3,B_3,s)\, or\; edge(A_2,B_2)\, or\; edge(A_2,B_3).\end{aligned}$$

This shows that the $shared(A_1,B_1,.)$ bit can be computed in constant time from the *shared* and *maxcov* values of the children of A_1 and B_1 and it finishes the proof of the following lemma.

LEMMA 2.40. *The extended ambivalent data structure can be updated in time $O(k)$.*

2.8. The c-structure. In this section we address the following problem. Given the c-nodes of a cluster graph (see section 2.5) or the c-nodes of a shared graph $G(s)$ for a new shared vertex s (see section 2.6.1), determine which c-nodes are CV-split by an update operation. For this problem we give in this subsection a data structure, called *c-structure* and show in the next subsection that in a phase $O(m/k)$ splits of c-node occur because of violation of condition (a) or (b) (called *CV-splits*). Additionally we show that the e-nodes of a shared graph $\tilde{G}(s)$ for an old shared vertex s (see section 2.6.2) fulfill the conditions of a c-node and therefore the same data structure and proof apply.

First we recall the definitions of c-node and e-node; next we show that an e-node also fulfills the conditions of a c-node, and then we define the c-structure exactly .

Let $H = H_1$ for c-nodes in cluster graphs and $H = H_2$ for c-nodes in shared graphs. Given a node C in H with ancestor A a c-node represents a maximal set X of nodes of H such that

(a) every node $C' \in X$ is a neighbor of C,
(b) all nodes in X are connected in $H \setminus C$,
(c) all nodes in X have the same ancestor which is different from A,
(d) at the creation of C, the set X contains only one node, and
(e) at each previous point in time since the creation of C all nodes of H that contain the vertices in $\cup_{C' \in X} C'$ existing at this time are represented by the same c-node.

We show next that every e-node in the graph $\tilde{G}(s)$ of an old shared vertex s fulfills the conditions of a c-node with $H = H_2$. Thus the amortization lemma of the next section also applies to e-nodes.

LEMMA 2.41. *Every e-node in the graph $\tilde{G}(s)$ of an old shared vertex s fulfills the conditions of a c-node with $H = H_2$.*

Proof. By definition every e-node fulfills conditions (a)–(d) of a c-node. We only have to show that it also fulfills condition (e).

Let X be an e-node. By definition the vertices in $\cup_{C' \in X} C'$ used to belong to the same node C_{old} of H_2 and since the split of C_{old}, the graph $G(s)$ was not modified and the connected components of $H_2 \setminus C_s$ did not change. Thus, before the last change in $G(s)$ or $H_2 \setminus C_s$ the nodes in X belonged to the same node of H_2 and thus were represented by the same e-node.

Assume by contradiction that the nodes in X were represented by different e-nodes at some point since the last change in $G(s)$ or $H_2 \setminus C_s$. While the nodes were represented by different e-nodes they either must violate condition (a) or (b) of an e-node, since conditions (c), (d), and (e) continue to hold. However, now they fulfill conditions (a) and (b), i.e., either $G(s)$ or $H_2 \setminus C_s$ must have changed, which is a contradiction. □

Thus, e-nodes are just a special case of c-nodes and we will just use the term c-node in the following to denote c-nodes as well as e-nodes.

A c-node of C is *CV-split* iff conditions (a) or (b) of a c-node are no longer fulfilled.

Given the high-level graph H and its data structures the c-structure maintains the c-nodes of each node in H under the following operations:

(1) *c-split* (C, C_1, C_2, u, v), where C is a node of H split by the *delete*(u, v) or *insert*(u, v) operation, C_1 and C_2 are the two nodes of H created by the split. Split the node C into C_1 and C_2.

(2) *c-add* (C_1, C_2), where C_1 and C_2 are nodes of H. Add one edge between C_1 and C_2.

(3) *c-remove* (C_1, C_2), where C_1 and C_2 are nodes of H. Remove the edge between C_1 and C_2 and return a (possibly empty) list of CV-split c-nodes and for each newly created c-node return its element list.

We use the following data structure for the c-structure, which uses $O((m/k)^2)$ space.

(T1) For each node of H we keep a list of its c-nodes. For each c-node we keep a list of its elements. For each node in H we keep a list of all the c-nodes it belongs to. The position of the node in the list of the c-node and the position of the c-node in the list of the node point to each other.

We keep two c-structures, namely, one with $H = H_1$ to determine the CV-splits in c-nodes of the cluster graphs, and one with $H = H_2$ to determine the CV-splits in c-nodes of the shared graph for new shared vertices.

2.8.1. Implementing the c-structure.

We implement the operations as follows.

c-split (C, C_1, C_2, u, v): This requires (i) updating the c-nodes of C and (ii) updating the c-nodes containing C. (i) Discard all c-nodes of C. Each neighbor of C_1 (resp., C_2) forms a 1-element c-node for C_1 (resp., C_2). (ii) Use (T1) to determine all c-nodes X to which C belongs. Replace C by either C_1 or C_2 or both in X, depending on which of the new nodes are incident to D. Note that all nodes in X still fulfill (a), (c), (d), and (e) of a c-node. By Lemma 2.8 all nodes continue to fulfill (b) as well.

c-add (C_1, C_2): If C_1 and C_2 have the same ancestor, do nothing. Otherwise, search the c-nodes to which C_1 belongs to determine whether C_2 is one of them. If not, add to the c-nodes of C_2 a 1-element c-node consisting of C_1. Repeat with the roles of C_1 and C_2 exchanged.

c-remove (C_1, C_2): If C_1 and C_2 have the same ancestor, do nothing. Otherwise, determine the c-node of C_2 to which C_1 belongs and remove C_1 from it. If this c-node becomes empty, discard it. If the c-node is modified, output it and its new element list. Repeat with the roles of C_1 and C_2 exchanged. Finally determine all articulation points D on $\pi(C_1, C_2)$ in the (updated) graph H using (HL4). Test as follows for each c-node X of D whether (b) is violated, and if so, how to partition X. Using (HL3) determine for each node C' in X the tree neighbor of D on $\pi(C', D)$ and bucketsort the node according to the blockid of "its" tree neighbor using (HL4) and (HL6). This results in either one or two nonempty buckets. In the former case (b) is not violated. In the latter case, split the list of X according to the two buckets and report the CV-split of X and return the two resulting lists.

To analyze the running time note that the intersection of two different c-nodes of C is empty. The time spent by a *c-split* or *c-add* operation is linear in the number of c-nodes of a node in H, which is $O(m/k)$. In *c-remove* we spend the time $O(m/k)$ to determine all articulation points and then the following time per articulation point D: $O(\log n)$ per non-tree neighbor of D to bucketsort it and constant time to remove it from the bucket again. Since the nodes D are articulation points on a path in H, this sums up to $O((m/k)\log n)$ by Lemma 2.1. Additionally the *c-remove* operation spends time $O(m/k)$ to update the c-nodes of C_1 and the c-nodes of C_2. Thus, the total time spent is $O((m/k)\log n)$.

2.8.2. Updating the c-structure. At the beginning of a phase each c-node consists of one node: every neighbor of a node in H forms its own c-node.

Whenever an edge is inserted in G and H changes, then first the data structures of H are updated and then a *c-add* and potentially afterward a constant number of *c-split*'s are executed in the c-structure. Whenever an edge is deleted from G and H changes, then first the data structures of H are updated and then potentially a constant number of *c-split*'s and afterward a *c-remove* are executed in the c-structure. If an internal tree edge of a cluster C is deleted, then this implies that first the cluster is split at this tree edge and afterward the tree edge is deleted. Each operation can be implemented in time $O((m/k)\log n)$. Since there are only a constant number of them per update in G, this gives a total time of $O((m/k)\log n)$ to update the c-structure.

THEOREM 2.42. *The c-structure*

(1) *can be updated in time $O((m/k)\log n)$ after each update in G, and returns all the c-nodes CV-split by the update and the resulting c-nodes, and*

(2) *can be built in time $O(m)$.*

2.9. The amortization lemma. We show next that during a sequence of l updates in a phase $O(l)$ CV-splits of c-nodes occur. A similar, but less general lemma was shown in [11].

LEMMA 2.43. *During l updates in G in a phase at most $2l$ CV-splits of a c-node occur because of violation of condition* (a).

Proof. Condition (a) is violated if a node C' belongs to a c-node of node C, but C' is no longer incident to C. This is only possible if C as well as C' contains an endpoint of the update edge. Since all c-nodes of C are disjoint, condition (a) is violated for at most one c-node of C. Similarly, condition (a) is violated for at most one c-node of C' and for no c-nodes at other nodes. ☐

LEMMA 2.44. *During l updates in G in a phase $O(l + m/k)$ CV-splits occur because of the violation of condition* (b) *for $l \geq m/k$.*

Proof. We construct a bipartite graph K consisting initially of $O(m/k)$ blue nodes, $O(m/k)$ red nodes, and $O(m/k)$ edges between red and blue nodes. A red node is incident to at least one blue node. We show that during a sequence of l updates in G the number of blue nodes in K increases by $O(l)$ (Proposition 2.45), each CV-split of a c-node increases the number of connected components of K by at least one (Proposition 2.46), and no other operation decreases the number of components (Proposition 2.51). Thus, there are at most $O(l + m/k)$ splits of c-nodes during l updates in G.

The proof will exploit the following fact: Whenever a c-node at C containing D_1 and D_2 is CV-split, then there is no c-node at another node C' that contains both D_1 and D_2. (Otherwise the path "through" C' would connect D_1 and D_2 in $H \setminus C$.) Thus, the split discards the last common c-node of D_1 and D_2. We will show that an even stronger property holds: Assume the relation $r(D_1, D_2)$ holds iff D_1 and D_2 have a common c-node. Let r^* be the transitive closure of r. Then whenever the c-node containing D_1 and D_2 is split, then $r^*(D_1, D_2)$ does not hold after the split. The graph K is constructed so that this fact implies that the connected components of K increase.

Recall that an edge of H consists of a set of edges of G'. An edge of H is called *new* if all edges of G' in its set are new, i.e., have been inserted after the last rebuild. All other edges of H are *old*. We "treat" new edges in a special way to guarantee that edge insertions do not decrease the number of connected components of K. Note that there are at most l new edges in H at each point in time.

We next define K.

(1) For each node C in H and each c-node X at C, K contains a red node (C, X).

(2) For each node D in H, K contains a blue node D.

(3) For each node D in a c-node X at C such that (D, C) is new there exists a blue node (D, X). These nodes are called *special*.

(4) Let D be in the c-node X at C. If both a red node (C, X) and a blue node (D, X) exist, there exists an edge between (C, X) and (D, X). If (D, X) does not exist, there is an edge between (C, X) and D.

By abuse of notation we will equate a blue node in K with the node of H represented by the blue node. Note that every edge in K corresponds to an edge of H. Thus, if two blue nodes are connected in K, their nodes are connected in H.

There are four events that modify K: (A) a *c-split* operation, (B) a *c-add* operation, (C) a *c-remove* operation, and (D) the change of an edge from old to new.

Next we describe each event in detail:

(A) A *c-split* (C, C_1, C_2, u, v) operation. (1) Every red node (C, X) is removed. For each $D \in X$ incident to C_1 we create a red node $(C_1, \{D\})$, and if the blue node (D, X) exists, it is replaced by a blue node $(D, \{D\})$. The new red node is connected to $(D, \{D\})$ if it exists and to D otherwise. We proceed in the same way with C_2. (2) The blue node C and all blue nodes (C, X) are split into two nodes and connected to the appropriate neighbors of the split nodes.

(B) A *c-add* (C_1, C_2) operation. It might add a new red node at $(C_1, \{C_2\})$, a new blue node $(C_2, \{C_2\})$, and connect them by an edge. It might do the same with the roles of C_1 and C_2 reversed.

(C) A *c-remove* (C_1, C_2) operation. Let X be the c-node at C_1 containing C_2. Remove the edge between the red node (C_1, X) and the corresponding blue node representing C_2. If the blue node (C_2, X) exists, remove it. If $X = \{C_2\}$, also remove (C_1, X). Proceed in the same way with the roles of C_1 and C_2 reversed. Finally for each split c-node X' of an articulation point D on

$\pi(C_1, C_2)$ in H replace the red node (D, X') by two red nodes, one for each new c-node and connect their blue neighbors suitably.

(D) An old edge (D, C) of H becomes new. If D belongs to the c-node X at C, then add a new blue node (D, X) with edge to (C, X) and remove the edge from D to (C, X). Then proceed in the same way with the roles of D and C reversed.

We prove next the three missing propositions.

PROPOSITION 2.45. *During l update operations the number of blue nodes increases by $O(l)$.*

Proof. A sequence of l update operations in G leads to at most $7l$ *c-split* operations, l *c-add* operations, and l *c-remove* operations. At each point there are at most $2l$ special blue nodes. Next we bound the number of nonspecial blue nodes. A *c-add* operation, a *c-remove* operation, and the change of an edge from old to new do not increase the number nonspecial blue nodes. A *c-split* increases the number of nonspecial blue nodes by at most 1. Thus, the number of nonspecial blue nodes increases by $O(l)$. □

Next we show that the CV-split of a c-node increases the number of connected components by at least 1.

PROPOSITION 2.46. *A CV-split of a c-node increases the number of connected components by at least* 1.

Proof. Consider the split of the c-node X at node C'. A c-node is CV-split only during a *c-remove* operation. So consider the removal of edge (C_1, C_2). Let $\{X_1, X_2, \ldots, X_p\}$ be all the c-nodes that are CV-split at C'. Let D_1 and D_2 be the tree neighbors of C' on $\pi(C_1, C_2)$ and let Y_1 and Y_2 be the blue nodes representing D_1 and D_2 and incident to the red node (C', X_i) for some $1 \le i \le p$ in K. To update K, each red node (C', X_j) is replaced by two new red nodes, one representing each new c-node. Each (blue) neighbor of (C', X_j) is connected to exactly one of the new c-nodes depending on which new c-node it belongs to. Obviously, D_1 and D_2 are connected to different new red nodes. As we show in Proposition 2.50 after the *c-remove* operation there exists no path in K anymore between D_1 and D_2, i.e., the number of connected components in K has increased by at least 1. □

We are left with proving Proposition 2.50 and showing that the number of connected components of K does never decrease. We first need some intermediate results.

PROPOSITION 2.47. *Every blue node (D, X) has degree* 1 *in K.*

Proof. Let X be a c-node of node C of H. By definition of K, a blue node (D, X) can only be adjacent to node (C, X). □

PROPOSITION 2.48. *Let C be a node in H. Each blue node representing a node D in H is incident to at most one red node (C, X), and X is the c-node to which D belongs at C.*

Proof. The proof follows from the construction of K since each node D belongs to at most one c-node at C. □

PROPOSITION 2.49. *If two blue nodes are connected in K, then they represent nodes with the same ancestor.*

Proof. If there is a path in K between the two blue nodes Y and Y', then let $B_1, \ldots, B_j$ be the blue nodes on this path with $Y = B_1$ and $Y' = B_j$. Since B_i and B_{i+1} are adjacent to the same red node, they belong to the same c-node at that node and thus have the same ancestor. By the transitivity of the ancestor relation the claim follows. □

PROPOSITION 2.50. *Consider the operation c-remove(C_1, C_2). Let $\{X_1, X_2, \ldots,$*

$X_p\}$ *be all the c-nodes that are CV-split at a node* C' *of* H. *Let* D_1 *and* D_2 *be the tree neighbors of* C' *on* $\pi(C_1, C_2)$. *Let* Y_1 *and* Y_2 *be the blue nodes representing* D_1 *and* D_2 *that are incident to a red node* (C', X_i) *for some* $1 \leq i \leq p$. *Then after the c-remove operation no path exists connecting* Y_1 *and* Y_2.

Proof. Consider first the case that either (D_1, C') or (D_2, C') is new. By Proposition 2.47 every path between Y_1 and Y_2 contains (C', X_i) and hence is disconnected after the remove operation.

Assume next that both edges are old, i.e., $Y_1 = D_1$ and $Y_2 = D_2$, and assume that a path P exists between them after the *c-remove* operation. Since the c-node of D_1 and D_2 was CV-split, after the deletion of (C_1, C_2) every path in H connecting D_1 with D_2 in H contains C'. We will show that the existence of P implies the existence of a path in $H \setminus C'$ connecting D_1 and D_2, which gives the contradiction.

For this we show (1) that no blue node representing C' belongs to P, and (2) that the blue nodes incident to a red node (C', X') on P are connected in $H \setminus C'$ after the update.

(1) Since D_1 and D_2 belonged to a c-node at C', their ancestor differs from the ancestor of C'. By Proposition 2.49 the nodes of H represented by the blue nodes of P all have the same ancestor. Thus, no blue node representing C' belongs to P.

(2) Let F_k and F'_k be the two nodes incident on P to the kth red node (C', X') for some c-node X'. Then F_k and F'_k both belong to the same c-node X'. It follows that F_k and F'_k are connected in $H \setminus C'$ after the deletion of edge (C_1, C_2).

From (1) it follows that P forms a path without a blue node representing C': (2) shows that every red node on P representing C' can be avoided by a path in $H \setminus C'$. Let l be the number of red nodes representing C' on P. Note that the subpaths of P between F'_k and F_{k+1}, the subpath from D_1 to F_1, and the subpath from F'_l to D_2 contain no edge incident to C' and thus correspond to paths in $H \setminus C'$. It follows that P induces a path in $H \setminus C'$ between D_1 and D_2 after the deletion of (D_1, D_2), which is a contradiction. ▯

Proposition 2.51. *The number of connected components of* K *never decreases.*

Proof. As shown in Proposition 2.46 a *c-remove* operation does not decrease the number of connected components.

A *c-split* operation consists of two parts. In part 1 the red node (C, X) is replaced by many red nodes, each being connected at most to all the nodes that (C, X) was connected to. This does not decrease the number of connected components. In part 2 the blue node C and all blue nodes (C, X) are each split into two new nodes such that each new node is connected to at most all the nodes that the original blue node was connected to. So again, the number of connected components is not decreased.

A *c-add* (C_1, C_2) operation might add a new blue node (C_2, X), a new red node (C_1, X), an edge between them, and the same with the roles of C_1 and C_2 reversed. Since they do not connect to the rest of K, an *add* operation does not decrease the number of connected components in K either.

Note that an old edge (D, C) of H can become new, but not vice versa. If this happens an edge is removed from K, a new blue node (D, X) is added and is connected to (C, X), where X is the c-node of C to which D belongs. The same happens with the roles of D and C reversed. Thus the number of connected components does not decrease. ▯

This completes the proof of the lemma. ▯

2.10. Complete block queries. A complete block query determines all the blocks to which a vertex belongs by computing for each tree edge the block to which it belongs. A vertex belongs to exactly the blocks to which the tree edges adjacent to the vertex belong. We can find the blocks in $I(C)$ for every tree edge internal or incident to the cluster C in time $O(k)$ whenever we recompute $I(C)$. To compute all the blocks in G, we have to determine which blocks of different cluster graphs form the same block of G, i.e., have to be combined.

Perform a depth-first traversal of the spanning tree T_2 of H_2. For each tree edge $e = (u, v)$ with $u \in C_1$ and $v \in C_2$ such that u is a parent of v in the (rooted) depth-first search (dfs) tree, test for each tree edge (x, w) with $x \in C_2$ and $w \in C_3$ whether u and w are biconnected: if C_2 is also a node of H_1, then test whether the shared vertex of C_2 separates u and w and if not use the internal data structure of C_2 to test the biconnectivity of u and w in G. If C_2 is no node of H_1, then $v = x$ is a shared vertex. In this case test the biconnectivity of u and w using the shared graph of v. If we recursively know all tree edges of T_2 in the dfs subtree of edge (x, w) that belong to the same block as (x, w), then we can construct for (u, v) the set of all tree edges of T_2 in the dfs subtree of (u, v) that belong to the same block as (u, v). The dfs takes time $O(m/k)$.

When the dfs is completed we combine the blocks of all the tree edges in the same set and mark all the edges in T' accordingly. Thus the total cost is proportional to the number of tree edges in T', which is $n - 1$.

THEOREM 2.52. *A complete block query in a graph of n vertices can be answered in time $O(n)$.*

2.11. Biconnectivity queries. Given a *query*(u, v) operation, let $x^{(i)}$ and $y^{(i)}$ be defined as in Lemma 2.7. The lemma shows that u and v are biconnected in G iff

(Q1) u and $y^{(1)}$ are biconnected in G,
(Q2) $x^{(i)}$ and $y^{(i+1)}$ are biconnected in G, for all $1 \leq i < p$, and
(Q3) $x^{(p)}$ and v are biconnected in G.

Condition (Q2) holds iff $e_i = (x^{(i)}, y^{(i)})$ and $e_{i+1} = (x^{(i+1)}, y^{(i+1)})$ belong to the same block of G for all $1 \leq i < p$. This is equivalent to the requirement that e_1 belongs to the same block as e_p. Thus, it suffices to determine and test e_1 and e_p and to test (Q1) and (Q3).

By definition all edges e_i are solid intercluster tree edges, i.e., tree edges on the T_2-path between the node C_u in H_2 and the node C_v in H_2. Therefore, we keep the following data structure.

(HL9) We store a least common ancestor data structure [10] for T_2 rooted at a leaf R, such that least common ancestor queries between any two nodes of H_2 can be answered in constant time. If C is the least common ancestor of C and D, then the data structure also returns in constant time the tree edge, incident to C on $\pi(C, D)$. We also keep at each node of H_2 the tree edge to its parent.

(HL10) We store at each solid intercluster tree edge its block in G.

Both data structures are recomputed from scratch after each update in G. The computation of (HL10) proceeds in the same way as a complete block query: we perform a dfs on T_2 that determines the sets of solid intercluster tree edges that belong to the same block. This takes time $O(m/k)$. The time to build both data structures is thus $O(m/k)$.

Determining e_1, e_p, $y^{(1)}$, *and* $x^{(p)}$: We first use (HL9) to determine the least common ancestor of C_u and C_v in H_2. If C_u is the least common ancestor, the data structure returns the tree edge incident to C_u on $\pi(C_u, C_v)$. This is edge e_1; the edge from C_v to its parent is the edge e_p. If the least common ancestor of C_u and C_v is a third node, then e_1 is the edge from C_v to its parent and e_p is the edge from C_u to its parent. This also provides $y^{(1)}$ and $x^{(p)}$.

Testing conditions (Q1) *and* (Q3): We test conditions (Q1) and (Q3) in constant time as described in section 2.3.

Testing condition (Q2)*:* To test condition (Q2) we simply test with (HL10) whether e_1 and e_p belong to the same block.

THEOREM 2.53. *The given data structure can answer a biconnectivity query in constant time.* The total update cost is

(1) time $O(k)$ for restoring the relaxed partition,

(2) amortized time $O(k)$ to update all cluster graphs,

(3) amortized time $O((m/k)\log n + \sqrt{m})$ to update all shared graphs,

(4) time $O(k + (m/k)\log n)$ to update all data structures for high-level graphs (HL1)–(HL10), and

(5) time $O((m/k)\log n)$ to update all c-structures.

Thus, choosing $k = \sqrt{m \log n}$ gives the following update time.

THEOREM 2.54. *The given data structure can be updated in amortized time $O(\sqrt{m \log n})$ after an edge insertion or deletion.*

3. Plane graphs.

In this section we present an algorithm for fully dynamic biconnectivity in plane graphs with $O(\log n)$ query time and $O(\log^2 n)$ update time, where insertions are required to maintain the planarity of the embedding. We modify the extended topology tree data structure of [14] and prove that this data structure dynamically maintains biconnectivity information.

3.1. Definitions.

As in general graphs (see section 2) we transform a given graph G into a degree-3 graph G' by replacing every vertex x of degree $d > 3$ with a chain of $d-1$ *dashed* edges $(x_1, x_2), \ldots, (x_{d-1}, x_d)$. We say each x_i is a *representative* of x and x is the *original node* of every x_i. Then we find an embedding of G' and a spanning tree T' of G'. A *topology tree* of G' based on T' is a hierarchical representation of G' introduced by Frederickson [5]. On each level of the hierarchy it partitions the vertices of G' into connected subsets called *clusters*. An edge is *incident* to a cluster if exactly one endpoint of the edge is contained in the cluster. The *external degree* of a cluster is the number of tree edges that are incident to the cluster. Each vertex of G' is a level-0 cluster. Two clusters at level $i > 0$ are formed by either

(1) the union of two clusters of level $i-1$ that are joined by an edge in the spanning tree and either both are of external degree 2 or one of them has external degree 1, or

(2) one cluster of level $i-1$, if the previous rule does not apply.

Each cluster at level i is a node of height i in the topology tree. If a cluster C at level i is formed by two clusters A and B of level $i-1$, then A and B are the children of C in the topology tree. If C is formed by one cluster A of level $i-1$, then A is the only child of C in the topology tree. The topology tree has depth $D = O(\log n)$ [5]. In the following, *node* denotes a vertex of the topology tree.

In [14] the topology tree data structure is extended to maintain non-tree edges of G' and additional connectivity information at each node, called *recipe*. We use the same technique to maintain dynamic 2-vertex connectivity.

Every insert(u,v), delete(u,v), or query(u,v) operation requires that the topology tree is *expanded* at an (arbitrary) representative of u and of v: we mark all clusters containing the two representatives in the topology tree. Note that all these clusters lie on a constant number of paths to the root. Then we build the graph which consists of the two representatives and a compressed representation of all the clusters that are unmarked children of a marked node in the topology tree. This creates a compressed version of G, called $G(u, v)$, of size $O(\log n)$. This graph is used to answer queries. In the case of update operations, the edge is added to or deleted from $G(u, v)$. Afterward the topology tree is *merged together* again, i.e., a topology tree representation is created for the (possibly modified) graph $G(u, v)$.

To add non-tree edges to the topology tree data structure we define a bundle between two clusters C and C' as follows: If neither C is an ancestor of C' nor vice versa, let $e(C, C')$ be the set of all edges between C and C'. Otherwise, assume w.l.o.g. that C' is the ancestor of C. We define $e(C, C')$ to be the set of all edges incident to C whose least common ancestor in the topology tree is C'. Since we are considering an embedded graph, the edges incident to a cluster C are embedded at C in a fixed circular order. A *bundle* between a cluster C and C' is a subset of $e(C, C')$ that forms a maximal continuous subsequence in the circular order at C and C'. Note that this definition is independent of the level of the clusters and planarity guarantees that there are at most three bundles between two clusters [14]. The first and last edge of a bundle in this order are called the *extreme* edges of the bundle. In the topology tree a bundle between C and C' is represented by two bundles, one from C to the least common ancestor of C and C' (called the *LCA-bundle of* C) and one from C' to the least common ancestor. Whenever the topology tree is expanded and the graph $G(u, v)$ is created, we convert these two bundles back into one.

An edge (u, v) with $u, v \in C$ is called an *internal edge* of the cluster C. Assume all dashed internal edges of C are contracted. The *projection* of an edge (x, y) onto a tree path P is the path $\pi(x, y) \cap P$. Note that, by definition, the vertices of each cluster are connected by a subtree of T'. In the following we define the projection edge of an edge, the projection path $p(C)$, and the coverage graph of C which consists of small and big supernodes of C. All these definitions are independent of the level of the cluster.

(1) If C has external degree 1, the *projection path* $p(C)$ of C consists of the endpoint z of the (unique) tree edge incident to C. This endpoint is a *small supernode.* The *coverage graph* of C consists of this supernode and of all LCA-bundles of C. For each edge e incident to C where y is the endpoint in C, the *projection edge* of e is e if $y = z$ and otherwise the tree edge incident to z that lies on $\pi(y, z)$.

(2) If C has external degree 3, it consists of only one vertex z. Both the *projection path* $p(C)$ and the *coverage graph* consist of only this one vertex which is a *small supernode.*

(3) If the external degree of a cluster C is 2, there is a unique simple tree path between the tree edges that are incident to C. This path is the *projection path* $p(C)$ of C. The *projection* $p(x)$ of a vertex x in C is the vertex closest to x on the projection path. The *projection edge* of a vertex x is the edge on $\pi(x, p(x))$ incident to $p(x)$. If $x = p(x)$, the projection edge of x is undefined. The *projection edge* of an edge (x, y) with one endpoint x in C is the projection edge of x, if it is defined and it is (x, y) otherwise. The *projection edges* of an edge (x, y) with $x, y \in C$ are the projection edge of x if it is defined and (x, y) otherwise and also the projection edge of y if it is defined and (x, y) otherwise.

If (x, y) is an internal edge of C, then the subpath $\pi(x, y) \cap p(C)$ is the *projection* of (x, y) on $p(C)$, $p(x)$ and $p(y)$ are the *extreme vertices* of the projection, and all vertices on the subpath except for $p(x)$ and $p(y)$ are the *internal vertices* of the projection.

Let (w, z) and (x, y) be the extreme edges of an LCA-bundle between a cluster C and a cluster C' with $w, x \in C$ and $z, y \in C'$. The path $\pi(w, x) \cap p(C)$ is called the *projection* of the edge bundle on $p(C)$, $p(w)$ and $p(x)$ are called the *extreme vertices* of the projection, and all vertices on the subpath except $p(w)$ and $p(x)$ are *internal vertices* of the projection. The *projection edges* of a bundle are the projection edges of the extreme edges of the bundle.

The *coverage graph* of C is built by compressing $p(C)$ as follows:

(1) Let $u_1, u_2, \dots, u_p$ be a maximal subpath of $p(C)$ such that

(a) $\pi(u_1, u_p)$ intersects the projection of an LCA-bundle on $p(C)$,

(b) u_1 is the extreme vertex of the projection of an LCA-bundle or an internal edge,

(c) u_p is the extreme vertex of the projection of an LCA-bundle or an internal edge, and

(d) every vertex u_i for $1 < i < p$ is an internal vertex of the projection of a bundle or an internal edge, or there exist two projections with projection node u_i and the same projection edge at u_i such that u_i and u_j with $j < i$ are the extreme vertices of one projection and u_i and u_k with $k > i$ are the extreme vertices of the other projection.

If $p > 2$, we contract the path $u_2, \dots, u_{p-1}$ to one vertex u, called *big supernode*, and we say $u_2, \dots, u_{p-1}$ are *replaced* by the big supernode. The vertices u_1 and u_p are called *small supernodes* and the edges (u_1, u) and (u, u_p) are called *superedges*. All edges incident to $u_2, \dots, u_{p-1}$ are now incident to u. This splits a bundle that is incident to u_1 and/or u_p and also u_i with $1 < i < p$ into up to three *subbundles*, one incident to u and the other(s) incident to u_1 and/or u_p. If the edge (u_1, u_2) (resp., (u_{p-1}, u_p)) is dashed, then the edge (u_1, u) (resp., (u, u_p)) is dashed.

If $p \leq 2$ then no nodes are compressed.

(2) After replacing all subpaths that fulfill condition 1, let $v_1, v_2, \dots, v_q$ be a subpath of $p(C)$ such that v_1 and v_q are two small supernodes and no vertex v_i with $1 < i < q$ is a supernode. We contract the path $v_2, \dots, v_{q-1}$ to one *superedge* (v_1, v_q) and we say $v_2, \dots, v_{q-1}$ are replaced by the superedge. If all edges $(v_1, v_2), \dots, (v_{q-1}, v_q)$ are dashed, then the superedge is dashed; otherwise it is solid.

The *coverage graph* of C consists of this compressed representation of $p(C)$ and all LCA-bundles grouped into sets according to their projection edges.

Note that our definition of a supernode replaces a supernode of [14] by two small and one big supernode and each bundle is split into at most three *subbundles*, one incident to each small supernode and one incident to the big supernode.

When expanding the topology tree, we build the coverage graph for each node that was marked and each child of a marked node. For each subbundle that is incident to a supernode in a coverage graph we maintain its projection edges implicitly as described below.

The coverage graph of a cluster C is maintained as a doubly linked path of supernodes. Each supernode stores up to two doubly linked lists of projection edges incident to it (called *projection list*), one list for each side of the tree path $p(C)$. Each projection edge e stores a doubly linked list of the subbundles such that e is the projection edge of the subbundle. If C has external degree 1, there is only one supernode and only one list of projection edges. If C has external degree 3, it consists of only one supernode without any projection edges or subbundles. The projection edges and the subbundles are listed in the counterclockwise order of their embedding. Only the first and last subbundles in a list have direct access to the projection edge and only the first and last projection edges in a list have direct access to the supernode to which they are incident. The data structure lets us coalesce two adjacent supernodes or two projection lists into one in constant time; we can also split a supernode or a projection edge list into two in constant time if we are given pointers that tell where to split the lists. Note that each subbundle can be contained in at most two lists and if it is contained in two lists, it is the first element of the one and the last element of the other list.

3.2. Recipes. Each node in the topology tree is enhanced by a *recipe* that describes how the coverage graph of the children of the node can be created from the coverage graph of the node. The only difference in the algorithm of [14] and this biconnectivity algorithm is in the contents of the recipes. We describe our recipes in the following. A recipe contains four kinds of instructions:

(1) *Split a subbundle.* Replace a subbundle of m edges that have the same target by up to four adjacent subbundles that have that target and whose (specified) sizes sum to m.

(2) *Split a projection edge.* Split the subbundle list at specified locations, and replace the old subbundle list at the supernode by the new subbundle lists.

(3) *Split a supernode.* Split the two projection lists on either side of the supernode into two pieces at specified locations. Replace the old supernode by two new ones linked by a superedge, and give the appropriate piece of each projection list to each of the new supernodes.

(4) *Create a new subbundle.* Create a subbundle with a specified target and number of edges, and insert it at a specified place in a subbundle list of at most two projection edges.

Using these instructions the coverage graphs of the children of a cluster C can be transformed into a coverage graph of C. The sequence of instructions together with the appropriate parameters (e.g., which subbundle list has to be split at which location) is called a *recipe* and is stored at the node in the topology tree that represents C. These parameters are either a record of a subbundle (consisting of the number of edges in the subbundle and its target), a record of a projection edge (consisting of the edge), or a pointer, called *location descriptor.* A location descriptor consists of a pointer to a subbundle and an offset into the subbundle (in terms of number of edges) or a pointer into a projection list. It takes constant time to follow a location descriptor.

Whenever we expand the topology tree, we use the recipes to create the coverage graphs along the expanded path. Whenever we merge the topology tree, we first determine how to combine the coverage graphs of two clusters to create the coverage graph of their parent, and then we remember how to undo this operation in a recipe. We now describe the instructions in the recipe of C, depending on the number of children of C and their external degrees. In the following *subbundle* stands for LCA-subbundle.

Case 1: C has only one child. In this case the coverage graph of C is identical to the coverage graph of its child. The recipe is therefore empty.

Case 2: C has two children with external degrees 3 and 1. Let Y be the child with external degree 3 and let Z be the child with external degree 1. The coverage graph of Y and of Z consists of one supernode. We build the coverage graph of C as follows:

If the tree edge between Y and Z is dashed, we simply contract it by making the projection list of Z the projection list of one side of the path of C. The projection list of the other side is empty. The projection edges of the bundles do not change and, thus, the subbundle lists do not change.

If the edge (Y, Z) is not dashed, then the supernode of C has only one projection edge, namely, the tree edge between Y and Z. Thus, the supernode of C has one projection list (the projection list of the other side is empty) containing one projection edge. The subbundle list of this projection edge consists of the concatenation of all subbundle lists of Z. In the recipe we use location descriptors to point to the locations of the concatenation. The number of location descriptors is proportional to the number of removed projection edges.

Case 3: C has two children, both with external degree 1. In this case C is the root of the topology tree. Its coverage graph is empty. The coverage graphs of the children contain one supernode and at most one subbundle apiece, corresponding to the set of non-tree edges linking the children. Since each subbundle is contained in at most two projection lists, there are at most four projection lists. The recipe stores these projection lists (i.e., whether a bundle is contained in one or two lists) and subbundles (i.e., the number of non-tree edges linking the children).

Case 4: C has two children with external degrees 2 and 1. Let Y be the child of degree 2 and Z be the child of degree 1. We collapse all supernodes of Y to one supernode s to build the coverage graph of C from the coverage graph of Y as follows:

On each side of the tree edge between Y and Z there may be a subbundle that connects Y and Z. We remove these subbundles and make all remaining subbundles incident to s.

If the edge (Y, Z) is dashed, then the projection edge of the subbundles incident to Y does not change. Thus, we concatenate the two projection lists of Y and the projection list of Z (in the order of the embedding). This creates a single supernode with a single projection list.

If the edge (Y, Z) is solid, then this edge becomes the projection edge for all subbundles incident to Y. Thus, we concatenate all bundle lists of all projection edges of Y to create the bundle list for (Y, Z). Then we concatenate the two projection lists of Y and the projection list of Z (in the order of the embedding). This creates a single supernode with a single projection list.

In both cases, if two newly adjacent subbundles have the same target, we merge them into one subbundle and update the subbundle and projection lists appropriately.

In the recipe we need a location descriptor to point to each subbundle where we concatenated projection lists or subbundle lists or merged subbundles. We also have to store any subbundles that connect Y and Z and all projection edges that we removed. The number of location descriptors we store is proportional to the number of supernodes of Y plus the number of removed projection edges.

Case 5: C has two children, both with external degree 2. Let Y and Z be the children of C. To join the coverage graphs of Y and Z we consider two cases: if the tree edge between Y and Z is dashed, we join the two coverage graphs by identifying the appropriate small supernodes (that are terminating the coverage graphs) and concatenating their projection lists. If the tree edge between Y and Z is not dashed, we connect the two coverage graphs by an edge.

In both cases we then remove all subbundles between Y and Z. If one of the supernodes that was incident to a removed subbundle is no longer incident to a bundle, we replace it by a superedge. Afterward we coalesce all the supernodes between the (Y, Z)-subbundle endpoints into three supernodes as follows: If the path P between their endpoints contains only one supernode other than the endpoints, nothing has to be done. Otherwise, we replace these (at least two) supernodes by one supernode by concatenating their projection lists. We also merge newly adjacent subbundles into a single subbundle if they have the same target.

The recipe contains a location descriptor pointing to each subbundle where we coalesced supernodes and concatenated projection lists (and possibly merged adjacent subbundles). We also store the subbundles that were merged together or deleted. If there is a subbundle that loops around the tree, we need two more location descriptors to mark its endpoints. The number of location descriptors is proportional to the number of coalesced supernodes in Y and Z.

New subbundles may be created during recipe evaluation. For each new subbundle, the recipe stores a bundle record, preloaded with the count of bundle edges, and a location descriptor pointing to the place in the old subbundle list where the new subbundle is to be inserted. The target field of the subbundle is easy to set: the least common ancestor of the bundled edges is exactly the node at which the recipe is being evaluated. In a way similar to [14] we can show the following lemma.

LEMMA 3.1. *If the topology tree is expanded at a constant number of vertices and recipes are evaluated at the expanded clusters, the total number of edge bundles, supernodes, and superedges created is $O(\log n)$. The expansion takes $O(\log n)$ time.*

Proof. Since the topology tree has depth $O(\log n)$, there are $O(\log n)$ marked nodes and $O(\log n)$ children of marked nodes. Thus, the cluster graph consists of the coverage graph of $O(\log n)$ clusters. Planarity guarantees that these clusters are connected by $O(\log n)$ bundles; each bundle is split into up to three subbundles. Thus, there are $O(\log n)$ subbundles. Since each supernode in a cluster with more than one supernode is incident to a subbundle, there are $O(\log n)$ supernodes. Because the supernodes and superedges form a tree, the number of superedges is also $O(\log n)$. Each subbundle has two projection edges. Thus, the total number of projection edges is $O(\log n)$.

Evaluating a recipe takes time proportional to the number of supernodes or projection edges created by the recipe plus constant "overhead" time. Thus, the total expansion time is $O(\log n)$. $\square$

3.2.1. Queries. To answer a query (u, v), we mark all the clusters containing u and v in the topology tree. Then we create the graph $G(u, v)$ in the following steps:

(1) We build the cluster graph by expanding the topology tree at a representative of u and of v.

(2) Let $e_1, e_2, \dots, e_p$ with $p > 1$ be all the subbundles whose extreme edges have the same projection edge (x, y) in a cluster C with $x \in p(C)$. We add a small supernode y and connect all these extreme edges to y.

(3) We contract all dashed edges. When contracting a dashed edge between two supernodes, the resulting supernode is a small supernode.

Since the cluster graph consists of $O(\log n)$ supernodes, subbundles, and superedges and can be computed in time $O(\log n)$, the graph $G(u, v)$ resulting from these 3 steps contains $O(\log n)$ supernodes, subbundles, and superedges and can be computed in time $O(\log n)$.

The following lemmas show that two vertices u and v are not biconnected in G iff there is an articulation point in $G(u, v)$ separating u and v that is not a big supernode. Since the cluster graph has size $O(\log n)$ this can be tested in time $O(\log n)$.

LEMMA 3.2. *Let u and v be two vertices of G_2 and of G_1 and let G_2 be a graph created from G_1 by*

(1) *contracting connected subgraphs into one vertex,*

(2) *replacing the only two edges* (a, b) *and* (b, c) *incident to a vertex* b *by the edge* (a, c),

(3) *replacing parallel edges, and*

(4) *removing self-loops.*

Let x *be a vertex of* G_1 *that is not contained in the contracted subgraphs and not a removed degree-2 vertex. Then* x *is an articulation point in* G_1 *separating* u *and* v *iff* x *is an articulation point separating* u *and* v *in* G_2.

Proof. Consider first the case that x separates u and v in G_1. To achieve that u and v are not separated by x in G_2 a cycle has to be created that contains u, x, and v. Contracting pieces of G_1 that do not contain x or removing degree-2 vertices (other that x) cannot create new cycles. Thus, x is also an articulation point separating u and v in G_2.

If x separates u and v in G_2, then expanding vertices (other than x) of G_2 to connected subgraphs, replacing one edge by two edges and a degree-2 vertex, or adding parallel edges to edges not on $\pi(u, v)$ and self-loops does not create a cycle that contains x, u, and v. Thus, x separates u and v also in G_1. $\square$

LEMMA 3.3. *Let* u *and* v *be two vertices of* G. *The graph* $G(u, v)$ *is created from* G *by*

(1) *contracting connected subgraphs into one vertex,*

(2) *replacing the only two edges* (a, b) *and* (b, c) *incident to a degree-*2 *vertex* b *by the edge* (a, c),

(3) *collapsing parallel edges, and*

(4) *removing self-loops.*

No small supernode on $\pi(u, v)$ *(except for* u *and* v *itself) in* $G(u, v)$ *is contained in a contracted subgraph of any of these operations.*

Proof. The graph $G(u, v)$ can be created from G by the three operations given in the lemma using the following steps. Note that $G(u, v)$ does not contain dashed edges and every small supernode of $G(u, v)$ represents a unique vertex x of G.

(1) Mark as red all the nodes that are small supernodes of $G(u, v)$.

(2) Collapse all nodes on the tree path between two red nodes to one blue node.

(3) Contract every blue node and all the subtrees whose roots are uncolored and connected to the blue node by a tree edge to a green node.

Now we are left with red, green, and uncolored nodes and every green node is connected by tree edges to two red nodes.

(4) Replace all parallel edges by one edge and remove all self-loops.

(5) Replace every degree-2 green node by a superedge. (All remaining green nodes correspond to big supernodes.)

(6) If a red node x lies on $\pi_G(u, v)$ and does not lie on $\pi(u, v)$, shrink all subtrees whose roots are uncolored and connected by a tree edge to x to a yellow node. Otherwise contract all subtrees whose roots are uncolored and connected to x by a tree edge to the node x.

(7) Replace all parallel edges by one edge and remove all self-loops.

The resulting graph is $G(u, v)$. Note that u and v are small supernodes in $G(u, v)$ and then marked red. Hence, if a small supernode x lies on $\pi(u, v)$, it is not replaced by step 6. No small supernodes are contained in a connected subgraph that is contracted in steps (1)–(5). The lemma follows. $\square$

LEMMA 3.4. *No vertex on a subpath that is replaced by a big supernode in* $G(u, v)$ *is an articulation point separating* u *and* v *in* G.

Proof. Let C be the cluster of $G(u, v)$ containing a vertex x that is replaced by a big supernode. Since x is replaced by a big supernode, it follows that x is an internal vertex of the projection path P creating this supernode. Let z_1 and z_2 be the extreme vertices of P. Then z_1 and z_2 are connected by a path in G that does not use x. It follows that x does not separate u and v in G. ∎

Lemma 3.5. *If a vertex x of G is replaced by a superedge (y, z) and if x separates u and v in G, then y and z also separate u and v in G.*

Proof. Let C be the cluster of $G(u, v)$ that contains x, and let $v_1, v_2, \ldots, v_q$ be the subpath P that is replaced by (y, z) with $y = v_1$ and $z = v_q$ and $x = v_i$ for some $1 < i < q$. W.l.o.g. let the tree path from v_2 to u contain v_1. From the definition of a superedge it follows that no vertex v_i with $1 < i < q$ is a supernode. Thus, the projection of none of the subbundles incident of C (i.e., edges with one endpoint in C) contains a vertex v_i. Since x is an articulation point separating u and v, no edge with both endpoints outside C exists whose projection on $\pi(u, v)$ contains a node v_i for $1 \leq i \leq q$. Since v_1 is a small supernode, it is the extreme vertex of a projection of an edge or subbundle whose projection onto $\pi(u, v)$ lies inside $\pi(v_1, u)$. Thus, no edge or subbundle exists whose projection onto $\pi(u, v)$ contains a vertex on $\pi(v_1, u)$ other than v_1 and v_2. Additionally, if such a projection contains v_1 it does not have the same projection edge as any edge whose projection contains v_2. Thus, every path from u to v_2 contains y and, hence, every path from u to v contains y. The symmetric argument shows that z separates u and v in G. ∎

Lemma 3.6. *Two vertices u and v are not biconnected in G iff there is an articulation point separating u and v that is not a big supernode in the cluster graph $G(u, v)$.*

Proof. Lemma 3.3 shows that the cluster graph $G(u, v)$ is created from G by contracting subgraphs, removing degree-2 nodes, collapsing parallel edges, and removing self-loops. Thus, Lemma 3.2 does apply with $G_1 = G$ and $G_2 = G(u, v)$.

Let x be an articulation point separating u and v in G. Then x lies on $\pi(u, v)$. From Lemma 3.4 it follows that x is cannot be represented by a big supernode in $G(u, v)$. If x is represented by a small supernode, then according to Lemma 3.3, x was not affected by the contraction of G to $G(u, v)$. Thus, Lemma 3.2 shows that x is an articulation point separating u and v in $G(u, v)$. If x is represented by a superedge (y, z), then according to Lemma 3.5 y is an articulation point separating u and v in G as well. Since y is a small supernode, the same argument as above shows that y separates u and v in $G(u, v)$.

If a small supernode x is an articulation point separating u and v in $G(u, v)$, then by Lemma 3.3 x was not part of a contracted subgraph. It follows from Lemma 3.2 that x is an articulation point separating u and v in G. ∎

Theorem 3.7. *The given data structure can answer biconnectivity queries in time $O(\log n)$.*

Proof. Lemma 3.6 shows that to test the biconnectivity of u and v in G it suffices to test whether u and v are separated by a small supernode in $G(u, v)$. Since $G(u, v)$ has size $O(\log n)$, this can be done in time $O(\log n)$. ∎

3.3. Updates. An insert(u,v) or query(u,v) operation consists of three steps. First, the topology tree is expanded at a representative of u and of v to create the cluster graph as discussed in section 3.2. Second, we add or remove the edge (u, v) from the cluster graph. Third, we merge the topology tree back together.

By adding or deleting a constant number of vertices and edges we guarantee that the graph stays a degree-3 graph. Note that if a tree edge is deleted, we run along the faces adjacent to (u, v) to find a subbundle that connects the two disconnected spanning trees. We can determine one of the edges of the subbundle by repeatedly expanding the clusters containing the endpoints. This edge becomes the new tree edge.

The details of merging the topology tree back together are given in [14]. There are three basic steps. First, the new topology tree for the updated cluster graph is computed. Second, the new subbundles and their LCA-targets are computed. Third, the recipes in all clusters that are affected by the modification of subbundles are recomputed. Steps one and two are identical to [14] and take time $O(\log n)$.

In step three of [14] the recipe of clusters is recomputed that contain the endpoint of an extreme edge of a modified subbundle. The following lemma shows that with the recipes described in section 3.2 it suffices to update these clusters also for 2-vertex connectivity. Thus, the same algorithm as in [14] can be used to update the data structure after each update operation.

LEMMA 3.8. *If a subbundle is split into a constant number of subbundles or if a constant number of subbundles is merged, the only recipes that have to be updated are the recipes of clusters containing the endpoints of the extreme edges of the modified subbundles.*

Proof. A recipe at a cluster C contains location pointers into subbundles, subbundle lists, and projection lists. Additionally, it contains subbundle records and projection edges.

All subbundles in the subbundle lists of C are incident to C. All projection edges for whom we keep a projection list at C are projection edges of subbundles whose extreme edges have at least one endpoint in C. These lists have to be updated only if one of these subbundles is modified.

For each subbundle whose record is stored in the recipe or that is pointed to by a location descriptor at least one of the endpoints is contained in C. The record has to be updated only if the subbundle is modified.

Each projection edge that is stored in the recipe is the projection edge of a subbundle whose extreme edges have at least one endpoint in C. The projection edge information changes only if this subbundle is modified. ☐

This results in the following theorem.

THEOREM 3.9. *The given data structure can answer biconnectivity queries in time $O(\log n)$ and can be updated in time $O(\log^2 n)$ after an edge insertion or deletion under the requirement that the edge insertions maintain the planarity of the embedding.*

OPTIMAL COMBINATORIAL FUNCTIONS COMPARING MULTIPROCESS ALLOCATION PERFORMANCE IN MULTIPROCESSOR SYSTEMS*

HÅKAN LENNERSTAD† AND LARS LUNDBERG‡

Abstract. For the execution of an arbitrary parallel program P, consisting of a set of processes with any executable interprocess dependency structure, we consider two alternative multiprocessors.

The first multiprocessor has q processors and allocates parallel programs dynamically; i.e., processes may be reallocated from one processor to another. The second employs cluster allocation with k clusters and u processors in each cluster: here processes may be reallocated within a cluster only. Let $T_d(P,q)$ and $T_c(P,k,u)$ be execution times for the parallel program P with optimal allocations. We derive a formula for the program independent performance function

$$G(k,u,q) = \sup_{\text{all parallel programs } P} \frac{T_c(P,k,u)}{T_d(P,q)}.$$

Hence, with optimal allocations, the execution of P can never take more than a factor $G(k,u,q)$ longer time with the second multiprocessor than with the first, and there exist programs showing that the bound is sharp.

The supremum is taken over all parallel programs consisting of any number of processes. Overhead for synchronization and reallocation is neglected only.

We further present a tight bound which exploits a priori knowledge of the class of parallel programs intended for the multiprocessors, thus resulting in a sharper bound. The function $g(n,k,u,q)$ is the above maximum taken over all parallel programs consisting of n processes.

The functions G and g can be used in various ways to obtain tight performance bounds, aiding in multiprocessor architecture decisions.

Key words. dynamic allocation, cluster allocation, static allocation, scheduling, multiprocessor, optimal performance, extremal combinatorics, combinatorial formula, 0,1-matrices, optimal partition

1. Introduction.

It is relatively easy and cheap to build large multiprocessors, i.e., systems with a large number of processors, by connecting a number of small clusters with a communication network. The message passing interface (MPI) [16] and parallel virtual machine (PVM) [2] environments make it possible to write a parallel program which executes on a number of clusters. Systems which consist of a number of clusters can easily scale up; i.e., one can simply connect more clusters to the communication network. Another advantage of using multiple clusters is that communication within one cluster does not interfere with communication within other clusters. An alternative to having multiple small clusters is to have one large cluster. The processors in a cluster are often connected with a shared bus, which becomes a bottleneck when the number of processors grows. Consequently, systems with multiple small clusters have a number of advantages compared with systems consisting of one large cluster. A major disadvantage with multiple clusters is that, since processes

may not be reallocated between clusters, some clusters may be idle while others are very busy. In most cases the time when processors are idle can be reduced by careful allocation of processes to clusters.

The problem of finding allocations which result in minimum makespan, i.e., minimum completion time, is NP-hard [1]. In this report tight worst case bounds comparing the minimum makespan for a program on two multiprocessors are established. The multiprocessors have identical processors but different organization and different numbers of processors.

2. Problem definition and results.

The parallel program model under consideration is general. The multiprocessors execute parallel programs P which may have any set of processing times and any possible structure of interprocess dependency, only excepting deadlock.

A parallel program consists of a set of processes, some of which may run in parallel, and a set of synchronization signals between the processes, which introduce dependencies between the processes. A synchronization signal is a prohibition on one process at a specific time point to execute, unless another process has reached a certain time point; see section 4 for further details. We have no limitations on such dependencies in a program, other than that the program is required to be executable.

There are no restrictions on the numbers denoting processing times of the process parts or synchronization time points—the numbers are not required to be integers or multiples of a certain time unit. The only requirement is that all numbers are rational numbers, which from a practical point of view is a weak restriction.

The processors are assumed to be identical. In cluster allocation the processors are organized in k groups, the clusters, where each cluster contains u processors. Here we thus have in total ku processors. Once a process is allocated to a processor in a specific cluster it can only be executed on a processor in this cluster. It may be transferred any time, but only to a processor in the same cluster. The cost of transferring processes is neglected. If a process is put into a waiting state, it will thus later be restarted on a processor in the same cluster.

Dynamic and static allocations are both special cases of cluster allocation. Dynamic allocation represents the case of having all processors in one cluster, $k = 1$; hence the processes may be transferred between all processors without limitations. Static allocation can be described as the case when each cluster has one single processor, $u = 1$, so a process may never be transferred from the processor where it was initiated.

A cluster organized multiprocessor with k clusters, each containing u processors, will be compared with a multiprocessor with q processors using dynamic allocation, executing a program with n processes.

For a parallel program P, there is a certain number of different cluster allocations. Consider the simple example of a program P with three processes ($n = 3$) p_1, p_2, and p_3 and a multiprocessor with two clusters ($k = 2$). Then there are four different cluster allocations. One allocation is to put all processes on the same cluster. The other three allocations correspond to the three possible ways to put two processes on one cluster and one process on the other cluster. We may put p_1 and p_2 on the same cluster or we may put p_1 and p_3 on the same cluster or we may put p_2 and p_3 on the same cluster. The number of different cluster allocations is very large even for moderate values of n and k, however certainly finite.

Continuing the same example, assume that the structure of P is such that processes p_1 and p_2 execute for one time unit, and then they terminate. Neither p_1 nor

p_2 has to wait for any other process. Process p_3 may, however, not start its execution until p_2 has completed. Process p_3 then executes for one time unit before it terminates; i.e., the program contains one dependency—the dependency between p_2 and p_3. Consider the allocation where p_1 and p_2 are allocated to cluster one and p_3 to cluster two. At the start of the program both p_1 and p_2 can execute. Process p_3 may, however, not start its execution before p_2 has completed. If p_1 executes before p_2 on cluster one the makespan of the program will be three time units. However, if p_2 executes before p_1 the makespan will be two time units.

This example shows that the makespan of each allocation is affected by the order in which the processes allocated to the same cluster are executed. However, each of the allocations of the program has a well-defined minimal makespan. We are interested in the minimal makespans for two multiprocessor organizations. Therefore, we only need to consider the minimal makespan for each allocation.

Since we now have a well-defined minimal makespan for each allocation, the set of minimal makespans of the program P for all cluster allocations is finite, so it has a minimum. An allocation which results in a minimal makespan, i.e., shorter than or equal to the makespan of any other allocation, is called an optimal allocation.

For any fixed parallel program P, we compare the minimal makespans of P for two multiprocessors.

The first multiprocessor has q processors and allocates parallel programs dynamically. For a parallel program P, we denote the makespan for P with optimal dynamic allocation by $T_d(P, q)$.

The second multiprocessor performs cluster allocation with k clusters and u processors in each cluster. Let $T_{c,A}(P, k, u)$ denote the makespan for the parallel program P with the cluster allocation A. The makespan for the parallel program P with optimal cluster allocation is denoted by $T_c(P, k, u)$. Hence, $T_c(P, k, u) = \min T_{c,A}(P, k, u)$, where the minimum is taken over all possible cluster allocations A.

Overhead for synchronization and reallocation is neglected throughout the report.

We now define the performance function g:

$$g(n, k, u, q) = \max_{\text{all } n\text{-programs } P} \frac{T_c(P, k, u)}{T_d(P, q)}.$$

Here n-programs denote parallel programs with n processes. The formula for g is presented in section 6. Programs P for which we have equality, $g(n, k, u, q) = T_c(P, k, u)/T_d(P, q)$, are referred to as extremal programs.

The function $g(n, k, u, q)$ is also a tight bound for the same ratio taken over all programs with *at most* n processes. This follows from Theorem 6.4, where we show that the function $g(n, k, u, q)$ is increasing in the variable n.

This increasing property can furthermore be used to compute a formula for the process independent performance function

$$G(k, u, q) = \sup_{\text{all parallel programs } P} \frac{T_c(P, k, u)}{T_d(P, q)} = \lim_{n\to\infty} g(n, k, u, q).$$

The performance function $G(k, u, q)$ is applicable for a multiprocessor intended for any parallel program. This is the best possible bound in the case of no prior knowledge of the parallel programs. In the case when the number of processes of the parallel programs is a priori bounded to at most n processes, the function $G(k, u, q)$ is still an upper bound, but not tight. In this case the function $g(n, k, u, q)$ gives a tight bound.

Note that besides the allocations, the performance functions themselves are optimal, while representing bounds which cannot be improved. The term "optimal" thus appears in two senses. We have optimality as a minimum over allocations, and we have optimality as a maximum over programs.

This second sense of "optimal" appears in the expressions "optimal function" and "optimal performance function." However, when we refer to the bounds we use the term "tight bound."

3. Previous results and applications. The present report extends the results in [4]. Here the formula for the function g in the case $u = 1, k = q$ is treated only, representing static versus dynamic allocation on the same multiprocessor.

The mathematics of the subject is focused in this report. It can be viewed as the theoretical base for the reports [6], [8], and [10], which treat different applications from a computer science point of view.

The report [9] provides an application not covered by the present report. Here extra information is provided by a test execution of the program. In light of this information, the general bound is not tight. In [9], tight bounds for this situation are established. The results involve linear programming where values of the function G occur as coefficients.

Furthermore, the basic method presented here has proved to be useful in other contexts. In the report [11], the efficiency of cache memories for single processors is studied. Here tight bounds comparing more flexible with less flexible cache memory organization alternatives are derived. The final part of the argument is similar to that of the present report, while a different set of transformations and arguments is needed to reach the corresponding matrix problem. The report [7] is a survey article of the results in [11].

Other than the reports [4] to [15], the only general results concerning allocation strategies of parallel programs where synchronization is not neglected appear to be the results by R. L. Graham [3]. The overhead for process reallocation and synchronization is neglected also in this work. Here so-called list scheduling algorithms are considered. This term is used for dynamic allocation algorithms where, when a processor becomes idle and there are waiting executable processes, one of the executable processes is immediately allocated to the idle processor. It is established in [3] that the makespan for a program allocated with a list scheduling algorithm is never higher than two times the makespan with optimal dynamic allocation.

The most general result in this report is clearly the one represented by the function G. Here we have no demands on the program. The function g is restricted to programs with at most n processes. It is expected that the techniques presented here can be extended to take advantage of further kinds of program specifics, thus improving the bounds by keeping away from those programs which maximize the ratio studied in this work.

One example of a multiprocessor architecture feature which immediately follows from the function $G(k, u, q)$ is the number of extra processors which would compensate for a more static allocation. The concluding graphics section shows plots of this and many other ways to exploit the performance functions for multiprocessor architecture purposes.

We next give an overview of the report.

In the following section the allocation problem is described and analyzed in detail and transformed to a mathematical problem. In section 5 we give a full formulation of the mathematical problem and introduce necessary notation. In section 6 the formula for the program dependent performance function $g(n, k, u, q)$ is stated and proved. Basic properties of the function $g(n, k, u, q)$ are also established here. Section 7 deals with the general performance function $G(k, u, q)$. The report is concluded with a graphics section. The purpose of this section is twofold: to show the performance functions quantitatively and geometrically, and to suggest how the functions can be used to aid in multiprocessor design decisions.

4. From programs to matrices. A program P consists of n processes of possibly very different execution times. The processes are usually dependent on each other. One can expect dependencies of the type that process i cannot execute further at the time point t_i unless process j has reached the time point t_j. When process j has reached the time point t_j it is said to execute a synchronizing signal to process i, restarting this process. Certainly there can be many synchronizing signals to a time point t_j, in which case all have to be executed before the process restarts. The execution time of synchronizing signals is neglected. Most parallel programs contain many synchronizing signals. In this report any set of synchronization signals is allowed, except those which include a deadlock.

Now consider a parallel program P and a multiprocessor with q processors. Assume that we have found an optimal dynamic allocation, with makespan $T_d(P, q)$. This optimal dynamic allocation will be kept fixed during the rest of this section. Next we introduce a discretization of the time interval in m subintervals (t_i, t_{i+1}) of equal length, such that all synchronizing signals, process initiations, and process terminations appear on the time points t_i, where $t_i = \frac{i}{m} T_d(P, q), i = 0, \dots, m$. Consequently, there is no time point t: $t_i < t < t_{i+1}$ for any i so that a process of the program P starts or stops or a synchronization signal is executed at the time t. Obviously, all processes in the interval (t_{i-1}, t_i) are completed before any part of the processes corresponding to the interval (t_i, t_{i+1}) start when using this allocation, since this is so without the discretization. For instance, a process which is active from time t_{i-1} to time t_{i+1} completes the processing in the interval (t_{i-1}, t_i) before any processing corresponding to the interval (t_i, t_{i+1}) starts, and when the process starts processing the time interval (t_i, t_{i+1}), all processing corresponding to the interval (t_{i-1}, t_i) is completed.

Such a discretization is possible if all synchronizing signals and process terminations occur at rational time points, which we can assume. Therefore the discretization involves no approximation; exactly the same program is represented in a discrete way. Observe that m might be very large even if the program P is small and has a simple structure.

From the program P we next construct another program P' which will prolong or not affect the makespan using cluster allocation $T_c(P, k, u) \leq T_c(P', k, u)$ but leave the makespan using dynamic allocation unchanged, $T_d(P, q) = T_d(P', q)$.

The construction of P' is obtained by two changes of the program P: we introduce new synchronizing signals and prolong certain processes. At every time point t_i we introduce all possible synchronization between the processes. This means that the synchronization structure now requires that all processes in the interval (t_{i-1}, t_i) have to be completed before any part of the processes corresponding to the interval (t_i, t_{i+1}) may start. Since the execution time of synchronizing signals is neglected, this does not change the makespan with the fixed optimal dynamic allocation, which is $T_d(P, q)$. Further, all processors are made to be busy at all time intervals. This is achieved by, if necessary, prolonging some processes. However, no process is prolonged beyond $T_d(P, q)$; hence $T_d(P, q) = T_d(P', q)$. It is of no importance that the prolonging of processes can be made in many ways; many programs can play the role of P' to a specific program P.

By the construction we thus have $T_d(P, q) = T_d(P', q)$. However, since introducing more synchronization and prolonging processes never shortens the makespan, for other allocations the makespan is either increased or unchanged. In particular, for optimal cluster allocation we therefore have $T_c(P, k, u) \le T_c(P', k, u)$. Consequently,

$$\frac{T_c(P, k, u)}{T_d(P, q)} \le \frac{T_c(P', k, u)}{T_d(P', q)}.$$

Certainly there are programs P which are left unchanged by the above transformation: programs such that $P = P'$. Since these programs constitute a subset of the parallel programs we consider, we actually have

$$g(n, k, u, q) = \max_{P} \frac{T_c(P, k, u)}{T_d(P, q)} = \max_{P'} \frac{T_c(P', k, u)}{T_d(P', q)}.$$

Therefore, in order to calculate the maximum, only programs of the type P' need to be considered.

We next represent a program P' by an $m \times n$ matrix of zeros and ones only. Here each process is represented by a column, and each time period is represented by a row. The entry at the position (i, j) of the matrix is one if the jth process is active between t_{i-1} and t_i; if it is inactive the entry is zero. Each row contains exactly q ones, since each processor is constantly busy. Because of the complete synchronization, each row has to be completed before the next row may start.

Our next objective is to compute the makespan for cluster allocation of the program P'.

Since we consider a time ratio, the choice of time unit is immaterial. Then we can choose the time unit so that $T_d(P', q) = m$; hence the processing time for each time period using the optimal dynamic allocation is 1.

To compute the makespan for cluster allocations we need to decide how the n processes are to be allocated to the k clusters. In this case every process is to be executed within one cluster, so each cluster allocation corresponds to a way of grouping the n processes onto the k clusters. In the matrix formulation each cluster allocation corresponds to a way of grouping the n columns of the matrix together in k sets. Here each set represents one cluster.

Consider one such cluster allocation A. Assume that l of the processes which are allocated to a specific cluster are executable at a specific time interval. Within a cluster there are u processors and the processes are allocated dynamically. Since there is no synchronization within a time interval, the programs are independent and we will next see that the completion time of this cluster in this time interval is $\max(l/u, 1)$. The completion time clearly cannot be lower than l/u. Further, the completion time cannot be lower than 1 since no part of a process can be executed in parallel with another part of the same process. In the case $l \ge u$ the limit l/u is reached, which has been proved by McNaughton (see Theorem 3.1 in [17]).

Because of the complete synchronization at the time points t_i, processing in the next time interval cannot start before completion of the slowest cluster in the current time interval. Since the clusters are identical, the slowest cluster is the cluster with a maximal number of active processes at that time interval. Hence, we obtain the completion time of a time interval as the maximum of $\max(l_i/u, 1)$ over the k clusters, where $l_i, i = 1, \ldots, k$ is the number of active processes in cluster i during the time interval. The makespan with the cluster allocation A is the sum of these maxima. If we have found an allocation of the n columns together in k sets which minimizes the makespan using cluster allocation, this is an *optimal* cluster allocation, and the makespan is denoted $T_c(P', k, u)$.

5. The matrix problem. We have seen in section 4 that for the sake of computing $T_c(P', k, u)$ and $T_d(P', q)$, the program P' can be replaced by a certain $m \times n$ matrix P' of zeros and ones only. In this matrix each row has exactly q ones, and thus $n - q$ zeros, $1 \le q \le n$. We say that a matrix P' of this type is an n, q*-matrix.*

We call an n, q-matrix *complete* if all $\binom{n}{q}$ permutations of the q ones occur equally frequently as rows. For a complete matrix, the number of rows is thus necessarily divisible by $\binom{n}{q}$. When considering n and q fixed, complete n, q-matrices differ from each other only in that they may have different number of copies of each row, and that the rows may occur in different order. Here are examples of two complete $4, 2$-matrices ($n = 4$ and $q = 2$):

$$\begin{pmatrix} 1 & 1 & 0 & 0 \\ 1 & 0 & 1 & 0 \\ 0 & 1 & 1 & 0 \\ 1 & 0 & 0 & 1 \\ 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 1 \\ 1 & 1 & 0 & 0 \\ 1 & 0 & 1 & 0 \\ 0 & 1 & 1 & 0 \\ 1 & 0 & 0 & 1 \\ 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 1 \end{pmatrix}, \quad \begin{pmatrix} 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 1 \\ 1 & 0 & 0 & 1 \\ 1 & 0 & 1 & 0 \\ 0 & 1 & 1 & 0 \\ 1 & 1 & 0 & 0 \end{pmatrix}.$$

THEOREM 5.1. *If P' and Q' are complete n, q-matrices, then*

$$\frac{T_c(P', k, u)}{T_d(P', q)} = \frac{T_c(Q', k, u)}{T_d(Q', q)}.$$

Proof. The order of the rows does not affect the ratio $T_c(P', k, u)/T_d(P', q)$, since each row must be completed before the execution of the next row may start. Having x ($x > 1$) copies of each row will multiply both quantities $T_c(P', k, u)$ and $T_d(P', q)$ by x; hence this does not affect the ratio $T_c(P', k, u)/T_d(P', q)$. Consequently, the ratio $T_c(P', k, u)/T_d(P', q)$ is the same for all complete n, q-matrices. The theorem is proved. ∎

Consider a complete n, q-matrix P' and a partition A of the n column vectors into k sets. Each set is allocated to a cluster. Denote the makespan for partition A with $T_{c,A}(P', k, u)$. Denote the number of ones in cluster l at row j by $c(l, j)$. As described in the previous section, the makespan with cluster allocation using the partition A is then

$$T_{c,A}(P', k, u) = \sum_{j=1}^{m} \max_{l=1,\dots,k} (c(l, j)/u, 1).$$

THEOREM 5.2.

$$g(n, k, u, q) = \max_{\textit{all } n,q\textit{-matrices } P'} \frac{T_c(P', k, u)}{T_d(P', q)} = \frac{T_c(P'', k, u)}{T_d(P'', q)},$$

where P'' is a complete n, q-matrix.

Proof. Consider an arbitrary n, q-matrix P' of m rows. From P' we will produce a complete n, q-matrix P'' where

$$\frac{T_c(P', k, u)}{T_d(P', q)} \le \frac{T_c(P'', k, u)}{T_d(P'', q)}.$$

Since this can be done for any n, q-matrix P', and since P' itself may be complete, the theorem then follows by Theorem 5.1.

We create $n!$ copies P'_i of P', and in each copy we permute the columns according to one of the $n!$ possible permutations of n columns. Next we form an n, q-matrix P'' of $n!m$ rows by concatenating the $n!$ copies. It is easy to see that the matrix P'' is complete. We obviously have $T_d(P'', q) = T_d(P', q)n!$.

Now we will show that the makespan of each copy cannot be less than $T_c(P', k, u)$, using cluster allocation. Let A be an optimal partition for P''. Consider one of the parts P'_i of P'', and consider the quantity $T_{c,A}(P'_i, k, u)$. Since P'_i is produced from P' by permuting columns, and A is a specific partition of the columns of P'_i, we can find a partition of P', denoted A_i, containing exactly the same columns as the partition A of P'_i. This is an essential observation for this proof. Hence, $T_{c,A_i}(P', k, u) = T_{c,A}(P'_i, k, u)$. We can produce A_i by letting the permutation corresponding to P_i act on the partition A.

Therefore we obtain $T_c(P', k, u) \le T_{c,A}(P'_i, k, u)$ for all $i = 1, \dots, n!$. Then we also have $T_c(P', k, u) \le \sum_{i=1}^{n!} T_{c,A}(P'_i, k, u)/n!$.

Furthermore, $T_c(P'', k, u) = \sum_{i=1}^{n!} T_{c,A}(P'_i, k, u)$. Consequently, $T_c(P', k, u) \le T_c(P'', k, u)/n!$. Hence

$$\frac{T_c(P', k, u)}{T_d(P', q)} \le \frac{T_c(P'', k, u)}{T_d(P'', q)}.$$

Can there exist a noncomplete matrix Q' with a ratio $\frac{T_c(Q',k,u)}{T_d(Q',q)}$ larger than the complete matrices? No, since by duplicating the columns of Q' as above, we get a complete matrix Q'' with

$$\frac{T_c(Q', k, u)}{T_d(Q', q)} \le \frac{T_c(Q'', k, u)}{T_d(Q'', q)}.$$

The theorem is proved. ∎

In order to compute the functions g and G representing the rightmost side of the theorem, we therefore only need to consider complete n, q-matrices.

Consider a partition A, such that column vector v_1 is in set X and column vector v_2 is in set Y. Consider also another partition A' which is identical to A, with the exception that vector v_1 is in set Y and vector v_2 is in set X. In that case the symmetry of a complete n, q-matrix P' guarantees that $T_{c,A}(P', k, u) = T_{c,A'}(P', k, u)$. Consequently, $T_{c,A}(P', k, u)$ is only affected by the number of vectors in each set.

We want to choose the partition A so that $T_{c,A}(P', k, u)$ is minimal. The execution time with optimal cluster allocation is thus

$$T_c(P', k, u) = \min_{\text{all partitions } A} T_{c,A}(P', k, u).$$

We refer to partitions where the sizes of the sets in the partition differ as little as possible as *even partitions*.

If n/k is an integer w, every set in an even partition has w members. Denote the integer part of n/k, the floor function, by $\lfloor n/k \rfloor$, and the smallest integer greater than or equal to n/k, the ceiling function, by $\lceil n/k \rceil$. If n/k is not an integer, the sets in an even partition have $\lfloor n/k \rfloor$ or $\lceil n/k \rceil$ members.

Theorem 5.3. *All even partitions are optimal partitions for a complete n, q-matrix.*

Proof. Consider a complete matrix P and an arbitrary partition A. Suppose A is not even. Then there are two partition sets where one set contains at least two columns more than the other one. In this proof we will modify the partition A into a partition A' by moving one of the columns in the larger partition set to the smaller. We will prove that

$$T_{c,A}(P', k, u) \geq T_{c,A'}(P', k, u).$$

By repeating this argument, we finally obtain an even partition $\tilde{A}$ where

$$T_{c,A}(P', k, u) \geq T_{c,\tilde{A}}(P', k, u).$$

Since this can be done for any partition A, it follows that even partitions are optimal.

Consider a partition A where there are x column vectors allocated to set X, there are y column vectors allocated to set Y, and $x - y > 1$. Consider another partition A' which is identical to A, with the exception that one vector is moved from set X to set Y, resulting in the sets X' and Y'.

We order the vectors in such a way that vectors 1 to x are in set X and vectors $x + 1$ to $x + y$ are in set Y in partition A, and vectors 1 to $x - 1$ are in set X' and vectors x to $x + y$ are in set Y' in partition A'. Hence the xth column is moved from the first set to the second. The example below shows how this looks for one row ($x = 5$ and $y = 3$):

$$\underbrace{01011}_{X}\underbrace{111}_{Y}\cdots$$

$$\underbrace{0101}_{X'}\underbrace{1111}_{Y'}\cdots .$$

The rows in a complete n, q-matrix P contain all permutations. By Theorem 5.1 we may consider a complete n, q-matrix P where each permutation occurs exactly once: P has $\binom{n}{q}$ rows. We next consider a row r in the matrix P. We denote by $r(i)$ the ith element in the row r. Then, for each row r such that $\sum_{x+1}^{x+y} r(i) > \sum_{1}^{x} r(i)$, there is another row r' which is obtained by switching the entry at index i with the entry at index $x+y+1-i$ for $i = 1, \ldots, y$: $r'(i) = r(x+y+1-i)$ for $i = 1, \ldots, y$ and for $i = y + 1, \ldots, x + y$. For all other i we have $r'(i) = r(i)$. Note that two different such rows are never mapped to the same row. Below we have an example of a row r and the corresponding row r' for the case when $x = 5$ and $y = 3$:

$$r = \underbrace{01011}_{X}\underbrace{111}_{Y}\cdots$$

$$r' = \underbrace{11111}_{X}\underbrace{010}_{Y}\cdots .$$

We will show that if the shift from A to A' gives a problem at row r in that the maximum here increases, then we can find another row where the maximum necessarily decreases. Therefore the sum of maxima cannot increase, and we have $T_{c,A}(P, k, u) \geq T_{c,A'}(P, k, u)$.

Suppose that $\max_{l=1,\ldots,k}(c(l, r)/u, 1)$ is larger with partition A' than with partition A for row r. Then necessarily $r(x) = 1$, and the set Y' has more ones than the set X: $\sum_x^{x+y} r(i) > \sum_1^x r(i)$. Also, $\sum_x^{x+y} r(i)$ is larger than the sum corresponding to any other partition set.

Then, at the row r' the maximum $\max_{l=1,\ldots,k}(c(l, r')/u, 1)$ will necessarily be smaller. We have $r'(x) = r(x) = 1$, and from $\sum_x^{x+y} r(i) > \sum_1^x r(i)$ and the mapping from r to r' we get $\sum_1^x r'(i) \geq \sum_1^y r'(i) + 1 = \sum_x^{x+y} r(i) > \sum_1^x r(i) \geq \sum_x^{x+y} r'(i)$. The sum corresponding to any other partition set is unchanged since here $r'(i) = r(i)$ and $A' = A$.

Hence the sum of ones in X at row r' is larger than the sum in Y'. The sum in Y' is also larger than the sum in any other set at row r, from which it follows that the sum in X at row r' is larger than the sum corresponding to any other partition set at row r'. Hence the maximum at row r' decreases.

Consequently, $T_{c,A}(P, k, u) \geq T_{c,A'}(P, k, u)$.

The theorem is proved. $\square$

Referring to the definition of $g(n, k, u, q)$ in section 2, we may now conclude that it holds for the performance function $g(n, k, u, q)$ that

$$g(n, k, u, q) = \frac{T_c(P', k, u)}{T_d(P', q)} = \frac{T_{c,A}(P', k, u)}{T_d(P', q)},$$

where P' is any complete n, q-matrix and A is any even partition.

Then g can be obtained by explicitly calculating the ratio $T_{c,A}(P', k, u)/T_d(P', q)$ for some arbitrary complete n, q-matrix P' and an even partition A. Unfortunately, this is extremely inefficient, making it impossible to handle reasonable parameters n, k, u, and q. In the next section we present a formula for g which makes it possible to handle realistic values on n, k, u, and q.

The function g is defined only for $q \leq n$. This is due to the matrix formulation, since there cannot be more than n ones in each row of the matrix: n is the number of columns. From the parallel program application it is clear that the function g should be extended by $g(n, k, u, q) = g(n, k, u, n)$ when $q > n$. We here have more processors than processes in the dynamic case. If $q > n$ we have $q - n$ unnecessary processors, and we can safely reduce the number of processors from q to n.

6. Process dependent performance function.

For the next theorem we need the following three combinatorial functions. Let $I = \{i_1, \ldots, i_{k-1}\}$ be a decreasing finite sequence of nonnegative integers. Then we define the following:

$b(l, I)$ = the number of distinct integers in $\{l, i_1, \ldots, i_{k-1}\}$;

$a(l, I, j)$ = the number of occurrences of the jth distinct integer in $\{l, i_1, \ldots, i_{k-1}\}$, enumerated in size order, $1 \leq j \leq b(l, I)$;

$\pi(k, w, q, l)$ = the number of permutations of q ones distributed in kw slots, which are divided in k sets with w slots in each, such that the set with maximum number of ones has exactly l ones. Note that all parameters to π are integers.

We can now state the formula for $g(n, k, u, q)$, from which an explicit formula for the function $G(k, u, q)$ follows.

Theorem 6.1. *Given positive integers $n, k, q,$ and u where $n \geq q$, in the case where $w = n/k$ is an integer, we have*

$$g(n,k,u,q) = \frac{1}{u\binom{n}{q}} \sum_{l=1}^{\min(w,q)} \max(l,u)\pi(k,w,q,l).$$

If n/k is not an integer we let $w = \lfloor n/k \rfloor$ and denote the remainder of n divided by k by n_k. Then we have

$$g(n,k,u,q) = \frac{1}{u\binom{n}{q}} \sum_{l_1=\max(0,\lceil \frac{q-(k-n_k)w}{n_k} \rceil)}^{\min(w+1,q)} \sum_{l_2=\max(0,\lceil \frac{q-l_1 n_k}{k-n_k} \rceil)}^{\min(w,q-l_1)} \max(l_1,l_2,u)$$
$$\times \sum_{i=\max(l_1,q-l_2(k-n_k))}^{\min(l_1 n_k, q-l_2)} \pi(n_k, w+1, i, l_1)\pi(k-n_k, w, q-i, l_2).$$

The formula for π is given in the following lemma.

Lemma 6.2. *In the special cases $\min(q,w) < l$ and $q > kl$, $\pi(k,w,q,l) = 0$. Otherwise, if $k = 1$ and $q = l$, $\pi(1,w,q,l) = \binom{w}{l}$. In all other cases we have*

$$\pi(k,w,q,l) = \binom{w}{l} \sum_{I \in \mathcal{I}} \binom{w}{i_1} \cdot \ldots \cdot \binom{w}{i_{k-1}} \frac{k!}{\Pi_{j=1}^{b(l,I)} a(l,I,j)!}.$$

The set $\mathcal{I}$ is the set of all sequences of nonnegative integers $I = \{i_1, \ldots, i_{k-1}\}$ which are decreasing: $i_j \geq i_{j+1}$ for all $j = 1, \ldots, k-2$, bounded by $l : i_1 \leq l$, and have sum $q - l$: $\sum_{j=1}^{k-1} i_j = q - l$.

Proof of Theorem 6.1. We consider the smallest complete n, q-matrix P' possible, i.e., the complete n, q-matrix with $\binom{n}{q}$ rows.

We start by considering the case when n/k is an integer. In this case, the n column vectors can be mapped to k sets containing w vectors each. Choose the time unit so that $T_d(P', q) = \binom{n}{q}$. The processing time of each row is then $\max(l, u)/u$, where l is the maximum number of ones in one set for the row. Obviously, l is an integer in the interval 1 to $\min(w, q)$.

From the definition of the function π we know that for each specific l in the interval 1 to $\min(w, q)$, $\pi(k, w, q, l)$ denotes the number of rows with completion time $\max(l, u)/u$. Consequently,

$$T_c(P', k, u) = \frac{1}{u} \sum_{l=1}^{\min(w,q)} \max(l,u)\pi(k,w,q,l).$$

We get

$$g(n,k,u,q) = T_c(P',k,u)/T_d(P',q) = \frac{1}{u\binom{n}{q}} \sum_{l=1}^{\min(w,q)} \max(l,u)\pi(k,w,q,l).$$

The formula for the case when n/k is not an integer follows by considering n_k sets of size $w + 1$ and $k - n_k$ sets of size w. In this case the first sum runs over the number of ones the n_k first sets. The theorem is proved.

Proof of Lemma 6.2. We take care of the trivial cases first. We have $\pi(k, w, q, l) = 0$ if $w < l$ (l is too large for the partition sets), $q < l$ (there are not ones enough to get l ones in one set), or if $q > kl$ (there are at least $l + 1$ ones in some set). If $k = 1$ we have one partition set only, and we have $n = w$, so one of the conditions $q < l$ and $q > kl$ applies unless $q = l$. If $k = 1$ and $q = l$ we get $\pi(k, w, q, l) = \pi(k, n, q, q) = \binom{n}{q}$, so $g(n, 1, u, q) = \max(l/u, 1) = \max(q/u, 1)$.

The formula for π is obtained in the following way. Consider a complete matrix and an even partition of the columns in k sets. Each row corresponds to a sequence $I = \{i_1, \ldots, i_k\}$ of nonnegative integers, where each integer i_j denotes the number of ones in set j. The sequence clearly has sum equal to q. We assume that the sequence is decreasing; hence we may rearrange the order of the i_j's derived from the matrix to obtain a decreasing sequence. In this way the set of possible rows of n, q-matrices is grouped into subsets, where each subset corresponds to a certain sequence $I = \{i_1, \ldots, i_k\}$.

Note that for all rows in the subset represented by the sequence $I = \{i_1, \ldots, i_k\}$, the maximal number of ones in one set is i_1. To compute the sum of maxima for a complete matrix where each row occurs exactly once, we then only need to compute the number of rows in each subset.

The number of rows corresponding to a sequence I can be obtained by permuting the number of ones allocated to each set and by permuting the sets. Permuting within the sets causes a product of binomial coefficients: $\binom{w}{i_1}\binom{w}{i_2}\cdots\binom{w}{i_k}$. Since we know that $i_1 = l$ is the maximal integer, we can extract the factor $\binom{w}{l}$ and consider decreasing sequences of length $k - 1$ and with sum $q - l$. Permuting the sets gives a factor $k!$; however, since no new rows are obtained when permuting sets with equal number of ones, we have to divide by the number of permutations of equal sets. We therefore get the factor $k!/(\Pi_{j=1}^{b(l,I)} a(l, I, j)!)$. (The functions $a(l, I, j)$ and $b(l, I)$ have been defined previously.)

The summation in the formula for π sums the number of rows where the maximum number of ones in a set is l. The lemma is proved.

As described earlier, $g(n, k, u, q)$ is defined also in the case $q > n$; here we have $g(n, k, u, q) = g(n, k, u, n) = \max(\lceil \frac{n}{k} \rceil/u, 1)$. A consequence of this and of Theorem 6.1 is that for $k = 1$ we have $g(n, 1, u, q) = \max(\min(n, q)/u, 1)$.

In section 8, the 256 first values of $g(n, k, u, q)$, for $1 \le n, k, u, q \le 4$, are presented in Figure 8.2. Figure 8.3 shows three plots of g representing three cases of increasing degrees of cluster organization using the same number of processors.

The following lemma provides an algorithm which generates all decreasing sequences appearing in Theorems 6.1 and 7.1.

We say that the least decreasing sequence of length μ and sum σ is the sequence $\{\lceil \frac{\sigma}{\mu} \rceil, \ldots, \lceil \frac{\sigma}{\mu} \rceil, \lfloor \frac{\sigma}{\mu} \rfloor, \ldots, \lfloor \frac{\sigma}{\mu} \rfloor\}$. If σ_μ is the remainder when σ is divided by μ, the number of $\lceil \frac{\sigma}{\mu} \rceil$'s is σ_μ, and the number of $\lfloor \frac{\sigma}{\mu} \rfloor$'s is $\mu - \sigma_\mu$, making the sum of the sequence σ.

LEMMA 6.3. *Let λ and σ be nonnegative integers and μ be a positive integer such that $\lambda \le \sigma \le \lambda\mu$.*

Every sequence of μ integers in the interval $0 \le i \le \lambda$ which is decreasing, bounded by λ, and has sum σ is generated exactly once by the following algorithm:

(1) *Take I as the least decreasing sequence of length μ and sum σ.*
(2) *Find the* rightmost *position in I, say, j, which fulfills*
  (a) $i_j < l$,
  (b) $i_j < i_{j-1}$ *or* $j = 1$,

(c) $i_{j+1} > 0$.

The algorithm terminates if no such j can be found.

(3) *The next sequence is obtained from I by increasing the entry in position j by one and replacing the subsequence $\{i_{j+1}, \ldots, i_\mu\}$ with the least decreasing subsequence of length $\mu - j$ and sum $\sum_{k=j+1}^{\mu} i_k - 1$.*

(4) *Go to step* 2.

Proof. The lemma is proved on page 758 in [4].

Observe that if n/k is an integer, $\sum_{l=1}^{\min(w,q)} \pi(k, w, q, l) = \binom{n}{q}$. Otherwise we have

$$\sum_{l_1=0}^{\min(w+1,q)} \sum_{l_2=0}^{\min(w,q-l_1)} \sum_{i=\max(l_1, q-l_2(k-n_k))}^{\min(l_1 n_k, q-l_2)} \pi(n_k, w+1, i, l_1)\pi(k-n_k, w, q-i, l_2) = \binom{n}{q},$$

since we are only counting all permutations of the q ones in the n slots in different ways. Thus the formula can be regarded as a weighted average of the numbers $\{\max(l/u, 1) : l = 1, 2, \ldots, \min(\lceil n/k \rceil, q)\}$. In the case $u \geq \min(\lceil n/k \rceil, q)$ all these numbers are 1; hence we in this case obtain $g(n, k, u, q) = 1$. In multiprocessor terms this corresponds to a collapse of cluster allocation into dynamic allocation since then one cluster alone is equally large as the first multiprocessor.

For the sake of the following theorem, we remark that we use the term "increasing" in the nonstrict sense: $f(k)$ is increasing if $f(k) \leq f(k+1)$ for all k. We do not require $f(k) < f(k+1)$.

THEOREM 6.4. *The function $g(n, k, u, q)$ has the following properties:*

(1) *$g(n, k, u, q)$ is increasing in the variables n and q and decreasing in the variables u and k.*

(2) *Given positive integers ν, w, and u, we have*

$$\begin{aligned}
\max\left(\frac{w+1}{u}, 1\right) - \left(\max\left(\frac{w+1}{u}, 1\right) - \max\left(\frac{w}{u}, 1\right)\right)(1 - w^{-(w+1)})\nu \\
\geq \lim_{k\to\infty} g(wk + \nu, k, u, k) \\
\geq \max\Big(\max\left(\frac{w}{u}, 1\right), \max\left(\frac{w+1}{u}, 1\right) - \Big(\max\left(\frac{w+1}{u}, 1\right) \\
- 1\Big)(1^{-(w+1)})^\nu\Big).
\end{aligned}$$

(3) *The function $g(n, k, u, q)$ is unbounded.*

Note further that $g(n, k, u, q) = 1$ if $u \geq \min(\lceil n/k \rceil, q)$ or if $k \geq n$, and $g(n, k, u, q) = g(n, k, u, n) = \max(\lceil n/k \rceil/u, 1)$ for all $q \geq n$.

If $w > u$, (2) reduces to

$$\begin{aligned}
\frac{w+1}{u} - \left(\frac{w+1}{u} - 1\right)(1 - w^{-(w+1)})^\nu \\
\geq \lim_{k\to\infty} g(wk + \nu, k, u, k) \\
\geq \max\left(\frac{w}{u}, \frac{w+1}{u} - \frac{1}{u}(1 - w^{-(w+1)})^\nu\right).
\end{aligned}$$

Proof. (1) That g is increasing as a function of n follows by considering an extremal program P with n processes, i.e., $T_c(P, k, u)/T_d(P, q) = g(n, k, u, q)$. Consider also a program P' which is identical to P with the exception that a new process has been added. This new process is inactive during the entire execution of P'; i.e., there are $n+1$ processes in P'. Obviously, $T_c(P,k,u)/T_d(P,q) = T_c(P',k,u)/T_d(P',q)$. From the definition of g we know that $T_c(P',k,u)/T_d(P',q) \leq g(n+1,k,u,q)$. Consequently, $g(n,k,u,q) = T_c(P',k,u)/T_d(P',q) \leq g(n+1,k,u,q)$.

Consider $q < n$. That g is increasing as a function of q follows by considering a complete n,q-matrix P, i.e., $T_c(P,k,u)/T_d(P,q) = g(n,k,u,q)$. If we replace the first zero in each row with a one we get an $n,q+1$-matrix P'. Obviously, $T_d(P,q) = T_d(P',q+1)$ and $T_c(P,k,u) \leq T_c(P',k,u)$, i.e., $g(n,k,u,q) = T_c(P,k,u)/T_d(P,q) \leq T_c(P',k,u)/T_d(P',q+1) \leq g(n,k,u,q+1)$.

Since $\max(1,l/u)$ is decreasing as a function of u, so is $g(n,k,u,q)$.

$T_c(P,k,u)$ is obviously a decreasing function of k for any program P, and $T_d(P,q)$ is not affected by k. Consequently, $g(n,k,u,q) = \max_{\text{all } n\text{-programs } P} \frac{T_c(P,k,u)}{T_d(P,q)} \geq \max_{\text{all } n\text{-programs } P} \frac{T_c(P,k+1,u)}{T_d(P,q)} = g(n,k+1,u,q)$. Here n-programs denotes parallel programs with n processes.

(2) The idea of the proof of (2) is to exploit the fact that g is a weighted average of the numbers $\{\max(l/u,1) : l = 1,2,\ldots,\min(\lceil n/k\rceil,k)\}$. We calculate the weight W_k corresponding to the number $\max((w+1)/u,1)$ in the weighted average. We then let $k \to \infty$, in which case $W_k \to W$. Since k is large we may assume $\min(\lceil n/k\rceil,k) = \lceil n/k\rceil = w+1$. Then the estimate follows from $W\max((w+1)/u,1) + (1-W)1 \leq \lim_{k\to\infty} g(wk+\nu,k,u,k) \leq W\max((w+1)/u,1) + (1-W)\max(w/u,1)$. On page 763 in [4] we prove that $W = 1-(1-w^{-(w+1)})^{\nu}$.

The lower bound on $\lim_{k\to\infty} g(wk+\nu,k,u,k)$ for a certain w and ν is bounded from below by $\frac{w}{u}$. This follows from the fact that g is increasing in n.

If we let $\nu \to \infty$, the upper and lower bounds coincide, so

$$\lim_{\nu\to\infty}\left(\lim_{k\to\infty} g(wk+\nu,k,u,k)\right) = \frac{w+1}{u}.$$

Furthermore, for each k and ν, there is a ν_0 so that

$$g(wk+\nu,k,u,k) \geq g((w-1)k+\nu_1,k,u,k)$$

for all $\nu_1 > \nu_0$. Hence,

$$\lim_{k\to\infty} g(wk+\nu,k,u,k) \geq \frac{w}{u}.$$

(3) follows immediately from (2). We remark that $g(n,k,u,q)$ being unbounded means that for any real M there exist positive integers n,k,u,q so that $g(n,k,u,q) > M$. $\square$

Analogously to the function $g(n,k)$ described in [4], the existence of plateaus for the graph of $g(n,k,u,k)$ follows. From

$$\lim_{\nu\to\infty}\left(\lim_{k\to\infty} g(wk+\nu,k,u,k)\right) = \frac{w+1}{u},$$

and the fact that $g(n,k,u,k)$ is increasing in n, it follows that there exists an unbounded plateau at level $(w+1)/u$ for each integer w. For example, for each $\epsilon > 0$ there is a number N so that for all (n,k) in the domain $\{(n,k) : wk+N < n < (w+1)k\}$ we have $|\,g(n,k,u,k) - w/u\,| < \epsilon$. For a given ϵ, N appears to increase very rapidly with w.

The function $g(n,k) = g(n,k,1,k)$, which compares static with dynamic allocation, is neither increasing nor decreasing as a function of k (see [4]). A plot of the local extreme values of $g(n, k)$ as a function of k, for each fixed n, is shown in section 8. Detail structure otherwise not visible is revealed in this plot.

The optimal performance function $g(n, k, u, k)$ thus has a shape resembling a winding staircase with constant step height $1/u$ and an infinite number of steps, where each step is narrower, less sharp edged, and much farther from the origin than the previous step.

7. The process independent performance function.

It turns out that it is also possible to compute explicitly the optimal performance function $G(k, u, q)$.

THEOREM 7.1. *For any positive integers $k, u,$ and q,*

$$G(k,u,q) = \lim_{n\to\infty} g(n,k,u,q) = \sup_{n\in\mathbf{N}} g(n,k,u,q),$$

where $G(1, u, q) = \max(q/u, 1)$, and if $k > 1$,

$$G(k,u,q) = \frac{k!q!}{k^q u}\sum_{l=1}^{l=q}\frac{\max(l,u)}{l!}\sum_{I\in\mathcal{I}}\left(\Pi_{j=1}^{k-1} i_j!\,\Pi_{j=1}^{b(l,I)} a(l,I,j)!\right)^{-1}.$$

The set $\mathcal{I}$ is the set of all sequences $I = \{i_1, \dots, i_{k-1}\}$ of nonnegative integers which are decreasing; $i_j \geq i_{j+1}$ for all $j = 1, \dots, k-2$, bounded by $l; i_1 \leq l$, and have sum $q - l$; $\sum_{j=1}^{k-1} i_j = q - l$.

Further, the function $G(k, u, q)$ is decreasing as a function of k and as a function of u, and increasing as a function of q. $G(k) = G(k, 1, k)$ is an increasing function.

Proof. By Theorem 6.4 the function $g(n, k, u, q)$ is increasing as a function of n; hence the limit and the supremum in the theorem coincide. Furthermore it follows that $\lim_{n\to\infty} g(n, k, u, q) = \lim_{w\to\infty} g(wk, k, u, q)$. Note also that exactly the same decreasing sequences are generated in the function $\pi(k, w, k, l)$ for all $w \geq k$, if l and k are fixed. This fact makes it possible to explicitly compute the function $G(k, u, q)$. When letting $w \to \infty$, it is enough to study the behavior of the w-dependent part of each term, which is

$$\frac{\binom{w}{l}\binom{w}{i_1}\cdot\dots\cdot\binom{w}{i_c}}{\binom{wk}{q}}.$$

We will next prove that

$$\lim_{w\to\infty}\frac{\binom{w}{l}\binom{w}{i_1}\cdot\dots\cdot\binom{w}{i_c}}{\binom{wk}{q}} = \frac{q!k^{-q}}{l!i_1!\cdot\dots\cdot i_c!}.$$

Here c is the number of nonzero entries in the sequence I. In the following we will use the fact that $l + i_1 + \cdots + i_c = q$. From the Stirling formula $n! \approx (\frac{n}{e})^n\sqrt{2\pi n}$, we get for large n:

$$\binom{n}{k} \approx \frac{e^{-k}}{k!}\sqrt{\frac{n}{n-k}}\frac{n^n}{(n-k)^{n-k}}.$$

Thus the quotient approximately equals

$$\frac{e^{-l}}{l!}\sqrt{\frac{w}{w-l}}\frac{w^w}{(w-l)^{w-l}}\frac{e^{-i_1}}{i_1!}\sqrt{\frac{w}{w-i_1}}\frac{w^w}{(w-i_1)^{w-i_1}}\cdot\ldots$$

$$\cdot\frac{e^{-i_c}}{i_c!}\sqrt{\frac{w}{w-i_c}}\frac{w^w}{(w-i_c)^{w-i_c}}\frac{q!}{e^{-q}}\sqrt{\frac{kw-q}{kw}}\frac{(kw-q)^{kw-q}}{(kw)^{kw}}$$

$$=\frac{q!}{l!i_1!\cdot\ldots\cdot i_c!}$$

$$\cdot\sqrt{\frac{w}{w-l}\frac{w}{w-i_1}\cdot\ldots\cdot\frac{w}{w-i_c}\frac{kw-q}{kw}}$$

$$\cdot\Big(1-\frac{q}{kw}\Big)^{kw}\frac{w^{w-l}w^{w-i_1}\cdot\ldots\cdot w^{w-i_c}}{(w-l)^{w-l}(w-i_1)^{w-i_1}\cdot\ldots\cdot(w-i_c)^{w-i_c}}w^q(kw-q)^{-q}.$$

The first line after the last equality clearly is independent of w. The second line tends to 1. The first factor of the third line tends to e^{-q}. The second factor consists of $c+1$ factors, where each can be written as

$$\Big(1+\frac{i}{w-i}\Big)^w\cdot\Big(\frac{w}{w-i}\Big)^{-i}$$

for $i=l,i_1,\ldots,i_c$. The factors $(\frac{w}{w-i})^{-i}$ together with the third factor on the third line gives

$$\Big(\frac{kw-q}{w-l}\Big)^{-l}\Big(\frac{kw-q}{w-i_1}\Big)^{-i_1}\cdot\ldots\cdot\Big(\frac{kw-q}{w-i_c}\Big)^{-i_c}\to k^{-l}k^{-i_1}\cdot\ldots\cdot k^{-i_c}=k^{-q}.$$

Now,

$$\Big(1+\frac{i}{w-i}\Big)^w\to e^i\text{ as }w\to\infty,$$

so the remaining factors contributes with

$$e^le^{i_1}\cdot\ldots\cdot e^{i_c}=e^q$$

as $w\to\infty$. This leaves

$$\frac{\binom{w}{l}\binom{w}{i_1}\cdot\ldots\cdot\binom{w}{i_c}}{\binom{wk}{q}}\to\frac{q!}{l!i_1!\cdot\ldots\cdot i_c!}\cdot e^{-q}\cdot e^q\cdot k^{-q}=\frac{q!}{l!i_1!\cdot\ldots\cdot i_c!}k^{-q}.$$

Since $g(n,1,u,q)=\max(\min(n,q)/u,1)$, it immediately follows that $G(1,u,q)=\max(q/u,1)$. Note that this case represents the worst case ratio of dynamic versus dynamic allocation, with u and q processors, respectively. This completes the proof of the formula for $G(k,u,q)$.

The increasing and decreasing properties for $G(k,u,q)$ follow from (1) in Theorem 6.4. In Theorem 2 part (2) on page 762 in paper [4] we show that $g(wk,k,1,k)$ is increasing as a function of k for any positive integer w. From this we immediately get that $G(k) = G(k,1,k)$ is increasing. The theorem is proved. $\square$

In the case of static allocation and $k = q$, the case considered in [4], we get $G(k) = G(k,1,k)$, where

$$G(k) = \frac{(k!)^2}{k^k} \sum_{l=1}^{l=k} \frac{1}{(l-1)!} \sum_I \left(\Pi_{j=1}^{k-1} i_j! \, \Pi_{j=1}^{b(\{l\}+I)} a(\{l\}+I,j)! \right)^{-1}.$$

The last sum is taken over the same sequences I as in the previous formula, with $q = k$.

Note that the number of terms in the sum increases rapidly with k. However, being unit fractions with products of factorials as denominators, all terms are very small if k is large. From the Stirling formula it indeed follows that $(k!)^2 \gg k^k \gg k!$ for large k.

We give the first values of $G(k)$ as maximally reduced rational numbers, prime factorizations, and decimal expansions:

$G(1) = 1$,
$G(2) = \frac{3}{2} = 1.5$,
$G(3) = \frac{17}{9} = \frac{17}{3^2} = 1.888\ldots$,
$G(4) = \frac{17}{8} = \frac{17}{2^3} = 2.125$,
$G(5) = \frac{1429}{625} = \frac{1429}{5^4} = 2.2864$,
$G(6) = \frac{3121}{1296} = \frac{3121}{2^4 3^4} = 2.40818\ldots$,
$G(7) = \frac{295189}{117649} = \frac{211 \cdot 1399}{7^6} = 2.50907\ldots$,
$G(8) = \frac{680849}{262144} = \frac{13 \cdot 83 \cdot 631}{2^{18}} = 2.597232\ldots$,
$G(9) = \frac{38404547}{14348907} = \frac{43 \cdot 107 \cdot 491 \cdot 1717}{3^{15}} = 2.67648\ldots$,
$G(10) = \frac{274868911}{100000000} = \frac{3929 \cdot 69959}{2^8 5^8} = 2.74868911.$

We conclude with some notes on the computability of the functions.

The variable u does not affect the number of floating point operations necessary for computing the value of the function $g(n,k,u,q)$. This number increases slightly with q and n, if n is a multiple of k, because of the larger values in the binomials and factorials to be computed. However, the number of operations increases rapidly with the variable k since the number of decreasing sequences increase rapidly. This is also true for the variable n if it is not a multiple of k.

The approximation $h(n,k,u,q) = g(k\lceil n/k \rceil, k, u, q)$ is much faster to compute, since only a fraction of the values are needed. Furthermore, by Theorem 6.1 it is evident that the values which are calculated involve a simple sum in the function π only; hence they are the computationally lightest. The function h is close to optimal upper bound since $h(n,k,u,q) \geq g(n,k,u,q)$ for all n,k,u, and q, with equality whenever n/k is an integer.

8. Graphics.

The graphics and tables in this section refer to and illustrate functions and concepts of the report. One aim is to describe the performance functions quantitatively and geometrically. Another is to give examples of how the functions can be used to provide optimal trade-off estimates, aiding in the choices between multiprocessor design alternatives.

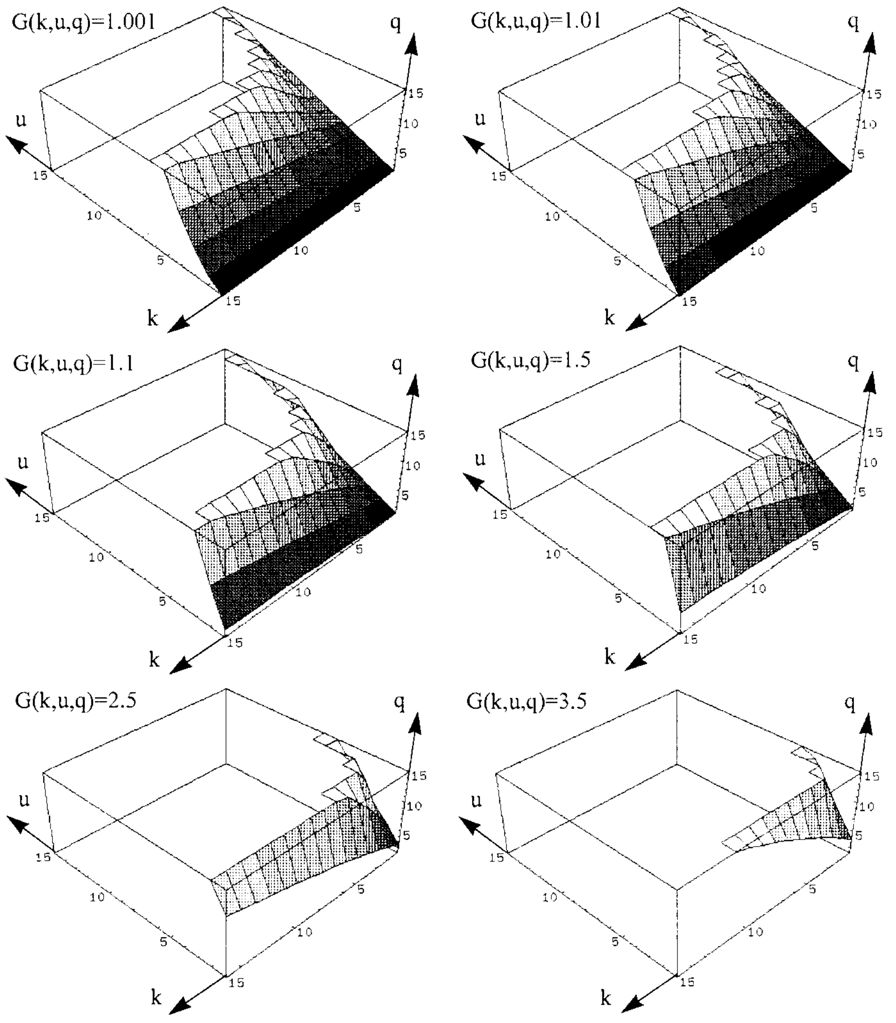

FIG. 8.1. *Level surfaces $G(k, u, q) = C$.*

In Figure 8.1 we plot a version of $G(k, u, q)$ where the discrete variable q is turned into a continuous variable Q by linear interpolation between neighboring values. Thus, given k, u, and C, all values Q such that $(\lceil Q\rceil - Q)G(k, u, \lfloor Q\rfloor) + (Q - \lfloor Q\rfloor)G(k, u, \lceil Q\rceil) = C$ are plotted, if any exist. Since $G(k, u, q) \geq 1$ is a sharp bound of G, every $C \geq 1$ gives a plot. The grayscale in the plots emphasizes the value of q: black is $q = 1$, white is $q = 15$. $G(k, u, q) = 1$ if $u \geq q$, so there are no level surfaces here for $C > 1$. $G(k, u, q) > 1$ if $q > u$; however, G clearly increases very slowly with q when $q - u$ is small.

Most of the values of $g(n, k, u, q)$ are 1. Figure 8.2 indicates in which directions $g(n, k, u, q)$ is not 1 and indicates the initial growth here. $g(n, k, u, q) = 1$ if $u \geq \lceil n/k\rceil$, $u \geq q$, or $k \geq n$. Further, $g(n, k, u, q) = g(n, k, u, n)$ if $q > n$. In all these cases there are more processors than processes in some sense. $g(n, 1, 1, n) = n$ is the direction of fastest growth. For example, here we have the only value where $g(n, k, u, q) > 1$ if

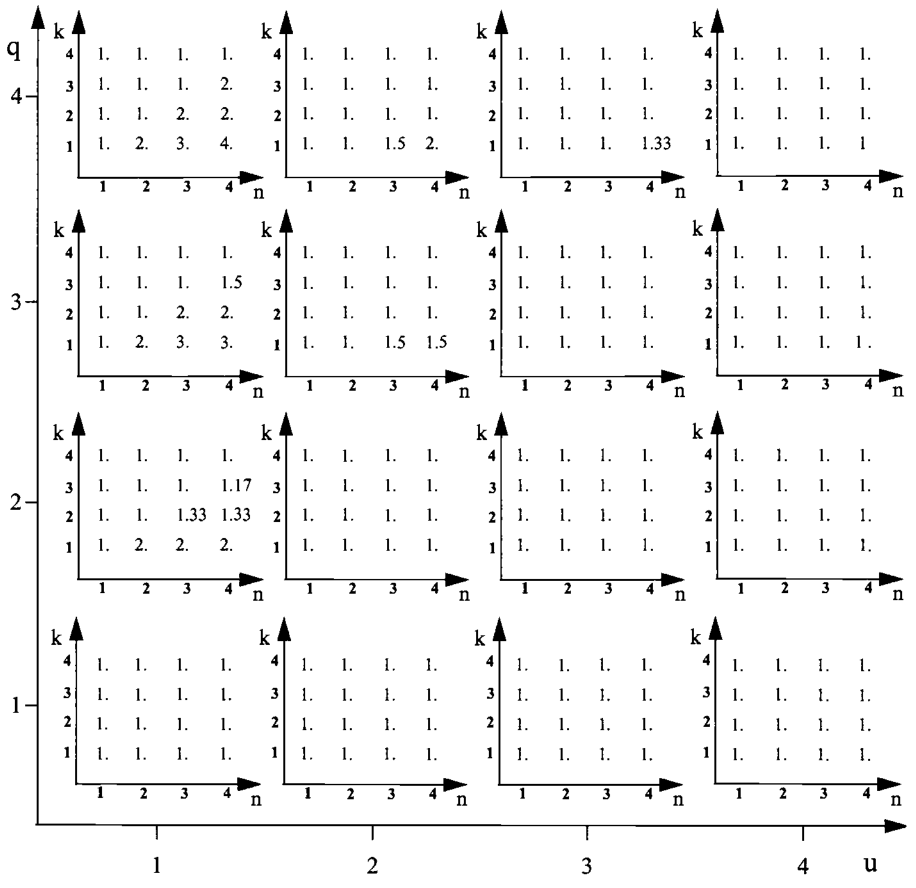

FIG. 8.2. *The* 256 *first values of* $g(n, k, u, q)$.

all arguments are one or two. In multicomputing terms this corresponds to the worst case ratio of one processor compared to n processors, running a multiprogram with n subprocesses.

The plot in Figure 8.3 shows the worst case execution time for three degrees of cluster allocation, compared to dynamic allocation. The number of processors in corresponding points is equal. Note that when there are $u > 1$ processors in each cluster, the plateaus for the case $u = 1$ split into several, where plateau number i have asymptotic height $g = 1 + (i - 1)/u$.

The function $G(k, u, ku)$ expresses the worst case ratio of cluster allocation with k clusters and u processors in each cluster, compared to dynamic allocation with the same processor quantity: ku processors. See Figure 8.4.

Note the following: $G(k, 1, k)$ is static versus dynamic allocation (k-axis). $G(1, u, u)$ $= 1$; this is dynamic versus dynamic allocation (u-axis). The function G exists only for integer arguments; in the plot, linear interpolation is done between these points. The grayscale in the figure indicates the value linearly, where black is minimum and white is maximum.

A measure of the trade-off between processor organization and processor power is

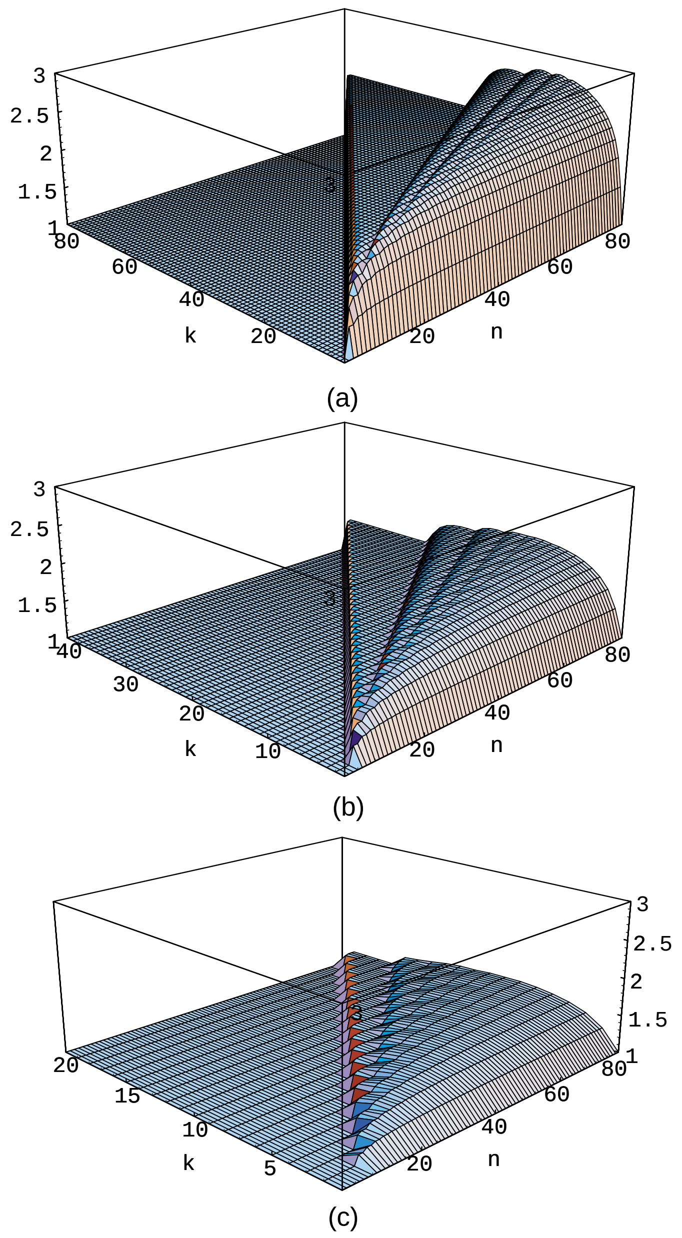

FIG. 8.3. *Increasing degree of cluster allocation.* (a) $g(n, k, 1, k)$, $n \leq 80$, $k \leq 80$; (b) $g(n, k, 2, 2k)$, $n \leq 80$, $k \leq 40$; (c) $g(n, k, 4, 4k)$, $n \leq 80$, $k \leq 20$.

provided by the graphs in Figure 8.5. The gain in execution time $G(k, u, q)$ for each possible cluster allocations using a fixed number of processors (ku) is compared to dynamic allocation with various numbers of processors (q). For example, if we assume $ku = 6$, constant worst case efficiency implies that the four possible cluster allocation strategies correspond to dynamic allocation with 7, 11, 13, and 16 processors, in increasing degree of cluster organization of the processors. Optimal bounds comparing

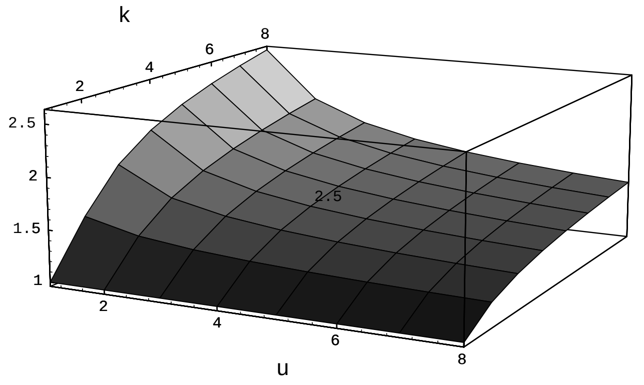

FIG. 8.4. *Cluster versus dynamic allocations on the same multiprocessor.*

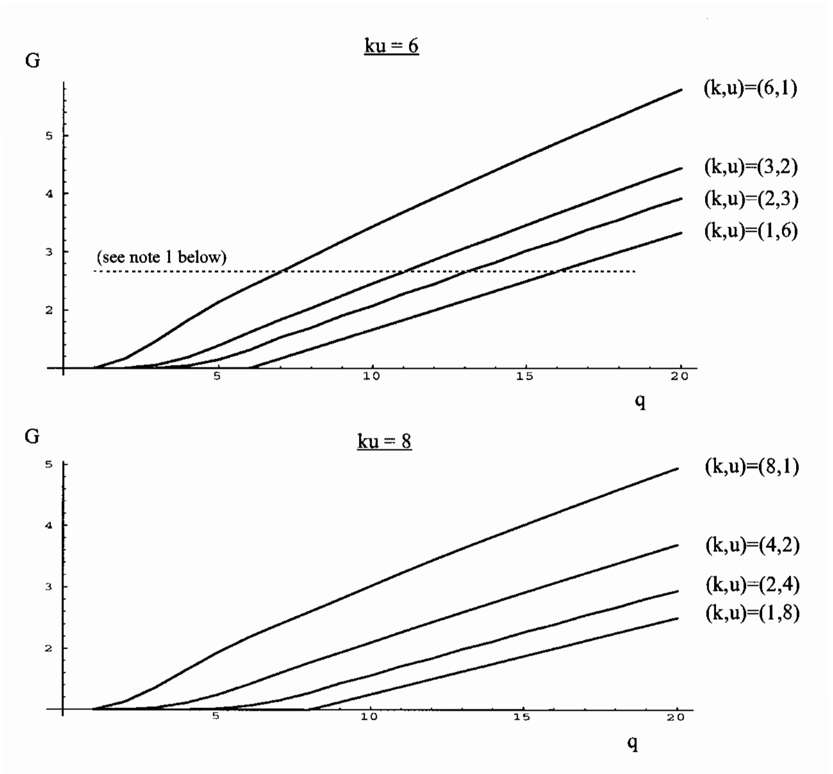

FIG. 8.5. *Degree of clustering versus processor quantity.*

any two cluster allocations, generalizing the main results of the article, cannot be concluded. The worst case estimate of dynamic (u) versus dynamic (q) allocations, $G(1, u, q) = \max(q/u, 1)$, appears in the figure.

Functions giving upper and lower bounds for the diagonal limit function

$$D(w, \nu) = \lim_{k\to\infty} g(wk + \nu, k, 1, k)$$

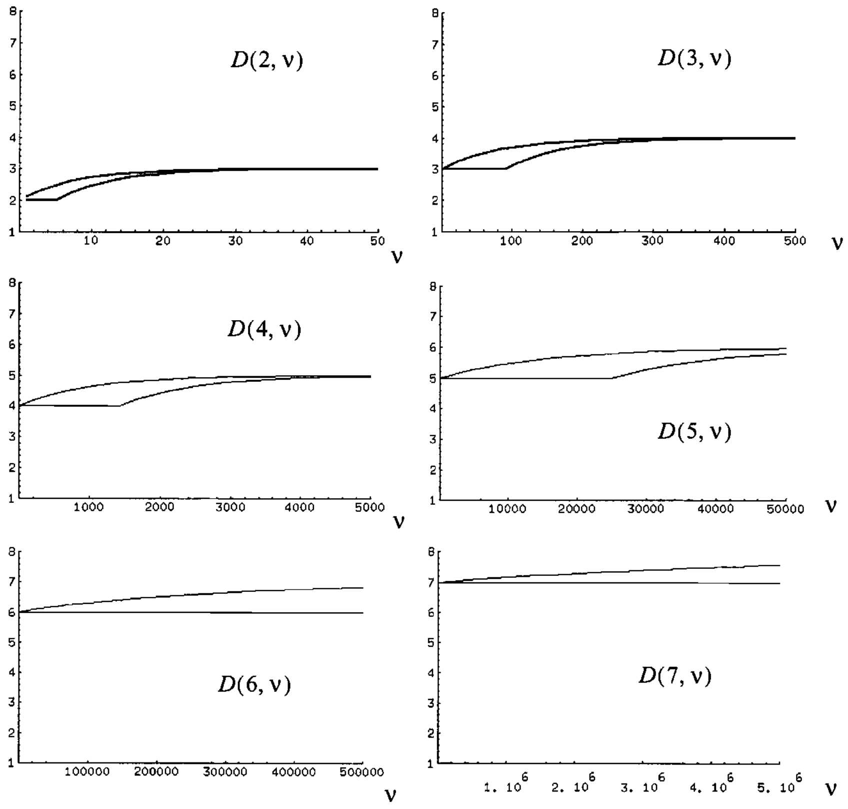

FIG. 8.6. *Bounds on diagonal limit functions.*

are plotted in Figure 8.6 given by the estimate of Theorem 6.4(2) in the case $u = \alpha = 1$:

$$\max(w, w + 1 - w(1 - w^{-w-1})^{\nu}) \leq D(w, \nu) \leq w + 1 - (1 - w^{-w-1})^{\nu}.$$

Observe the increasing scale of the ν-axis. The plots illustrate the fact that the distance from the wth plateau to the next increases very rapidly with w.

THE CREW PRAM COMPLEXITY OF MODULAR INVERSION*

JOACHIM VON ZUR GATHEN† and IGOR E. SHPARLINSKI‡

Abstract. One of the long-standing open questions in the theory of parallel computation is the parallel complexity of the integer gcd and related problems, such as modular inversion. We present a lower bound $\Omega(\log n)$ for the parallel time on a concurrent-read exclusive-write parallel random access machine (CREW PRAM) computing the inverse modulo certain n-bit integers, including all such primes. For infinitely many moduli, our lower bound matches asymptotically the known upper bound. We obtain a similar lower bound for computing a specified bit in a large power of an integer. Our main tools are certain estimates for exponential sums in finite fields.

Key words. modular inversion, parallel computation, CREW PRAM complexity, exponential sums

1. Introduction.

In this paper we address the problem of parallel computation of the inverse of integers modulo an integer M. That is, given positive integers $M \geq 3$ and $x < M$, with $\gcd(x, M) = 1$, we want to compute its modular inverse $\mathrm{inv}_M(x) \in \mathbb{N}$ defined by the conditions

$$x \cdot \mathrm{inv}_M(x) \equiv 1 \bmod M, \qquad 1 \leq \mathrm{inv}_M(x) < M. \tag{1.1}$$

Since $\mathrm{inv}_M(x) \equiv x^{\varphi(M)-1} \bmod M$, where φ is the Euler function, inversion can be considered as a special case of the more general question of modular exponentiation. Both these problems can also be considered over finite fields and other algebraic domains.

For inversion, exponentiation, and gcd, several parallel algorithms are in the literature [1, 2, 3, 9, 10, 11, 12, 13, 14, 15, 17, 19, 20, 22, 27, 29]. The question of obtaining a general parallel algorithm running in polylogarithmic time $(\log n)^{O(1)}$ for n-bit integers M is wide open [11, 12].

Some lower bounds on the depth of arithmetic circuits are known [11, 15]. On the other hand, some examples indicate that for this kind of problem the Boolean model of computation may be more powerful than the arithmetic model; see discussions of these phenomena in [9, 11, 15].

In this paper we show that the method of [5, 25] can be adapted to derive nontrivial lower bounds on Boolean concurrent-read exclusive-write parallel random access machines (CREW PRAMs). It is based on estimates of exponential sums.

Our bounds are derived from lower bounds for the *sensitivity* $\sigma(f)$ (or *critical complexity*) of a Boolean function $f(X_1, \ldots, X_n)$ with binary inputs $X_1, \ldots, X_n$. It is defined as the largest integer $m \leq n$ such that there is a binary vector $x = (x_1, \ldots, x_n)$ for which $f(x) \neq f(x^{(i)})$ for m values of $i \leq n$, where $x^{(i)}$ is the vector obtained from x by flipping its ith coordinate. In other words, $\sigma(f)$ is the maximum, over all input

vectors x, of the number of points y on the unit Hamming sphere around x with $f(y) \neq f(x)$; see, e.g., [30].

Since [4], the sensitivity has been used as an effective tool for obtaining lower bounds of the CREW PRAM complexity, i.e., the *time complexity* on a parallel random access machine with an unlimited number of all-powerful processors, where each machine can read from and write to one memory cell at each step, but where no write conflicts are allowed: each memory cell may be written into by only one processor, at each time step.

By [21], $0.5 \log_2(\sigma(f)/3)$ is a lower bound on the parallel time for computing f on such machines; see also [6, 7, 8, 30]. This yields immediately the lower bound $\Omega(\log n)$ for the OR and the AND of n input bits. It should be contrasted with the common concurrent-read concurrent-write (CRCW) PRAM, where write conflicts are allowed, provided every processor writes the same result, and where all Boolean functions can be computed in constant time (with a large number of processors).

The contents of the paper are as follows. In section 2, we prove some auxiliary results on exponential sums. We apply these in section 3 to obtain a lower bound on the sensitivity of the least bit of the inverse modulo a prime. In section 4, we use the same approach to obtain a lower bound on the sensitivity of the least bit of the inverse modulo an odd squarefree integer M. The bound is somewhat weaker, and the proof becomes more involved due to zero-divisors in the residue ring modulo M, but for some such moduli we are able to match the known upper and the new lower bounds. Namely, we obtain the lower bound $\Omega(\log n)$ on the CREW PRAM complexity of inversion modulo, an n-bit odd squarefree M with not “too many” prime divisors, and we exhibit infinite sequences of M for which this bound matches the upper bound $O(\log n)$ from [11] on the depth of P-uniform Boolean circuits for inversion modulo a “smooth” M with only “small” prime divisors; see (4.6) and (4.7). For example, the bounds coincide for moduli $M = p_1 \cdots p_s$, where $p_1, \ldots, p_s$ are any $\lceil s/\log s \rceil$ prime numbers between s^3 and $2s^3$.

We apply our method in section 5 to the following problem posed by Allan Borodin (see Open Question 7.2 of [11]): given n-bit positive integers m, x, e, compute the mth bit of x^e.

Generally speaking, a parallel lower bound $\Omega(\log n)$ for a problem with n inputs is not a big surprise. Our interest in these bounds comes from their following features:

- some of these questions have been around for over a decade;
- no similar lower bounds are known for the gcd;
- on the common CRCW PRAM, the problems can be solved in constant time;
- for some types of inputs, our bounds are asymptotically optimal;
- the powerful tools we use from the theory of finite fields might prove helpful for other problems in this area.

2. Exponential sums.

The main tool for our bounds are estimates of exponential sums. For positive integers M and z, we write $\mathbf{e}_M(z) = \exp(2\pi i z/M) \in \mathbb{C}$. Thus $\mathbf{e}_M(z_1 + z_2) = \mathbf{e}_M(z_1) + \mathbf{e}_M(z_2)$ for any z_1, z_2.

The following identity follows from the formula for a geometric sum.

LEMMA 2.1. *For any integer a,*

$$\sum_{0 \le a < M} \mathbf{e}_M(au) = \begin{cases} 0, & \textit{if } u \not\equiv 0 \bmod M, \\ M, & \textit{if } u \equiv 0 \bmod M. \end{cases}$$

LEMMA 2.2. *For positive integers M and H, we have*

$$\sum_{0\le a<M}\left|\sum_{0\le x,y<H}\mathbf{e}_M\left(a(y-x)\right)\right| = H^2+(r+1)(M-r-1),$$

where $r\equiv H-1 \bmod M$ with $0\le r<M$ is the remainder of $H-1$ modulo M.

Proof. We note that

$$\sum_{0\le x,y<H}\mathbf{e}_M\left(a(y-x)\right) = \left|\sum_{0\le x<H}\mathbf{e}_M(ax)\right|^2 > 0.$$

Thus

$$\begin{aligned}\sum_{0\le a<M}\left|\sum_{0\le x,y<H}\mathbf{e}_M\left(a(y-x)\right)\right| &= \sum_{0\le a<M}\sum_{0\le x,y<H}\mathbf{e}_M\left(a(y-x)\right)\\ &= \sum_{0\le x,y<H}\sum_{0\le a<M}\mathbf{e}_M\left(a(y-x)\right).\end{aligned}$$

From Lemma 2.1 we see that the last sum is equal to MW, where W is the number of (x,y) with $x\equiv y \bmod M$ and $0\le x,y<H$. It is easy to see that

$$W=\sum_{0\le i<M}\left(\left\lfloor\frac{H-1-i}{M}\right\rfloor+1\right)^2.$$

Let $s=r+1$ and $q=\lfloor (H-1)/M\rfloor$, thus $q=(H-s)/M$. Then,

$$\begin{aligned}W&=(r+1)(q+1)^2+(M-r-1)q^2=Mq^2+s(2q+1)\\ &=(H-s)q+2sq+s=(H+s)q+s\\ &=\frac{H^2-s^2}{M}+s=\frac{1}{M}(H^2+sM-s^2),\end{aligned}$$

and the result follows. □

Taking into account that $(r+1)(M-r-1)\le M^2/4$, we derive from Lemma 2.2 that the bound

$$\sum_{0\le a<M}\left|\sum_{0\le x,y<H}\mathbf{e}_M\left(a(y-x)\right)\right|\le H^2+M^2/4 \tag{2.1}$$

holds for any H and M.

Also, it is easy to see that for $H\le M$, we have $r=H-1$, and the identity of Lemma 2.2 takes the form

$$\sum_{0\le a<M}\left|\sum_{0\le x,y<H}\mathbf{e}_M\left(a(y-x)\right)\right| = MH, \qquad 0\le H\le M. \tag{2.2}$$

Finally, we have

$$\sum_{1\le a<M}\left|\sum_{0\le x,y<H}\mathbf{e}_M\left(a(y-x)\right)\right| = (r+1)(M-r-1)\le M^2/4. \tag{2.3}$$

Indeed, this sum is smaller by the term corresponding to $a = 0$, which equals H^2.

In what follows, we consider several sums over values of rational functions in residue rings, which may not be defined for all values. We use the symbol $\sum^*$ to express that the summation is extended over those arguments for which the rational function is well defined, so that its denominator is relatively prime to the modulus. We give an explicit definition only in the example of the following statement, which is known as the *Weil bound*; see [18, 24, 31].

LEMMA 2.3. *Let $f, g \in \mathbb{Z}[X]$ be two polynomials of degrees n, m, respectively, and p a prime number such that the rational function f/g is defined and not constant modulo p. Then*

$$\left|\sum_{0\le x<p}{}^{*}\,\mathbf{e}_p\left(f(x)/g(x)\right)\right| = \left|\sum_{\substack{0\le x<p\\ \gcd(g(x),p)=1}} \mathbf{e}_p\left(f(x)/g(x)\right)\right| \le (n+m-1)p^{1/2}.$$

Let $\omega(k)$ denote the number of distinct prime divisors of an integer k. The following statement is a combination of the Chinese remainder theorem and the Weil bound.

LEMMA 2.4. *Let $M \in \mathbb{N}$ be squarefree with $M \ge 2$, d a divisor of M, and $f, g \in \mathbb{Z}[X]$ of degrees n, m, respectively, such that the rational function f/g is defined and not constant modulo each prime divisor $p > \max\{n, m\}$ of M. Then*

$$\left|\sum_{0\le x<M}{}^{*}\,\mathbf{e}_M\left(d\,f(x)/g(x)\right)\right| \le (n+m-1)^{\omega(M)}M^{1/2}d^{1/2}.$$

Proof. In the following, p stands for a prime divisor of M. We define $M_p \in \mathbb{N}$ by the conditions

$$M_p \equiv 0 \bmod M/p, \qquad M_p \equiv 1 \bmod p, \qquad 1 \le M_p \le M.$$

Then, one easily verifies the identity

$$\sum_{0\le x<M}{}^{*}\,\mathbf{e}_M\left(d\,f(x)/g(x)\right) = \prod_{p|M}\sum_{0\le x<p}{}^{*}\,\mathbf{e}_p\left(d\,f(M_p x)/g(M_p x)\right).$$

We use the estimate of Lemma 2.3 for those p for which $p\nmid d$ and $p > \max\{n, m\}$, and estimate trivially by p the sum for each other p. Then

$$\begin{aligned}\left|\sum_{0\le x<M}{}^{*}\,\mathbf{e}_M\left(d\,f(x)/g(x)\right)\right| &\le \prod_{p\nmid d}(n+m-1)p^{1/2}\prod_{p|d}p \\ &= (n+m-1)^{\omega(M/d)}(Md)^{1/2}.\end{aligned}$$

Since $\omega(M/d) \le \omega(M)$, we obtain the desired estimate. □

LEMMA 2.5. *Let $M \ge 2$ be a squarefree integer, $f, g \in \mathbb{Z}[X]$ of degrees n, m, respectively, such that f/g is defined and neither constant nor a linear function modulo each prime divisor p of M. Then for any $N, H, d \in \mathbb{N}$ with $H \le M$ and $d|M$, we have*

$$\left|\sum_{0\le x,y<H}{}^{*}\,\mathbf{e}_M\left(d\,\frac{f(N+x-y)}{g(N+x-y)}\right)\right| \le (n+m-1)^{\omega(M)}HM^{1/2}d^{1/2}.$$

Proof. From Lemma 2.1 we obtain

$$\begin{aligned}
&\left|\sum_{0\le x,y<H}{}^{*}\,\mathbf{e}_M\left(d\,\frac{f(N+x-y)}{g(N+x-y)}\right)\right| \\
&= \left|\sum_{0\le u<M}{}^{*}\,\mathbf{e}_M\left(d\,f(u)/g(u)\right)\sum_{0\le x,y<H}\frac{1}{M}\sum_{0\le a<M}\mathbf{e}_M\left(a(u-N-x+y)\right)\right| \\
&= \frac{1}{M}\left|\sum_{0\le u<M}{}^{*}\,\mathbf{e}_M\left(d\,f(u)/g(u)\right)\sum_{0\le a<M}\sum_{0\le x,y<H}\mathbf{e}_M\left(a(u-N-x+y)\right)\right| \\
&= \frac{1}{M}\left|\sum_{0\le a<M}\mathbf{e}_M(-aN)\sum_{0\le u<M}{}^{*}\,\mathbf{e}_M\left(d\frac{f(u)}{g(u)}+au\right)\sum_{0\le x,y<H}\mathbf{e}_M\left(a(y-x)\right)\right| \\
&\le \frac{1}{M}\sum_{0\le a<M}\left|\sum_{0\le u<M}{}^{*}\,\mathbf{e}_M\left(d\frac{f(u)}{g(u)}+au\right)\right|\cdot\left|\sum_{0\le x,y<H}\mathbf{e}_M\left(a(y-x)\right)\right|.
\end{aligned}$$

From Lemma 2.4 we see that for each $a < M$ the sum over u can be estimated as

$$\left|\sum_{0\le u<M}{}^{*}\,\mathbf{e}_M\left(d\frac{f(u)}{g(u)}+au\right)\right| \le \left(\max\{n+m-1,2m\}\right)^{\omega(M)}M^{1/2}\delta^{1/2},$$

where $\delta = \gcd(d,a) \le d$. Applying the estimate (2.2), we obtain the result. ∎

The following result is the particular case $p = 2$ of Theorem 1 of [28].

LEMMA 2.6. *There exists a constant c such that for all polynomials $f = a_tX^t + \cdots + a_1X + a_0 \in \mathbb{Z}[X]$ with $\gcd(a_t,\ldots,a_1,2) = 1$ and all integers $m \ge 1$ we have*

$$\left|\sum_{0\le x<2^m}\mathbf{e}_{2^m}\left(f(x)\right)\right| \le c\cdot 2^{m(1-1/t)}.$$

For $a_0,\ldots,a_{k-1} \in \mathbb{Z}$, not all zero, we define $\mu(a_0,\ldots,a_{k-1})$ to be the largest exponent e for which 2^e divides $a_0,\ldots,a_{k-1}$.

LEMMA 2.7. *Let $a_0,\ldots,a_{k-1} \in \mathbb{Z}$ not be all zero, and*

$$b_j = \sum_{0\le i<k} a_i 2^{ij}$$

for $0 \le j < k$. Then $\mu(b_0,\ldots,b_{k-1}) \le \mu(a_0,\ldots,a_{k-1}) + (k-1)(k-2)/2$.

Proof. We extend μ to $\mathbb{Q}$ by $\mu(a/b) = \mu(a) - \mu(b)$ and to nonzero matrices in $\mathbb{Q}^{k\times k}$ by taking the minimum value at all nonzero entries. Then $\mu(U\cdot v) \ge \mu(U) + \mu(v)$ for a matrix U and a vector v such that $Uv \ne 0$.

Let $C_k = (2^{ij})_{0\le i,j<k}$. The determinant of this Vandermonde matrix has value

$$\mu(\det C_k) = \mu\left(\prod_{0\le i<j<k}(2^j-2^i)\right) = \sum_{0\le i<j<k} i = \frac{1}{6}k(k-1)(k-2).$$

We consider an entry of the adjoint $\mathrm{ad}C_k$ of C_k. Each of the summands contributing to the determinant expansion of that entry is divisible by

$$2^{(k-3)+2(k-4)+\cdots+(k-3)},$$

so that

$$\mu(\mathrm{ad}C_k) \geq \sum_{1\leq i<k-2} i\cdot(k-2-i) = \frac{1}{6}(k-1)(k-2)(k-3).$$

(In fact, we have equality, since $\det C_{k-1}$ has the right-hand side as its μ-value and is one entry of $\mathrm{ad}C_k$.) Therefore

$$\begin{aligned}\mu(C_k^{-1}) &\geq \mu(\mathrm{ad}C_k) - \mu(\det C_k)\\ &\geq \frac{1}{6}(k-1)(k-2)(k-3) - \frac{1}{6}k(k-1)(k-2)\\ &= -\frac{1}{2}(k-1)(k-2).\end{aligned}$$

Now from the inequality $\mu(a) = \mu(C_k^{-1}b) \geq \mu(C_k^{-1}) + \mu(b)$ the result follows. ◻

We also need an estimate on the number of terms in the sum of Lemma 2.5. For a polynomial $g \in \mathbb{Z}[X]$ and $M, H \in \mathbb{Z}$, we denote by $T_g(M,H)$ the number of $x \in \mathbb{Z}$ for which $0 \leq x < H$ and $\gcd(g(x), M) = 1$. The following result is, probably, not new and can be improved via more sophisticated sieve methods.

LEMMA 2.8. *Let $M > 1$ be squarefree and $g \in \mathbb{Z}[x]$ of degree m such that* $\gcd(g(x), M) = 1$ *for some $x \in \mathbb{Z}$. Then for all integers $H \leq M$, we have*

$$T_g(M,H) \geq H\prod_{p|M}\left(1 - \frac{\min\{m, p-1\}}{p}\right) - (m+1)^{\omega(M)}.$$

Proof. We denote by $\rho(M,H)$ the number of $x \in \{0,\ldots,H-1\}$ such that

$$g(x) \equiv 0 \bmod M,$$

and set $\rho(M) = \rho(M,M)$. Since M is squarefree, the inclusion–exclusion principle yields

$$T_g(M,H) = H + \sum_{1\leq k\leq\omega(M)} (-1)^k \sum_{\substack{d|M\\ \omega(d)=k}} \rho(d,H).$$

For any divisor d of M we have

$$\left|\rho(d,H) - \rho(d)\frac{H}{d}\right| \leq \rho(d) = \prod_{p|d}\rho(p).$$

Therefore,

$$\begin{aligned}T_g(M,H) &\geq H + H\sum_{1\leq k\leq\omega(M)} (-1)^k \sum_{\substack{d|M\\ \omega(d)=k}} \frac{\rho(d)}{d} - \sum_{d|M}\rho(d)\\ &= H\prod_{p|M}\left(1 - \frac{\rho(p)}{p}\right) - \prod_{p|M}\left(1+\rho(p)\right).\end{aligned}$$

By assumption, g takes a nonzero value modulo every prime divisor p of M. Thus $\rho(p) \le \min\{m, p-1\}$, and the claim follows. $\square$

Throughout this paper, $\log z$ means the logarithm of z in base 2, $\ln z$ means the natural logarithm, and

$$\operatorname{Ln} z = \begin{cases} \ln z, & \text{if } z > 1, \\ 1, & \text{if } z \le 1. \end{cases}$$

LEMMA 2.9. *For positive integers m and M, with $M > 1$ squarefree, we have*

$$\prod_{p \mid M} \left(1 - \frac{\min\{m, p-1\}}{p}\right) \ge \exp\left(-2m \operatorname{Lnln} \omega(M) - 7m\right).$$

Proof. We split the logarithm of the product as follows:

$$\ln \prod_{p \mid M} \left(1 - \frac{\min\{m, p-1\}}{p}\right) \ge \sum_{\substack{p \mid M \\ p \le 2m}} \ln\left(\frac{1}{p}\right) + \sum_{\substack{p \mid M \\ p > 2m}} \ln\left(1 - \frac{m}{p}\right); \tag{2.4}$$

and we prove a lower bound on each summand. For the first one, we use that

$$\sum_{p \le x} \ln p \le x\left(1 + \frac{1}{2\ln x}\right) \text{ for } x > 1$$

by [24, (3.15)]. Thus, for $m > 1$,

$$\sum_{\substack{p \mid M \\ p \le 2m}} \ln p \le \sum_{p \le 2m} \ln p \le 2m\left(1 + \frac{1}{2\ln 2m}\right) \le 3m. \tag{2.5}$$

It is easy to verify that for $m = 1$ the sum on the left-hand side does not exceed $3m$ as well.

For the second summand, we use that $(1 + 2\delta)(1 - \delta) = 1 + \delta(1 - 2\delta) \ge 1$ for $0 \le \delta < 1/2$, so that $\exp(2\delta) > 1 + 2\delta \ge (1 - \delta)^{-1}$ and $\ln(1 - \delta) > -2\delta$. This implies that

$$\sum_{\substack{p \mid M \\ p > 2m}} \ln\left(1 - \frac{m}{p}\right) \ge -2m \sum_{\substack{p \mid M \\ p > 2m}} \frac{1}{p}.$$

From [24, (3.20)], we know that

$$\sum_{p \le x} \frac{1}{p} \le \operatorname{Lnln} x + B + \frac{1}{\ln^2 x},$$

where $B < 0.262$ is a constant. Let $s = \omega(M)$ and p_s be the sth prime number, so that $p_s \le s^2$ for $s \ge 2$. Thus for $s \ge 2$ we have

$$\sum_{\substack{p \mid M \\ p > 2m}} \frac{1}{p} \le \sum_{p \le p_s} \frac{1}{p} \le \sum_{p \le s^2} \frac{1}{p} \le \operatorname{Lnln}(s^2) + B + (\ln s^2)^{-2} \le \operatorname{Lnln}(s) + 2. \tag{2.6}$$

The inequality between the first and last term is also valid for $s = 1$. Now (2.4), (2.5), and (2.6) imply the claim. $\square$

3. PRAM complexity of the least bit of the inverse modulo a prime number.

In this section, we prove a lower bound on the sensitivity of the Boolean function representing the least bit of the inverse modulo p, for an n-bit prime p. For $x \in \mathbb{N}$ with $\gcd(x, p) = 1$, we recall the definition of $\mathrm{inv}_p\,(x) \in \mathbb{N}$ in (1.1). Furthermore, for $x_0, \dots, x_{n-2} \in \{0, 1\}$, we let

$$\mathrm{num}(x_0, \dots, x_{n-2}) = \sum_{0 \le i \le n-2} x_i 2^i. \tag{3.1}$$

We consider Boolean functions f with $n-1$ inputs which satisfy the congruence

$$f(x_0, \dots, x_{n-2}) \equiv \mathrm{inv}_p\,(\mathrm{num}(x_0, \dots, x_{n-2})) \bmod 2 \tag{3.2}$$

for all $x_0, \dots, x_{n-2} \in \{0, 1\}$ with $(x_0, \dots, x_{n-2}) \neq (0, \dots, 0)$. Thus no condition is imposed for the value of $f(0, \dots, 0)$.

Finally we recall the sensitivity σ from the introduction.

THEOREM 3.1. *Let p be a sufficiently large n-bit prime. Suppose that a Boolean function $f(x_0, \dots, x_{n-2})$ satisfies the congruence* (3.2). *Then*

$$\sigma(f) \ge \frac{1}{6}n - \frac{1}{2}\log n - 1.$$

Proof. We let k be an integer parameter to be determined later, with $2 \le k \le n-3$, and show that $\sigma(f) \ge k$ for p large enough. For this, we prove that there is some integer z with $1 \le z \le 2^{n-k-1}$ and

$$\mathrm{inv}_p\,(2^k z) \equiv 1 \bmod 2, \qquad \mathrm{inv}_p\,(2^k z + 2^{i-1}) \equiv 0 \bmod 2 \quad \text{for } 1 \le i \le k,$$

provided that p is large enough. We note that all these $2^k z$ and $2^k z + 2^{i-1}$ are indeed invertible modulo p.

We set $e_0 = 0$, $\delta_0 = 1$, and $e_i = 2^{i-1}$, $\delta_i = 0$ for $1 \le i \le k$. Then it is sufficient to show that there exist integers $z, w_0, \dots, w_k$ with

$$\begin{gathered}(2^k z + e_i)^{-1} \equiv 2w_i + \delta_i \bmod p,\\ 1 \le z \le 2^{n-k-1}, \quad 0 \le w_i \le (p-3)/2 \quad \text{for } 0 \le i \le k.\end{gathered} \tag{3.3}$$

Next we set $A = 2^k$, $H = 2^{n-k-2}$, $K = \lfloor (p-3)/4 \rfloor$, and $\Delta_i = 2K + \delta_i$ for $0 \le i \le k$. Then it is sufficient to find integers $x, y, u_0, \dots, u_k, v_0, \dots, v_k$ satisfying

$$\begin{gathered}\left(A(H + x - y) + e_i\right)^{-1} \equiv 2(u_i - v_i) + \Delta_i \bmod p,\\ 0 \le x, y < H, \qquad 0 \le u_0, \dots, u_k, v_0, \dots, v_k < K.\end{gathered} \tag{3.4}$$

Indeed from each solution of the system (3.4) we obtain a solution of the system (3.3) by putting $z = H + x - y$ and $w_i = K + u_i - v_i$, $i = 0, \dots, k$. On the other hand, the system (3.4) contains more variables and is somewhat easier to study. A typical application of character sum estimates to systems of equations proceeds as follows. One expresses the number of solutions as a sum over $a \in \mathbb{Z}_p$, using Lemma 2.1, then isolates the term corresponding to $a = 0$, and (hopefully) finds that the remaining sum is less than the isolated term. Usually, the challenge is to verify the last part. In the task at hand, Lemma 2.1 expresses the number of solutions of (3.4) as

$$
\begin{aligned}
&p^{-(k+1)} \sum_{0\le x,y<H}{}^{*} \sum_{\substack{0\le u_0,\dots,u_k,\\ v_0,\dots,v_k<K}} \\
&\cdot \sum_{0\le a_0,\dots,a_k<p} \mathbf{e}_p\left(\sum_{0\le i\le k} a_i\left((A(H+x-y)+e_i)^{-1} - 2(u_i-v_i) - \Delta_i\right)\right)\\
&\quad = p^{-(k+1)} \sum_{0\le a_0,\dots,a_k<p} \mathbf{e}_p\left(-\sum_{0\le i\le k} a_i\Delta_i\right)\\
&\qquad \cdot \sum_{0\le x,y<H}{}^{*}\, \mathbf{e}_p\left(\sum_{0\le i\le k} a_i\,(A(H+x-y)+e_i)^{-1}\right)\\
&\qquad\quad \cdot \sum_{\substack{0\le u_0,\dots,u_k,\\ v_0,\dots,v_k<K}} \mathbf{e}_p\left(\sum_{0\le i\le k} 2a_i(v_i-u_i)\right)\\
&\quad = p^{-(k+1)}(H^2K^{2(k+1)} + R),
\end{aligned}
$$

where the first summand corresponds to $a_0 = \cdots = a_k = 0$ and R to the remaining sum; we also used (2.2). For other $k+1$ tuples $(a_0,\dots,a_k)$, the sum over x,y satisfies the conditions of Lemma 2.5, with $n=k$ and $m=k+1$; indeed, we have

$$
\sum_{0\le i\le k} a_i\,(A(H+x-y)+e_i)^{-1} = \frac{f(H+x-y)}{g(H+x-y)},
$$

where

$$
g = \prod_{0\le i\le k}(AX+e_i),\;\; f = \sum_{0\le i\le k} a_i\frac{g}{AX+e_i} \in \mathbb{Z}[X].
$$

Therefore f/g is neither constant nor linear modulo p. Thus,

$$
\begin{aligned}
|R| &\le 2(k+1)Hp^{1/2} \sum_{0\le a_0,\dots,a_k<p} \left| \sum_{\substack{0\le u_0,\dots,u_k,\\ v_0,\dots,v_k<K}} \mathbf{e}_p\left(\sum_{0\le i\le k} 2a_i(v_i-u_i)\right)\right|\\
&= 2(k+1)Hp^{1/2} \prod_{0\le i\le k}\sum_{0\le a_i<p}\left|\sum_{0\le u_i,v_i<K} \mathbf{e}_p\left(a_i(v_i-u_i)\right)\right|\\
&\le 2(k+1)Hp^{1/2}(pK)^{k+1}.
\end{aligned}
$$

We have left out the factors $|\mathbf{e}_p(-a_i\Delta_i)|$, which equal 1, transformed the summation index $2a_i$ into a_i, and used the identity (2.2).

It is sufficient to show that $H^2K^{2(k+1)}$ is larger than $|R|$, or that

$$
HK^{k+1} > 2(k+1)p^{k+3/2}. \tag{3.5}
$$

Since $K \ge (p-6)/4$, it is sufficient that

$$
2^{n-k-2} > 2(k+1)\left(\frac{p}{p-6}\right)^{k+1} p^{1/2}4^{k+1}. \tag{3.6}
$$

We now set $k = \lfloor (n - 3\log n)/6 \rfloor$, so that $6(k+1) \le n \le 2^{n-2}\ln 2 < (p-6)\ln 2$. Now $(1+z^{-1})^z < e$ for real $z > 0$, and

$$\left(\frac{p}{p-6}\right)^{k+1} < e^{6(k+1)/(p-6)} < 2.$$

Furthermore, $p^{1/2} < 2^{n/2}$ and $32n/3 < n^{3/2}$, and (3.6) follows from

$$2^{n/2} > 2^{n/2} \cdot \frac{32}{3} n \cdot 2^{-\frac{3}{2}\log n} = 64 \cdot \frac{n}{6} \cdot 2^{n/2 - \frac{3}{2}\log n} \ge 64(k+1) \cdot 2^{3k}.$$

Hence the inequality (3.5) holds, and we obtain $\sigma(f) \ge k \ge n/6 - 0.5\log n - 1$. □

From [21] we know that the CREW PRAM complexity of any Boolean function f is at least $0.5\log(\sigma(f)/3)$, and we have the following consequence.

COROLLARY 3.2. *Any CREW PRAM computing the least bit of the inverse modulo a sufficiently large n-bit prime needs at least* $0.5\log n - 3$ *steps.*

4. PRAM complexity of inversion modulo an odd squarefree integer.

In this section, we prove a lower bound on the PRAM complexity of finding the least bit of the inverse modulo an odd squarefree integer.

To avoid complications with gcd computations, we make the following (generous) definition. Let M be an odd squarefree n-bit integer and f a Boolean function with n inputs. Then f *computes the least bit of the inverse modulo M* if and only if

$$\mathrm{inv}_M\,(\mathrm{num}(x)) \equiv f(x) \bmod 2$$

for all $x \in \{0,1\}^{n-1}$ with $\gcd(\mathrm{num}(x), M) = 1$, where $\mathrm{num}(x)$ is the nonnegative integer with binary representation x, similar to (3.1). Thus no condition is imposed for integers $x \ge 2^n$ or for integers that have a nontrivial common factor with M.

THEOREM 4.1. *Let $M > 2$ be an odd squarefree integer with $\omega(M)$ distinct prime divisors, and f the Boolean function representing the least bit of the inverse modulo M, as above. Then*

$$\sigma(f) \ge \frac{\ln M - 2\omega(M)\mathrm{Lnln}\, M}{4\mathrm{Lnln}\,\omega(M) + O(1)}.$$

Proof. We let $n = \lfloor \log_2 M \rfloor$ and k be an integer parameter to be determined later. We want to show that there is some integer z with $1 \le z \le 2^{n-k-1}$ for which

$$\mathrm{inv}_M\,(2^k z) \equiv 1 \bmod 2, \qquad \mathrm{inv}_M\,(2^k z + 2^{i-1}) \equiv 0 \bmod 2 \quad \text{for } 1 \le i \le k.$$

As in the proof of Theorem 3.1, we see that in this case $\sigma(f) \ge k$.

We put $e_0 = 0$, $\delta_0 = 1$, and $e_i = 2^{i-1}$, $\delta_i = 0$ for $1 \le i \le k$. It is sufficient to show that there exist integers $z, w_0, \ldots, w_k$ such that

$$\begin{gathered}(2^k z + e_i)^{-1} \equiv 2w_i + \delta_i \bmod M,\\ 1 \le z \le 2^{n-k-1}, \quad 0 \le w_i \le (M-3)/2 \quad \text{for } 0 \le i \le k.\end{gathered}$$

Next, we set $A = 2^k$, $H = 2^{n-k-2}$, $K = \lfloor (M-3)/4 \rfloor$, and $\Delta_i = 2K + \delta_i$ for $0 \le i < k$. As in the proof of Theorem 3.1 we see that it is sufficient to find integers $x, y, u_0, \ldots, u_k, v_0, \ldots, v_k$ satisfying the following conditions for $0 \le i \le k$:

$$\begin{gathered}(A(H + x - y) + e_i)^{-1} \equiv 2(u_i - v_i) + \Delta_i \bmod M,\\ 0 \le x, y < H, \qquad 0 \le u_0, \ldots, u_k, v_0, \ldots, v_k < K.\end{gathered}$$

Lemma 2.1 expresses the number of solutions as

$$\begin{aligned}
&M^{-(k+1)} \sum_{0\le x,y<H}{}^{*} \sum_{\substack{0\le u_0,\dots,u_k,\\ v_0,\dots,v_k<K}} \\
&\quad\cdot \sum_{0\le a_0,\dots,a_k<M} \mathbf{e}_M\left(\sum_{0\le i\le k} a_i\left(\left(A(H+x-y)+e_i\right)^{-1} - 2(u_i-v_i) - \Delta_i\right)\right)\\
&= M^{-(k+1)} \sum_{0\le a_0,\dots,a_k<M} \mathbf{e}_M\left(-\sum_{0\le i\le k} a_i\Delta_i\right)\\
&\quad\cdot \sum_{0\le x,y<H}{}^{*}\, \mathbf{e}_M\left(\sum_{0\le i\le k} a_i\left(A(H+x-y)+e_i\right)^{-1}\right)\\
&\quad\cdot \sum_{\substack{0\le u_0,\dots,u_k,\\ v_0,\dots,v_k<K}} \mathbf{e}_M\left(2\sum_{0\le i\le k} a_i(v_i-u_i)\right)\\
&= M^{-(k+1)} \sum_{d\mid M} S_d,
\end{aligned}$$

where S_d is the subsum over those $0\le a_0,\dots,a_k<M$ for which

$$\gcd(a_0,\dots,a_k,M)=d.$$

It is sufficient to show that

$$S_M > \sum_{\substack{d\mid M\\ d<M}} |S_d|. \tag{4.1}$$

First we note that S_M consists of only one summand corresponding to $a_0=\cdots=a_k=0$. Since all values to be added equal 1, we only have to estimate the number of terms for which the argument of $\sum^*$ is defined. For each y with $0\le y<H$, we apply Lemma 2.8 to the polynomial

$$g=\prod_{0\le i\le k}\left(A(H+X-y)+e_i\right)\in\mathbb{Z}[X]$$

of degree $k+1$. We set $s=\omega(M)$, and using Lemmas 2.8 and 2.9, we deduce that

$$S_M \ge H\Big(H\exp\left(-2(k+1)\mathrm{Lnln}\, s - 7(k+1)\right) - (k+2)^s\Big)K^{2(k+1)}. \tag{4.2}$$

The other $|S_d|$ are bounded from above by

$$\begin{aligned}
|S_d| \le &\sum_{\substack{0\le a_0,\dots,a_k<M\\ \gcd(a_0,\dots,a_k,M)=d}} \left|\sum_{0\le x,y<H}{}^{*}\, \mathbf{e}_M\left(\sum_{0\le i\le k} a_i\left(A(H+x-y)+e_i\right)^{-1}\right)\right|\\
&\cdot\left|\sum_{\substack{0\le u_0,\dots,u_k,\\ v_0,\dots,v_k<K}} \mathbf{e}_M\left(2\sum_{0\le i\le k} a_i(v_i-u_i)\right)\right|.
\end{aligned}$$

Now let $d = \gcd(a_0, \dots, a_k, M)$ and

$$g = \prod_{0 \le i \le k} (AX + e_i), \quad f = \sum_{0 \le i \le k} \frac{a_i}{d} \frac{g}{AX + e_i} \in \mathbb{Z}[X].$$

Then

$$\sum_{0 \le i \le k} \frac{a_i}{d} \left(A(H + x - y) + e_i\right)^{-1} = \frac{f(H + x - y)}{g(H + x - y)},$$

and f/g is neither constant nor linear modulo any prime divisor $p \ge k+1$ of M. Thus we can apply Lemma 2.5 and find that

$$\left| \sum_{0 \le x, y < H}{}^{*} \mathbf{e}_M \left(d \sum_{0 \le i \le k} a_i/d \left(A(H + x - y) + e_i\right)^{-1} \right) \right| \le (2k+2)^s H M^{1/2} d^{1/2};$$

the hypothesis of the lemma is satisfied because M is squarefree. If $d < M$, then $a_i = db_i$ for some $0 \le b_0, \dots, b_k < M/d$, with at least one $b_i \ne 0$. Then

$$\begin{aligned}
&\sum_{\substack{0 \le a_0, \dots, a_k < M \\ \gcd(a_0, \dots, a_k, M) = d}} \left| \sum_{\substack{0 \le u_0, \dots, u_k, \\ v_0, \dots, v_k < K}} \mathbf{e}_{M/d} \left(\sum_{0 \le i \le k} 2a_i(v_i - u_i) \right) \right| \\
&\le (k+1) \sum_{\substack{1 \le b_0 < M/d \\ 0 \le b_1, \dots, b_k < M/d}} \left| \sum_{\substack{0 \le u_0, \dots, u_k, \\ v_0, \dots, v_k < K}} \mathbf{e}_{M/d} \left(\sum_{0 \le i \le k} 2b_i(v_i - u_i) \right) \right| \\
&= (k+1) \sum_{1 \le b_0 < M/d} \left| \sum_{0 \le u_0, v_0 < K} \mathbf{e}_{M/d} \left(2b_0(v_0 - u_0)\right) \right| \\
&\quad \cdot \prod_{1 \le i \le k} \sum_{0 \le b_i < M/d} \left| \sum_{0 \le u_i, v_i < K} \mathbf{e}_{M/d} \left(2b_i(v_i - u_i)\right) \right|.
\end{aligned}$$

Since M/d is odd, we may replace the summation index $2b_i$ by b_i. From the inequalities (2.3) and (2.1) we find

$$\sum_{1 \le b_0 < M/d} \left| \sum_{0 \le u_0, v_0 < K} \mathbf{e}_{M/d} \left(b_0(v_0 - u_0)\right) \right| \le \frac{M^2}{4d^2},$$

$$\sum_{0 \le b_i < M/d} \left| \sum_{0 \le u_i, v_i < K} \mathbf{e}_{M/d} \left(b_i(v_i - u_i)\right) \right| \le K^2 + \frac{M^2}{4d^2} \le \frac{5}{16} M^2 \le M^2.$$

Combining these inequalities, we obtain

$$|S_d| \le (k+1)(2k+2)^s H M^{2k+5/2} d^{-3/2};$$

therefore

$$\sum_{\substack{d|M\\ d<M}} |S_d| \le (k+1)(2k+2)^s H M^{2k+5/2} \sum_{d|M} d^{-3/2}$$
$$< \zeta(3/2)(k+1)^{s+1}2^s H M^{2k+5/2},$$

where

$$\zeta(3/2) = \sum_{h\ge 1} h^{-3/2} = 2.61\ldots.$$

Using (4.1) and (4.2) it is now sufficient to prove that

$$H\Big(H\exp\left(-2(k+1)\mathrm{Lnln}\, s - 7(k+1)\right) - (k+2)^s\Big)K^{2(k+1)}$$
$$> \zeta(3/2)(k+1)^{s+1}2^s H M^{2k+5/2}$$

for some

$$k \ge \frac{\ln M - 2s\mathrm{Lnln}\, M}{4\mathrm{Lnln}\, s + O(1)}. \tag{4.3}$$

To do so we suppose that

$$\begin{aligned}&\left(H\exp\left(-2(k+1)\mathrm{Lnln}\, s - 7(k+1)\right) - (k+2)^s\right)K^{2(k+1)}\\ &\le \zeta(3/2)(k+1)^{s+1}2^s M^{2k+5/2}\end{aligned} \tag{4.4}$$

and will show that k satisfies the opposite inequality. Obviously, we may assume that

$$k \le 0.5\ln M - 1.$$

We also recall that $K \ge (M-6)/4$ and $H = 2^{n-k-2} \ge M2^{-k-3}$. Now if

$$(k+2)^s \le 0.5H\exp\left(-2(k+1)\mathrm{Lnln}\, s - 7(k+1)\right),$$

then, because $s \le \log_2 M$, we immediately obtain (4.3). Otherwise, we derive from (4.4) that

$$\exp\left(-2(k+1)\mathrm{Lnln}\, s + O(k)\right) \le (2k+2)^s M^{-1/2} \le M^{-1/2}\exp(s\mathrm{Lnln}\, M).$$

Comparing this inequality with the inequality (4.3), we are able to obtain the desired statement. □

Our bound takes the form

$$\sigma(f) = \Omega(n/\mathrm{Lnln}\, n) \tag{4.5}$$

for an odd squarefree n-bit M with $\omega(M) \le \beta\ln M/\mathrm{Lnln}\, M$ for some constant $\beta < 0.5$. We recall that $\omega(M) \le (1+o(1))\ln M/\mathrm{Lnln}\, M$ for any $M > 1$, and that $\omega(M) = O(\mathrm{Lnln}\, M)$ for almost all odd squarefree numbers M.

We denote by $i_{\mathrm{PRAM}}(M)$ and $i_{\mathrm{BC}}(M)$ the CREW PRAM complexity and the Boolean circuit complexity, respectively, of inversion modulo M. We know from [11, 20] that

$$i_{\mathrm{PRAM}}(M) \le i_{\mathrm{BC}}(M) = O(n) \tag{4.6}$$

for any n-bit integer M. The *smoothness* $\gamma(M)$ of an integer M is defined as its largest prime divisor, and M is b-smooth if and only if $\gamma(M) \le b$. Then

$$i_{\mathrm{PRAM}}(M) \le i_{\mathrm{BC}}(M) = O(\log(n\gamma(M))). \tag{4.7}$$

Since we are mainly interested in lower bounds in this paper, we do not discuss the issue of uniformity.

COROLLARY 4.2.

$$i_{\mathrm{BC}}(M) \ge i_{\mathrm{PRAM}}(M) \ge (0.5 + o(1)) \log n \tag{4.8}$$

for any odd squarefree n-bit integer M with $\omega(M) \le 0.49 \ln M/\mathrm{Lnln}\, M$.

THEOREM 4.3. *There is an infinite sequence of moduli M such that the CREW PRAM complexity and the Boolean circuit complexity of computing the least bit of the inverse modulo M are both $\Theta(\log n)$, where n is the bit length of M.*

Proof. We construct infinitely many odd squarefree integers M with $\omega(M) \le 0.34 \ln M/\mathrm{Lnln}\, M$, thus satisfying the lower bound (4.8); and with smoothness $\gamma(M) = O(\log^3 M)$, thus satisfying the upper bound $O(\ln\ln M) = O(\log n)$ of [11] on the depth of Boolean circuits for inversion modulo such M.

For each integer $s > 1$ we select $\lfloor s/\ln s \rfloor$ primes between s^3 and $2s^3$ and let M be the product of these primes. Then, $M \ge s^{3s/\ln s} = \exp(3s)$, and thus $\omega(M) \le s/\ln s \le 0.34 \ln M/\ln\ln M$, provided that s is large enough. ∎

5. Complexity of one bit of an integer power.

For nonnegative integers u and m, we let $\mathrm{Bt}_m(u)$ be the mth lower bit of u, i.e., $\mathrm{Bt}_m(u) = u_m$ if $u = \sum_{i\ge 0} u_i 2^i$ with each $u_i \in \{0,1\}$. If $u < 2^m$, then $\mathrm{Bt}_m(u) = 0$.

In this section, we obtain a lower bound on the CREW PRAM complexity of computing $\mathrm{Bt}_m(x^e)$. For small m, this function is simple; for example, $\mathrm{Bt}_0(x^e) = \mathrm{Bt}_0(x)$ can be computed in one step. However, we show that for larger m this is not the case, and the PRAM complexity is $\Omega(\log n)$ for n-bit data.

Exponential sums modulo M are easiest to use when M is a prime, as in section 3. In section 4 we had the more difficult case of a squarefree M, and now we have the extreme case $M = 2^m$.

THEOREM 5.1. *Let m and n be positive integers with $n \ge m + m^{1/2}$, and let f be the Boolean function with $2n$ inputs and*

$$f(x_0, \ldots, x_{n-1}, e_0, \ldots, e_{n-1}) = \mathrm{Bt}_{m-1}(x^e),$$

where $x = \mathrm{num}(x_0, \ldots, x_{n-1})$ and $e = \mathrm{num}(e_0, \ldots, e_{n-1})$; see (3.1). *Then*

$$\sigma(f) \ge \gamma m^{1/2} + O(m^{1/3}),$$

where $\gamma = 3 - 7^{1/2} = 0.3542\ldots$.

Proof. We set $e = \lceil m^{1/2} \rceil$ and consider $g(x) = f(x, e)$, so that $\sigma(f) \ge \sigma(g)$. Furthermore, k is an integer parameter with $e \ge k \ge 2$ to be determined later.

To prove that $\sigma(g) \ge k$, it is sufficient to show that there exists an integer x with $0 \le x < 2^{n-e}$, $\mathrm{Bt}_{m-1}((2^e x)^e) = 0$, and $\mathrm{Bt}_{m-1}\left((2^e x + 2^i)^e\right) = 1$ for $0 \le i < k$.

The first equality holds for any such x because $e^2 \ge m$, and thus the conditions are equivalent to the existence of integers $x, u_0, \ldots, u_{k-1}$ such that

$$\begin{gathered}(2^e x + 2^i)^e \equiv 2^{m-1} + u_i \bmod 2^m, \\ 0 \le x < 2^{n-e}, \qquad 0 \le u_0, \ldots, u_{k-1} < 2^{m-1} \quad \text{for } 0 \le i < k,\end{gathered}$$

which is implied by the existence of $x, u_0 \ldots, u_{k-1}, v_0, \ldots, v_{k-1}$ with

$$\begin{gathered}(2^e x + 2^i)^e \equiv 2^{m-1} + 2^{m-2} + u_i - v_i \bmod 2^m, \\ 0 \le x < 2^{n-e}, \qquad 0 \le u_i, v_i < 2^{m-2} \quad \text{for } 0 \le i < k.\end{gathered} \tag{5.1}$$

We set $H = 2^{m-2}$ and $K = 2^{m-1} + 2^{m-2}$.

Lemma 2.1 expresses the number of solutions of (5.1) as

$$\begin{aligned}
&2^{-mk} \sum_{0 \le x < 2^{n-e}} \sum_{\substack{0 \le u_0, \ldots, u_{k-1} \\ v_0, \ldots, v_{k-1} < H}} \\
&\quad \cdot \sum_{0 \le a_0, \ldots, a_{k-1} < 2^m} \mathbf{e}_{2^m}\left(\sum_{0 \le i < k} a_i \left((2^e x + 2^i)^e - (K + u_i - v_i) \right) \right) \\
&= 2^{-mk} \sum_{0 \le a_0, \ldots, a_{k-1} < 2^m} \mathbf{e}_{2^m}(-K \sum_{0 \le i < k} a_i) \sum_{0 \le x < 2^{n-e}} \mathbf{e}_{2^m}\left(\sum_{0 \le i < k} a_i (2^e x + 2^i)^e \right) \\
&\quad \cdot \sum_{\substack{0 \le u_0, \ldots, u_{k-1}, \\ v_0, \ldots, v_{k-1} < H}} \mathbf{e}_{2^m}(\sum_{0 \le i < k} a_i (v_i - u_i)) \\
&= 2^{-mk} \sum_{0 \le \delta \le m} S_\delta,
\end{aligned}$$

where S_δ is the subsum over all integers $0 \le a_0, \ldots, a_{k-1} < 2^m$ with

$$\gcd(a_0, \ldots, a_{k-1}, 2^m) = 2^\delta.$$

It is sufficient to show that

$$S_m > \sum_{0 \le \delta < m} |S_\delta|. \tag{5.2}$$

S_m contains only one summand, for $a_0 = \cdots = a_{k-1} = 0$, and equals

$$S_m = 2^{n-e} H^{2k} = 2^{n+2mk-4k-e}. \tag{5.3}$$

Using the function μ from section 2, we have for $\delta < m$ that

$$\begin{aligned}
|S_\delta| \le \sum_{\substack{0 \le a_0, \ldots, a_{k-1} < 2^m \\ \mu(a_0, \ldots, a_{k-1}) = \delta}} &\left| \sum_{0 \le x < 2^{n-e}} \mathbf{e}_{2^m}\left(\sum_{0 \le i < k} a_i (2^e x + 2^i)^e \right) \right| \\
&\cdot \left| \sum_{\substack{0 \le u_0, \ldots, u_{k-1}, \\ v_0, \ldots, v_{k-1} < H}} \mathbf{e}_{2^m}\left(\sum_{0 \le i < k} a_i (v_i - u_i) \right) \right|.
\end{aligned}$$

Now let $a_0, \ldots, a_{k-1} < 2^m$. We set

$$h(X) = \sum_{0 \le i < k} a_i (2^e X + 2^i)^e = \sum_{0 \le j \le e} A_j X^j \in \mathbb{Z}[X], \tag{5.4}$$

so that

$$A_j = 2^{ej}\binom{e}{j}\sum_{0\le i<k} a_i 2^{i(e-j)} \qquad \text{for } 0 \le j \le e.$$

We put

$$\Delta = \mu(A_1, \ldots, A_e).$$

If $\Delta < m$, then h is periodic modulo 2^m with period $2^{m-\Delta}$:

$$h(X + 2^{m-\Delta}) \equiv h(X) \bmod 2^m.$$

Since $n - e \ge m$ and $\mathbf{e}_M(z)$ is periodic with period M, then

$$\begin{aligned}(5.5)\qquad & \left|\sum_{0\le x<2^{n-e}} \mathbf{e}_{2^m}\left(\textstyle\sum_{0\le i<k} a_i(2^e x + 2^i)^e\right)\right| \\ &= 2^{n-e-m+\Delta}\left|\sum_{0\le x<2^{m-\Delta}} \mathbf{e}_{2^{m-\Delta}}\left(2^{-\Delta}h(x)\right)\right| \\ &\le 2^{n-e-m+\Delta}\cdot c\cdot 2^{m-\Delta-(m-\Delta)/e} = c\cdot 2^{n-e-(m-\Delta)/e},\end{aligned}$$

where c is the constant from Lemma 2.6. This bound also holds for $\Delta \ge m$, because the sum contains 2^{n-e} terms with absolute value 1. Using the (crude) estimate

$$\mu\left(\binom{e}{j}\right) \le \log_2\binom{e}{j} \le \log_2 2^e \le e,$$

and noting that

$$A_{k-j} = 2^{e(k-j)}\binom{e}{k-j}\sum_{0\le i<k}\left(a_i 2^{i(e-k)}\right)2^{ij},$$

from Lemma 2.7 we derive that for tuples with $\mu(a_0, \ldots, a_{k-1}) = \delta$,

$$\begin{aligned}\Delta \le \mu(A_1, \ldots, A_k) &\le ek + e + \delta + (k-1)(e-k) + (k-1)(k-2)/2 \\ &= 2ek + \delta - (k-1)(k+2)/2 \le 2ek + \delta - k^2/2,\end{aligned}$$

provided that $k \ge 2$. Substituting this bound in (5.5), we obtain

$$|S_\delta| \le c\cdot 2^{n-e-(m-2ek-\delta+k^2/2)/e}T_\delta = c\cdot 2^{n-e-m/e+\delta/e+2k-k^2/2e}T_\delta,$$

where

$$T_\delta = \sum_{\substack{0\le a_0,\ldots,a_{k-1}<2^m \\ \mu(a_0,\ldots,a_k)=\delta}} \left|\sum_{\substack{0\le u_0,\ldots,u_{k-1}, \\ v_0,\ldots,v_{k-1}<H}} \mathbf{e}_{2^m}\left(\sum_{0\le i<k} a_i(v_i - u_i)\right)\right|.$$

We set

$$U_\delta = \begin{cases} 2^{2(m-\delta)} + 2^{2(m-2)} & \text{if } \delta \ge 3, \\ 2^{2m-\delta-2} & \text{if } 0 \le \delta \le 2.\end{cases}$$

Then $U_\delta \le 2^{2m-3}$ for all $\delta \ge 0$, and as in the proof of Theorem 4.1, from Lemma 2.2 we find

$$\begin{aligned} T_\delta &\le k \cdot \sum_{1 \le b_0 < 2^{m-\delta}} \sum_{0 \le b_1,\dots,b_{k-1} < 2^{m-\delta}} \left| \sum_{\substack{0 \le u_0,\dots,u_{k-1},\\ v_0,\dots,v_{k-1} < H}} \mathbf{e}_{2^{m-\delta}} \left(\sum_{0 \le i < k} b_i(v_i - u_i) \right) \right| \\ &\le k \cdot 2^{2(m-\delta)} U_\delta^{k-1} \le k \cdot 2^{2mk-3k-2\delta+3}. \end{aligned}$$

Next, we obtain

$$\begin{aligned} \sum_{0 \le \delta < m} |S_\delta| &\le c \cdot \sum_{0 \le \delta < m} 2^{n-e-m/e+\delta/e+2k-k^2/2e} \cdot k \cdot 2^{2mk-3k-2\delta+3} \\ &= ck \cdot 2^{n+2mk-k-e-m/e-k^2/2e+3} \sum_{0 \le \delta < m} 2^{-\delta(2-1/e)} \\ &< ck \cdot 2^{n+2mk-k-e-m/e-k^2/2e+4}. \end{aligned}$$

We set

$$k = \left\lfloor \gamma m^{1/2} - m^{1/3} \right\rfloor,$$

where $\gamma = 3 - 7^{1/2} = 0.3542\dots$ satisfies $-\gamma - 1 - \gamma^2/2 = -4\gamma$. It easy to verify that the inequality (5.2) holds for this choice of k, provided that m is large enough. ☐

COROLLARY 5.2. *Let $n \ge m + m^{1/2}$. The CREW PRAM complexity of finding the mth bit of an n-bit power of an n-bit integer is at least $0.25 \log m - o(\log m)$. In particular, for $m = \lceil n/2 \rceil$ it is $\Omega(\log n)$.*

6. Conclusion and open problems.

Inversion in arbitrary residue rings can be considered along these lines. There are two main obstacles for obtaining similar results. Instead of the powerful Weil estimate of Lemma 2.3, only essentially weaker (and unimprovable) estimates are available [16, 26, 28]. Also, we need a good explicit estimate, while the bounds of [16, 26] contain nonspecified constants depending on the degree of the rational function in the exponential sum. The paper [28] deals with polynomials rather than with rational functions, and its generalization has not been worked out yet.

OPEN QUESTION 6.1. *Extend Theorem 4.1 to arbitrary moduli M.*

Moduli of the form $M = p^m$, where p is a small prime number, are of special interest because Hensel's lifting allows to design efficient parallel algorithms for them [2, 11, 15]. Theorem 5.1 and its proof demonstrate how to deal with such moduli and what kind of result should be expected.

Each Boolean function $f(X_1, \dots, X_n)$ can be uniquely represented as a multilinear polynomial of degree n over $\mathbb{F}_2$ of the form

$$f(X_1, \dots, X_n) = \sum_{0 \le k \le d} \sum_{1 \le i_1 < \dots < i_k \le r} A_{i_1 \dots i_k} X_{i_1} \dots X_{i_k} \in \mathbb{F}_2[X_1, \dots, X_n].$$

We define its weight as the number of nonzero coefficients in this representation. Both the weight and the degree can be considered as measures of complexity of f. In [5, 25], the same method was applied to obtain good lower bounds on these characteristics of the Boolean function f deciding whether x is a quadratic residue modulo p. However, for the Boolean functions of this paper, the same approach produces rather poor results.

OPEN QUESTION 6.2. *Obtain lower bounds on the weight and the degree of the Boolean function f of Theorem* 4.1.

It is well known that the modular inversion problem is closely related to the GCD-problem.

OPEN QUESTION 6.3. *Obtain a lower bound on the PRAM complexity of computing integers u, v such that $Mu + Nv = 1$ for given relatively prime integers $M \geq N > 1$.*

In the previous question we assume that $\gcd(N, M) = 1$ is guaranteed. Otherwise one can easily obtain the lower bound $\sigma(f) \geq \Omega(n)$ on the *sensitivity* of the Boolean function f which on input of two n-bit integers M and N, returns 1 if they are relatively prime, and 0 otherwise. Indeed, if $M = p$ is an n bit integer, then the function returns 0 for $N = p$ and 1 for all other n bit integers. That is, the PRAM complexity of this Boolean function is at least $0.5 \log n + O(1)$.

Acknowledgment. This paper was essentially written during a sabbatical visit by the second author to the University of Paderborn, and he gratefully acknowledges its hospitality and excellent working conditions.

DYNAMIC MAINTENANCE OF MAXIMA OF 2-D POINT SETS[*]

SANJIV KAPOOR[†]

Abstract. This paper describes an efficient scheme for the dynamic maintenance of the set of maxima of a 2-d set of points. Using the fact that the maxima can be stored in a staircase structure, we use a technique in which we maintain approximations to the staircase structure. We first describe how to maintain the maxima in $O(\log n)$ time per insertion and deletion when there are n insertions and deletions. $O(\log n)$ is charged per change for reporting changes to the staircase structure which stores the maxima. $O(n)$ space is used. We also show another scheme which requires a total of $O(n \log n + r)$ time when r maximal points are listed. We finally consider extensions to higher dimensions.

Key words. maximal points, dynamic maintenance, balanced trees

1. Introduction. Given a set S of points in the x-y plane, $p_i = (x_i, y_i) \in S$ is a maximal point iff it is not dominated by another point p_j, where a point p_j dominates p_i iff $x_i < x_j$ and $y_i < y_j$. The set of maximal points of S form a structure which monotonically decreases in the y direction as the x-coordinate of the points increases. Such a structure is called a staircase structure. The problem of computing the maxima occurs in a large number of applications in statistics, economics, operations research, etc. The reader is referred to the book by Preparata and Shamos for [FP] further details.

In this paper we describe an efficient data structure for the dynamic maintenance of the maxima of a point set. We maintain approximations to the maxima set in a structure called the approximate staircase structure.

For the static case it has been shown that the staircase structure can be computed in $O(n \log n)$ time, eliminating dominated points [KLP]. In the dynamic case, however, one needs to keep track of the dominated points. In this case Overmars and Van Leeuwen [OL] have designed a data structure which requires splitting and merging balanced trees when points are inserted and deleted. In their scheme $O(\log^2 n)$ operations are required for each insertion and deletion. A scheme by Willard and Lueker [WL] gives a bound of $O(\log n)$ for updates but the set of maxima is not maintained. Frederickson and Rodger [GR] and Janardan [J] have designed schemes which maintain the staircase structure of the set of maxima and allow for insertions and deletions in $O(\log n)$ and $O(\log^2 n)$ operations, respectively. These are the most asymptotically efficient schemes known. Their data structure requires $O(n)$ space. Also, Hershberger and Suri [HS] give a scheme for off-line maintenance.

We first present an improved data structure that maintains an approximate staircase structure in $O(\log n)$ time per insertion and deletion. A point can be tested

for maximality in $O(\log n)$ time in our representation. The staircase structure representing the set of maxima can be listed in linear time but $O(\log n)$ operations have to be spent on removal of every approximation present in the current semistaircase structure to be reported. Our data structure is simple and requires $O(n)$ space.

We further show that the data structure can be modified to give a total bound of $O(n \log n + m \log n + r)$ when there are n insertions, m deletions, and r maximal points are reported.

The methodology that we have presented here may also be applicable to dynamic maintenance of other geometric structures such as convex hulls, intersections of half planes, and kernels of simple polygons. Since the optimal dynamic maintenance of these geometric structures has been an open problem for some time, the solution in this paper may be of interest in terms of technique.

We also outline an extension of our scheme to higher dimensions but only for the case of insertions. Maintaining the maxima efficiently, under both deletions and insertions, in higher dimensions is a challenging problem.

2. Preliminaries and outline of the paper.

2. Preliminaries and outline of the paper. In this paper we first describe the structural changes required for maintaining the maxima under insertions and deletions. We then show how to implement the scheme in a data structure requiring $O(n)$ space.

The underlying data structure that we use for storing the points is the red-black tree [T]. We call it the maxima balanced tree. The set of points, S, are stored at the leaves of a red-black tree, which we denote by $MT(S)$, in order of increasing x-coordinate values. At each node we store the set of maxima of the subset of points stored in the subtree rooted at that node. This subset is not stored explicitly as we will see. The initial tree can be constructed in $O(n \log n)$ time easily. Note that red-black trees can be maintained in $O(\log n)$ steps at each update.

We let $ST(q)$ be the set of points in the subtree rooted at q and $MAX(q)$ the set of maxima of $ST(q)$ at node q in the tree. Furthermore, we assume that at each node the maxima are specified in a sorted order with points having decreasing y-coordinate and increasing x-coordinate. We let $M(q)$ represent this ordered set. It is known that the set $M(q)$ has a staircase structure. $Top(M(q))$ represents the point with the maximum y-coordinate in $M(q)$. We let $y(p)$ refer to the y-coordinate of point p. We use $y(TOP(M(q)))$ and $TOP(M(q))$ interchangeably when making comparisons for ease of presentation. Finally, we let $right(v)$ and $left(v)$ refer to the left and right children of an internal node v in the binary tree, $MT(S)$ storing the maxima.

The first scheme that we propose uses the fact that during insertions binary search is performed only once after which the inserted point is dominated. This fact has also been used in [GR], [J] in their data structure. We thus obtain a solution with $O(\log n)$ insertion time and $O(\log^2 n)$ deletion time. We also isolate the reason for the $O(\log^2 n)$ behavior of the scheme. We consider only *structural* changes, i.e., changes to the staircase structure. This scheme is briefly described in section 3 to motivate the final improved method.

Then, in section 4, we refine the algorithm so that both insertions and deletions can be done in $O(\log n)$ time. We do so by maintaining approximations to the staircase structure. This allows us to use only a constant number of binary searches to update the balanced tree structure storing the maxima. We describe the improvements in time complexity for making structural changes without a description of the secondary structures required to store the maxima at the nodes of the balanced binary tree.

Finally, in section 5, the secondary structures required to store the maxima are described. The space requirements are shown to be $O(n)$. In section 6 we show how to modify the scheme to list the maximal points in linear amortized time. In section 7 we consider insertions of points in d-dimensions.

3. An $O(\log n)$ insertion and $O(\log^2 n)$ deletion scheme.

In this section we describe a scheme for insertions and deletions which is suboptimal. The scheme is described without details of secondary structures which we consider in detail for the improved scheme in a later section.

The following definitions will be required.

The *staircase* structure is a sequence of points, simultaneously sorted in increasing x order and in decreasing y order, such that two adjacent points are connected by a horizontal and vertical Manhattan path.

A *stairstep* is the horizontal and vertical Manhattan path that connects two adjacent points in a staircase structure.

A point p is *located* onto a point q in $M(v), v \in MT(S)$ when $q \in M(v)$ is the point with the least y-coordinate such that $y(q) > y(p)$. The point p is also said to be located onto the stairstep formed by q.

We will use the following characterization [GR, FP].

LEMMA 1. *The maximal elements of a set of points in the plane form a staircase structure.*

We will refer to the staircase structure, comprising maximal elements of the set of points in the subtree rooted at a node v, as the staircase structure at the node. This structure is also referred to by $M(v)$.

We first consider insertions. Let p be the point to be inserted into the tree $MT(S)$ storing the set of maxima of the point set S. Since the leaves are arranged in x-sorted order a binary search gives us the leaf at which the point p is to be inserted. Let P be the path from the root to the leaf. Suppose, on the path P, we encounter a triple of nodes (u, v, w), where v is the common parent of u and w. u is the left child and is referred to by $left(v)$, and w is the right child and referred to by $right(v)$. P uses v and one of u and w.

First suppose the path P uses w. Assume that the maxima of the points in the subtree at w has been recomputed because of the insertion of the new point p. $M(v)$ has to be recomputed from $M(u)$ and $M(w)$ by a merger. The merger, in general, involves locating $Top(M(w))$ in $M(u)$ and then replacing the portion of $M(u)$ dominated by $M(w)$ by $M(w)$ itself. However when a single point, p, is inserted, $M(w)$ changes only locally. The merger operation can now be accomplished by changes to the current staircase structure instead of complete recomputation. There are a number of cases depending on the topmost point of $M'(w)$, $Top(M'(w))$, where $M'(w)$ is the updated staircase structure at w. We assume that $Top(M'(w))$ has changed. If it has not, then no change in the merged staircase structure, $M(v)$, is required.

Case R.1. $Top(M'(w))$ is above $Top(M(v))$. In this case the merger requires constant time since $M'(v)$ is actually $M'(w)$ (Figure 1(i)).

Case R.2. $Top(M'(w))$ is not above $Top(M(v))$. In this case the merger is done by first locating $Top(M'(w))$ by a binary search on $M(u)$ to obtain the first point, q, in $M(u)$ such that $y(q) > Top(M'(w))$. The portion of $M(u)$ below q is now replaced by $M'(w)$ (Figure 1(ii)). This requires $O(\log n)$ time. Note that from this node upwards to the root the topmost point of any staircase structure does not change since the inserted point is now within a staircase structure and new merger points need not be recomputed.

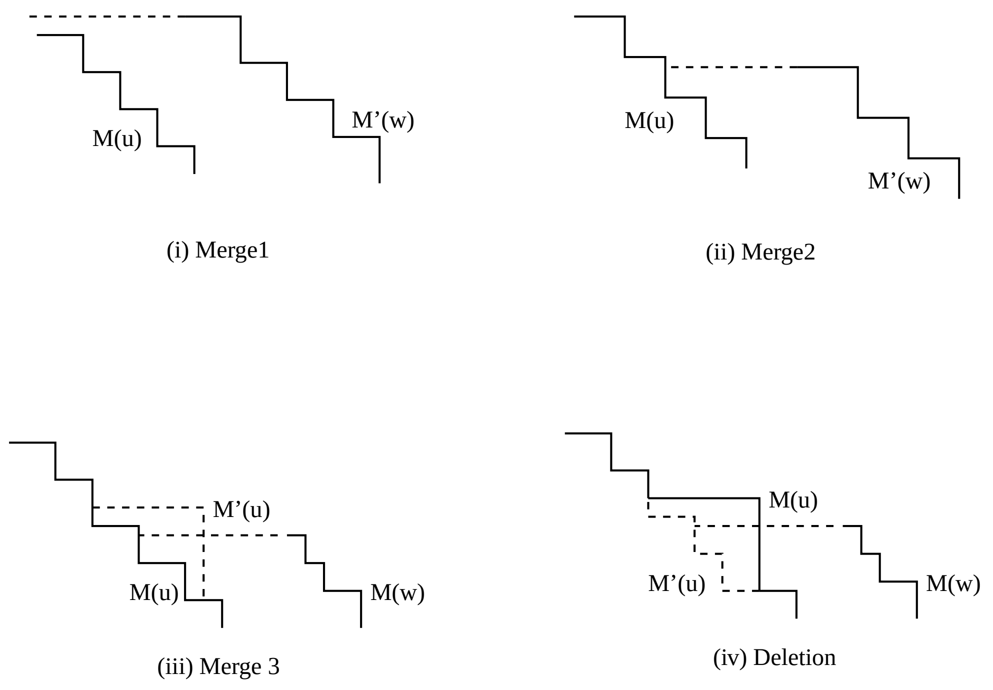

FIG. 1. *Insertion and deletion cases.*

Next consider the case when P uses u. Again, suppose $M(u)$ has been modified and let the modified structure be $M'(u)$. There are two cases:

Case L.1. $Top(M(u))$ has changed. There are two subcases. If $Top(M(w))< Top(M'(u))$, then locate $Top(M(w))$ in $M'(u)$. This is done by comparing $Top(M(w))$ with the stairstep formed by the inserted point. If $Top(M(w))$ is located below this stairstep, then the previous location of $Top(M(w))$ is valid, and $M(u)$ is updated using this merge point. Otherwise, $Top(M(w))$ is located onto the stairstep, and $M'(v)$ is obtained by adding $Top(M'(u))$ to the staircase structure $M(w)$.

Alternatively, suppose $Top(M(w)) \geq Top(M'(u))$. Then $M'(v)$ is $M(w)$.

Case L.2. The topmost point of $M(u)$ has not changed. In this case we have to determine the changes that are to be made to $M(v)$ since the top of $M(w)$ has to be positioned with respect to the changes in $M(u)$. As in the previous case this can be done in constant time since only a comparison of $Top(M(w))$ with the stairstep formed by the point inserted into $M(u)$ has to be made, provided that point is in the set of maxima (Figure 1(iii)). This information is easily maintained as we proceed up the path P.

We thus see that the above procedure requires $O(\log n)$ steps for an insertion since a binary search is performed once only in Case L.2.

We next consider the effect of deletions. Again, we consider a path P from leaf to root and a triple of nodes (u, v, w) on the path. First consider the case when the path P uses w. Suppose the maximal set has been recomputed at w and is $M'(w)$. There are two cases depending on $Top(M(w))$: Case R.1, where $Top(M(w))$ changes (this case has two subcases); and Case R.2, when $Top(M(w))$ does not change. We consider the cases.

Case R1.1. $Top(M'(w)) < Top(M(u))$. Then $M(v)$ can be computed in $O(\log n)$ time by locating $Top(M'(w))$ in $M(u)$ by a binary search.

Case R1.2. $Top(M'(w)) > Top(M(u))$. Update $Top(M(v))$ in $O(1)$ time since $M(v)$ is $M'(w)$.

Case R2. $Top(M(w))$ does not change. $M(v)$ changes exactly as $M(w)$ is changed in the portion of the staircase common to both $M(v)$ and $M(w)$. In this case the staircase structure at v need not be searched but only changed at $Top(M(w))$ to incorporate $M'(w)$.

Next consider the case when the path P uses u. $M(v)$ is obtained from $M'(u)$ and $M(w)$ by a merge operation and requires $O(\log n)$ operations (Figure 1(iv)).

Finally we consider the rebalancing operations. Rebalancing involves $O(1)$ single or double rotations. Consider single rotations. The update of $M(u)$, where u is a node with right and left child u_1 and u_2, respectively, and which participates in the rebalancing can be performed in $O(\log n)$ time since the update requires a location of $Top(M(u_1))$ in $M(u_2)$. Double rotations can be handled similarly.

From the above case description, we obtain the following theorem.

THEOREM 1. *The structural changes required to maintain the set of maxima require $O(\log n)$ steps for each insertion and $O(\log^2 n)$ steps for each deletion.*

It is the first subcase of the first case, Case R1.1, during deletions, when the path uses w and v, that creates the first problem. It gives a time bound of $O(\log^2 n)$ since the merge of $M(u)$ and $M'(w)$ requires $O(\log n)$ time, because of the search for $Top(M'(w))$ in $M(u)$, and there may be $O(\log n)$ such merges to be performed. The second problem occurs since $Top(M'(u))$ may be changed at $O(\log n)$ nodes along path P. This occurs when the path P uses u in the second case above. There may be $O(\log n)$ merges of this type requiring $O(\log n)$ operations each.

We next show how to improve the performance of the deletion operation to $O(\log n)$ per deletions also.

4. Improving the performance.

4.1. Outline. In order to improve the performance we attempt to remove the bottlenecks introduced by the repeated mergers that are required on path P when either $M'(w)$ and $M(u)$ or $M'(u)$ and $M(w)$ are merged after a deletion. This is done by performing a constant number of mergers as outlined below:

Let $Mset(P)$ be the set of nodes on the path P where the staircase structure is changed due to the deletion. Let w_i be a node on P with $left(w_i)$ its left child and $right(w_i)$ its right child. $Mset(P)$ consists of two types of nodes. One type, type 1, has the property that $Top(M(w_i)), w_i \in Mset(P)$ is changed due to the deletion. The other type, type 2, has the property that $M(right(w_i))$ is merged with $M(left(w_i))$ when $Top(right(M(w_i)))$ intersects the section of the staircase, $M(left(w_i))$, that is changed due to the deletion. Note that $|Mset(P)| = O(\log n)$. We only do two mergers requiring a binary search for each type of nodes in $Mset(P)$. One is the merger at $M(w_k)$, where w_k is the node in the binary tree such that $Top(M(w_k))$ exceeds the top, $Top(M(w_i))$, of all nodes w_i, of type 2 in the set $Mset(P)$. The other merger is due to the location of $Top(M(w_l))$, where $Top(M(w_l))$ exceeds the top, $TOP(M(w_j))$, of all nodes, w_j, of type 1. All the other mergers required are deferred. Instead, $M(right(w_i))$ is merged with $M(left(w_i))$ by joining $Top(M(right(w_i)))$ to one of the following points:

(i) The point in $M(left(w_i))$ with y-coordinate just less than that of $TOP(M(w_k))$ when w_i is a node of type 2.

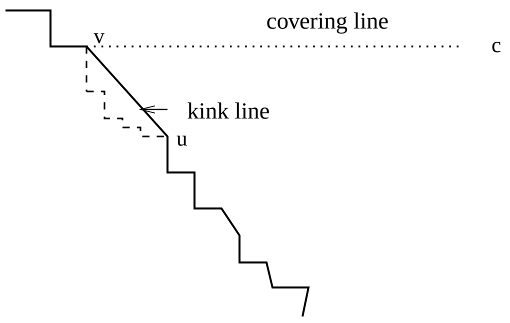

FIG. 2. *Semistaircase structure.*

(ii) $Top(M(left(w_i)))$, if $Top(M(left(w_i))) > Top(M(right(w_i)))$, when $right(w_i)$ is a node of type 1.

This destroys the staircase nature of the maximal set, creating nonhorizontal and vertical lines called "kinks," but the deletion now requires $O(\log n)$ steps.

The insertion also requires $O(\log n)$ steps. It may so happen that during insertion or deletion the top point of a set of "kinks" changes. The kinks thus shift. However, we show that there are only $O(\log n)$ kink edges to be shifted.

4.2. Detailed algorithm. First, we formally define the semistaircase structure.

DEFINITION 1. *The semistaircase structure is a sequence of points, simultaneously sorted in increasing x order and in decreasing y order, such that two adjacent points are either connected by a horizontal and vertical Manhattan path or by a straight line (called a kink line) (Figure 2).*

DEFINITION 2. *A stairstep is the horizontal and vertical Manhattan path that connects two adjacent points in a staircase or a semistaircase structure.*

DEFINITION 3. *A kink line (p, q) is an approximation to a staircase structure which connects the two points p and q with $x(p) > x(q)$ and $y(p) < y(q)$.*

DEFINITION 4. *A point p is said to be* located *onto a point q in $M(v), v \in MT(S)$ when $q \in MAX(v)$ is the point with the least y-coordinate such that $y(q) > y(p)$. The point p is also said to be located onto the stairstep formed by q.*

Note the difference in the definition of *located* with respect to the previous section.

At the nodes of the data structure $MT(S)$, we store approximations to sets of maxima. Each approximation will be a subset of the maximal elements, and at node v the approximation will be referred to by $M(v)$ for ease of notation. $M(v)$ will be represented by a semistaircase structure. The following invariant holds during the execution of the algorithm.

Property Semi. If $p \in M(v)$, then p is a maximal point in the set of points stored in the subtree rooted at V.

We next show how to dynamically maintain semistaircase structures under insertions and deletions.

4.3. Insertions. We first consider insertions. When inserting point p, let P be the path from the leaf containing p to the root. As we proceed up the path consider the triple of nodes (u, v, w) such that v is the parent of u and w.

Suppose the path P uses w. The cases are similar to the previous section and involve a binary search with $Top(M(w))$ onto a semistaircase structure. As in the previous section one location of $Top(M(w))$ in a semistaircase structure is required.

Before describing the updates we describe two generic procedures for the location of $Top(M(w))$ in $M(u)$. The procedure $LOCATE(p, z)$ locates a point p in a semistaircase at node z. And the procedure $RELOCATE(z_1, z_2)$ updates the semistaircase after locating $Top(M(z_1))$ in $M(z_2)$, where z_1 and z_2 are the right and left children of a node z.

Procedure $LOCATE(p, z)$.

The procedure is recursive. We start with node z. In the generic step, at any node a in the tree we check if the point is located in the part of the semistaircase at the left child or at the right child and we recur in the appropriate subtree. This check is done as follows: Suppose b and c are the right and left children at a and $M(b)$ is merged with $M(c)$ by a horizontal edge, h. Then the procedure branches to the left if $y(p)$ is greater than the y-coordinate of points on h; otherwise the procedure branches to the right. Alternatively, if at a there is a kink edge (r, s) merging the semistaircase at the right child with the one at the left child, then the procedure recurs to the left if $y(p) \geq y(r)$. Otherwise the procedure recurs to the right. The procedure stops at a leaf having discovered on the staircase a point with y-coordinate just greater than $y(p)$. This is the point adjacent to p in the staircase and defines the location of p. The procedure requires $O(\log n)$ steps. Also those $O(\log n)$ kink edges on the search path which intersect $y = y(p)$ are obtained. We summarize this below.

LEMMA 2. *$LOCATE(p, z)$ correctly locates point p in the semistaircase at node z in $O(\log n)$ steps.*

We next describe the second procedure.

Procedure $RELOCATE(z_1, z_2)$.

In this procedure, $Top(M(z_1))$, denoted by p', is first located in $M(z_2)$ using $LOCATE(Top(M(z_1)), z_2)$. To update the staircase structures after the location of p' is done, suppose the location of p' is q at node l. First, the stairstep joining $Top(M(z_1))$ to q is constructed, all points with the y-coordinate less than q in $M(z_2)$ are removed, and $M(z_1)$ is added to the semistaircase structure at z. Next all the kink edges intersected by $y = y(Top(M(z_1)))$ during the location procedure have their top point changed. The procedure for doing this is as follows: Let $lp(p')$ be the path followed by the location procedure for locating p'. Let d be a node on $lp(p')$ where a kink edge is used to merge $M(right(d))$ with $M(left(d))$. $Top(right(d))$ is merged using the point q', just below q, in the semistaircase $M(left(d))$, if such a point exists. Otherwise $Top(right(d))$ is located onto q. The point q' may be found as follows:

(i) Start at node l with q' being a point with y-coordinate $-\infty$.

(ii) At each node z, $z \in lp(p')$ such that $right(z) \notin lp(p')$, q' is updated as follows: If $y(Top(right(z))) > y(q')$, then $q' = Top(right(z))$.

Note that q' is defined not to exist if $y(q') = -\infty$.

The following result will be proved formally in a later section.

LEMMA 3. *$RELOCATE(z_1, z_2)$ correctly locates $TOP(M(z_1))$ in $M(z_2)$ and updates semistaircase structures in $O(\log n)$ steps.*

The above procedures are used to update the staircase structure when path $P(p)$ uses w and a location is required. The procedure called $RELOCATE(Top(M'(w)), u)$ suffices.

When path P uses u, the update after an insertion is again in constant time as described in the previous section.

Thus a point can be inserted and semistaircase structures updated in $O(\log n)$ steps.

4.4. Deletion. We consider the various cases that arise during a deletion. Again consider the triple (u, v, w). Suppose P, the path from the leaf deleted (corresponding to point q) to the root, uses w. We consider the cases depending on whether $M'(w)$ has its topmost point different from $M(w)$ or not.

Case L.1. $Top(M'(w))$ is changed, i.e., the topmost point of the previous maximal set has been deleted. In this case $Top(M'(w))$ is to be located in $M(u)$ to construct $M(v)$. There are two subcases: Either the new topmost point is the topmost point of $M(v)$ (this check can be done in $O(1)$ time); alternatively, the topmost point has to be relocated within $M(u)$ in $O(\log n)$ time. This can be achieved by the procedure $RELOCATE(w, u)$ which locates $Top(M'(w))$ in $M(u)$. However, we need to do this only when the set of maxima might be affected.

We first describe when the relocation of points in the semistaircases is necessary: Let $Wset$ be the set of nodes whose Top has changed due to the deletion of the particular node. The Top value of these nodes can be ordered by increasing y-coordinates. A relocation is done at the node, say t, with the highest Top value. Furthermore, consider a node $a, a \neq t$ and $a \in Wset$. Let b be the parent of a and c its sibling to the left. $Top(M(a))$ is not relocated but is joined to $Top(M(c))$ by a kink edge.

Case L.2. $Top(M'(w))$ has not changed. In this case , $M(u)$ changes in the section comprising points from $M'(w)$ but no new merger is required.

Next suppose the path P uses u. We assume by induction that $M'(u)$ has a semistaircase structure.

Case R.1. $M(w)$ intersects $M(u)$ at the stairstep associated with the removed point. Let $R(q)$ be the semistaircase that replaces the point q deleted. We let RP be the set of right children of nodes on the path P such that if $a \in RP$, then $Top(M(a))$ is to be located within the the stairstep associated with q and thus within $R(q)$. Let b be the node in RP such that $Top(M(b)) \geq Top(M(a)), a \in RP$. Then $Top(M(b))$ is located in $R(q)$ to give a point z which is used to form a stairstep onto which q is located, with z being the point just above $Top(M(b))$ in the semistaircase structure at the parent of b. For all $a \in RP, a \neq b$, a direct line (kink line) is drawn from $Top(M(a)), a \in RP$ to a point t in $R(q)$ where t is the point in $R(q)$ such that $y(t)$ is just less than $y(z)$ and $y(t) > Top(M(a))$. If such a t does not exist, say when $Top(M(a)) > y(t)$, then a normal staircase is constructed with z being the point next to $TOP(M(a))$ in the semistaircase structure at the parent of a. Note that this procedure involves delaying the construction of the straight lines until z is obtained. All the merges required can be done in $O(\log n)$ time (Figure 3).

Case R.2. $M(w)$ does not intersect $M(u)$ at the stairstep associated with the changed node. Then no change in the merger need be done.

The above cases complete the description of the changes required after a deletion. It is easily seen that $O(\log n)$ steps are required.

Furthermore, balancing requires $O(\log n)$ steps at each single or double rotation. Consider the case of a single rotation. Let z be a node affected by the rotation with z_1 and z_2 being the right and left child, respectively. The semistaircase structure at z is updated by locating $Top(M(z_1))$ in $M(z_2)$ using the procedure $RELOCATE(z_1, z_2)$. Since there are at most $O(1)$ nodes affected, maintenance of the semistaircase structure at a single rotation can be achieved in $O(\log n)$ steps. A similar analysis applies to the case of double rotations. Since there are at most $O(1)$ single and double rotations while balancing red-black trees, an overall bound of $O(\log n)$ on the balancing of the maxima balanced tree $MT(S)$ follows.

Note, however, that at the end of the deletion kinks may be left on the final staircase structure at the root.

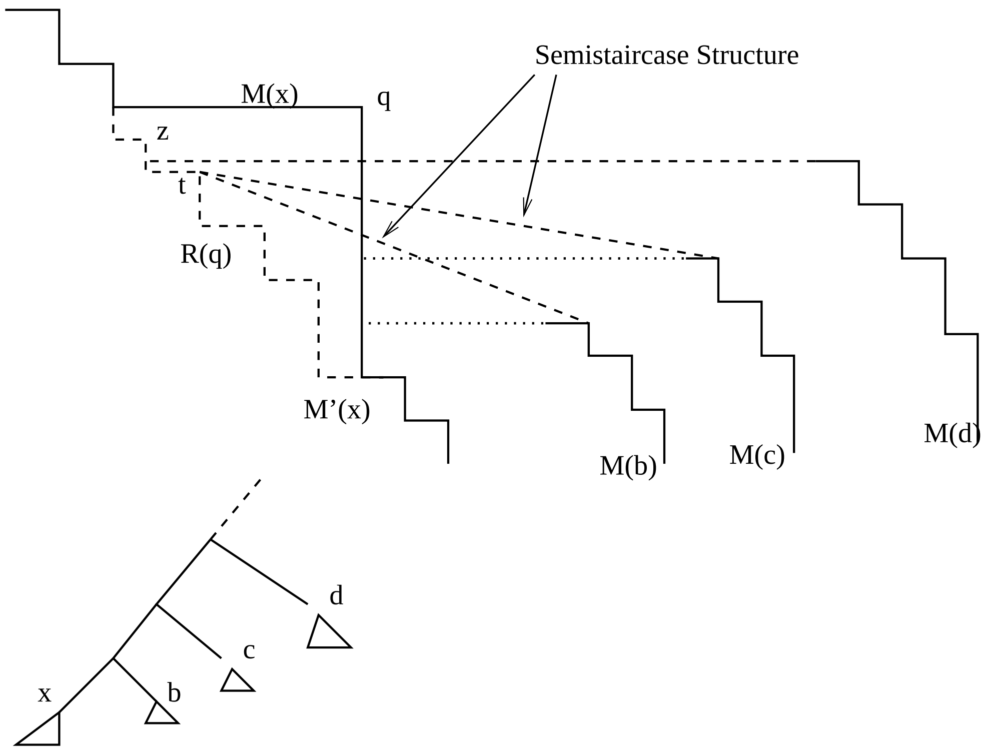

FIG. 3. *Deletion of point q.*

4.5. Correctness. We next show that the insertion and deletion procedures are correct. It suffices to show that a semistaircase is maintained at each of the nodes.

We first prove Lemma 3.

LEMMA 3. *$RELOCATE(z_1, z_2)$ correctly locates $TOP(M(z_1))$ in $M(z_2)$ and updates semistaircase structures in $O(\log n)$ steps.*

Proof. To prove the correctness first note that the $LOCATE$ procedure correctly computes the location of $p' = Top(M(z_1))$ in $M(z_2)$. Let $lp(p')$ be the set of nodes traversed during the location of p'. And let l be the node at which p' is located. We next show that kink edges intersected by $y = Top(M(z_1))$ are updated correctly. Let d be the node on $lp(p')$ where such a kink edge is present. It suffices to show that q', the point just below q in $M(left(d))$, is computed correctly. Note that q' is the point with the highest y-coordinate amongst points in $ST(d)$ located onto the stairstep formed by q. This point is a maximal point in $M(left(d))$. Consider the set of potentially maximal points in $ST(d)$ located onto the stairstep formed by q, $Mlp(d) = \{Top(M(right(z))), z \in Rlp(d)\}$, where $Rlp(d)$ is the set of nodes on $lp(p')$ lying between l and d with right children not on $lp(p')$. q' is an element of this set since for every point in $ST(d)$ located onto q there exists a point in $Mlp(d)$ with greater y-coordinate value. The set $Mlp(d)$ and thus q' is correctly computed by the procedure.

We next prove the correctness of the changes made to the semistaircase structures. Consider the path in MT, $lp(p')$, followed by $LOCATE$. The insertion procedure changes semistaircase structures on $lp(p')$ after the location of p'. We prove that semistaircases along $lp(p')$ are maintained correctly. The proof is by induction on the distance to the leaf node. The basis is easily established. Let q be the location of p'. And v be a node on $lp(p')$. Let q' be the point in $M(left(v))$ just below q. A merger is updated when the line $y = y(p')$ intersects a kink line joining $Top(right(v))$ to a point r with $y(r) > y(p')$. By induction $M(left(v))$ is a semistaircase structure. Thus all points s with $y(s) \geq y(q')$ in $M(left(v))$ are maximal in $ST(v)$. Moreover, all points in $M(right(v))$ are maximal in $ST(right(v))$. Since $Top(right(v))$ is connected to either q' or located onto q by a horizontal edge, all points in $M(v)$ are also maximal in $ST(v)$.

Finally, we bound the time complexity. First, $LOCATE$ requires $O(\log n)$ steps. Thus q is obtained in $O(\log n)$ steps. Next kink edges are changed along $lp(p')$. This requires computation of q' at each node on $lp(p')$. q' is maintained in constant time as we traverse nodes up $lp(p')$. Since there are $O(\log n)$ nodes on $lp(p')$, all the kink edge changes require $O(\log n)$ steps. □

We next prove the correctness of the insertion procedure.

LEMMA 4. *The insertion procedure maintains semistaircases, satisfying Property Semi, at each node of the maxima balanced tree.*

Proof. The proof is by induction. It is trivially true when there is only one point. Thus assume that there are n points and the data structure contains lists which are semistaircase structures.

On an insertion, let $P(p)$ be the path from the leaf containing the inserted point p to the root. Let c_p be the node at which the point p is located within a semistaircase structure. The semistaircase structures change at c_p and above and below c_p.

First, consider nodes below c_p. We prove the claim in the lemma by induction on the distance from the leaf node in $P(p)$. At a node v, $M(v)$ changes in two ways. Either $r = Top(M(right(v)))$ is located onto p or $M(v) = M(right(v))$. Since points in $M(right(v))$ are maximal in $ST(right(v))$ and since points in $M(left(v))$ with y-coordinates greater than p are maximal in $ST(v)$, points in $M(v)$ are maximal in $ST(v)$. At c_p, p is correctly located in $M(left((c_p)))$ by the procedure $RELOCATE$, as shown in Lemma 3.

Finally, consider a node, v, on $P(p)$ above c_p. The semistaircase structures at these nodes are updated when $Top(M(right(v))), v \in P(p)$ is located onto p. Again, it can be shown, by induction, that $M(v)$ contains only maximal points in $ST(v)$. □

Next consider deletions.

LEMMA 5. *The deletion procedure maintains semistaircases, satisfying Property Semi, at each node of the maxima balanced tree.*

Proof. Let p be the deleted point. Along the deletion path $P(p)$, at most two locations are done using procedure $RELOCATE$. Changes during this procedure correctly maintain the semistaircase structure as shown in Lemma 3. Let q be the point obtained on relocation and let c_p be the node at which a relocation takes place. We next consider changes along path $P(p)$ and show that these changes preserve semistaircase structures. We use induction on the distance from the leaf containing p. Consider any node $v, v \in P(p)$, which is below c_p. The semistaircase structure, $M(v)$, is changed in two ways. Either it is replaced by $M(right(v))$ or a merge is performed. This is done by either constructing a kink edge which connects $r = Top(M(right(v)))$ to a node $q', y(q') > y(r), q' \in M(left(v))$ or locating r onto q. Note that q' may be $Top(M(left(v)))$. By induction $M(left(v))$ and $M(right(v))$ are semistaircase structures. Thus $M(v)$ also comprises maximal points after the merger. Nodes above c_p on $P(p)$ are not affected during the deletion procedure. □

The arguments above, proving correctness under insertions and deletions, extend to proving that changes done during rebalancing, when relocations are performed, also correctly maintain semistaircases satisfying Property Semi.

To report the maximal elements of S, kinks in the semistaircase structure at the root of the tree MT are important since these kinks have to be removed to obtain the actual output. These kinks can be removed at the time of reporting along with other kinks that are discovered when points are located to remove kinks. This is done by the procedure $RELOCATE$ as in the case of insertions. Note that once the set of maxima is reported, no kinks remain in the staircase structure at the root. We thus define *chng* to be the number of changes in the semistaircase structure to be output as compared with the last staircase structure reported. The changes are kinks and new points added to the semistaircase structure representing the set of maxima. The time for output is now $O(m + chng. \log n)$. Note that *chng* can be $O(m)$. Details of the reporting will be discussed in the next section.

The following lemma follows from the discussion above and the insertion and deletion procedures.

LEMMA 6. *The structural changes carried out to maintain the semistaircase structures at each node of the maxima balanced tree under an insertion or deletion require $O(\log n)$ operations. Moreover, $O(\log n)$ operations are required for every change to be reported in the staircase representing the maximal set.*

4.6. Implementing the scheme in $O(n)$space.

In this section we show how to implement the scheme for insertion and deletion in $O(n)$ space. This is accomplished by maintaining $O(1)$ information at the nodes of the balanced binary search tree, MT.

First, at each node v are maintained left and right pointers, $left(v)$ and $right(v)$, to the children of the node, say u and w. We also maintain two variables $TOP(v)$ and $INTER(v)$ which contain points. $TOP(v)$ is the topmost point in the semistaircase structure at v (this point having been referred to by $Top(M(v))$ before). And $INTER(v)$ is the point at which $Top(M(w))$ is located in the semistaircase structure at u, i.e., $INTER(v)$ is the point in the staircase structure at v just above the point $TOP(w)$, in the staircase structure at v, if such a point exists. Otherwise $INTER(v)$ is $TOP(v)$. Note that $Top(M(w))$ may be attached to $INTER(v)$ by a kink edge. This can be detected by maintaining at each node a Boolean variable called $MARK$-$KINK$. In the description below the value of $INTER(v)$ for nodes where a kink line (p, q) is drawn from p to q is assumed to $y(q)$, the y-coordinate of the upper point of the kink line. To list the points more efficiently we need another variable $NextLeft$ which we detail below.

We first describe the listing procedure on the data structure without using $NextLeft$. We then show how to make the procedures more efficient using $NextLeft$.

4.7. Listing the maxima.

To list all the maxima we proceed as follows: We start at the root of the tree MT. At the root node TOP gives the leftmost point in the staircase structure. In general, to obtain points contributed by the left subtree at a node v in MT, we test if the topmost point of the right subtree, say w, is located strictly below the topmost point of the left subtree, say u. If so, then we list recursively those maximal elements in the subtree at u not yet reported and with y-coordinate greater than the y-coordinate of $TOP(w)$. We then list the maximal elements in the subtree rooted at w recursively.

This procedure is formalized as follows:

```
    Procedure $LIST1(v, stop)$.
(This procedure lists the maxima in the subtree at $v$ with
$y$-coordinate greater than or equal to $stop$. )
Begin
    If $y(TOP(v)) \geq stop$, then
    begin
        If $y(TOP(v)) = stop$ or $v$ is a leaf node, then
            output $TOP(v)$
        else
        begin
            if $y(TOP(v)) > y(TOP(right(v)))$, then
              begin
                $LIST1(left(v), \max(stop, y(TOP(right(v)))))$;
                $LIST1(right(v), stop)$
              end
            else $LIST1(right(v), stop)$
        end
    end
end.
```

The procedure $LIST1$ above is invoked at the root with *stop* being the y-coordinate of the point with the maximum x-coordinate.

LEMMA 7. *$LIST1$ correctly outputs the set of maxima of size m stored in tree MT in $O(m \log n)$ steps.*

Proof. At node v the procedure correctly outputs, in order of decreasing y-coordinate, all points in the staircase at v such that if p is to be reported, then $y(p) \geq stop$. It does so by first comparing $y(TOP(v))$ with *stop*. If $y(TOP(v)) \geq stop$, then there exist points to be reported in the staircase structure. There are two cases: If either $y(TOP(v)) = stop$ or v is a leaf node, then only the topmost point is to be reported. On the other hand, if $y(TOP(v)) > stop$, then the points to be reported are to be found in the left and right subtrees of v. Points in $M(v)$ are to be found in the left subtree iff $y(TOP(v)) > y(TOP(w))$, where $w = right(v)$. These points are output by the recursive call to the left child. Each point, p, which is to be output from the left subtree, lies on the staircase structure at v if $y(p) \geq y(TOP(right(v)))$ and $y(p) \geq stop$. Thus the recursive call to the left has $\max(stop, y(TOP(right(v))))$ as the new *stop* parameter. The remaining points are to be output from the right subtree. The parameter *stop* for the call to the right subtree is the same as the parameter *stop* at the current node, v, since all points in the staircase at the right subtree are in the staircase at v.

We next estimate the time required by $LIST1$. First note that a recursive call is made only when at least one point is to be reported. During a call, either a maximal point is reported or another recursive call is made. Furthermore, at each recursive call the procedure processes points at a node which is closer to a leaf node. In $O(\log n)$ steps a node will be reached where a point will be reported. The procedure thus requires time proportional to $O(m \log n)$, where m is the number of maximal points. ∎

To list the maximal points in linear time we make the following modification to the data structure: At each leaf node, say v, where point p is stored, we store a pointer called $NextLeft(p)$. For addressing $NextLeft$, v and p are used synonymously. $NextLeft(p)$ points to the node in the tree at which p is first located within a staircase structure. $NextLeft(p)$ is null if p is not located within any staircase structure.

Using these pointers we can recursively list the maxima as described in $LIST2(MT)$. In this procedure, $RELOCATE$ removes kinks in the staircase structure at the root node as well as other kinks along the location path in the tree MT. The time for listing the maxima is linear in addition to the time for removal of kinks.

```
    **Procedure** $LIST2(MT)$.
(This procedure lists the maxima in a tree $MT$.)
Begin
    Let $p$ be the point with maximum $x$-coordinate in the set of points in $MT$;
    $v = NextLeft(p)$;
    output($p$);
     while $v \neq$ null do
          begin
            if ($M(right(v))$ is merged with $M(left(v))$ by a kink edge), then
              RELOCATE($right(v), left(v)$) and update $NextLeft(q)$ for all $q$
              whose location is updated during the process;
            output($INTER(v)$);
            $v := NextLeft(INTER(v))$;
          end;
end.
```

Note that a kink is removed by locating $TOP(right(v))$. This requires $O(\log n)$ steps for every kink removal.

We next prove the correctness of the algorithm $LIST2(MT)$. We need the following property.

LEMMA 8. **Property Next:** *If a point, p, is maximal and p is not located by a kink edge then $INTER(NextLeft(p))$ is also maximal.*

Proof. Since p is maximal there does not exist any point with greater x and greater y-coordinate. Consider the location of p inside a staircase structure in MT. The node at which this location is performed is given by $w = NextLeft(p)$. $q = INTER(w)$ gives the point just above p in the staircase structure, $M(w)$. This point is maximal with respect to the set of points in the subtree rooted at w since it is on the staircase structure at w. Moreover, at tree nodes which are ancestors of w, there does not exist any point in the staircase structures at these nodes which has greater x-coordinate and greater y-coordinate. This is because such a point would also dominate p which is maximal and stored in the subtree rooted at w. Thus q is maximal. ☐

LEMMA 9. *LIST2(MT) correctly reports the set of maxima of S stored in MT.*

Proof. The proof is by induction on the number of maximal elements. For the base case note that the first element reported is in the set of maxima. To prove the lemma consider the report of the kth element of the set of maxima when $k-1$ elements have been reported. The kth point is reported after locating $Top(right(v))$, if necessary, where $v = NextLeft(q)$. After the location q is not located by a kink edge at v, Property Next is applicable to q and thus $INTER(v)$ is maximal. ☐

The complexity of the procedure is $O(m + chng. \log n)$ where m is the number of maxima and *chng* is bounded by the number of changes in the semistaircase structure representing the set of maxima since the last report of the maxima. Note that, at that report, no kink edges were left in the staircase structure.

It will be shown later that the pointers $NextLeft(p)$ can be maintained in $O(\log n)$ time per insertion and deletion. $NextLeft(p)$ changes only at locations of points within staircase structures and only one location is required during an insertion, deletion, or a rotation.

4.8. Searching for dominance. In this section we show how to determine if a given point, p, is dominated by the set of maxima or not. We do so by a search for the y-coordinate of the given point in the set of points with greater x-coordinates. Let P be the path from the root to the leaf where point p is stored. Let R be the set of roots of the subtrees to the right of path P. It suffices to check if $y(p) \geq y(TOP(v))$ for all $v \in R$. If it is, then the point is not dominated; otherwise it is dominated.

4.9. Insertions and deletions. To bound the time for insertions and deletions in the $O(n)$ space data structure we note that the crucial step while performing insertions and deletions is that of locating the topmost point of a semistaircase structure in another semistaircase structure. An $O(\log n)$ solution to this step has been presented above.

Moreover, the $O(1)$ rotations performed at every step can also be done in $O(\log n)$ steps since they require $O(1)$ mergers, each requiring $O(\log n)$ steps. The variables TOP and $INTER$ stored at the nodes at which relocations are performed can also be modified in $O(\log n)$ steps. Note that the value of $INTER$ is obtained by using $LOCATE$. The value of TOP is immediately available.

We would also like to update the value of $NextLeft(p)$ during the insertion, deletion, and rotation process. We describe the updated steps below.

First consider insertions. Let $P(p)$ be the insertion path in MT for point p. Let c_p be the node at which p is located within a staircase structure. $NextLeft(p)$ is defined at this point. Below that node, p is at the top of the staircase structures. For nodes below c_p on $P(p)$, $NextLeft(q)$ changes for points q which are located onto the stairstep defined by p. For each such point, say q, $NextLeft(q)$ is updated in $O(1)$ time. And $NextLeft(q)$ is made null for each point, say q, which was replaced by p as top of the staircase structures since these points are not located onto any staircase structures. Also let c_u be the node at which p is removed from the maxima set by a point that dominates it. Above this node the point p is no longer on the staircase and will not affect the value of $NextLeft(q)$ for any point q located at a node above c_u in the tree. For nodes between c_p and c_u, both included, the value of $NextLeft(q)$ changes and is updated when the point q is located onto the stairstep defined by p. Note that during the location of p a number of kink edges would have their top points changed. If a kink edge (r, s) is constructed from point r to point s, $NextLeft(r)$ is set to s. At most $O(\log n)$ such changes are made.

The modification of the $NextLeft$ pointers thus requires $O(\log n)$ steps since at most $O(\log n)$ values are changed along $P(p)$. The entire insertion procedure thus requires $O(\log n)$ steps.

A similar procedure to update $NextLeft$ values is used when a point p is deleted. Consider the path $P(p)$. During a deletion there are at most two nodes at which a relocation of a point, say q, is performed. Let the node at which a location takes place be called c_q. $NextLeft(q)$ is thus to be updated. Below node c_q, merges are performed using kink edges. Let r be the topmost point of the staircase structure which is to be merged by a kink edge. $NextLeft(r)$ is updated in $O(1)$ time. Above node c_q no changes in the location of any point occur. Note that during the relocation at node c_q, $O(\log n)$ steps are required for changes of $NextLeft$ values for points connected by new kink edges formed during the relocation procedure as already described in the case of insertions.

Finally, consider rebalancing operations. We consider single rotations only. The procedure is similar for double rotations. Let v be the node at which a rebalancing operation is performed. Consider the nodes affected by the rotation. These include v, the roots of the subtrees involved in the rotation, and the additional node created. At each of these nodes a relocation is performed and $NextLeft$ values are changed as described above. And no point, located at nodes not involved in the rotation, has its $NextLeft$ value affected. The updates require $O(\log n)$ operations.

We can thus state the following theorem.

THEOREM 2. *The maxima of a set of points S, of size n, can be maintained in a data structure which uses $O(n)$ space and which requires $O(\log n)$ operations per update when $O(n)$ points are deleted or inserted. The complexity of reporting the maxima is $O(m + chng. \log n)$ when there are m maximal points reported and chng changes in the semistaircase structure storing the maxima since the last report.*

5. An improved amortized bound. In this section we show how the maxima can be reported in linear amortized time.

To improve the reporting bound we note that the $O(\log n)$ factor in the reporting time bound essentially arises because a kink edge (p, q) repeatedly reoccurs in the changes in the semistaircase representing the maximal set, i.e., it occurs, is removed from the maxima semistaircase structure by, say, an insertion, and then reoccurs in the semistaircase structure representing the maxima after a deletion. Thus its location in the staircase is to be determined at each report. To remedy this we keep the location of p and update it whenever necessary.

Let p be a point and let v be a node in the tree where the point p first occurs within a semistaircase, i.e., is not at the top of the semistaircase at v. At this node the point has to be located within a staircase structure. This location, $LOC(p)$, is important since it may need to be redetermined during deletions. So we keep this location in a variable $SLOC(p)$. However, this location is not updated at every insertion or deletion since only the top points in any staircase are manipulated. Thus when this point is to be output, the value of $SLOC(p)$ may need to be updated. The update is necessary when the stairstep onto which the point is located is changed. If the location requires a binary search, the time for this search is charged to a point, say q, that is inserted or deleted and changes the location of p. However point q may already have been charged. This happens when a set of points are located on the stairstep with q as its corner point. Fortunately, this set of points can be ordered by domination and there is one point in this set which dominates the others. This point must be deleted before other points become maximal. A location onto a stairstep whose corner point is already charged by the location of another point, r, is charged to the deletion of this point r, an event which must occur for the current location to be computed.

We prove this formally below. We need the following definitions.

We let $P(p)$ be the path from the leaf containing p to the root and $LS(p)$ be the set of points such that for each point q, $x(q) < x(p), q \in S$.

$LOC(p)$ is the maximal point in $LS(p)$ with y-coordinate just greater than $y(p)$.

$CLOC(p) = \{q|$ such that $SLOC(q) = LOC(q)$ prior to the insertion or deletion of point p but not after $\}$. This is the set of points for which the $LOC(p)$ has changed due to insertion and deletion of p.

$MCLOC(p) = \{q|y(q) = \max_{q' \in CLOC(p)}\{y(q')\}\}$, $OTHER(p) = \{r|r \& p \in CLOC(q)$ and r is dominated by $p\}$. Note that $OTHER(p)$ is the set of points which are dominated by p and required to be located onto $R(q)$, when q is a deleted point and p is located onto q. $R(q)$ is the semistaircase structure that replaces the deleted point q at nodes on $P(q)$, the path from the leaf containing q to the root. Alternatively, $OTHER(p)$ is the set of points dominated by p which are to be located onto q at the insertion of q.

The dynamic maintenance scheme, described in the section before, is now modified so that for every point we maintain $LOC(p)$ in the variable $SLOC(p)$. This value may be precomputed initially and may be updated when the point is to be output as a maximal point. To reduce the time for relocations consider the following additional steps in the insertion and deletion procedures where certain points are marked.

Insertions. On an insertion the following additional step is done:

1. Mark $MCLOC(p)$.

Deletions. On a deletion the additional steps are the following.

1. Mark $MCLOC(p)$.
2. If $p = MCLOC(q)$, mark updated $MCLOC(q)$ obtained after deleting p.
3. Relocate maximal point op in $OTHER(p)$. Also let $OTHER(op) = OTHER(p) - \{op\}$.

Reporting. Finally, on the report, do the following step.

1. Locate all marked nodes encountered and unmark them while reporting the maximal points.

No marks are changed during rotations. The correctness of the reporting procedure is shown next.

LEMMA 10. *Let q be a maximal point which is unmarked. Then $LOC(q)$ is correctly maintained.*

Proof. The proof is by induction on the number of insertions and deletions. For the base case, the lemma is trivially true. Assume that it is true when k insertions or deletions have been made. Consider the $k+1$st operation.

Consider an insertion. Suppose $LOC(q)$ is modified due to insertion of p'. Then $q' = MCLOC(p)$ is marked. If $q \neq q'$, then q' dominates q and thus q is not maximal.

Next, consider deletions. Suppose a point q is affected. This occurs in two ways:

(i) q becomes maximal, and
(ii) $LOC(q)$ is changed.

Consider the following cases: q is already in some set $CLOC$ or not in any such set. In the first case, if $q \in OTHER(p)$, then q may become maximal and is marked. Otherwise it is in $OTHER(op)$, where op is the maximal point in $OTHER(p)$. Alternatively, $q \in CLOC(p)$ at the current deletion. Then either q is marked or some other point $q' = MCLOC(p)$ is marked. If q' dominates q, then q is not maximal but q is in $OTHER(q')$. Otherwise $x(q) > x(q')$ and thus $LOC(q) \neq p$ since q would be located onto either q' or some other point. No other point is affected by p. □

Since marking points requires maintaining sets $CLOC$ and $OTHER$, we omit the marking in our actual procedure. It suffices to simply determine if $SLOC(p) = LOC(p)$, i.e., if $LOC(p)$ is correctly maintained for a maximal point p. If not, then p is located. Let v be a node in the tree where a point p is located or to be located. To determine if $LOC(p)$ is correctly maintained we first check if $y(p) > y(TOP(v))$. If not, then $Top(v)$ is in the maximal set along with other points in $M(v)$. The points with y-coordinate greater than $y(LOC(p))$ are determined by traversing $M(v)$ in decreasing order of y-coordinate values, starting from $Top(v)$, until the last node, $q, q \in M(v)$, such that $y(q) > y(p)$ is reached. At this stage p is required to be located if either a kink edge connects p to q or if $SLOC(p)$ is not q. Let $L(M(v))$ be the list of points traversed, in order of decreasing y-coordinate values, until q is reached. $L(M(v))$ satisfies the following property.

Lemma 11. *All points in $L(M(v))$ are maximal. Furthermore, if r and s are adjacent points in $L(M(v))$ with $y(r) > y(s)$, then $LOC(s)$ is either r or is a point t such that $y(r) < y(t) < y(s)$.*

Proof. We first show that since p is maximal, all points in $M(v)$ with greater y-coordinate are also maximal. The proof is by contradiction. If not then there exists a point, say p', at a node above v in MT such that $y(p') > y(z)$ and $x(p') > x(z), z \in L(M(v))$. But p' also dominates p.

To show the second part of the lemma, consider r and s which are adjacent points in $L(M(v))$. s is connected to r by either a stairstep or by a kink edge. In the first case, $LOC(s)$ is r. In the second case, s is located in the staircase structure in between r and s. $LOC(s)$ is to be determined at $NextLeft(s)$ in the subtree rooted at $left(v)$, and thus $LOC(s)$ has y-coordinate less than that of r. $\square$

The following lemma justifies recomputation of $LOC(p)$.

Lemma 12. *If (p, q) is a kink edge or $SLOC(p) \neq q$, then p is marked.*

Proof. Suppose (p, q) is a kink edge. Then this kink edge must be due to the deletion of a point p' with x-coordinate less than $x(p)$. p is in $CLOC(p'')$ where p'' is such that $x(p'') < x(p)$. If p is not $MCLOC(p'')$, then either there exists a point that dominates p and thus p is not maximal or $p \notin CLOC(p'')$. Thus p is $MCLOC(p'')$ and is marked.

Next, consider the case when $SLOC(p) \neq q$. Since p must be located onto the stairstep formed by q, $p \in CLOC(q)$ when q is inserted or $p \in CLOC(q')$ when q' is deleted and since p is maximal, p is marked. $\square$

To traverse $M(v)$ efficiently we keep with every point p the point next to p when $M(v)$ is ordered by decreasing value of y-coordinates. This point, say $Nextdown(p)$, is located onto the stairstep formed by p in $M(u)$, $u \in P(p)$ where u is the highest node in $P(p)$ such that a point is located onto the stairstep formed by p at the nodes of the tree. Note that a point joined by a kink edge to p is also said to be located onto the stairstep formed by p. $Nextdown(p)$ is determined by keeping the following variable, $INTERLOC$, with every point p.

Definition 5. *$INTERLOC(p)$ is the node, say u, in the tree, MT, where $q = Nextdown(p)$ is located onto the stairstep formed by p in $M(u)$.*

$INTERLOC(p)$ can be computed in $O(\log n)$ steps. The sequence of points $M(v)$, starting from $TOP(v)$, can be listed using $INTERLOC$ values in linear time. Moreover $INTERLOC(p)$ can be easily maintained during insertions and deletions and rotations. The maintenance is similar to that of $NextLeft$ values.

Lemma 13. *$INTERLOC(p), p \in S$ can be maintained in $O(\log n)$ steps during insertions, deletions, and rotations.*

Proof. Consider an insertion of a point q. At most one location is performed during an insertion. Suppose q is located onto a point p. Only $INTERLOC(p)$ needs to be updated. This can be done by comparing with the current value of $INTERLOC(p)$. Moreover, during relocations kink edges are changed. Each $INTERLOC$ value affected during a relocation, say $INTERLOC(p)$, is updated by maintaining p and the highest node, denoted by $H(p)$, at which a kink edge is joined to p as the relocation path is traversed from a leaf to the root. At each step along this path only one point, q', and $H(q')$ need be maintained. This follows from the way that the relocation procedure, $RELOCATE$, modifies kink edges using the point q'. The procedure changes q' along the relocation path such that $y(q')$ increases. Let r and s be two points such that $q' = s$ and subsequently $q' = r$. Since $y(s) < y(r)$ no kink edge will be joined onto s once q' becomes r. Thus only $INTERLOC(p)$, where p is q' currently, needs to be modified as $RELOCATE$ processes nodes on the relocation path.

During a deletion, two relocations are performed. $INTERLOC$ values affected are updated again in $O(\log n)$ steps. Furthermore, kink edges are introduced. Each $INTERLOC$ value affected by kink edges can be updated in constant time since this value can be maintained as we traverse up the path where a deletion or relocation takes place. The maintenance detail is similar to that described for insertions.

Finally, during rotations, a constant number of relocations are performed. $INTERLOC$ values can again be updated as in the case of insertions and deletions in $O(\log n)$ steps. □

We thus have the following lemma.

LEMMA 14. *Let LS be the subset of maximal points such that $SLOC(p), p \in LS$, needs to be updated. Given $INTERLOC(p), p \in S$, LS can be determined in time linear in the output size.*

Proof. Consider the linear search performed at a node v using $INTERLOC$ values to determine if $LOC(p)$ is to be updated. By Lemma 11 all the points scanned are in the output, and by the discussion above $L(M(v))$ can be determined in linear time. Moreover, as shown in Lemma 11, these points need not be scanned more than once since this scan allows us to determine if LOC updates of points in $L(M(v))$ is either already determined or is to be determined by a location. □

Note that while updating $LOC(p)$, $NextLeft$ values at leaf nodes also need to be updated. This is done by a procedure similar to that which updates $NextLeft$ values during locations while inserting or deleting and requires $O(\log n)$ steps. We can thus state the following result.

THEOREM 3. *The set of maxima of a set of points in the plane can be maintained in $O(n \log n + m \log n + r)$ operations when there are n insertions, m deletions, and r is the number of points reported. Furthermore, each update requires $O(\log n)$ steps in the worst case.*

Proof. We need show the correctness of only the reporting procedure. By Lemma 12, during a report a point is located only if it is marked. Furthermore, a point, p such that $LOC(p)$ is not correctly maintained is always marked (Lemma 10).

We next analyze the time complexity. The time complexity for insertion, delete, and report operations without the maintenance of $LOC(p)$ has been shown before in Theorem 2. We consider the effect of marking of nodes ignoring the time required to compute sets $CLOC$ and $OTHER$ since our procedure avoids these computations. The analysis uses the following potential function:

$$PF = \log n \times (\text{ No. of marked points}).$$

When we use this potential function, the amortized time for an insertion is $O(\log n)$ since at most one location is done and one point is marked. The amortized time for a deletion operations is also $O(\log n)$ since apart from a constant number of locations at most three marked nodes are affected. During the reporting of the maxima, marked points are located and the points are unmarked. Since the number of locations is equal to the number of marked points decreased by becoming unmarked, the amortized time is $O(r)$ where there are r points reported.

In the actual procedure described above the marking is not explicitly done, but a marked point p is detected by checking $SLOC(p)$ or the existence of a kink edge onto which p is located. By Lemma 12 this suffices to detect marked points. Moreover, by Lemma 14 these points can be detected in $O(r)$ time since Lemma 13 shows that $INTERLOC$ values can be maintained in $O(\log n)$ steps. The theorem follows. □

6. Maintaining maximas under insertions in d-dimension. In this section we show how to extend the scheme of maintenance of maximas to higher dimensions. We only consider insertions.

We use the fact that the problem can be solved in two dimensions in $O(\log n)$ time per update. To this we add the range restriction technique [WL]. The ranges are added to all dimensions other than the last two where the solution described above is used.

The details of the data structure are as follows: The primary structure is a balanced tree T_d representing the dth dimension. It stores at its nodes secondary structures which represent the maximal points of the subset of points at that node. At each secondary structure it suffices to maintain the set of maxima in $d-1$ dimensions of a set of points. This set is obtained from the projection of the subset of points in the subtree rooted at the node onto a d-dimensional hyper-plane $x_d = xmin$ where $xmin$ is the minimum d-coordinate of the subset of points. Thus each node u in the tree is also associated with a hyperplane $H(u)$ onto which maximal points in the subtree are projected. The secondary structure is denoted by $T_{d-1}(u)$. To compute the maxima at a node the maxima obtained from the left child are filtered from those at its right child. The filtering operation is well known [KLP].

We next define the filtering operation when a point is added into the data structure. Let P be the path from the leaf where the point is added to the root in T_d. Suppose the point added is a maximal point in a subset of points present at node u in T_d. Let w be the node such that v is a child, and let u be its other child. First consider the case when v is a right child. Then the point p eliminates maxima from the set of maxima at u. This filtering operation is performed recursively as follows: Let p' be the projection of p on the hyperplane $H(u)$ at u. We determine the points that are eliminated in the secondary structure at u by p'. This is done by inserting p' into the secondary structure $T_{d-1}(u)$ using a similar procedure. The recursion stops when the secondary structure contains two-dimensional points. At this stage the procedure defined above for maintaining the maxima in two dimensions is used to obtain the set of points eliminated by the introduction of p. The time required for this filtering operation is $O(\log^{d-1} n)$.

We next consider the case when v is a left child of w. In this case it has to be determined whether p is eliminated by the set of maxima at u the other child of w. To do this we recursively evaluate whether p', the projection of p onto $H(u)$, is dominated by the set of maxima in $T_{d-1}(u)$. This is done recursively as follows: Let $P(p')$ be the path from the leaf to the root. For all subtrees along the path containing points with greater $d-1st$ coordinate it is determined whether p' is dominated by the points in the subtree in the remaining $d-2$ dimensions also. The recursion stops at the second dimension when the point is checked to be dominated or not in $O(\log n)$ steps using the staircase structure.

The filtering operation gives a set of points that are to be deleted and inserted from the set of maxima at w. Consider the deletion of a point q from a secondary structure $T_{d-1}(w)$. Again let $P(q)$ be the path from the leaf containing q to the root. The point is recursively removed from each of the secondary data structures at the nodes on the path. The recursion stops when the dimension is 2. At this point the procedure defined before is used to delete the point from the set of two-dimensional maxima in $O(\log n)$ operations. The insertion of a point is done similarly.

The details of the balancing procedures and the changes to the secondary structures are similar to that described in Willard and Leuker [WL] and are omitted here.

We thus achieve changes in the maxima tree structure in $O(\log^{d-2} n)$ time per change after the insert and filter steps which require $O(\log^{d-1} n)$ operations.

Conclusions and acknowledgments. We have shown efficient schemes for dynamically maintaining the set of maxima of a set of points in two dimensions. We do so by maintaining approximate information. Other applications of this technique would be interesting. I would like to thank A. Dutta and S. Sen for helpful discussions.

THE COMPLEXITY OF THE $A\ B\ C$ PROBLEM[*]

JIN-YI CAI[†], RICHARD J. LIPTON[‡], AND YECHEZKEL ZALCSTEIN[§]

Abstract. We present a deterministic polynomial-time algorithm for the $A\,B\,C$ problem, which is the membership problem for 2-generated commutative linear semigroups over an algebraic number field. We also obtain a polynomial-time algorithm for the (easier) membership problem for 2-generated abelian linear groups. Furthermore, we provide a polynomial-sized encoding for the set of all solutions.

Key words. polynomial-time algorithm, membership problem, semigroup, commutative, lattice

1. Introduction.

Most algorithmic questions about infinite groups and semigroups given by presentations (generators and relations) are known to be undecidable [11], [38], [1], [40]. However, the most useful and interesting representation of groups is by matrices over a field. Most groups occurring in physics and many finite simple groups arise as groups of matrices. Nonetheless, it should be noted that many interesting groups do not have faithful matrix representations. An interesting class of groups that cannot be represented by matrices is the uncountable class of infinite Burnside groups introduced by Grigorchuk [20] and whose computational properties were studied in [16]. Rabin has stated without proof in [41] that if the groups are represented by matrices over a field then the word problem is decidable. This result was improved to log space complexity by Lipton and Zalcstein [33] for fields of characteristic zero and by Simon [42] for fields of positive characteristic.

The word problem is a "checking" problem. The corresponding "search" problem is the membership problem: Precisely, given a finite number of elements $a_1, \ldots, a_k$ (given as matrices or permutations) of a group G and a target element g, does g belong to the group generated by $a_1, \ldots, a_k$?

In this generality the problem is undecidable [37], even for groups of 4-by-4 matrices. Thus work on this problem has focused on *finite* groups. Babai and Szemeredi [5] have shown that, for finite groups of matrices over a finite field the problem is in NP. This problem has also motivated the introduction of the complexity class AM [2]. Since, as has been observed in [5], the membership problem for finite matrix groups over finite fields is closely related in complexity to that of the discrete logarithm problem, further progress seems unlikely and most research has concentrated

on groups represented by *permutations* rather than matrices. Over the years, this research has culminated in efficient sequential and parallel algorithms [3, 4, 15, 22]. Progress on the matrix representation case is very recent. Luks [35] has presented a polynomial-time membership test for solvable matrix groups over "good" finite fields (where the discrete logarithm problem can be bypassed). Beals and Babai [6] have given a polynomial-time *Las Vegas* membership test for arbitrary finite matrix groups over an algebraic number field. For semigroups the problem is even harder. It is known to be undecidable even if the target element g is the zero matrix and the matrices are 3 by 3 [39] (for a related unsolvable problem for semigroups of triangular 3-by-3 matrices see [23]). For finite semigroups the problem is PSPACE-hard [25], even if the semigroups are inverse (this follows from [9, Theorem 5.4]) and it is NP-hard for finite *commutative* semigroups [8].

In this paper, we extend previous algorithmic results in two directions. First, we allow infinite systems, where even decidability is not clear, and second, we consider as semigroups as well. On the other hand, since the general problem is undecidable, some restrictions are needed. In 1980, Kannan and Lipton [28] solved the following *orbit problem*, which is the membership problem for a *cyclic* semigroup, by giving a polynomial-time algorithm:

Given two commuting matrices A and B over the rational numbers,
does there exist a nonnegative integer i, such that $A^i = B$?

The following *generalized orbit problem*, or *the A B C problem*, has remained open since 1980:

Given commuting matrices A, B, and C over the rational numbers,
does there exist nonnegative integers i and j, such that $A^iB^j = C$?

In this paper, we resolve the A B C problem by giving a polynomial-time algorithm which not only decides the solvability of a given instance A, B and C, but also finds all solutions by showing that the set of solutions is a (possibly empty) "affine lattice" and producing a polynomial-sized basis for that lattice.

We also obtain the corresponding result for the group case. We would like to point out that the semigroup problem is harder, even when the generating matrices are invertible, since we do not allow the use of the inverse operation. The results are new, even in the group case. Prior to this work, the best result for the problem in the group case was that it is decidable, a result by Kopytov [24]. The proof in [24], which constructs "yes" and "no" lists, does not give any complexity bounds. Nothing was previously known for the semigroup case.

The techniques presented here can be generalized and modified to solve the membership problem for the case of $k > 2$ generators, where k is fixed [7]. However, we should point out that, for semigroups, the number of generators must be fixed; otherwise, as noted above, the problem is already NP-hard in the finite case.

We will explain briefly why the problem is challenging. Let us assume first (this is seemingly the easiest case) that the matrices A, B, and C are all diagonalizable. Since they commute they must be simultaneously diagonalizable. In this case the problem is reduced to n instances of the following problem (n is the size of the matrices): Given algebraic numbers α, β, and γ, are there nonnegative integers i, j such that $\alpha^i\beta^j = \gamma$? Or more generally, for a fixed k, given algebraic numbers $\alpha_1, \ldots, \alpha_k$, and η, are there nonnegative integers $i_1, \ldots, i_k$ such that

$$\alpha_1^{i_1} \ldots \alpha_k^{i_k} = \eta \tag{1}$$

holds? In case some of the α's are not units, one can use Kummer's unique factorization of ideals and apply an argument based on the exponential growth of the norms $[\mathbf{N}(\alpha_i)]^i$. However, the hard case is when all the α's are units. The theorem of Blanksby and Montgomery [10] used in [28] is inadequate for the case $k \geq 2$. Another natural attempt is to use Dirichlet's unit theorem to decompose the α's in terms of fundamental units. However, the complexity of computing such decompositions has not, to our knowledge, been analyzed and it may not be computationally tractable. Furthermore, Dirichlet's theorem handles only the group case. Finally, in reducing the general case to the diagonalizable case, Dirichlet's theorem is not enough. We need a description of all solutions of (1). Such a description, for the special case that $\eta = 1$, has been obtained only recently by Masser [36]. A more recent result, by Ge [19] gives a polynomial-time algorithm for computing a basis for all solutions of (1), for $\eta = 1$.

The proof builds upon Ge's result and the observation that if a matrix A is given in Jordan normal form (JNF), then there are closed form formulas for the powers of A. A recent result [12], developed simultaneously with this paper, gives a polynomial-time algorithm for computing JNF. This observation, together with Theorem 3.2 which handles the scalar case, provides a quick proof of the Kannan–Lipton theorem. It should be pointed out that [12] uses the L^3 algorithm [31], which had not yet been discovered at the time that [28] was written. Generalizing to the case of two generators, if both generators are diagonalizable, the problem is reduced to the scalar case. If at least one of the generator matrices is not diagonalizable, it is tempting to believe that, since the matrices commute, they can be brought simultaneously to JNF. If this were true, an extension of the argument in the diagonalizable case could possibly be constructed. However, this is not true. To overcome this difficulty, we introduce a technique which we call *successive restriction.*

Our results are as follows.

THEOREM 1.1. *There is a polynomial-time algorithm for the following problem: Given $k+1$ algebraic numbers $\alpha_1, \ldots, \alpha_k$ and η, are there nonnegative integers $i_1, \ldots, i_k$ such that* (1) *holds? If so, find all solutions (in a polynomial-sized encoding).*

THEOREM 1.2. *There is a polynomial-time algorithm to decide the solvability of the A B C problem; namely, given commuting matrices A, B, and C over an algebraic number field, do there exist nonnegative integers i and j such that $A^iB^j = C$? Further, if there is a solution, the algorithm finds all solutions (in a polynomial-sized encoding).*

THEOREM 1.3. *There is a polynomial-time algorithm to solve the A B C problem in the group case, i.e., where the exponents are allowed to be arbitrary integers.*

It is possible to generalize Theorem 1.3 as follows. A group G satisfies the *permutation* (or *rewriting*) property P_3 iff for any three elements a_1, a_2, a_3 in G, the product $a_1a_2a_3$ equals a product which is a nontrivial permutation of a_1, a_2, a_3. Any abelian group satisfies the property P_3. It is known [14] (see also [17]) that a group satisfies P_3 iff it has at most one nontrivial commutator. Thus in a group satisfying P_3, any product of powers of the generators equals the product $a_1^{i_1} \ldots a_k^{i_k}$, possibly post-multiplied by the unique commutator. Thus membership testing is reduced to the abelian case. Unfortunately, the P_3 semigroups have not been characterized completely (for some partial results see [17]) and the complexity of the membership problem for P_3 semigroups is not known.

The plan for this paper is as follows. In section 2 we will deal with some preliminary issues. Proofs in section 2 are omitted. In section 3 we prove Theorem 3.2, from which Theorem 1.1 follows. In section 4, we first give an illustration of the power of our new techniques in a simple setting by giving a transparent proof of the Kannan–Lipton theorem. Then in section 4 we use the method of successive restriction to complete the solution of the A B C problem.

2. Preliminaries. First, without loss of generality, we may assume that the matrices are over the rationals. This reduction uses the classical matrix representation of a finite algebraic extension over the ground field [21]. Let A, B, and $C \in \mathbf{Q}^{n\times n}$ be $n \times n$ rational matrices. The input size to the problem is n plus the sum of binary lengths of all entries. By an extension of a technique from [28], we may assume that C is given as a polynomial in A and B with rational coefficients. This is certainly a necessary condition, and whether C is such a polynomial can be decided in polynomial time, as it is a question of linear dependence over the rationals [26].

Thus, we are given $A, B \in \mathbf{Q}^{n\times n}$ such that A, B commute, and a polynomial p in A and B. The question is to decide if p can be expressed as a product of nonnegative powers of A and B. In [28], the computation of eigenvalues could be circumvented, using the crucial fact that the ring of polynomials in one variable over a field is principal. Since the ring of polynomials in two variables is not principal, this strategy no longer works. We will compute in various number fields, mostly symbolically; i.e., we will have an irreducible polynomial f (proven so by the L^3-algorithm), and each element in the field will be represented by a polynomial of degree $< \deg(f)$ [31, 29]. This can be done over any number fields as well, not just $\mathbf{Q}$. However, an important issue is that we cannot allow the degree of the extension over $\mathbf{Q}$ to be too large; in general, to stay within polynomial time, we cannot operate in the splitting field of an irreducible polynomial of degree say, n, since the Galois group of this extension field might be too large. It is not known how to compute in polynomial time in an extension field where the Galois group has size $n!$ and in fact it is believed to be impossible [32].

We will need to compute the JNF for either of the matrices A or B. What we will show in the paper is a technique of successive restriction which is of independent interest and is almost as good for our purposes as simultaneous JNF. But before we get to that, let's first ask if we can compute a basis change for the JNF of a matrix A in polynomial time. The difficulty is that if we use the standard textbook algorithm, we will be dealing with the splitting field of χ_A over $\mathbf{Q}$. Thus the standard algorithm will not do. However, there is a polynomial-time algorithm [12] that finds an invertible matrix T, such that $T^{-1}AT = J_A$, the JNF for A. The matrix T has entries from the splitting field of χ_A, but the trick is that in [12] we can find a T where every entry t in fact belongs to a much smaller extension field, which varies with t and can be computed in polynomial time within the smaller field. The matrix J_A is *not* computed from the *product* $T^{-1}AT$; in fact, computing T^{-1} from T, say using Gaussian elimination, involves the splitting field again. However, a different technique is used in [12] to compute J_A, and to compute T^{-1} from T, without ever going to the splitting field, all accomplished in polynomial time.

Next there is the issue of how to apply this basis transformation to another matrix M. The fact is that this cannot be done in polynomial time. The same difficulty with the splitting field gets in the way. *But it can be done for the matrices B and C*, using the fact that they commute with A. It is only in this limited sense that we have obtained this basis transformation computationally. Fortunately, this is sufficient for the solution of the A B C problem.

There is another technical issue concerning conjugates of the same irreducible polynomial. When it is necessary to distinguish one root from another, we will use a "good enough" rational approximation, which gives a polynomial number of bits and uniquely identifies the root on the complex plane. We refer the reader to [34] for the details.

In the following we will speak freely of computing JNF, invariant subspaces, etc., all in polynomial time, without further comment. We will reduce the situation to the case where both A and B have exactly one eigenvalue each, λ and μ, respectively. We view A and B as linear transformations over the field $\mathbf{C}$ of complex numbers. Let $p(.)$ be a polynomial with complex coefficients. Consider a subspace V defined as $\ker(p(A))$ or $\mathrm{Im}(p(A))$. It is easy to see that V is an invariant subspace for both A and B

Now consider the subspace $V_\lambda = \ker(\lambda I_n - A)^{n-1}$, where λ is any eigenvalue of A, i.e., $\lambda \in \mathit{Spec}(A)$. Since A and B commute, V_λ is an invariant subspace for both A and B.

After some preparation, we can arrive at the following situation: we have a decomposition of $\mathbf{C}^n$ as a direct sum of subspaces $V_{\lambda,\mu}$, invariant for both A and B, where λ and μ range over $\mathit{Spec}(A)$ and $\mathit{Spec}(B)$, i.e., all eigenvalues of A and B, such that there is just one eigenvalue λ (and μ, respectively) for A (and B, respectively) on $V_{\lambda,\mu}$:

$$\mathbf{C}^n = \bigoplus_{\lambda \in \mathit{Spec}(A), \mu \in \mathit{Spec}(B)} V_{\lambda,\mu}.$$

Lemma 2.1.
Suppose A, B commute and C is a polynomial in A and B; then for any i, j,

$$A^i B^j = C \Longleftrightarrow (A\,|_{V_{\lambda,\mu}})^i (B\,|_{V_{\lambda,\mu}})^j = C\,|_{V_{\lambda,\mu}},$$

$\forall \lambda \in \mathit{Spec}(A), \mu \in \mathit{Spec}(B)$.

For what follows, we will fix any pair of eigenvalues $\lambda \in \mathit{Spec}(A)$ and $\mu \in \mathit{Spec}(B)$ and consider $A\,|_{V_{\lambda,\mu}}$ and $B\,|_{V_{\lambda,\mu}}$. We will call them A and B, respectively, when no confusion arises.

3. The affine lattice of solutions.

We will need the following theorem of Masser [36].

Theorem 3.1. *Fix any $k \geq 1$. Let $\alpha_1, \ldots, \alpha_k$ be nonzero algebraic numbers over $\mathbf{Q}$. Let $D = [\mathbf{Q}(\alpha_1, \ldots, \alpha_k) : \mathbf{Q}]$ be the degree of the algebraic extension, and let h be the maximum height* [1] *of $\alpha_1, \ldots, \alpha_k$ over $\mathbf{Q}$. Then, the relation group*

$$L = \{\ (e_1, \ldots, e_k) \in \mathbf{Z}^k \mid \alpha_1^{e_1} \cdots \alpha_k^{e_k} = 1\ \}$$

is a lattice with a small basis. More specifically, L has a generating set $v_1, \ldots, v_\ell \in \mathbf{Z}^k$, $1 \leq \ell \leq k$, such that the maximum entry in these vectors $\max_{1 \leq i \leq \ell\ 1 \leq j \leq k} |v_{i,j}|$ is at most

$$(ckh)^{k-1} D^{k-1} \frac{(\log(D+2))^{3k-3}}{(\log\log(D+2))^{3k-4}},$$

where c is some absolute constant.

In order to appreciate this remarkable theorem of Masser, let's look at its implication on the computational complexity of finding such a basis. Note that in the

[1] The height function of an algebraic number is essentially the sum of the degree and the binary length of all coefficients in the defining equation over $\mathbf{Q}$.

inequality, the left hand side refers to the *quantity* $v_{i,j}$, while the right hand side essentially refers to the binary length of the input data. (Recall that k is fixed.) Thus, an exhaustive search can be done in polynomial time to find a small basis.

We call a shift of a lattice $L + v$, for some $v \in \mathbf{Z}^k$, an *affine lattice*. We say that an affine lattice has *small description* if it is $L + v$ for some small v and L has a small basis; here small means all entries are polynomially bounded in *quantity* (not merely in binary length).

THEOREM 3.2. *Given nonzero algebraic numbers $\alpha, \beta_1, \ldots, \beta_k$, the set*

$$\{ \ (j_1, \ldots, j_k) \mid \alpha\beta_1^{j_1} \cdots \beta_k^{j_k} = 1 \ \}$$

is either empty or is an affine lattice with rank at most k and a small description. Moreover, it is decidable in polynomial time whether it is empty, and if not, to compute a small description in terms of an off-set vector v and a small basis. Finally, if the rank of the affine lattice is k, then all of $\alpha, \beta_1, \ldots, \beta_k$ are roots of unity.

Proof. Consider the lattice

$$L = \{ \ (i, j_1, \ldots, j_k) \mid \alpha^i \beta^{j_1} \cdots \beta^{j_k} = 1 \ \}.$$

By Ge's theorem [19], we get a small basis $v_1, \ldots, v_\ell$, $\ell \leq k + 1$. Now we wish to intersect this lattice with the affine lattice $\{(1, j_1, \ldots, j_k) \mid j_1, \ldots, j_k \in \mathbf{Z}\}$.

Write

$$\begin{pmatrix} v_1 \\ v_2 \\ \vdots \\ v_\ell \end{pmatrix} = \begin{pmatrix} v_{10} & v_{11} & \ldots & v_{1k} \\ v_{20} & v_{21} & \ldots & v_{2k} \\ \vdots & \vdots & \ddots & \vdots \\ v_{\ell 0} & v_{\ell 1} & \ldots & v_{\ell k} \end{pmatrix},$$

where $v_{ij} \in \mathbf{Z}$ and $|v_{ij}| \leq n^{O(1)}$.

We can first perform a basis reduction to transform the basis to a so-called canonical basis in the sense of Hermite. This can be done in polynomial time [27]

$$\begin{pmatrix} v_{10} & v_{11} & \ldots & v_{1k} \\ 0 & v_{21} & \ldots & v_{2k} \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \ldots & \cdot \end{pmatrix},$$

where $0 \leq v_{10}$, $0 \leq v_{11} \leq v_{21}$, etc. The row vectors still form a basis for L. We will still call them $v_1, \ldots, v_\ell$.

Now it is clear that this lattice intersects with $\{(1, j_1, \ldots, j_k) \mid j_1, \ldots, j_k \in \mathbf{Z}\}$ iff $v_{10} = 1$, and if so, then the intersection is $L' + v_1$, where L' is the lattice spanned by $v_2, \ldots, v_\ell$.

If the rank of the affine lattice is k, then $\ell = k + 1$. The basis matrix is a square matrix and all diagonal entries are nonzero. In particular, $v_{kk} \neq 0$, and $\beta_k^{v_{kk}} = 1$. Thus, β_k is a root of unity. Continuing, we have $v_{k-1,k-1} \neq 0$, and $\beta_{k-1}^{v_{k-1,k-1}} = \beta_k^{-v_{k-1,k}}$, which is a root of unity. Thus, β_{k-1} is also a root of unity. The proof is completed by an easy induction. $\square$

If any of the algebraic numbers $\alpha, \beta_1, \ldots, \beta_k$ are 0, we will adopt the convention that $0^0 = 1$ and $0^i = 0$ for $i > 0$. Under this convention, the statement in Theorem 3.2 can be easily adapted to allow 0's. Now to prove Theorem 1.1, note that the set of k-tuples of nonnegative integers $(i_1, \ldots, i_k)$ such that (1) holds is obtained by intersecting the affine lattice L of Theorem 3.2 with the set of k-tuples of nonnegative integers. By Lenstra [30], membership in the intersection can be decided in polynomial time.

4. The proof.

We will first illustrate the new technique, in a simple setting, by demonstrating how swiftly the Kannan–Lipton Theorem [28] can be proved using this technique.

4.1. The Kannan–Lipton theorem.

THEOREM 4.1. *There is a polynomial-time algorithm for the following problem:*
Given two rational matrices A, B, is there a nonnegative integer i
such that $A^i = B$?

Proof. Put A in JNF. Restrict to a subspace V_λ, where the only eigenvalue for A on V_λ is λ.

- Case 1. $\lambda = 0$. Then $A|_{V_\lambda}$ is nilpotent, $(A|_{V_\lambda})^n = 0$. Thus we need only check the cases $(A|_{V_\lambda})^i = (B|_{V_\lambda})$, for $0 \leq i \leq n$.
- Case 2. $\lambda \neq 0$. Consider the solutions to $\lambda^i = c$, which is obtained by looking at any diagonal entry in $(A|_{V_\lambda})^i = B|_{V_\lambda}$. If the solution set is empty, we are finished. Suppose the solution set is an affine lattice of rank 0, i.e., there is a unique solution i and since $i \leq n^{O(1)}$ we can directly check if $A^i = B$. The only nontrivial case is rank 1. Then by Theorem 3.2, λ is a root of unity. So must be c, hence $c \neq 0$. The order of λ must be polynomially bounded, since $\chi_A(\lambda) = 0$.
  1. $A|_{V_\lambda}$ is diagonal. Then it is completely determined by Theorem 3.2.
  2. $A|_{V_\lambda}$ is not diagonal. Then some Jordan block has size ≥ 2. We can symbolically compute the powers of $A|_{V_\lambda}$, up to $(A|_{V_\lambda})^i$, for $i \leq 2^{n^{O(1)}}$. This uses the fact that λ is a root of unity, and we know the closed form formula for powers of JNF. Thus, on the diagonal we get equation $\lambda^i = c$, and on the off-diagonal we get an equation $\binom{i}{1}\lambda^{i-1} = c'$. This gives the necessary condition that $i = \lambda c'/c$. If $\lambda c'/c$ is not a nonnegative integer, then there is no solution. Otherwise, we simply check directly if $\lambda^i = c$.

The Kannan–Lipton Theorem is proved. ∎

4.2. The method of successive restriction. Now the setting is $V_{\lambda,\mu}$. We will write A for $A|_{V_{\lambda,\mu}}$ and do the same for B. There will be four cases, depending on whether $\lambda = 0$ and/or $\mu = 0$. The cases when at least one of the eigenvalues is 0 are in fact simpler, since then the matrix is nilpotent, so that we need only check powers up to n. (Recall that on $V_{\lambda,\mu}$, each matrix has exactly one eigenvalue.) We will omit the details on these three cases and assume $\lambda \neq 0$ and $\mu \neq 0$. If both A and B are diagonal matrices $\lambda I$and μI, then this case is completely determined by Theorem 3.2. Suppose A is not diagonal. Put A in its JNF. Since $A \neq \lambda I$, at least one block is of dimension > 1.

Let

$$V' = \ker(\lambda I - A)$$

and

$$V'' = \ker(\lambda I - A)^2.$$

Since A and B commute, both V' and V'' are invariant subspaces of B as well as A. In terms of the Jordan form of A, V' corresponds to the first rows and columns of each λ-block. And V'' corresponds to the first and the second rows and columns (whenever a second row and column exists) of each λ-block. Since at least one block is of dimension > 1, $V' \neq V''$.

Let $n_1 = \dim V'$ and $n_1 + n_2 = \dim V''$; then $n_1 \geq n_2 \geq 1$.

Let $v_{11}, \ldots, v_{1k_1}, v_{21}, \ldots, v_{2k_2}, \ldots, v_{\ell 1}, \ldots, v_{\ell k_\ell}$ be the basis vectors for which A has its Jordan form, where $v_{i1}, \ldots, v_{ik_i}$ is the basis vectors corresponding to the ith block. We also assume that the blocks are ordered so that $k_1 \geq \cdots \geq k_\ell$. Then $v_{11}, \ldots, v_{\ell 1}$ spans the eigenspace $V' = \ker(\lambda I - A)$, and consequently $\ell = n_1$. By assumption $k_1 \geq 2$, and let $\ell' = \max\{i \mid k_i \geq 2\}$; then $v_{11}, \ldots, v_{\ell,1}, v_{12}, \ldots, v_{\ell' 2}$ spans V'' and $\ell' = n_2$.

Consider $A\mid_{V''}$ and $B\mid_{V''}$. If we order the basis vectors as $v_{11}, \ldots, v_{\ell,1}, v_{12}, \ldots,$ $v_{\ell' 2}$, then A has the form

$$A = \begin{pmatrix} \lambda I_{n_2} & 0 & I_{n_2} \\ 0 & \lambda I_{n_1 - n_2} & 0 \\ 0 & 0 & \lambda I_{n_2} \end{pmatrix}.$$

By decomposing B in blocks of the same dimensions, one can easily verify that

$$A \text{ and } B \text{ commute } \iff B \text{ is of the following} \\ \text{block upper triangular form:}$$

$$B = \begin{pmatrix} X & Y & Z \\ 0 & U & V \\ r0 & 0 & X \end{pmatrix},$$

where X, Y, Z, U, V are of the appropriate dimensions.

(If $n_1 = n_2$, then the middle blocks $\lambda I_{n_1 - n_2}$ in A, and Y, U, and V in B are understood not to appear.)

4.2.1. Restriction to V'. Choose a basis transformation of V' such that $B\mid_{V'}$ is in its Jordan form. Note that on V', $A\mid_{V'}$ is the scalar matrix λI_{n_1} which is unchanged under all basis transformations. Thus, under this basis, $A\mid_{V'}$ is still the scalar matrix λI_{n_1}, and $B\mid_{V'}$ is a direct sum of Jordan blocks all of which have μ on its diagonal, since *Spec*$(B\mid_{V'}) = \{\mu\}$. By comparing eigenvalues, we get $\lambda^i \mu^j = c$. By Theorem 3.2 we get either an empty set of solutions or an affine lattice of small description. If it is empty, we are finished; or if the rank is 0, we can directly check it. If the rank is 1, then we can reduce it to Kannan–Lipton's theorem. In fact, let $i = i_0 + as$ and $j = j_0 + bs$ for small i_0, j_0, a, b; then we have to solve for s in $(A^a B^b)^s = (CA^{-i_0} B^{-j_0})$.

Now suppose the rank is 2. Then both λ and μ are roots of unity. We note that in this case we can compute high powers of A and B, up to $2^{n^{O(1)}}$, in polynomial time. This is accomplished separately for A and B by first putting the target matrix in JNF, then taking its power, and finally reverting back.

Suppose $B\mid_{V'}$ is not a scalar matrix μI. Then some μ-block of $B\mid_{V'}$ has dimension > 1. Then consider

$$U' = \ker(\mu I - B\mid_{V'})$$

and

$$U'' = \ker(\mu I - B\mid_{V'})^2.$$

As before, both U' and U'' are invariant subspaces of A as well as B. Since at least one block of $B\,|_{V'}$ is of dimension > 1, $U' \neq U''$.

Let $m_1 = \dim U'$ and $m_1 + m_2 = \dim U''$; then $m_1 \geq m_2 \geq 1$, and if we order the basis vectors appropriately, we have $A\,|_{U''} = \lambda I_{m_1+m_2}$ and

$$B\,|_{U''} = \begin{pmatrix} \mu I_{m_2} & 0 & I_{m_2} \\ 0 & \mu I_{m_1-m_2} & 0 \\ 0 & 0 & \mu I_{m_2} \end{pmatrix}.$$

(Again, if $m_1 = m_2$, then the middle blocks are understood not to appear.)

Implied by the forms of $A\,|_{U''}$ and $B\,|_{U''}$ is the fact that the first and the last m_2 basis vectors together generate an invariant subspace for both A and B. By focusing on this subspace, we get a necessary condition of $A^iB^j = C$ in the form of a pair of equations

$$\lambda^i\mu^j = c, \qquad j\lambda^i\mu^{j-1} = c'.$$

This gives us, upon substitution, $j = \mu c'/c$, which reduces the problem to the one-variable case.

4.2.2. Restriction to V''. Now we suppose on V', $B\,|_{V'} = \mu I_{n_1}$; thus on V'',

$$B\,|_{V''} = \begin{pmatrix} \mu I_{n_2} & 0 & Z \\ 0 & \mu I_{n_1-n_2} & V \\ 0 & 0 & \mu I_{n_2} \end{pmatrix}.$$

(Once again, the middle blocks disappear if $n_1 = n_2$.)

Suppose $n_1 > n_2$. $V^* = \mathrm{span}\{v_{n_2+1\,1}, \ldots, v_{n_1 1}\}$, the subspace corresponding to the middle blocks, is an invariant subspace for both A and B. Consequently we may consider the quotient space V''/V^* and the induced action of A and B on this quotient space, denoted by $\tilde{A}$ and $\tilde{B}$, respectively. (If $n_1 = n_2$, then $V^* = 0$ and $V''/V^* = V''$.) Under the induced basis from $\{v_{11}, \ldots, v_{n_2,1}, v_{1,2}, \ldots, v_{n_2,2}\}$ for V''/V^*,

$$\tilde{A} = \begin{pmatrix} \lambda I_{n_2} & I_{n_2} \\ 0 & \lambda I_{n_2} \end{pmatrix}$$

and

$$\tilde{B} = \begin{pmatrix} \mu I_{n_2} & Z \\ 0 & \mu I_{n_2} \end{pmatrix}.$$

If $Z = 0$ then we will get a necessary condition

$$\lambda^i\mu^j = c, \qquad i\lambda^{i-1}\mu^j = c'.$$

This gives us, upon substitution, $i = \lambda c'/c$, which reduces the problem to the one-variable case.

If $Z \neq 0$ then we will get a necessary condition

$$\lambda^i\mu^j = c, \qquad j\lambda^i\mu^{j-1}z + i\lambda^{i-1}\mu^j = c',$$

for some known algebraic numbers c, c' and $z \neq 0$. Upon substitution, we get

$$\frac{i}{\lambda} + z\frac{j}{\mu} = \frac{c'}{c}.$$

Solving i in terms of j,

$$i = \frac{\lambda c'}{c} - \frac{z\lambda}{\mu} j.$$

If $\frac{z\lambda}{\mu}$ is not rational, then we will have at most one pair of integral solution (i, j), and we can easily find it and test it. If $\frac{z\lambda}{\mu}$ is rational, then unless $\lambda c'/c$ is rational, there is no solution, and if $\lambda c'/c$ is rational, then there is an integral relationship between i and j,

$$ui + vj = w.$$

We can solve this equation in general form, $i = i_0 + v_1 t$ and $j = j_0 - u_1 t$, where $u_1 = u/\gcd(u, v)$ and $v_1 = v/\gcd(u, v)$. Substituting back in $A^i B^j = C$, we get $(A^{i_0} B^{j_0})(A^{v_1} B^{-u_1})^t = C$, which reduces it to the case with one variable t. This proves Theorem 1.2. Theorem 1.3 is proved by removing the restriction to nonnegative exponents at the appropriate places in the proof. Alternatively, as suggested by the referee, apply Theorem 1.2 four times with the respective generator pairs A, B; A, B^{-1}; A^{-1}, B; and A^{-1}, B^{-1}.

Acknowledgments. This paper would not have been possible without the contribution of M. L. Robinson, who has pointed us to transcendental number theory and in particular to Masser's theorem. We thank him for this and for many helpful discussions. We would also like to acknowledge helpful discussions with Katalin Friedl, Ravi Kannan, Susan Landau, Laci Lovász, Andrew Odlyzko, Lajos Ronyai, and William Velez. Zeke Zalcstein would also like to thank Kamal Abdali for TEXnical assistance.

THE LOAD AND AVAILABILITY OF BYZANTINE QUORUM SYSTEMS*

DAHLIA MALKHI[†], MICHAEL K. REITER[‡], AND AVISHAI WOOL[‡]

Abstract. Replicated services accessed via *quorums* enable each access to be performed at only a subset (quorum) of the servers and achieve consistency across accesses by requiring any two quorums to intersect. Recently, b-masking quorum systems, whose intersections contain at least $2b+1$ servers, have been proposed to construct replicated services tolerant of b-arbitrary (Byzantine) server failures. In this paper we consider a hybrid fault model allowing benign failures in addition to the Byzantine ones. We present four novel constructions for b-masking quorum systems in this model, each of which has optimal *load* (the probability of access of the busiest server) or optimal availability (probability of some quorum surviving failures). To show optimality we also prove lower bounds on the load and availability of any b-masking quorum system in this model.

Key words. quorum systems, Byzantine failures, replication, load, availability, distributed computing

1. Introduction.

Quorum systems are well-known tools for increasing the efficiency of replicated services, as well as their availability when servers may fail benignly. A quorum system is a set of subsets (quorums) of servers, every pair of which intersect. Quorum systems enable each client operation to be performed only at a quorum of the servers, while the intersection property makes it possible to preserve consistency among operations at the service.

Quorum systems work well for environments where servers may fail benignly. However, when servers may suffer arbitrary (Byzantine) failures, the intersection property does not suffice for maintaining consistency; two quorums may intersect in a subset containing *faulty* servers only, which may deviate arbitrarily and undetectably from their assigned protocol. Malkhi and Reiter thus introduced *masking quorums systems* [25], in which each pair of quorums intersects in sufficiently many servers to mask out the behavior of faulty servers. More precisely, a *b-masking quorum system* is one in which any two quorums intersect in $2b+1$ servers, which suffices to ensure consistency in the system if at most b servers suffer Byzantine failures.

In this paper we develop four new constructions for b-masking quorum systems. For the first time in this context, we distinguish between masking Byzantine faults and surviving a possibly larger number of benign faults. Our systems remain available in the face of any f crashes, where f may be significantly larger than b (such a system is called f-resilient). In addition, our constructions demonstrate optimality (ignoring constants) in two widely accepted measures of quorum systems, namely *load* and *crash probability*. The load ($\mathcal{L}$), a measure of best-case performance of the quorum system, is the probability with which the busiest server is accessed under the best

possible strategy for accessing quorums. The crash probability (F_p) is the probability, assuming that each server crashes with independent probability p, that all quorums in the system will contain at least one crashed server (and thus will be unavailable). The crash probability is an even more refined measure of availability than f, as a good system will tolerate many failure configurations with more than f crashes. Three of our systems are the first systems to demonstrate optimal load for b-masking quorum systems, and two of our systems each demonstrate optimal crash probability for its resilience f. In proving optimality of our constructions, we prove new lower bounds for the load and crash probability of masking quorum systems.

The techniques for achieving our constructions are of interest in themselves. Two of the constructions are achieved using a *boosting* technique, which can transform any regular (i.e., benign fault-tolerant) quorum system into a masking quorum system of an appropriately larger system. Thus, it makes all known quorum constructions available for Byzantine environments (of appropriate sizes). In the analysis of one of our best systems we employ strong results from percolation theory.

The rest of this paper is structured as follows. We review related work and preliminary definitions in sections 2 and 3, respectively. In section 4 we prove bounds on the load and crash probability for b-masking quorum systems and introduce quorum composition. In sections 5–7 we describe our new constructions. We discuss our results in section 8.

2. Related work. Our work borrows from extensive prior work in benignly fault-tolerant quorum systems (e.g., [12, 39, 24, 11, 15, 4, 9, 1, 7, 31, 36]). The notion of availability we use here (crash probability) is well known in reliability theory [5] and has been applied extensively in the analysis of quorum systems (cf. [4, 34, 35] and the references therein). The load of a quorum system was first defined and analyzed in [31], which proved a lower bound of $\Omega(\frac{1}{\sqrt{n}})$ on the load of any quorum system (and, a fortiori, any masking quorum system) over n servers. In proving load-optimality of our constructions, we generalize this lower bound to $\Omega(\sqrt{\frac{b}{n}})$ for b-masking quorum systems.

Grids, which form the basis for our multigrid (denoted M-Grid) construction, were proposed in [24, 7, 21, 25]. The technique of quorum composition, which we use in our recursive threshold (RT) and boosted finite projective planes (boostFPP) constructions, has been studied in [29, 33, 32] under various names such as "coterie join" and "recursive majority." Our multipath (M-Path) construction generalizes the system of [41], coupled with the analysis of the Paths construction of [31], and the recent system of [6].

Several constructions of masking quorum systems were given in [25] for a variety of failure models. For the model we consider here—i.e., any b servers may experience Byzantine failures—that work gave two constructions. We compare those constructions to ours in section 8.

Hybrid failure models have been considered in other works (e.g., [10, 22, 23, 38]).

3. Preliminaries. In this section we introduce notation and definitions used in the remainder of the paper. Much of the notation introduced in this section is summarized in Table 1 for quick reference.

We assume a *universe* U of servers, $|U| = n$, over which our quorum systems will be constructed. Servers that obey their specifications are *correct*. A *faulty* server, however, may deviate from its specification arbitrarily. We assume that up to b servers may fail arbitrarily and that $4b < n$, since this is necessary for a b-masking quorum

TABLE 1
The notation used in this paper.

b	Maximum number of Byzantine server failures.
$c(\mathcal{Q})$	Size of the smallest quorum in $\mathcal{Q}$.
f	Resilience (Definition 3.4).
$F_p(\mathcal{Q})$	Crash probability (Definition 3.10).
$\mathcal{IS}(\mathcal{Q})$	Size of smallest intersection between any two quorums in $\mathcal{Q}$.
$\mathcal{L}(\mathcal{Q})$	Load of $\mathcal{Q}$ (Definition 3.8).
$\mathcal{MT}(\mathcal{Q})$	Size of a smallest transversal of $\mathcal{Q}$ (Definition 3.3).
n	Number of servers (i.e., $\|U\| = n$).
p	Independent probability that each server crashes.
$\mathcal{Q}$	A quorum system (Definition 3.1).
U	Universe of servers.

system to exist [25]. Beginning in section 3.2.2, we will also distinguish benign (crash) failures as a particular failure of interest, and in general there may be more than b such failures.

3.1. Quorum systems.

DEFINITION 3.1. *A* quorum system $\mathcal{Q} \subseteq 2^U$ *is a collection of subsets of* U*, each pair of which intersect. Each* $Q \in \mathcal{Q}$ *is called a* quorum.

We use the following notation. The cardinality of the smallest quorum in $\mathcal{Q}$ is denoted by $c(\mathcal{Q}) = \min\{|Q| : Q \in \mathcal{Q}\}$. The size of the smallest intersection between any two quorums is denoted by $\mathcal{IS}(\mathcal{Q}) = \min\{|Q \cap R| : Q, R \in \mathcal{Q}\}$. The degree of an element $i \in U$ in a quorum system $\mathcal{Q}$ is the number of quorums that contain i: $\deg(i) = |\{Q \in \mathcal{Q} : i \in Q\}|$.

DEFINITION 3.2. *A quorum system* $\mathcal{Q}$ *is* (s, d)-fair *if* $|Q| = s$ *for all* $Q \in \mathcal{Q}$ *and* $\deg(i) = d$ *for all* $i \in U$*.* $\mathcal{Q}$ *is called* fair *if it is* (s, d)*-fair for some* s *and* d*.*

DEFINITION 3.3. *A set* T *is a* transversal *of a quorum system* $\mathcal{Q}$ *if* $T \cap Q \neq \varnothing$ *for every* $Q \in \mathcal{Q}$*. The cardinality of the smallest transversal is denoted by* $\mathcal{MT}(\mathcal{Q}) = \min\{|T| : T \text{ is a transversal of } \mathcal{Q}\}$*.*

Regular quorum systems, with $\mathcal{IS}(\mathcal{Q}) = 1$, are insufficient to guarantee consistency in case of Byzantine failures. Malkhi and Reiter [25] defined several varieties of quorum systems for Byzantine environments, which are suitable for different types of services. In this paper we focus on masking quorum systems.

DEFINITION 3.4 (see [25]). *The* resilience f *of a quorum system* $\mathcal{Q}$ *is the largest* k *such that for every set* $K \subseteq U$, $|K| = k$*, there exists* $Q \in \mathcal{Q}$ *such that* $K \cap Q = \varnothing$*.*

Remark. The resilience of any quorum system $\mathcal{Q}$ is $f = \mathcal{MT}(\mathcal{Q}) - 1$.

DEFINITION 3.5 (see [25]). *A quorum system* $\mathcal{Q}$ *is a* b-masking quorum system *if it is resilient to* $f \geq b$ *failures, and obeys the following* consistency *requirement:*

$$\forall Q_1, Q_2 \in \mathcal{Q} : |Q_1 \cap Q_2| \geq 2b + 1. \tag{3.1}$$

Remark. Informally, if we view the service as a shared variable which is updated and read by the clients, then the resilience requirement of Definition 3.4 ensures that no set of $b \leq f$ faulty servers will be able to block update operations (e.g., by causing every update transaction to abort). The consistency requirement of Definition 3.5 ensures that read operations can mask out any faulty behavior of up to b servers. Examples of protocols implementing various data abstractions using b-masking quorum systems can be found in [25, 26, 27].

LEMMA 3.6. *Let* $\mathcal{Q}$ *be a quorum system. Then* $\mathcal{Q}$ *is* b*-masking if both the following conditions hold:*

(1) $\mathcal{MT}(\mathcal{Q}) \geq b+1$;
(2) $\mathcal{IS}(\mathcal{Q}) \geq 2b+1$.

Proof. Assume that $\mathcal{MT}(\mathcal{Q}) \geq b+1$. To see that $\mathcal{Q}$ is resilient to b failures, note that if there exists some K such that $K \cap Q \neq \varnothing$ for all $Q \in \mathcal{Q}$, then K is a transversal. By the minimality we have $|K| \geq b+1$, and we are done. Condition 2 immediately implies (3.1). $\square$

COROLLARY 3.7. *Let $\mathcal{Q}$ be a quorum system, and let $b = \min\{\mathcal{MT}(\mathcal{Q})-1, \frac{\mathcal{IS}(\mathcal{Q})-1}{2}\}$. Then $\mathcal{Q}$ is b-masking.*

3.2. Measures.

The goal of using quorum systems is to increase the availability of replicated services and decrease their access costs. A natural question is how well any particular quorum system achieves these goals, and moreover, how well it compares with other quorum systems. Several measures will be of interest to us.

3.2.1. Load.

A measure of the inherent performance of a quorum system is its *load*. Naor and Wool define the load of a quorum system as the frequency of accessing the busiest server using the best possible strategy [31]. More precisely, given a quorum system $\mathcal{Q}$, an *access strategy* w is a probability distribution on the elements of $\mathcal{Q}$; i.e., $\sum_{Q \in \mathcal{Q}} w(Q) = 1$. The value $w(Q) \geq 0$ is the frequency of choosing quorum Q when the service is accessed. The load is then defined as follows.

DEFINITION 3.8. *Let a strategy w be given for a quorum system $\mathcal{Q} = \{Q_1, \ldots, Q_m\}$ over a universe U. For an element $u \in U$, the load induced by w on u is $l_w(u) = \sum_{Q_i \ni u} w(Q_i)$. The load induced by a strategy w on a quorum system $\mathcal{Q}$ is $\mathcal{L}_w(\mathcal{Q}) = \max_{u \in U}\{l_w(u)\}$. The* system load *on a quorum system $\mathcal{Q}$ is $\mathcal{L}(\mathcal{Q}) = \min_w\{\mathcal{L}_w(\mathcal{Q})\}$, where the minimum is taken over all strategies.*

We reiterate that the load is a best-case definition. The load of the quorum system will be achieved only if an optimal access strategy is used and only in the case that no failures occur. A strength of this definition is that the load is a property of a quorum system and not of the protocol using it. Examples of load calculations can be found in [40]. As an aside, we note that not every quorum system can have a strategy that induces the same load on each server. In [16] it is shown that for some quorum systems it is impossible to balance the load perfectly.

Recall that $c(\mathcal{Q})$ denotes the cardinality of the smallest quorum in $\mathcal{Q}$. The next result will be useful to us in what follows (recall Definition 3.2).

PROPOSITION 3.9 (see [31]). *Let $\mathcal{Q}$ be a fair quorum system. Then $\mathcal{L}(\mathcal{Q}) = c(\mathcal{Q})/n$.*

3.2.2. Availability.

By definition a b-masking quorum system can mask up to b arbitrary (Byzantine) failures. However, such a system may be resilient to more *benign* failures. By benign failures we mean any failures that render a server unresponsive, which we refer to as *crashes* to distinguish them from Byzantine failures.

The resilience f of a quorum system provides one measure of how many crash failures a quorum system is *guaranteed* to survive, and indeed this measure has been used in the past to differentiate among quorum systems [3]. However, it is possible that an f-resilient quorum system, though vulnerable to a few failure configurations of $f+1$ failures, can survive many configurations of more than f failures. One way to measure this property of a quorum system is to assume that each server crashes independently with probability p and then to determine the probability F_p that some quorum survives with no faulty members. This is known as *crash probability* and is formally defined as follows.

Definition 3.10. *Assume that each server in the system crashes independently with probability p. For every quorum $Q \in \mathcal{Q}$ let $\mathcal{E}_Q$ be the event that Q is* hit, *i.e., at least one element $i \in Q$ has crashed. Let $crash(\mathcal{Q})$ be the event that all the quorums $Q \in \mathcal{Q}$ were hit, i.e., $crash(\mathcal{Q}) = \bigwedge_{Q \in \mathcal{Q}} \mathcal{E}_Q$. Then the system crash probability is $F_p(\mathcal{Q}) = \mathbb{P}(crash(\mathcal{Q}))$.*

We would like F_p to be as small as possible. A desirable asymptotic behavior of F_p is that $F_p \to 0$ when $n \to \infty$ for *all* $p < 1/2$, and such an F_p is called Condorcet (after the Condorcet jury theorem [8]).

4. Building blocks. In this section, we prove several theorems which will be our basic tools in what follows. First we prove lower bounds on the load and availability of b-masking quorum systems, against which we measure all our new constructions. Then we prove the properties of a quorum composition technique, which we later use extensively.

4.1. The load and availability of masking quorum systems. We begin by establishing a lower bound on the load of b-masking quorum systems, thus tightening the lower bound on general quorum systems [31] as presented in [25].

Theorem 4.1. *Let $\mathcal{Q}$ be a b-masking quorum system. Then $\mathcal{L}(\mathcal{Q}) \geq \max\{\frac{2b+1}{c(\mathcal{Q})}, \frac{c(\mathcal{Q})}{n}\}$.*

Proof. Let w be any strategy for the quorum system $\mathcal{Q}$, and fix $Q_1 \in \mathcal{Q}$ such that $|Q_1| = c(\mathcal{Q})$. Summing the loads induced by w on all the elements of Q_1, and using the fact that any two quorums have at least $2b+1$ elements in common, we obtain

$$\sum_{u \in Q_1} l_w(u) = \sum_{u \in Q_1} \sum_{Q_i \ni u} w(Q_i) = \sum_{Q_i} \sum_{u \in (Q_1 \cap Q_i)} w(Q_i)$$
$$\geq \sum_{Q_i} (2b+1) w(Q_i) = 2b+1.$$

Therefore, there exists some element in Q_1 that suffers a load of at least $\frac{2b+1}{|Q_1|}$.

Similarly, summing the total load induced by w on all of the elements of the universe, and using the minimality of $c(\mathcal{Q})$, we get

$$\sum_{u \in U} l_w(u) = \sum_{u \in U} \sum_{Q_i \ni u} w(Q_i) = \sum_{Q_i} |Q_i| w(Q_i)$$
$$\geq \sum_{Q_i} c(\mathcal{Q}) w(Q_i) = c(\mathcal{Q}).$$

Therefore, there exists some element in U that suffers a load of at least $\frac{c(\mathcal{Q})}{n}$. ◻

Corollary 4.2. *Let $\mathcal{Q}$ be a b-masking quorum system. Then $\mathcal{L}(\mathcal{Q}) \geq \sqrt{\frac{2b+1}{n}}$, and equality holds if $c(\mathcal{Q}) = \sqrt{(2b+1)n}$.*[1]

Remark. Corollary 4.2 shows that the threshold construction of [25] in fact has optimal load when $b = \Omega(n)$. E.g., when $b \approx n/4$ the obtained load is ≈ 0.75, but for such systems we can only hope for a constant load of $\approx 1/\sqrt{2} = 0.707$. However, the load of the threshold construction is always $\geq 1/2$, which is far from optimal for smaller values of b.

On the other hand, the grid-based construction of [25] does not have optimal load. It has quorums of size $O(b\sqrt{n})$ and load of roughly $2b/\sqrt{n}$. In what follows we

[1]To avoid repetitive notation, we omit floor and ceiling brackets from expressions for integral quantities.

show systems which significantly improve this: some of our new constructions have quorums of size $O(\sqrt{bn})$ and optimal load.

Our next propositions show lower bounds on the crash probability F_p in terms of $\mathcal{MT}(\mathcal{Q})$ and b.

PROPOSITION 4.3. *Let $\mathcal{Q}$ be a quorum system. Then $F_p(\mathcal{Q}) \geq p^{\mathcal{MT}(\mathcal{Q})} = p^{f+1}$ for any $p \in [0,1]$.*

Proof. Consider a minimal transversal T with $|T| = \mathcal{MT}(\mathcal{Q})$. If all the elements of T crash, then every quorum contains a crashed element, so $F_p(\mathcal{Q}) \geq p^{\mathcal{MT}(\mathcal{Q})}$. ∎

PROPOSITION 4.4. *Let $\mathcal{Q}$ be a b-masking quorum system. Then $F_p(\mathcal{Q}) \geq p^{c(\mathcal{Q})-2b}$ for any $p \in [0,1]$.*

Proof. Let $Q \in \mathcal{Q}$ be a minimal quorum with $|Q| = c(\mathcal{Q})$, and consider $Z \subset Q$, $|Z| = 2b$. Since $\mathcal{Q}$ is b-masking, then $|R \cap Q| \geq 2b+1$ for any $R \in \mathcal{Q}$, and so $|(Q \setminus Z) \cap R| \geq 1$ and $Q \setminus Z$ is a transversal. Therefore $\mathcal{MT}(\mathcal{Q}) \leq c(\mathcal{Q}) - 2b$, which we plug into Proposition 4.3. ∎

The next proposition is less general than Proposition 4.4, but it is applicable for most of our constructions and it gives a much tighter bound.

PROPOSITION 4.5. *Let $\mathcal{Q}$ be a b-masking quorum system such that $\mathcal{MT}(\mathcal{Q}) \leq (\mathcal{IS}(\mathcal{Q})+1)/2$. Then $F_p(\mathcal{Q}) \geq p^{b+1}$ for any $p \in [0,1]$.*

Proof. If $\mathcal{MT}(\mathcal{Q}) \leq (\mathcal{IS}(\mathcal{Q})+1)/2$, then from Corollary 3.7 we have that $b+1 = \mathcal{MT}(\mathcal{Q})$, which again we plug into Proposition 4.3. ∎

4.2. Quorum system composition. Quorum system composition is a well-known technique for building new systems out of existing components. We compose a quorum system $\mathcal{S}$ over another system $\mathcal{R}$ by replacing each element of $\mathcal{S}$ with a distinct copy of $\mathcal{R}$. In other words, when element i is used in a quorum $S \in \mathcal{S}$ we replace it with a complete quorum from the ith copy of $\mathcal{R}$. Using the terminology of reliability theory, the system $\mathcal{S} \circ \mathcal{R}$ has a *modular decomposition* where each module is a copy of $\mathcal{R}$. Formally, we have the following.

DEFINITION 4.6. *Let $\mathcal{S}$ and $\mathcal{R}$ be two quorum systems, over universes of sizes n_S and n_R, respectively. Let $\mathcal{R}_1, \dots, \mathcal{R}_{n_S}$ be n_S copies of $\mathcal{R}$ over disjoint universes. Then the* composition *of $\mathcal{S}$ over $\mathcal{R}$ is*

$$\mathcal{S} \circ \mathcal{R} = \left\{ \bigcup R_i : S \in \mathcal{S}, R_i \in \mathcal{R}_i \text{ for all } i \in S \right\}.$$

The next theorem summarizes the properties of quorum composition.

THEOREM 4.7. *Let $\mathcal{S}$ and $\mathcal{R}$ be two quorum systems, and let $\mathcal{Q} = \mathcal{S} \circ \mathcal{R}$. Then*

- *The universe size is $n_Q = n_S n_R$.*
- *The minimal quorum size is $c(\mathcal{Q}) = c(\mathcal{S})c(\mathcal{R})$.*
- *The minimal intersection size is $\mathcal{IS}(\mathcal{Q}) = \mathcal{IS}(\mathcal{S})\mathcal{IS}(\mathcal{R})$.*
- *The minimal transversal size is $\mathcal{MT}(\mathcal{Q}) = \mathcal{MT}(\mathcal{S})\mathcal{MT}(\mathcal{R})$.*
- *Denote the crash probability functions of $\mathcal{S}$ and $\mathcal{R}$ by $s(p) = F_p(\mathcal{S})$ and $r(p) = F_p(\mathcal{R})$. Then $F_p(\mathcal{Q}) = s(r(p))$.*
- *The load is $\mathcal{L}(\mathcal{Q}) = \mathcal{L}(\mathcal{S})\mathcal{L}(\mathcal{R})$.*

Proof. The behavior of the combinatorial parameters n_Q, $c(\mathcal{Q})$, $\mathcal{IS}(\mathcal{Q})$, and $\mathcal{MT}(\mathcal{Q})$ is obvious. The behavior of $F_p(\mathcal{Q})$ is standard in reliability theory (cf. [5]). As for the load, consider the following strategy: pick a quorum $S \in \mathcal{S}$ using the optimal strategy for $\mathcal{S}$. Then for each element $i \in S$, pick a quorum $R_i \in \mathcal{R}_i$ using the optimal strategy for (the ith copy of) $\mathcal{R}$. Clearly this strategy induces a load of $\mathcal{L}(\mathcal{S})\mathcal{L}(\mathcal{R})$, and hence $\mathcal{L}(\mathcal{Q}) \leq \mathcal{L}(\mathcal{S})\mathcal{L}(\mathcal{R})$.

We now show the inequality in the opposite direction. Enumerate the elements of $\mathcal{Q}$ by denoting the jth element in $\mathcal{R}_i$ by u_{ij}, let $Q(S) = \{\bigcup R_i : R_i \in \mathcal{R}_i \text{ for all } i \in S\}$

be the set of all quorums that are based on some $S \in \mathcal{S}$, and let $w^{\mathcal{Q}}$ be an access strategy on $\mathcal{Q}$. Then $w^{\mathcal{Q}}$ induces a strategy $w^{\mathcal{S}}$ on $\mathcal{S}$ defined by

$$w^{\mathcal{S}}(S) = \sum_{Q \in Q(S)} w^{\mathcal{Q}}(Q). \tag{4.1}$$

The load on an element $i \in \mathcal{S}$ (i.e., the frequency of accessing the quorum system $\mathcal{R}_i$) is then $l_{w^{\mathcal{S}}}(i) = \sum_{S \ni i, S \in \mathcal{S}} w^{\mathcal{S}}(S)$. Similarly, $w^{\mathcal{Q}}$ induces a strategy on each copy $\mathcal{R}_i$ defined by

$$w^{\mathcal{R}_i}(R) = \left(\sum_{Q \supseteq R} w^{\mathcal{Q}}(Q) \right) \Big/ l_{w^{\mathcal{S}}}(i). \tag{4.2}$$

This $w^{\mathcal{R}_i}$ is well defined when $l_{w^{\mathcal{S}}}(i) > 0$. It is easy to verify that $w^{\mathcal{S}}$ and $w^{\mathcal{R}_i}$ are indeed strategies, i.e., that the probabilities add up to 1.

CLAIM 4.8. *Let $l_{w^{\mathcal{Q}}}(u_{ij})$ be the load induced by $w^{\mathcal{Q}}$ on an element $u_{Ij} \in \mathcal{R}_i$, and let $l_{w^{\mathcal{R}_i}}(u_{ij})$ be the load induced on it by $w^{\mathcal{R}_i}$. Then $l_{w^{\mathcal{Q}}}(u_{ij}) = l_{w^{\mathcal{S}}}(i) \cdot l_{w^{\mathcal{R}_i}}(u_{ij})$.*

Proof of Claim. Using (4.1) and (4.2) we have that

$$\begin{aligned} l_{w^{\mathcal{S}}}(i) \cdot l_{w^{\mathcal{R}_i}}(u_{ij}) = l_{w^{\mathcal{S}}}(i) \sum_{R \ni u_{ij}} w^{\mathcal{R}_i}(R) \;&=\; l_{w^{\mathcal{S}}}(i) \sum_{R \ni u_{ij}} \left(\sum_{Q \supseteq R} w^{\mathcal{Q}}(Q) \right) \Big/ l_{w^{\mathcal{S}}}(i) \\ &= \sum_{R \ni u_{ij}} \sum_{Q \supseteq R} w^{\mathcal{Q}}(Q) \;=\; \sum_{Q \ni u_{ij}} w^{\mathcal{Q}}(Q) \;=\; l_{w^{\mathcal{Q}}}(u_{ij}). \qquad \square \end{aligned}$$

To complete the proof of Theorem 4.7, assume that $w^{\mathcal{Q}}$ is an optimal strategy for $\mathcal{Q}$. Consider the copy $\mathcal{R}_i$ for which $l_{w^{\mathcal{S}}}(i)$ is maximal, i.e., $\mathcal{L}_{w^{\mathcal{S}}}(\mathcal{S}) = l_{w^{\mathcal{S}}}(i)$, and let u_{ij} be the maximally loaded element in this $\mathcal{R}_i$. Clearly $l_{w^{\mathcal{S}}}(i) > 0$ so $w^{\mathcal{R}_i}$ is well defined for this i. Note that we do not require u_{ij} to be the maximally loaded element in all of $\mathcal{Q}$. Using the claim and the minimality of $\mathcal{L}(\mathcal{S})$ and $\mathcal{L}(\mathcal{R})$ we obtain that

$$\begin{aligned} \mathcal{L}(\mathcal{Q}) = \mathcal{L}_{w^{\mathcal{Q}}}(\mathcal{Q}) \;&\geq\; l_{w^{\mathcal{Q}}}(u_{ij}) \;=\; l_{w^{\mathcal{S}}}(i) \cdot l_{w^{\mathcal{R}_i}}(u_{ij}) \\ &= \mathcal{L}_{w^{\mathcal{S}}}(\mathcal{S}) \cdot \mathcal{L}_{w^{\mathcal{R}_i}}(\mathcal{R}) \;\geq\; \mathcal{L}(\mathcal{S})\mathcal{L}(\mathcal{R}). \end{aligned}$$

By combining this inequality with the upper bound we had before we conclude that $\mathcal{L}(\mathcal{Q}) = \mathcal{L}(\mathcal{S})\mathcal{L}(\mathcal{R})$. $\square$

The multiplicative behavior of the combinatorial parameters in composing quorum systems provides a powerful tool for "boosting" existing constructions into larger systems with possibly improved characteristics. Below, we use quorum composition in two cases and demonstrate that this technique yields improved constructions over their basic building blocks, for appropriately larger system sizes. In particular, in section 6 we show a composition that allows us to transform any regular quorum construction into a (larger) b-masking quorum system.

5. Simple systems.

In this section we show two types of constructions, M-Grid and RT. These systems significantly improve upon the original constructions of [25]; however, both are still suboptimal in some parameter: M-Grid has optimal load but can mask only up to $b = O(\sqrt{n})$ failures and has poor crash probability; and RT can mask up to $b = O(n)$ failures and has near-optimal crash probability but has suboptimal load.

In sections 6 and 7 we present systems which are superior to the M-Grid and RT. Nonetheless, we feel that the simplicity of the M-Grid and RT systems, and the fact that they are suitable for very small universe sizes, are what makes them appealing.

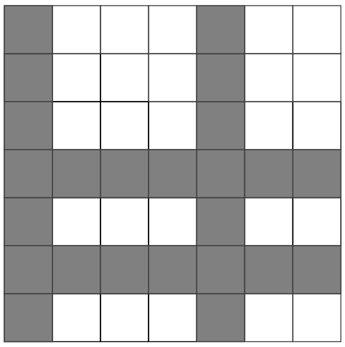

FIG. 1. *The multigrid construction, $n = 7 \times 7, b = 3$, with one quorum shaded.*

5.1. The M-Grid system. We begin with the M-Grid system, which achieves an optimal load among b-masking quorum systems, where $b \leq (\sqrt{n} - 1)/2$. The idea of the construction is as follows. Arrange the elements in a $\sqrt{n} \times \sqrt{n}$ grid. A quorum in an M-Grid consists of any choice of $\sqrt{b+1}$ rows and $\sqrt{b+1}$ columns, as shown in Figure 1. Formally, denote the rows and columns of the grid by R_i and C_i, respectively, where $1 \leq i \leq \sqrt{n}$. Then, the quorum system is

$$\text{M-Grid}(b) = \left\{ \bigcup_{j \in J} C_j \cup \bigcup_{i \in I} R_i : J, I \subseteq \{1 \dots \sqrt{n}\}, |J| = |I| = \sqrt{b+1} \right\}.$$

PROPOSITION 5.1. *The multigrid* M-Grid(b) *is a b-masking quorum system for* $b \leq (\sqrt{n} - 1)/2$.

Proof. Consider two quorums $R, S \in$ M-Grid(b). If they have either a row or a column in common, then $|R \cap S| \geq \sqrt{n} \geq 2b + 1$ and we are done. Otherwise the intersection of S's columns with R's rows is disjoint from the intersection of R's columns with S's rows, so $|R \cap S| \geq 2\sqrt{b+1}\sqrt{b+1} > 2b + 1$. Therefore consistency holds.

Resilience holds since $f = \mathcal{MT}(\text{M-Grid}(b)) - 1 = \sqrt{n} - \sqrt{b+1} \geq b$. Therefore $\mathcal{MT}(\text{M-Grid}(b)) \geq b + 1$, and Lemma 3.6 finishes the proof. □

PROPOSITION 5.2. $\mathcal{L}(\text{M-Grid}(b)) \approx 2\sqrt{\frac{b+1}{n}}$.

Proof. Since M-Grid(b) is fair we can use Proposition 3.9 to get $\mathcal{L}(\text{M-Grid}(b)) = c(\text{M-Grid}(b))/n$. □

Remark. The load of M-Grid(b) is within a factor of $\sqrt{2}$ from the optimal load which can be achieved for $b \approx \sqrt{n}/2$.

A disadvantage of the M-Grid system is its poor asymptotic crash probability. If crashes occur with some constant probability p, then any configuration of crashes with at least one crash per row disables the system. Therefore, as shown by [20, 40],

$$F_p(\text{M-Grid}) \geq (1 - (1-p)^{\sqrt{n}})^{\sqrt{n}} \underset{n \to \infty}{\longrightarrow} 1.$$

5.2. RT systems. An RT system RT(k, ℓ) of depth h is built by taking a simple building block, which is an ℓ-of-k threshold system (with $k > \ell > k/2$), and recursively composing it over itself to depth h. In what follows, we often omit the depth parameter h when it has no effect on the discussion. The RT systems generalize the recursive

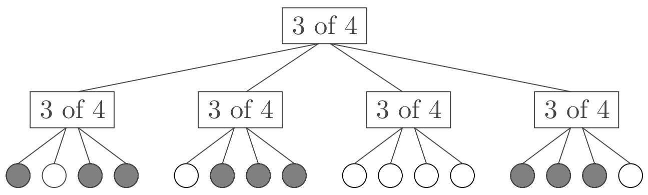

FIG. 2. *An* RT(4, 3) *system of depth $h = 2$, with one quorum shaded.*

majority constructions of [29], the HQC system of [19] is an RT(3, 2) system, and in fact the threshold system of [25] can be viewed as a trivial RT$(4b+1, 3b+1)$ system with depth $h = 1$. As an example throughout this section we will use the RT(4, 3) system, depicted in Figure 2.

PROPOSITION 5.3. *An* RT(k, ℓ) *system of depth h is a fair quorum system, with $n = k^h$ elements, quorums of size* $c(\mathrm{RT}(k,\ell)) = \ell^h$, *intersection size of* $\mathcal{IS}(\mathrm{RT}(k,\ell)) = (2\ell - k)^h$, *and minimal transversals of size* $\mathcal{MT}(\mathrm{RT}(k,\ell)) = (k - \ell + 1)^h$.

Proof. The basic ℓ-of-k system is symmetric (and therefore fair), with $c(\ell\text{-of-}k) = \ell$, $\mathcal{MT}(\ell\text{-of-}k) = k - \ell + 1$, and $\mathcal{IS}(\ell\text{-of-}k) = 2\ell - k$. The combinatorial parameters are computed by activating Theorem 4.7 h times and the composition preserves the fairness. □

Plugging this into Corollary 3.7 we obtain the following.

COROLLARY 5.4. *An* RT(k, ℓ) *system over a universe of size n is a b-masking quorum system for*

$$b = \min\{(n^{\log_k(2\ell-k)} - 1)/2, n^{\log_k(k-\ell+1)} - 1\}. \qquad \square$$

In the 3-of-4 example we have $\mathcal{IS}(\text{3-of-4}) = \mathcal{MT}(\text{3-of-4}) = 2$ and $c(\text{3-of-4}) = 3$. Therefore for the whole system (to depth $\log_4 n$) we get $c(\mathrm{RT}(4,3)) = n^{\log_4 3} = n^{0.79}$, with $\mathcal{IS}(\mathrm{RT}(4,3)) = \mathcal{MT}(\mathrm{RT}(4,3)) = \sqrt{n}$ and thus $b = (\sqrt{n} - 1)/2$. Note that the basic 3-of-4 system is not even 1-masking since intersections of size 2 are too small; however, already from $h = 2$ (i.e., $n = 16$) we obtain a masking system.

PROPOSITION 5.5. *The load* $\mathcal{L}(\mathrm{RT}(k,\ell)) = n^{-(1-\log_k \ell)}$.

Proof. Since RT(k, ℓ) is fair we can use Proposition 3.9 to get $\mathcal{L}(\mathrm{RT}(k,\ell)) = c(\mathrm{RT}(k,\ell))/n$. □

Remark. In general the load is suboptimal for this construction. For instance, in the RT(4, 3) system we obtain $\mathcal{L}(\mathrm{RT}(4,3)) = n^{-0.21}$. However for $b = (\sqrt{n} - 1)/2$ we could hope for a load of $\sqrt{(2b+1)/n} = n^{-0.25}$.

PROPOSITION 5.6. *There exists a unique critical probability* $0 < p_c < 1/2$ *for which*

$$\lim_{h\to\infty} F_p(\mathrm{RT}(k,\ell) \text{ of depth } h) = \begin{cases} 0, & p < p_c, \\ 1, & p > p_c. \end{cases}$$

Proof. Let $g(p)$ be the crash probability function of the ℓ-of-k system and let $F(h) = F_p(\mathrm{RT}(k,\ell) \text{ of depth } h)$ denote the crash probability for the RT(k, ℓ) system of depth h. Then $F(h)$ obeys the recurrence

$$F(h) = \begin{cases} g(F(h-1)), & h \geq 1, \\ p, & h = 0. \end{cases} \tag{5.1}$$

Now $g(p)$ is a reliability function, and therefore it is "S-shaped" (see [5]). This implies that there exists a unique critical probability $0 < p_c < 1$ for which $g(p_c) = p_c$, such that $g(p) < p$ when $p < p_c$ and $g(p) > p$ when $p > p_c$ (and [34] shows that for quorum systems such as RT in fact $p_c < 1/2$). Therefore if $p < p_c$, then repeated applications of recurrence (5.1) would decrease $F(h)$ arbitrarily close to 0, and when $p > p_c$ the limit is 1. ◻

PROPOSITION 5.7. *If $p < 1/\binom{k}{\ell-1}$ and $\ell < k$, then $F_p(\mathrm{RT}(k,\ell)) < \exp(-\Omega(n^{\log_k(k-\ell+1)}))$, which is optimal for systems with resilience $f = n^{\log_k(k-\ell+1)}$.*

Proof. Let $g(p)$ and $F(h)$ be as in the proof of Proposition 5.6. Any configuration of at least $k-\ell+1$ crashes disables the ℓ-of-k system, so

$$g(p) = \sum_{j=k-\ell+1}^{k} \binom{k}{j} p^j (1-p)^{k-j}.$$

By Lemma A.2 (see Appendix A) we have that

$$g(p) \le \binom{k}{\ell-1} p^{k-\ell+1}.$$

Plugging this into (5.1) gives that

$$\begin{aligned} F(h) &\le \binom{k}{\ell-1}^{1+(k-\ell+1)+\cdots+(k-\ell+1)^{h-1}} p^{(k-\ell+1)^h} \\ &< \left[\binom{k}{\ell-1} p\right]^{(k-\ell+1)^h}. \end{aligned}$$

If $p < 1/\binom{k}{\ell-1}$, then the last expression decays to zero with h, so $F_p(\mathrm{RT}(k,\ell)) < \exp(-\Omega(n^{\log_k(k-\ell+1)}))$.

The lower bound of Proposition 4.3 shows that

$$F_p(\mathrm{RT}(k,\ell)) \ge p^{n^{\log_k(k-\ell+1)}},$$

so our analysis is tight. ◻

For the $\mathrm{RT}(4,3)$ system a direct calculation shows that $g(p) = 6p^2 - 8p^3 + 3p^4$ and $p_c = 0.2324$. Therefore Proposition 5.6 guarantees that when the element crash probability is in the range $p < 0.2324$, then $F_p \to 0$ when $n \to \infty$. Furthermore, when $p < 1/6$ then Proposition 5.7 shows that the decay is rapid, with $F_p(\mathrm{RT}(4,3)) < (6p)^{\sqrt{n}}$, which is optimal.

6. boostFPP.

In this section we introduce a family of b-masking quorum systems, the *boosted finite projective planes*, which we denote by boostFPP. A boostFPP system is a composition of a finite projective plane (FPP) over a threshold system (Thresh).

The first component of a boostFPP system is an FPP of order q (a good reference on FPPs is [14]). It is known that FPPs exist for $q = p^r$ when p is prime. Such an FPP has $n_F = q^2 + q + 1$ elements and quorums of size $c(\mathrm{FPP}) = q + 1$. This is a regular quorum system, i.e., it has intersections of size $\mathcal{IS}(\mathrm{FPP}) = 1$. The minimal transversals of an FPP are of size $\mathcal{MT}(\mathrm{FPP}) = q + 1$ (in fact the only transversals of this size are the quorums themselves). The load of FPP was analyzed in [31] and shown to be $\mathcal{L}(\mathrm{FPP}) = \frac{q+1}{n_F} \approx 1/\sqrt{n_F}$, which is optimal for regular quorum systems.

The second component of a boostFPP is a Thresh system, with $n_T = 4b+1$ elements and a threshold of $3b+1$. This is a b-masking quorum system in itself, with $\mathcal{IS}(\text{Thresh}) = 2b+1$, $\mathcal{MT}(\text{Thresh}) = b+1$, and a load of $\mathcal{L}(\text{Thresh}) \approx 3/4$.

PROPOSITION 6.1. *Let* $\text{boostFPP}(q,b) = \text{FPP}(q) \circ \text{Thresh}(3b+1 \text{ of } 4b+1)$. *Then the composed system has* $n = (4b+1)(q^2+q+1)$ *elements, with quorums of size* $c(\text{boostFPP}(q,b)) = (3b+1)(q+1)$*, intersections of size* $\mathcal{IS}(\text{boostFPP}(q,b)) = 2b+1$*, and minimal transversals of size* $\mathcal{MT}(\text{boostFPP}(q,b)) = (b+1)(q+1)$*. Therefore* $\text{boostFPP}(q,b)$ *is a* b*-masking quorum system.*

Proof. We obtain the combinatorial parameters by plugging the values of the component systems into Theorem 4.7. By Corollary 3.7 we have that the system can mask $\min\{(b+1)(q+1)-1, b\} = b$ failures. $\square$

PROPOSITION 6.2. $\mathcal{L}(\text{boostFPP}(q,b)) \approx \frac{3}{4q}$*, which is optimal for* b*-masking quorum systems with* $n \approx 4bq^2$ *elements.*

Proof. $\text{boostFPP}(q,b)$ is a fair quorum system since both its components are fair, so by Proposition 3.9 we have

$$\mathcal{L}(\text{boostFPP}(q,b)) = \frac{c(\text{boostFPP}(q,b))}{n} = \frac{(3b+1)(q+1)}{(4b+1)(q^2+q+1)} \approx \frac{3}{4q}.$$

On the other hand, for b-masking systems with $n \approx 4bq^2$ elements the lower bound of Theorem 4.1 gives

$$\mathcal{L}(\text{boostFPP}(q,b)) \geq \sqrt{\frac{2b}{n}} \approx \frac{1}{\sqrt{2}q}. \qquad \square$$

Note that the optimality of the load holds for *any* choice of q and b. Therefore when the number of servers (or elements) increases, the $\text{boostFPP}(q,b)$ system can scale up using different policies while maintaining load optimality. There are two extremal policies:

(1) Fix q and increase b; then the system can mask more failures when new servers are added; however, the load on the servers does not decrease.

(2) Fix b and increase q; then the load decreases when new servers are added, but the number of failures that the system can mask remains unchanged.

It is important to note that systems of arbitrarily high resilience can be constructed using the first policy since b can be chosen independently of q. In particular, we can choose $b = q^a$ for any $a > 0$. Then the resulting system has $n \approx 4bq^2 = 4b^{\frac{a+2}{a}}$, and so $b \approx \left(\frac{n}{4}\right)^{\frac{a}{a+2}}$, thus asymptotically approaching the resilience upper bound of $\frac{n}{4}$.

Finally we analyze the crash probability of boostFPP. The following proposition shows that boostFPP has good availability as long as $p < 1/4$.

PROPOSITION 6.3. *If* $p < 1/4$*, then* $F_p(\text{boostFPP}(q,b)) \leq \exp(-\Omega(b - \log q))$.

Proof. We start by estimating $F_p(\text{Thresh})$. Let *#crashed* denote the number of crashed elements in a universe of size $4b+1$. Let $\gamma = \frac{b+1}{4b+1} - p$; thus $0 < \gamma < 1$ when $p < 1/4$. Then using the Chernoff bound we obtain

$$\begin{aligned} F_p(\text{Thresh}) &= \mathbb{P}(\#\textit{crashed} \geq b+1) \\ &= \mathbb{P}(\#\textit{crashed} \geq (p+\gamma)(4b+1)) \\ &\leq e^{-2(4b+1)\gamma^2} \approx e^{-b(1-4p)^2/2}. \end{aligned} \tag{6.1}$$

Next we estimate $F_p(\text{FPP})$. Let $Q_0 \in \text{FPP}$ be some quorum. Then

$$F_p(\text{FPP}) = 1 - \mathbb{P}(\text{there exists } Q \in \text{FPP} : Q \text{ is alive})$$
$$\leq 1 - \mathbb{P}(Q_0 \text{ is alive}) = 1 - (1-p)^{q+1} \leq (q+1)p. \tag{6.2}$$

Using Theorem 4.7 we plug (6.1) into (6.2) to obtain

$$F_p(\text{boostFPP}(q,b)) \leq (q+1)e^{-b(1-4p)^2/2} = e^{-\Omega(b-\log q)}. \qquad \square$$

Remarks.

- In general the crash probability is not optimal; since $\mathcal{MT}(\text{boostFPP}(q,b)) \approx bq$ then the lower bound of Proposition 4.3 shows we could hope for a crash probability of $\exp(-\Omega(bq))$. Nevertheless if q is constant, then F_p is asymptotically optimal, and if $b \gg q$, then the gap between the upper and lower bounds is small.
- The final estimate we get for $F_p(\text{boostFPP})$ seems poor, as the bound is *higher* than the crash probability of the Thresh components. However, this is not an artifact of overestimates in our analysis. Rather, it is a result of the property that the crash probability of FPP is higher than p, and in fact $F_p(\text{FPP}) \to 1$ as shown by [37, 40]. In this light it is not surprising that boostFPP does not have an optimal crash probability.
- The requirement $p < 1/4$ is essential for this system; if $p > 1/4$, then in fact $F_p(\text{boostFPP}) \to 1$ as $n \to \infty$.

7. The M-Path system.

Here we introduce the construction we call the multipath system, denoted by M-Path. The elements of this system are the vertices of a triangulated square $\sqrt{n} \times \sqrt{n}$ grid; formally, the vertices are the points $\{(i,j) \in \mathbb{R}^2 : 1 \leq i,j \leq \sqrt{n};\ i,j \in \mathbb{Z}\}$. The triangulated grid has an edge between (i_1, j_1) and (i_2, j_2) if one of the following three conditions holds: (i) $i_1 = i_2$ and $j_2 = j_1 + 1$; (ii) $j_1 = j_2$ and $i_2 = i_1 + 1$; (iii) $i_2 = i_1 - 1$ and $j_2 = j_1 + 1$. A quorum in the M-Path system consists of $\sqrt{2b+1}$ disjoint paths from the left side to the right side of the grid (LR paths) and $\sqrt{2b+1}$ disjoint top-bottom (TB) paths (see Figure 3).

The M-Path system has several characteristics similar to the basic M-Grid system of section 5, namely an ability to mask $b = O(\sqrt{n})$ failures and optimal load. Its major advantage is that it also has an optimal crash probability F_p. Moreover, it is the only construction we have for which $F_p \to 0$ as $n \to \infty$ when the individual crash probability p is arbitrarily close to $1/2$. We are able to prove this behavior of F_p using results from percolation theory [18, 13].

Remark. The system we present here is based on a triangular lattice, with elements corresponding to vertices, as in [41, 6]. We have also constructed a second system which is based on the square lattice with elements corresponding to the edges, as in [31]. The properties of this second system are almost identical to those of M-Path, so we omit it.

PROPOSITION 7.1. *M-Path(b) has minimal quorums of size $c(\text{M-Path}) \leq 2\sqrt{n(2b+1)}$, minimal intersections of size $\mathcal{IS}(\text{M-Path}) \geq 2b+1$, and minimal transversals of size $\mathcal{MT}(\text{M-Path}) = \sqrt{n} - \sqrt{2b+1} + 1$. Therefore M-Path is a b-masking quorum system for $b \leq \sqrt{n} - \sqrt{2}n^{1/4}$.*

Proof. Let $Q_1, Q_2 \in \text{M-Path}(b)$. Then the $\sqrt{2b+1}$ LR paths of Q_1 intersect the $\sqrt{2b+1}$ TB paths of Q_2 in $\geq 2b+1$ elements, since the LR and TB paths are disjoint. As in the M-Grid system we have that $\mathcal{MT}(\text{M-Path}(b)) = \sqrt{n} - \sqrt{2b+1} + 1$, so when $b \leq \sqrt{n} - \sqrt{2}n^{1/4}$ it follows that $\mathcal{MT}(\text{M-Path}(b)) \geq b+1$ and we are done. $\square$

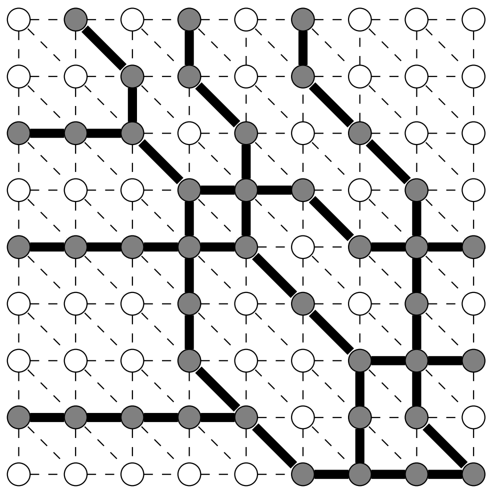

FIG. 3. *A multipath construction on a 9×9 grid, $b = 4$, with one quorum shaded.*

PROPOSITION 7.2. *$\mathcal{L}(\text{M-Path}(b)) \le 2\sqrt{\frac{2b+1}{n}}$, which is optimal.*

Proof. The strategy only uses straight line LR and TB paths. It picks $\sqrt{2b+1}$ of the $\sqrt{n}$ rows uniformly at random and likewise for the columns. Clearly the load equals the probability of accessing some element in position i, j, which is

$$\begin{aligned}\mathcal{L}(\text{M-Path}) &\le \mathbb{P}(\text{row } i \text{ chosen}) + \mathbb{P}(\text{column } j \text{ chosen})\\ &\le 2\binom{\sqrt{n}-1}{\sqrt{2b+1}-1}\Big/\binom{\sqrt{n}}{\sqrt{2b+1}}\\ &= 2\sqrt{2b+1}/\sqrt{n}.\end{aligned}$$

By Corollary 4.2 this is optimal. □

PROPOSITION 7.3. *$F_p(\text{M-Path}(b)) \le \exp(-\Omega(\sqrt{n} - \sqrt{b}))$ for any $p < 1/2$, which is optimal for systems with resilience $f = O(\sqrt{n} - \sqrt{b})$.*

Proof. We use the notation $\mathbb{P}_p(\mathcal{E})$ to denote the probability of event $\mathcal{E}$ defined on the grid when the individual crash probability is p. A path is called "open" if all its elements are alive.

Let LR be the event "there exists an open LR path in the grid," and let LR_k be the event "there exist k open LR paths." A failure configuration in M-Path(b) is one in which either $\sqrt{2b+1}$ open LR paths or $\sqrt{2b+1}$ open TB paths do not exist. By symmetry we have that

$$F_p(\text{M-Path}(b)) \le 2\mathbb{P}_p(\overline{LR_{\sqrt{2b+1}}}) = 2(1 - \mathbb{P}_p(LR_{\sqrt{2b+1}})). \tag{7.1}$$

Fix some p' such that $p < p' < 1/2$. Then by Theorem B.3 (see Appendix B) we have that

$$1 - \mathbb{P}_p(LR_{\sqrt{2b+1}}) \le \left(\frac{1-p}{p'-p}\right)^{\sqrt{2b+1}-1} [1 - \mathbb{P}_{p'}(LR)]. \tag{7.2}$$

TABLE 2
Constructions in this paper (n = number of servers).

System	$b <$	f	$\mathcal{L}$	F_p
Threshold [25]	$n/4$	$O(n-b)$	$1/2 + O(b/n)$	$\exp(-\Omega(f))$ *
Grid [25]	$\sqrt{n}/3$	$O(\sqrt{n}-b)$	$O(b/\sqrt{n})$	$\underset{n\to\infty}{\longrightarrow} 1$
M-Grid	$\sqrt{n}/2$	$O(\sqrt{n}-\sqrt{b})$	$O(\sqrt{b/n})$ †	$\underset{n\to\infty}{\longrightarrow} 1$
RT(k, ℓ)‡	$O(\min\{n^{\alpha_1}, n^{\alpha_2}\})$ ‡	$O(b)$	$n^{-(1-\log_k \ell)}$	$\exp(-\Omega(f))$ *
boostFPP	$n/4$	$O(\sqrt{bn})$	$O(\sqrt{b/n})$ †	$\exp(-\Omega(b - \log(n/b)))$
M-Path	$(1-o(1))\sqrt{n}$	$O(\sqrt{n}-\sqrt{b})$	$O(\sqrt{b/n})$ †	$\exp(-\Omega(f))$ *

† Optimal for b-masking systems
* Optimal for f-resilient systems
‡ $\alpha_1 = \log_k(2\ell - k)$ and $\alpha_2 = \log_k(k - \ell + 1)$

Plugging the bound on $\mathbb{P}_{p'}(LR)$ from Theorem B.1 into (7.2) and (7.1) yields

$$\begin{aligned} F_p(\text{M-Path}(b)) &\le 2\left(\frac{1-p}{p'-p}\right)^{\sqrt{2b+1}-1} e^{-\psi(p')\sqrt{n}} \\ &= 2e^{-\psi(p')\sqrt{n}+(\sqrt{2b+1}-1)\ln\left(\frac{1-p}{p'-p}\right)} \end{aligned}$$

for some function $\psi(p') > 0$. Now $\sqrt{2b+1} = O(n^{1/4})$, so for large enough n we can certainly write

$$F_p(\text{M-Path}(b)) \le \exp(-\Omega(\sqrt{n} - \sqrt{b})).$$

This is optimal by Proposition 4.3. □

8. Discussion. We have presented four novel constructions of b-masking quorum systems. For the first time in this context, we considered the resilience of such systems to crash failures in addition to their tolerance of (possibly fewer) Byzantine failures. Each of our constructions is optimal in either its load or its crash probability (for sufficiently small p). Moreover, one of our constructions, namely M-Paths, is optimal in both measures. One of our constructions is achieved using a novel boosting technique that makes all known benign fault-tolerant quorum constructions available for Byzantine environments (of appropriate sizes). In proving optimality of our constructions, we also contribute lower bounds on the load and crash probability of any b-masking quorum system.

The properties of our various constructions are summarized in Table 2, alongside the properties of two other b-masking constructions proposed in [25], namely Threshold and Grid.

Determining the best quorum construction depends on the goals and constraints of any particular settings, as no system is advantageous in all measures. For example, suppose we fix n to be 1024, the desired load $\mathcal{L}$ to be approximately 1/4, and assume that the individual failure probability of components is 1/8. In these settings, an M-Grid system can tolerate $b = 15$ Byzantine failures and up to $f = 28$ benign failures, but it has a failure probability $F_p \ge 0.638$. In the same settings, a boostFPP system (with $n = 1001$, $q = 3$) can tolerate $b = 19$, up to $f = 79$ benign failures, with somewhat better failure probability: it has $F_p \le 0.372$. The M-Path construction, with four LR and four TB paths per quorum, has $b = 7$ here and can tolerate up to $f = 29$ benign failures, but it has a good crash probability: $F_p \le 0.001$ (using the estimate following Theorem B.1, together with Theorem B.3 with $p' = 1/7$). In this setting, the RT$(4,3)$ construction, with depth $h = 5$, is the best, with $b = 15$, $f = 31$, and an excellent failure probability of only $F_p \le 0.0001$.

More generally, if masking large numbers of Byzantine server failures is important, then of the systems listed in Table 2, only Threshold and boostFPP can provide the highest possible masking ability, i.e., up to $b < n/4$. However, Threshold can mask $n/4$ Byzantine failures for any system size, whereas boostFPP approaches such degree of Byzantine resilience only for very large n. If, on the other hand, load is more crucial, then Threshold suffers in load whereas boostFPP offers reduced load, as do the other three systems in this paper, albeit with lower masking ability. If masking fewer Byzantine server failures is allowable, then other quorum constructions can be used, in particular RT and M-Path. These two constructions have similar masking ability, resilience, and load, but M-Path has asymptotically superior crash probability when p is close to $1/2$.

Finally, we note that it is impossible to achieve optimal resilience and load simultaneously: since necessarily $f \le c(\mathcal{Q})$, Theorem 4.1 implies that $f \le n\mathcal{L}(\mathcal{Q})$, i.e., when load is low then so is resilience, and when resilience is high then so is load. In order to break this trade-off, in [28] we propose relaxing the intersection property of masking quorum systems, so that "quorums" chosen according to a specific strategy intersect each other in enough correct servers to maintain correctness of the system with a high probability.

Appendix A. Combinatorial lemmas.

Lemma A.1. *Let $0 \le i, d \le k$ be integers. Then* $\frac{\binom{k}{d+i}}{\binom{k}{d}} \le \binom{k-d}{i}$.

Proof.

$$\frac{\binom{k}{d+i}}{\binom{k}{d}} = \frac{k!d!(k-d)!}{(d+i)!(k-d-i)!k!} = \frac{(k-d)!}{(k-d-i)!}\frac{d!}{(d+i)!} \le \frac{(k-d)!}{(k-d-i)!i!} = \binom{k-d}{i}. \qquad \square$$

Lemma A.2. *Let $0 \le d \le k$ be integers and let $p \in [0,1]$. Then*

$$\sum_{j=d}^{k} \binom{k}{j} p^j (1-p)^{k-j} \le \binom{k}{d} p^d.$$

Proof.

$$\sum_{j=d}^{k} \binom{k}{j} p^j (1-p)^{k-j} = \binom{k}{d} p^d \sum_{j=d}^{k} \frac{\binom{k}{j}}{\binom{k}{d}} p^{j-d}(1-p)^{k-j},$$

so it suffices to show that the last sum is ≤ 1. But using Lemma A.1 we get

$$\sum_{j=d}^{k} \frac{\binom{k}{j}}{\binom{k}{d}} p^{j-d}(1-p)^{k-j} = \sum_{i=0}^{k-d} \frac{\binom{k}{d+i}}{\binom{k}{d}} p^i (1-p)^{k-d-i}$$
$$\le \sum_{i=0}^{k-d} \binom{k-d}{i} p^i (1-p)^{k-d-i} = [p + (1-p)]^{k-d} = 1. \qquad \square$$

Appendix B. Theorems of percolation theory. In this section we list the definitions and results that are used in our analysis of the M-Path system, following [18, 13].

The percolation model we are interested in is as follows. Let $\mathbb{Z}$ be the graph of the (infinite) triangle lattice in the plane. Assume that a vertex is *closed* with probability p and *open* with probability $1 - p$, independently of other vertices. This model is known as site percolation on the triangle lattice. Another natural model, which plays a minor role in our work, is the bond percolation model. In it the *edges* are closed with probability p.

A key idea in percolation theory is that there exists a *critical probability*, p_c, such that graphs with $p < p_c$ exhibit qualitatively different properties than graphs with $p > p_c$. For example, $\mathbb{Z}$ with $p < p_c$ has a single connected (open) component of infinite size. When $p > p_c$ there is no such component. For site percolation on the triangle $p_c = 1/2$ [17].

The following theorem shows that when the probability p for a closed vertex is below the critical probability, the probability of having long open paths tends to 1 exponentially fast. Recall that LR is the event "there exists an open LR path in the $\sqrt{n} \times \sqrt{n}$ grid." Then [30] (see also [13, p. 287]) implies the following.

THEOREM B.1. *If $p < 1/2$, then $\mathbb{P}_p(LR) \geq 1 - e^{-\psi(p)\sqrt{n}}$, for some $\psi(p) > 0$ independent of n.*

Remark. The dependence of ψ on p is such that $\psi(p) \to 0$ when $p \to 1/2$. However, for p's not too close to $1/2$ we can obtain concrete estimates using elementary techniques. For instance, a counting argument similar to that of Bazzi [6] shows that

$$\mathbb{P}_p(LR) \geq 1 - \frac{\sqrt{n}(3p)^{\sqrt{n}}}{1 - 3p},$$

when $p < 1/3$.

DEFINITION B.2. *Let $\mathcal{E}$ be an event defined in the percolation model. Then the* interior *of $\mathcal{E}$ with depth r, denoted $I_r(\mathcal{E})$, is the set of all configurations in $\mathcal{E}$ which are still in $\mathcal{E}$ even if we perturb the states of up to r vertices.*

We may think of $I_r(\mathcal{E})$ as the event that $\mathcal{E}$ occurs and is "stable" with respect to changes in the states of r or fewer vertices. The definition is useful to us in the following situation. If LR is the event "there exists an open left-right path in a rectangle D," then it follows that $I_r(LR)$ is the event "there are at least $r+1$ disjoint open left-right paths in D."

THEOREM B.3 (see [2]). *Let $\mathcal{E}$ be an increasing event and let r be a positive integer. Then*

$$1 - \mathbb{P}_p(I_r(\mathcal{E})) \leq \left(\frac{1-p}{p'-p}\right)^r [1 - \mathbb{P}_{p'}(\mathcal{E})]$$

whenever $0 \leq p < p' \leq 1$.

The theorem amounts to the assertion that if $\mathcal{E}$ is likely to occur when the crash probability is p', then $I_r(\mathcal{E})$ is likely to occur when the crash probability p is smaller than p'.

AN ONLINE ALGORITHM FOR IMPROVING PERFORMANCE IN NAVIGATION[*]

AVRIM BLUM[†] AND PRASAD CHALASANI[‡]

Abstract. We consider the following scenario. A point robot is placed at some start location s in a 2-dimensional scene containing oriented rectangular obstacles. The robot must repeatedly travel back and forth between s and a second location t in the scene. The robot knows the coordinates of s and t but initially knows nothing about the positions or sizes of the obstacles. It can only determine the obstacles' locations by bumping into them. We would like an intelligent strategy for the robot so that its trips between s and t both are relatively fast initially and improve as more trips are taken and more information is gathered.

In this paper we describe an algorithm for this problem with the following guarantee: in the first $k \leq n$ trips, the average distance per trip is at most $O(\sqrt{n/k})$ times the length of the shortest s-t path in the scene, where n is the Euclidean distance between s and t. We also show a matching lower bound for deterministic strategies. These results generalize known bounds on the one-trip problem. Our algorithm is based on a novel method for making an optimal trade-off between search effort and the goodness of the path found. We improve this algorithm to a "smooth" variant having the property that for *every* $i \leq n$, the robot's ith trip length is $O(\sqrt{n/i})$ times the shortest s-t path length.

A key idea of this paper is a method for analyzing obstacle scenes using a tree structure that can be defined based on the positions of the obstacles.

Key words. online algorithms, robot path planning, exploration vs. exploitation, learning, navigation, unfamiliar terrain, competitive analysis, lower bounds

1. Introduction.

This paper addresses an abstraction of the following type of scenario. Imagine you have just moved to a new city. You are at your home and must travel to your office, but you do not have a map (let's assume you know the coordinates of your office; you just do not know the street layout). Several papers in recent literature have discussed strategies that can be used to plan one's route in this type of situation so that the distance traveled is not too much longer than the shortest path. But now, suppose you have reached your office, spent the day there, and it is time to go home. You could retrace your path, but you now have some information about the city (what you saw on your way to work in the morning) and would like to do better. The next morning you have even more information and so on. What is a strategy that allows your path taken each time to be good and to improve with experience? Perhaps you might even design your paths explicitly so as to gain more information for future trips.

Specifically, we consider the scenario (examined in [17, 7, 11, 10]) where there is a start point s and target t in a 2-dimensional plane filled with nonoverlapping, axis-parallel rectangular obstacles, having corners at integral coordinates. A point robot begins at s, and knows its current position and that of the target, but it does *not*

know the positions and extents of the obstacles; it only discovers their existence as it bumps into them. In the problem considered in previous papers, the robot's goal is to travel from s to t as quickly as possible. We call this the *one-trip* problem. For this problem, if n is the Euclidean s-t distance, [7] presents an algorithm that guarantees an $O(\sqrt{n})$ ratio of the distance traveled to the shortest path length, which is known to be optimal for deterministic algorithms [17]. Here, we consider the situation where the robot may be asked to make *multiple* trips between s and t. We would like an intelligent strategy for the robot so that its trips between s and t both are as fast as can be hoped for initially and improve as more trips are made and more information is gathered. For instance, after making one trip that achieves the above $O(\sqrt{n})$ ratio, the robot has some partial information about the scene. Can it exploit this information to improve its ratio on the second trip? Can it continue to exploit new information gained on future trips? It is important to note that partial information may not help if it is somehow not sufficiently relevant. Thus the challenge is to perform as well as possible on each trip given the information gained so far and at the same time acquire information that will be useful for improving on later trips. This makes the multitrip problem more difficult than the single trip problem.

The multitrip problem has aspects of both a machine learning and an online algorithms problem. As in machine learning settings, we would like our algorithm to improve its performance with experience. As in standard online algorithms settings (e.g., [16]), decisions the robot makes now may affect the costs it experiences in the future. However, our scenario also exhibits key differences. In particular, unlike typical online algorithms problems, here the algorithm may have *partial information* about the future—namely, the positions of obstacles that lie ahead that it has already encountered. There is also a value associated with information gathering in our setting in the sense that such information may (or may not) prove to be useful on the future trips made. One contribution of our work is a method for analyzing problems of this sort and quantifying the information that is most relevant in this setting.

We study the case of oriented rectangular obstacles for two main reasons. First, scenes containing such obstacles are complex enough to embody many of the strategic issues that arise in path planning. For example, there is the question of when one should "give up" on a difficult region in the scene and move to a new region that might be more promising, and there is also the question of which information is worth gathering. Second, if one allows arbitrarily shaped obstacles, it is known [7] that one cannot perform much better in the worst case than a simpleminded depth-first-search strategy. Thus, such scenes do not allow one to demonstrate theoretically the value of a useful approach by the performance guarantees achieved.

An extended abstract of this paper appears as [6].

1.1. Results and goodness measures. Given the basic scenario described above, the first question to be addressed is the measure of success to use. Clearly we do not want to give high marks to a solution in which the robot makes an artificially long first trip and then subsequently "improves" on future trips. Instead we would like an algorithm that performs as well as possible at all times. For this reason, we will analyze our algorithms using a type of "competitive analysis." The idea of competitive analysis is to compare the performance of one's algorithm to the best one could hope to do if there were no missing information (in our case, if a map of the scene were known). For instance, for the one-trip problem, Papadimitriou and Yannakakis [17] showed that for any deterministic algorithm and integer $n > 0$, there exist scenes having Euclidean s-t distance n (the width of the thinnest obstacle is taken as 1 unit), forcing the algorithm to travel $\Omega(\sqrt{n})$ times the length of the shortest path. Subsequently, Blum, Raghavan, and Schieber [7] showed an algorithm (BRS algorithm) having a performance guarantee that matches this lower bound.

For the multitrip problem we consider two similar measures of performance. In the *cumulative* measure, we compare the total distance traveled on the first k trips to the length of the optimal path. Our first main result is a deterministic strategy having the property that given $k \leq n$, it guarantees that the total distance traveled in the first k trips is at most $O(L\sqrt{nk})$, where L is the length of the shortest s-t path. (If $k \geq n$ the distance becomes $O(Lk)$.) We also show that up to constant factors this is the best guarantee achievable by a deterministic strategy. In particular, for any deterministic strategy and any n and $k \leq n$, there exist scenes which force the strategy to travel distance $\Omega(L\sqrt{nk})$ on the first k trips. One problem with the cumulative measure is that it does not force the algorithm to perform as well as possible on *each* trip. For this reason, we also consider a *per-trip* measure in which we separately bound the cost of each trip. Our second main result is an improvement on the cumulative algorithm having the property that for *all* $i \leq n$, the ith trip of the robot has length at most $O(L\sqrt{n/i})$. This is optimal in the sense that (up to constant factors) it meets the cumulative lower bound simultaneously for all i.

1.2. Main ideas and the basic strategy. The core of our results (and the bulk of the paper) is a method for achieving a smooth *search-quality trade-off*: smoothly trading off in a single trip the exploration cost with the goodness of the path found. Specifically, we design an algorithm that, given any $k \leq n$, searches a distance $O(L\sqrt{nk})$ and finds an s-t path of length at most $O(L\sqrt{n/k})$. In other words, at a cost of only t times the cost of the BRS algorithm ($t = \sqrt{k}$ in our case) we find a path that is a factor of t better than the BRS guarantee. In addition, our method for achieving this trade-off has the property that it can be performed in a "piecemeal" fashion (somewhat like the piecemeal learning of [5]). In particular, the searching can be performed a little bit at a time on each trip. This latter property is what allows us to turn our cumulative algorithm into one that is more like a learning algorithm, with optimal per-trip performance. As more trips are made, better searches are performed, and cheaper paths are found for the future trips. An example of an exploratory trip achieving the desired trade-off is given in Figure 1.1.

Our main idea for achieving this search-quality trade-off is a method for analyzing an obstacle scene and determining which pieces of information are the most important. In particular, we show that a *tree* structure can be defined in the scene, where the nodes are portions of certain obstacles and the edges are short paths from a node to its children. This tree can be tailored to the search cost and path quality desired. Our search algorithm is essentially an online strategy to traverse a sequence of trees optimally, and the path found is a concatenation of specific root-to-leaf paths from each tree. Besides its use for achieving a search-quality trade-off on a single trip, the tree structure enables us to spread the search over several trips: since there is a "short" path from the root to each node, we can suspend our tree-traversal on one trip and resume the exploration on a later trip by moving quickly to the point where we stopped. The tree structure is defined formally in section 5.

1.3. Related work. Versions of the multitrip problem have been addressed in the framework of reinforcement learning. Thrun [18] describes heuristics for path improvement in scenes containing (possibly concave) obstacles and presents empirical results. Koenig and Simmons [12] consider a similar problem on graphs. In other

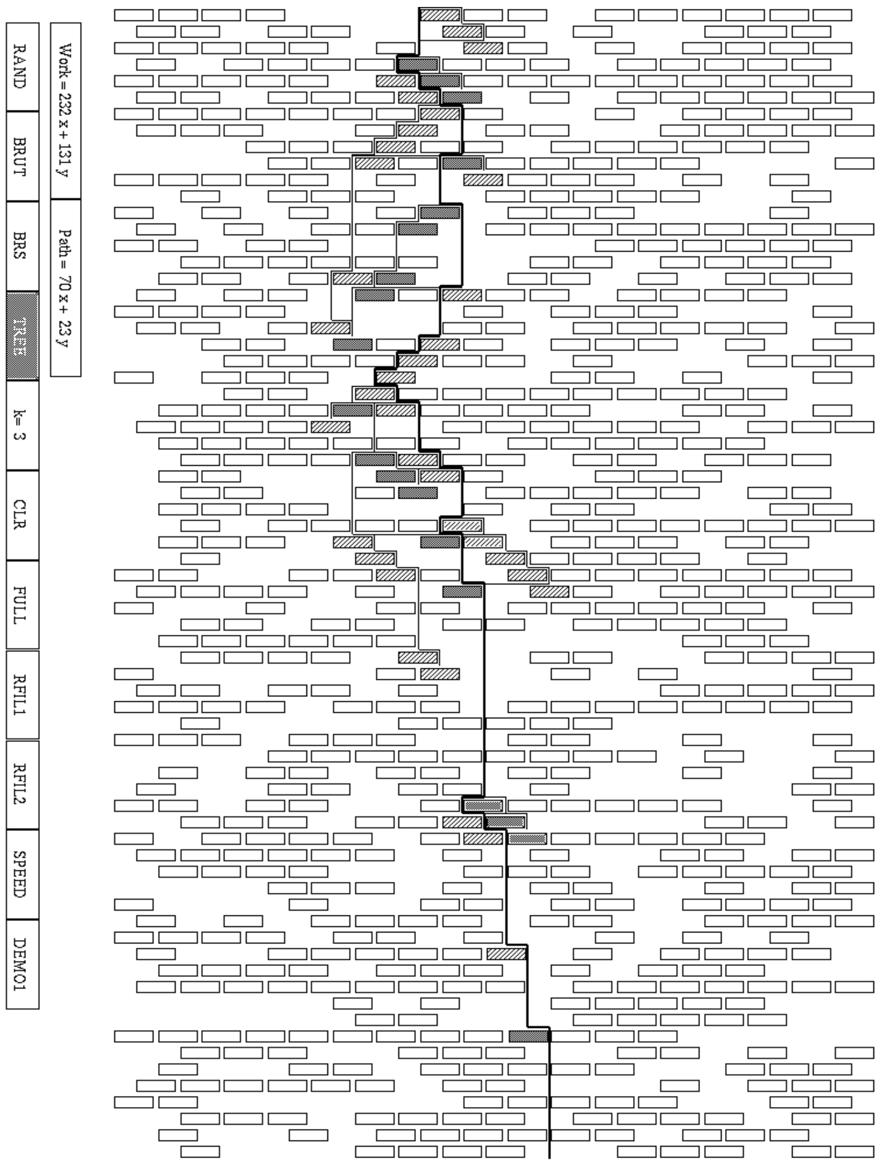

FIG. 1.1. *An example of an initial search trip, $k = 3$. The thick line shows the s-t path found (s is at center top, t is at the bottom), and the thin and thick lines are the search path. The robot occasionally will back up, which accounts for the dead ends. Obstacles hit are shaded. In each "fence group" (see section* 5.1*) fences* 1 *and* 3 *are lightly shaded and fence* 2 *is darkly shaded. This figure is a screen dump of a demonstration program that allows a user to create a "simple scene" (see section* 4*) and then run various algorithms on it.*

machine learning literature, Chen [9] considers how the computation *time* for path-planning in a *known* scene can be improved by making use of (portions of) solutions to previous path planning problems in the same scene.

Betke, Rivest, and Singh [5] consider a related problem of completely exploring an environment, but with the restriction that the robot must return to the start to refuel every d steps for some distance d. They call this *piecemeal learning* and provide algorithms for the case of a bounded region with axis-parallel rectangular obstacles.

Lumelsky [13, 14] and Lumelsky and Stepanov [15] describe some very simple algorithms that can be used to solve the one-trip problem for *arbitrary* (nonconvex) obstacles having the property that the distance traveled is at most the Euclidean s-t distance plus 1.5 times the sum of the perimeters of all the obstacles.

2. The model.

Let $\mathcal{S}(n)$ denote the class of scenes in which the Euclidean distance between s and t is n. We define s to be at the origin $(0, 0)$. As mentioned above, we assume that the width and height of each obstacle is at least 1 (this in essence defines the units of n) and for simplicity assume that the x-coordinates of the corners of obstacles are integral. Thus no more than n obstacles can be placed side by side between s and t. We assume that when obstacles touch, the point robot can move between them.

To simplify the exposition, for most of this paper we will take t to be the infinite vertical line (a "wall") $x = n$ and require the robot only to get to any point on this line; this is the wall problem of [7]. Our algorithms are easily extended to the case where t is a point, using the room problem algorithms of [7] or [3], and we describe this modification in section 8.

We model the robot as having only *tactile* sensors; that is, it discovers an obstacle only when it bumps into it. It will be convenient to assume, however, that when the robot hits an obstacle, it is told which corner of the obstacle is nearest to it and how far that corner is from its current position. As in [7], our algorithms can be modified to work without this assumption with only a constant factor penalty. We describe these modifications toward the end of the paper.

Consider a robot strategy R for making k trips between s and t. Let $R_i(S)$ be the distance traveled by the robot in the ith trip, in scene S. Let $L(S)$ be the length of the shortest obstacle-free path in the scene between s and t. We define the *cumulative* k-trip competitive ratio as

$$\rho(R, n, k) = \max_{S \in \mathcal{S}(n)} \frac{R^{(k)}(S)}{kL(S)},$$

where $R^{(k)}(S) = \sum_{i=1}^{k} R_i(S)$ is the *total* distance traveled by the robot in k trips. That is, $\rho(R, n, k)$ is the ratio between the robot's average distance traveled in k trips and L. We define the per-trip competitive ratio for the ith trip as

$$\rho_i(R, n) = \max_{S \in \mathcal{S}(n)} \frac{R_i(S)}{L(S)}.$$

Given this notation, our main results can be described as follows. First, we show for any k, n, and deterministic algorithm R, that $\rho(R, n, k) = \Omega(\sqrt{n/k})$. Second, we describe a deterministic algorithm that given $k \leq n$ achieves $\rho(R, n, k) = O(\sqrt{n/k})$. Finally, we show an improvement to that algorithm that achieves $\rho_i(R, n) = O(\sqrt{n/i})$ for *all* $i \leq n$. Notice that the latter algorithm is optimal in that it matches the lower bound simultaneously for all k. I.e., $\frac{1}{k}\sum_{i=1}^{k}\sqrt{n/i} = O(\sqrt{n/k})$. The simplest of these results is the lower bound, which we describe first.

Conventions. We will use the words up, down, left, and right to mean the directions $+y, -y, -x$, and $+x$, respectively. When we say point A is above, below, behind, or ahead of a point B we will mean that A is in the $+y, -y, -x$, or $+x$

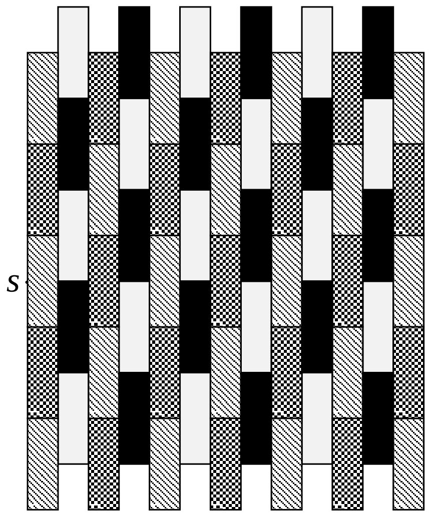

FIG. 3.1. *A 4-coloring of the brick pattern for the lower bound.*

direction, respectively, from B. Finally, vertical (respectively, horizontal) motion is parallel to the y (respectively, x) axis. At any point in time, the current coordinates of the robot (which are known to the robot) are denoted by (x, y).

3. A lower bound for k-trips.

THEOREM 3.1 (k-trip cumulative lower bound). *For $k \leq n$, the ratio $\rho(R, n, k)$ is at least $\Omega(\sqrt{n/k})$ for any deterministic algorithm R.*

Proof. Since R is deterministic, an adversary can simulate it and place obstacles in $\mathcal{S}$ as follows. Recall that s is the point $(0, 0)$.

The adversary first places obstacles of fixed height $2h \geq \sqrt{n}$ and width 1, in a full "brick pattern" on the entire plane, as shown in Figure 3.1, with s at the center of the left side of an obstacle. (Recall that the point robot can "squeeze" between bricks.) The adversary simulates R on this scene, notes which obstacles it has touched at the end of k trips, then removes all other obstacles from the scene. This is the final scene that the adversary creates for the algorithm. Let us say it contains M obstacles. The brick pattern ensures that R must have hit at least one brick at every integer x-coordinate, so $M \geq n$. Further, this arrangement forces the robot to hit a brick at every integer x-coordinate on *every* trip. Whenever it hits a brick, it must move vertically up or down a distance h, so its total k-trip distance $R^{(k)}$ is at least nkh.

We now show that there is a path from s to the wall of length at most $O(\sqrt{R^{(k)}h})$. Imagine the full brick pattern to be built out of four kinds of bricks (red, blue, yellow, and green, say) arranged in a periodic pattern as shown in the figure. This arrangement has the following property: for each color, to go from a point on an obstacle of that color to a point on any other obstacle of the same color, the robot must move a distance at least h. Out of the M obstacles hit by the robot, at least $M/4$ must have the same color, say blue. So regardless of how the robot moved, since it has visited $M/4$ blue obstacles, we have $R^{(k)} \geq Mh/4$, which implies $M \leq 4R^{(k)}/h$.

We claim there is a nonnegative integer $j \leq \sqrt{M}$ such that at most $\sqrt{M}$ obstacles have centers at the y-coordinate jh. This is because a given obstacle intersects at most one y-coordinate of the form jh, and there are M obstacles. Thus, there is a path to t that goes vertically to the y-coordinate jh, then horizontally along this y-coordinate, going around at most $\sqrt{M}$ obstacles. The total length of this path is at most $2h\sqrt{M} + 2h\sqrt{M} + n$, which is at most $6h\sqrt{M}$ since $n \leq M$ and $\sqrt{n} \leq 2h$. Since $M \leq 4R^{(k)}/h$, this path is in fact of length at most $6\sqrt{4hR^{(k)}}$. Thus the k-trip ratio is at least $R^{(k)}/(6k\sqrt{4hR^{(k)}})$. Recalling that $R^{(k)} \geq nkh$, this is at least $\frac{1}{12}\sqrt{n/k} = \Omega(\sqrt{n/k})$. □

It is not hard to see that this lower bound also holds for the case where t is a point rather than a wall.

4. The k-trip cumulative algorithm: Preliminaries.

We now give some preliminary observations needed for our algorithm.

We begin by assuming for simplicity that the algorithm knows the length L of the shortest obstacle-free path from s to t. In section 5.1 we show that this assumption can be removed by using a standard "guessing and doubling" trick. One simple observation is that the shortest obstacle-free s-t path must lie entirely within a *window* of height $2L$ centered at s, since any s-t path that leaves the window must be longer than L. *In the remainder of the paper we will refer to the rectangular region of height* $2L$ *centered vertically at* s, *and extending horizontally between* s *and* t, *as "the window."* This observation immediately leads to an easy algorithm to achieve a cumulative k-trip ratio of $O(1)$ for $k \geq n$:

First trip: Using a depth-first-search, explore the entire window. This can be done by walking a total distance of $O(Ln)$. Compute the shortest obstacle-free s-t path (of length L).

Remaining trips: Use the shortest path.

Clearly the average trip length is $O(L)$, so the cumulative n-trip ratio is $O(1)$.

Thus, the cases $k = 1$ (the BRS algorithm) and $k \geq n$ can be done with known methods. In fact, at the high level, our optimal cumulative strategy for $1 \leq k \leq n$ trips is similar to the n-trip algorithm just described:

First trip: Somehow perform an "exploratory" walk of length $O(L\sqrt{nk})$, in such a way that an s-t path P of length $O(L\sqrt{n/k})$ is discovered.

Remaining $k - 1$ trips: Use the path P.

The average trip length of this algorithm is $O(\frac{1}{k}(L\sqrt{nk}+(k-1)L\sqrt{n/k})) = O(L\sqrt{n/k})$, so the cumulative k-trip ratio is $O(\sqrt{n/k})$. Thus, as mentioned in the introduction, the key question is how to find a path that is a factor $\Omega(\sqrt{k})$ better than the BRS guarantee while traveling a distance that is only $O(\sqrt{k})$ longer.

In order to make the main ideas clear, we first describe our algorithm for a class of scenes we call *simple scenes* that capture most of the difficulties in designing online navigation algorithms (for both the one-trip and k-trip problems). In section 6 we show how to extend this algorithm to handle the general case. A scene is *simple* if (a) all obstacles have the same height $2h$ and width 1 and (b) the obstacle corners have coordinates of the form (i, jh) for integer i and j. For instance, the obstacles in the lower bound of section 3 form a simple scene. Observe that in a simple scene one can move unimpeded vertically along any integer x-coordinate without encountering any obstacles.

Notice that if $h \leq L/\sqrt{nk}$, then a brute-force strategy that moves forward when possible and otherwise arbitrarily goes around any obstacle encountered will hit at most n obstacles and therefore travel a distance at most $O(nL/\sqrt{nk}) = O(L\sqrt{n/k})$, which is our desired bound. Thus, we may assume in what follows that $h > L/\sqrt{nk}$.

Conventions. For convenience, in a simple scene we define the *position* of an obstacle A to be the coordinates of the midpoint of the left edge of the obstacle. A horizontal path whose y coordinate is a multiple of h is said to *hit* an obstacle if it hits the obstacle's center (as opposed to grazing the top or bottom edge), i.e., if it reaches the obstacle's position. We reiterate that we will use the phrase "the window" to refer to the rectangular region of height $2L$ centered vertically at s and extending horizontally between s and t. As mentioned above, we will assume in what follows that $h > L/\sqrt{nk}$.

5. The algorithm for simple scenes.

5.1. Fences and the one-trip BRS algorithm. One key notion used in both the one-trip BRS algorithm and our k-trip algorithm is that of a *fence*.[1] An *up-fence* F is a sequence of M obstacles at points $(X(1), Y(1)), (X(2), Y(2)), \ldots, (X(M), Y(M))$ such that $Y(1) \leq -L$, $Y(M) \geq L$, and for $m = 1, 2, \ldots, M-1$,

$$X(m) \leq X(m+1), \tag{5.1}$$

$$Y(m+1) = Y(m) + h. \tag{5.2}$$

See Figure 5.1. A *down-fence* has the same definition except $Y(1) \geq L$, $Y(M) \leq -L$, and (5.2) is replaced by $Y(m+1) = Y(m) - h$. The mth obstacle (counting from the left) of fence F_i is denoted by $F_i(m)$ and its coordinates are $(X_i(m), Y_i(m))$. For each m, the rectangular region of height h whose opposite corners are $(X(m), Y(m))$ and $(X(m+1), Y(m+1))$ is called a *band.* A fence can thus be viewed as a contiguous sequence of bands extending across the window.

A point P is said to be *left* (respectively, *right*) of a fence F if an imaginary horizontal line from P to the left (respectively, right) does not intersect any obstacle of F. A path is said to *cross the fence* if it connects some point left of the fence to some point right of the fence *and* stays inside the window. Any path that crosses a fence has vertical length at least h since it must completely cross some band (see Figure 5.1).

It is easy to see how a robot can find a fence with vertical motion at most $2L$. Specifically, starting from the bottom of the window, an up-fence can be found as follows:

```
    **Repeat until** at top of the window (i.e., $y = +L$): walk to the right until
    an obstacle is hit, then move up to the top of the obstacle.
```

The one-trip BRS algorithm restricted to simple scenes (and assuming L is known) reduces to the following:

```
    Initially, walk from $s$ down to the bottom of the window. Until the wall is
    reached, walk to the right, alternately building up- and down-fences across
    a window of height $2L$ centered at $s$.
```

The robot never walks backward in the BRS algorithm, so its total horizontal cost is n, and since $L \geq n$, this cost is only a small order term. Note that every obstacle hit by the robot is part of some fence. Thus every time the robot spends $2L$ (vertically) to build a fence, it is also forcing the optimal offline path to spend at least h to cross the fence. So if $h \geq L/\sqrt{n}$, the competitive ratio is $O(\sqrt{n})$. The case $h < L/\sqrt{n}$ is even easier to handle: the robot hits at most n obstacles (since they have width 1 and the robot never walks backward), so its total vertical cost is at most $nh < L\sqrt{n}$.

We say that two fences are *disjoint* if their bands do not intersect each other (see Figure 5.2). Because the bands of disjoint fences do not overlap, any path that crosses t disjoint fences must pay (vertically) at least th. For the k-trip problem an

[1]This is called a *sweep* in [7].

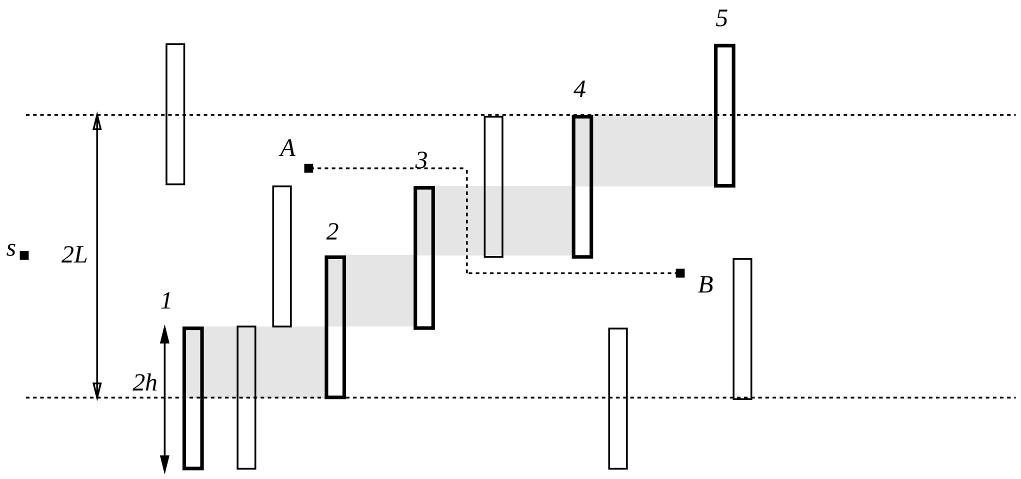

FIG. 5.1. *A fence in a simple scene. The obstacles* $\langle 1,2,3,4,5\rangle$ *with thick boundaries form a fence. The dashed line connecting points* A *and* B *crosses the fence. The shaded regions are the bands of the fence. Note: since* $L \geq n$*, the window in this figure should really be taller than its width. However for the sake of clarity, in this and all figures in this paper the vertical dimension has been compressed considerably.*

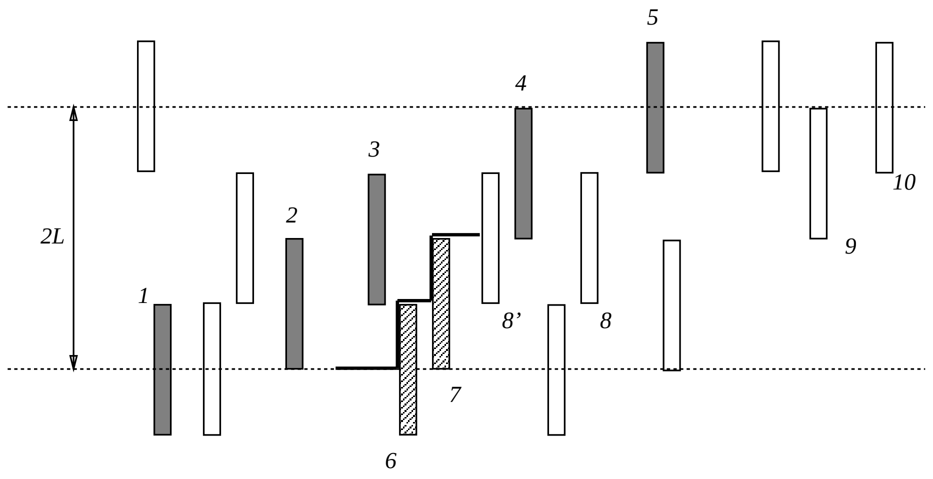

FIG. 5.2. *The fences* $F_1 = \langle 1,2,3,4,5\rangle$ *and* $F_2 = \langle 6,7,8,9,10\rangle$ *are disjoint.* F_1 *and* $F_3 = \langle 6,7,8',9,10\rangle$ *are not disjoint since the band of* F_3 *between* $8'$ *and* 9 *overlaps the band of* F_1 *between* 3 *and* 4. *In fact, one can cross both* F_1 *and* F_3 *at a total cost of only* h *by traveling between* $8'$ *and* 4. *A greedy strategy for constructing a fence such as* F_2 *disjoint from the previously found fence* F_1 *might be to go up and over obstacle* $8'$ *until obstacle* 4 *is hit, and then down around* 4 *to reach obstacle* 8. *However, this type of strategy might be expensive, as shown in Figure* 5.3.

intuitively reasonable approach is to extend the BRS idea as follows: On each trip, make new fences that are *disjoint* from previous fences. If on each trip one could find new disjoint fences "cheaply" ($O(L)$ cost) *and* one could cross old fences cheaply ($O(h)$ cost), then this would result in an optimal algorithm. However, we know of no way to find new disjoint fences this cheaply. The naive strategy of extending each new fence greedily and using previously found paths to bypass obstacles that enter

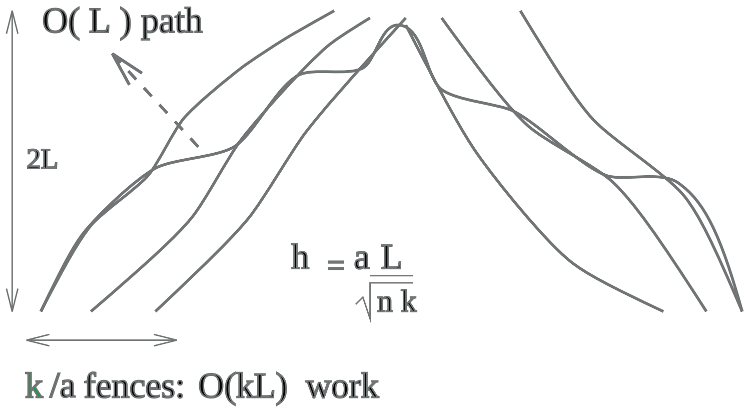

FIG. 5.3. *High-level view of the optimal k-trip strategy. First trip: create groups of fences with short group-crossing paths. Remaining trips: follow these short paths.*

existing fences can be too expensive in certain scenes. Examples of such scenes are given in [8].

Our approach, as hinted in section 4, is to give up on trying to create new disjoint fences on each trip and instead to try to find a group of disjoint fences all at once on one trip. Specifically, we do the following. Suppose that $h = aL/\sqrt{nk}$ for some $a \geq 1$ (recall that $2h$ is the obstacle height, and $a < 1$ is an easy case to handle). Then our strategy is the following.

First trip: Build a sequence of fence groups in which each group consists of $\lceil \frac{k}{a} \rceil$ disjoint fences (alternate between groups of up-fences and groups of down-fences) until the wall is reached. Ensure that
- (a) the cost of building each group is $O(kL)$,
- (b) an $O(L)$ length path crossing each group (i.e., going from the x-coordinate of the leftmost obstacle of the leftmost fence to the x-coordinate of the rightmost obstacle of the rightmost fence) is found, and
- (c) the right end of each group-crossing path is the left end of the next group-crossing path.

Remaining $k-1$ trips: Follow the group-crossing paths to the wall.

The first trip is shown schematically in Figure 5.3. To see why the above strategy achieves an $O(\sqrt{n/k})$ ratio, assuming we can somehow satisfy (a), (b), and (c), notice that the *average* online cost per trip to get past each fence group is $O(L)$ (amortizing the $O(kL)$ building cost). Crossing each group costs the optimal offline path at least $(k/a)h = L/\sqrt{n/k}$, so the average online trip length is within an $O(\sqrt{n/k})$ factor of optimal, as desired.

A search-quality trade-off. Since each fence group costs the offline optimum path at least $L/\sqrt{n/k}$ to cross, the robot will find at most $\sqrt{n/k}$ groups before reaching the wall. Thus the total length of its first trip is $O(kL\sqrt{n/k}) = O(L\sqrt{nk})$, and the total length of the group-crossing paths is $O(L\sqrt{n/k})$. Therefore, this achieves the search-quality trade-off mentioned earlier.

The doubling strategy when L is unknown. Note that if L is not known, we can just begin with a guess of $L = n$, and if the wall has not been reached after building $\sqrt{n/k}$ fence groups, we can double our guess and repeat the entire procedure. Thus there is only a constant factor penalty for not knowing L.

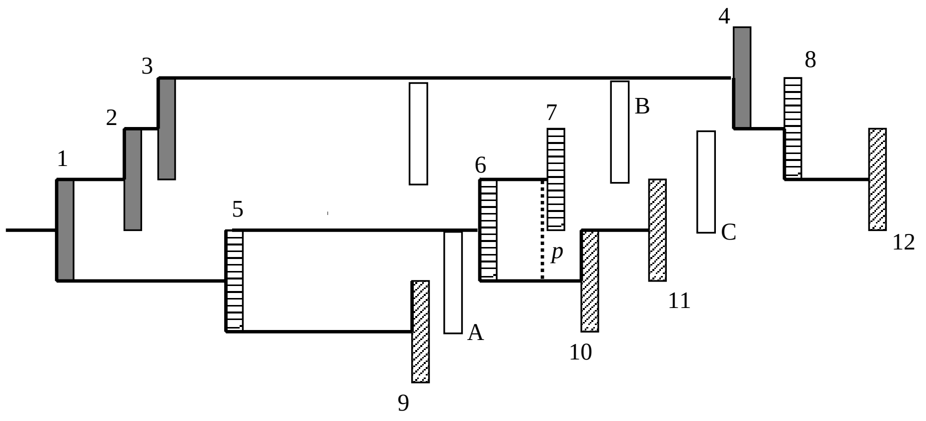

FIG. 5.4. *A scene showing a* 3×4 *fence-tree, where the root* $F_1(1)$ *is obstacle* 1. *The shaded obstacles are the nodes of the tree, and the dark lines are the edges. Differently-shaded obstacles constitute different fences; other obstacles are not part of any fence. For instance, obstacle* 4 *is node* $F_1(4)$, *obstacle* 7 *is node* $F_2(3)$, *and obstacle* 8 *is node* $F_2(4)$. *Note that the tree defines three disjoint fences with four obstacles each. If we had failed to follow the fence-tree rules and instead had made* $F_2(4)$ *be up-right from* $F_2(3)$ *(that is, obstacle B) then fences* 1 *and* 2 *would not be disjoint.*

The advantage of building an entire collection of fences on one trip is that this allows the robot to make more effective use of its movements. In [8] a detailed example is given where building fences one-by-one on consecutive trips can be too expensive. In fact a crucial property of the fence collections we will define is that the ith obstacle of a fence is always easily reachable either from the preceding obstacle on the same fence or the corresponding obstacle of the fence above.

5.2. Fence-trees. We would like to build a collection of $G = \lceil \frac{k}{a} \rceil$ up-fences across the window, and find an $O(L)$ length path crossing the collection, while paying a cost of only $O(kL)$. Our key idea is to define a *tree* structure whose nodes are obstacles in the scene and whose edges are "short" paths between the nodes. These nodes will constitute the desired collection of fences, and the path from the root node to the rightmost node is the desired $O(L)$ length path that crosses the collection. Furthermore, traversing all edges of this tree with a cost of $O(kL)$ is equivalent to building the desired collection of fences.

In order to define the tree structure we introduce some notation and terminology. The nodes of this tree will be denoted by $F_i(m)$, for $i = 1, 2, \ldots, G$ and $m = 1, 2, \ldots, M$ (M is roughly $2L/h$ and will be fully specified later). The reason for this notation is that $F_i(m)$ will turn out to be the mth obstacle of the ith fence. The coordinates of obstacle $F_i(m)$ are denoted by $(X_i(m), Y_i(m))$. We say an obstacle Q is *down-right* (*up-right*) from an obstacle P if Q is the first obstacle hit when moving to the right from the *bottom* (*top*) of P. The following rules then define the $G \times M$ fence-tree with root $F_1(1)$ (an example is given in Figure 5.4).

Fence-Tree Rules.

```
(1)  For $i = 2, 3, \ldots, G$, $F_i(1)$ is down-right from $F_{i-1}(1)$.
(2)  For $m = 2, 3, \ldots, M$, $F_1(m)$ is up-right from $F_1(m-1)$.
(3)  For $i = 2, 3, \ldots, G$:
         For $m = 2, 3, \ldots, M$:
             If $X_i(m-1) \geq X_{i-1}(m)$,
                 then $F_i(m)$ is up-right from $F_i(m-1)$
```

else $F_i(m)$ is down-right from $F_{i-1}(m)$.
(E.g., in Figure 5.4, obstacle 7 is up-right from obstacle 6, and obstacle 8 is down-right from obstacle 4.)

Thus each node $F_i(m)$ (except the root node $F_1(1)$) is defined to be either up-right from $F_i(m-1)$ or down-right from $F_{i-1}(m)$. We will call that "defining obstacle" of $F_i(m)$ its *parent*, and call the up-right or down-right path from the parent to $F_i(m)$ (consisting of a vertical portion of height h followed by a horizontal portion) an *edge* in the tree. That is, if rule (2) is used or if $F_i(m-1)$ is to the right of $F_{i-1}(m)$, then $F_i(m-1)$ is the parent of $F_i(m)$ and otherwise $F_{i-1}(m)$ is the parent of $F_i(m)$.

The fence-tree rules define a natural *binary rooted tree* structure. The tree structure is visually apparent in Figure 5.4. The $G \times M$ fence-tree in fact defines exactly the group of fences that we want to build.

THEOREM 5.1 (fence-tree). *Let P be an obstacle with y-coordinate $-L$ in a simple scene, and let $M \geq \lceil \frac{2L}{h} \rceil + \lceil \frac{k}{a} \rceil$. Then, the obstacles in a $G \times M$ fence-tree with root P form G disjoint up-fences with M obstacles each, with P as the first obstacle of the leftmost fence.*

Proof. It is easy to see that the obstacles $F_1(m)$ defined by rule (2) constitute a fence F_1. In addition, for all $i > 1$, the obstacles $F_i(m)$, $m = 1, 2, \ldots, M$, constitute a fence F_i since each is to the right of and exactly h higher than the previous obstacle. By rule (1), the initial obstacle of each fence is down-right from the initial obstacle of the fence F_{i-1} above it. Therefore, the fences are disjoint if and only if for each $m = 2, 3, \ldots, M$, $F_i(m)$ is to the right of $F_{i-1}(m)$, and this is guaranteed by rule (3).

It is easy to verify that the value $M = \lceil \frac{2L}{h} \rceil + \lceil \frac{k}{a} \rceil$ is sufficient to ensure that even the fence F_G that starts $Gh = h\lceil \frac{k}{a} \rceil$ below the bottom of the window extends at least $2L$ above the obstacle P, and thus all fences cross the window. ∎

Recall that we wanted to define the fence group so that there is a cheap ($O(L)$ length) path that crosses the group. One such path is the path from the root of the tree to the rightmost obstacle on the rightmost fence (strictly speaking, this path does not cross the rightmost fence, but it can be cheaply extended to one that does). In fact, the unique path in the tree from the root $F_1(1)$ to each node has length at most $O(L)$, as we show below.

LEMMA 5.2. *In a $G \times M$ fence-tree in a simple scene, where $G = \lceil \frac{k}{a} \rceil$ and $M = \lceil \frac{k}{a} \rceil + \lceil \frac{2L}{h} \rceil$,*

(a) *the unique path in the tree from the root to each node has length $O(L)$, and*

(b) *the total length of all edges is $O(kL)$.*

Proof. Recall first that $k \leq n$ and $L \geq n$. Since the unique tree path from the root to any given node always proceeds to the right, the total horizontal cost of this path is at most n. On this path, each down-edge leads to a lower fence (and there are only $G = \lceil \frac{k}{a} \rceil$ fences), and each up-edge leads to an obstacle on the same fence (and there are only $M = \lceil \frac{k}{a} \rceil + \lceil \frac{2L}{h} \rceil$ obstacles per fence). So, the total vertical cost of this path is at most $h(G + M)$. Thus the total length of any such path is at most $n + h(G+M) = n + h(2\lceil \frac{k}{a} \rceil + \lceil \frac{2L}{h} \rceil)$, which is $O(L)$ since $h = aL/\sqrt{nk} \leq aL/k$.

To bound the total length of all edges, note that each edge can be associated with a unique node, namely the one on its right (the child). Thus, the sum of the *vertical* portions of all edges is at most $h(GM-1) = O(kL)$. By fence rules (2) and (3), the length of the horizontal portion of the edge associated with $F_i(m)$ is no more than the horizontal distance between $F_i(m)$ and its predecessor $F_i(m-1)$ on the same fence. Thus the sum of the *horizontal* portions of the edges is a most Gn: n for each fence. This is also $O(kL)$. ∎

Thus if the robot traverses all edges of this tree it will have found not only a group of disjoint fences but also a cheap path that crosses all of them.

As noted in the proof above, there are GM obstacles in the fence-tree, and $GMh \leq kMh = O(kL)$. Thus we would like the robot to traverse the fence-tree with a cost proportional to h times the number of obstacles in the fences, or a cost proportional to the total length of the tree edges. We remark here that the fence-tree must be traversed online; a simple approach based on depth-first-traversal may not be efficient since the algorithm does not know where exactly the nodes are: the robot can locate $F_i(m)$ only after it has located both its potential parents $F_{i-1}(m)$ and $F_i(m-1)$ or at least after it has determined whether or not $X_i(m-1) \geq X_{i-1}(m)$. So, intuitively the difficulty is that before visiting a node such as $F_i(m)$ we need to visit both potential parent nodes, which may be in very different parts of the tree. (Actually, one could imagine an algorithm that attempted to visit nodes before finding both parents and only later verified whether or not those nodes were actually legally part of the tree; our algorithm does not do this.)

Conventions. In the subsequent sections, we will find it convenient to associate an edge in the tree with the obstacle at its right end, and we define the coordinates of an edge to be the coordinates of its associated obstacle. We say an edge belongs to a fence F_i if its associated obstacle belongs to F_i. When we say an object A, such as an edge or obstacle, is left (right) of another object B we will mean that the x-coordinate of A is strictly smaller (greater) than that of B. We will often identify a fence with its rightmost obstacle; thus when we say "fence F_i is to the left of obstacle P" we mean that the last obstacle of F_i is left of P. We use (X_i, Y_i) to denote the coordinates of the rightmost obstacle of F_i, and $|F_i|$ will denote the number of obstacles currently in F_i. To simplify the wording of our algorithms we will assume that $X_0 = \infty$, and $|F_0| = M + 1$.

5.3. Finding the fence-tree. Our algorithm builds a tree using a conservative strategy in the following sense. It adds a new edge to the current partial tree only when such an edge is certain to be part of the final tree being built. In addition, the algorithm visits a node $F_i(m)$, $i > 1, m > 1$, only after both its possible parents $F_{i-1}(m)$ and $F_i(m-1)$ have been visited. At any stage our algorithm will be located at the rightmost node found so far for some partial fence and then either adds a (down-right or up-right) edge from the current fence, or "jumps" to another fence.

It is reasonable to wonder whether an efficient fence-tree-traversal strategy exists that only walks along the tree edges when jumping from one fence to another. We do not know of any such strategy; our algorithm may often shortcut to another fence without necessarily walking along tree edges. Even with this freedom to walk outside the tree, it is important to note that a bad order of visiting the nodes of the fence-tree may make the jumps prohibitively expensive.

The key problems in designing a traversal strategy therefore are (a) deciding the order in which the nodes will be discovered, and (b) designing the jump procedures. Procedure FindFenceTree in Figure 5.5 finds the desired fence-tree, using a recursive procedure Raise described in Figure 5.6. In these procedures, it should be understood that if the "wall" $x = n$ is reached at any time, the robot halts and the procedures terminate. The procedure JumpDownLeft (i) and JumpDownRight (i) take the robot from the last obstacle of the current fence F_i to the last obstacle of the next lower fence F_{i+1}. These procedures are described in Figures 5.7 and 5.8. In all the procedures, the "retrace to $F_i(j)$" statements are executed by simply retracing the path used to reach the current position from $F_i(j)$.

```
1  procedure FindFenceTree
2    Move to the right until at an obstacle; this defines $F_1(1)$
3    for $i := 2$ to $G$ do
4        Add a down-right edge to define$F_i(1)$;
5    end
6    Retrace to $F_1(1)$;
7    Raise $(1, 0)$;
8  end
```

FIG. 5.5. *The main procedure for finding the fence-tree.*

```
1  procedure Raise $(i, q)$
2    while (Up($i$)) do
3            Retrace to $F_i$; $j := i$;
4            Add an up-right edge to $F_i$;
5            while ($j < G$ and $X_j > X_{j+1}$) do
6                    Retrace to $F_j$;
7                    if (Down($j$))
8                      Add a down-right edge;   $j := j + 1$;
9                    else
10                        JumpDownLeft $(j)$;
11                        Raise $(j + 1, j)$;
12                   fi
13           od
14   od
15   Let $F_d$ be the current fence;
16   if ($d < G$ and $X_{d+1} < X_q$)
17     JumpDownRight $(d)$;
18     Raise $(d + 1, q)$;
19   fi
20 end
```

FIG. 5.6. *Recursive procedure* Raise *used by* FindFenceTree.

We start with an intuitive description of the algorithm. The algorithm begins (FindFenceTree) by finding the first obstacle in each fence and placing itself at the first obstacle of the topmost one. It then calls the recursive procedure Raise $(1, 0)$. In general for $q < i$, the job of Raise (i, q) is to raise all fences i and lower that are currently behind F_q, as far as possible given the constraints imposed by the location of F_q. (For $i = 1, q = 0$, this means to raise all the fences until they each have M obstacles.)

The Raise procedure is a bit complicated, so is perhaps best described through the example of Figure 5.4. In this example, Raise $(1, 0)$ is first called at obstacle 1, and the algorithm knows only about obstacles 1, 5, and 9. Raise begins by adding new obstacles to its current fence (in line 4) so long as these are legal with respect to constraints imposed from above, until it has overshot the fence below it. In the example, these are obstacles 2, 3, and 4. Once it reaches obstacle 4, Raise realizes it

```
1 procedure JumpDownLeft ($j$)
2    Move left along tree edges until $x$-coordinate = $X_{j+1}$;
3    Move vertically down to last obstacle of $F_{j+1}$;
4 end
```

FIG. 5.7. *Procedure* JumpDownLeft *to jump from current fence F_j to the next lower fence F_{j+1} when $X_{j+1} < X_j$.*

```
1 procedure JumpDownRight ($d$)
2    Move vertically down until on a previously found tree edge;
3    Follow tree edges to the right until at last obstacle of $F_{d+1}$;
4 end
```

FIG. 5.8. *Procedure* JumpDownLeft *to jump from current fence F_d to the next lower fence F_{d+1} when $X_{d+1} \geq X_d$.*

is to the right of the fence F_2 below it (formally, the conditions of the inner while loop become satisfied) and will try to make sufficient progress on F_2 (and any others that are behind and below F_1, in this case F_3). Unfortunately, because the current obstacle (number 4) of fence F_1 is too high relative to obstacle 5 on fence F_2, the algorithm cannot simply add a down-right edge (formally, Down(j) is not satisfied) from obstacle 4 to discover the next obstacle of fence F_2. So, the algorithm runs the JumpDownLeft(1) procedure to reach the last obstacle (number 5) of fence F_2 and calls Raise $(2, 1)$ recursively to raise that fence. This call to Raise begins by finding obstacle 6. At this point the robot is to the right of the fence below it (the condition of the inner while loop is satisfied) and it is just high enough above the last obstacle of F_3 (i.e., Down(j) is satisfied) so it adds the down-right edge to obstacle 10 (line 8). At this point it goes back to obstacle 6 (since Up(i) is still satisfied) and makes the up-right edge to obstacle 7. Now, Up(i) is no longer satisfied because the current fence has bumped into the constraint imposed by the fence above it. So, Raise $(1, 0)$ drops down to line 17, where it calls JumpDownRight (2) to get back to obstacle 10 (using the path indicated by "p" in the figure) and then recursively calls itself to work on raising that fence. Finally, that recursive call ends with obstacle 11, we pop out of both levels of recursion, and at the very top level we retrace our path all the way to obstacle 4, finally adding down-right edges to obstacles 8 and 12 in the inner while loop.

We now give a formal analysis of the formal algorithm given in Figures 5.5–5.8. In order to establish the correctness and bound the cost of these procedures, we need to show that certain pre- and postconditions hold whenever they are invoked. For ease of reference we use mnemonic names for the various conditions:

- Up(i): $i \geq 1$ and an up-right edge is legal from fence F_i, i.e., either $X_i < X_{i-1}$ and $|F_i| < |F_{i-1}| - 1$, or $X_i \geq X_{i-1}$ and $|F_i| < |F_{i-1}|$.
- Down(i): $i < G$ and a down-right edge is legal from F_i, i.e., $X_{i+1} < X_i$ and $|F_{i+1}| = |F_i| - 1$.
- Ord(i, j): if $i \leq j$, then $X_i \leq \cdots \leq X_j$.
- At(i) means that the robot is at the last known obstacle of fence F_i.
- Eq(i, j) means "if $i \leq j$, then $|F_i| = \cdots = |F_j|$."
- Unch(i, j) stands for "if $i \leq j$, then the values of $|F_i|$ through $|F_j|$ have not

PreRaise(i, q):
1. $\mathrm{Eq}(q+1, i-1)$,
2. $\mathrm{At}(i)$,
3. $i > q$,
4. $X_i < X_q$,
5. $\mathrm{Ord}(q+1, G)$,
6. If $q+1 < i$, then NOT $\mathrm{Up}(q+1)$,
7. $\mathrm{Up}(i)$.

OuterWhile(k) (F_c is the current fence):
1. $\mathrm{Unch}(1, i-1)$,
2. $\mathrm{Eq}(i, c)$ and $c \geq i$,
3. $\mathrm{Ord}(i, G)$,
4. AtNewest holds after the first (if any) iteration of the loop.

PreJDL(j):
1. $\mathrm{At}(j)$,
2. $X_{j+1} < X_j$,
3. $\mathrm{Up}(j+1)$.

PostRaise(i, q) (F_c is the current fence):
1. $\mathrm{Unch}(1, i-1)$,
2. $\mathrm{Eq}(q+1, c)$,
3. $\mathrm{Ord}(q+1, G)$,
4. If $c < G$, $X_{c+1} \geq X_q$,
5. NOT $\mathrm{Up}(q+1)$,
6. AtNewest.

InnerWhile(k) (F_c is the current fence):
1. $\mathrm{Unch}(1, i-1)$,
2. $\mathrm{Eq}(i, j)$,
3. $\mathrm{Ord}(j+1, G)$,
4. AtNewest.
5. If $c > j$, then all PostRaise$(j+1, j)$ conditions hold.

PreJDR(d):
1. $\mathrm{At}(d)$,
2. $X_d \leq X_{d+1} < X_q$,
3. $\mathrm{Eq}(q+1, d)$,
4. NOT $\mathrm{Up}(q+1)$,
5. $\mathrm{Up}(d+1)$.

FIG. 5.9. *Various conditions required for the formal proof.*

changed since the start of the procedure or while loop under consideration."
- AtNewest means that the robot is at the newest obstacle found so far.
- AlmostOrd: No fence has more than one obstacle to the right of a lower fence. That is, for $i = 1, 2, \ldots, G$, if $|F_i| = m$, then $X_i(m-1) \leq X_j$ for all $j > i$.

We prepend a condition by NOT to signify that the logical negation of the condition holds. For easy reference, in Figure 5.9 we define several collections of conditions that will be useful in the correctness proof of the algorithm.

We use the next several lemmas to establish the correctness of the procedure FindFenceTree (Theorem 5.8).

LEMMA 5.3. *Whenever* Raise (i, q) *is called, the PreRaise*(i, q) *conditions hold. Moreover, the procedure terminates, and the PostRaise*(i, q) *conditions hold at that time.*

Proof. It is easy to verify that when FindFenceTree makes the first call Raise $(1, 0)$, the PreRaise$(1, 0)$ conditions hold. We claim that if the PreRaise(i, q) conditions hold when Raise (i, q) is called, then Raise (i, q) terminates and the PostRaise(i, q) conditions hold. We prove this by induction. The base case is $i = G$, i.e., an invocation of the form Raise (G, q): in this case there are no recursive calls to Raise, the inner while loop is not entered, and JumpDownLeft and JumpDownRight are not called. The only effect of Raise (G, q) is that up-right edges are added (line 4) to fence F_G until $\mathrm{Up}(G)$ is not true. It is easy to check that Raise (G, q) terminates with all the PostRaise(G, q) conditions holding.

Next, let us inductively assume that the claim holds for all calls to Raise $(j, .)$, for $j = i+1, \ldots, G$. Consider an invocation of Raise (i, q) at some point when the PreRaise(i, q) conditions hold. Before the outer while loop is entered, the current fence is F_c, where $c = i$. It is easily verified that the PreRaise(i, q) conditions imply that all the OuterWhile conditions hold at this point. By Lemma 5.4, when the outer while loop is exited, all the OuterWhile conditions continue to hold, *and* NOT Up(i) holds. At this point, if the "If" condition on line 16 fails, then we claim that all the PostRaise(i, q) conditions hold. Most of these conditions are easy to check, so we will only argue the less trivial ones. To argue that condition (2) Eq$(q + 1, c)$ holds, note that NOT Up(i), combined with Ord$(q + 1, G)$ and $i > q$ (from PreRaise(i, q)), imply Eq$(i - 1, i)$. This, combined with Eq$(q + 1, i - 1)$ (in PreRaise(i, q)) and Eq(i, c) (in OuterWhile) implies Eq$(q+1, c)$. Condition (5) NOT Up$(q+1)$ follows from Eq$(q+1, c)$ (which implies Eq$(q + 1, i)$) and NOT Up(i).

Thus if the condition on line 16 fails, then Raise (i, q) terminates with the PostRaise (i, q) conditions holding, and the lemma is proved. But if the condition on line 16 is true upon exit of the outer while loop, then we claim that the conditions PreJDR(d) hold. Again we will only show the arguments for the nontrivial ones among these: condition (2) $X_d \leq X_{d+1} < X_q$ follows from Ord(i, G) and $c \geq i$ (in OuterWhile), which imply $X_d \leq X_{d+1}$ (where $d = c$), and from the truth of the If condition. The reasoning to show that (5) Up$(d + 1)$ holds is as follows. Since AtNewest holds (from OuterWhile), this means that the robot has just found the new obstacle on F_c. Since obstacle number $|F_d|$ on F_{d+1} can only be found after the corresponding obstacle on F_d, this means that $|F_{d+1}| < |F_d|$. From the condition $X_d \leq X_{d+1}$ that we just argued, this implies that Up$(d + 1)$ must hold.

Now when JumpDownRight (d) is invoked on line 17, by Lemma 5.7, the robot ends up at (the most-recently discovered obstacle of) F_{d+1}. At this point we claim that the conditions PreRaise$(d + 1, q)$ hold. In particular, condition (3) $d + 1 > q$ holds since $d \geq i$ (from OuterWhile) and $i > q$ (from PreRaise(i, q)). (This actually implies that $d > q$, a fact we will use below.) Condition (4) Ord$(q + 1, G)$ is one of the PreRaise(i, q) conditions, which we assumed to hold. The fact that $d > q$ implies $q + 1 < d + 1$, and NOT Up$(q + 1)$ was already argued above, so (5) holds. The remaining PreRaise$(d + 1, q)$ conditions are easy to check.

By induction assumption, therefore, procedure Raise $(d + 1, q)$ terminates with the conditions PostRaise$(d + 1, q)$ holding. Of these conditions, all but condition (1) depend only on q and the number c of the current fence at the end of the procedure. So the conditions PostRaise(i, q) (2) through (6) hold. Finally, condition (1) Unch$(1, i-1)$ holds because it is an OuterWhile condition, and this completes the proof. ∎

LEMMA 5.4. *The conditions OuterWhile are invariants for the outer while loop.*

Proof. Suppose all the OuterWhile conditions hold just before entry of the outer while loop. If the outer while loop is entered, an obstacle is added to the current fence $F_c = F_i$ via an up-right edge at line 4, and at this point $j = i$. At this stage it is trivial to verify that the InnerWhile conditions hold. By Lemma 5.5, upon exit of the inner while loop, all the invariants InnerWhile continue to hold, *and* either $j = G$ or $j < G$ and Ord$(j, j + 1)$ holds. At this point we claim that the OuterWhile conditions hold: condition (1) Unch$(1, i-1)$ is an InnerWhile condition. We argue condition (2) Eq(i, c) as follows. If $c = j$, then Eq(i, j) (from InnerWhile) implies Eq(i, c). Otherwise, $c > j$, in which case from the InnerWhile conditions, all the PostRaise$(j + 1, j)$ conditions hold. In particular, Eq$(j + 1, c)$ holds and Up$(j + 1)$ is false. Since $c > j$ we must also have $j < G$ and Ord$(j, j + 1)$ (the failure of the conditions of the inner while loop), i.e., $X_j \leq X_{j+1}$. Since Up$(j + 1)$ is false, this must mean that $|F_j| = |F_{j+1}|$. Thus we have Eq(j, c). This, combined with Eq(i, j) from the InnerWhile conditions, implies Eq(i, c). Condition (3) Ord(i, G) is argued as follows. The InnerWhile conditions

Ord$(j+1, G)$ and Eq(i, j), and the condition Ord$(j, j+1)$ that holds because the inner while loop was just exited, imply Ord(i, G). Finally, condition (4) AtNewest follows from the fact that just before returning to the start of the outer while loop, either an up-right edge was added at line 4, or the inner while loop was executed, and AtNewest is one of its invariants. ☐

LEMMA 5.5. *The conditions InnerWhile are invariants for the inner while loop.*

Proof. Suppose all the conditions InnerWhile hold at the start of an iteration of the inner while loop. If the loop is entered, then clearly $X_j > X_{j+1}$. If at this point Down(j) holds, then a down-right edge is added, and j is incremented to $j+1$. At this point it is easy to check that all the InnerWhile conditions continue to hold. On the other hand, if Down(j) does not hold, then we claim that the conditions PreJDL(j) hold: (1) At(j) is clearly true. (2) $X_{j+1} < X_j$ holds as we observed above. (3) Up$(j+1)$ holds since $X_{j+1} < X_j$ and NOT Down(j) holds.

By Lemma 5.6, after JumpDownLeft is executed, the robot is at F_{j+1}. At this point we claim that all the conditions PreRaise$(j+1, j)$ hold. For instance, condition (5) Ord$(j+1, G)$ holds since by assumption it held when the inner while loop was entered (being one of the InnerWhile conditions), and before this invocation of Raise $(j+1, j)$, no new obstacles were discovered on any fence. The remaining Raise $(j+1, j)$ conditions are trivially checked.

By Lemma 5.3, after Raise is executed, all the conditions PostRaise$(j+1, j)$ will hold. At this point we claim that all the conditions InnerWhile continue to hold: (1) Unch$(1, i-1)$ is maintained since fences F_j and above are unaffected by Raise$(j+1, j)$ (this is the Unch$(1, j)$ condition in PostRaise$(j+1, j)$), and $j \geq i$. (2) Eq(i, j) is maintained for the same reason. Conditions (3) Ord$(j+1, G)$ and (4) AtNewest are also PostRaise$(j+1, j)$ conditions. Finally, we just argued above that the PostRaise$(j+1, j)$ conditions hold, and this is condition (5) of InnerWhile. ☐

We establish below that the procedures JumpDownLeft and JumpDownRight work correctly if they are invoked under appropriate conditions.

LEMMA 5.6. *Whenever* JumpDownLeft (j) *is invoked, the conditions PreJDL(j) hold, and the procedure terminates with the robot at the last known obstacle of F_{j+1}.*

Proof. That the conditions PreJDL(j) hold whenever JumpDownLeft (j) is invoked can easily be seen from the proofs of Lemmas 5.3 and 5.5. The PreJDL(j) condition $X_{j+1} < X_j$ implies that the motion in line 2 (following tree edges to the left) leads to a point where the x-coordinate is X_{j+1} (see Figure 5.10). Since edges followed to the left only lead to the same fence or to a higher one, this implies that the point at the end of the motion in line 2 is vertically above (and not below) the last known obstacle P of F_{j+1}. Thus moving vertically down in line 3 leads to obstacle P. ☐

LEMMA 5.7. *Whenever the procedure* JumpDownRight (d) *is invoked, the conditions PreJDR(d) hold, and the procedure terminates with the robot at the last known obstacle of F_{d+1}.*

Proof. That the conditions PreJDR(d) hold whenever JumpDownRight (d) is invoked can easily be seen from the proof of Lemma 5.3. Since $X_d \leq X_{d+1}$, moving vertically down from F_d will lead to a tree edge that is to the left of F_{d+1}. Therefore, following the tree edges to the right will lead to the most recently discovered obstacle of F_{d+1}. ☐

From the above lemmas it is easy to prove that the procedure FindFenceTree finds the desired fence-tree.

THEOREM 5.8. *When executing procedure* FindFenceTree*, the robot either finds a*

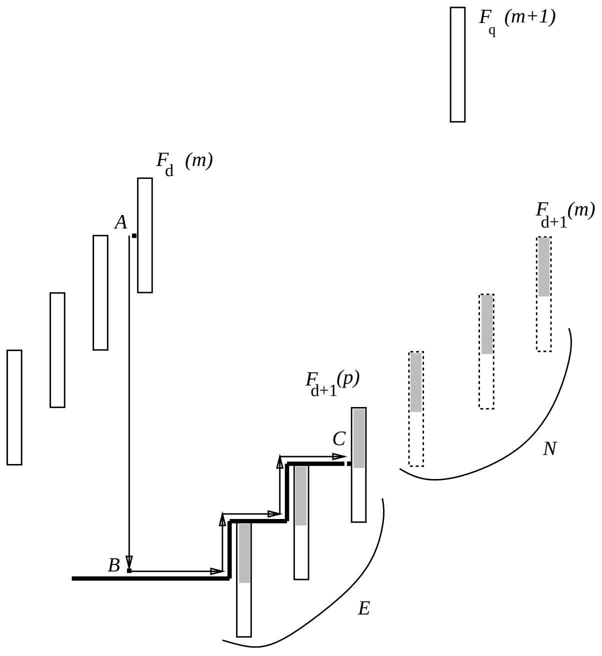

FIG. 5.10. *Showing a use of procedure* JumpDownRight *to jump from $F_d(m)$ to $F_{d+1}(p)$. Solid-boundary rectangles are obstacles found so far in the tree. The set N of dotted rectangles represents obstacles that will be found on fence F_{d+1} immediately following this procedure. Thick solid lines are tree edges. The thin solid line shows the path followed when executing the procedure. The procedure starts from A (obstacle $F_d(m)$), goes vertically down to a tree edge (point B), then follows the edges to the right to the final obstacle of F_{d+1} (point C). The set E is the set of edges followed in BC. The length of AB is no more than the lengths of the edges in E plus the heights of the obstacles in N.*

complete $G \times M$ fence-tree or reaches the wall (the line $x = n$) after having found a collection of i partial fences $F_1, F_2, \ldots, F_i$ that satisfy the fence-tree rules.

Proof. Recall that we have set $|F_0|$ to be $M + 1$ and X_0 to be infinite. After the first obstacle on fence $F_1, F_2, \ldots, F_G$ is found in line 4 of FindFenceTree, the robot returns to $F_1(1)$. At this point it is easy to check that the PreRaise$(1, 0)$ conditions are satisfied. When Raise $(1, 0)$ is invoked in line 7, by Lemma 5.3, the robot completes the procedure (if it hasn't reached the wall) with the PostRaise$(1, 0)$ conditions holding. In particular, condition (4) implies that the current fence upon completion of the procedure must be $F_c = F_G$ (since otherwise $X_{c+1} \geq X_0$, which is impossible since $X_0 = \infty$). Also, conditions (2) Eq$(1, c)$ and (5) NOT Up(1) imply that $|F_1| = |F_2| = \cdots = |F_G| = |F_0| - 1 = M$. ∎

Finally, we establish an invariant that will be useful later.

LEMMA 5.9. *The AlmostOrd invariant holds throughout any execution of* Raise (i, q).

Proof. The only two statements of the procedure which could possibly result in a violation of the AlmostOrd invariant are 4 (where an up-right edge is added) and 8 (where a down-right edge is added). But whenever line 4 is reached, Ord(i, G) holds: this follows from Ord$(q + 1, G)$, which is one of the OuterWhile conditions (which we prove below to be invariants for the outer while loop), and $i > q$, which is a PreRaise(i, q) condition. Thus even if the new obstacle added to F_i in line 4 is to the right of (the last obstacle of) a lower fence, this would be the only such obstacle of F_i. Similarly, whenever a down-right edge is added from fence F_j (thereby adding an obstacle to F_{j+1}), $\mathrm{Ord}(j+1, G)$ holds: this is one of the InnerWhile conditions, which we show below to be invariants for the inner while loop. Thus even if the new obstacle added to F_{j+1} in line 8 is to the right of some lower fence, it would be the only such obstacle of F_{j+1}. ∎

5.4. Cost analysis. Recall from subsection 5.2 that we would like our fence-tree-finding algorithm to travel a distance of no more than $O(kL)$. The next theorem establishes this.

THEOREM 5.10. *For* $G = \lceil \frac{k}{a} \rceil$ *and* $M = \lceil \frac{k}{a} \rceil + \lceil \frac{2L}{h} \rceil$, *the algorithm* FindFenceTree *for finding a* $G \times M$ *fence-tree in a simple scene has total cost* $O(kL)$.

Proof. From Lemma 5.2, it suffices to show that the total distance traveled by the robot while executing FindFenceTree is bounded by some constant times the total length of all edges plus the heights of all obstacles in the fence-tree. There are four kinds of motions performed by the algorithm:

- adding an up-right edge (line 4 of Raise);
- adding a down-right edge (line 8 of Raise);
- retracing an old path (lines 3, 6 of Raise);
- jumping from a fence to the next lower one, using procedures JumpDownLeft and JumpDownRight.

Consider a specific iteration of the outer while loop of Raise. If the robot is not at F_i at the start of this iteration, it executes "Retrace to F_i" at line 3. This motion consists simply of retracing the paths it walked while executing the remaining lines of this loop, during the *previous* iteration of the loop. So the retracing motion at line 3 in a given iteration of the outer while loop can be charged off to the non-line-3 motions executed during the previous iteration of the outer loop. Similarly, the retracing motion at line 6 in a given iteration of the inner while loop can be charged off to the non-line-6 motions executed during the previous iteration of this loop. Thus it suffices to bound the cost of the remaining three kinds of motions. Clearly, the motion required to add up-right and down-right edges can be charged off to the edges created, so we only need to bound the cost of the procedures JumpDownLeft and JumpDownRight. Lemmas 5.11 and 5.12 below establish that the total cost of these procedures is $O(kL)$, which implies our theorem. ∎

LEMMA 5.11. *The total distance traveled during all invocations of* JumpDownLeft *is* $O(kL)$.

Proof. Consider a call to JumpDownLeft (j) at line 10 of Raise (i, q), and suppose the robot is at obstacle $F_j(m)$ when this procedure is invoked. The edge-following motion in line 2 of this procedure can be charged to the set E of edges followed. The right ends of all these edges are at obstacle number m of different fences. Note that just before JumpDownLeft (j) is invoked, $\mathrm{Up}(j+1)$ is true (this is a $\mathrm{PreJDL}(j)$ condition), and when Raise $(j+1, j)$ is completed after JumpDownLeft (j), $\mathrm{Up}(j+1)$ is *not* true (this is a $\mathrm{PostRaise}(j+1, j)$ condition). This means that the procedure Raise $(j+1, j)$ has discovered a collection N of *new* obstacles on fence F_{j+1}, so that $|F_{j+1}|$ would be at least $m-1$. The cost of the vertical motion in line 3 of JumpDownLeft (j) is clearly no more than the total length of the edges E plus the heights of the new obstacles N discovered by the subsequent call to Raise. We can thus charge the total cost of this specific invocation of JumpDownLeft (j) to the set E of edges and the set N of new obstacles. Now we need to argue that the sets E and N of future calls to JumpDownLeft will not overlap with those of the present call. Since the obstacles N

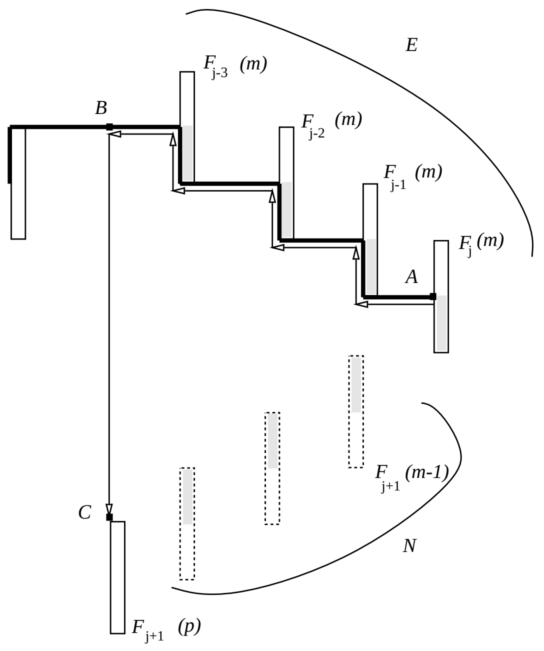

FIG. 5.11. *Showing a use of procedure* JumpDownLeft *to jump from $F_j(m)$ to $F_{j+1}(p)$. Solid-boundary rectangles are obstacles found so far in the tree. The set N of rectangles with dotted boundaries are obstacles that will be found on fence F_{j+1} immediately after this procedure completes. Thick solid lines are tree edges. The thin solid line is the path followed when executing the procedure. The procedure starts from A (obstacle $F_j(m)$), retraces tree edges to the left to point B, then goes vertically down to C, at the top of the final obstacle of F_{i+1}. The set E is the set of edges retraced in AB. The length of BC is no more than the total length of the edges in E plus the heights of the obstacles in N.*

are *new* obstacles discovered on F_{j+1} just after the present call to JumpDownLeft (j), the only future calls to JumpDownLeft whose N-sets can possibly overlap with the N set of the present one are calls to JumpDownLeft from the same fence F_j, i.e., calls to JumpDownLeft (j). However, as we observed above, the Raise $(j+1, j)$ executed just after the present JumpDownLeft (j) finds the obstacles on N before any future call to JumpDownLeft (j) is made. Moreover, it is easy to see that the execution of Raise $(j+1, j)$ does not involve any calls to JumpDownLeft (j). Therefore the N-sets of different calls to JumpDownLeft do not overlap.

Now we show that the E-sets of different calls to JumpDownLeft do not overlap. Again consider a specific invocation of JumpDownLeft (j) from obstacle $F_j(m)$. As we noted above, all the edges in E have at their ends the mth obstacle of different fences. Therefore the only future invocations of JumpDownLeft whose E sets can possibly overlap with the current E set are those from obstacle m of some fence F_u below F_j. We established before that an invocation of JumpDownLeft (u) is only made when the conditions PreJDL(u) hold, and in particular (a) $X_{u+1} < X_u$ and (b) Up$(u+1)$ must hold. However, just after the present execution of JumpDownLeft (j), Raise $(j+1, j)$ is executed, and at that point the PostRaise$(j+1, j)$ conditions hold. In particular, for any fences F_u below F_j such that $X_u < X_j$, Up(u) does not hold. Therefore when (if at all) a future call to JumpDownLeft (u) is made from obstacle m of a fence F_u below F_j, $X_{u+1} \geq X_j(m)$ must hold at that time. In such a future invocation, in line

2, edges are followed to the left until the x-coordinate equals X_{u+1}, so these edges would be to the *right* of $X_j(m)$ and so would not overlap with the edges E of the present set (all of which are to the *left* of X_j). Thus the "charge sets" E and N for different calls to JumpDownLeft (j) will not overlap. ∎

LEMMA 5.12. *The total distance traveled during all invocations of* JumpDownRight *is $O(kL)$.*

Proof. Consider an invocation of JumpDownRight (d) at line 17 of Raise (i, q). We will present a charging scheme where different invocations of JumpDownRight (d) will be charged to distinct portions of the fence-tree. When JumpDownRight (d) is invoked, $\mathrm{Up}(d+1)$ is true (this is a $\mathrm{PreJDR}(d)$ condition). Subsequent to this invocation of JumpDownRight (d), Raise $(d+1, q)$ is invoked, and when that procedure completes, the $\mathrm{PostRaise}(d+1, q)$ conditions imply that $\mathrm{Up}(d+1)$ is no longer true. This means that Raise $(d+1, q)$ has found a collection N of new obstacles on fence F_{d+1}, and then $|F_{d+1}|$ would equal $|F_d| = m$ (this is a $\mathrm{PostRaise}(d+1, q)$ condition). The edge-following motion in line 3 of JumpDownRight (d) can be charged to the set E of edges that are followed. The vertical motion in line 2 of JumpDownRight (d) is clearly no more than the lengths of the edges E plus the heights of the obstacles N, so this motion can be charged to the edge-set E and the obstacle-set N (see Figure 5.11).

Note that since $\mathrm{Up}(d+1)$ is not true after the Raise procedure completes just after this invocation JumpDownRight (d), the next invocation of JumpDownRight (d) can only occur from obstacle $m+1$ or later of F_d. Since presently $X_d < X_q$, and NOT $\mathrm{Up}(q+1)$ and $\mathrm{Eq}(q+1, d)$ hold, the obstacle $m+1$ of F_d will be to the right of X_q. So the edge-set E followed by any future invocation of JumpDownRight (d) will be distinct from the set E of the present invocation. Also, since N is the set of *new* obstacles discovered just after the present invocation of JumpDownRight (d), the set N of any future call to JumpDownRight (d) will not overlap with the set N of the present one. In fact, since we are charging the motion of JumpDownRight (d) only to obstacles and edges associated with fence F_{d+1}, the sets N and E of any future call to JumpDownRight (d') will also not overlap with the sets N and E of the present call. ∎

6. Extension to arbitrary axis-parallel rectangular obstacles.

We now show how to extend the search algorithm to scenes with arbitrary axis-parallel rectangular obstacles (for brevity we call such scenes *general* scenes). That is, we will show how to explore a distance of $O(L\sqrt{nk})$ and find a path of length $O(L\sqrt{n/k})$. Fortunately it turns out that algorithm FindFenceTree, interpreted appropriately, can be used unchanged for these scenes. However, the procedures JumpDownRight and JumpDownLeft must be modified since for general scenes vertical motion is not always unobstructed. In fact if all obstacles have width 1 (but arbitrary heights and positions), then even these procedures remain unchanged. In the next two subsections, we define the notions of *τ-post* and a *τ-fence,* which are the analogues of "obstacle" and "fence" for general scenes. As stated earlier, we will assume throughout that all obstacles have their corners at integer coordinates.

6.1. τ-posts.

Throughout this section we will denote the value $L/\sqrt{nk}$ by τ. We assume $k \le n$ so $\tau \ge 1$. Recall that in a simple scene if the obstacles have height less than $2\tau = 2L/\sqrt{nk}$, then they can be considered "small"—in the sense that the simple strategy of just moving horizontally forward (walking around any obstacles on the way by the shortest route) achieves the optimal ratio of $O(\sqrt{n/k})$ on *each* trip. This motivates the following definition in a general scene. A point P on the left side of an obstacle is called a *τ-post* if the obstacle extends vertically at least τ above and

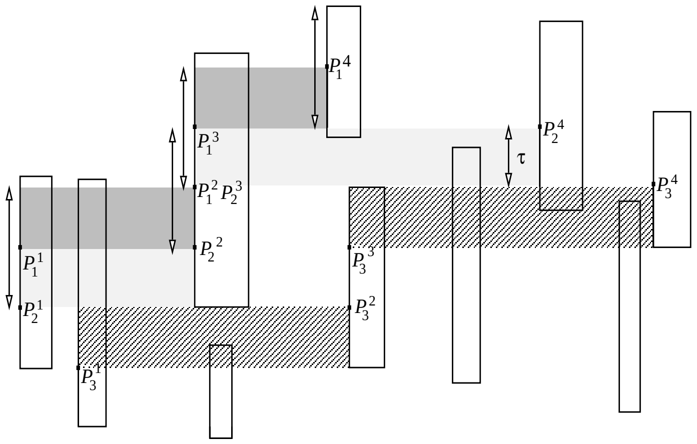

FIG. 6.1. *A collection of three disjoint fences with four posts each. The solid rectangles are the obstacles. The bands of different fences are shaded differently. For convenience, post $F_i(m)$ is denoted P_i^m.*

below P. We will use the term τ-post to refer either to the entire segment of height 2τ or just to the center of that segment. Roughly speaking when the robot encounters a τ-post P while moving horizontally, the obstacle encountered is "big," otherwise it is "small."

6.2. τ-fences. We define a τ-fence as the generalization of the fence defined in section 5.1. The definitions (and notations) for *up τ-fence*, *down τ-fence*, *band*, as well as the definition of a point being *left* or *right* of a fence, and of a path *crossing* a fence, remain the same as in simple scenes, except that we replace the word "obstacle" with "τ-post" throughout and replace h by τ in the relations (5.1) and (5.2) of section 5.1. Note that consecutive τ-posts of a fence may lie on the *same* obstacle, since the inequality (5.1) is not strict. The band between two such posts is empty. We say two τ-fences are *disjoint* if their *nonempty* bands are disjoint. Thus a collection of k disjoint τ-fences costs at least $k\tau$ to cross. In Figure 6.1, the sequence of τ-posts $\langle F_1^1, F_1^2, F_1^3, F_1^4\rangle$ form a τ-fence F_1. Note that F_1^2, F_1^3 are on the same obstacle and that the three fences in the figure are disjoint.

For future reference we define a (right) *τ-path* as the path of the robot when it moves to the right along a fixed horizontal line $y = y_0$ until it hits a τ-post or the wall, moving around any nonpost obstacle on its way. For instance, in Figure 6.2, the path from A to τ-post $F_1(2)$ is a τ-path. Observe that a τ-path has vertical motion at most 2τ at every (integer) x-coordinate on the path, so we have the following.

FACT 6.1. *A τ-path between two points (x, y) and $(x + \delta x, y)$ has length at most $\delta x + 2\tau\ \delta x$.*

6.3. The initial search trip. Roughly speaking, a general scene is treated as if it is a simple scene with obstacles of height $2h = 2\tau = 2L/\sqrt{nk}$. Recall that for simple scenes, the initial trip consists of building groups of G fences of M obstacles each (where $G = \lceil \frac{k\tau}{h} \rceil$ and $M = \lceil \frac{k\tau}{h} \rceil + \lceil \frac{2L}{h} \rceil$), where each group must be built "cheaply" (i.e., with cost $O(kL)$) and must have a known "short" (cost $O(L)$) path crossing it. Analogously for general scenes, we have $h = \tau$ and we would like to build groups of k τ-fences with $M = k + \lceil \frac{2L}{\tau} \rceil$ τ-posts each. We will now pay more

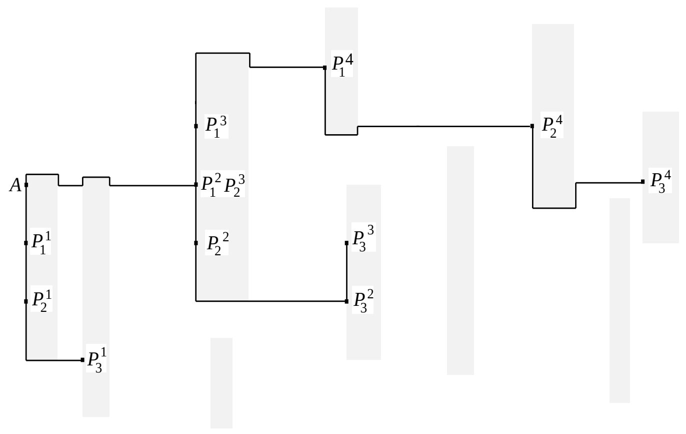

FIG. 6.2. *A 3×4 τ-fence-tree. The shaded rectangles are the obstacles, and solid lines are tree edges. The fences corresponding to this tree are shown in Figure* 6.1. *For convenience, post $F_i(m)$ is denoted P_i^m.*

attention to our progress in the x direction and will build each group with cost at most $O(kL + k\tau\ \Delta x)$ and give each group a group-crossing path of length $O(L + \tau\ \Delta x)$. Here Δx is the x-distance between the leftmost τ-post $F_1(1)$ and rightmost τ-post $F_k(M)$ in the group.

These bounds are sufficient for our purposes for the following reason. Since a fence costs $\tau = L/\sqrt{nk}$ to cross, there can be at most $\sqrt{nk}$ disjoint τ-fences in the window between s and t, so the algorithm will find at most $\sqrt{n/k}$ groups of k fences each. Since the x-motions do not overlap between the groups of fences, the Δx terms add to at most n, so the total distance traveled is $O(kL\sqrt{n/k} + nk\tau) = O(L\sqrt{nk})$. In addition, the concatenation of the group-crossing paths has total cost $O(L\sqrt{n/k} + n\tau) = O(L\sqrt{n/k})$.

6.4. Extending FindFenceTree to general scenes. Once we fix the τ-post $F_1(1)$ in a scene, the three fence-tree definition rules given for simple scenes can be used in a general scene to define a group of $G = k$ τ-fences with M τ-posts each, with the following interpretation. First, "τ-post" replaces the word "obstacle" everywhere. Second, an up-right edge from a τ-post $F_i(m)$ is simply a path that goes up to the top of the τ-post, then right along a τ-path until a τ-post is reached; this τ-post is $F_i(m+1)$. A down-right edge is a similar path that leads to the τ-post $F_{i+1}(m)$. With this interpretation, the algorithm FindFenceTree can be used unchanged for general scenes; only the jump procedures must be changed to handle arbitrary obstacle widths, since the vertical motions (in line 3 of JumpDownLeft and line 2 of JumpDownRight) may no longer be possible. The modified jump algorithms are described in the next two subsections, and we will show that they work correctly, i.e., that the analogues of Lemmas 5.6 and 5.7 hold. We will also show that these procedures are not expensive, i.e., that the analogues of Lemmas 5.11 and 5.12 hold. Given the correctness of the jump procedures, it is easy to verify that the Raise procedure works correctly, i.e., satisfies Lemma 5.3, and consequently that the procedure FindFenceTree does indeed find a $k \times M$ τ-fence-tree, if it exists, with the given post $F_1(1)$ as root. Furthermore, the invariant AlmostOrd also holds (Lemma 5.9) throughout the execution of FindFenceTree.

We must show that this algorithm is still "cheap" in a general scene. Note that if the robot does not encounter any small obstacles when adding the various edges, then (assuming the jump procedures are cheap) our previous arguments suffice. We begin with the fairly straightforward argument that in general the cost of going around small obstacles is not too large. To do this, we show the analogue of Lemma 5.2, namely, that the total cost of the tree edges and the cost of the path from the root to the rightmost node are both within our required bounds.

LEMMA 6.2. *Suppose there is a $k \times M\tau$-fence-tree consisting of fences $F_1, F_2, \dots, F_k$, with $M = k + \lceil \frac{2L}{\tau} \rceil$, where $\tau = L/\sqrt{nk}$. Let Δx be the x-distance from $F_1(1)$ to $F_k(M)$. Then*

(a) *The unique path in the tree from $F_1(1)$ to $F_k(M)$ has length at most $4L + 3\tau\Delta x$.*

(b) *The total length of all the edges in the fence-tree is at most $k(3L + 3\tau\Delta x)$.*

Proof. Since $k \le n$ it follows that $k\tau = kL/\sqrt{nk} \le L$. This implies $M\tau = 2L + k\tau \le 3L$.

Part (a). There are exactly $(M + k - 2)$ edges in the tree path from $F_1(1)$ to $F_k(M)$. Since the vertical portion of each edge has length τ, and the τ-path portions of the edges do not overlap in the x-direction, the total length of these edges is at most $(M + k - 2)\tau + 2\tau\Delta x + \Delta x$, which is at most $(4L + 3\tau\Delta x)$ from the inequalities above.

Part (b). Note that we can associate each edge with a unique post, namely the one at the right-end of the edge. For any given post $F_i(m)$ other than $F_1(1)$, the x-distance to its parent is at most the x-distance δx to its predecessor $F_i(m-1)$ on the same fence. So the edge associated with this post has length at most $(\tau + 2\tau\delta x + \delta x)$. The sum of the δx terms over all posts of the fence F_i is the x-distance between the first and last posts of F_i, which is at most Δx. So the total length of the edges associated with the M posts of a fence is at most $(M\tau + 2\tau\Delta x + \Delta x)$, which sums to $k(M\tau + 2\tau\Delta x + \Delta x)$ for k fences. This last expression is at most $k(3L + 3\tau\Delta x)$ from the previous inequalities. $\square$

Thus, just as in simple scenes, we need to argue only that the total cost of each jump procedure is at most a constant times the total length of the tree edges plus the heights of all τ-posts in the tree. In the next two subsections we show how these procedures can be modified to handle arbitrary obstacle widths, and we prove that they are not too expensive. As before, our approach will be to argue that for each jump procedure, no portion of the tree is charged too often for different executions of that procedure.

6.5. Modifying JumpDownRight.

To describe the modifications, it will be useful to introduce the notion of a *greedy down-left* path: it is a path that repeatedly goes "*down* till it hits an obstacle, then to the *left* corner of the obstacle." Other greedy paths are defined similarly. Also, a point (x, y) will be said to be *down-left* of another point (x_0, y_0) if $x \le x_0$ and $y \le y_0$. As in the case of simple scenes, we will find it convenient to associate an edge in the fence-tree with the post at its right end. Our modified procedure is shown in Figure 6.3, and a typical path walked while executing this procedure is shown in Figure 6.4.

We first establish the correctness of this modified procedure, i.e., the analogue of Lemma 5.7.

LEMMA 6.3. *If the general procedure* JumpDownRight (d) *is called when the PreJDR(d) conditions hold, then after the procedure is completed, the robot will be at the last known τ-post of F_{d+1}.*

```
Procedure JumpDownRight (d)
    1. Let $m = |F_d|$ and $p = |F_{d+1}|$.
    2. Move greedy down-left until down-left of top of $F_{d+1}(p)$.
    3. Move greedy right-down until:
        • at $\tau$-post $F_{d+1}(p)$, or
        • on a tree edge. In this case, follow tree-edges to the right until at $F_{d+1}(p)$.
```

FIG. 6.3. *General procedure for jumping down from F_d to F_{d+1} when $X_d \leq X_{d+1}$.*

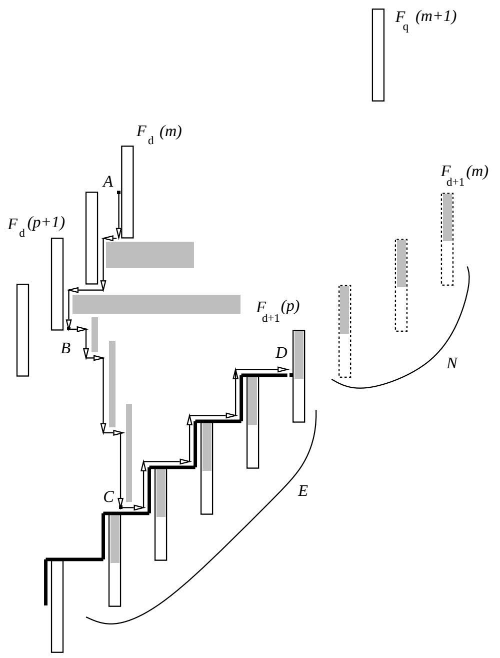

FIG. 6.4. *A use of the generalized procedure* JumpDownRight *to jump from $F_d(m)$ to $F_{d+1}(p)$, for clarity shown in a scene where the fence posts correspond exactly to obstacles of height 2τ. Shaded rectangles with no boundaries are obstacles that are not part of any fence. Solid-boundary rectangles are nodes found so far in the tree. Dotted-boundary rectangles are posts on F_{d+1} that will be found immediately following this procedure. Thick solid lines are tree edges. The thin arrow line shows the path followed when executing the procedure.*

Proof. It will be useful to consult Figure 6.4 which shows a typical path followed while executing this procedure. From the PreJDR(d) conditions, the robot is initially at (the last known τ-post of) F_d, so the initial y-coordinate is $Y_d(m)$. The PreJDR(d) conditions $X_d \leq X_{d+1}$ and Up($d+1$) also imply that $|F_{d+1}| < |F_d|$, or $p < m$, which means that the bottom of the τ-post $F_d(m)$ is no lower than the top of the τ-post $F_{d+1}(p)$. Therefore the greedy down-left path in step 2 will not encounter any tree-edges, since even a down-right leading to the destination τ-post $F_{d+1}(p)$ can only originate at τ-post number p or lower of F_d, which must be lower than $F_d(m)$. Note that the path in step 2 is bounded on the left by the τ-posts of F_i. Also, at the end of this step, the robot's y-coordinate is the same as the top of the τ-post $F_{d+1}(p)$ to which the robot is jumping. Even if the greedy right-down path of step 3 goes

```
Procedure JumpDownLeft ($j$)
    1. Let $m = |F_j|$, $p = |F_{j+1}|$.
    2. Follow tree edges to the left until $x = X_{j+1}(p)$.
    3. Go greedy down-left until robot is either
        • down-left of top of $F_{j+1}(p)$, or
        • down-left of top of $F_u(m-1)$ for some $u \leq j$. In this case:
            (a) While $u \leq j$ do the following:
                i. Go greedy right-down until at $F_u(m-1)$ or on a tree edge.
                ii. If at a tree edge, follow edges to right until at $F_u(m-1)$.
                iii. $u := u + 1$.
            (b) Go greedy down-left until down-left of top of $F_{j+1}(p)$.
    4. Go greedy right-down until at $F_{j+1}(p)$ or on a tree edge. If at a tree edge, follow
       edges to right until at $F_{j+1}(p)$.
```

FIG. 6.5. *General procedure for jumping down from F_j to F_{j+1} when $X_j > X_{j+1}$.*

only to the right, it will hit this τ-post. In the *worst* case, the motion in step 3 is just vertically down until a tree edge (down-right or up-right) is reached. From the definition of the fence-tree, it is easy to see that following the tree edges to the right must lead to $F_{d+1}(p)$. ∎

In the lemma below, we show that the cost of all calls to JumpDownRight can be charged off to the lengths of all edges in the fence-tree.

LEMMA 6.4. *The total cost of all calls to* JumpDownRight *is at most a constant times the total length of all edges in the fence-tree, plus the heights of all τ-posts in the tree.*

Proof. As in the case of simple scenes (Lemma 5.12) we will present a charging scheme where the cost of different invocations of JumpDownRight is charged to distinct portions of the fence-tree. Consider a particular call to JumpDownRight (d) from Raise (i, q), to jump from $F_d(m)$ to $F_{d+1}(p)$ (that is, when this procedure is called, $|F_d| = m$ and $|F_{d+1}| = p$). See Figure 6.4. By a reasoning similar to the one in the proof of Lemma 5.12, we can see that there is a set N of new obstacles that will be added to F_{d+1} by the Raise ($d+1, q$) procedure that is invoked just after this invocation of JumpDownRight (d). After these new obstacles are added to F_{d+1}, $|F_{d+1}|$ would equal $|F_d| = m$. Let E be the set of edges of F_{d+1} (if any) that are followed in step 3 of JumpDownRight.

Clearly the total horizontal and vertical motion of this procedure (in steps 2 and 3) is no more than twice the total length of the edges in E plus the heights of the obstacles in N. (This bound is actually quite loose but will suffice for our purposes.) As before it is easy to argue that the sets N and E of any future call of JumpDownRight (d) will not overlap with the corresponding sets of the present call. ∎

6.6. Modifying JumpDownLeft.

The general procedure JumpDownLeft is shown in Figure 6.5, and a sample path executed by that procedure is shown in Figure 6.6.

We first establish the correctness of this general procedure, i.e., the analogue of Lemma 5.6.

LEMMA 6.5. *If the general procedure* JumpDownLeft (j) *is called under the conditions PreJDL(j), then the procedure terminates with the robot at the last known τ-post of F_{j+1}.*

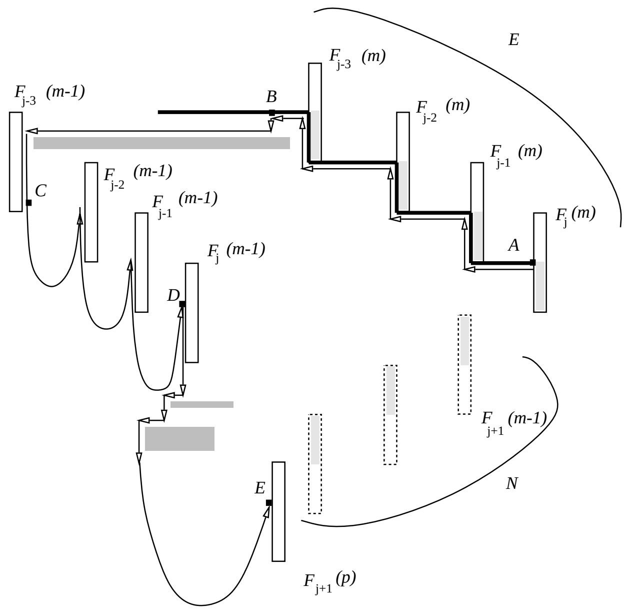

FIG. 6.6. *A use of procedure* JumpDownLeft *to jump from $F_j(m)$ to $F_{j+1}(p)$, for clarity shown in a scene where the fence posts correspond exactly to obstacles of height 2τ. Shaded rectangles with no boundaries are obstacles that are not part of any fence. Solid-boundary rectangles are posts found so far in the tree. Dotted-boundary rectangles are posts of F_{j+1} that will be found immediately following this procedure. Thick solid lines are tree edges. The thin arrow line is the path followed when executing the procedure. Curved arrows represent motions executed during steps* 3*(a)(i) and* 4 *of the procedure.*

Proof. Let m and p be the quantities defined in the procedure. See Figure 6.6 for a typical path of this procedure. The PreJDL(j) condition $X_{j+1} < X_j$ implies that following tree edges to the left in step 2 will lead to a point where $x = X_{j+1} = X_{j+1}(p)$. The PreJDL(j) conditions $X_{j+1} < X_j$ and Up($j+1$) imply that $p = |F_{j+1}| < m-1$, so the $(m-1)$st posts of fences F_j and above are higher than the top of the destination post $F_{j+1}(p)$. Suppose F_r is the highest fence reached in step 2, i.e., the last edge retraced has its right end on a τ-post of F_r. By the AlmostOrd invariant, no fence can have more than one post to the right of a lower one, so only the last edge retraced in step 2 can be an up-right edge; the others must be *down-right* edges. The same invariant implies that the x-coordinate of the robot at the end of step 2 (i.e., $X_{i+1}(p)$) lies in the interval $[X_u(m-1), X_u(m)]$, for each $u = r, r+1, \dots, j$. This means that in step 3 when the robot goes greedily down-left, the robot must either reach a point down-left of the top of some post $F_u(m-1)$, or else reach a point down-left of $F_{j+1}(p)$, the destination post. In the former case, the robot enters the while loop of step 3(a). We claim that in each iteration of this while loop, the robot jumps down to post $(m-1)$ of the next lower fence until it reaches $F_j(m-1)$. This motion is similar to that of procedure JumpDownRight, so we can reason as in the proof of Lemma 6.3 (correctness of JumpDownRight) to show this claim. Once the robot is at $F_j(m-1)$, step 3(b) will take the robot to a point down-left of the top of $F_{j+1}(p)$. Finally step 4 is similar to step 3 in the general version of JumpDownRight, so by reasoning as in the proof of Lemma 6.3, we can show that the robot will eventually be at $F_{j+1}(p)$. □

LEMMA 6.6. *The total cost of all calls to* JumpDownLeft *is at most a constant times the total length of all the tree edges, plus the heights of all the τ-posts in the fence-tree.*

Proof. Consider a call to JumpDownLeft (j). As in the case of simple scenes, we can use a charging scheme where different calls to JumpDownLeft will be charged to distinct portions of the fence-tree. As in the proof of Lemma 5.11, let E be the set of edges followed in step 2 of the procedure, and let N be the set of $m-1-p$ "new" obstacles that will be added to F_{j+1} by the Raise procedure invoked just after this procedure completes. By the same reasoning as in that Lemma, the E and N sets of this call to JumpDownLeft will not overlap with the corresponding sets of any future call. The edge-following motion of the robot during step 2 of the procedure can be charged to the edge-set E, and so we only need to account for the motions in the remaining steps of the procedure.

If step 3 takes the robot vertically down to the τ-post $F_{j+1}(p)$, then as in the case of simple scenes this vertical motion can be charged to the edge-set E and the set N. In this case we are done with the proof. However, in general scenes there are two possibilities for the motion of the robot during this step:

- (A) The robot may reach some point down-left of the top of $F_{j+1}(p)$. Let (x_1, y_1) be the coordinates of the robot at this point. In this case, step 3 is done, and we charge the vertical motion to the total heights of the τ-posts in N plus the lengths of the edges in E. Also in this case, while going greedy down-left, the robot cannot go to the left of post $F_j(p+1)$, since the bottom of this post has the same y-coordinate as the top of $F_{j+1}(p)$. (If the robot were forced to go to the left of $F_j(p+1)$, case (B) below would occur.) Therefore the horizontal motion in this case is no more than $X_{j+1}(p) - X_j(p+1)$, which in turn is no more than the lengths of the portions of the edges of F_{j+1} that lie between $x = X_j(p+1)$ and $x = X_{j+1}(p)$; we can charge the horizontal motion to this edge-set E_1. We now claim that the edge-set E_1 of this call to JumpDownLeft (j) will not overlap with the E_1 set of any future call to JumpDownLeft (j). As we argued in the proof of Lemma 5.11, by the time any future call to JumpDownLeft (j) is made, F_{j+1} would have at least $m-1$ obstacles. Since $X_j(m) > X_{j+1}(p)$, the E_1 set of such a call would lie entirely to the right of $x = X_j(m+1) > X_j(m)$, which is to the right of $x = X_{j+1}(p)$ (the right-boundary of the present E_1 set). Therefore the edge-sets E_1 of different calls to JumpDownLeft (j) cannot overlap.
- (B) The robot may reach some point down-left of the top of post $(m-1)$ of some fence F_j or above. In this case the robot enters the while loop of step 3(a), and repeatedly moves down to the $(m-1)$st post of the next lower fence until it reaches $F_j(m-1)$. The motion in each iteration of this while loop is similar to the motion in the JumpDownRight procedure. The only difference is that instead of going from post number m of one fence to a lower-numbered obstacle of the next lower fence, in this case the robot goes to the *same*-numbered post of the next lower fence. Consider some iteration of this while loop, where the robot is jumping down from $F_u(m-1)$ to $F_{u+1}(m-1)$. Let E_2 be the set of edges of F_{u+1} contained in the region between the lines $x = X_u(m-1)$ and $x = X_{u+1}(m-1)$. The vertical motion in step 3(a)(i) is no more than the height of the destination post, plus the heights of the posts associated with the edges E_2. The horizontal motion in steps 3(a)(i) and 3(a)(ii) is no more than the lengths of the edges in E_2. In any future call

to JumpDownLeft the E_2 set corresponding to fence F_{u+1} must lie entirely to the right of $F_u(m)$, which in turn is to the right of $F_{u+1}(m-1)$ (the right-boundary of the present E_2 set). Thus in any future call to JumpDownLeft, the E_2 set associated with F_{u+1} will not overlap with the E_2 set of the present call. Similarly, as argued in the case of simple scenes, in any future call to JumpDownLeft from post m of a fence below F_j the edge-set E followed in step 2 will lie entirely to the right of $X_j(m)$, so none of the E_2 sets of that call will overlap with those of the present call. After exiting the while loop of step 3(a), the robot executes step 3(b): go greedy down-left until down-left of top of $F_{j+1}(p)$. The charging for this step is similar to case (A) above, except that we do not need to charge the vertical motion to the edge-set E since this step starts at $F_j(m-1)$. The same argument as in case (A) establishes that the charge-sets for this step will not overlap with the corresponding charge-sets of any future call to JumpDownLeft.

Finally in step 4, the robot performs a motion similar to the one in the (generalized) procedure JumpDownRight, and we can use a charging-scheme similar to the one used there. The argument to show that the portions of the tree charged for step 4 of this call to JumpDownLeft (j) do not overlap with the corresponding charge-sets of any future call is similar to the one used above for case (B) of step 3. □

7. An incremental algorithm. We describe here an improvement of our cumulative algorithm, so that the per-trip ratio on the ith trip, for all $i \le n$, is $O(\sqrt{n/i})$. Let us for simplicity say that we know L. From the earlier results in this paper, we know that by searching a distance at most $cL\sqrt{nk}$ we can find an s-t path of length at most $c'L\sqrt{n/k}$, for some constants c, c' and any $k \le n$.

Let us suppose that at the end of i trips we know an s-t-path π of length at most $c'L\sqrt{n/i}$ (for the base case, simply use the BRS algorithm). What we now want to do is to search with cost at most $cL\sqrt{n2i}$ and find a path of length at most $c'L\sqrt{n/2i}$. Let us denote by Π the path we would have traveled if we did this entire search in one trip using the algorithm of the previous sections. In order to maintain a per-trip ratio of $O(\sqrt{n/i})$, we spread the work of Π over the next i trips as follows. Each trip consists of two phases: The first is a *search* phase, where we walk an additional portion of Π of length $\frac{1}{i}cL\sqrt{n2i} = cL\sqrt{2n/i}$, starting from where we left off on the previous trip. We can always do this because the fences are in a tree structure, so that the last point in Π during the previous search can always be reached from the start point by a known short path whose length adds only a small constant factor to the total trip length. Once the search phase is completed, we "give up" and enter the *follow* phase, where we complete the trip by joining (by a greedy path) the known path π of length $c'L\sqrt{n/i}$ and following it to t. Thus our trip length is still $O(L\sqrt{n/i})$. Since in each such search-follow trip we traverse a portion of Π of length $cL\sqrt{2n/i}$, and the length of Π is at most $cL\sqrt{2ni}$, after i trips we will have completely walked the path Π. So after the first $2i$ trips we have a path of length at most $c'L\sqrt{n/2i}$. This reestablishes our invariant. Thus, we have the following theorem.

THEOREM 7.1. *There is a deterministic algorithm R that for every $i \le n$ achieves a per-trip ratio on the ith trip, $\rho_i(R, n)$, of $O(\sqrt{n/i})$.*

8. Modification for point-to-point navigation. Our algorithms can be extended to the case where t is a point rather than a wall, with the same bounds, up to constant factors, as follows. Let us assume for simplicity that the shortest path length L is known. As before, if we do not know L, we can use the standard "guessing and doubling" approach and suffer only a constant factor penalty in performance. On the first trip, the robot can get to t using the optimal point-to-point algorithms of [7] or [3], with a single-trip ratio of $O(\sqrt{n})$. Once at t, the robot creates a greedy up-left path and a greedy down-left path from t, within a window of height $4L$ centered at t. Note that the highest post in a $k \times M$ τ-fence-tree is $M\tau \leq 3L$ above the root (which is always distance L below t) and the lowest post is $k\tau \leq L$ below the root. So the robot is guaranteed to stay within a window of height $4L$ centered at t. Thus after the first trip, these greedy paths play the role of a wall; once the robot hits one of these paths, it can reach t with an additional cost that is only a low-order term in the total cost.

9. Modification for a purely tactile robot.

We assumed so far that whenever our robot hits an obstacle, it is told how far the nearest corner of the obstacle is. This information is used only to tell the robot whether or not there is a τ-post at the point of encounter. With only a constant factor penalty (see the analysis in [1]) the robot can obtain this information on its own, using the standard doubling strategy: Move up a distance 1, then down 2, then up 4, and so on, each time moving double the previous distance.

10. Conclusion and open problems.

The core result of this paper is an algorithm that performs a smooth trade-off between search effort and the goodness of the path found. This algorithm may be of interest independently of the performance-improvement problem. For instance when a robot has more time or fuel available, one would like it to spend more effort and find a better route. The fence-tree structure is central to this search algorithm. Intuitively, one can think of the fence-tree as representing the collection of those obstacles in the scene which are responsible for making the scene difficult to cross from s to t. Thus the fence-tree in a sense captures the "essence" of a scene, as far as the difficulty (i.e., cost) of crossing the scene is concerned. It would be interesting to explore whether an analogous structure can be defined in more general scenes. This might lead to a generalization of our results to such scenes.

At a higher level, our approach in designing a "learning" navigation algorithm was to start with an algorithm that achieves the above-mentioned cost/performance trade-off and convert that to a more incremental algorithm by spreading the work over several trips. This high-level idea may well be useful in designing performance-improvement algorithms for other tasks.

There are several other interesting research directions that can be explored. For instance, can randomization provide a better or simpler algorithm? For the one trip problem, the best lower bound known is $\Omega(\log\log n)$ by Karloff, Rabani, and Ravid [11], and the best upper bound is $O(n^{4/9}\log n)$ by Berman et al. [2]. What about extending our multitrip results to more general scenes? Recently, Berman and Karpinski [4] designed a randomized $O(n^{3/4})$-competitive single-trip algorithm for 2-dimensional scenes containing arbitrary convex obstacles within which a unit circle can be inscribed. Achieving an $O(\sqrt{n})$ ratio for such scenes seems considerably harder. A good first step might be to consider scenes with rectangular obstacles in arbitrary orientations (i.e., not necessarily axis-parallel).

A related problem is the question of how the robot can efficiently visit several destinations in a scene, improving performance wherever possible. One difficulty here is devising a useful performance measure (depending on the location of the destinations, one may be able to use previous information to varying degrees) that appropriately captures the essence of the problem.

ON INTERPOLATION AND AUTOMATIZATION FOR FREGE SYSTEMS[*]

MARIA LUISA BONET[†], TONIANN PITASSI[‡], AND RAN RAZ[§]

Abstract. The interpolation method has been one of the main tools for proving lower bounds for propositional proof systems. Loosely speaking, if one can prove that a particular proof system has the *feasible interpolation* property, then a generic reduction can (usually) be applied to prove lower bounds for the proof system, sometimes assuming a (usually modest) complexity-theoretic assumption. In this paper, we show that this method *cannot* be used to obtain lower bounds for Frege systems, or even for TC^0-Frege systems. More specifically, we show that unless factoring (of Blum integers) is feasible, neither Frege nor TC^0-Frege has the feasible interpolation property. In order to carry out our argument, we show how to carry out proofs of many elementary axioms/theorems of arithmetic in polynomial-sized TC^0-Frege.

As a corollary, we obtain that TC^0-Frege, as well as any proof system that polynomially simulates it, is not automatizable (under the assumption that factoring of Blum integers is hard). We also show under the same hardness assumption that the k-provability problem for Frege systems is hard.

1. Introduction.

One of the most important questions in propositional proof complexity is to show that there is a family of propositional tautologies requiring superpolynomial-sized proofs in a Frege or extended Frege proof system. The problem is still open, and it is thus a very important question to understand which techniques can be applied to prove lower bounds for these systems, as well as for weaker systems. In recent years, the interpolation method has been one of the most promising approaches for proving lower bounds for propositional proof systems and for bounded arithmetic. Here we show that this method is not likely to work for Frege systems and some weaker systems. The basic idea behind the interpolation method is as follows.

We begin with an unsatisfiable statement of the form $F(x, y, z) = A_0(x, z) \wedge A_1(y, z)$, where z denotes a vector of shared variables, and x and y are vectors of private variables for formulas A_0 and A_1, respectively. Since F is unsatisfiable, it follows that for any truth assignment α to z, either $A_0(x, \alpha)$ is unsatisfiable or $A_1(y, \alpha)$ is unsatisfiable. An interpolation function associated with F is a Boolean function that takes such an assignment α as input, and outputs 0 only if A_0 is unsatisfiable, and 1 only if A_1 is unsatisfiable. (Note that both A_0 and A_1 can be unsatisfiable, in which case either answer will suffice.)

How hard is it to compute an interpolation function for a given unsatisfiable statement F as above? It has been shown, among other things, that interpolation functions are not always computable in polynomial time unless $P = NP \cap co - NP$ [M1, M2, M3]. Nevertheless, it is possible that such a procedure exists for some special cases. In particular, a very interesting and fruitful question is whether one can find (or whether there exists) a polynomial-sized circuit for an interpolation function in the case where F has a short refutation in some proof system S. We say that a proof system S admits *feasible interpolation* if, whenever S has a polynomial-sized refutation of a formula F (as above), an interpolation function associated with F has a polynomial-sized circuit. Krajíček [K2] was the first to make the connection between proof systems having feasible interpolation and circuit complexity.

There is also a monotone version of the interpolation idea. Namely, for conjunctive normal form formulas A_0 and A_1, $F = A_0(x, z) \wedge A_1(y, z)$ is *monotone* if the variables of z occur only positively in A_1 and only negatively in A_0. In this case, an associated interpolant function is monotone, and we are thus interested in finding a polynomial-sized monotone circuit for an interpolant function. We say that a proof system S admits *monotone feasible interpolation* if whenever S has a polynomial-sized refutation of a monotone F, a monotone interpolation function associated with F has a monotone polynomial-sized circuit.

Beautiful connections exist between circuit complexity and proof systems with feasible interpolation in both (monotone and nonmonotone) cases.

In the monotone case, superpolynomial lower bounds can be proven for a (sufficiently strong) proof system that admits feasible interpolation. This was presented by the sequence of papers [IPU, BPR, K1] and was first used in [BPR] to prove lower bounds for propositional proof systems. (The idea is also implicit in [Razb2].)

In short, the statement F that is used is the clique interpolation formula, $A_0(g, x) \wedge A_1(g, y)$, where A_0 states that g is a graph containing a clique of size k (where the clique is described by the x variables), and A_1 states that g is a graph that can be colored with $k - 1$ colors (where the coloring is described by the y variables). By the pigeonhole principle, this formula is unsatisfiable. However, an associated monotone interpolation function would take as input a graph g and distinguish between graphs containing cliques of size k from those that can be colored with $k - 1$ colors. By [Razb1, AB], when $k = n^{2/3}$, such a circuit is of exponential size. Thus, exponential lower bounds follow for any propositional proof system S that admits feasible monotone interpolation.

Similar ideas also work in the case where S admits feasible interpolation (but not necessarily monotone feasible interpolation). The first such result, by [Razb2], gives *explicit* superpolynomial lower bounds for (sufficiently strong) proof systems S admitting feasible interpolation, under a cryptographic assumption. In particular, it was shown that a (nonmonotone) interpolation function, associated with a certain statement expressing $P \neq NP$, is computable by polynomial-sized circuits only if there do not exist pseudorandom number generators. Therefore, lower bounds follow for any (sufficiently strong) propositional proof system that admits feasible interpolation (conditional on the cryptographic assumption that there exist pseudorandom number generators). It is also possible to prove nonexplicit superpolynomial lower bounds for a (sufficiently strong) proof system under the assumption that NP is not computable by polynomial-sized circuits.

Many researchers have used these ideas to prove lower bounds for propositional proof systems. In particular, in the last five years, lower bounds have been shown for all of the following systems using the interpolation method: resolution [BPR], cutting planes [IPU, BPR, Pud, CH], generalizations of cutting planes [BPR, K1, K3], relativized bounded arithmetic [Razb2], Hilbert's Nullstellensatz [PS], the polynomial calculus [PS], and the Lovasz–Schriver proof system [Pud3].

1.1. Automatizability and *k*-provability. As explained in the previous paragraphs, the existence of feasible interpolation for a particular proof system S gives rise to lower bounds for S. Feasible interpolation, moreover, is a very important paradigm for proof complexity (in general) for several other reasons. In this section, we wish to explain how the lack of feasible interpolation for a particular proof system S implies that S is not automatizable.

We say that a proof system S is *automatizable* if there exists a deterministic procedure D that takes as input a formula f and returns an S-refutation of f (if one exists) in time polynomial in the size of the shortest S-refutation of f. Automatizability is a crucial concept for automated theorem proving: in proof complexity we are mostly interested in the length of the shortest proof, whereas in theorem proving it is also essential to be able to find the proof. While there are seemingly powerful systems for the propositional calculus (such as extended resolution or even axiomatic set theory (ZFC)), they are scarce in theorem proving because it seems difficult to search efficiently for a short proof in such systems. In other words, there seems to be a tradeoff between proof simplicity and automatizability—the simpler the proof system, the easier it is to find the proof.

In this section, we formalize this tradeoff in a certain sense. In particular, we show that if S has no feasible interpolation, then S is not automatizable. This was first observed by Impagliazzo. The idea is to show that if S is automatizable (using a deterministic procedure D), then S has feasible interpolation.

THEOREM 1.1. *If a proof system S does not have feasible interpolation, then S is not automatizable.*

Proof. Suppose that S is automatizable, and suppose D is the deterministic procedure to find proofs, and moreover, D is guaranteed to run in time n^c, where n is the size of the shortest proof of the input formula. Let $A_0(x,z) \wedge A_1(y,z)$ be the interpolant statement, and let α be an assignment to z. We want to output an interpolant function for $A_0(x,\alpha) \wedge A_1(y,\alpha)$. First, we run D on $A_0(x,z) \wedge A_1(y,z)$ to obtain a refutation of size s. Next, we simulate D on $A_0(x,\alpha)$ for $T(s)$ steps, and return 0 if and only if D produces a refutation of $A_0(x,\alpha)$ within time $T(s)$. $T(s)$ will be chosen to be the maximum time for D to produce a refutation for a formula that has a refutation of size s; thus $T(s) = s^c$ in this case. This works because in the case where $A_1(y,\alpha)$ is satisfiable with satisfying assignment γ, we can plug γ into the refutation of $A_0(x,\alpha) \wedge A_1(y,\alpha)$ to obtain a refutation of $A_0(x,\alpha)$ of size s. Therefore S has feasible interpolation. $\square$

Thus, feasible interpolation is a simple measure that formalizes the complexity/search tradeoff: the existence of feasible interpolation implies superpolynomial lower bounds (sometimes modulo complexity assumptions), whereas the nonexistence of feasible interpolation implies that the proof system cannot be automatized.

A concept that is very closely related to automatizability is k-provability. The k-symbol provability problem for a particular Frege system S is as follows. The problem is to determine, given a propositional formula f and a number k, whether or not there is a k-symbol S proof of f. The k-line provability problem for S is to determine whether or not there is a k-line S proof of f. The k-line provability is an undecidable problem for first-order logic [B1]; the first complexity result for the k-provability problem for propositional logic was provided by Buss [B2], who proved the rather surprising fact that the k-symbol propositional provability problem is NP-complete for a particular Frege system. More recently, [ABMP] show that the k-symbol and k-line provability problems cannot be approximated to within linear factors for a variety of propositional proof systems, including resolution and all Frege systems, unless $P = NP$.

The methods in our paper show that both the k-symbol and k-line provability problems cannot be solved in polynomial time for any TC^0-Frege system, Frege system, or extended Frege system, assuming hardness of factoring (of Blum integers). More precisely, using the same idea as above, we can show that if there is a polynomial time algorithm A solving the k-provability problem for S, then S has feasible interpolation: suppose that $F = A_0(x, z) \wedge A_1(y, z)$ is the unsatisfiable statement. We first run A with $k = n, n^2, n^3, \ldots$ on F, until A first verifies that there is a size $s = |F|^c$ proof of F for some fixed value of c. Now let α be an assignment to z. As above, we run A to determine if there is an $O(s)$-symbol (or $O(s)$-line) refutation of $A_0(x, \alpha)$ and return 0 if and only if A accepts. In fact, this proof can be extended easily to show that both the k-symbol and k-line provability problems cannot be approximated to within polynomial factors for the same proof systems (TC^0-Frege, Frege, extended Frege) under the same hardness assumption.

1.2. Interpolation and one way functions. How can one prove that a certain propositional proof system S does not admit feasible interpolation? One idea, due to Krajíček and Pudlák [KP], is to use one way permutations in the following way. Let h be a one way permutation and let $A_0(x, z), A_1(y, z)$ be the following formulas.

The formula A_0:
$h(x) = z$, AND the ith bit of x is 0.
The formula A_1:
$h(y) = z$, AND the ith bit of y is 1.

Since h is one to one, $A_0(x, z) \wedge A_1(y, z)$ is unsatisfiable. Assume that A_0, A_1 can be formulated in the proof system S and that in S there exists a polynomial-sized refutation for $A_0(x, z) \wedge A_1(y, z)$. Then, if S admits feasible interpolation, it follows that given an assignment α to z there exists a polynomial-sized circuit that decides whether $A_0(x, \alpha)$ is unsatisfiable or $A_1(y, \alpha)$ is unsatisfiable. Obviously, such a circuit breaks the ith bit of the input for h. Since A_0, A_1 can be constructed for any i, all bits of the input for h can be broken. Hence, assuming that the input for h is secure, and that in the proof system S there exists a polynomial-sized refutation for $A_0 \wedge A_1$, it follows that S does not admit feasible interpolation.

A major step towards the understanding of feasible interpolation was made by Krajíček and Pudlák [KP]. They considered formulas A_0, A_1 based on the Rivest–Shamir–Adleman (RSA) cryptographic scheme and showed that unless RSA is not secure, extended Frege systems do not have feasible interpolation. It has been open, however, whether or not the same negative results hold for Frege systems and for weaker systems such as bounded depth threshold logic or bounded depth Frege.

1.3. Our results. In this paper, we prove that Frege systems, as well as constant-depth threshold logic (referred to below as TC^0-Frege), do not admit feasible interpolation, unless factoring of Blum integers is computable by polynomial-sized circuits. (Recall that Blum integers are integers P of the type $P = p_1 \cdot p_2$, where p_1, p_2 are both primes such that $p_1 \bmod 4 = p_2 \bmod 4 = 3$.) Thus our result significantly extends [KP] to weaker proof systems. In addition, our cryptographic assumption is weaker.

To prove our result, we use a variation of the ideas of [KP]. In a conversation with Moni Naor [N], he observed that the cryptographic primitive needed here is not a one way permutation as in [KP], but the more general structure of *bit commitment.* Our formulas A_0, A_1 are based on the Diffie–Hellman secret key exchange scheme [DH]. For simplicity, we state the formulas only for the least significant bit. (Our argument works for any bit.)

Informally, our propositional statement DH will be

$$DH_n = A_0(P, g, X, Y, a, b) \wedge A_1(P, g, X, Y, c, d).$$

The common variables are two integers X, Y, and P and g. P represents a number (not necessarily a prime) of length n, and g an element of the group Z_P^*. The private variables for A_0 are integers a, b, and the private variables for A_1 are integers c, d.

Informally, $A_0(P, g, X, Y, a, b)$ will say that $g^a \bmod P = X$, $g^b \bmod P = Y$, and $g^{ab} \bmod P$ is even. Similarly, $A_1(P, g, X, Y, c, d)$ will say that $g^c \bmod P = X$, $g^d mod P = Y$, and $g^{cd} \bmod P$ is odd. The statement $A_0 \wedge A_1$ is unsatisfiable since (informally) if A_0, A_1 are both true we have

$$g^{ab} \bmod P = (g^a \bmod P)^b \bmod P = X^b \bmod P$$

$$= (g^c \bmod P)^b \bmod P = g^{bc} \bmod P = (g^b \bmod P)^c \bmod P$$

$$= Y^c \bmod P = (g^d \bmod P)^c \bmod P = g^{cd} \bmod P.$$

We will show that the above informal proof can be made formal with a (polynomial-sized) TC^0-Frege proof. On the other hand, an interpolant function computes one bit of the secret key exchanged by the Diffie–Hellman procedure. Thus, if TC^0-Frege admits feasible interpolation, then all bits of the secret key exchanged by the Diffie–Hellman procedure can be broken using polynomial-sized circuits, and hence the Diffie–Hellman cryptographic scheme is not secure. Note, that it was proved that for $P = p_1 \cdot p_2$, where p_1, p_2 are both primes such that $p_1 \bmod 4 = p_2 \bmod 4 = 3$ (i.e., P is a Blum integer), breaking the Diffie–Hellman cryptographic scheme is harder than factoring P! (See [BBR] and also [Sh, Mc]).

It will require quite a bit of work to formalize the above statement and argument with a short TC^0-Frege proof. Notice that we want the size of the propositional formula expressing the Diffie–Hellman statement to be polynomially bounded in the number of binary variables. And additionally, we want the size of the TC^0-Frege proof of the statement also to be polynomially bounded. A key idea in order to define the statement and prove it efficiently is to introduce additional common variables to our propositional Diffie–Hellman statement. The bulk of the argument then involves showing how (with the aid of the auxiliary variables) one can formalize the above proof by showing that basic arithmetic facts, including the Chinese remainder theorem, can be stated and proven efficiently within TC^0-Frege.

1.4. Section description. The paper is organized as follows. In section 2, we define our TC^0-Frege system. In section 3, we define the TC^0-formulas used for the proof. In section 4, we define precisely the interpolation formulas which are based on the Diffie–Hellman cryptographic scheme. In section 5, we show how to prove our main theorem, provided we have some technical lemmas that will be proved fully in section 7. In section 6, there is a discussion and some open problems. Finally, in section 7, we prove all the technical lemmas required for the main theorem.

The unusual organization of the paper is due to the many very technical lemmas required to show the result, which are essential to the correctness of the argument but which not every reader might want to go through. Sections 1–6 give an exposition of the result, relying on the complete proofs in the technical part.

2. TC^0-Frege systems.

For clarity, we will work with a specific bounded-depth threshold logic system, which we call TC^0-Frege. However, any reasonable definition of such a system should also suffice. Our system is a sequent-calculus logical system where formulas are built up using the connectives $\vee$, $\wedge$, Th_k, $\neg$, $\oplus_0$, and $\oplus_1$. ($\mathrm{Th}_k(x)$ is true if and only if the number of 1's in x is at least k, and $\oplus_i(x)$ is true if and only if the number of 1's in x is i mod 2.)

Our system is essentially the one introduced in [MP], (which is, in turn, an extension of the system PTK introduced by Buss and Clote [BC, section 10]).

Intuitively, a family of formulas $f_1, f_2, f_3, \ldots$ has polynomial-sized TC^0-Frege proofs if each formula has a proof of size polynomial in the size of the formula, and such that every line in the proof is a TC^0 formula.

DEFINITION 2.1. *Formulas are built up using the connectives* $\wedge$, $\vee$, Th_k, $\oplus_1$, $\oplus_0$, $\neg$. *All connectives are assumed to have unbounded fan-in.* $\mathrm{Th}_k(A_1, \ldots, A_n)$ *is interpreted to be true if and only if the number of true* A_i*'s is at least* k*;* $\oplus_j(A_1, \ldots, A_n)$ *is interpreted to be true if and only if the number of true* A_i*'s is equal to* j mod 2.

The formula $\wedge(A_1, \ldots, A_n)$ denotes the logical AND of the multiset consisting of $A_1, \ldots A_n$, and similarly for $\vee$, $\oplus_j$, and Th_k. Thus commutativity of the connectives is implicit. Our proof system operates on sequents which are sets of formulas of the form $A_1, \ldots, A_i \rightarrow B_1, \ldots, B_j$. The intended meaning is that the conjunction of the A_i's implies the disjunction of the B_j's. A proof of a sequent S in our logic system is a sequence of sequents, $S_1, \ldots, S_q$, such that each sequent S_i either is an initial sequent or follows from previous sequents by one of the rules of inference, and the final sequent, S_q, is S. The size of the proof is $\sum_{1\le i\le q} \mathrm{size}(S_i)$, and its depth is $\max_{1\le i\le q}(\mathrm{depth}(S_i))$.

The *initial sequents* are of the form (1) $A \rightarrow A$, where A is any formula; (2) $\rightarrow \wedge()$; $\vee() \rightarrow$; (3) $\oplus_1() \rightarrow$; $\rightarrow \oplus_0()$; and (4) $\mathrm{Th}_k() \rightarrow$ for $k \geq 1$; $\rightarrow \mathrm{Th}_0(A_1, \ldots, A_n)$ for $n \geq 0$. The rules of inference are as follows. Note that the logical rules are defined for $n \geq 1$ and $k \geq 1$. First we have simple structural rules such as weakening (formulas can always be added to the left or to the right), contraction (two copies of the same formula can be replaced by one), and permutation (formulas in a sequent can be reordered). The remaining rules are the cut rule and logical rules, which allow us to introduce each connective on both the left side and the right side. The cut rule allows the derivation of $\Gamma, \Gamma' \rightarrow \Delta, \Delta'$ from $\Gamma, A \rightarrow \Delta$, and $\Gamma' \rightarrow A, \Delta'$.

The logical rules are as follows.

1. (Negation-left) From $\Gamma \rightarrow A, \Delta$, (for consistency) derive $\neg A, \Gamma \rightarrow \Delta$.
2. (Negation-right) From $A, \Gamma \rightarrow \Delta$, derive $\Gamma \rightarrow \neg A, \Delta$.
3. (And-left) From $A_1, \wedge(A_2, \ldots, A_n), \Gamma \rightarrow \Delta$, derive $\wedge(A_1, \ldots, A_n), \Gamma \rightarrow \Delta$.
4. (And-right) From $\Gamma \rightarrow A_1, \Delta$ and $\Gamma \rightarrow \wedge(A_2, \ldots, A_n), \Delta$, derive $\Gamma \rightarrow \wedge(A_1, \ldots, A_n), \Delta$.
5. (Or-left) From $A_1, \Gamma \rightarrow \Delta$ and $\vee(A_2, \ldots, A_n), \Gamma \rightarrow \Delta$, derive $\vee(A_1, \ldots, A_n), \Gamma \rightarrow \Delta$.
6. (Or-right) From $\Gamma \rightarrow A_1, \vee(A_2, \ldots, A_n), \Delta$, derive $\Gamma \rightarrow \vee(A_1, \ldots, A_n), \Delta$.
7. (Mod-left) From $A_1, \oplus_{1-i}(A_2, \ldots, A_n), \Gamma \rightarrow \Delta$ and $\oplus_i(A_2, \ldots, A_n), \Gamma \rightarrow A_1, \Delta$, derive $\oplus_i(A_1, \ldots, A_n)$, $\Gamma \rightarrow \Delta$.
8. (Mod-right) From $A_1, \Gamma \rightarrow \oplus_{1-i}(A_2, \ldots, A_n), \Delta$ and $\Gamma \rightarrow A_1, \oplus_i(A_2, \ldots, A_n)$,

Δ, derive $\Gamma \rightarrow \oplus_i(A_1, \ldots, A_n), \Delta$.

9. (Threshold-left) From $\mathrm{Th}_k(A_2, \ldots, A_n), \Gamma \rightarrow \Delta$ and $A_1, \mathrm{Th}_{k-1}(A_2, \ldots, A_n), \Gamma \rightarrow \Delta$, derive $\mathrm{Th}_k(A_1, \ldots, A_n), \Gamma \rightarrow \Delta$.
10. (Threshold-right) From $\Gamma \rightarrow A_1, \mathrm{Th}_k(A_2, \ldots, A_n), \Delta$, and $\Gamma \rightarrow \mathrm{Th}_{k-1}(A_2, \ldots, A_n), \Delta$, derive $\Gamma \rightarrow \mathrm{Th}_k(A_1, \ldots, A_n), \Delta$.

A TC^0 proof is a bounded-depth proof in our system of polynomial size. More formally, we have the following definitions.

DEFINITION 2.2. *Let $F = \{(\Gamma_n \rightarrow \Delta_n) : n \in N\}$ be a family of sequents. Then $\{R_n : n \in \mathbf{N}\}$ is a family of TC^0 proofs for F if there exist constants c and d such that the following conditions hold:* (1) *each R_n is a valid proof of* $(\Gamma_n \rightarrow \Delta_n)$ *in our system;* (2) *for all i, the depth of R_n is at most d; and* (3) *for all n, the size of R_n is at most* $(\mathrm{size}(\Gamma_n \rightarrow \Delta_n))^c$.

We note that we have defined a specific proof system for clarity; our result still holds for any reasonable definition of a TC^0-Frege proof. (It can be shown that our system polynomially simulates any Frege-style system.) The difference between a polynomial-sized proof in our system and a polynomial-sized TC^0 proof is similar to the difference between NC^1 and TC^0.

3. The TC^0-formulas.

In this section, we will describe some of the TC^0-formulas needed to formulate and to refute the Diffie–Hellman formula. For simplicity of the description, let us assume that we have a fixed number N which is an upper bound for the *length* of all numbers used in the refutation of the Diffie–Hellman formula. The number N will be used to define some of the formulas below. After seeing the statement and the refutation of the Diffie–Hellman formula, it will be clear that it is enough to take N to be a small polynomial in the *length* of the number P used for the Diffie–Hellman formula.

3.1. Addition and subtraction.

We will use the usual carry-save AC^0-formulas to add two n-bit numbers. Let $x = x_n, \ldots, x_1$ and $y = y_n, \ldots, y_1$ be two numbers. Then $x + y$ will denote the following AC^0-formula: There will be $n + 1$ output bits, $z_{n+1}, \ldots, z_1$. The bit z_i will equal the mod 2 sum of C_i, x_i, and y_i, where C_i is the carry bit. Intuitively, C_i is 1 if there is some bit position less than i that generates a carry that is propagated by all later bit positions until bit i. Formally, C_i is computed by $OR(R_{i(i-1)}, \ldots, R_{i1})$, where $R_{ij} = AND(P_{i-1}, \ldots, P_{j+1}, G_j)$, where $P_k = Mod_2(x_k, y_k)$, and $G_j = AND(x_j, y_j)$. (G_j is 1 if the jth bit position generates a carry, and P_k is 1 if the k^{th} bit position propagates but does not generate a carry.)

As for subtraction, let us show how to compute $z = |x - y|$. Think of x, y as N-bit numbers. Let $s = x + \overline{y} + 1$, and similarly let $t = y + \overline{x} + 1$, where $\overline{y}$ is the complement (modulo 2) of the N bits of y, and $\overline{x}$ is the complement of the N bits of x. Denote $s = s_{N+1}, s_N, \ldots, s_1$, and note that s is equal to $2^N + (x - y)$, and similarly t is equal to $2^N + (y - x)$. If $s_{N+1} = 1$, then we know that $x - y \geq 0$ and thus $s = z$. Otherwise, if $s_{N+1} = 0$, then we know that $y - x > 0$ and thus $t = z$. Thus, for any i, we can compute z_i by $(s_{N+1} \wedge s_i) \vee (\neg s_{N+1} \wedge t_i)$.

3.2. Iterated addition.

We will now describe the TC^0-formula $SUM[x_1, \ldots, x_m]$ that inputs m numbers, each n bits long, and outputs their sum $x_1 + x_2 + \cdots + x_m$ (see [CSV]). We assume that $m \leq N$. The main idea is to reduce the addition of m numbers to the addition of two numbers. Let x_i be $x_{i,n}, \ldots, x_{i,1}$ (in binary representation). Let $l = \lceil \log_2 N \rceil$. Let $r = \frac{n}{2l}$, and assume (for simplicity) that r is an integer.

Divide each x_i into r blocks, where each block has $2l$ bits, and let $S_{i,k}$ be the number in the k^{th} block of x_i. That is,

$$S_{i,k} = \sum_{j=1}^{2l} x_{i,(k-1)\cdot 2l+j} \cdot 2^{j-1}.$$

Now, each $S_{i,k}$ has $2l$ bits. Let $L_{i,k}$ be the low-order half of $S_{i,k}$, and let $H_{i,k}$ be the high-order half. That is, $S_{i,k} = H_{i,k} \cdot 2^l + L_{i,k}$.

Denote

$$H = \sum_{i=1}^{m} \sum_{k=1}^{r} H_{i,k} \cdot 2^l \cdot 2^{(k-1)2l},$$

$$L = \sum_{i=1}^{m} \sum_{k=1}^{r} L_{i,k} \cdot 2^{(k-1)2l}.$$

Then,

$$x_1 + \cdots + x_m = \sum_{i=1}^{m} \sum_{k=1}^{r} S_{i,k} \cdot 2^{(k-1)2l}$$

$$= \sum_{i=1}^{m} \sum_{k=1}^{r} H_{i,k} \cdot 2^l \cdot 2^{(k-1)2l} + \sum_{i=1}^{m} \sum_{k=1}^{r} L_{i,k} \cdot 2^{(k-1)2l} = H + L.$$

Hence, we just have to show how to compute the numbers H, L. Let us show how to compute L; the computation of H is similar.

Denote $L_k = \sum_{i=1}^{m} L_{i,k}$. Then

$$L = \sum_{k=1}^{r} L_k \cdot 2^{(k-1)2l}.$$

Since each $L_{i,k}$ is of length l, each L_k is of length at most $l + \log_2 m$, which is at most $2l$. Hence, the bits of L are just the bits of the L_k's combined. That is, $L = L_r, L_{r-1}, \ldots, L_1$.

As for the computation of the L_k's, note that since each L_k is a polysize sum of logarithmic length numbers, it can be computed using polysize threshold gates.

3.3. Modular arithmetic. Next, we describe our TC_0-formulas that compute the quotient and remainder of a number z modulo p, where z is of length n. The remainder and the inputs for the remainder and the quotient formulas are as follows:

1. the number z,
2. numbers $p_1, p_2, \ldots, p_n$,
3. numbers k_i and r_i for all $1 \leq i \leq n$.

The intended values for the variables k_i and r_i are such that $2^i = p \cdot k_i + r_i$, where $0 \leq r_i < p$ for all $1 \leq i \leq n$. The intended values for the variables p_i are $i \cdot p$.

Suppose that $z = kp + r$, where $0 \leq r < p$, and assume that the input variables k_i, r_i, and p_i take the right values. Then our formula $[z]_p$ will output r, and our formula $div_p(z)$ will output k. The formulas are computed as follows.

Let $z = z_n, \ldots, z_1$; i.e., $z = \sum_{i=1}^{n} 2^{i-1} z_i$. Suppose that the k_i, r_i, and p_i variables satisfy $2^i = k_i \cdot p + r_i$, where $0 \leq r_i < p$, and $p_i = i \cdot p$ for all $1 \leq i \leq n$. Then z satisfies

$$z = \sum_{i=1}^{n} 2^{i-1} z_i = \sum_{i=1}^{n} (p \cdot k_{i-1} + r_{i-1}) z_i$$

$$= p \cdot \sum_{i=1}^{n} k_{i-1} \cdot z_i + \sum_{i=1}^{n} r_{i-1} \cdot z_i.$$

Denote $s = \sum_{i=1}^{n} r_{i-1} \cdot z_i$, and let l be such that $l \cdot p \leq s < (l+1) \cdot p$. Then $[z]_p = s - l \cdot p$ and can therefore be computed by

$$[z]_p = SUM_{i=1}^{n} [r_{i-1} \cdot z_i] - p \cdot l.$$

$div_p(z)$ is computed by $SUM_{i=1}^{n}[k_{i-1} \cdot z_i] + l$.

Notice that if the k_i, r_i, and p_i's are not such that $2^i = k_i \cdot p + r_i$, $0 \leq r_i < p$, and $p_i = i \cdot p$, then the formulas are not required to compute the correct values of the quotient or remainder and can give an arbitrary answer.

3.4. Product and iterated product. We will write $x \cdot y$ to denote the formula $SUM_{i,j}[2^{i+j-2} x_i y_j]$, computing the product of two n-bit numbers x and y. By $2^{i+j-2} x_i y_j$, we mean 2^{i+j-2} if both x_i and y_j are true, and 0 otherwise.

Last, we will describe our TC^0-formula for computing the iterated product of m numbers. This formula is basically the original formula of [BCH] and is articulated as a TC^0-formula in [M].

The iterative product $PROD[z_1, \ldots, z_m]$ gives the product of $z_1, \ldots, z_m$, where each z_i is of length n, and we assume that m, n are both bounded by N. The basic idea is to compute the product modulo small primes using iterated addition and then to use the constructive chinese remainder theorem to construct the actual product from the product modulo small primes.

Let Q be the product of the first t primes $q_1, \ldots, q_t$, where t is the first integer that gives a number Q of length larger than N^2. Since $q_1, \ldots, q_t$ are all larger than 2, t is at most N^2, and by the well-known bounds for the distribution of prime numbers the length of each q_j is at most $O(\log N)$. For each q_j, let g_j be a fixed generator for $Z^*_{q_j}$. Also, for each q_j, let $u_j \leq Q$ be a fixed number with the property that $u_j \bmod q_j = 1$ and for all $i \neq j$, $u_j \bmod q_i = 0$ (such a number exists by the Chinese remainder theorem). $PROD[z_1, \ldots, z_m]$ is computed as follows.

1. First we compute $r_{i,j} = [z_i]_{q_j}$ for all i, j. This is calculated using the modular arithmetic described earlier.
2. For each $1 \leq j \leq t$ we will compute $r_j = (\prod_{i=1}^{m} r_{i,j}) \bmod q_j$ as follows.
   a. Compute a_{ij} such that $(g_j^{a_{ij}}) \bmod q_j = r_{i,j}$. This is done by a table lookup.
   b. Calculate $c_j = SUM_{i=1}^{m}[a_{ij}]_{(q_j-1)}$.
   c. Compute r_j such that $g_j^{c_j} \bmod q_j = r_j$. This is another table lookup.
3. Finally, compute

$$PROD[z_1, \ldots, z_m] = SUM_{j=1}^{t}[u_j \cdot r_j]_Q.$$

We will hardwire the values $u_j \cdot k$ for all $k \leq q_j$. Thus, this computation is obtained by doing a table lookup to compute $u_j \cdot r_j$ followed by an iterated sum followed by a mod Q calculation.

3.5. Equality and inequality. Often we will write $x = y$, where x and y are both vectors of variables or formulas: $x = x_1, \dots, x_n$, and $y = y_1, \dots, y_n$. When we write $x = y$, we mean the formula $\wedge_i((\neg x_i \vee y_i) \wedge (x_i \vee \neg y_i))$. We apply the same conventions when writing $\neq, <, \leq, >, \geq$.

4. The Diffie–Hellman formula.

We are now ready to formally define our propositional statement DH. DH will be the conjunction of A_0 and A_1. The common variables for the formulas will be

(a) P and g representing n-bit integers, and for every $i \leq 2n$, we will also add common variables for g^{2^i} mod P.

(b) X, Y, and for every $i \leq 2n$, we will also add common variables for X^{2^i} mod P and for Y^{2^i} mod P.

(c) We also add variables for $P_2, \dots, P_N$, and for $k_1, \dots, k_N$ and $r_1, \dots, r_N$. These variables are needed to define arithmetic modulo P (see section 3.3).

For $e \in \{0, 1\}$, denote by $g^{2^i \cdot e}$ (respectively, $X^{2^i \cdot e}$, $Y^{2^i \cdot e}$) the following: the common variable g^{2^i} mod P (respectively, X^{2^i} mod P, Y^{2^i} mod P) if $e = 1$, and 1 if $e = 0$. The formula $A_0(P, g, X, Y, a, b)$ will be the conjunction of the following TC^0-formulas:

1.
$$PROD_i \left[g^{2^i \cdot a_i}\right]_P = X,$$
which means g^a mod $P = X$.

2. For every $j \leq n$,
$$PROD_i \left[g^{2^{i+j} \cdot a_i}\right]_P = X^{2^j} \text{ mod } P,$$
which means $(g^{2^j})^a \text{mod} P = X^{2^j} \text{mod} P$. Note that from this, it is easy to prove for $e \in \{0, 1\}$,
$$PROD_i \left[g^{2^{i+j} \cdot a_i \cdot e}\right]_P = X^{2^j \cdot e}.$$

3. Similar formulas for g^b mod $P = Y$, and for $(g^{2^j})^b$ mod $P = Y^{2^j}$ mod P.

4. $PROD_{i,j}[g^{2^{i+j} \cdot a_i \cdot b_j}]_P$ is even, which means g^{ab} mod P is even.

5. For every $i \leq N$, formulas expressing $2^i = P \cdot k_i + r_i$, $1 \leq r_i < P$, and $P_i = i \cdot P$. (These formulas are added to guarantee that the modulo P arithmetic is computed correctly.)

Similarly, the formula $A_1(P, g, X, Y, c, d)$ will be the conjunction of the above formulas, but with a replaced by c, b replaced by d, and the fourth item stating that g^{cd} mod P is odd.

Note that the definition of the iterated product ($PROD$) requires the primes $q_1, \dots, q_t$ (as well as their product Q, and the numbers $u_1, \dots, u_t$), which are fixed for the length n. So we are going to hardwire the numbers $q_1, \dots, q_t, Q, u_1, \dots u_t$, as well as the correct values for the r_i's and k_i's needed for the modulo q_j arithmetic for each one of these numbers.

5. A TC^0-Frege refutation for DH.

We want to describe a TC^0-Frege refutation for DH. As mentioned above, the proof proceeds as follows.

1. Using A_0, show that g^{ab} mod $P = X^b$ mod P.
2. Using A_1, show that X^b mod $P = g^{cb}$ mod P.

3. Show that $g^{cb} \bmod P = g^{bc} \bmod P$.
4. Using A_0, show that $g^{bc} \bmod P = Y^c \bmod P$.
5. Using A_1, show that $Y^c \bmod P = g^{dc} \bmod P$.
6. Show that $g^{dc} \bmod P = g^{cd} \bmod P$.

We can conclude from the above steps that A_0 and A_1 imply that $g^{ab} \bmod P = g^{cd} \bmod P$, but now we can reach a contradiction since A_0 states that $g^{ab} \bmod P$ is even, while A_1 states that $g^{cd} \bmod P$ is odd.

We formulate $g^{ab} \bmod P$ as

$$PROD_{i,j}\left[g^{2^{i+j}\cdot a_i\cdot b_j}\right]_P$$

and $X^b \bmod P$ as

$$PROD_j\left[X^{2^j\cdot b_j}\right]_P.$$

Thus, step 1 is formulated as

$$PROD_{i,j}\left[g^{2^{i+j}\cdot a_i\cdot b_j}\right]_P = PROD_j\left[X^{2^j\cdot b_j}\right]_P,$$

and so on.

Steps 1, 2, 4, and 5 are all virtually identical. Steps 3 and 6 follow easily because our formulas defining g^{ab} make symmetry obvious. Thus the key step is to show step 1; that is, to show how to prove $g^{ab} \bmod P = X^b \bmod P$. As mentioned above, this is formulated as follows:

$$PROD_{i,j}\left[g^{2^{i+j}\cdot a_i\cdot b_j}\right]_P = PROD_j\left[X^{2^j\cdot b_j}\right]_P.$$

We will build up to the proof that $g^{ab} \bmod P$ equals $X^b \bmod P$ by proving many lemmas concerning our basic TC^0-formulas. The final lemma that we need is the following.

LEMMA 5.1. *For every $z_{1,1},\ldots,z_{m,m'}$ and p, there are TC^0-Frege proofs of*

$$PROD_{i,j}[z_{i,j}]_p = PROD_i[PROD_j[z_{i,j}]_p]_p.$$

The proof of the lemma is given in section 7.

Using Lemma 5.1 for the first equality and point 2 from section 4 for the second equality, we can now obtain

$$PROD_{i,j}\left[g^{2^{i+j}\cdot a_i\cdot b_i}\right]_P$$

$$= PROD_j\left[PROD_i\left[g^{2^{i+j}\cdot a_i\cdot b_j}\right]_P\right]_P = PROD_j\left[X^{2^j\cdot b_j}\right]_P,$$

which proves step 1.

Hence, the main goal of section 7 is to show that the statement

$$PROD_{i,j}[z_{i,j}]_p = PROD_i[PROD_j[z_{i,j}]_p]_p$$

has a short TC^0-Frege proof. This is not trivial because our TC^0-Frege formulas are quite complicated (and in particular the formulas for iterated product and modular arithmetic). In order to prove the statement, we will need to carry out a lot of the basic arithmetic in TC^0-Frege. Before we go on to the technical part, we will try to give some intuition on how the proof of the main lemma is built.

We organized the proof as a sequence of lemmas that show how many basic facts of arithmetic can be formulated and proved in TC^0-Frege (using our TC^0-formulas). The proofs of these lemmas require careful analysis of the exact formula used for each operation. The proofs of some of these lemmas are straightforward (using the well-known TC^0-formulas), while the proofs of other lemmas require some new tricks.

In short, the main lemmas that are used for the TC^0-Frege proof of the final statement (Lemma 5.1) are the following:

1. (Lemma 7.34) For every x, y, and p, there are TC^0-Frege proofs of
$$[x \cdot y]_p = [x \cdot [y]_p]_p.$$
2. (Lemma 7.37) For every $z_1, \ldots, z_m$, and every $1 \leq k \leq m$, there are TC^0-Frege proofs of
$$PROD[z_1, \ldots, z_m] = PROD[z_1, \ldots, z_{k-1}, PROD[z_k, \ldots, z_m]].$$
3. (Lemma 7.43) For every z_1, z_2, there are TC^0-Frege proofs of
$$PROD[z_1, z_2] = z_1 \cdot z_2.$$

First, we prove some basic lemmas about addition, subtraction, multiplication, iterative-sum, less-than, and modular arithmetic. Among these lemmas will be Lemma 7.34.

The proof of Lemma 7.37 is cumbersome, but it is basically straightforward, given some basic facts about modular arithmetic. Recall that to do the iterated product we have to first compute the product modulo small primes and then combine all these products to get the right answer using iterated sum. Therefore, many basic facts of the modulo arithmetic need to be proven in advance, as well as some basic facts of the iterated sum.

Once this is done, we need to obtain the same fact modulo p (Lemma 7.44). At this point it is easier to go through the regular product, where the basic facts of modular arithmetic are easier to prove. Therefore it is important to show that TC^0-Frege can prove
$$PROD[z_1, z_2] = z_1 \cdot z_2$$
(Lemma 7.43). In our application, z_1 and z_2 will themselves be iterated products.

To show this fact we use the Chinese remainder theorem. We first prove the equality modulo small primes. This is relatively easy, since the sizes of these primes are sufficiently small ($O(\log N)$), and we can basically check all possible combinations. Once this is done, we apply the Chinese remainder theorem to obtain the equality modulo the product of the primes, and since this product is big enough, we obtain the desired result.

Our TC^0-Frege proof of the Chinese remainder theorem is different than the standard textbook one. The main fact that we need to show is that if for every j, $[R]_{q_j} = [S]_{q_j}$, then there are TC^0-Frege proofs of $[R]_Q = [S]_Q$ ($Q = q_1 \cdot \ldots \cdot q_t$). The usual proofs use some basic facts of division of primes that would be hard to implement here. Instead we prove by induction on $i < t$ that $[R]_{Q_i} = [S]_{Q_i}$, where $Q_i = \prod_{j=1}^{i} q_j$. This method allows us to work with numbers smaller than the q_i's, and again since these numbers are sufficiently small, we can verify all possibilities.

6. Discussion and open problems. We have shown that TC^0-Frege does not have feasible interpolation, assuming that the factoring of Blum integers is not efficiently computable. This implies (under the same assumptions) that TC^0-Frege as well as any system that can polynomially simulate TC^0-Frege is not automatizable. It is interesting to note that our proof and even the definition of the Diffie–Hellman formula itself is nonuniform, essentially due to the nonuniform nature of the iterated product formulas that we use. It would be interesting to know to what extent our result holds in the uniform TC^0 proof setting.

A recent paper [BDGMP] extends our results to prove that bounded-depth Frege does not have feasible interpolation assuming factoring Blum integers is sufficiently hard (actually their assumptions are stronger than ours). As a consequence bounded-depth Frege is not automatizable under somewhat weaker hardness assumptions.

An important question that is still open is whether resolution, or some restricted forms of it, is automatizable. A positive answer to this question would have important applied consequences.

7. Formal proof of the main lemma. The goal of this section is to prove Lemma 5.1. As mentioned earlier, we will build up to the proof of this lemma by showing that basic facts concerning arithmetic, multiplication, iterated multiplication, and modulus computations can be efficiently carried out in our proof system. Before we begin the formal presentation, we would like to note that we will be giving a precise description of a sequence of lemmas that are sufficient in order to carry out a full, formal proof of Lemma 5.1. However, since there are many lemmas and many of them have obvious proofs, we will describe at a meta-level what is required in order to formalize the argument in TC^0-Frege, rather than give an excessively formal TC^0-Frege proof of each lemma.

In what follows, x, y, and z will be numbers. Each one of them will denote a vector of n variables or formulas (representing the number), where $n \leq N$ and x_i (respectively, y_i, z_i) denotes the ith variable of x (representing the ith bit of the number x). When we need to talk about more than three numbers, we will write $z_1, \dots, z_m$ to represent a sequence of m n-bit numbers, (where $m, n \leq N$), and now $z_{i,j}$ is the jth variable of z_i (representing the jth bit in the ith number).

Recall that whenever we say below "there are TC^0-Frege proofs," we actually mean to say "there are polynomial-sized TC^0-Frege proofs." Some trivial properties like $x = y \wedge y = z \rightarrow x = z$ are not stated here.

7.1. Some basic properties of addition, subtraction, and multiplication.

LEMMA 7.1. *For every x, y, there are TC^0-Frege proofs of $x + y = y + x$.*

Proof of Lemma 7.1. The proof is immediate from the fact that the addition formula was defined in a symmetric way. □

LEMMA 7.2. *For every x, y, z, there are TC^0-Frege proofs of $x + (y + z) = (x + y) + z$.*

Proof of Lemma 7.2. By the definition of the addition formula, the ith bit of $((x + y) + z)$ is equal to $\oplus_1(\oplus_1(x_i, y_i, C_i(x, y)), z_i, C_i((x + y), z))$, where $C_i(x, y)$ is the carry bit going into the ith position, when we add x and y, and $C_i((x + y), z)$ is similarly defined to be the carry bit going into the ith position when we add $(x + y)$ and z.

Using basic properties of $\oplus_1$ and the above definitions, there is a simple TC^0-Frege proof that if $\oplus_1(C_i(x, y), C_i((x + y), z)) = \oplus_1(C_i(y, z), C_i(x, (y + z)))$, then it follows that $((x+y)+z) = (x+(y+z))$. Thus it is left to show that for all $i \le n+2$,

$$\oplus_1(C_i(x,y), C_i((x+y),z)) = \oplus_1(C_i(y,z), C_i(x,(y+z))).$$

We will show how to prove the stronger equality

$$C_i(x,y) + C_i((x+y),z) = C_i(y,z) + C_i(x,(y+z)).$$

(It can be verified that this is the strongest equality possible for the four quantities $C_i(x,y), C_i((x+y),z), C_i(y,z), C_i(x,(y+z))$. That is, all six assignments for $C_i(x,y)$, $C_i((x+y),z), C_i(y,z), C_i(x,(y+z))$ that satisfy the above equality are actually possible.)

We will prove this by induction on i. For $i=1$, the carry bits going into the first position are zero, so the above identity holds trivially. To prove the above equality for i, we assume that it holds for $i-1$. We will prove the equality by considering many cases, where a particular case will assume a fixed value to each of the following seven quantities: $x_{i-1}, y_{i-1}, z_{i-1}, C_{i-1}(x,y), C_{i-1}(y,z), C_{i-1}((x+y),z)$, $C_{i-1}(x,(y+z))$, subject to the condition that $C_{i-1}(x,y) + C_{i-1}((x+y),z) = C_{i-1}(y,z) + C_{i-1}(x,(y+z))$. It is easy to check that the number of cases is 48 since there are 2 choices for x_{i-1}; 2 choices for y_{i-1}; 2 choices for z_{i-1}; and 6 choices in total for $C_{i-1}(x,y)$, $C_{i-1}((x+y),z)$, $C_{i-1}(y,z)$, and $C_{i-1}(x,(y+z))$.

Each case will proceed in the same way. We will first show how to compute $C_i(x,y), C_i(y,z), C_i((x+y),z)$, and $C_i(x,(y+z))$ using the above seven values. Then we simply verify that in all 48 cases where the inductive hypothesis holds, the equality is true.

First, we will show that

$$C_i(x,y) = 1 \leftrightarrow x_{i-1} + y_{i-1} + C_{i-1}(x,y) \ge 2.$$

This requires a proof along the following lines. If $x_{i-1} = y_{i-1} = 1$, then the left-hand side of the above statement is true since position $i-1$ generates a carry, and the right-hand side of the statement is also true. Similarly, if $x_{i-1} = y_{i-1} = 0$, then both sides of the above statement are false (since position $i-1$ absorbs a carry). The last case is when $x_{i-1} = 1$ and $y_{i-1} = 0$ (or vice-versa). In this case, position $i-1$ propagates a carry, so the ith carry bit is 1 if and only if there exists a $j < i-1$ such that the jth position generates a carry and all positions between j and $i-1$ propagate carries—but this is exactly the definition of $C_{i-1}(x,y)$. Thus, we have in this last case that both sides of the statement are true if and only if $C_{i-1}(x,y)$ is true.

Using the above fact and also that $(x+y)_i = x_i \oplus y_i \oplus C_i(x,y)$, we have that $C_i((x+y),z) = 1$ if and only if $z_{i-1} + (x_{i-1} \oplus y_{i-1} \oplus C_{i-1}(x,y)) + C_{i-1}((x+y),z) \ge 2$. Identical arguments show that $C_i(y,z) = 1$ and $C_i(x,(y+z)) = 1$ can also be computed as simple formulas of the seven pieces of information. $\square$

LEMMA 7.3. *For every x, y, there are TC^0-Frege proofs of $(x+y) - y = x$.*

Proof of Lemma 7.3. $(x+y) - y$ is computed by taking the first N bits of $(x+y) + \overline{y} + 1$. Note that by the definition of the addition formula it follows easily that all bits of $(y + \overline{y})$ are 1, and hence that $((y+\overline{y}) + 1) = 2^N$. Thus,

$$(x+y) + \overline{y} + 1 = x + ((y+\overline{y}) + 1) = x + 2^N,$$

and hence the first N bits of this number are the same as the first N bits of x. $\square$

LEMMA 7.4. *For every x, y, there are TC^0-Frege proofs of $x \ge y \rightarrow (x-y) + y = x$.*

Proof of Lemma 7.4. $(x-y)$ is computed by taking the first N bits of $x+\overline{y}+1$. By the definition of the addition formula, and since $x \geq y$, it can be proved that the $(N+1)$th bit of $x+\overline{y}+1$ is 1, and hence that

$$(x-y)+2^N = x+\overline{y}+1.$$

Therefore, as in Lemma 7.3,

$$(x-y)+y+2^N = x+\overline{y}+y+1 = x+2^N.$$

In particular, the first N bits of $(x-y)+y+2^N$ are the same as those of $x+2^N$. Thus, $(x-y)+y=x$. ∎

Lemma 7.5. *For every x, y, z, there are TC^0-Frege proofs of $x+z=y+z \rightarrow x=y$.*

Proof of Lemma 7.5. The proof follows immediately from Lemmas 7.3 and 7.2 as follows: $x=(x+z)-z=(y+z)-z=y$. ∎

Lemma 7.6. *For every z, there are TC^0-Frege proofs of*

$$z = SUM_i[2^{i-1}z_i].$$

Proof of Lemma 7.6. We need to show that for every j,

$$z_j = [SUM_i[2^{i-1}z_i]]_j.$$

This is shown by a rather tedious but straightforward proof following the definition of the formula SUM for iterated addition. Namely, we show first that

$$H = z_n..z_{n-l+1}0..0z_{n-2l}..z_{n-3l+1}0..0.....z_{2l}..z_{l+1}0..0$$

and, similarly, that

$$L = 0..0z_{n-l}..z_{n-2l+1}0..0z_{n-3l}..z_{n-4l+1}.....0..0z_l..z_1.$$

Secondly, we show that $[H+L]_j = z_j$, using the definition of $+$. This second step is not difficult because all carry bits are zero. ∎

Lemma 7.7. *For every $z_1, \ldots, z_m$, and every fixed permutation α, there are TC^0-Frege proofs of*

$$SUM[z_1, \ldots, z_m] = SUM[z_{\alpha(1)}, ..., z_{\alpha(m)}].$$

(That is, the iterated sum is symmetric.)

Proof of Lemma 7.7. The proof is immediate from the fact that the formula SUM was defined in a symmetric way. ∎

Lemma 7.8. *For every z, there are TC^0-Frege proofs of*

$$SUM[z] = z.$$

Proof of Lemma 7.8. By definition of the iterated addition formula SUM, it is straightforward to prove that

$$H = z_n..z_{n-l+1}0..0z_{n-2l}..z_{n-3l+1}0..0.....z_{2l}..z_{l+1}0..0$$

and, similarly, that

$$L = 0..0z_{n-l}..z_{n-2l+1}0..0z_{n-3l}..z_{n-4l+1}.....0..0z_l..z_1.$$

Then it is also straightforward to show, using the definition of the formula for +, that $[H+L]_j = z_j$ for every j. (Again, all carry bits are zero.) ∎

LEMMA 7.9. *For every $z_1, \ldots, z_m$, there are TC^0-Frege proofs of*

$$SUM[z_1, \ldots, z_m] = z_1 + SUM[z_2, \ldots, z_m].$$

Proof of Lemma 7.9. Recall that $SUM[z_1, \ldots, z_m]$ is computed by adding two numbers H, L. Recall that L is computed by first computing the numbers $L_k = \sum_{i=1}^m L_{i,k}$, where $L_{i,k}$ is the low-order half of the kth block of z_i. The first equality follows from Lemma 7.9, and similarly, $SUM[z_2, \ldots, z_m]$ is computed by $H' + L'$, where L' is computed by first computing the numbers $L'_k = \sum_{i=2}^m L_{i,k}$. We can also write $z_1 = H'' + L''$, where $H'' = \sum_{k=1}^r H_{1,k} \cdot 2^l \cdot 2^{(k-1)2l}$ and $L'' = \sum_{k=1}^r L_{1,k} \cdot 2^{(k-1)2l}$.

In both L_k, L'_k the sum is computed using polysize threshold gates, e.g., by using the unary representation of each $L_{i,k}$. It is therefore straightforward to prove for each k, $L_k = L'_k + L_{1,k}$, (e.g., by trying all the possibilities for $L'_k, L_{1,k}$, and proving the formula separately for each possibility).

Now consider the formula $L' + L''$. Since in this addition there is no carry flow from one block to the next one, and since the bits of L, L', L'' in each block are just the bits of $L_k, L'_k, L_{1,k}$ (respectively), we can conclude that $L = L' + L''$. Since in a similar way we can prove that $H = H' + H''$, we are now able to conclude

$$SUM[z_1, \ldots, z_m] = H + L$$

$$= (H'' + L'') + (H' + L') = z_1 + SUM[z_2, \ldots, z_m]. \quad ∎$$

LEMMA 7.10. *For every $z_1, \ldots, z_m$, there are TC^0-Frege proofs of*

$$SUM[z_1 + z_2, z_3, \ldots, z_m] = SUM[z_1, z_2, \ldots, z_m].$$

Proof of Lemma 7.10. The lemma can be proved easily from Lemmas 7.9 and 7.2 as follows:

$$SUM[z_1, \ldots, z_m] = z_1 + SUM[z_2, \ldots, z_m]$$

$$= z_1 + (z_2 + SUM[z_3, \ldots, z_m]) = (z_1 + z_2) + SUM[z_3, \ldots, z_m]$$

$$= SUM[z_1 + z_2, z_3, \ldots, z_m]. \quad ∎$$

LEMMA 7.11. *For every $z_1, \ldots, z_m$, and every $1 \le k \le m$, there are TC^0-Frege proofs of*

$$SUM[z_1, \ldots, z_{k-1}, SUM[z_k, \ldots, z_m]] = SUM[z_1, \ldots, z_m].$$

Proof of Lemma 7.11. By Lemmas 7.9, 7.10, and 7.7, we have

$$SUM[z_1, \ldots, z_{k-1}, SUM[z_k, \ldots, z_m]]$$

$$= SUM[z_1, \ldots, z_{k-1}, z_k + SUM[z_{k+1}, \ldots, z_m]]$$

$$= SUM[z_1, \ldots, z_{k-1}, z_k, SUM[z_{k+1}, \ldots, z_m]].$$

The proof now follows by repeating the same argument $m-k$ times, where Lemma 7.8 is used for the base case. $\square$

LEMMA 7.12. *For every x, y, there are TC^0-Frege proofs of*

$$x \cdot y = y \cdot x.$$

Proof of Lemma 7.12. The proof is immediate from the fact that the product formula was defined in a symmetric way. $\square$

LEMMA 7.13. *For every x, y, z, where x is a power of 2, there are TC^0-Frege proofs of*

$$x \cdot (y + z) = x \cdot y + x \cdot z.$$

Proof of Lemma 7.13. It is straightforward to prove that $2^i \cdot y$, where y is any sequence of bits, consists of adding to the end of y, i 0's. The lemma easily follows. $\square$

LEMMA 7.14. *For every $z_1, \dots, z_m$, and every x where x is a power of 2, there are TC^0-Frege proofs of*

$$x \cdot SUM[z_1, \dots, z_m] = SUM[x \cdot z_1, \dots, x \cdot z_m].$$

Proof of Lemma 7.14. The proof of this lemma is like the proof of Lemma 7.17 but uses Lemma 7.13 instead of 7.16. $\square$

LEMMA 7.15. *For every x, y, z, where x, y are powers of 2, there are TC^0-Frege proofs of*

$$x \cdot (y \cdot z) = (x \cdot y) \cdot z.$$

Proof of Lemma 7.15. The proof is the same as the proof of Lemma 7.13. $\square$

The following three lemmas are generalizations of the previous three lemmas.

LEMMA 7.16. *For every x, y, z there are TC^0-Frege proofs of*

$$x \cdot (y + z) = x \cdot y + x \cdot z.$$

Proof of Lemma 7.16. By definition of the product formula,

$$x \cdot (y + z) = SUM_{i,j}[2^{i+j-2} x_i (y + z)_j].$$

Similarly,

$$x \cdot y + x \cdot z = SUM_{i,j}[2^{i+j-2} x_i y_j] + SUM_{i,j}[2^{i+j-2} x_i z_j].$$

By iterative application of Lemma 7.11 (also using Lemma 7.7),

$$SUM_{i,j}[2^{i+j-2} x_i (y + z)_j] = SUM_i[SUM_j[2^{i+j-2} x_i (y + z)_j]].$$

Similarly (also using Lemmas 7.9 and 7.10),

$$SUM_{i,j}[2^{i+j-2} x_i y_j] + SUM_{i,j}[2^{i+j-2} x_i z_j]$$

$$= SUM_i[SUM_j[2^{i+j-2} x_i y_j + 2^{i+j-2} x_i z_j]],$$

and in the same way (using the same lemmas)

$$SUM_i[SUM_j[2^{i+j-2}x_iy_j + 2^{i+j-2}x_iz_j]]$$

$$= SUM_i[SUM_j[2^{i+j-2}x_iy_j] + SUM_j[2^{i+j-2}x_iz_j]].$$

Thus, we have to prove

$$SUM_i[SUM_j[2^{i+j-2}x_i(y+z)_j]] = SUM_i[SUM_j[2^{i+j-2}x_iy_j] + SUM_j[2^{i+j-2}x_iz_j]].$$

We will prove this by proving that for every i,

$$SUM_j[2^{i+j-2}x_i(y+z)_j] = SUM_j[2^{i+j-2}x_iy_j] + SUM_j[2^{i+j-2}x_iz_j].$$

If $x_i = 0$, this is trivial. Otherwise, $x_i = 1$, and using Lemmas 7.15, 7.14, and 7.6 we have

$$SUM_j[2^{i+j-2}x_i(y+z)_j] = 2^{i-1}SUM_j[2^{j-1}(y+z)_j] = 2^{i-1}\cdot(y+z).$$

In the same way (also using Lemma 7.13),

$$SUM_j[2^{i+j-2}x_iy_j] + SUM_j[2^{i+j-2}x_iz_j] = 2^{i-1}SUM_j[2^{j-1}y_j] + 2^{i-1}SUM_j[2^{j-1}z_j]$$

$$= 2^{i-1}\cdot y + 2^{i-1}\cdot z = 2^{i-1}\cdot(y+z). \qquad \square$$

LEMMA 7.17. *For every $z_1,\dots,z_m$, and every x, there are TC^0-Frege proofs of*

$$x\cdot SUM[z_1,\dots,z_m] = SUM[x\cdot z_1,\dots,x\cdot z_m].$$

Proof of Lemma 7.17. We will show that for every i,

$$\begin{aligned} x\cdot SUM[z_1,\dots,z_i] + SUM[x\cdot z_{i+1},\dots,x\cdot z_m] = x\cdot &SUM[z_1,\dots,z_{i+1}] \\ &+ SUM[x\cdot z_{i+2},\dots,x\cdot z_m]. \end{aligned}$$

The lemma then follows by the combination of all these equalities. The case $i = 0$ is proven as follows:

$$\begin{aligned} SUM[x\cdot z_1,\dots,x\cdot z_m] &= x\cdot z_1 + SUM[x\cdot z_2,\dots,x\cdot z_m] \\ &= x\cdot SUM[z_1] + SUM[x\cdot z_2,\dots,x\cdot z_m]. \end{aligned}$$

The first equality follows by applying Lemma 7.9, and the second equality by applying Lemma 7.8.

For the general step,

$$\begin{aligned} &x\cdot SUM[z_1,\dots,z_i] + SUM[x\cdot z_{i+1},\dots,x\cdot z_m] \\ &= x\cdot SUM[z_1,\dots,z_i] + x\cdot z_{i+1} + SUM[x\cdot z_{i+2},\dots,x\cdot z_m] \\ &= x\cdot(SUM[z_1,\dots,z_i] + z_{i+1}) + SUM[x\cdot z_{i+2},\dots,x\cdot z_m] \\ &= x\cdot SUM[z_1,\dots,z_{i+1}] + SUM[x\cdot z_{i+2},\dots,x\cdot z_m]. \end{aligned}$$

The first equality follows from Lemmas 7.9, the second equality follows from Lemma 7.16, and the third equality follows from Lemma 7.9. $\square$

LEMMA 7.18. *For every x, y, z, there are TC^0-Frege proofs of*

$$x \cdot (y \cdot z) = (x \cdot y) \cdot z.$$

Proof of Lemma 7.18. We will show that $x \cdot (y \cdot z)$ is equal to $SUM_{i,j,k}[2^{i+j+k-3} x_i y_j z_k]$. The same will be true for $(x \cdot y) \cdot z$, and the lemma follows.

By the definition of the product,

$$y \cdot z = SUM_{j,k}[2^{j+k-2} y_j z_k].$$

Hence, by Lemma 7.6 and two applications of Lemma 7.17 (and freely using Lemma 7.12),

$$x \cdot (y \cdot z) = SUM_i[2^{i-1} x_i] \cdot SUM_{j,k}[2^{j+k-2} y_j z_k]$$

$$= SUM_i[(2^{i-1} x_i) \cdot SUM_{j,k}[2^{j+k-2} y_j z_k]]$$

$$= SUM_i[SUM_{j,k}[(2^{i-1} x_i) \cdot 2^{j+k-2} y_j z_k]].$$

Since it can be easily verified that $(2^{i-1} x_i) \cdot 2^{j+k-2} y_j z_k = 2^{i+j+k-3} x_i y_j z_k$, the above is equal to

$$SUM_i[SUM_{j,k}[2^{i+j+k-3} x_i y_j z_k]],$$

and by an iterative application of Lemma 7.11 (using also Lemma 7.7) the above is equal to

$$SUM_{i,j,k}[2^{i+j+k-3} x_i y_j z_k]. \quad \square$$

7.2. Some basic properties of less-than.

LEMMA 7.19. *For every x, y, there are TC^0-Frege proofs of $x > y \vee y > x \vee x = y$ and also of $x > 0 \vee x = 0$.*

Proof of Lemma 7.19. Either there is a bit i such that i is the most significant bit where x and y differ, or not. If all bits are equal, then $x = y$. But if there is i such that it is the most significant bit where they differ, then if $x_i = 1$ and $y_i = 0$, then $x > y$, and if $x_i = 0$ and $y_i = 1$, then $y > x$. $\square$

LEMMA 7.20. *For every x, y, there are TC^0-Frege proofs of $x > y \rightarrow (x - y) > 0$.*

Proof of Lemma 7.20. By Lemma 7.19, $(x - y) = 0 \vee (x - y) > 0$. Suppose for a contradiction that $x - y = 0$. Then $x = (x - y) + y = y$, and we get $x > x$ (which is easily proved to be false). So $x - y > 0$. $\square$

LEMMA 7.21. *For every x, y, z, there are TC^0-Frege proofs of $x > y \ \wedge \ y \geq z \rightarrow x > z$; and also $x \geq y \ \wedge y > z \rightarrow x > z$.*

Proof of Lemma 7.21. If $y = z$, then the proof of the first statement is obvious. Otherwise, suppose that i is the most significant bit where $x_i \neq y_i$ and that $x_i = 1$ and $y_i = 0$. Similarly, suppose that j is the most significant bit where $y_j \neq z_j$ and that $y_j = 1$ and that $z_j = 0$. If $i \geq j$, then it is easy to show that i is the most significant bit where $x_i \neq z_i$, $x_i = 1$, $z_i = 0$, and thus $x > z$. Similarly, if $j > i$, then j is the most significant bit where $x_j \neq z_j$, $x_j = 1$, $z_j = 0$, and thus $x > z$. Similar reasoning also implies the second statement in the lemma. $\square$

LEMMA 7.22. *For every x, z, there are TC^0-Frege proofs of $x + z \geq x$; and also $z > 0 \rightarrow x + z > x$.*

Proof of Lemma 7.22. If $z = 0$, then it is clear that $x + z = x$. For $z > 0$, we will show inductively for decreasing k that

$$x + SUM_{i \geq k}[2^{i-1}z_i] > x.$$

Then when $k = 1$, we have $x + SUM_i[2^{i-1}z_i] = x + z > x$, by Lemma 7.6.

Assuming that $z > 0$, let $z_{i'}$ be the most significant bit such that $z_{i'} = 1$. The base case of the induction will be to show that $x + SUM_{i \geq i'}[2^{i-1}z_i] > x$. Because $z_i = 0$ for all $i > i'$, and applying Lemma 7.8, it suffices to show that $x + z' > x$, where $z' = 2^{i'-1}z_{i'}$. There are two cases. If $x_{i'} = 0$, then $x + z'$ is equal to $x_n x_{n-1} \cdots x_{i'+1} 1 x_{i'-1} \cdots x_1$, and so clearly $x + z' > x$. The other case is when $x_{i'} = 1$. Let j be the most significant bit position greater than i' such that $x_j = 0$. One clearly exists because $x_{n+1} = 0$. Then $(x + z')_j = 1$, $x_j = 0$, and all higher bits are equal, and thus $x + z' > x$ as desired.

For the inductive step, we assume that $x + SUM_{i \geq k}[2^{i-1}z_i] > x$ and want to show that $x + SUM_{i \geq k-1}[2^{i-1}z_i] > x$. Using the same argument as in the base case, one can prove that (a) $x + SUM_{i \geq k}[2^{i-1}z_i] + 2^{k-2}z_{k-1} \geq x + SUM_{i \geq k}[2^{i-1}z_i]$. By the inductive hypothesis, (b) $x + SUM_{i \geq k}[2^{i-1}z_i] > x$. Applying Lemma 7.21 to (a) and (b), we obtain $x + SUM_{i \geq k}[2^{i-1}z_i] + 2^{k-2}z_{k-1} > x$. By Lemma 7.9, this implies $x + SUM_{i \geq k-1}[2^{i-1}z_i] > x$, as desired. □

LEMMA 7.23. *For every x, y, z there are TC^0-Frege proofs of $x > y \rightarrow x + z > y$.*

Proof of Lemma 7.23. If $z = 0$, then $x + z = x > y$. Otherwise, $z > 0 \rightarrow x + z > x$ by Lemma 7.22. Then by Lemma 7.21, $x + z > y$ as desired. □

LEMMA 7.24. *For every x, y, z there are TC^0-Frege proofs of $x > y \rightarrow x + z > y + z$.*

Proof of Lemma 7.24.

$$\begin{aligned} x + z &= (x - y) + y + z \\ &> y + z. \end{aligned}$$

The first equality follows from Lemma 7.4, and the second follows from Lemma 7.22 and the fact that $x > y \rightarrow x - y > 0$. □

LEMMA 7.25. *For every x, y, there are TC^0-Frege proofs of $y > 0 \rightarrow x \leq x \cdot y$.*

Proof of Lemma 7.25. $x \cdot y = SUM_{i,j}[2^{i+j-2}x_i y_j]$ by definition. Also, since $y > 0$, there is a bit of y that is 1, and suppose that it is y_l. Then

$$\begin{aligned} x \cdot y &= SUM_{i,j}[2^{i+j-2}x_i y_j] \\ &= SUM_i[2^{i+l-2}x_i y_l] + SUM_{i,j,j \neq l}[2^{i+j-2}x_i y_j] \\ &\geq SUM_i[2^{i+l-2}x_i y_l] \\ &= 2^{l-1}SUM_i[2^{i-1}x_i] \\ &= 2^{l-1} \cdot x \geq x. \qquad \square \end{aligned}$$

7.3. Some basic properties of modular arithmetic. Recall that the formulas for $[z]_p$ and $div_p(z)$ take as inputs not only the variables p and z, but also variables k_i, r_i (for every $1 \leq i \leq n$), and variables $p_1, \ldots, p_n$. The formulas give the right output if $2^i = p \cdot k_i + r_i$, $r_i < p$, and $p_i = i \cdot p$ (for all $1 \leq i \leq n$). So the following theorems will all have the hypothesis that the values for the variables k_i, r_i, and p_i are correct, and that there are short TC^0-Frege proofs for $2^i = p \cdot k_i + r_i$, $r_i < p$, and $p_i = i \cdot p$. We will state this hypothesis for the first lemma and omit it afterwards for simplicity. For simplicity, we will also use the notations $k_0 = 0$ and $r_0 = 1$, thus $2^0 = p \cdot k_0 + r_0$.

The lemmas will be used with either $p = P$, where P is the number used for the DH formula, or with $p = q$, where q is some fixed hardwired value (e.g., $q = q_j$ or $q = Q$, where q_j is one of the primes used for the iterated product formula, and Q is the product of all these primes). If $p = q$ for some hardwired q, then k_i, r_i, and $p_1, \ldots p_n$ can also be hardwired. Hence, their values are correct and it is straightforward to check (i.e., to prove) that the nonvariable formulas $2^i = p \cdot k_i + r_i$, $r_i < p$, and $p_i = i \cdot p$ are all correct. If $p = P$, then k_i, r_i, and $p_1, \ldots, p_n$ are inputs for the DH formula itself, and the requirements $2^i = p \cdot k_i + r_i$, $r_i < p$, and $p_i = i \cdot p$ are part of the requirements in the DH formula.

LEMMA 7.26. *Let z and p be n-bit numbers. Then there are TC^0-Frege proofs of*

$$2^i = k_i \cdot p + r_i, 0 \leq r_i < p, p_i = i \cdot p \text{ (for all } 0 \leq i \leq n) \longrightarrow z = SUM_i[(r_{i-1} + p \cdot k_{i-1})z_i].$$

Proof of Lemma 7.26. From Lemma 7.6, and if $2^i = r_i + p \cdot k_i$,

$$z = SUM_i[2^{i-1} z_i] = SUM_i[(r_{i-1} + p \cdot k_{i-1})z_i]. \qquad \square$$

LEMMA 7.27. *For every z and p, there are TC^0-Frege proofs of*

$$z = [z]_p + \mathrm{div}_p(z) \cdot p.$$

Also, the following uniqueness property has a TC^0-Frege proof: If $z = x + y \cdot p$ where $0 \leq x < p$, then $x = [z]_p$ and $y = \mathrm{div}_p(z)$.

Proof of Lemma 7.27. From the previous lemma, we can express z as $SUM_i[(r_{i-1} + p \cdot k_{i-1})z_i]$. Let l be the same as in the definition of the modulo formulas. Then

$$\begin{aligned}
[z]_p + p \cdot \mathrm{div}_p(z) &= (SUM_i[r_{i-1}z_i] - p \cdot l) + p \cdot (SUM_i[k_{i-1}z_i] + l) \\
&= (SUM_i[r_{i-1}z_i] - p \cdot l) + (p \cdot SUM_i[k_{i-1}z_i] + p \cdot l) \\
&= ((SUM_i[r_{i-1}z_i] - p \cdot l) + p \cdot l) + p \cdot SUM_i[k_{i-1}z_i] \\
&= SUM_i[r_{i-1}z_i] + p \cdot SUM_i[k_{i-1}z_i] \\
&= SUM_i[r_{i-1}z_i] + SUM_i[p \cdot k_{i-1}z_i] \\
&= SUM[SUM_i[r_{i-1}z_i], SUM_i[p \cdot k_{i-1}z_i]] \\
&= SUM[r_0 z_1, .., r_{n-1}z_n, p \cdot k_0 z_1, .., p \cdot k_{n-1}z_n] \\
&= SUM_i[(r_{i-1} + p \cdot k_{i-1})z_i] \\
&= z.
\end{aligned}$$

The first equality follows from the definitions of the formulas $[z]_p$ and $\mathrm{div}_p(z)$. The remaining equalities follow from Lemmas 7.16, 7.2, 7.4, 7.17, 7.9, 7.11, 7.10, and 7.26.

Let us now prove the uniqueness part. Suppose $z = [z]_p + \mathrm{div}_p(z) \cdot p = x + y \cdot p$, where $0 \leq x, [z]_p < p$. If $\mathrm{div}_p(z) = y$, then we are finished. But if $\mathrm{div}_p(z) > y$, then by the claim below $x \geq p$, which is a contradiction. (A similar argument holds when $\mathrm{div}_p(z) < y$.)

CLAIM 7.28. *If $x + y \cdot p = u + v \cdot p$ and $v > y$, then $x \geq p$.*

Proof of the claim. Since $v > y$, by Lemmas 7.4 and 7.20, $y + (v - y) = v$, and $v - y > 0$. Then $x + y \cdot p = u + (y + (v - y)) \cdot p$, and by Lemma 7.16, $x + y \cdot p = u + y \cdot p + (v - y) \cdot p$. By Lemma 7.5 we get that $x = u + (v - y) \cdot p$. Therefore by Lemmas 7.25 and 7.22,

$$p \leq (v - y) \cdot p \leq u + (v - y) \cdot p = x,$$

and by Lemma 7.21 we get $p \leq x$. ∎

LEMMA 7.29. *For every z, k, and p, there are TC^0-Frege proofs of*

$$[z]_p = [z + k \cdot p]_p.$$

Proof of Lemma 7.29. Let $x = z + k \cdot p$. Then $x = [x]_p + \mathrm{div}_p(x) \cdot p$, and $z = [z]_p + div_p(z) \cdot p$ (by Lemma 7.27).

So, $z + k \cdot p = x = [x]_p + \mathrm{div}_p(x) \cdot p$. Therefore, $[z]_p + \mathrm{div}_p(z) \cdot p + k \cdot p = [x]_p + \mathrm{div}_p(x) \cdot p$. By the uniqueness part of Lemma 7.27 applied to x, $[z]_p = [x]_p$. ∎

LEMMA 7.30. *For every x, y, z, and p, there are TC^0-Frege proofs of*

$$[x + y]_p = [[x]_p + [y]_p]_p,$$

$$[x + y]_p = [[x]_p + y]_p,$$

and

$$[x + y + z]_p = [[x]_p + [y]_p + z]_p.$$

Proof of Lemma 7.30. By Lemma 7.27, $x = [x]_p + \mathrm{div}_p(x) \cdot p$ and $y = [y]_p + \mathrm{div}_p(y) \cdot p$. Hence,

$$[x + y]_p = [[x]_p + [y]_p + (\mathrm{div}_p(x) + \mathrm{div}_p(y)) \cdot p]_p,$$

and by Lemma 7.29,

$$[x + y]_p = [[x]_p + [y]_p]_p.$$

A similar argument shows that $[x + y]_p = [[x]_p + y]_p$ and $[x + y + z]_p = [[x]_p + [y]_p + z]_p$. ∎

LEMMA 7.31. *For every $z_1, \dots, z_m$ and p, there are TC^0-Frege proofs of*

$$SUM[z_1, \dots, z_m]_p = [[z_1]_p + SUM[z_2, \dots, z_m]_p]_p.$$

Proof of Lemma 7.31. The lemma follows easily from Lemmas 7.9 and 7.30. ∎

LEMMA 7.32. *For every x, y, and p, there are TC^0-Frege proofs of*

$$[x]_p = [y]_p \longrightarrow [x + z]_p = [y + z]_p.$$

Proof of Lemma 7.32.

$$[x + z]_p = [[x]_p + [z]_p]_p = [[y]_p + [z]_p]_p = [y + z]_p.$$

The first equality follows from Lemma 7.30, the next equality follows from the assumption that $[x]_p = [y]_p$, and the third equality follows from Lemma 7.30. ∎

LEMMA 7.33. *For every x, y, z, and p, there are TC^0-Frege proofs of*

$$[x + z]_p = [y + z]_p \longrightarrow [x]_p = [y]_p.$$

Proof of Lemma 7.33. Assuming that $[x+z]_p = [y+z]_p$, it follows from the above Lemma 7.32 that $[x + z + (p - [z]_p)]_p = [y + z + (p - [z]_p)]_p$. The left side of the equation is equal to

$$\begin{aligned}[x + z + (p - [z]_p)]_p &= [[x]_p + [z]_p + (p - [z]_p)]_p \\ &= [[x]_p + p]_p \\ &= [x]_p.\end{aligned}$$

The first equality follows from Lemma 7.30; the second equality follows from Lemmas 7.1, 7.2, and 7.3; and the third equality follows from Lemma 7.29. Similarly, it can be shown that $[y + z + (p - [z]_p)]_p = [y]_p$ and thus the lemma follows. □

LEMMA 7.34. *For every x, y, and p, there are TC^0-Frege proofs of*

$$[x \cdot y]_p = [x \cdot [y]_p]_p.$$

Proof of Lemma 7.34.

$$\begin{aligned}[x \cdot y]_p &= [x \cdot ([y]_p + \mathrm{div}_p(y) \cdot p)]_p \\ &= [x \cdot [y]_p + x \cdot \mathrm{div}_p(y) \cdot p]_p \\ &= [x \cdot [y]_p]_p,\end{aligned}$$

where the last equality follows from Lemma 7.29. □

LEMMA 7.35. *Let A, B, C be fixed numbers such that $A = BC$. Then for every z, there are TC^0-Frege proofs of*

$$[z]_B = [[z]_A]_B.$$

This lemma will be used in situations where $A = Q$ and $B = q_i$ for some i. Recall that the numbers $Q, q_1, \ldots q_t$ are hardwired, along with their corresponding k_i, r_i, and the variables for the $j \cdot q_i$'s. Hence, we think of A, B, C as hardwired.

Proof of Lemma 7.35. Using Lemmas 7.27, 7.29, and 7.18, we get

$$[z]_B = [[z]_A + A \cdot \mathrm{div}_A(z)]_B = [[z]_A + B \cdot (C \cdot \mathrm{div}_A(z))]_B = [[z]_A]_B. \qquad □$$

7.4. Some basic properties of iterative product.

LEMMA 7.36. *For every $z_1, \ldots, z_m$ and every fixed permutation α, there are TC^0-Frege proofs of*

$$PROD[z_1, \ldots, z_m] = PROD[z_{\alpha(a)}, \ldots, z_{\alpha(m)}].$$

(That is, the iterated product is symmetric.)

Proof of Lemma 7.36. The proof of this lemma is immediate from the symmetric definition of $PROD$. □

LEMMA 7.37. *For every $z_1, \ldots, z_m$ and every $1 \le k \le m$, there are TC^0-Frege proofs of*

$$PROD[z_1, \ldots, z_m] = PROD[z_1, \ldots, z_{k-1}, PROD[z_k, \ldots, z_m]].$$

Proof of Lemma 7.37. Recall that we have hard-coded the numbers u_j, such that $u_j \bmod q_j = 1$ and for all $i \neq j$, $u_j \bmod q_i = 0$. For all primes q_j dividing Q and for all m, $1 \le m \le q_j$, we can verify the following statements: $[u_j \cdot m]_{q_j} = m$, and for all $i \neq j$, $[u_j \cdot m]_{q_i} = 0$. (Note that these statements are variable-free and hence they can be easily proven by doing a formula evaluation.)

Recall that for any k, the iterated product of the numbers $z_k, \dots, z_m$ is calculated as follows:

$$PROD[z_k, \dots, z_m] = SUM_{j=1}^{t}[u_j \cdot r_j^{[k,..,m]}]_Q,$$

where $r_j^{[k,\dots,m]}$ is computed like r_j as defined in section 3.4 but using r_{ij} only for i such that $k \leq i \leq m$.

In the same way,

$$PROD[z_1, \dots, z_{k-1}, PROD[z_k, \dots, z_m]]$$

$$= SUM_{j=1}^{t}[u_j \cdot r_j^{[1,\dots,k-1,[k,\dots,m]]}]_Q,$$

where $r_j^{[1,\dots,k-1,[k,\dots,m]]}$ is calculated as before by the following steps:

1. For $i < k$, calculate $r_{i,j} = [z_i]_{q_j}$, and also calculate $r_{*,j} = PROD[z_k, \dots, z_m]_{q_j}$.
2. For $i < k$, calculate $a_{i,j}$ such that $(g_j^{a_{i,j}}) \bmod q_j = r_{i,j}$, and also $a_{*,j}$ such that $(g_j^{a_{*,j}}) \bmod q_j = r_{*,j}$ by table lookup.
3. Calculate $c'_j = SUM[a_{1,j}, \dots, a_{k-1,j}, a_{*,j}]_{(q_j-1)}$.
4. Calculate $r_j^{[1,\dots,k-1,[k,\dots,m]]}$ such that $g^{c'_j} \bmod q_j = r_j^{[1,\dots,k-1,[k,..,m]]}$ by table lookup.

Therefore, all we have to do is to show that

$$SUM_{j=1}^{t}[u_j \cdot r_j^{[1,\dots,m]}]_Q = SUM_{j=1}^{t}[u_j \cdot r_j^{[1,\dots,k-1,[k,\dots,m]]}]_Q.$$

Hence, all we need to do to prove Lemma 7.37 is to show the following claim.

CLAIM 7.38. *For every j, there are TC^0-Frege proofs of $r_j^{[1,\dots,k-1,[k,\dots,m]]} = r_j^{[1,\dots,m]}$.*

The first step is to prove the following claim:

CLAIM 7.39. *There are TC^0-Frege proofs of $PROD[z_k, \dots, z_m]_{q_j} = r_j^{[k,\dots,m]}$.*

Claim 7.39 is proven as follows.

$$PROD[z_k, \dots, z_m]_{q_j}$$

$$= [SUM_{i=1}^{t}[u_i \cdot r_i^{[k,\dots,m]}]_Q]_{q_j} = SUM_{i=1}^{t}[u_i \cdot r_i^{[k,\dots,m]}]_{q_j}$$

$$= [[u_j \cdot r_j^{[k,\dots,m]}]_{q_j} + SUM_{i \neq j}[u_i \cdot r_i^{[k,\dots,m]}]_{q_j}]_{q_j}$$

$$= [r_j^{[k,\dots,m]} + 0]_{q_j} = r_j^{[k,\dots,m]}.$$

The second equality follows by Lemma 7.35; the third equality follows by Lemmas 7.31 and 7.7. To prove the fourth equality, we need to use the fact that $[u_j \cdot r_j^{[k,\dots,m]}]_{q_j} = r_j^{[k,\dots,m]}$, and also for all $i \neq j$, $[u_i \cdot r_i^{[k,\dots,m]}]_{q_j} = 0$. These facts can be easily proved just by checking all possibilities for $r_i^{[k,\dots,m]}$ (proving the statement for each possibility is easy, because these statements are variable-free and hence they can be easily proven by doing a formula evaluation). In order to prove the fourth equality formally, we can show that $SUM_{i\neq j}[u_i \cdot r_i^{[k,\ldots,m]}]_{q_j}$ equals zero by induction on the number of terms in the sum. $\square$

We can now turn to the proof of Claim 7.38. The quantity $r_j^{[1,\ldots,m]}$ is obtained by doing a table lookup to find the value equal to $g_j^{c_j} \bmod q_j$, where $c_j = SUM_{i=1}^m[a_{i,j}]_{(q_j-1)}$. Similarly, the quantity $r_j^{[1,\ldots,k-1,[k,\ldots,m]]}$ is obtained by doing a table lookup to find the value equal to $g_j^{c'_j} \bmod q_j$, where

$$c'_j = SUM[a_{1,j}, a_{2,j}, .., a_{k-1,j}, a_{*,j}]_{(q_j-1)}.$$

Hence, it is enough to prove that $c_j = c'_j$. Using previous lemmas,

$$c_j = [SUM_{i=1}^{k-1}[a_{i,j}]_{(q_j-1)} + SUM_{i=k}^m[a_{i,j}]_{(q_j-1)}]_{(q_j-1)},$$

$$c'_j = [SUM_{i=1}^{k-1}[a_{i,j}]_{(q_j-1)} + a_{*,j}]_{(q_j-1)}.$$

Thus, it suffices to show that

$$SUM_{i=k}^m[a_{i,j}]_{(q_j-1)} = a_{*,j}.$$

Recall that $a_{*,j}$ is the value obtained by table lookup such that $(g_j^{a_{*,j}}) \bmod q_j = r_{*,j}$, and by Claim 7.39, we have that $r_{*,j} = r_j^{[k,\ldots,m]}$. Now $r_j^{[k,\ldots,m]}$, in turn, is the value obtained by table lookup to equal $(g_j^d) \bmod q_j$, where $d = SUM_{i=k}^m[a_{i,j}]_{(q_j-1)}$.

Now it is easy to verify that our table lookup is one to one. That is, for every $x, y, z \leq q_j$, if $g_j^x \bmod q_j = z$, and $g_j^y \bmod q_j = z$, then $x = y$. Using this property (with $x = SUM_{i=k}^m[a_{i,j}]_{(q_j-1)}$, $y = a_{*,j}$ and $z = r_{*,j} = r_j^{[k,\ldots,m]}$), it follows that

$$SUM_{i=k}^m[a_{i,j}]_{(q_j-1)} = a_{*,j}. \qquad \square$$

7.5. The Chinese remainder theorem and other properties of iterative product. The heart of our proof is a TC^0-Frege proof for the following lemma, which gives the hard direction of the Chinese remainder theorem (a TC^0-Frege proof for the other direction is simpler).

LEMMA 7.40. *Let R, S be two integers, such that for every j, $[R]_{q_j} = [S]_{q_j}$. Then there are TC^0-Frege proofs of*

$$[R]_Q = [S]_Q,$$

where $q_1, \ldots, q_t$ are the fixed primes used for the $PROD$ formula (i.e., the first t primes), and Q is their product.

Proof of Lemma 7.40. Without loss of generality, we can assume that $0 \leq R, S \leq Q - 1$, and prove that $R = S$. Otherwise, define $R' = [R]_Q$, and $S' = [S]_Q$, and use Lemma 7.35 to show that for every j, $[R']_{q_j} = [S']_{q_j}$. Since $0 \leq R', S' \leq Q - 1$, we can then conclude that

$$[R]_Q = R' = S' = [S]_Q.$$

For every k, let Q_k denote $\prod_{j=1}^k q_j$. Note that the numbers Q_k can be hardwired, and that one can easily prove the following statements. (These statements are variable-free and hence they can be easily proven by doing a formula evaluation.)

For every i, $Q_{i+1} = Q_i \cdot q_{i+1}$.

The proof of the lemma is by induction on t (the number of q_j's). For $t = 1$, $Q = q_1$, and the lemma is trivial. Assume therefore by the induction hypothesis that

$$[R]_{Q_{t-1}} = [S]_{Q_{t-1}},$$

and hence

$$[[R]_{Q_{t-1}}]_{q_t} = [[S]_{Q_{t-1}}]_{q_t}.$$

Denote, $D_R = \text{div}_{Q_{t-1}}[R]$, and $D_S = \text{div}_{Q_{t-1}}[S]$. Then by Lemma 7.27,

$$R = D_R \cdot Q_{t-1} + [R]_{Q_{t-1}},$$

and

$$S = D_S \cdot Q_{t-1} + [S]_{Q_{t-1}},$$

and since we know that $[R]_{q_t} = [S]_{q_t}$, we have

$$[D_R \cdot Q_{t-1} + [R]_{Q_{t-1}}]_{q_t} = [D_S \cdot Q_{t-1} + [S]_{Q_{t-1}}]_{q_t},$$

and by $[R]_{Q_{t-1}} = [S]_{Q_{t-1}}$ and Lemma 7.33,

$$[D_R \cdot Q_{t-1}]_{q_t} = [D_S \cdot Q_{t-1}]_{q_t}.$$

Since R, S are both lower than Q, it follows that D_R, D_S are both lower than q_t. Hence, by Claim 7.41, $D_R = D_S$. Therefore, we can conclude that

$$R = D_R \cdot Q_{t-1} + [R]_{Q_{t-1}} = D_S \cdot Q_{t-1} + [S]_{Q_{t-1}} = S. \qquad \square$$

CLAIM 7.41. *For every i, there are TC^0-Frege proofs of: if $d_1, d_2 < q_i$, and $[d_1 \cdot Q_{i-1}]_{q_i} = [d_2 \cdot Q_{i-1}]_{q_i}$; then $d_1 = d_2$.*

Proof. Since $d_1, d_2 < q_i$, there are only $O(\log n)$ possibilities for d_1, d_2. Therefore, one can just check all the possibilities for d_1, d_2. Proving the statement for each possibility is easy, because these statements are variable-free and hence they can be easily proven by doing a formula evaluation.

Alternatively, one can define the function $f(x) = [x \cdot Q_{i-1}]_{q_i}$, in the domain $\{0, \dots, q_i\}$, and prove that $f(x)$ is onto the range $\{0, \dots, q_i\}$. Then, by applying the propositional pigeonhole principle, which is efficiently provable in TC^0-Frege, it follows that f is one to one. $\square$

We are now able to prove the following lemmas.

LEMMA 7.42. *For every z, there are TC^0-Frege proofs of*

$$PROD[z] = z.$$

Proof of Lemma 7.42. Recall that $PROD[z]$ is calculated as follows:

$$PROD[z] = SUM_{j=1}^{t}[u_j \cdot r_j]_Q,$$

where r_j is computed by $r_j = [z]_{q_j}$.

By Claim 7.39, for every i, $PROD[z]_{q_i} = r_i$. We thus have for every i, $PROD[z]_{q_i} = [z]_{q_i}$. The proof of the lemma now follows by Lemma 7.40. $\square$

LEMMA 7.43. *For every z_1, z_2, there are TC^0-Frege proofs of*

$$PROD[z_1, z_2] = z_1 \cdot z_2.$$

Proof of Lemma 7.43. Let us prove that for every i,

$$[PROD[z_1, z_2]]_{q_i} = [z_1 \cdot z_2]_{q_i}.$$

The proof of the lemma then follows by Lemma 7.40. By two applications of Lemma 7.34, it is enough to prove for every i,

$$[PROD[z_1, z_2]]_{q_i} = [[z_1]_{q_i} \cdot [z_2]_{q_i}]_{q_i}.$$

Recall that $PROD[z_1, z_2]$ is calculated as follows:

$$PROD[z_1, z_2] = SUM_{j=1}^{t}[u_j \cdot r_j^{[1,2]}]_Q,$$

where $r_j^{[1,2]}$ is computed like r_j as defined in section 3.4. By Claim 7.39, for every i,

$$PROD[z_1, z_2]_{q_i} = r_i^{[1,2]}.$$

Recall that $[z_1]_{q_i} = r_{1,i}$, and $[z_2]_{q_i} = r_{2,i}$. Therefore, all we have to prove is that for every i,

$$r_i^{[1,2]} = [r_{1,i} \cdot r_{2,i}]_{q_i}.$$

By the definitions: $r_{1,i} = (g_i^{a_{1,i}}) \bmod q_i$, and $r_{2,i} = (g_i^{a_{2,i}}) \bmod q_i$, and therefore,

$$[r_{1,i} \cdot r_{2,i}]_{q_i} = [(g_i^{a_{1,i}}) \bmod q_i \cdot (g_i^{a_{2,i}}) \bmod q_i]_{q_i}.$$

Also,

$$r_i^{[1,2]} = (g_i^{SUM[a_{1,i}, a_{2,i}]_{(q_i - 1)}}) \bmod q_i.$$

Therefore, one can just check all the possibilities for $a_{1,i}, a_{2,i}$. $\square$

Using the previous lemmas, we are now able to prove the following.

LEMMA 7.44. *For every $z_1, \dots, z_m$, every $k \leq m - 1$, and every p, there are TC^0-Frege proofs of*

$$PROD[z_1, \dots, z_m]_p$$

$$= PROD[z_1, \dots, z_k, PROD[z_{k+1}, \dots, z_m]_p]_p$$

(as before, given that $2^i = k_i \cdot p + r_i, 0 \leq r_i < p, p_i = i \cdot p$ for all i).

Proof of Lemma 7.44.

$$PROD[z_1,\dots,z_k,PROD[z_{k+1},\dots,z_m]_p]_p$$

$$= PROD[PROD[z_1,\dots,z_k],PROD[z_{k+1},\dots,z_m]_p]_p$$

$$= [PROD[z_1,\dots,z_k]\cdot PROD[z_{k+1},\dots,z_m]_p]_p$$

$$= [PROD[z_1,\dots,z_k]\cdot PROD[z_{k+1},\dots,z_m]]_p$$

$$= PROD[PROD[z_1,\dots,z_k],PROD[z_{k+1},\dots,z_m]]_p$$

$$= PROD[z_1,\dots,z_k,PROD[z_{k+1},\dots,z_m]]_p$$

$$= PROD[z_1,\dots,z_k,z_{k+1},\dots,z_m]_p.$$

The lemmas used for each equality in turn are Lemmas 7.37, 7.43, 7.34, 7.43, 7.37, and 7.37. □

We are now ready to prove Lemma 5.1: For every $z_{1,1},\dots,z_{m,m'}$ and p, there are TC^0-Frege proofs of

$$PROD_{i,j}[z_{i,j}]_p = PROD_i[PROD_j[z_{i,j}]_p]_p,$$

(given that $2^i = k_i\cdot p + r_i, 0\le r_i < p, p_i = i\cdot p$ for all i).

Proof of Lemma 5.1. This lemma is proved by an iterative application of the previous lemma. □

Acknowledgments. We are very grateful to Omer Reingold and Moni Naor for collaboration at early stages of this work and in particular for suggesting the use of the Diffie–Hellman cryptographic scheme. We also would like to thank Uri Feige for conversations and for his insight about extending this result to bounded-depth Frege. Part of this work was done at Dagstuhl during the complexity of Boolean functions workshop (1997).

SPACE-TIME TRADEOFFS FOR EMPTINESS QUERIES[*]

JEFF ERICKSON[†]

Abstract. We develop the first nontrivial lower bounds on the complexity of online hyperplane and halfspace emptiness queries. Our lower bounds apply to a general class of geometric range query data structures called *partition graphs*. Informally, a partition graph is a directed acyclic graph that describes a recursive decomposition of space. We show that any partition graph that supports hyperplane emptiness queries implicitly defines a halfspace range query data structure in the Fredman/Yao semigroup arithmetic model, with the same asymptotic space and time bounds. Thus, results of Brönnimann, Chazelle, and Pach imply that any partition graph of size s that supports hyperplane emptiness queries in time t satisfies the inequality $st^d = \Omega((n/\log n)^{d-(d-1)/(d+1)})$. Using different techniques, we improve previous lower bounds for Hopcroft's problem—Given a set of points and hyperplanes, does any hyperplane contain a point?—in dimensions four and higher. Using this offline result, we show that for online hyperplane emptiness queries, $\Omega(n^d/\operatorname{polylog} n)$ space is required to achieve polylogarithmic query time, and $\Omega(n^{(d-1)/d}/\operatorname{polylog} n)$ query time is required if only $O(n \operatorname{polylog} n)$ space is available. These two lower bounds are optimal up to polylogarithmic factors. For two-dimensional queries, we obtain an optimal continuous tradeoff $st^2 = \Omega(n^2)$ between these two extremes. Finally, using a lifting argument, we show that the same lower bounds hold for both offline and online halfspace emptiness queries in $\mathbb{R}^{d(d+3)/2}$.

1. Introduction.

A geometric range searching data structure stores a finite set of points so that we can quickly compute some function of the points inside an arbitrary region of space, or *query range*. For example, a reporting query asks for the list of points in the query range, and a counting query asks for their number. Perhaps the simplest type of query is an *emptiness* query (also called an *existential* query [6, 45]), which asks whether the query range contains any points in the set. Emptiness query data structures have been used to solve several geometric problems, including point location [20], ray shooting [2, 20, 41, 44], nearest and farthest neighbor queries [2], linear programming queries [40, 11], depth ordering [25], collision detection [19], and output-sensitive convex hull construction [40, 12].

This paper presents the first nontrivial lower bounds on the complexity of data structures that support online emptiness queries, where the query ranges are either arbitrary hyperplanes or arbitrary halfspaces. Most of our results take the form of tradeoffs between space and query time; that is, we prove lower bounds on the size of the data structure as a function of its worst-case query time, or vice versa. We also prove tradeoffs between preprocessing time and query time. These are the first such lower bounds for any range searching problem in any model of computation; earlier models do not even define preprocessing time.

1.1. Previous results. Most geometric range searching lower bounds are presented in the Fredman/Yao *semigroup arithmetic* model [33, 56]. In this model, the points are given weights from a semigroup, and the goal of a range query is to determine the total weight of the points in a query region. A data structure in this model can be informally regarded as a set of precomputed partial sums in the underlying semigroup. The size of such a data structure is the number of partial sums, and the query time is the minimum number of semigroup additions performed on these partial sums to obtain the required answer. (We define the model more formally in section 2.) Lower bounds have been established in this model for several types of query ranges [10, 14, 16, 56], in many cases matching the complexities of the corresponding data structures, at least up to polylogarithmic factors.

Unfortunately, emptiness queries are completely trivial in the semigroup arithmetic model. If the query range is empty, we perform no additions; conversely, if we perform even a single addition, the query range must not be empty. Similar arguments apply to Tarjan's *pointer machine* model [54], which has been used to derive output-sensitive lower bounds for several types of reporting queries [15, 22]. In fact, the only lower bounds previously known for hyperplane emptiness queries are essentially trivial. The size of any range searching data structure must be $\Omega(n)$, since it must store each of the points. The time to answer any range query must be at least $\Omega(\log n)$, even for a fixed one-dimensional point set, in any reasonable model of computation such as algebraic decision trees [50], algebraic computation trees [8], pointer machines [54], or real RAMs [49].[1] Since there are both linear-size data structures (with large query times) [38] and data structures with logarithmic query time (with large space requirements) [17, 42], any better lower bound must take the form of a tradeoff between space and time.

The only nontrivial lower bound previously known for *any* class of online emptiness queries, in *any* model of computation, is due to Andersson and Swanson [6]. They show that $\Omega(n \log n / \log t)$ space is required to answer axis-aligned rectangular emptiness queries in time t, in the so-called layered partition model. In particular, $\Omega(n \log n / \log \log n)$ space is required to achieve polylogarithmic query time in this model (but see [13] for better upper bounds in the integer RAM model).

Very recently, Borodin, Ostrovsky, and Rabani [9] derived lower bounds for hyperplane and halfspace emptiness, nearest-neighbor, point-location, and related queries in high-dimensional spaces, in Yao's extremely general *cell probe* model [57]. (See also [46].) In the cell probe model, a data structure is an array of s cells, each containing b bits. A query is answered by probing t of these cells in sequence; the address of each probe may depend arbitrarily on the query and the results of previous probes. Borodin, Ostrovsky, and Rabani show that for hyperplane queries among n points in the d-dimensional Hamming cube $\{0,1\}^d$, either $t \log s = \Omega(\log n \log d)$ or $tb = \Omega(n^{1-\varepsilon})$ for any fixed $\varepsilon > 0$. Unfortunately, this lower bound is trivial for any fixed dimension d, since it requires $n \ll 2^d$. Even when the dimension is allowed to vary, the bound is extremely weak unless the number of probes t is nearly constant.

1.2. New results. We derive our new lower bounds with respect to a general class of geometric range query data structures called *partition graphs*. Informally, a

[1]Sublogarithmic or even constant query times can be obtained for axis-aligned rectangular queries in models of computation that allow bit manipulation and require integer inputs within a known bounded universe; see, for example, [4, 5, 13, 46, 47, 55]. No such result is known for nonorthogonal ranges, however. We will take the traditional computational-geometric view that geometric objects are represented by arbitrary real coordinates, for which bit manipulation is impossible.

Table 1
Best known upper bounds for online hyperplane emptiness queries.

Space	Preprocessing	Query Time	Source
$O(n^d/\log^d n)$	$O(n^d/\log^{d-\varepsilon} n)$	$O(\log n)$	[17, 42]
$O(n)$	$O(n^{1+\varepsilon})$	$O(n^{1-1/d})$	[42]
$O(n)$	$O(n \log n)$	$O(n^{1-1/d} \operatorname{polylog} n)$	[38]
$n \le s \le n^d/\log^d n$	$O(n^{1+\varepsilon} + s\log^{\varepsilon} n)$	$O(n/s^{1/d})$	[17, 42]

partition graph is a directed acyclic graph that describes a recursive decomposition of space into connected regions. This recursive decomposition provides a natural search structure that is used both to preprocess points and to answer queries. (A formal definition is provided in section 3.) Our model is powerful enough to describe most, if not all, known hyperplane range searching data structures.[2] Partition graphs were originally introduced to study the complexity of Hopcroft's problem—Given a set of points and hyperplanes, does any hyperplane contain a point?—and similar offline geometric searching problems [31].

We summarize our results below. In each of these results and throughout the paper, s denotes space, p denotes preprocessing time, and t denotes worst-case query time. For comparison, the best known upper bounds are listed in Table 1. For a thorough overview of range searching techniques, results, and applications, see the surveys by Matoušek [43] and by Agarwal and Erickson [1].

- Any partition graph that supports hyperplane queries requires $\Omega(n)$ space, $\Omega(n \log n)$ preprocessing time, and $\Omega(\log n)$ query time.
- Any partition graph that supports hyperplane emptiness queries implicitly defines a halfspace range query data structure in the Fredman/Yao semigroup arithmetic model, with the same time and space bounds. Thus, results of Brönnimann, Chazelle, and Pach [10] immediately imply that $st^d = \Omega((n/\log n)^{d-(d-1)/(d+1)})$. This lower bound applies with high probability to a randomly generated set of points. This is the first nontrivial lower bound for hyperplane emptiness queries in any model of computation.
- We generalize earlier lower bounds on the complexity of Hopcroft's problem [31] for the special case of *polyhedral* partition graphs. Specifically, we prove that in the worst case, the time to preprocess n points in $\mathbb{R}^d$ and perform k hyperplane emptiness queries is

$$\Omega(n \log k + n^{1-2/d(d+1)}k^{2/(d+1)} + n^{2/(d+1)}k^{1-2/d(d+1)} + k \log n),$$

even if the query hyperplanes are specified in advance. This lower bound was previously known in dimensions less than four and in arbitrary dimensions for offline counting and reporting queries, for arbitrary partition graphs [31].
- The previous result implies the worst-case tradeoffs $pt^{(d+2)(d-1)/2} = \Omega(n^d)$ and $pt^{2/(d-1)} = \Omega(n^{(d+2)/d})$. These lower bounds match known upper bounds up to polylogarithmic factors when $d = 2$, $p = O(n \operatorname{polylog} n)$, or $t = O(\operatorname{polylog} n)$ [38, 42]. These results apply to polyhedral partition graphs when $d \ge 4$ and to all partition graphs when $d \le 3$. Under a mild assumption about the partition graphs, these bounds imply similar tradeoffs between

[2]Difficulties in directly modeling existing range searching data structures as partition graphs are discussed in [31, section 3.5].

space and query time, improving the earlier space-time tradeoffs whenever $s = \Omega(n^{d-1})$ or $s = O(n^{1+2/(d^2+d)})$ and giving us the optimal lower bound $st^2 = \Omega(n^2)$ in two dimensions.

- Finally, using a lifting argument, we show that all of these lower bounds also apply to online and offline halfspace emptiness queries in $\mathbb{R}^{d(d+3)/2}$, at least for *semialgebraic* partition graphs. The lower bounds we obtain match existing upper bounds up to polylogarithmic factors in dimensions 2, 3, and 5. In most other cases, our bounds are extremely weak; nevertheless, they are an improvement over all previous (trivial) lower bounds for halfspace emptiness searching.

All our lower bounds for hyperplane emptiness queries in $\mathbb{R}^d$ also apply to hyperplane and halfspace counting, reporting, or semigroup queries in $\mathbb{R}^d$.

We also show that lower bounds in the semigroup arithmetic model imply lower bounds for the corresponding counting or reporting queries in the partition graph model. Thus, any partition graph supporting halfspace counting or reporting queries satisfies $st^d = \Omega((n/\log n)^{d-(d-1)/(d+1)})$, even in the average case. We also derive the worst-case lower bound $st^{d(d+1)/2} = \Omega(n^d)$ for hyperplane queries in the semigroup model (no lower bound was previously known in this model) and thus for hyperplane counting or reporting in the partition graph model as well. Surprisingly, in two dimensions, the lower bound $st^3 = \Omega(n^2)$ is tight in the semigroup model.

From a practical standpoint, our results are quite strong. Even for very simple query ranges, and even if we only want to know whether the range is empty, range searching algorithms based on geometric divide-and-conquer techniques cannot be significantly faster than the naïve linear-time algorithm that simply checks each point individually, unless the dimension is very small or we have almost unlimited storage.[3] For example, answering 10-dimensional hyperplane emptiness queries in, say, $\sqrt{n}$ time—quite far from the desired $O(\log n)$ time bound—requires $\Omega(n^4)$ space, which is simply impossible for large data sets. In practice, we can only afford to use linear space, and this drives the worst-case query time up to roughly $n^{9/10}$. This behavior is unfortunately not a feature of some pathological input; most of our space-time tradeoffs hold in the average case, so in fact, most point sets are this difficult to search. The lower bounds that do not (as far as we know) hold in the average case apply to extremely simple point sets, such as regular lattices.

1.3. Outline. The rest of the paper is organized as follows. In section 2, we review the definition of the semigroup arithmetic model, state a few useful results, and derive new bounds on the complexity of hyperplane queries in this model. Section 3 defines partition graphs, describes how they are used to answer hyperplane and halfspace queries, and states a few of their basic properties. We prove our new space-time tradeoff lower bounds for hyperplane emptiness queries in section 4. In section 5, we define *polyhedral covers* and develop bounds on their worst-case complexity. Using these combinatorial bounds, in section 6, we (slightly) improve earlier lower bounds on the complexity of Hopcroft's offline point-hyperplane incidence problem in dimensions four and higher. From these offline results, we derive new tradeoffs between preprocessing and query time for online hyperplane queries in section 7. Section 8 describes a reduction argument that implies lower bounds for halfspace emptiness queries in both the online and offline settings. Finally, in section 9, we offer our conclusions.

[3]This "curse of dimensionality" can sometimes be avoided by requiring only an approximation of the correct output; see, for example, [7, 24, 37].

2. Semigroup arithmetic.

2.1. Definitions. We begin by reviewing the definition of the semigroup arithmetic model, originally introduced by Fredman to study dynamic range searching problems [33] and later refined for the static setting by Yao [56].

A *semigroup* $(S, +)$ is a set S equipped with an associative addition operator $+ : S \times S \to S$. A semigroup is *commutative* if the equation $x + y = y + x$ is true for all $x, y \in S$. A *linear form* is a sum of variables over the semigroup, where each variable can occur multiple times, or equivalently, a homogeneous linear polynomial with positive integer coefficients. A commutative semigroup is *faithful* if any two identically equal linear forms have the same set of variables, although not necessarily with the same set of coefficients.[4] For example, $(\mathbb{Z}, +)$ and $(\{\text{true}, \text{false}\}, \vee)$ are faithful semigroups, but $(\{0, 1\}, + \bmod 2)$ is not faithful.

A semigroup is *idempotent* if $x + x = x$ for all semigroup elements x, and *integral* if $x \neq \alpha x$ for all semigroup elements x and all integers $\alpha > 1$. For example, the semigroups $(\{\text{true}, \text{false}\}, \vee)$ and $(\mathbb{Z}, \max)$ are idempotent, $(\mathbb{Z}, +)$ and $(\mathbb{R}, \times)$ are integral, and $(\mathbb{C}, \times)$ is neither. (All these semigroups are faithful.)

Let P be a set of n points in $\mathbb{R}^d$, let $(S, +)$ be a faithful commutative semigroup, and let $w : P \to S$ be a function that assigns a weight $w(p)$ to each point $p \in P$. For any subset $P' \subseteq P$, let $w(P') = \sum_{p \in P'} w(P)$, where addition is taken over the semigroup.[5] The range searching problem considered in the semigroup model is to preprocess P so that $w(P \cap q)$ can be calculated quickly for any query range q.

Let $x_1, x_2, \ldots, x_n$ be a set of n variables over S. A *generator* $g(x_1, \ldots, x_n)$ is a linear form $\sum_{i=1}^{n} \alpha_i x_i$, where the α_i's are nonnegative integers, not all zero. Given a class Q of query ranges (subsets of $\mathbb{R}^d$), a *storage scheme* for (P, Q, S) is a collection of generators $\{g_1, g_2, \ldots, g_s\}$ with the following property: For any query range $q \in Q$, there is a set of indices $I_q \subseteq \{1, 2, \ldots, s\}$ and an indexed set of nonnegative integers $\{\beta_i \mid i \in I_q\}$ such that

$$w(P \cap q) = \sum_{i \in I_q} \beta_i g_i(w(p_1), w(p_2), \ldots, w(p_n))$$

holds for *any* weight function $w : P \to S$. The size of the smallest such set I_q is the *query time* for q.

We emphasize that although a storage scheme can take advantage of special properties of the semigroup S or the point set P, it must work for *any* assignment of weights to P. In particular, this implies that lower bounds in the semigroup model do *not* apply to the problem of counting the number of points in the query range, even though $(\mathbb{Z}, +)$ is a faithful semigroup, since a storage scheme for that problem only needs to work for the particular weight function $w(p) = 1$ for all $p \in P$ [14]. For the same reason, even though the semigroups $(\{\text{true}, \text{false}\}, \vee)$ and $(2^P, \cup)$ are faithful, the semigroup model cannot be used to prove lower bounds for emptiness

[4]More formally, $(S, +)$ is faithful if for each $n > 0$, for any sets of indices $I, J \subseteq \{1, \ldots, n\}$ where $I \neq J$, and for all indexed sets of positive integers $\{\alpha_i \mid i \in I\}$ and $\{\beta_j \mid j \in J\}$, there are semigroup elements $s_1, s_2, \ldots, s_n \in S$ such that

$$\sum_{i \in I} \alpha_i s_i \neq \sum_{j \in J} \beta_j s_j.$$

[5]Since S need not have an identity element, we may need to assign a special value *nil* to the empty sum $w(\varnothing)$.

or reporting queries. Emptiness queries can also be formulated as queries over the one-element semigroup $(\{*\}, * + * = *)$, but this semigroup is not faithful.

For any linear form $\sum_{1=1}^{n} \alpha_i x_i$, we call the set of points $\{p_i \mid \alpha_i \neq 0\}$ its *cluster*. The faithfulness of the semigroup S implies that the union of the clusters of the generators used to determine $w(P \cap q)$ is precisely $P \cap q$ (since each $\alpha_i > 0$):

$$\bigcup_{i \in I_q} \text{cluster}(g_i) = P \cap q.$$

Thus, we can think of a storage scheme as a collection of clusters, such that any set of the form $P \cap q$ can be expressed as the (not necessarily disjoint) union of several of these clusters. The size of a storage scheme is the number of clusters, and the query time for a range q is the minimum number of clusters whose union is $P \cap q$. This is the formulation actually used to prove lower bounds in the semigroup arithmetic model[6] [10, 14, 16, 56].

Whether or not the clusters used to answer a query must be disjoint depends on the semigroup. If the semigroup is integral, the clusters must be disjoint for every query; on the other hand, if the semigroup is idempotent, clusters can overlap arbitrarily. Thus, upper bounds developed for integral semigroups and lower bounds developed for idempotent semigroups apply to all other semigroups as well.

Some of our lower bounds derive from the following result.

THEOREM 2.1 (see Brönnimann, Chazelle, Pach [10]). *Let P be a uniformly distributed set of points in the d-dimensional unit hypercube $[0,1]^d$. With high probability, any storage scheme of size s that supports halfspace queries over P in time t satisfies the inequality $st^d = \Omega((n/\log n)^{d-(d-1)/(d+1)})$.*

2.2. Unreasonably good bounds for hyperplane queries. Although lower bounds are known for offline hyperplane searching in the semigroup model [18, 31], we are unaware of any previous results for online hyperplane queries. In particular, Chazelle's lower bound $st^d = \Omega(n^d/\log^d n)$ for simplex range searching [14], which holds when the query ranges are slabs bounded by two parallel hyperplanes, does not apply when the ranges are hyperplanes; Chazelle's proof requires a positive lower bound on the width of the slabs.

We easily observe that for any set of points in general position, the smallest possible storage scheme, consisting of n singleton sets, allows hyperplane queries to be answered correctly in constant "time." We can obtain better lower bounds by considering degenerate point sets, as follows.

First consider the two-dimensional case. Let $\mathcal{C}$ be (the set of clusters associated with) an optimal storage scheme of size s that supports line queries for some n-point set P in the plane. The storage scheme $\mathcal{C}$ must contain n singleton sets, one containing each point in P. Without loss of generality, each of the other $s - n$ clusters in $\mathcal{C}$ is a maximal colinear subset of P; that is, each has the form $P \cap \ell$ for some line ℓ. (If a cluster contains three noncolinear points, it can be discarded. If a cluster contains at least two points on a line ℓ, but not every point on ℓ, then adding the missing points decreases the query time for ℓ without changing the number of clusters or the query time for any other line.) Thus, the query time for any line ℓ is 1 if $P \cap \ell \in \mathcal{C}$, and $|P \cap \ell|$ otherwise. It follows that an optimal storage scheme of size s consists of n singleton sets plus the $s - n$ largest maximal colinear subsets of P, and the worst-case query time is the size of the $(s - n + 1)$th largest maximal colinear subset of P.

[6]Despite the complete absence of both semigroups and arithmetic!

Theorem 2.2. *A storage scheme of size $s \geq 2n$ that supports line queries in time t satisfies the inequality $st^3 = \Omega(n^2)$ in the worst case.*

Proof. Let P be a $\sqrt{n} \times \sqrt{n}$ integer lattice of points. Erdős showed that for any integer k, there is a set of k lines L such that the number of point-line incidences between P and L is $\Omega(n^{2/3}k^{2/3})$; see [33] or [48, p. 177]. In particular, we can take L to be the lines containing the k largest colinear subsets of P. Erdős's lower bound implies that the kth largest maximal colinear subset of P contains at least $\Omega(n^{2/3}/k^{1/3})$ points. Thus, the worst-case query time for any storage scheme of size s is $\Omega(n^{2/3}/(s-n+1)^{1/3}) = \Omega(n^{2/3}/s^{1/3})$. □

Surprisingly, this lower bound is optimal for most values of s.

Theorem 2.3. *For any set P of n points in the plane and any integer s with $2n \leq s \leq n^2$, there is a storage scheme of size s that supports line queries for P in time t, where $st^3 = O(n^2)$.*

Proof. Szemerédi and Trotter [53] proved that there are at most $O(n+n^{2/3}k^{2/3}+k)$ incidences between any set of n points and any set of k lines. (See also [19, 52].) Thus, for any k in both $\Omega(\sqrt{n})$ and $O(n^2)$, the kth largest maximal colinear subset of any n-point set has at most $O(n^{2/3}/k^{1/3})$ elements. The theorem follows by setting $k = s - n + 1$. □

In order to derive bounds in higher dimensions, we focus our attention on *restricted* point sets [35], in which any d points lie on a unique hyperplane. The optimal storage scheme for a restricted point set again consists of n singleton sets plus the $s - n$ largest subsets of the form $P \cap h$ for some hyperplane h, and the worst-case query time is the size of the $(s-n+1)$th largest subset of the form $P \cap h$. Of course, lower bounds for restricted point sets also apply to the general case, but the upper bounds do not similarly generalize.

Given a set P of points and a set H of hyperplanes, let $I(P, H)$ denote the number of incidences between P and H, that is, point-hyperplane pairs $(p, h) \in P \times H$ such that $p \in h$. Our higher-dimensional lower bounds, both here and later in the paper, use the following generalization of the Erdős point-line construction.

Lemma 2.4 (see Erickson [31]). *For any integers n and k with $n > \lfloor k^{1/d} \rfloor$, there is a restricted set P of n points and a set H of k hyperplanes in $\mathbb{R}^d$, such that $I(P, H) = \Omega(n^{2/(d+1)}k^{1-2/d(d+1)})$.*

Theorem 2.5. *A storage scheme of size s that supports d-dimensional hyperplane queries in time t satisfies the inequality $st^{d(d+1)/2} = \Omega(n^d)$ in the worst case.*

Using probabilistic counting techniques of Clarkson et al. [23], Guibas, Overmars, and Robert [35] prove that for any restricted set P of n points and any set H of k hyperplanes, $I(P, H) = O(n+n^{d/(2d-1)}k^{(2d-2)/(2d-1)}+k)$. The following upper bound follows immediately from their result.

Theorem 2.6. *For any restricted set P of n points in $\mathbb{R}^d$ and any integer s such that $2n \leq s \leq n^d$, there is a storage scheme of size s that supports hyperplane queries for P in time t, where $st^{2d-1} = O(n^d)$.*

The general case is unfortunately not so straightforward. Optimal storage schemes could have clusters contained in lower-dimensional flats, in which case the query time for a hyperplane h is no longer necessarily either 1 or $|P \cap h|$. If the semigroup is idempotent, every cluster in an optimal storage scheme still has the form $P \cap h$ for some hyperplane h, but this may not be true for all semigroups. We leave further generalization of our upper bounds as an open problem.

Except when s is near n^d, our upper bounds in the semigroup model are significantly better than the best known upper bounds in more realistic models of computation. The most efficient data structure known satisfies the upper bound $st^d = O(n^d)$ [17, 42], and this is believed to be optimal, especially in light of Chazelle's simplex range searching lower bounds. We are not suggesting that this data structure can be significantly improved, but rather that the semigroup model is too powerful to permit tight lower bounds for this range searching problem. This raises the frustrating possibility that closing the existing gaps between upper and lower bounds for other types of ranges, such as halfspaces [10], will be impossible unless more realistic computational models are considered.

In the remainder of this paper, we derive tighter lower bounds by considering a model that more accurately describes the behavior of geometric range searching algorithms.

3. Partition graphs.

3.1. Definitions. A *partition graph* is a directed acyclic (multi-)graph, with one source, called the *root*, and several sinks, called *leaves*. Associated with each nonleaf node v is a set $\mathcal{R}_v$ of *query regions* satisfying three conditions.

1. $\mathcal{R}_v$ contains at most Δ query regions, for some constant $\Delta \geq 2$.
2. Every query region is a connected subset of $\mathbb{R}^d$.
3. The union of the query regions in $\mathcal{R}_v$ is $\mathbb{R}^d$.

We associate an outgoing edge of v with each query region in $\mathcal{R}_v$. Thus, the outdegree of the graph is at most Δ. The indegree can be arbitrarily large. In addition, every internal node v is labeled either a *primal node* or a *dual node*, depending on whether its query regions $\mathcal{R}_v$ are interpreted as a partition of primal or dual space. The query regions associated with primal (resp., dual) nodes are called primal (resp., dual) query regions.

We do not require the query regions to be disjoint. In the general case, we do not require the query regions to be convex, semialgebraic, simply connected, of constant complexity, or even computable in any sense. However, a few of our results only hold for partition graphs with particular types of query regions. If all the query regions in a partition graph are constant-complexity polyhedra, we call it a *polyhedral* partition graph. If all the query regions are constant-complexity semialgebraic sets (also called *Tarski cells*), we call it a *semialgebraic* partition graph.

Given a partition graph, we preprocess a set P of points for hyperplane queries as follows. We preprocess each point $p \in P$ individually by performing a depth-first search of the partition graph, using the query regions to determine which edges to traverse. Whenever we reach a primal node v, we traverse the edges corresponding to the query regions in $\mathcal{R}_v$ that contain p. Whenever we reach a dual node v, we traverse the edges corresponding to the query regions in $\mathcal{R}_v$ that intersect the dual hyperplane p^*. The same point may enter or leave a node along several different edges, but we only test the query regions at a node once for each point. Thus, each point traverses a given edge at most once. For each leaf ℓ, we maintain a *leaf subset* P_ℓ containing the points that reach ℓ. See Figure 1(a).

To answer a hyperplane query, we use almost exactly the same algorithm as to preprocess a point: a depth-first search of the partition graph, using the query regions to determine which edges to traverse. The only difference is that the behavior at the primal and dual nodes is reversed. See Figure 1(b).

Whenever the query algorithm reaches a leaf ℓ, it *examines* the corresponding leaf subset P_ℓ. The output of the query algorithm is computed from the examined subsets, by assuming that the query hyperplane contains each examined subset. For example, the output of an emptiness query is "yes" if and only if all the examined subsets are

```
Preprocess($p$):
at each primal node $v$:
    for each query region $R \in \mathcal{R}_v$:
        if $R$ contains $p$:
            traverse the edge corresponding to $R$
at each dual node $v$:
    for each query region $R \in \mathcal{R}_v$:
        if $R$ intersects $p^*$:
            traverse the edge corresponding to $R$
at each leaf $\ell$:
    add $p$ to $P_\ell$
```

(a)

```
Query($h$):
at each dual node $v$:
    for each query region $R \in \mathcal{R}_v$:
        if $R$ contains $h^*$:
            traverse the edge corresponding to $R$
at each primal node $v$:
    for each query region $R \in \mathcal{R}_v$:
        if $R$ intersects $h$:
            traverse the edge corresponding to $R$
at each leaf $\ell$:
    examine $P_\ell$
```

(b)

FIG. 1. *Preprocessing and query algorithms for hyperplane searching.*

empty. (In fact, we can assume that if the algorithm ever examines a nonempty leaf subset, it immediately halts and answers "no.") The output of a counting query is the sum of the sizes of the examined subsets; here, examining a leaf subset means adding its size to a running counter. The output of a reporting query is the union of the examined subsets; here, "examine" simply means "output." More generally, if the points are given weights from a (*not* necessarily faithful) semigroup $(S, +)$, the output is the semigroup sum over all examined subsets P_ℓ of the total weight of the points in P_ℓ. (We will not explicitly consider semigroup queries in the rest of the paper.)

By modifying the preprocessing algorithm slightly, we can also use partition graphs to answer halfspace queries. For any hyperplane h, let h^+ denote its closed upper halfspace and h^- its closed lower halfspace.[7] Recall that the standard duality transformation $(a_1, a_2, \ldots, a_d) \longleftrightarrow x_d + a_d = a_1x_1 + a_2x_2 + \cdots + a_{d-1}x_{d-1}$ preserves incidences and relative orientation between points and hyperplanes: If a point p is above (on, below) a hyperplane h, then the dual point h^* is above (on, below) the dual hyperplane p^*.

To support halfspace queries, we associate one or two subsets of P with every query region, called *internal subsets.* With each primal region $R \in \mathcal{R}_v$, we associate a single internal subset P_R, which contains the points that reach v and lie inside R. With each dual region $R \in \mathcal{R}_v$, we associate two internal subsets P_R^+ and P_R^-, which contain the points that reach v and whose dual hyperplanes lie below and above R, respectively. Our modified preprocessing and halfspace query algorithms are shown in Figure 2. Note that the modified preprocessing algorithm can still be used for hyperplane searching.

For purposes of proving lower bounds, the *size* of a partition graph is the number of edges in the graph, the *query time* for a particular hyperplane is the number of edges traversed by the query algorithm, and the *preprocessing time* is the total number of edge traversals during the preprocessing phase. We ignore, for example, the time required in practice to construct the graph, the complexity of the query regions, the time required to determine which query regions intersect a hyperplane or contain a point, the sizes of the subsets P_R, P_R^+, P_R^-, and P_ℓ, the time required to maintain and test these subsets, and the size of the output (in the case of reporting queries).

[7]We assume throughout the paper that query halfspaces are closed and that no query halfspace is bounded by a vertical hyperplane. Handling open halfspaces involves only trivial modifications to our query algorithm, which have almost no effect on our analysis. Vertical halfspace queries can be handled either through standard perturbation techniques or by using a lower-dimensional data structure.

```
Preprocess($p$):
at each primal node $v$:
    for each query region $R \in \mathcal{R}_v$:
        if $R$ contains $p$:
            add $p$ to $P_R$
            traverse the edge corresponding to $R$
at each dual node $v$:
    for each query region $R \in \mathcal{R}_v$:
        if $R$ intersects $p^*$:
            traverse the edge corresponding to $R$
        else if $R$ is above $p^*$:
            add $p$ to $P_R^+$
        else if $R$ is below $p^*$:
            add $p$ to $P_R^-$
at each leaf $\ell$:
    add $p$ to $P_\ell$
```

(a)

```
Query($h^\pm$):
at each dual node $v$:
    for each query region $R \in \mathcal{R}_v$:
        if $R$ contains $h^*$:
            examine $P_R^\pm$
            traverse the edge corresponding to $R$
at each primal node $v$:
    for each query region $R \in \mathcal{R}_v$:
        if $h$ intersects $R$:
            traverse the edge corresponding to $R$
        else if $h^\pm$ contains $R$:
            examine $P_R$
at each leaf $\ell$:
    examine $P_\ell$
```

(b)

FIG. 2. *Modified preprocessing algorithm and query algorithm for halfspace searching.*

We emphasize that since we never charge for the construction of the partition graph itself, the graph and its query regions can depend arbitrarily on the input point set P and on the types of queries we expect to receive. Our preprocessing algorithm has "time" to construct the *optimal* partition graph for any given input, and even very similar inputs may result in radically different partition graphs.

We will also consider offline range searching problems, where we are given both a set P of points and a set H of ranges (either hyperplanes or halfspaces), and are asked, for example, whether any range contains a point. A *partitioning algorithm* constructs a partition graph, which can depend arbitrarily on the input, preprocesses each point in P, and performs a query for each range in H. The running time of the partitioning algorithm is the sum of the preprocessing and query times. In the original definition [31], the preprocessing and queries were performed concurrently, but this has no effect on the overall running time.[8] Again, since we ignore the time required in practice to construct the partition graph, partitioning algorithms have the full power of nondeterminism.

3.2. Basic properties. Partition graphs have several properties that are very useful in proving lower bounds.

LEMMA 3.1. *In any partition graph, if a point lies in a query range, it also lies in at least one of the subsets P_R, P_R^+, P_R^-, or P_ℓ examined during a query.*

Proof. First suppose some point p lies on some hyperplane h. Clearly, any primal query region that contains p also intersects h, and any dual query region that contains h^* also intersects p^*. Thus, there is at least one path from the root to a leaf ℓ that is traversed both while preprocessing p (so $p \in P_\ell$) and while querying h (so P_ℓ is examined).

Now suppose some point p lies in some upper halfspace h^+. (The argument for lower halfspaces is symmetric.) Let v be a node farthest from the root that is reached both while preprocessing p and while querying h^+. If v is a leaf, we are done. If v is a primal node, then some query region $R \in \mathcal{R}_v$ contains p but does not intersect h.

[8]However, if we perform all the searches concurrently using the *streaming* technique of Edelsbrunner and Overmars [28], we only need to maintain a single root-to-leaf path in the graph at any time. Thus, the space used by an offline partitioning algorithm is more reasonably modeled by the *depth* of its partition graph. We will not pursue this idea further in this paper.

Since $p \in R$, the subset P_R contains p, and since $p \in h^+$, R must lie above h, so P_R is examined. Finally, if v is a dual node, some query region $R \in \mathcal{R}_v$ contains the dual point h^* but does not intersect the dual hyperplane p^*. Since $h^* \in R$, the subset P_R^+ is examined. Since $p \in h^+$, the dual point h^* and thus the query region R lie above the dual hyperplane p^*, so $p \in P_R^+$. ∎

LEMMA 3.2. *In any partition graph, if an internal subset P_R, P_R^+, or P_R^- is examined during a halfspace query, then the query halfspace contains every point in that set.*

Proof. Suppose we are performing a query for the upper halfspace h^+. (Again, the argument for lower halfspaces is symmetric.) If the primal subset P_R is examined, then $P_R \subset R \subseteq h^+$. If the dual subset P_R^+ is examined, then every point $p \in P_R^+$ is above the hyperplane h, since the dual point $h^* \in R$ is above each dual hyperplane p^*. ∎

Lemma 3.1 implies that partition graphs are "conservative"—the output of a reporting query contains every point in the query range, the output of a counting query is never smaller than the actual number of points in the query range, and an emptiness query never reports that a nonempty query range is empty. Lemma 3.2 further implies that the output of a query can be incorrect only if the query algorithm examines a leaf subset that contains a point outside the query range.

The following lemma follows immediately from a close examination of the query algorithm.

LEMMA 3.3. *A counting query is correct if and only if the points in the query range are the disjoint union of the subsets examined by the query algorithm. A reporting query is correct if and only if the points in the query range are the (not necessarily disjoint) union of the subsets examined by the query algorithm.*

We say that a partition graph *supports* a particular class of online range queries for a given set of points if, after the points are preprocessed, any query in the class is answered correctly. Even though we have a single preprocessing algorithm, a single partition graph need not support all query types. However, in several cases, support for one type of query automatically implies support for another type of query, with the same (or possibly smaller) worst-case query time. These implications are summarized in the following lemma.

LEMMA 3.4. *The following hold for any partition graph.*

(a) *If a counting query is answered correctly, then a reporting query for the same range is also answered correctly.*

(b) *If a reporting query is answered correctly, then an emptiness query for the same range is also answered correctly.*

(c) *For any hyperplane h, if counting (resp. reporting) queries for the halfspaces h^+ and h^- are answered correctly, then a counting (resp., reporting) query for h is also answered correctly.*

(d) *For any hyperplane h, if a reporting query for h is answered correctly, then reporting queries for the halfspaces h^+ and h^- are also answered correctly.*

Proof. Parts (a) and (b) follow immediately from Lemma 3.3.

Fix a hyperplane h, and let $P^+ = P \cap h^+$, $P^- = P \cap h^-$, and $P^\circ = P \cap h$. Suppose reporting queries for the halfspaces h^+ and h^- are answered correctly. The reporting query algorithms for h^+, h^-, and h traverse precisely the same set of edges and reach precisely the same set of nodes. Let $\mathcal{L}$ be the set of leaves reached by any of these three queries, and let $P_{\mathcal{L}} = \bigcup_{\ell \in \mathcal{L}} P_\ell$. By Lemma 3.3, both P^+ and P^- are reported as the union of several internal subsets and $P_{\mathcal{L}}$. It follows that $P_{\mathcal{L}} \subseteq P^+ \cap P^- = P^\circ$.

Lemma 3.1 implies that every point in P° lies in some leaf subset P_ℓ where $\ell \in \mathcal{L}$, so $P^\circ \subseteq P_{\mathcal{L}}$. Thus, a reporting query for h is also answered correctly. The argument for counting queries is identical, except that the examined subsets are disjoint. This proves part (c).

To prove part (d), suppose a reporting query for h is answered correctly. A reporting query for the halfspace h^+ traverses exactly the same edges and visits exactly the same nodes as the reporting query for h. In particular, the leaf subsets P_ℓ examined by the halfspace query algorithm contain only points on the hyperplane h. Lemma 3.2 implies that every internal subset examined by the reporting query algorithm lies in h^+, and Lemma 3.1 implies that every point in P^+ lies in some examined subset. It follows that precisely the points in P^+ are reported. □

3.3. "Trivial" lower bounds. We conclude this section by proving "trivial" lower bounds on the size, preprocessing time, and query time of any partition graph, for points in any dimension.

THEOREM 3.5. *Any partition graph that supports hyperplane emptiness queries has size $\Omega(n)$, preprocessing time $\Omega(n \log n)$, and worst-case query time $\Omega(\log n)$.*

Proof. Let P be an arbitrary set of n points in $\mathbb{R}^d$. Without loss of generality, all the points in P have distinct x_d coordinates; otherwise, rotate the coordinate system slightly. Let H be a set of n hyperplanes normal to the x_d-axis, with each hyperplane just above (farther in the x_d-direction than) one of the points in P. Thus, for all $1 \le i \le n$, there is a hyperplane in H with i points below it and $n-i$ points above it. Any partition graph that correctly answers hyperplanes queries for P must at least detect that every hyperplane in H is empty.

For each point in P, call the hyperplane in H just above it its *partner*. We say that a point is *active* at a node v of the partition graph if both the point and its partner reach v. We say that a node v *deactivates* a point p if both p and its partner h reach v but no edge out of v is traversed by both p and h. Every point in P must be deactivated by some node in the partition graph, since otherwise some active point p and its partner h would reach a common leaf, so a query for h would be answered incorrectly.

Any primal query region R contains at most one active point whose partner does not intersect R. Similarly, for any dual query region R, there is at most one active point whose dual hyperplane misses R and whose partner's dual point lies in R. Thus, any node deactivates at most Δ points. Moreover, since every point in P must be deactivated, the partition graph must have at least n query regions and thus at least n edges.

The *level* of a node is its distance from the root. There are at most Δ^k nodes at level k. At least $n - \sum_{i=0}^{k-1} \Delta^{k+1} \ge n - \Delta^{k+2}$ points are active at some node at level k. In particular, at least $n(1-1/\Delta)$ points are active at level $\lfloor \log_\Delta n - 3 \rfloor$. It follows that at least $n(1-1/\Delta)$ points in P each traverse at least $\lfloor \log_\Delta n - 2 \rfloor$ edges, so the total preprocessing time is at least

$$n(1-1/\Delta)\lfloor \log_\Delta n - 2 \rfloor = \Omega(n \log n).$$

Similarly, at least $n(1-1/\Delta)$ hyperplanes in H each traverse at least $\lfloor \log_\Delta n - 2 \rfloor$ edges, so the worst-case query time is $\Omega(\log n)$. □

Lemma 3.4 implies that the same lower bounds also apply to counting and reporting queries, both for hyperplanes and for halfspaces. Theorem 3.5 also implies that any partitioning algorithm, given n points and k hyperplanes (or halfspaces, if we are not performing emptiness queries), requires at least $\Omega(n \log k + k \log n)$ time in the worst case; this was previously proved in [31], using essentially the same argument. We will prove similar lower bounds for halfspace emptiness queries in section 8.

4. Space-time tradeoffs. We now present our space-time tradeoff lower bounds for hyperplane emptiness and related queries in the partition graph model. All of these bounds are derived from results in the semigroup arithmetic model, which we described in section 2, using the following theorem.

THEOREM 4.1. *Let P be a set of points. Given a partition graph of size s that supports hyperplane (resp., halfspace) counting or reporting queries for P in time t, we can construct a storage scheme of size $O(s)$ that supports hyperplane (resp., halfspace) queries for P, over any idempotent faithful semigroup, in time $O(t)$.*

Proof. For each query region R and leaf ℓ, define the subsets P_R, P_R^-, P_R^+, and P_ℓ by the preprocessing algorithm in Figure 2. We claim that these subsets of P form the clusters of the required storage scheme. There are at most $3s$ of these clusters: at most two for each of the s query regions, plus one for each of the $\leq s$ leaves. To prove the theorem, it suffices to show that the points in any query range can be expressed as the union of $O(t)$ clusters.

Suppose the partition graph supports hyperplane reporting queries. By Lemma 3.3, the points on any hyperplane h are reported as the union of several leaf subsets P_ℓ. Since the query algorithm reaches at most t leaves, the set $P \cap h$ is the union of at most t clusters.

Similarly, if the partition graph supports halfspace reporting queries, then the points in any halfspace $h^\pm$ are reported as the union of at most t subsets P_R, at most Δt subsets $P_R^\pm$, and at most t subsets P_ℓ. Thus, the set $P \cap h^\pm$ is the union of at most $(2+\Delta)t = O(t)$ clusters.

The argument for counting queries is identical, except that the $O(t)$ clusters used to answer any query are disjoint. (In fact, the resulting storage scheme works for *any* faithful semigroup.) □

This theorem implies that lower bounds for range queries in the semigroup arithmetic model are also lower bounds for the corresponding counting and reporting queries in the partition graph model. The following results now immediately follow from Theorems 2.1 and 2.5.

COROLLARY 4.2. *Let P be a uniformly generated set of n points in $[0,1]^d$. With high probability, any partition graph of size s that supports halfspace counting or reporting queries for P in time t satisfies the inequality $st^d = \Omega((n/\log n)^{d-(d-1)/(d+1)})$.*

COROLLARY 4.3. *Any partition graph of size s that supports d-dimensional hyperplane counting or reporting queries in time t satisfies the inequality $st^{d(d+1)/2} = \Omega(n^d)$ in the worst case.*

One way to determine if a hyperplane is empty is by counting or reporting the points in its two halfspaces—the hyperplane is empty if any only if every point in the original point set is counted or reported exactly once. Thus, any halfspace counting or reporting data structure also supports hyperplane emptiness queries. The following result implies that the reverse is *almost* true in our model of computation.

THEOREM 4.4. *Let P be a set of points. Given a partition graph of size s that supports hyperplane emptiness queries for P in time t, we can construct a storage scheme of size $O(s)$ that supports halfspace queries for P, over any idempotent faithful semigroup, in time $O(t)$.*

Proof. Suppose a partition graph G supports hyperplane emptiness queries for the set P in time t. Clearly, G also supports reporting queries for any *empty* hyperplane in time t, since all the examined subsets are empty. Then by Lemma 3.4 (d), G correctly answers any halfspace reporting query in time at most t, provided the boundary of the query halfspace is empty. However, for any halfspace, there is another halfspace with empty boundary that contains precisely the same points. It follows that every set of the form $P \cap h^+$ or $P \cap h^-$ can be expressed as the union of at most $(2+\Delta)t = O(t)$ internal subsets. $\square$

The following lower bound now follows immediately from Theorem 2.1.

COROLLARY 4.5. *Let P be a uniformly generated set of n points in $[0,1]^d$. With high probability, any partition graph of size s that supports hyperplane emptiness queries for P in time t satisfies the inequality $st^d = \Omega((n/\log n)^{d-(d-1)/(d+1)})$.*

Lemma 3.4 implies that the same lower bound applies to hyperplane counting or reporting queries. This improves the lower bound in Corollary 4.3 whenever $s = O(n^{d-1})$ or $t = \Omega(n^{2/d(d+1)})$. Similarly, this lower bound also applies to halfspace counting or reporting queries, giving us a rather roundabout proof of Corollary 4.2. However, none of these results applies immediately to halfspace emptiness queries; we will derive lower bounds for these queries in section 8.

5. Polyhedral covers.

5.1. Definitions. In order to derive our improved offline lower bounds and preprocessing-query time tradeoffs, we first need to define a combinatorial object called a *polyhedral cover*. The formal definition is fairly technical, but intuitively, one can think of a polyhedral cover of a set P of points and a set H of hyperplanes as a collection of constant-complexity convex polytopes such that for every point $p \in P$ and hyperplane $h \in H$, some polytope in the collection contains p and does not intersect h. A polyhedral cover of P and H provides a compact representation of the relative orientation of every point in P and every hyperplane in H.

Our combinatorial bounds rely heavily on certain properties of convex polytopes and polyhedra. Many of these properties are more easily proved, and have fewer special cases, if we state and prove them in projective space rather than affine Euclidean space. In particular, developing these properties in projective space allows us to more easily deal with unbounded polyhedra, degenerate polyhedra, and duality transformations. Everything we define in this subsection can be formalized algebraically in the language of polyhedral cones and linear subspaces one dimension higher; we will give a less formal, purely geometric treatment. For more technical details, we refer the reader to the first two chapters of Ziegler's lecture notes [58] or to the survey by Henk, Richter-Gebert, and Ziegler [36].

The d-dimensional real projective space $\mathbb{RP}^d$ can be defined as the set of lines through the origin in the $(d+1)$-dimensional real vector space $\mathbb{R}^{d+1}$. Every k-dimensional linear subspace of $\mathbb{R}^{d+1}$ induces a $(k-1)$-dimensional *flat* f in $\mathbb{RP}^d$, and its orthogonal complement induces the $(d-k-1)$-dimensional *dual flat* f^*. Hyperplanes are $(d-1)$-dimensional flats, points are 0-dimensional flats, and the empty set is the unique (-1)-flat.

Any finite set H of (at least two) hyperplanes in $\mathbb{RP}^d$ defines a regular cell complex called an *arrangement*, each of whose cells is the closure of a maximal connected subset of $\mathbb{RP}^d$ contained in the intersection of a fixed subset of H and not intersecting any other hyperplane in H. The largest cells in the arrangement are the closures of the connected components of $\mathbb{RP}^d \setminus \bigcup H$; the intersection of any pair of cells is another cell of lower dimension.

A *projective polyhedron* is a single cell, not necessarily of full dimension, in an arrangement of hyperplanes in $\mathbb{RP}^d$. A *projective polytope* is a simply-connected polyhedron, or equivalently, a polyhedron that is disjoint from some hyperplane (not necessarily in the polyhedron's defining arrangement). Every projective polyhedron is (the closure of) the image of a convex polyhedron under some projective transformation, and every projective polytope is the projective image of a convex polytope. Every flat is also a projective polyhedron.

The *(projective) span* of a polyhedron $\Pi \subseteq \mathbb{RP}^d$, denoted span$(\Pi)$, is the flat of minimal dimension that contains it. The *dimension* of a polyhedron is the dimension of its span. The *relative interior* (resp., *relative boundary*) of a polyhedron is its interior (resp., boundary) in the subspace topology of its span. A hyperplane *supports* a polyhedron if it intersects the polyhedron but not its relative interior. In particular, a flat has no supporting hyperplanes.

A *proper face* of a polyhedron is the intersection of the polyhedron and one or more supporting hyperplanes. Every proper face of a polyhedron is a lower-dimensional polyhedron. A *face* of a polyhedron is either a proper face or the entire polyhedron. We write $|\Pi|$ to denote the number of faces of a polyhedron Π, and $\phi \leq \Pi$ to denote that ϕ is a face of Π. The faces of a polyhedron form a graded lattice under inclusion. Every projective polyhedron has a face lattice isomorphic to that of a convex polytope, possibly of lower dimension.

The *dual* of a polyhedron Π, denoted Π^*, is the set of points whose dual hyperplanes intersect Π in one of its faces:

$$\Pi^* \triangleq \{p \mid (p^* \cap \Pi) \leq \Pi\}.$$

In other words, $p \in \Pi^*$ if and only if p^* either contains Π, supports Π, or completely misses Π. This definition generalizes both the polar of a convex polytope containing the origin and the projective dual of a flat. We easily verify that Π^* is a projective polyhedron whose face lattice is the inverse of the face lattice of Π. In particular, Π and Π^* have the same number of faces. See [58, pp. 59–64] and [51, pp. 143–150] for similar definitions.

We say that a polyhedron Π *separates* a set P of points and a set H of hyperplanes if Π contains P and the dual polyhedron Π^* contains the dual points H^*, or equivalently, if any hyperplane in H either contains Π or is disjoint from its relative interior. In particular, if Π is of full dimension, then the hyperplanes in H avoid the interior of Π. Both P and H may intersect the relative boundary of Π, and points in P may lie on hyperplanes in H. See Figure 3. Note that Π separates P and H if and only if Π^* separates H^* and P^*. We say that P and H are *r-separable*, denoted $P \bowtie_r H$, if there is a projective polyhedron with at most r faces that separates them. We write $P \not\bowtie_r H$ if P and H are not r-separable.

Finally, an *r-polyhedral cover* of a set P of points and a set H of hyperplanes is an indexed set of subset pairs $\{(P_i, H_i)\}$ with the following properties.

- $P_i \subseteq P$ and $H_i \subseteq H$ for all i.
- If $p \in P$ and $h \in H$, then $p \in P_i$ and $h \in H_i$ for some i.
- $P_i \bowtie_r H_i$ for all i.

We emphasize that the subsets P_i are not necessarily disjoint, nor are the subsets H_i. We refer to each subset pair (P_i, H_i) in a polyhedral cover as a *r-polyhedral minor*. The *size* of a cover is the sum of the sizes of the subsets P_i and H_i.

Let $\pi_r(P, H)$ denote the size of the smallest r-polyhedral cover of P and H. Let $\pi^\circ_{d,r}(n, k)$ denote the maximum of $\pi_r(P, H)$ over all sets P of n points and H of k hyperplanes in $\mathbb{RP}^d$, such that no point lies on any hyperplane. In all our terminology and notation, whenever the parameter r is omitted, we take it to be a fixed constant. In the remainder of this section, we derive asymptotic lower bounds for $\pi^\circ_d(n, k)$.

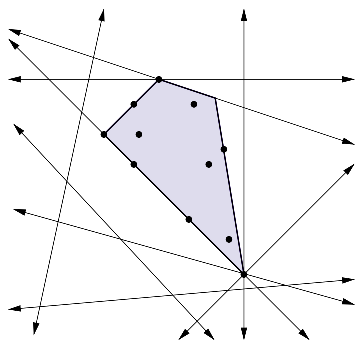

FIG. 3. *A polygon separating a set of points and a set of lines in* $\mathbb{RP}^2$.

5.2. Topological properties. The lower bound proofs in [31] relied on the following trivial observation: If we perturb a set of points and hyperplanes just enough to remove any point-hyperplane incidences, and every point is above every hyperplane in the perturbed set, then no point was below a hyperplane in the original set. In this section, we establish the corresponding, but no longer trivial, property of separable sets and polyhedral covers. Informally, if a set of points and hyperplanes is not separable, then arbitrarily small perturbations cannot make it separable. Similarly, arbitrarily small perturbations of a set of points and hyperplanes cannot decrease its minimum polyhedral cover size.

We start by proving a more obvious property of convex polytopes, namely, that infinitesimally perturbing a set of points can only increase the complexity of its convex hull.

LEMMA 5.1. *For any integers n and r, the set of n-point configurations in $\mathbb{R}^d$ whose convex hulls have at most r faces is topologically closed.*

Proof. Let $A = \{a_1, a_2, \dots, a_n\}$ and $B = \{b_1, b_2, \dots, b_n\}$ be two n-point configurations (i.e., indexed sets of n points) in $\mathbb{R}^d$. We say that A *is simpler than* B, written $A \sqsubseteq B$, if for any subset of B contained in a facet of $\operatorname{conv}(B)$, the corresponding subset of A is contained in a facet of $\operatorname{conv}(A)$.[9] Equivalently, $A \sqsubseteq B$ if and only if for any subset of $d+1$ points in B, d of whose vertices lie on a facet of $\operatorname{conv}(B)$, the corresponding simplex in A either has the same orientation or is degenerate. Simpler point sets have less complex convex hulls: if $A \sqsubseteq B$, then $|\operatorname{conv}(A)| \le |\operatorname{conv}(B)|$. If both $A \sqsubseteq B$ and $B \sqsubseteq A$, then the convex hulls of A and B are combinatorially equivalent.

If B is fixed, then the relation $A \sqsubseteq B$ can be encoded as the conjunction of a finite number of algebraic inequalities of the form

$$\begin{vmatrix} 1 & a_{i_0 1} & a_{i_0 2} & \cdots & a_{i_0 d} \\ 1 & a_{i_1 1} & a_{i_1 2} & \cdots & a_{i_1 d} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 1 & a_{i_d 1} & a_{i_d 2} & \cdots & a_{i_d d} \end{vmatrix} \Diamond 0,$$

where $\Diamond$ is either $\ge$, $=$, or $\le$, and a_{ij} denotes the jth coordinate of $a_i \in A$. In every such inequality, the corresponding points $b_{i_1}, b_{i_2}, \dots, b_{i_d} \in B$ lie on a single facet of

[9]Every set of points is simpler than itself. It would be more correct, but also more awkward, to say "A is at least as simple as B."

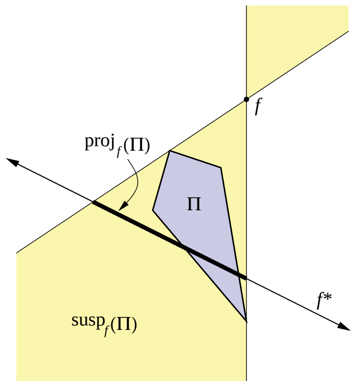

FIG. 4. *Suspension (double wedge) and projection (line segment) of a polygon by a point in* $\mathbb{RP}^2$.

$\mathrm{conv}(B)$. For every d-tuple of points in B contained in a facet of $\mathrm{conv}(B)$, there are $n-d$ such inequalities, one for every other point in B. (If we replaced the loose inequalities $\leq, \geq$ with strict inequalities $<, >$, the resulting expression would encode the combinatorial equivalence of $\mathrm{conv}(A)$ and $\mathrm{conv}(B)$.) Thus, for any *fixed* n-point set B, the set $\{A \in (\mathbb{R}^d)^n \mid A \sqsubseteq B\}$ is the intersection of a finite number of closed algebraic halfspaces, and is thus a closed semialgebraic set.

There are only finitely many equivalence classes of convex polytopes with a given number of faces or vertices [34]. Thus, there is a *finite* set $\mathcal{B} = \{B^1, B^2, \ldots\}$ of n-point configurations, one of each possible combinatorial type, such that if $\mathrm{conv}(A)$ has at most r faces, then $A \sqsubseteq B^i$ for some configuration $B^i \in \mathcal{B}$. It follows that the set of n-point configurations whose convex hulls have at most r faces is the union of a finite number of closed sets and is therefore closed. $\square$

Before continuing, we need to introduce one more important concept. For any subset $X \subseteq \mathbb{RP}^d$ and any flat f, the *suspension of* X *by* f, denoted $\mathrm{susp}_f(X)$, is formed by replacing each point in X by the smallest flat containing that point and f:

$$\mathrm{susp}_f(X) \triangleq \bigcup_{p \in X} \mathrm{span}(p \cup f).$$

The suspension of a subset of projective space roughly corresponds to an infinite cylinder over a subset of an affine space, at least when the suspending flat f is on the hyperplane at infinity. The *projection of* X *by* f, denoted $\mathrm{proj}_f(X)$, is the intersection of the suspension and the dual flat f^*:

$$\mathrm{proj}_f(X) \triangleq \mathrm{susp}_f(X) \cap f^*.$$

In particular, $\mathrm{susp}_f(X)$ is the set of all points in $\mathbb{RP}^d$ whose projection by f is in $\mathrm{proj}_f(X)$. The projection of a subset of projective space corresponds to the orthogonal projection or shadow of a subset of affine space onto a lower-dimensional flat. See Figure 4. For any polyhedron Π and any flat f, $\mathrm{susp}_f(\Pi)$ and $\mathrm{proj}_f(\Pi)$ are also polyhedra. These two polyhedra have the same number of faces (in fact, they have isomorphic face lattices), although in general they have fewer faces than Π. In particular, $\mathrm{susp}_f(f) = f$ and $\mathrm{proj}_f(f) = \varnothing$.

LEMMA 5.2. *Let* H *be a set of hyperplanes in* $\mathbb{RP}^d$. *For any integers* r *and* n, *the set* $\mathrm{Sep}_r(H, n)$ *of* n*-point configurations* $P \in (\mathbb{RP}^d)^n$ *such that* P *and* H *are* r*-separable is topologically closed.*

Proof. There are two cases to consider: Either the hyperplanes in H do not have a common intersection, or they intersect in a common flat. The proof of the second case relies on the first.

Case 1 ($\bigcap H = \varnothing$). Any polyhedron that separates P and H must be completely contained in a closed d-dimensional cell of the arrangement of H. Since there are only finitely many such cells, it suffices to show, for each closed d-cell $\mathcal{C}$, that the set $\operatorname{Sep}_r(H,n) \cap \mathcal{C}^n$ of n-point configurations contained in $\mathcal{C}$ and r-separable from H is topologically closed. We will actually show that $\operatorname{Sep}_r(H,n) \cap \mathcal{C}^n$ is a compact semialgebraic set.

Fix a cell $\mathcal{C}$. Since the hyperplanes in H do not have a common intersection, both $\mathcal{C}$ and any polyhedra it contains must be polytopes. By choosing an appropriate hyperplane "at infinity" that misses $\mathcal{C}$, we can treat $\mathcal{C}$ and any polytopes it contains as *convex* polytopes in $\mathbb{R}^d$. Any separating polytope with r or fewer faces is the (closed) convex hull of some set of r points, all contained in $\mathcal{C}$. Thus, we can write

$$\operatorname{Sep}_r(H,n) \cap \mathcal{C}^n = \left\{P \in \mathcal{C}^n \;\middle|\; \exists\, A \in \mathcal{C}^r \colon P \subset \operatorname{conv}(A) \,\wedge\, |\operatorname{conv}(A)| \le r\right\}.$$

Lemma 5.1 implies that the set

$$\left\{(P,A) \in \mathcal{C}^{n+r} \;\middle|\; |\operatorname{conv}(A)| \le r\right\} = \left\{A \in \mathcal{C}^r \;\middle|\; |\operatorname{conv}(A)| \le r\right\} \times \mathcal{C}^n$$

is compact (closed and bounded). The set

$$\left\{(P,A) \in \mathcal{C}^{n+r} \;\middle|\; P \subset \operatorname{conv}(A)\right\}$$

can be rewritten as

$$\left\{(P,A) \in \mathcal{C}^{n+r} \;\middle|\; \bigwedge_{i=1}^{n} \left(\exists \lambda_i \in [0,1]^r \colon \sum_{j=1}^{r} \lambda_{ij} a_j = p_i \;\wedge\; \sum_{j=1}^{r} \lambda_{ij} = 1\right)\right\}.$$

(Here p_i is the ith point in P, a_j is the jth point in A, λ_i is the vector of barycentric coordinates for the point p_i, and λ_{ij} is its jth component.) This set is an orthogonal projection of the compact semialgebraic set

$$\left\{(P,A,\Lambda) \in \mathcal{C}^{n+r} \times [0,1]^{r\times n} \;\middle|\; \bigwedge_{i=1}^{n} \left(\sum_{j=1}^{r} \lambda_{ij} a_j = p_i \;\wedge\; \sum_{j=1}^{r} \lambda_{ij} = 1\right)\right\}$$

and is thus also compact. (Here Λ is the $n \times r$ matrix of barycentric coordinates λ_{ij}.) It follows that $\operatorname{Sep}_r(H,n) \cap \mathcal{C}^n$ is an orthogonal projection of the intersection of two compact sets and so must be compact.

Case 2 ($\bigcap H \neq \varnothing$). The previous argument does not work in this case, because the cells in the arrangement of H are not simply connected and thus are not polytopes. However, they are combinatorially equivalent to polytopes of lower dimension. To prove that $\operatorname{Sep}_r(H,n)$ is closed, we essentially project everything down to a lower-dimensional subspace in which the hyperplanes do not have a common intersection and apply our earlier argument.

We will actually prove that the complement of $\operatorname{Sep}_r(H,n)$ is open. Let P be an arbitrary set of n points in $\mathbb{RP}^d$ such that P and H are *not* r-separable. To prove the lemma, it suffices to show that there is an open set $\mathcal{U} \subseteq (\mathbb{RP}^d)^n$ with $P \in \mathcal{U}$, such that $Q \not\bowtie H$ for all $Q \in \mathcal{U}$.

Let $f = \bigcap H$, and let f^* be the flat dual to f. Without loss of generality, suppose that $P \setminus f = \{p_1, p_2, \ldots, p_m\}$ and $P \cap f = \{p_{m+1}, \ldots, p_n\}$ for some integer m. (Either of these two subsets may be empty.) The lower-dimensional hyperplanes $H \cap f^*$ do not have a common intersection, so by our earlier argument, $\mathrm{Sep}_r(H \cap f^*, m)$ is closed.

If some polyhedron Π separated P and H, then its projection $\mathrm{proj}_f(\Pi) \subseteq f^*$ would separate the projected points $\mathrm{proj}_f(P)$ and the lower-dimensional hyperplanes $H \cap f^*$. Conversely, if any polyhedron $\Pi \subseteq f^*$ separated $\mathrm{proj}_f(P)$ and $H \cap f^*$, then its suspension $\mathrm{susp}_f(\Pi)$ would separate P and H. Thus, $P \bowtie H$ if and only if $\mathrm{proj}_f(P) \bowtie (H \cap f^*)$. Moreover, since $\mathrm{proj}_f(P) = \mathrm{proj}_f(P \setminus f)$, it follows that $P \bowtie H$ if and only if $(P \setminus f) \bowtie H$. (Note that this argument is not valid for arbitrary flats f, but only for $f = \bigcap H$.)

Since by assumption $P \not\bowtie H$, it follows that $\mathrm{proj}_f(P) \not\bowtie (H \cap f^*)$. Thus, by Case 1, there is an open set $\mathcal{U}' \subseteq (f^*)^m$, with $\mathrm{proj}_f(P) \in \mathcal{U}'$, such that $S \not\bowtie H$ for any $S \in \mathcal{U}'$. Let $\mathcal{U}'' \subseteq (\mathbb{RP}^d \setminus f)^m$ be the set of m-point configurations R with $\mathrm{proj}_f(R) \in \mathcal{U}'$. Since $\mathbb{RP}^d \setminus f \cong f^* \times \mathbb{R}^{\dim f}$, we have $\mathcal{U}'' \cong \mathcal{U}' \times (\mathbb{R}^{\dim f})^m$, so $\mathcal{U}''$ is an open neighborhood of $P \setminus f$. For any $R \in \mathcal{U}''$, since $\mathrm{proj}_f(R) \not\bowtie (H \cap f^*)$, we have $R \not\bowtie H$. Finally, let $\mathcal{U} = \mathcal{U}'' \times (\mathbb{RP}^d)^{n-m}$; clearly, $\mathcal{U}$ is an open neighborhood of P. For every configuration $Q \in \mathcal{U}$, there is a subset $R \subseteq Q$ such that $R \not\bowtie H$, so $Q \not\bowtie H$. □

LEMMA 5.3. *Let P be a set of n points and H a set of k hyperplanes in $\mathbb{RP}^d$. For all $Q \in (\mathbb{RP}^d)^n$ in an open neighborhood of P, $\pi_r(Q, H) \geq \pi_r(P, H)$.*

Proof. For any indexed set of objects (points or hyperplanes) $X = \{x_1, x_2, \ldots\}$ and any set of indices $I \subseteq \{1, 2, \ldots, |X|\}$, let X_I denote the subset $\{x_i \mid i \in I\}$.

Fix two sets of indices $I \subseteq \{1, 2, \ldots, n\}$ and $J \subseteq \{1, 2, \ldots, k\}$, and consider the corresponding subsets $P_I \subseteq P$ and $H_J \subseteq H$. If $P_I \bowtie H_J$, define $\mathcal{U}_{I,J} = (\mathbb{RP}^d)^n$. Otherwise, define $\mathcal{U}_{I,J} \subseteq (\mathbb{RP}^d)^n$ to be an open neighborhood of P such that $Q_I \not\bowtie H_J$ for all $Q \in \mathcal{U}_{I,J}$. Lemma 5.2 implies the existence of such an open neighborhood.

Let $\mathcal{U}$ be the intersection of the $2^n 2^k$ open sets $\mathcal{U}_{I,J}$. Since each $U_{I,J}$ is an open neighborhood of P, $\mathcal{U}$ is also an open neighborhood of P. For all $Q \in \mathcal{U}$ and for all index sets I and J, if $Q_I \bowtie H_J$, then $P_I \bowtie H_J$. In other words, every r-polyhedral minor of Q and H corresponds to a r-polyhedral minor of P and H. Thus, for any r-polyhedral cover of Q and H, there is a corresponding r-polyhedral cover of P and H with exactly the same size. □

5.3. Lower bounds.

We are finally in a position to prove our combinatorial lower bounds. As in section 2, let $I(P, H)$ denote the number of point-hyperplane incidences between P and H.

LEMMA 5.4. *Let P be a set of n points and let H be a set of k hyperplanes, such that no subset of a hyperplanes contains b points in its intersection. If P and H are r-separable, then $I(P, H) \leq r(a + b)(n + k)$.*

Proof. Let Π be a polyhedron with r faces that separates P and H. For any point $p \in P$ and hyperplane $h \in H$ such that p lies on h, there is some face ϕ of Π that contains p and is contained in h. For each face $\phi \leq \Pi$, let P_ϕ denote the points in P that are contained in ϕ, and let H_ϕ denote the hyperplanes in H that contain ϕ. Every point in P_ϕ lies on every hyperplane in H_ϕ.

Since no set of a hyperplanes can all contain the same b points, it follows that for all ϕ, either $|P_\phi| < b$ or $|H_\phi| < a$. Thus, we can bound $I(P, H)$ as follows.

$$I(P, H) \leq \sum_{\phi \leq \Pi} I(P_\phi, H_\phi) = \sum_{\phi \leq \Pi} \bigl(|P_\phi| \cdot |H_\phi|\bigr) \leq (a + b) \sum_{\phi \leq \Pi} \bigl(|P_\phi| + |H_\phi|\bigr).$$

Since Π has r faces, the last sum counts each point in P and each hyperplane in H at most r times. □

THEOREM 5.5. $\pi_d^\circ(n,k) = \Omega\left(n^{1-2/d(d+1)}k^{2/(d+1)} + n^{2/(d+1)}k^{1-2/d(d+1)}\right)$.

Proof. Let P be a restricted set of n points and H a set of k hyperplanes in $\mathbb{R}^d$, such that $I(P,H) = \Omega(n^{2/(d+1)}k^{1-2/d(d+1)})$ as described by Lemma 2.4. Consider any subsets $P_i \subseteq P$ and $H_i \subseteq H$ such that $P_i \bowtie_r H_i$. Applying Lemma 5.4 with $s = 2$ and $t = d$, we have $I(P_i, H_i) \le (2+d)r(|P_i| + |H_i|)$. It follows that any collection of r-polyhedral minors that includes every incidence between P and H must have size at least $I(P,H)/(2+d)r$. Thus, $\pi_r(P,H) = \Omega(n^{2/(d+1)}k^{1-2/d(d+1)})$. Finally, Lemma 5.3 implies that we can perturb P slightly, removing all the incidences, without decreasing the polyhedral cover size.

The symmetric lower bound $\Omega(n^{1-2/d(d+1)}k^{2/(d+1)})$ follows by considering the dual points H^* and the dual hyperplanes P^*. □

When $d \le 3$, this result follows from earlier bounds on the complexity of monochromatic covers derived in [31]. (In a monochromatic minor, either every point lies above every hyperplane, or every point lies below every hyperplane.)

Our d-dimensional lower bound only improves our $(d-1)$-dimensional lower bound when $k = O(n^{2/(d-1)})$ or $k = \Omega(n^{(d-1)/2})$. We can combine the lower bounds from all dimensions $1 \le i \le d$ into a single expression, as in [31, 30]:

$$\pi_d^\circ(n,k) = \Omega\left(\sum_{i=0}^{d}\left(n^{1-2/i(i+1)}k^{2/(i+1)} + n^{2/(i+1)}k^{1-2/i(i+1)}\right)\right).$$

If the relative growth rates of n and k are fixed, this entire sum reduces to a single term. In particular, when $k = n$, the best lower bound we can prove is $\pi_d^\circ(n,n) \ge \pi_2^\circ(n,n) = \Omega(n^{4/3})$, the proof of which requires only the original point-line configuration of Erdős. (See Theorem 2.2.)

We conjecture that $\pi_d^\circ(n,n) = \Theta(n^{2d/(d+1)})$. The lower bound would follow from a construction of n points and n hyperplanes with $\Omega(n^{2d/(d+1)})$ incident pairs, such that no d points lie on the intersection of d hyperplanes, or in other words, such that the bipartite incidence graph of P and H does not have $K_{d,d}$ as a subgraph. (The results of Clarkson et al. [23] and of Guibas, Overmars, and Robert [35] imply that this is the smallest forbidden subgraph for which the desired lower bound is possible.) An upper bound of $\pi_d^\circ(n,n) = O(n^{2d/(d+1)}2^{O(\log^* n)})$ follows from the running time of Matoušek's algorithm for Hopcroft's problem [42], using the results in the next section.

6. Better offline lower bounds.

Recall that a *partitioning algorithm*, given a set of points and hyperplanes, constructs a partition graph (which may depend arbitrarily on the input, at no cost), preprocesses the points, and queries the hyperplanes, using the algorithms in Figure 1. For a *polyhedral* partitioning algorithm, the partition graph's query regions are all convex (or projective) polyhedra, each with at most r faces, where r is some fixed constant.[10]

In [31], it was shown that the worst-case running time of any partitioning algorithm that solves Hopcroft's point-hyperplane incidence problem, given n points and k hyperplanes as input, requires time $\Omega(n \log k + n^{2/3}k^{2/3} + k \log n)$ when $d = 2$, or $\Omega(n \log k + n^{5/6}k^{1/2} + n^{1/2}k^{5/6} + k \log n)$ for any $d \ge 3$. Here, by restricting our attention to polyhedral partitioning algorithms, we derive (slightly) better lower bounds in arbitrarily high dimensions.

[10]In most actual partitioning algorithms, every query region is either a simplex ($r = 2^{d+1}$) or a combinatorial cube ($r = 3^d + 1$).

Theorem 6.1. *Let P be a set of points and H a set of hyperplanes, such that no point lies on any hyperplane. The running time of any polyhedral partitioning algorithm that solves Hopcroft's problem, given P and H as input, is at least $\Omega(\pi(P, H))$.*

Proof. For any partitioning algorithm $\mathcal{A}$, let $T_\mathcal{A}(P, H)$ denote its running time given the points P and hyperplanes H as input. Recall that $T_\mathcal{A}(P, H)$ is defined as follows:

$$\begin{aligned} T_\mathcal{A}(P,H) &\triangleq \sum_{p\in P} \#\text{edges traversed by } p + \sum_{h\in H} \#\text{edges traversed by } h \\ &= \sum_{\text{edge } e} \big(\#\text{points traversing } e + \#\text{hyperplanes traversing } e\big). \end{aligned}$$

We say that a point or hyperplane *misses* an edge from v to w if it reaches v but does not traverse the edge. (It might still reach w by traversing some other edge.) Recall that each node in the partition graph has at most Δ outgoing edges, for some fixed constant Δ. Thus, for every edge that a point or hyperplane traverses, there are at most $\Delta - 1$ edges that it misses.

$$\begin{aligned} \Delta\cdot T_\mathcal{A}(P,H) \geq \sum_{\text{edge } e} \big(&\#\text{points traversing } e + \#\text{points missing } e \\ &+ \#\text{hyperplanes traversing } e + \#\text{hyperplanes missing } e\big). \end{aligned}$$

Call any edge that leaves a primal node a primal edge, and any edge that leaves a dual node a dual edge.

$$\begin{aligned} \Delta\cdot T_\mathcal{A}(P,H) \geq &\sum_{\substack{\text{primal}\\ \text{edge } e}} \big(\#\text{points traversing } e + \#\text{hyperplanes missing } e\big) \\ &+ \sum_{\substack{\text{dual}\\ \text{edge } e}} \big(\#\text{hyperplanes traversing } e + \#\text{points missing } e\big) \end{aligned}$$

For each primal edge e, let P_e be the set of points that traverse e, and let H_e be the set of hyperplanes that miss e. The edge e is associated with a query region Π, a polyhedron with at most r faces. The polyhedron Π separates P_e and H_e, since every point in P_e is contained in Π, and every hyperplane in H_e is disjoint from Π.

Similarly, for each dual edge e, let H_e be the set of hyperplanes that traverse it, and let P_e be the points that miss it. The associated polyhedral query region Π separates the dual points H_e^* and the dual hyperplanes P_e^*. By the definitions of separation and dual polyhedra, Π^* separates P_e and H_e.

Now our argument is similar to the proof of Theorem 3.5. Say that a node v *splits* a point p and a hyperplane h if both p and h reach v but no edge out of v is traversed by both p and h. For every point $p \in P$ and hyperplane $h \in H$, some node must split p and h, since otherwise p and h would both reach a leaf, and the output of the algorithm would be incorrect. Thus, for some outgoing edge e of this node, we have $p \in P_e$ and $h \in H_e$.

It follows that the collection of subset pairs $\{(P_e, H_e)\}$ is an r-polyhedral cover of P and H. The size of this cover is at least $\Delta \cdot T_\mathcal{A}(P, H)$ and, by definition, at most $\pi_r(P, H)$. ∎

We emphasize that in order for this lower bound to hold, no point can lie on a hyperplane. If some point lies on a hyperplane, then the trivial partitioning algorithm, whose partition graph consists of a single leaf, correctly "detects" the incident pair at no cost. This is consistent with the intuition that it is trivial to prove that some point lies on some hyperplane, but proving that no point lies on any hyperplane is more difficult.

COROLLARY 6.2. *The worst-case running time of any polyhedral partitioning algorithm that solves Hopcroft's problem, given n points and k hyperplanes in $\mathbb{R}^d$, is*

$$\Omega\left(n^{1-2/d(d+1)}k^{2/(d+1)} + n^{2/(d+1)}k^{1-2/d(d+1)}\right).$$

Again, our d-dimensional bound improves our $(d-1)$-dimensional bound only for certain values of n and k. We can combine the lower bounds for different dimensions into the following single expression:

$$\Omega\left(n\log k + \sum_{i=0}^{d}\left(n^{1-2/i(i+1)}k^{2/(i+1)} + n^{2/(i+1)}k^{1-2/i(i+1)}\right) + k\log n\right).$$

This lower bound was previously known for *arbitrary* partitioning algorithms for counting or reporting versions of Hopcroft's problem—Given a set of points and lines, return the number of point-hyperplane incidences, or a list of incident pairs—as well as for offline *halfspace* counting and reporting problems [31].

7. Preprocessing-query time tradeoffs.

Based on the offline results in the previous section, we now establish tradeoff lower bounds between preprocessing and query time for online hyperplane emptiness and related queries. These are the first such lower bounds for any range searching problem in any model of computation; preprocessing time is not even defined in earlier models such as semigroup arithmetic and pointer machines. In some instances, our bounds allow us to improve the space-time tradeoff bounds established in section 4.

THEOREM 7.1. *Any partition graph that supports line emptiness queries in time t after preprocessing time p satisfies the inequality $pt^2 = \Omega(n^2)$ in the worst case.*

Proof. Suppose $p < n^2$, since otherwise there is nothing to prove. Let $k = cp^{3/2}/n$, where c is a constant to be specified later. Note that $k = O(n^2)$, and since $p = \Omega(n\log n)$ by Theorem 3.5, we also have $k = \Omega(n^{1/2}\log^{1/2} n)$. Thus, there is a set of n points and k lines such that for any partition graph, the total time required to preprocess the n points and correctly answer the k line queries is at least $\alpha n^{2/3}k^{2/3} = \alpha c^{2/3}p$ for some positive constant α [31]. If we choose $c = (2/\alpha)^{3/2}$, the total query time is at least p. Thus, at least one query requires time at least $p/k = \Omega(n/p^{1/2})$. ◻

This lower bound almost matches the best known upper bound $pt^2 = O(n^2\log^{\varepsilon} n)$, due to Matoušek [42].

The following higher-dimensional bound follows from Corollary 6.2 using precisely the same argument.

THEOREM 7.2. *Any polyhedral partition graph that supports d-dimensional hyperplane emptiness queries in time t after preprocessing time p satisfies the inequalities $pt^{(d+2)(d-1)/2} = \Omega(n^d)$ and $pt^{2/(d-1)} = \Omega(n^{(d+2)/d})$ in the worst case. When $d \leq 3$, these bounds apply to arbitrary partition graphs.*

Although in general these bounds are far from optimal, there are two interesting special cases that match known upper bounds [17, 38, 42] up to polylogarithmic factors.

COROLLARY 7.3. *Any polyhedral partition graph that supports hyperplane emptiness queries after $O(n\,\mathrm{polylog}\,n)$ preprocessing time requires query time $\Omega(n^{(d-1)/d}/$

polylog n) *in the worst case. When $d \leq 3$, this bound applies to arbitrary partition graphs.*

Corollary 7.4. *Any polyhedral partition graph that supports hyperplane emptiness queries in $O(\operatorname{polylog} n)$ time requires preprocessing time $\Omega(n^d/\operatorname{polylog} n)$ in the worst case. When $d \leq 3$, this bound applies to arbitrary partition graphs.*

In any realistic model of computation, the size of a data structure is a lower bound on its preprocessing time. However, partition graphs can have large subgraphs that are never visited during the preprocessing phase or that cannot be visited by any query. In principle, since we do not charge for the actual construction of a partition graph, its size can be arbitrarily larger than its preprocessing time.

We say that a partition graph is *trim* if every edge that does not point to a leaf is traversed both while preprocessing some point and while answering some query. Given any partition graph, we can easily make it trim (trim it?) without increasing any of its resource bounds. Since $s \geq \Delta \cdot p$ for any trim partition graph, any asymptotic lower bound on the preprocessing time for a trim partition graph is also a lower bound on its size.

Corollary 7.5. *Any trim partition graph of size s that supports line emptiness queries in time t satisfies the inequality $st^2 = \Omega(n^2)$ in the worst case.*

This lower bound is optimal, up to constant factors. Chazelle [17] and Matoušek [42] describe a family of line query data structures satisfying the matching upper bound $st^2 = O(n^2)$.

Corollary 7.6. *Any trim polyhedral partition graph of size s that supports d-dimensional hyperplane emptiness queries in time t satisfies the inequality $st^{(d+2)(d-1)/2} = \Omega(n^d)$ in the worst case. In particular, if $t = O(\operatorname{polylog} n)$, then $s = \Omega(n^d/\operatorname{polylog} n)$. When $d \leq 3$, these bounds apply to arbitrary trim partition graphs.*

Corollary 7.7. *Any trim polyhedral partition graph of size s that supports d-dimensional hyperplane emptiness queries in time t satisfies the inequality $st^{2/(d-1)} = \Omega(n^{(d+2)/d})$ in the worst case. In particular, if $s = O(n \operatorname{polylog} n)$, then $t = \Omega(n^{(d-1)/d}/\operatorname{polylog} n)$. When $d \leq 3$, these bounds apply to arbitrary trim partition graphs.*

Corollary 7.6 is an improvement over Theorem 4.5 for all $s = \Omega(n^{d-1})$ or $t = O(n^{2(d-1)/d^3})$; and Corollary 7.7 is an improvement whenever $s = O(n^{1+2/(d^2+d)})$ or $t = \Omega(n^{1-2/d})$. (These bounds are conservative; the actual breakpoints are much messier.) The lower bounds for near-linear space and polylogarithmic query time are optimal up to polylogarithmic factors.

All of these lower bounds apply to hyperplane and halfspace counting and reporting queries as well, by Lemma 3.4. In fact, the results in [31] imply that for counting and reporting queries, the preprocessing-query tradeoffs apply to *arbitrary* partition graphs, and the space-time tradeoffs to arbitrary trim partition graphs, in all dimensions. Corollary 7.6 is always an improvement (although a small one) over the lower bound in Corollary 4.3.

8. Halfspace emptiness queries. The space and time bounds for the best hyperplane (or simplex) emptiness query data structures are only a polylogarithmic factor smaller than the bounds for hyperplane (or simplex) counting queries. The situation is entirely different for halfspace queries. The best halfspace counting data structure known requires roughly $\Omega(n^d)$ space to achieve logarithmic query time [17, 42]; whereas, the same query time can be achieved with $o(n^{\lfloor d/2 \rfloor})$ space if we only want to know whether the halfspace is empty [44].

Table 2
Best known upper bounds for halfspace emptiness queries.

	Space	Preprocessing	Query Time	Source
$d \le 3$	$O(n)$	$O(n \log n)$	$O(\log n)$	[21, 3, 26]
$d \ge 4$	$O(n^{\lfloor d/2 \rfloor} / \log^{\lfloor d/2 \rfloor} n)$	$O(n^{\lfloor d/2 \rfloor} / \log^{\lfloor d/2 \rfloor - \varepsilon} n)$	$O(\log n)$	[44]
	$O(n)$	$O(n^{1+\varepsilon})$	$O(n^{1-1/\lfloor d/2 \rfloor} 2^{O(\log^* n)})$	[39]
	$O(n)$	$O(n \log n)$	$O(n^{1-1/\lfloor d/2 \rfloor} \operatorname{polylog} n)$	[44]
	$n \le s \le n^{\lfloor d/2 \rfloor}$	$O(s \operatorname{polylog} n)$	$O((n \operatorname{polylog} n)/s^{1/\lfloor d/2 \rfloor})$	[44]

Table 2 lists the resource bounds for the best known online halfspace emptiness data structures. The fastest offline algorithm, given n points and k halfspaces, requires

$$O\left(n \log k + (nk)^{\lfloor d/2 \rfloor/(\lfloor d/2 \rfloor + 1)} \operatorname{polylog}(n+k) + k \log n\right)$$

time to decide if any point lies in any halfspace [44]. In contrast, the only lower bounds previously known for halfspace emptiness queries are trivial. Linear space and logarithmic query time are required to answer online queries. A simple reduction from the set intersection problem shows that $\Omega(n \log k + k \log n)$ time is required for the offline problem in the algebraic decision tree and algebraic computation tree models [8, 50].

In this section, we derive the first nontrivial lower bounds on the complexity of halfspace emptiness queries. To prove our results, we use a simple reduction argument to transform hyperplane queries into halfspace queries in a higher-dimensional space [31, 29]. A similar transformation is described by Dwyer and Eddy [27].

Define the function $\sigma_d : \mathbb{R}^{d+1} \to \mathbb{R}^{\binom{d+2}{2}}$ as follows:

$$\sigma_d(x_0, x_1, \ldots, x_d) = \left(x_0^2, x_1^2, \ldots, x_d^2, \sqrt{2}\, x_0 x_1, \sqrt{2}\, x_0 x_2, \ldots, \sqrt{2}\, x_{d-1} x_d\right).$$

This map has the property that $\langle \sigma_d(p), \sigma_d(h) \rangle = \langle p, h \rangle^2$ for any vectors $p, h \in \mathbb{R}^{d+1}$, where $\langle \cdot, \cdot \rangle$ denotes the usual inner product. In a more geometric setting, σ_d maps points and hyperplanes in $\mathbb{R}^d$, represented as homogeneous coordinate vectors, to points and hyperplane in $\mathbb{R}^{d(d+3)/2}$, also represented in homogeneous coordinates. For any point p and hyperplane h in $\mathbb{R}^d$, the point $\sigma_d(p)$ is contained in the hyperplane $\sigma_d(h)$ if and only if p is contained in h; otherwise, $\sigma_d(p)$ is strictly above $\sigma_d(h)$. Thus, a hyperplane h intersects a point set P if and only if the closed lower halfspace $\sigma_d(h)^-$ intersects the lifted point set $\sigma_d(P)$. In other words, any (lower) halfspace emptiness data structure for $\sigma_d(P)$ is also a hyperplane emptiness data structure for P.

Unfortunately, this is not quite enough to give us our lower bounds, since the reduction does not preserve the model of computation. Specifically, the query regions in a partition graph used to answer d-dimensional queries must be subsets of $\mathbb{R}^d$. To complete the reduction, we need to show that the $d(d+3)/2$-dimensional partition graph can be "pulled back" to a d-dimensional partition graph.

In order for such a transformation to be possible, we need to restrict the query regions allowed in our partition graphs. A *Tarski cell* is a semialgebraic set defined by a constant number of polynomial equalities and inequalities, each of constant degree. Every Tarski cell has a constant number of connected components, and the intersection of any two Tarski cells is another Tarski cell (with larger constants). A *semialgebraic* partition graph is a partition graph whose query regions are all Tarski cells.

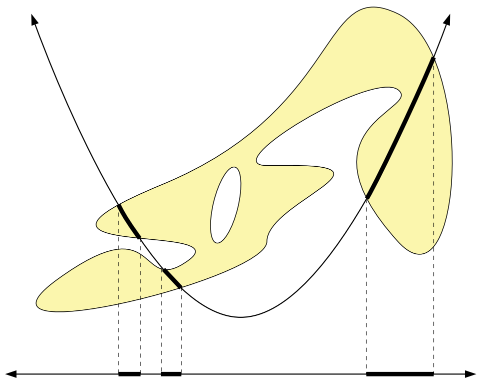

FIG. 5. *Each Tarski cell induces a constant number of lower-dimensional query regions.*

THEOREM 8.1. *Let P be a set of points in $\mathbb{R}^d$, and let $\hat{P} = \sigma_d(P)$. Given a semialgebraic partition graph $\hat{G}$ that supports $d(d+3)/2$-dimensional halfspace emptiness queries over $\hat{P}$, we can construct a semialgebraic partition graph G that supports d-dimensional hyperplane emptiness queries over P, with the same asymptotic space, preprocessing time, and query time bounds.*

Proof. We actually prove a stronger theorem, by assuming only that $\hat{G}$ supports emptiness queries for hyperplanes of the form $\sigma_d(h)$. Since no point in $\hat{P}$ is ever below such a hyperplane, any partition graph that supports lower halfspace emptiness queries also supports our restricted class of hyperplane emptiness queries. As we noted earlier, these queries are equivalent to hyperplane emptiness queries over the original point set P.

Given $\hat{G}$, we construct G as follows. G has the same set of nodes as $\hat{G}$, but with different query regions. Since each query region $\hat{R}$ in the original partition graph $\hat{G}$ is a Tarski cell, it intersects the algebraic surface $\sigma_d(\mathbb{R}^d)$ in a constant number of connected components $\hat{R}_1, \hat{R}_2, \ldots, \hat{R}_\delta$, where the constant δ depends on the number and degree of the inequalities that define $\hat{R}$. The query regions in G are the preimages $R_i = \sigma_d^{-1}(\hat{R}_i)$ of these components. See Figure 5.

The edge associated with each d-dimensional query region R_i has the same endpoints as the edge associated with the original query region $\hat{R}$. Thus, there may be several edges in G with the same source and target. (Recall that partition graphs are directed acyclic *multi*graphs.) If a query region $\hat{R}$ does not intersect $\sigma_d(\mathbb{R}^d)$, then the corresponding edge in $\hat{G}$ is not represented in G at all, so G may not be a connected graph. Nodes in G that are not connected to the root can be safely discarded. The size, preprocessing time, and query time for G are clearly at most a constant factor more than the corresponding resources for $\hat{G}$.

The leaf subsets P_ℓ in G cannot be larger than the corresponding subsets $\hat{P}_\ell$ in $\hat{G}$. (They might be smaller, but that only helps us.) Similarly, a hyperplane query cannot reach more leaves in G than the corresponding query reaches in $\hat{G}$. It follows that G supports hyperplane emptiness queries: For any hyperplane h, if $\hat{G}$ reports that $\sigma_d(h)$ is empty, G (correctly) reports that h is empty. □

We emphasize that some restriction on the query regions is necessary to prove any nontrivial lower bounds for halfspace emptiness queries. There is a partition graph of constant size, requiring only linear preprocessing, that supports halfspace emptiness queries in constant time. The graph consists of a single primal node with two query regions—the convex hull of the points and its complement—and two leaves. On the other hand, our restriction to Tarski cells is stronger than necessary. It suffices that every query region intersects (some projective transformation of) the surface $\sigma_d(\mathbb{R}^d)$ in a constant number of connected components.

The following corollaries are now immediate consequences of our earlier results.

Corollary 8.2. *For any $d \geq 2$, any semialgebraic partition graph that supports d-dimensional halfspace emptiness queries has size $\Omega(n)$, preprocessing time $\Omega(n \log n)$, and worst-case query time $\Omega(\log n)$.*

Corollary 8.3. *Any semialgebraic partition graph of size s that supports $d(d+3)/2$-dimensional halfspace emptiness queries in time t satisfies the inequality $st^d = \Omega((n/\log n)^{d-(d-1)/(d+1)})$ in the worst case.*

Corollary 8.4. *The worst-case running time of any semialgebraic partitioning algorithm which, given n points and k halfspaces in $\mathbb{R}^d$, decides if any halfspace contains a point, is $\Omega(n \log k + k \log n)$ for all $2 \leq d \leq 4$, $\Omega(n \log k + n^{2/3}k^{2/3} + k \log n)$ for all $5 \leq d \leq 8$, and $\Omega(n \log k + n^{5/6}k^{1/2} + n^{1/2}k^{5/6} + k \log n)$ for all $d \geq 9$.*

Corollary 8.5. *Any semialgebraic partition graph that supports 5-dimensional halfspace emptiness queries in time t after preprocessing time p satisfies the inequality $pt^2 = \Omega(n^2)$ in the worst case. Any trim semialgebraic partition graph of size s that supports 5-dimensional halfspace emptiness queries in time t satisfies the inequality $st^2 = \Omega(n^2)$ in the worst case.*

Corollary 8.6. *Any semialgebraic partition graph that supports 9-dimensional halfspace emptiness queries in time t after preprocessing time p satisfies the inequalities $pt^5 = \Omega(n^3)$ and $pt = \Omega(n^{5/3})$ in the worst case. Any trim semialgebraic partition graph of size s that supports 9-dimensional halfspace emptiness queries in time t satisfies the inequalities $st^5 = \Omega(n^3)$ and $st = \Omega(n^{5/3})$ in the worst case.*

Corollaries 8.2 and 8.4 are optimal when $d \leq 3$; Corollary 8.4 is also optimal up to polylogarithmic factors when $d = 5$; and Corollary 8.5 is optimal up to polylogarithmic factors.

Theorem 8.1 does not imply better offline lower bounds or preprocessing/query tradeoffs for halfspace emptiness queries in dimensions higher than 9, since the corresponding hyperplane results require polyhedral query regions. Marginally better lower bounds can be obtained directly in dimensions 14 and higher(!) in the *polyhedral* partition graph model by generalizing the arguments in sections 5 and 6 (as in [30]). However, since these lower bounds are far from optimal, we omit further details.

9. Conclusions.

We have presented the first nontrivial lower bounds on the complexity of hyperplane and halfspace emptiness queries. Our lower bounds apply to a broad class of range query data structures based on recursive decomposition of primal and/or dual space.

The lower bounds we developed for counting and reporting queries actually apply to any type of query where the points in the query range are required as the union of several subsets. For example, simplex range searching data structures are typically constructed by composing several levels of halfspace "counting" data structures [42]. To answer a query for the intersection of k halfspaces, the points in the first halfspace are (implicitly) extracted as the disjoint union of several subsets, and a $(k-1)$-halfspace query is recursively performed on each subset.

With a few notable exceptions, our lower bounds are far from the best known upper bounds, and a natural open problem is to close the gap. In particular, we have only "trivial" lower bounds for 4-dimensional halfspace emptiness queries. We conjecture that the correct space-time tradeoffs are $st^d = \Theta(n^d)$ for hyperplanes and $st^{\lfloor d/2 \rfloor} = \Theta(n^{\lfloor d/2 \rfloor})$ for halfspaces. Since these bounds are achieved by current algorithms—exactly for hyperplanes [42], within polylogarithmic factors for halfspaces [44]—the only way to prove our conjecture is to improve the lower bounds.

Our space-time tradeoffs derive from lower bounds for halfspace queries in the semigroup arithmetic model [10], and our preprocessing-query tradeoffs follow from lower bounds on the combinatorial complexity of polyhedral covers. Any improvements to these lower bounds would improve our results as well. Both of these results ultimately reduce to bounds on the minimum size of a decomposition of the (weighted) incidence graph of a set of points and a set of halfspaces into complete bipartite subgraphs.

The best known data structures for d-dimensional hyperplane emptiness queries and $2d$- or $(2d+1)$-dimensional halfspace emptiness queries have the same resource bounds. We conjecture that this is also true of *optimal* data structures for these problems. Is there a reduction from hyperplane queries to halfspace queries that only increases the dimension by a constant factor (preferably two)?

Finally, can our techniques be applied to other closely related problems, such as nearest neighbor queries [2], linear programming queries [40, 11] and ray shooting queries [2, 20, 41, 44]?

Acknowledgments. I thank Pankaj Agarwal for suggesting studying the complexity of online emptiness problems.

PARALLEL SORTING WITH LIMITED BANDWIDTH[*]

MICAH ADLER[†], JOHN W. BYERS[‡], AND RICHARD M. KARP[§]

Abstract. We study the problem of sorting on a parallel computer with limited communication bandwidth. By using the PRAM(m) model, where p processors communicate through a globally shared memory which can service m requests per unit time, we focus on the trade-off between the amount of local computation and the amount of interprocessor communication required for parallel sorting algorithms. Our main result is a lower bound of $\Omega(\frac{n \log m}{m \log n})$ on the time required to sort n numbers on the exclusive-read and queued-read variants of the PRAM(m). We also show that Leighton's Columnsort can be used to give an asymptotically matching upper bound in the case where m grows as a fractional power of n. The bounds are of a surprising form in that they have little dependence on the parameter p. This implies that attempting to distribute the workload across more processors while holding the problem size and the size of the shared memory fixed will not improve the optimal running time of sorting in this model. We also show that both the lower and the upper bounds can be adapted to bridging models that address the issue of limited communication bandwidth: the LogP model and the bulk-synchronous parallel (BSP) model. The lower bounds provide further convincing evidence that efficient parallel algorithms for sorting rely strongly on high communication bandwidth.

1. Introduction.

A large body of theoretical research has concentrated on algorithms designed in the parallel random access machine (PRAM) model of computation. The PRAM allows processors to communicate with each other in unit time through a large globally shared memory, which leads to algorithms that have a high degree of parallelism but perform a great deal of interprocessor communication, an inexpensive operation in the PRAM model. This leaves unresolved the question of how to design algorithms for machines which have limited interprocessor communication bandwidth.

Addressing this limitation has motivated the development of other models of parallel computation, representative of which are the BSP model [33], the LogP model [15], and the PRAM(m) model [35]. Provably efficient algorithms in the PRAM model are not necessarily the most efficient algorithms for these models, so a host of problems must be reevaluated in this framework. In this paper, we examine the problem of sorting in the context of parallel machines with limited communication bandwidth. We formalize the sorting problem as follows.

DEFINITION 1.1. **The Sorting Problem.**
Input: *n distinct keys $k_1 \dots k_n$, with total order $k_{(1)} < k_{(2)} < \cdots < k_{(n)}$.*

Output at processor i: *A sorted list of keys:* $k_{(\frac{in}{p}+1)} \cdots k_{(\frac{in}{p}+\frac{n}{p})}$.

We concentrate on the complexity of sorting in the PRAM(m) model. In this variant of the classical PRAM model, p processors communicate through a globally shared memory consisting of m memory cells and the entire input, assumed to be of size n, is provided to each processor in a globally shared read-only memory (ROM). This model allows us to focus on the trade-off between the amount of information derived from local computation and the amount of information derived from interprocessor communication.

Each of the m shared memory cells consists of $\log n$ bits. As in traditional PRAM models, the resolution of contention for these shared memory cells can be defined in a variety of ways. In this paper, we focus on the exclusive-read and queued-read variants of the PRAM(m) model (ER PRAM(m) and QR PRAM(m), respectively); these are defined in section 2. The main result of this paper is the proof of a lower bound that holds for both the ER PRAM(m) and the QR PRAM(m) on the time required to sort n distinct keys of

$$\Omega\left(\frac{n \log m}{m \log n}\right).$$

The bound holds when $n > p^2$, which is the case of primary interest, since typical parallel applications involve problems where the input size is much larger than the number of processors. This lower bound does not rely on any restriction on the local computation of a processor. This is in contrast to sorting results which prove lower bounds on comparison-based algorithms. The proof extends to both Monte Carlo and Las Vegas randomized algorithms and to algorithms which allow for the m shared memory cells to employ a concurrent write contention resolution rule.

In order to prove the lower bound, we introduce the *oracle model of computation*, a model that allows us to quantify a trade-off between local computation and information received from other processors. In this model, which is defined more fully in section 2.1, processors are not required to transmit any information. Rather, all interprocessor communication is simulated by an oracle that is assumed to know the entire input before computation begins. The oracle is of unlimited computational power, and thus can precompute any function of the inputs before computation begins. We prove that even in this setting, local computation is of such limited utility that the oracle must provide a large amount of information in order to enable the processors to solve the sorting problem efficiently.

When $m = O(n^\beta)$, for some $\beta < 1$, we show that a version of Columnsort [26] has a running time that is bounded by

$$O\left(\frac{n}{m}(1-\beta)^{-3.42}\right).$$

For $n \gg m$, the case of greatest interest, the final factor becomes a small constant and so in this setting the ratio between the upper and lower bounds is $\Theta(\frac{\log n}{\log m})$. When sorting k-bit keys, the algorithm used in the upper bound runs with a slowdown of a factor of $O(\frac{k}{\log n})$ on a machine model in which the input is distributed among all processors rather than stored in a globally shared ROM. This gives the algorithm more credibility from a practical standpoint.

We also show that our results can be generalized to two other models that incorporate limited communication throughput, the LogP model and the BSP model. In both of these models, the processors communicate using point-to-point messages, and a parameter g represents the minimum number of cycles between transmission of successive messages from a processor. To prove a lower bound for the ER PRAM(m) model, we show a lower bound on the number of bits which must be transmitted through the network in order to solve the sorting problem efficiently. Coupling this bound with model-dependent lower bounds on the amount of time required to transmit a fixed number of bits in the BSP and LogP models results in lower bounds for sorting in these two models. We defer definitions of the models and the exact form of the bounds to the section where those results are discussed.

Our results show that fast parallel algorithms to solve the sorting problem must rely on large amounts of communication. Furthermore, we have the surprising result that both our upper and lower bounds are unaffected by attempting to distribute the work across an unlimited number of processors, while holding fixed the problem size, the size of the shared memory, and the number of processors that actually output the result. Therefore, to increase the speed of parallel sorting on a machine with limited communication bandwidth, increasing bandwidth is more likely to improve the running time than is increasing the number or computational power of processors.

The remainder of the paper is organized as follows. In the rest of section 1, we briefly compare our results with previous work in parallel sorting. In section 2, we provide a complete description of both the PRAM(m) model and our lower bound tool, the oracle model of communication. Sections 3 and 4 provide proofs of our lower bound for deterministic and randomized algorithms for sorting in the ER PRAM(m) and QR PRAM(m) models of computation. Section 5 provides the matching upper bound, and section 6 briefly describes extensions of those proofs to the LogP and BSP models.

1.1. Previous work. From the large body of research in the realm of parallel sorting algorithms, we discuss several results which also focus on interprocessor communication requirements. Using Thompson's VLSI model [32], Leighton, in [26], proves a lower bound of $\mathrm{AT}^2 = \Omega(n^2 \log^2 n)$ for sorting n keys of size $\Theta(\log n)$, where A is the area of a VLSI chip and T is the running time of the chip. His methods can be used to show bounds of the form $\Omega\left(\frac{n}{m}\right)$ in a PRAM model with a globally shared memory of size m, but in which the input is evenly distributed across the p processors, rather than stored in a globally shared ROM. Indeed, an interesting question would be to determine whether we could apply our lower bound technique to a nonstandard VLSI model in which the chip could receive each input in more than one location and at more than one time.

Other related work on parallel sorting includes [12], where Borodin and Cook prove that sorting requires $\mathrm{TIME} \cdot \mathrm{SPACE} = \Omega(\frac{n^2}{\log n})$. Aggarwal, Chandra, and Snir show in [3] that any parallel comparison-based algorithm that sorts n words requires $\Omega(\frac{n \log n}{p \log(\frac{n}{p})})$ communication steps. Also, the same authors show in [5] that sorting requires time $\Omega(\frac{n \log n}{p} + l \log p)$ in a model where reading or writing a block of size b from memory takes time $l + b$.

The PRAM(m) model was introduced in [35] and has been studied subsequently in [28], [19], [18], [9], [30], [1], and [10]. The case where $n \gg p$ was first examined in [30], where Mansour, Nisan, and Vishkin prove a lower bound of $\Omega(\frac{n}{\sqrt{mp}})$ for several problems, including sorting, in a concurrent read version of the PRAM(m), which implies the same bound in the ER PRAM(m) and the QR PRAM(m).

An easy upper bound on the time required for sorting can be obtained by using a variant of Cole's parallel merge sort [13] for the PRAM. Cole's algorithm uses

n processors to sort n keys in time O($\log n$) time. This algorithm requires the use of a total of $O(n \log n)$ shared memory cells per time step, but by letting each of the m words of shared memory simulate $O(\frac{n \log n}{m})$ cells of the PRAM memory, we can run Cole's algorithm in time O($\frac{n \log^2 n}{m}$) on the ER PRAM(m). Related work on upper bounds includes [16], in which Cypher and Sanz discuss a recursive version of Columnsort and introduce Cubesort, which can be used to obtain a running time of $O(\frac{n}{m}(1-\beta)^{-2})25^{\log^* n - \log^*(n/m)}$ for sorting on the ER PRAM(m), where $m = O(n^{\beta})$. However, this algorithm has substantial overhead and is considerably more involved then the one presented in this paper. A recursive version of Columnsort is also used by Aggarwal and Huang in [6] to obtain an algorithm for sorting in fixed connection networks.

Subsequent to a preliminary version of this paper in [2], Adler [1] provides an algorithm for sorting in the concurrent-read PRAM(m) (CR PRAM(m)) that is considerably faster than the lower bound for the ER PRAM(m) presented in this paper. Thus, that result together with the lower bound presented here imply that the CR PRAM(m) is strictly more powerful than the ER PRAM(m). [1] also slightly improves the ER PRAM(m) upper bound to $O(\frac{n \log p}{m \log n})$.

Finally, with respect to BSP algorithms for sorting, Gerbessiotis and Valiant [21] introduce a randomized algorithm for parallel sorting in the BSP model. Also, subsequent to an earlier version of this paper, the upper bound for sorting in the BSP model has been improved by both Goodrich [24] and by Gerbessiotis and Siniolakis [20]. The form of these bounds is deferred to section 5.2, where they are described in the context of our description of the BSP model.

2. The PRAM(m) model.

In this section, we define the PRAM(m) model, and then describe a theoretical tool derived from the PRAM(m) model, the oracle model of communication. The primary goal of these models is to examine the effectiveness of parallel computation given a sharp limitation on interprocessor communication.

In a classical PRAM, p processors communicate by writing to and reading from a large globally shared memory in unit time. However, in practice, the available per-processor bandwidth to shared memory can be quite small. Access to shared memories is slowed by such factors as long message send overheads [15], contention at memory banks, the fact that memory banks are much slower than processors [11], and bandwidth limitations of the network connecting processors to memory banks. Similar difficulties exist in distributed memory parallel machines. The parameter m of the PRAM(m) model focuses attention on this bottleneck, by enforcing the condition that the shared memory can service only m requests per unit time, where $m < p$. This is modeled as a PRAM consisting of m shared memory cells, each of size $\log n$ bits, as shown in Figure 2.1. We note that all the results in this paper can easily be extended to a model in which each memory cell can hold a word of w bits, independent of the input size.

The input of size n is provided to the PRAM(m) in a read-only shared memory (ROM) concurrently available to all of the processors. Conceptually, this is equivalent to having each processor begin with an identical copy of the input in its local memory. This capability serves to concentrate our lower bound efforts on the amount of communication required for actual computation, rather than on the amount required to distribute the input. Since such a ROM may be unrealistic from a practical standpoint, upper bounds achieved in this model that rely on use of the ROM are only applicable to problems in which the entire input is initially known by all the proces-

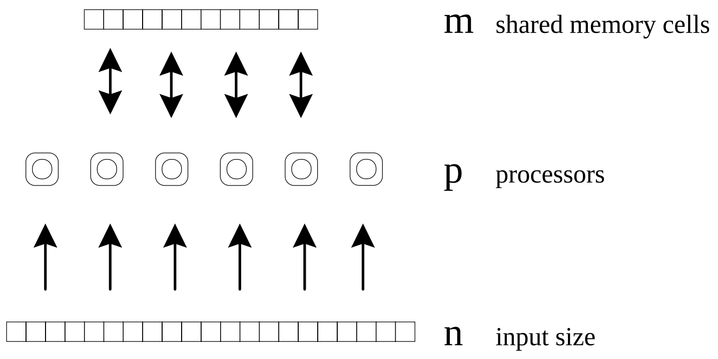

FIG. 2.1. *The PRAM(m) model.*

sors. During each synchronized round of computation, every processor can perform one of four actions: it can read the contents of a ROM location, read the contents of a globally shared memory location, write to a globally shared memory location, or perform local computation.

As defined in [35], the PRAM(m) model allows processors concurrent read, concurrent write access to the globally shared memory. In this paper, we consider exclusive-read and queued-read variants of the PRAM(m) model. In the ER PRAM(m), two distinct processors are forbidden from reading the same memory cell at the same time step. We also define the QR PRAM(m), where read contention at a memory cell is resolved as follows: each step of an algorithm completes in k time steps, where k is the maximum number of processors reading the same memory location during that step of the algorithm. Finally, we define the asynchronous QR PRAM(m), where every memory cell services one request if any requests to that cell are pending, and all other requests are stored in a FIFO queue. We note that both queued contention resolution strategies are analogous to those devised in [22] and [23] for the standard PRAM. The contention resolution strategy for write access to the shared memory can be either concurrent write, queued write, or exclusive write. Our upper and lower bounds are not affected by this choice, and thus, we leave this component of the model unspecified.

2.1. The oracle model of communication. It is often the case in parallel computing that the amount of computation required by a processor is greatly reduced by receiving results of computations performed by other processors. In order to quantify a trade-off between local computation and information received from other processors, we define the oracle model of computation. This lower bound tool uses the principle that the combined information a processor receives from all other processors is no more useful than the information it can receive from a single processor with unlimited computational resources and access to all the information the processors have.

In the oracle model, shown in Figure 2.2, processors do not transmit any information. Rather, each processor only receives information from an oracle of unlimited computational power, and a read-only memory (ROM) that contains the input. The oracle transmits information to the processors through p *oracle memories* consisting of cells of size $\log n$ bits. Each of these memory cells is referred to as an *oracle word*. Processor i has read-only access to the ith oracle memory but is not able to access any of the other oracle memories. We subject the oracle to the restriction that it compute

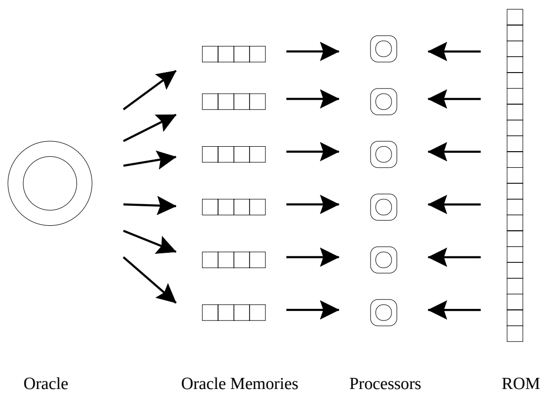

FIG. 2.2. *The flow of information in the oracle model.*

and set all the values of the oracle memory before the processors begin computation. This restriction does not alter the power of the model; it only serves to simplify the analysis.

The processors access the input using a concurrently readable ROM, which is identical to the ROM of the PRAM(m) model. During computation, at each synchronous time step every processor is allowed to perform one of three actions: it can read the contents of a cell from its oracle memory, read an input from the ROM, or perform local computation. The oracle knows the entire input and the programs executed by each of the processors. We are interested in the trade-off between the maximum number of time steps required by any processor and the total number of cells read from the oracle memory. Lower bounds on the number of cells that must be read from the oracle memory by all processors combined with the limited throughput of the memory give corresponding lower bounds on the execution time.

More formally, consider algorithms A_e and A_o designed for the ER PRAM(m) and the oracle model, respectively. Let $r(A_e, i, p)$ denote the aggregate number of reads the p processors perform from the shared memory and the ROM on input i. Likewise, let $t(A_e, i, p)$ denote the number of time steps A_e runs on i with p processors. Define $r(A_o, i, p)$ and $t(A_o, i, p)$ similarly for algorithm A_o.

DEFINITION 2.1. *An oracle algorithm A_o* exactly simulates *a PRAM(m) algorithm A_e if for all values of p and on all inputs i, $r(A_o, i, p) = r(A_e, i, p)$, $t(A_o, i, p) = t(A_e, i, p)$, and A_o computes the same output as A_e.*

LEMMA 2.2. *Given any ER PRAM(m) algorithm A_e, there is an oracle algorithm A_o such that A_o exactly simulates A_e.*

Proof. Consider the execution of the ER PRAM(m) algorithm A_e on input i. Let $w(u, v)$ denote the contents of the cell processor u would read at time v. The oracle can compute $w(u, v)$ for all u, v instantaneously in advance of the simulation by using its unlimited resources. To perform the simulation, the oracle simply furnishes $w(u, v)$ in oracle memory u at time v for all u, v. The processors then execute their ER PRAM(m) algorithms, ignoring all write operations and reading from their oracle memory in place of reading from shared memory locations. The simulation has zero slowdown and the processors read the same total number of cells in both executions. $\square$

Note that the oracle model can also exactly simulate any QR PRAM(m) algorithm, as well as any asynchronous QR PRAM(m) model. Furthermore, a similar lemma shows that an oracle model in which processors have concurrent read access to a single, m cell oracle memory can exactly simulate any CR PRAM(m) algorithm, but proving strong lower bounds for sorting in this model remains open. The oracle model can also be used to prove lower bounds for randomized algorithms. To allow the oracle to simulate the programs of processors in such a setting, we give the oracle access to the random bits used by each processor prior to the execution of the algorithm.

3. Lower bounds.

In this section, we prove lower bounds for sorting algorithms in the oracle model by showing that even when all processors know the range of keys that need to be output by each processor, the task of locating those keys within the input is difficult. If we wish to sort n keys, and if all processors know the range of key values that will be output by each processor, but not the value of these keys, nor their location within the ROM, then the work remaining can be formalized as the *permutation routing problem.*

DEFINITION 3.1.

The permutation routing problem.

Input: *n memory locations, each containing a processor ID, such that each processor ID appears exactly $\frac{n}{p}$ times.*

Output at processor i: *a list of the locations where i appears.*

LEMMA 3.2. *Any algorithm for the ER PRAM(m) that sorts n distinct keys in time T can solve any instance of the permutation routing problem of size n in time T. The same is true for the QR PRAM(m).*

Proof. We derive from each location of the permutation routing problem a key to be sorted, where the key is the concatenation of the processor ID stored at that location and the location index within the ROM. Sorting these keys is sufficient to inform each processor i of the locations where i appears. $\square$

Thus, any lower bound for the permutation routing problem implies an identical lower bound for sorting. In order to prove our lower bounds for this problem in different scenarios, we first prove a lower bound on a simpler problem in the oracle model. This problem is called the *processor d permutation routing problem*, and is defined as follows, with d any processor ID between 1 and p. The input is chosen uniformly at random from the set of all possible n element inputs to the permutation routing problem. Processor d is required to determine the list of locations in the ROM where d appears, but the remaining processors are not required to do anything. We are interested in the average, over all possible n element inputs to the permutation routing problem, of the number of oracle words processor d reads, given a limitation on how many ROM locations processor d reads.

LEMMA 3.3. *In any deterministic algorithm for the oracle model that solves the processor d permutation routing problem when $n > p^2$, if the average number of oracle words read by processor d is at most $\frac{n \log m}{8p \log n}$, and processor d never reads more than $\frac{n \log m}{m \log n}$ ROM locations, then on an input chosen uniformly at random, processor d produces an incorrect result with probability at least $\frac{1}{4}$.*

The proof of this lemma is the main technical portion of our lower bound, and is deferred to section 3.1. We first discuss its implications.

THEOREM 3.4. *For any deterministic ER PRAM(m) algorithm that solves the sorting problem for any set of n distinct keys, where $n > p^2$, the average over all permutations of the input keys of the time required by the algorithm is at least $\frac{n \log m}{8m \log n}$. The same is true for any deterministic algorithm for the QR PRAM(m).*

Proof. We assume there is a sorting algorithm A for the ER PRAM(m), where the average over all permutations of the input keys of the time to perform A is less than $\frac{n \log m}{8m \log n}$, and we reach a contradiction. Let $w(A, C)$ be the total number of words read from the shared memory when algorithm A is executed on input C. Let $r(A, C, i)$ be the number of ROM locations read by processor i when A is executed on input C. We shall use $w(A, C)$ and $r(A, C, i)$ to represent these quantities for both the PRAM(m) as well as the oracle model.

Since at most m words can be read from the shared memory at any time step, when C ranges over all permutations of the input keys, the average of $w(A, C)$ is less than $\frac{n \log m}{8 \log n}$. Also, the average over all such C of $\max_i r(A, C, i)$ is less than $\frac{n \log m}{8m \log n}$. By Lemmas 2.2 and 3.2, this implies the existence of an oracle algorithm A' for the permutation routing problem, where the average over all input permutations C of $w(A', C)$ is less than $\frac{n \log m}{8 \log n}$, and the average over all input permutations of $\max_i r(A, C, i)$ is less than $\frac{n \log m}{8m \log n}$.

For any such A', there is some processor d such that the average over all inputs of the number of oracle words read from the oracle memory for processor d is less than $\frac{n \log m}{8p \log n}$, and the average over all inputs of $r(A', C, d)$ is at most $\frac{n \log m}{8m \log n}$. By Markov's inequality, in A', the fraction of inputs C where $r(A', C, d) \geq \frac{n \log m}{m \log n}$ is at most $\frac{1}{8}$. Thus, we can use A' to construct algorithm A'' for the oracle model. In A'', processor d behaves the same as in A', except that it only performs at most $\frac{n \log m}{m \log n}$ ROM queries. If in A' processor d requires more ROM queries on a given input, on that input in A'', processor d returns an arbitrarily chosen permutation. Since algorithm A' responds correctly on all inputs, A'' responds correctly on at least $\frac{7}{8}$ of all possible inputs. This contradicts Lemma 3.3, and thus there does not exist such an algorithm A for the ER PRAM(m). The proof for the QR PRAM(m) is identical. ∎

For Las Vegas algorithms, or randomized strategies that are guaranteed to provide a correct solution with a bound only on the expected running time, we have a lower bound which follows from a direct application of Yao's lemma [36].

THEOREM 3.5. *For any Las Vegas algorithm A_v for the ER PRAM(m) where $n > p^2$, there is some permutation of the inputs* I *for the sorting problem such that A_v requires expected time at least $\frac{n \log m}{8m \log n}$ to solve* I. *Also, the expected running time of any Las Vegas algorithm on an input chosen uniformly at random from the set of all inputs is at least $\frac{n \log m}{8m \log n}$. The same is true for the QR PRAM(m).*

Proof. Yao's lemma [36] states that if there is a distribution over the inputs such that every deterministic algorithm requires time at least L for that distribution, then for any randomized algorithm there exists an input for which the expected running time is at least L. This combined with Theorem 3.4 directly implies the first claim of Theorem 3.5. The second claim follows from Theorem 3.4 and the fact that any Las Vegas algorithm is actually a distribution over deterministic algorithms and thus cannot fare better than the best deterministic algorithm. ∎

For Monte Carlo algorithms, or randomized strategies with bounded running time which provide a correct solution with probability greater than $\frac{3}{4}$, we have the following lower bound.

THEOREM 3.6. *For any Monte Carlo algorithm A_m for the ER PRAM(m) where $n > p^2$, there is some input* I *for the sorting problem such that A_m requires time at least $\frac{n \log m}{8m \log n}$ to solve* I. *Also, for the uniform distribution over all possible inputs, the running time of any Monte Carlo algorithm is at least $\frac{n \log m}{8m \log n}$. The same is true for* *the QR PRAM(m).*

We prove this theorem using an alternate formulation of Yao's lemma, provided in [29].

LEMMA 3.7. *Let P_1 be the success probability of a T step randomized algorithm solving problem B, where the success probability is taken over the random choices made by the algorithm and minimized over all possible inputs. Let P_2 be the success probability over a distribution $\mathcal{D}$ of inputs, maximized over all possible T step deterministic algorithms to solve B. Then, $P_1 \leq P_2$.*

Theorem 3.6 follows from a direct application of Lemma 3.7 to the following lemma.

LEMMA 3.8. *For any deterministic ER PRAM(m) algorithm A that solves the sorting problem for any set of n distinct keys, where $n > p^2$, if A always uses fewer than $\frac{n \log m}{8m \log n}$ time steps, then when the input is chosen uniformly at random from the set of all possible permutations of the inputs, the probability that every processor successfully produces the correct output is $\leq \frac{3}{4}$. The same is true for any deterministic algorithm for the QR PRAM(m).*

Proof. We assume that there is such a deterministic algorithm A_d which produces the correct output with probability greater than $\frac{3}{4}$, and we reach a contradiction. In such an algorithm, for every input C, $w(A_d, C) < \frac{n \log m}{8 \log n}$ and $\max_i r(A_d, C, i) < \frac{n \log m}{8m \log n}$. By Lemmas 2.2 and 3.2, this implies the existence of an oracle algorithm A'_d for the permutation routing problem, where the total number of oracle words read by all of the processors is less than $\frac{n \log m}{8 \log n}$, and $\max_i r(A'_d, C, i) < \frac{n \log m}{8m \log n}$. For any such A', there is some processor d such that the average over all inputs of the number of oracle words read from the oracle memory for processor d is less than $\frac{n \log m}{8p \log n}$, and $r(A'_d, C, d) \leq \frac{n \log m}{8m \log n}$. However, this implies the existence of an algorithm for the processor d permutation routing problem, where the average over all inputs of the number of oracle words read from the oracle memory for processor d is less than $\frac{n \log m}{8p \log n}$, $r(A'_d, C, d) < \frac{n \log m}{8m \log n}$, and yet processor d responds correctly with probability $> \frac{3}{4}$. This contradicts Lemma 3.3, and thus there does not exist such an algorithm A_d. ◻

3.1. The processor d permutation routing problem. In this subsection, we prove Lemma 3.3, restated here for convenience.

LEMMA 3.9. *In any deterministic algorithm for the oracle model that solves the processor d permutation routing problem when $n > p^2$, if the average number of oracle words read by processor d is at most $\frac{n \log m}{8p \log n}$, and processor d never reads more than $\frac{n \log m}{m \log n}$ ROM locations, then on an input chosen uniformly at random, processor d produces an incorrect result with probability at least $\frac{1}{4}$.*

For concreteness and simplicity, we represent an input to the permutation routing problem as a bit matrix B with n rows and p columns. If processor ID j appears in location i in the permutation routing problem instance, then $B_{ij} = 1$; otherwise $B_{ij} = 0$. Rows of B correspond to locations, and columns of B correspond to processors, so each column of B has exactly $\frac{n}{p}$ ones, and there is exactly one 1 in each row. A ROM query to location k reveals row k of this matrix. In order to solve the processor d permutation routing problem correctly, processor d must be able to specify column d of B exactly.

The proof of this lower bound employs the "little birdie" principle: giving a processor additional information never increases the complexity of the problem that the processor must solve. The side information that the "little birdie" reveals a priori

$$\begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \end{bmatrix}$$

FIG. 3.1. *Permutation routing problem input:* $n = 6$, $p = 3$.

$$\begin{bmatrix} 0 & 0 & 1 \\ 0 & 1 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{bmatrix}$$

FIG. 3.2. *A hidden matrix for processor* 1 *consistent with input in Figure* 3.1

to processor d is a perturbed representation of the input specification B called a *hidden matrix*. Providing this matrix to processor d allows us to prove lower bounds on the amount of information subsequent ROM queries provide to processor d.

The hidden matrix is chosen as follows. A permutation routing problem instance B is chosen uniformly at random and revealed to the oracle. Then, based on the choice of B, a hidden matrix H is chosen and revealed to processor d and the oracle. To construct the hidden matrix H, we first choose an $n \times p$ matrix G uniformly at random from binary matrices whose dth column is identical to the dth column of B, and the remaining columns each have either $\lfloor \frac{n}{p(p-1)} \rfloor$ 1's or $\lceil \frac{n}{p(p-1)} \rceil$ 1's, such that every row with a 1 in column d has exactly one 1 in some other column, and all other rows have no 1's. The hidden matrix H is defined to be $H = B \oplus G$, where $\oplus$ denotes the bitwise XOR of the two matrices. This mapping evenly redistributes the 1's from column d of B across the other columns while leaving all other rows unchanged. A pictorial representation of an input matrix and a possible hidden matrix constructed from it are given in Figures 3.1 and 3.2. Based on B and H, the oracle places some number of words in processor d's oracle memory. Processor d then executes its deterministic algorithm and produces its output.

We say that an input C is *consistent* with a hidden matrix H if there is a matrix G perturbing C as defined above such that $C \oplus G = H$. Let $\mathcal{C}(H)$ denote the set of inputs that are consistent with hidden matrix H. For deterministic algorithms, the pair $\langle C, H \rangle$, where C is an input consistent with hidden matrix H uniquely determines S, the setting of oracle memory d. We say that S is consistent with hidden matrix H if there is $C \in \mathcal{C}(H)$ such that H and C determine S. Let $\mathcal{S}(H)$ be the set of all settings of the oracle memory S that are consistent with H. Also, we say that input C is consistent with both H and S if H and C determine S. Let $\mathcal{C}(H, S)$ be the set of all inputs C that are consistent with H and S. Finally, for a hidden matrix H and an input $C \in \mathcal{C}(H)$, let the indicator variable $R(H, C) = 1$ if processor d produces the correct output on C when given H and 0 otherwise.

We first demonstrate that for any given hidden matrix, setting of the oracle memory, and algorithm, there cannot be too many inputs for which the algorithm produces the correct result.

CLAIM 3.9. *In any algorithm for the processor d permutation routing problem, where processor d is provided with any hidden matrix H and any setting of the oracle memory S, if processor d performs no more than $\frac{n \log m}{m \log n}$ ROM queries, then*

$$\sum_{C \in \mathcal{C}(H,S)} R(H,C) \leq Z, \text{ where } Z = \sum_{r=1}^{\frac{n}{p}} \binom{\frac{n \log m}{m \log n}}{r}.$$

Proof. After the setting of the oracle memory and the hidden matrix have been fixed, we can model processor i's actions by a decision tree, in which each node of the decision tree corresponds to a ROM query, and each leaf of the tree corresponds to a processor state achievable after performing at most $\frac{n \log m}{m \log n}$ ROM queries. The number of distinct results that processor d can produce is at most the number of leaves in this tree. We show that for any nonredundant algorithm, i.e., an algorithm that only examines each ROM location once, the tree has at most Z leaves. Any redundant algorithm can be simulated by a nonredundant algorithm, and thus the number of distinct results processor d can produce is at most Z for all algorithms.

Suppose processor d reads the value of row i of C from the ROM. Then, either (a) row i of H is identical to row i of C, or (b) C has a 1 in column d of row i whereas H has a 1 in some other column. Since processor d knows H at the start of the algorithm, the decision tree has branching factor two. Since processor ID d only appears in $\frac{n}{p}$ elements, at most $\frac{n}{p}$ of these ROM queries can discover elements where processor ID d appears. Mapping successful discoveries to left branches and unsuccessful queries to right branches ensures that any algorithm which is nonredundant has a decision tree where any path from root to leaf can have at most $\frac{n}{p}$ left branches. The number of distinct leaves of the decision tree that can be reached by a path from root to leaf with k left branches is at most $\binom{\frac{n \log m}{m \log n}}{k}$. Thus, the possible number of leaves in the decision tree is at most $\binom{\frac{n \log m}{m \log n}}{0} + \binom{\frac{n \log m}{m \log n}}{1} + \cdots + \binom{\frac{n \log m}{m \log n}}{n/p}$. ∎

For any algorithm for the processor d permutation routing problem, let $a(H)$ be the average number of oracle words provided to processor d, where the average is taken over all inputs in $\mathcal{C}(H)$.

CLAIM 3.10. *Consider any algorithm for the processor d permutation routing problem where $n > p^2$, where the little birdie provides processor d with a hidden matrix, and where processor d performs at most $\frac{n \log m}{m \log n}$ ROM queries. For any H, if $a(H) < \frac{n \log m}{4p \log n}$, then on an input chosen uniformly at random from the set $\mathcal{C}(H)$, the probability that processor d produces the correct output is $< \frac{1}{2}$.*

Proof. The total number of inputs in $\mathcal{C}(H)$ on which processor d responds correctly is at most

$$\sum_{C \in \mathcal{C}(H)} R(H,C) = \sum_{S \in \mathcal{S}(H)} \sum_{C \in \mathcal{C}(H,S)} R(H,C),$$

and so the probability of a successful response is at most

$$\frac{1}{|\mathcal{C}(H)|} \sum_{S \in \mathcal{S}(H)} \sum_{C \in \mathcal{C}(H,S)} R(H,C).$$

But, by Claim 3.9, this is at most Y, where

$$Y = \sum_{S \in \mathcal{S}(H)} \min\left(\frac{Z}{|\mathcal{C}(H)|}, \frac{|\mathcal{C}(H,S)|}{|\mathcal{C}(H)|}\right).$$

We assume that $Y \geq \frac{1}{2}$, and we reach a contradiction by showing that this implies that $a(H) \geq \frac{n \log m}{4p \log n}$. First, note that $Y \geq \frac{1}{2}$ implies that $|\mathcal{S}(H)| \geq \frac{|\mathcal{C}(H)|}{2Z}$. Let $|S|$ denote the number of words in oracle memory setting S. Because there are at most $2^{r \log n}$ settings of the oracle memory with $\leq r$ words, there are at least $\frac{3|\mathcal{C}(H)|}{8Z}$ oracle memory settings $S \in \mathcal{S}(H)$ such that

$$|S| \geq \frac{\log\left(\frac{|\mathcal{C}(H)|}{8Z}\right)}{\log n}.$$

We call such oracle memory settings *large settings*. We use this to minimize $a(H)$ subject to $Y \geq \frac{1}{2}$. Note that

$$a(H) = \sum_{S \in \mathcal{S}(H)} |S| \frac{|\mathcal{C}(H,S)|}{|\mathcal{C}(H)|}.$$

By counting the total contribution to $a(H)$ of the large settings, we see that

$$a(H) \geq \frac{3|\mathcal{C}(H)|}{8Z} \cdot \frac{\log\left(\frac{|\mathcal{C}(H)|}{8Z}\right)}{\log n} \cdot \frac{|\mathcal{C}(H,S)|}{|\mathcal{C}(H)|}.$$

We can assume that for any $S \in \mathcal{S}(H)$, $|\mathcal{C}(H,S)| \geq Z$, since given any valid solution, any sets $\mathcal{C}(H,S)$ of smaller cardinality can be combined into sets of cardinality Z without changing the value of Y and without increasing $a(H)$. Thus,

$$a(H) \geq \frac{3 \log\left(\frac{|\mathcal{C}(H)|}{8Z}\right)}{8 \log n}.$$

Using the fact that $n > p^2$, we have that for any H,

$$|\mathcal{C}(H)| \geq \binom{\lfloor \frac{n}{p-1} \rfloor}{\lfloor \frac{n}{p(p-1)} \rfloor}^{p-1}.$$

Using the inequality $\left(\frac{a}{b}\right)^b \leq \binom{a}{b} \leq \left(\frac{ae}{b}\right)^b$, and the fact that $m \leq p$ implies that the sum expressed by Z is dominated by the final term, this gives us

$$a(H) \geq \frac{3n \log m}{8p \log n} - o\left(\frac{n \log m}{p \log n}\right),$$

which is a contradiction. Thus, the probability of a correct response from processor d is less than $\frac{1}{2}$. $\square$

Proof of Lemma 3.3. The number of hidden matrices consistent with a given input is invariant over the choice of input and the number of inputs consistent with a given hidden matrix is invariant over the choice of matrix. Thus, if the average, over all inputs, of the number of oracle words read by processor d is at most $\frac{n \log m}{8p \log n}$, then the average of $a(H)$ over all H is at most $\frac{n \log m}{8p \log n}$. By Markov's inequality, this implies that $a(H) \leq \frac{n \log m}{4p \log n}$ for at least $\frac{1}{2}$ of the hidden matrices H. The input to the permutation routing problem is chosen uniformly at random from the set of all inputs. One method for producing this uniform distribution is as follows: first a hidden matrix H_i is chosen uniformly at random from the set of all hidden matrices that can be given to d. Then, an input C_i is chosen uniformly at random from $\mathcal{C}(H_i)$. With probability at least $\frac{1}{2}$, for the resulting choice of H_i, $a(H_i) \leq \frac{n \log m}{4p \log n}$. By Claim 3.10, if $a(H_i) \leq \frac{n \log m}{4p \log n}$, then the probability that processor d responds correctly is at most $\frac{1}{2}$. Therefore, the probability that processor d responds correctly on an input chosen uniformly at random, when given a hidden matrix, is at most $\frac{3}{4}$. By the little birdie principle, the probability that processor d responds correctly on an input chosen uniformly at random, when not given a hidden matrix, also is at most $\frac{3}{4}$. $\square$

4. The upper bound.

We show that a version of Leighton's Columnsort [26] performs well in both the ER PRAM(m) and the QR PRAM(m). Moreover, this algorithm runs in a model where there is no globally shared ROM for the input (which may not always be realistic in practice), but instead the input is distributed across the processor's local memories.

THEOREM 4.1. *There is an ER PRAM(m) algorithm for sorting n keys which runs in time*

$$O\left(\frac{n}{m}(1-\beta)^{-3.42)}\right),$$

provided $p \geq m \log n$ and $m = O(n^{\beta})$, for some $\beta < 1$. This algorithm has the same running time on the QR PRAM(m).

Proof. It is sufficient to provide a sorting algorithm for the ER PRAM(m). To do so, we use a recursive version of Columnsort, which we describe below. In Columnsort, the n keys are thought of as elements in a matrix M. There is a requirement on the aspect ratio of M: if M is an $s \times r$ matrix, then s must be larger than r^2. The elements are sorted using seven phases, where each phase is one of three types: phases that sort the columns of the matrix, phases that perform an odd-even transposition sort along the rows of the matrix, and phases that route a fixed permutation of the matrix elements, where each column routes an equal number of elements to every other column. The following simple description of Columnsort is provided in [27]. In phases 1, 3, and 7, the columns are sorted into increasing order. In phase 5, odd columns are sorted into increasing order and even columns are sorted into decreasing order. In phase 2, the matrix is "transposed": the items are picked up in column-major order and set down in row-major order (preserving the shape of the matrix). Phase 4 applies the reverse of the permutation applied in phase 2, and phase 6 performs two steps of odd-even transposition sort to each row.

We specify a call to recursive Columnsort in the ER PRAM(m) by two parameters: k, the number of keys to be sorted, and a, the number of memory cells dedicated to this function call. We develop the following recurrence relation for the running time of recursive Columnsort, where the keys are contained in a ROM of size n:

$$RC(k,a) = \text{ O } \left(\frac{k}{a}\right) \text{ if } k \geq a^3 \log n,$$

$$RC(k,a) = 4\ RC\left(k^{2/3},\ ak^{-1/3}\right) + \text{ O}\left(\frac{k}{a}\right) \qquad \text{otherwise.}$$

In the version of Columnsort we use to obtain this recurrence, each of the m memory cells is assigned a set of $\log n$ processors. These $m \log n$ processors sort the n keys, and inform each of the $p - m\log n$ remaining processors of the range of keys that they need to output. Note that since the algorithm makes effective use of only $m \log n$ processors, this algorithm is consistent with the observation that increasing communication throughput, as opposed to adding processors, is required for faster parallel sorting.

The base case for the recurrence, where $k \geq a^3 \log n$, works as follows. The k keys are thought of as being entries in a matrix M of keys of size $\frac{k}{a \log n} \times a \log n$; this matrix satisfies the aspect ratio requirement of Columnsort. We have $a \log n$ available processors, and each of these is assigned to one column of M. Thus, a memory cell serving a set of $\log n$ processors handles data transfer for $\log n$ columns. Recall that each memory cell is assigned to the set of $\log n$ columns to which its processors are assigned. We now show that we can implement each of the three types of phases of Columnsort on the PRAM(m) in time $\mathrm{O}(\frac{k}{a})$. Sorting the columns can be performed by each of the a processors locally in time $O(\frac{k \log k}{a \log n}) = O(\frac{k}{a})$ by any of a variety of known serial algorithms.

Routing the fixed permutation on the matrix elements requires each processor to send an identical number of keys to every other processor, and thus can be done with a single pass through all the entries. A single element is routed by the source and destination processors using the shared memory location that is assigned to the destination processor. The source processor writes to this memory cell the key's address in the ROM, and then the destination processor reads this address. Since each memory cell handles $\log n$ columns, and each column contains $\frac{k}{a \log n}$ keys, the total number of addresses written to each memory cell is $O(\frac{k}{a})$. Thus, the entire permutation can be routed in time $O(\frac{k}{a})$. One phase of odd-even transposition sort can be performed by each processor routing all the keys currently in its column to the processor that is assigned to the neighboring column. This can also be done in time $O(\frac{k}{a})$.

For the case where $k < a^3 \log n$, we sort the keys as follows. The keys are thought of as the elements in a matrix M of size $k^{2/3} \times k^{1/3}$. This matrix satisfies the aspect ratio of Columnsort, and thus we use Columnsort to sort this matrix as well. We can still route the permutations of the matrix M and perform the phases of odd-even transposition sort in time $\mathrm{O}(\frac{k}{a})$. This follows from the fact that for each permutation only k keys need to be routed through the shared memory and this operation can be performed without conflict while making use of each cell during each of the $\mathrm{O}(\frac{k}{a})$ time steps. For the phases which sort the columns of the matrix, we employ parallel calls to recursive Columnsort, one call per column. Each column consists of $k^{2/3}$ keys, and we evenly distribute the a available memory cells (with their associated processors) across the columns. Thus, each of the 4 sorting phases takes time RC $\left(k^{2/3}, ak^{-1/3}\right)$. An example which graphically describes one level of this recursive procedure is given in Figure 4.1.

The algorithm starts with a call to recursive Columnsort with n keys and m memory cells (with each assigned $\log n$ processors). After the n keys are sorted, the $m \log n$ processors can inform each of the remaining $p - m \log n$ processors of the correct sorted list of $\frac{n}{p}$ keys to output in the same amount of time as is required to route one permutation. To analyze the running time of sorting n keys on the ER PRAM(m), we evaluate the recurrence RC (n, m). The running time of the algorithm is dominated by the time for sorting at the bottom of the recursion at level j: $\mathrm{O}(\frac{n}{m}4^j)$. When m is a fixed function of n where $m = \mathrm{O}(n^\beta)$ for $\beta < 1$, this j is the smallest

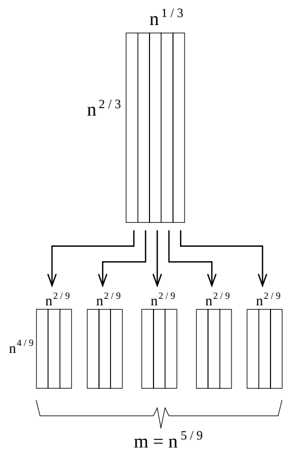

FIG. 4.1. *The recursive algorithm when $m = n^{5/9}$*

integer that satisfies $n^{((2/3)^j)} \leq n^{1-\beta}$, and the following bound on 4^j follows directly:

$$4^j \leq (1-\beta)^{\frac{2}{\log \frac{2}{3}}} \approx (1-\beta)^{-3.42}.$$

Substituting into the formula above gives an upper bound on the running time of $O(\frac{n}{m}(1-\beta)^{-3.42})$. □

5. Other limited bandwidth models. We can use the techniques discussed for the PRAM(m) to derive bounds in other parallel models which address the issue of limited communication throughput. We give a brief discussion of translating the ER PRAM(m) lower bound for sorting into the LogP model [15] and the BSP model [33] and state the best known upper bounds for sorting in these models.

5.1. The LogP model. In the LogP model, limited communication throughput in a parallel machine is enforced by requiring that each processor must wait for a gap of at least g cycles between the transmission of consecutive point-to-point messages. The three other LogP parameters are P, the number of processors, L, the latency of a message in the network, and o, the overhead (in cycles) to place a fixed-size message onto the network. Note that this model uses point-to-point messages for communication, as opposed to using the global shared memory used in the PRAM(m) model. We make the additional assumption that the point-to-point messages, or packets, have a maximum size w, measured in bits.

In this model, only P packets can be issued into the network each g time steps, and thus the throughput of the network is

$$m_L = \left\lceil \frac{wP}{g \log n} \right\rceil$$

$\log n$-bit words per machine cycle. We denote this expression for throughput by m_L to make plain its correspondence with m in the PRAM(m) model. In order to prove a lower bound for sorting in the LogP model, we first show that any LogP model algorithm can be simulated in the oracle model.

LEMMA 5.1. *If $w > \log g$, then given any LogP algorithm A_l that completes in time T, there is an oracle algorithm A_o that computes the same function as A_l, also in time T, and A_o writes at most $2m_LT$ words to each of the oracle memories.*

Proof. We partition the time steps of the LogP algorithm A_l into *epochs*, where each epoch consists of g consecutive time steps. Note that each processor receives at most one message during any epoch. We number the bits of each oracle memory, ignoring word boundaries. We can simulate A_l with an oracle algorithm A_o, where epoch i in A_l is represented in A_o by the oracle utilizing bits $(i-1)(\lfloor\log g\rfloor+1+w)+1$ through $i(\lfloor\log g\rfloor+1+w)+1$ in each oracle memory. The first $\lfloor\log g\rfloor+1$ of the bits for each epoch are used to inform processor j of whether or not a message arrives during that epoch, and in the case of an arrival, the exact time step of the arrival during the epoch. In the case of an arrival, the remaining w bits contain the message contents. In A_o, the processors execute their algorithms for A_l, ignoring steps where messages are sent, and reading from the oracle memory at the start of every epoch. The total number of bits read is $P(\lfloor\log g\rfloor+1+w)\lceil\frac{T}{g}\rceil$. When $w > \log g$, this is $O(m_L T\log n)$, and thus at most $O(m_L T)$ words are required in each oracle memory. □

We briefly point out why we require that the oracle give each processor the timing information provided by the $\lfloor\log g\rfloor+1$ additional bits used for each epoch. The LogP model is an asynchronous model, and thus processors cannot use the timing information to ensure the correctness of the algorithm. However, for the purpose of running time analysis, it is assumed that each processor behaves synchronously. Thus, in the optimal algorithm, it is possible that a processor is able to use the timing information to achieve a better running time than an algorithm that does not make inferences based on this information. Note that any algorithm that does not use this timing information can be simulated in the oracle model using at most $O(m_L T)$ words, even in the case where $w \leq g$.

As in the ER PRAM(m) model, when m_L grows as a fractional power of n, the time required to sort n keys is asymptotically no less than the time required to route all n keys through the network, even in the case where every processor knows all the keys in advance. Let $T_s(n)$ be the optimal sequential time required to sort the n keys.

Theorem 5.2. *In the LogP model, sorting n distinct keys requires expected time*

$$\Omega\left(\frac{T_s(n)}{P}+\frac{n\log m_L}{m_L\log n}+L+o+g\right),$$

provided that $n > P^2$, $w > \log g$, and $T_s(n) \geq L$. This bound holds even in the case that every processor has access to every key at the start of the algorithm.

Proof. We first assume there exists an algorithm A_l for the LogP model, where the average over all inputs of the time to perform A_l is at most $\frac{n\log m_L}{16 m_L\log n}$, and we reach a contradiction. By Lemma 5.1, such an algorithm A_l implies the existence of an oracle model algorithm where the average number of oracle words used is at most $\frac{n\log m_L}{8\log n}$, and the average of the maximum number of ROM queries by any processor is at most $\frac{n\log m_L}{8 m_L\log n}$. However, as we saw in Theorem 3.4, this leads to a contradiction of Lemma 3.3, and thus there does not exist such an algorithm A_l for the ER PRAM(m). The lower bound then follows from the fact that at least one transmission, which requires time at least $\max(L, o, g)$, is required in any algorithm that sorts in time faster than time $T_s(n)$, and that the time to sort on P processors is no faster than the optimal time to sort on one processor divided by P. □

A recursive implementation of Columnsort similar to that presented in section 4 can be tuned to deliver the following asymptotic performance.

Theorem 5.3. *In the LogP model, sorting n keys known to all processors can be* *completed in time*

$$O\left(T_s\left(\frac{n}{P}\right)+\frac{n}{m_L}+L+o+g\right),$$

provided that $P=O(n^\beta)$ for some constant $\beta<1$ and that $w\le\log n$.

The case where the input is distributed across the processors requires long keys to be sent in their entirety, rather than sending just the original index of the key. Otherwise, the algorithm, as well as the resulting bounds, are the same.

5.2. The BSP model. We now briefly describe analogous bounds for sorting in the BSP model proposed by Valiant [33], [34]. The model consists of a set of processors capable of transmitting point-to-point messages through a communication network and facilities for performing barrier synchronization across any subset of the processors. The three parameters of the model are P, the number of processors, L, the minimum number of local computation steps between successive synchronization operations, and g, the ratio between the throughput of local computation to the throughput at which a processor may inject point-to-point messages into the network. As in the LogP model, g enforces a limit on the communication throughput available to each processor. We assume that each transmitted packet is at most w bits in size.

Computation in the BSP model proceeds in *supersteps*, wherein each processor in parallel executes a task consisting of some number of local computation steps, message transmissions, and message receipts, subject to the constraints imposed by the parameter g. The superstep lasts for kL time steps, where k is the minimum integer such that all processors have completed their tasks before time kL. As in the LogP model, the total communication throughput in the BSP model is $m_B=\lceil\frac{wP}{g\log n}\rceil$ words per step of local computation, where each word consists of $\log n$ bits.

THEOREM 5.4. *In the BSP model, sorting n distinct keys requires time*

$$\Omega\left(\frac{T_s(n)}{P}+\frac{n\log m_B}{m_B\log n}+L+o+g\right)$$

when $n>P^2$ and $T_s(n)\ge L$.

Proof. Using the technique from Lemma 5.1, we see that the oracle model is also capable of simulating any BSP algorithm. Thus, the existence of any algorithm that sorts faster than $\frac{n\log m_B}{16m_B\log n}$ again implies the existence of an algorithm that contradicts Lemma 3.3. ◻

Using recursive Columnsort, it is straightforward to show that in the BSP model, sorting any n keys can be completed in time $\mathrm{O}(T_S(\frac{n}{P})+\frac{n}{m_B}+L+g+o)$, provided that $P=\mathrm{O}(n^\beta)$ for some constant $\beta<1$ and that $w\le\log n$. This result for sorting in the BSP model compares with the previous best randomized methods of Gerbessiotis and Valiant [21] for the BSP model with the assumption that each packet that is transmitted consists of exactly one key. Their algorithms run in time $\mathrm{O}(\frac{n\log n}{P}+gp^\epsilon+\frac{gn}{P}+L)$, with high probability, for any positive constant $\epsilon<1$, and for $P\le n^{1-\delta}$, where δ is a small constant depending on ϵ. After the preliminary version of this paper appeared in [2], work on this problem by Goodrich [24] tightened the bounds for sorting on the BSP, giving deterministic algorithms which run in time $\mathrm{O}(\frac{n\log n}{P}+(L+\frac{gn}{P})(\log n/\log(n/P)))$ for all values of P, coupled with a matching lower bound. Other recent work by Gerbessiotis and Siniolakis [20] gives a deterministic algorithm for sorting on the BSP which runs in time $(1+\mathrm{o}(1))(\frac{n\log n}{P}+L)+\mathrm{O}(\frac{gn}{P})$ for $P=n^{1-\epsilon}$, $0<\epsilon<1$, and uses 1-optimal local computation.

6. Conclusion. We have examined the problem of sorting on parallel models with limited communication bandwidth. Our main results include upper and lower bounds for sorting on exclusive- and queued-read variants of the PRAM(m) model which are asymptotically optimal for many practical settings of the parameters and are otherwise asymptotically tight to within at most a logarithmic factor. The form of our bound is noteworthy in that it demonstrates that all efficient parallel algorithms for sorting in this limited bandwidth model depend on large amounts of interprocessor communication. The techniques used to develop the bounds also apply to the LogP model and the BSP model, bridging models which consider the effect of limited bandwidth on parallel computation. For all three models of computation considered, when $m = \Omega(n^{\beta})$, the time to sort and the time to transmit all the keys through the shared memory (or the network) are asymptotically equivalent, even in the case where the entire input is known to each of the processors. Furthermore, as long as $n > p^2$, the bounds do not depend on the parameter p, so that when attempting to improve the performance of parallel sorting on machines with limited communication bandwidth, increasing communication bandwidth is more likely to be beneficial than increasing the number of processors. The lower bound, however, does not apply to the concurrent read version of the PRAM(m) originally introduced by Mansour, Nisan, and Vishkin in [30], and thus the asymptotic complexity of sorting in this model remains an open question.

Acknowledgments. We would like to thank Ralph Werchner for his useful comments and suggestions on an earlier version of this paper and for the valuable and insightful suggestions of the anonymous SICOMP referees.

CONSTRUCTING PLANAR CUTTINGS IN THEORY AND PRACTICE[*]

SARIEL HAR-PELED[†]

Abstract. We present several variants of a new randomized incremental algorithm for computing a cutting in an arrangement of n lines in the plane. The algorithms produce cuttings whose expected size is $O(r^2)$, and the expected running time of the algorithms is $O(nr)$. Both bounds are asymptotically optimal for nondegenerate arrangements. The algorithms are also simple to implement, and we present empirical results showing that they perform well in practice. We also present another efficient algorithm (with slightly worse time bound) that generates small cuttings whose size is guaranteed to be close to the best known upper bound of J. Matoušek [*Discrete Comput. Geom.*, 20 (1998), pp. 427–448].

1. Introduction.

A natural approach for solving various problems in computational geometry is the divide-and-conquer paradigm. A typical application of this paradigm to problems involving a set $\hat{S}$ of n lines in the plane is to fix a parameter $r > 0$ and to partition the plane into regions $R_1, \ldots, R_m$ (those regions are usually vertical trapezoids, or triangles, but we will consider here also convex polygons with more edges) such that the number of lines of $\hat{S}$ that intersect the interior of R_i is at most n/r for any $i = 1, \ldots, m$ (see Figure 1). This allows us to split the problem at hand into subproblems, each involving the subset of lines intersecting a region R_i. Such a partition is called a $(1/r)$-*cutting* of the plane. See [Aga91] for a survey of algorithms that use cuttings. For further work related to cuttings, see [AM95].

The first (though not optimal) construction of cuttings is due to Clarkson [Cla87]. Chazelle and Friedman [CF90] showed the existence of $(1/r)$-cuttings with $m = O(r^2)$ (a bound that is worst-case tight). They also showed that such cuttings, consisting of vertical trapezoids, can be computed in $O(nr)$ time. An optimal deterministic algorithm for generating cuttings was given by [Cha93]. Although those constructions are asymptotically optimal, they do not seem to produce a practically small number of regions. Coming up with a really small number of regions (i.e., reducing the constant of proportionality) is important for the efficiency of (recursive) data structures and algorithms that use cuttings. Currently, the best lower bound on the number of vertical trapezoids in a $(1/r)$-cutting in an arrangement of lines is $2.54(1 - o(1))r^2$, and the optimal cutting has at most $8r^2 + 6r + 4$ trapezoids; see [Mat98]. Improving the upper and lower bounds on the size of cuttings is still open, indicating that our understanding of cuttings is still far from being fully satisfactory. In section 3, we outline Matoušek's construction for achieving the upper bound and show a slightly improved construction (see below for details).

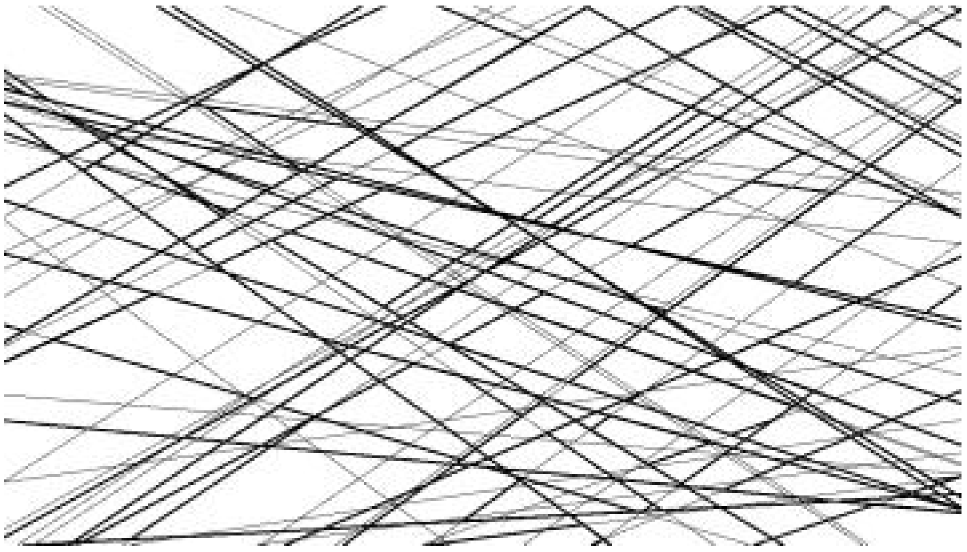

FIG. 1. $(1/20)$-*cutting of* 100 *lines as computed by our demo program* [HP98]*, using the* `PolyTree` *algorithm* (*see section* 4.2). *The boundaries of the cutting regions are marked by thick lines, and each such region intersects at most* 5 *lines in its interior.*

In this paper we propose several variants of a new and simple randomized incremental algorithm `CutRandomInc` for constructing cuttings and prove the expected worst-case tight performance bounds, as stated in the abstract, for `CutRandomInc` and for some of its variants. We also present empirical results on several algorithms/heuristics for computing cuttings that we have implemented. They are mostly variants of our new algorithm, and they all perform well in practice.[1] As already stated, $O(r^2)$ bounds on the expected size of the cuttings for some of those variants can be proved. For the other improved algorithms, no formal proof of performance is currently available, and we leave this as an open question for further research.

Matoušek [Mat98] gave an alternative construction for cuttings, showing that there exists a $(1/r)$-cutting with at most (roughly) $8r^2$ vertical trapezoids. Unfortunately, this construction relies on computing the whole arrangement, and its computation thus takes $O(n^2)$ time. We present a new randomized algorithm that is based on Matoušek's construction; it generates a $(1/r)$-cutting of size $\leq (1+\varepsilon)8r^2$, in $O\left(\frac{nr}{\varepsilon}\log^2 n\right)$ expected time, where $0 < \varepsilon \leq 1$ is any prescribed constant.

In section 2, we present the main two variants of the new algorithm `CutRandomInc` and analyze their expected running time and the expected number of trapezoids that they produce. Specifically, the expected running time is $O(nr)$ and the expected size of the output cutting is $O(r^2)$. We also analyze, in section 2.1, another variant `CRIVPolygon` of the algorithm that also has similar performance bounds. In section 3, we present and analyze our variant of Matoušek's construction. In section 4, we present our empirical results, comparing the new algorithms with several other algorithms/heuristics for constructing cuttings. These algorithms are mostly also variants of `CutRandomInc` (except that we still do not have a formal analysis of their performance bound), but they also include a variant of the older algorithm of Chazelle

[1]In spite of the theoretical importance of cuttings (in the plane and in higher dimensions), we are not aware of any (other) implementation of efficient algorithms for constructing cuttings.

and Friedman. The first batch of the implemented algorithms generate cuttings that consist of vertical trapezoids. Our empirical results show that the cuttings generated by the new algorithm `CutRandomInc` and its variants have between $10r^2$ and $14r^2$ vertical trapezoids. (The algorithms generate smaller cuttings when r is small. For example, for $r = 2$ the constant is about 9.) In contrast, the Chazelle–Friedman algorithm generates cuttings of size roughly $70r^2$. Some variants of our algorithm are based on cuttings by convex polygons with a small number of edges rather than by vertical trapezoids. These perform even better in practice, and we have a proof of optimality for one of the methods `CRIVPolygon`, which can be interpreted as an extension of `CutRandomInc` (see section 2.1). We conclude in section 5 by mentioning a few open problems. A program with a graphical user interface (GUI) demonstrating the algorithms and heuristics presented in the paper is available on the web in source form [HP98].

2. Incremental randomized construction of cuttings.

Given a set $\hat{S}$ of n lines in the plane, let $\mathcal{A}(\hat{S})$ denote the arrangement of $\hat{S}$, namely, the partition of the plane into faces, edges, and vertices as induced by the lines of $\hat{S}$ [Ede87]. Let $\mathcal{A}_{\mathcal{VD}}(\hat{S})$ denote the partition of the plane into vertical trapezoids (i.e., the vertical decomposition of $\mathcal{A}(\hat{S})$), obtained by erecting two vertical segments up and down from each vertex of $\mathcal{A}(\hat{S})$ and extending each of them until it either reaches a line of $\hat{S}$, or otherwise all the way to infinity.

Computing the decomposed arrangement $\mathcal{A}_{\mathcal{VD}}(\hat{S})$ can be done as follows. Pick a random permutation $S = \langle s_1, \dots, s_n \rangle$ of $\hat{S}$. Put $S_i = \langle s_1, \dots, s_i \rangle$ for $i = 1, \dots, n$. We compute incrementally the decomposed arrangements $\mathcal{A}_{\mathcal{VD}}(S_i)$ for $i = 1, \dots, n$ by inserting the ith line s_i of S into $\mathcal{A}_{\mathcal{VD}}(S_{i-1})$. To do so, we compute the *zone* Z_i of s_i in $\mathcal{A}_{\mathcal{VD}}(S_{i-1})$, which is the set of all trapezoids in $\mathcal{A}_{\mathcal{VD}}(S_{i-1})$ that intersect s_i. We split each trapezoid of Z_i into at most four trapezoids, such that no trapezoid intersects s_i in its interior, as in [SA95]. Finally, we perform a pass over all the newly created trapezoids, merging vertical trapezoids that are adjacent and have identical top and bottom lines. The merging step guarantees that the resulting decomposition is $\mathcal{A}_{\mathcal{VD}}(S_i)$, independently of the insertion order of elements in S_i; see [dBvKOS97].

However, if we decide to skip the merging step, the resulting structure, denoted as $\mathcal{A}^{|}(S_i)$, depends on the order in which the lines are inserted into the arrangement. In fact, $\mathcal{A}^{|}(S_i)$ is $\mathcal{A}_{\mathcal{VD}}(S_i)$ with additional superfluous vertical walls. Each such vertical wall is a fragment of a vertical wall that was created at an earlier stage and got split during a later insertion step.

DEFINITION 2.1. *Let $\hat{S}$ be a set of n lines in the plane, and let $0 < c < 1$ be a constant. A* c-cutting *of $\hat{S}$ is a partition of the plane into regions $R_1, \dots, R_m$ such that, for each $i = 1, \dots, m$, the number of lines of $\hat{S}$ that intersect the interior of R_i is at most cn.*

A region C in the plane is c-active *if the number of lines of $\hat{S}$ that intersect the interior of C is larger than cn.*

A $(1/r)$-*cutting* is thus a partition of the plane into m regions such that none of them is $(1/r)$-active. Chazelle and Friedman [CF90] showed that one can compute, in $O(nr)$ time, a $(1/r)$-cutting that consists of $O(r^2)$ vertical trapezoids. Both bounds are asymptotically tight in the worst case.

We propose a new algorithm for computing a cutting that works by incrementally computing the arrangements $\mathcal{A}^{|}(S_i)$, using a random insertion order S of the lines. The new idea in the algorithm is that any "light" trapezoid (i.e., a trapezoid that is not $(1/r)$-active) constructed by the algorithm is immediately added to the final

```
ALGORITHM  CutRandomInc($\hat{S}$, $r$, $merge\text{–}flag$)
    Input:  A set $\hat{S}$ of $n$ lines, a positive integer $r$, and
            a flag $merge\text{–}flag$ that indicates whether merging is used or not
    Output: A $(1/r)$-cutting of $\hat{S}$ by vertical trapezoids
begin
    Choose a random permutation $S = \langle s_1, s_2, \ldots, s_n \rangle$ of $\hat{S}$.
    $\mathcal{C}_0 \leftarrow \{\mathbb{R}^2\}$.
    $i \leftarrow 0$.
    while there are $(1/r)$-active trapezoids in $\mathcal{C}_i$ do
        $i \leftarrow i + 1$
        $Zone_i \leftarrow$ The set of $(1/r)$-active trapezoids in $\mathcal{C}_{i-1}$ that intersect $s_i$.
        $Zone'_i \leftarrow \cup_{\Delta \in Zone_i} split(\Delta, s_i)$,
            where $split(\Delta, s)$ is the operation of splitting a vertical trapezoid $\Delta$
            crossed by a line $s$ into at most four vertical trapezoids, as in
            [dBvKOS97], such that the new trapezoids cover $\Delta$, and they do not
            intersect $s$ in their interior.
        if $merge\text{–}flag$ then
            Merge adjacent trapezoids in $Zone'_i$ that have the same top
                and bottom lines (one of which is $s_i$).
        end if
        $\mathcal{C}_i \leftarrow (\mathcal{C}_{i-1} \setminus Zone_i) \cup Zone'_i$.
    end while

    return $\mathcal{C}_i$
end CutRandomInc
```

FIG. 2. *Algorithm for constructing a $(1/r)$-cutting of an arrangement of lines.*

cutting, and the algorithm does not maintain the arrangement inside such a trapezoid from this point on. In this sense, one can think of the algorithm as being greedy; that is, it adds a trapezoid to the cutting as soon as one is constructed and proceeds in this manner until the whole plane is covered. The algorithm, called `CutRandomInc`, is depicted in Figure 2.

The algorithm has two variants. One does not merge adjacent trapezoids (as in the construction of $\mathcal{A}^{|}(S)$), while the other performs such mergings (as in the construction of $\mathcal{A}_{\mathcal{VD}}(S)$).

If `CutRandomInc` outputs $\mathcal{C}_k$ for some $k < n$, then $\mathcal{C}_k$ has no $(1/r)$-active trapezoids, and it is thus a $(1/r)$-cutting. After the ith line is inserted, it is guaranteed that no active trapezoid of $\mathcal{C}_j$ intersects s_i in its interior for $j \geq i$. This remains true even if merging is done by `CutRandomInc`. In particular, $\mathcal{C}_n$ has no active region, and it is a cutting.

To appreciate the following proof of correctness and optimality of `CutRandomInc`, one has to observe that the covering $\mathcal{C}_i$ of the plane maintained by `CutRandomInc` depends heavily on the order in which the lines are inserted into the arrangement. Indeed, the set of active trapezoids maintained by `CutRandomInc` falls outside the classical frameworks of Clarkson and Shor [CS89], lazy randomized incremental construction [dBDS95], and epsilon nets [HW87]. See Figures 3 and 4 for situations that illustrate the difference between these frameworks and ours. In order to analyze our

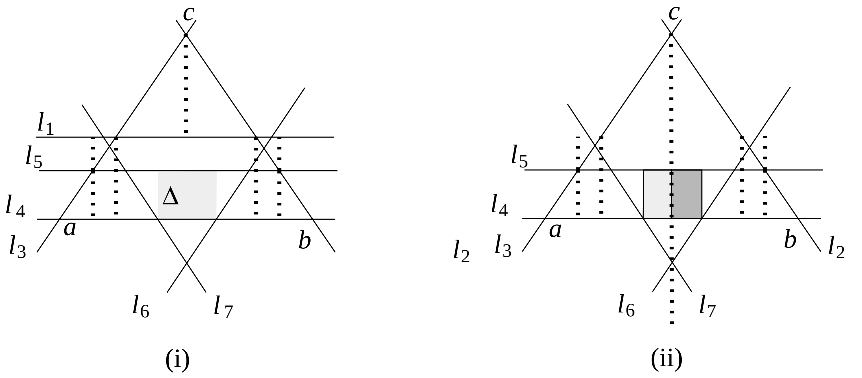

FIG. 3. *If merging is* not *used by* `CutRandomInc`*, an active trapezoid $\Delta \in \mathcal{C}_i$ might disappear if we skip an insertion of a line which does not belong to the defining or crossing sets of Δ. Indeed, if* `CutRandomInc` *inserts the lines in the order $l_1, l_2, \ldots, l_7$, then the trapezoid Δ is created; see* (i)*. However, if we skip the insertion of the line l_1, then the trapezoid Δ is not created, because the ray emanating downward from $l_2 \cap l_3$ intersects it. This implies that there is no "locality" in the determination of which trapezoids arise in the execution of* `CutRandomInc`*, so the standard techniques of* [CS89, dBDS95, HW87] *cannot be applied directly in analyzing* `CutRandomInc`.

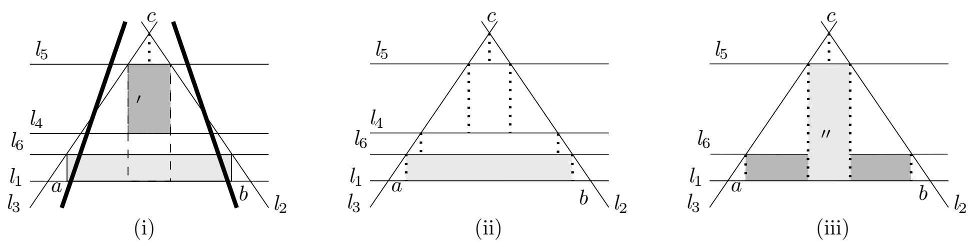

FIG. 4. *Even if merging is used by* `CutRandomInc`*, an active trapezoid $\Delta \in \mathcal{C}_i$ might disappear if we skip an insertion of a line which is completely unrelated to Δ. The thick lines represent two sets of* 100 *parallel lines, and we want to compute a* (1/10)*-cutting. We execute* `CutRandomInc` *with the first 6 lines $l_1, \ldots, l_6$ in this order. Note that any trapezoid that intersects a thick line is active. The first trapezoid Δ' inside $\triangle abc$ that becomes inactive is created when the line l_5 is being inserted; see parts* (i) *and* (ii)*. However, if we skip the insertion of the line l_4 (as in part* (iii)*), the corresponding inactive trapezoid Δ'' will extend downward and intersect Δ. Since Δ'' is inactive, the decomposition of the plane inside Δ'' is no longer maintained. In particular, this implies that the trapezoid Δ will not be created, since it is being blocked by Δ'', and no merging involving areas inside Δ'' will take place. Here too l_4 belongs neither to the defining nor to the crossing sets of Δ.*

algorithms, new techniques need to be developed.

In the following, we denote by R a *selection* of $\hat{S}$ of length $r \le n$, i.e., an ordered sequence of r distinct elements of $\hat{S}$. By a slight abuse of notation, we also denote by R the unordered set of its elements. We define the *weight* of a trapezoid to be the number of lines that cross its interior.

DEFINITION 2.2. Let $\mathcal{T} = \mathcal{T}(\hat{S})$ denote the set of all vertical trapezoids whose top and bottom edges are contained in lines of $\hat{S}$, and whose vertical sides are contained in lines that pass through vertices of $\mathcal{A}(\hat{S})$.

For a selection R of $\hat{S}$, let $\mathcal{CT}_{\mathcal{VD}}(R)$ denote the set of trapezoids of $\mathcal{A}_{\mathcal{VD}}(R)$. A trapezoid in $\mathcal{CT}_{\mathcal{VD}}(R)$ is defined by at most four lines. For an integer $0 \le k \le n$, let $\mathcal{CT}_{\mathcal{VD}}(R, k)$ denote the trapezoids of $\mathcal{CT}_{\mathcal{VD}}(R)$ having weight at least k.

DEFINITION 2.3. A vertical segment that serves as a left or right side of a trapezoid in $\mathcal{T}(\hat{S})$ is called a *splitter*. The *weight* of a splitter is the number of lines of $\hat{S}$

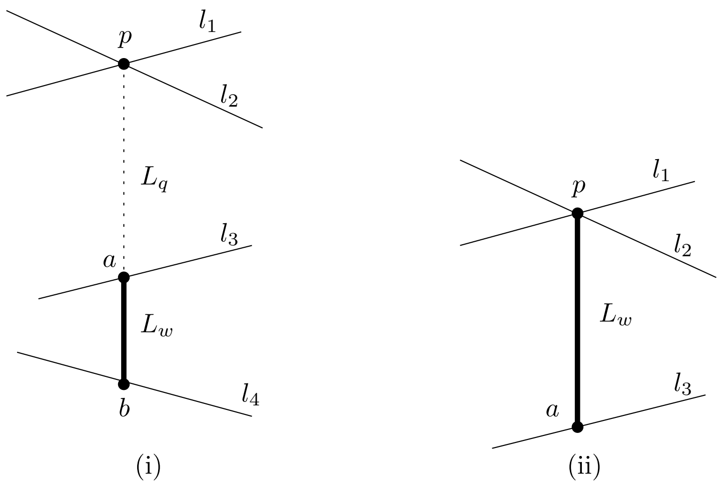

FIG. 5. *Splitters created by* `CutRandomInc`.

that cross the relative interior of the splitter. For a selection R of $\hat{S}$, let $\mathcal{CT}_{\mathcal{SP}}(R)$ denote the set of splitters of the trapezoids of $\mathcal{A}^{|}(R)$, and let $\mathcal{CT}_{\mathcal{SP}}(R,k)$ denote the set of splitters in $\mathcal{CT}_{\mathcal{SP}}(R)$ of weight at least k, where $0 \leq k \leq n$. In general, a splitter in $\mathcal{CT}_{\mathcal{SP}}(R)$ is uniquely defined by four lines: two define the vertex of the arrangement through which the vertical line containing the splitter passes, and two define (pass through) its top and bottom endpoints; see Figure 5(i). There are also splitters that are adjacent to the vertex that induces them (see Figure 5(ii)); these are defined uniquely by three lines.

In the following, S denotes the random permutation of $\hat{S}$ used by `CutRandomInc`.

LEMMA 2.4. *Let s be a splitter induced by $\{l_1, l_2, l_3, l_4\} \subseteq \hat{S}$, so that l_1 and l_2 intersect at a vertex p; s is contained in the vertical line l passing through p; and the endpoints of s are $a = l_3 \cap l$, $b = l_4 \cap l$, with a nearer to p than b. Let L_w be the set of lines of $\hat{S}$ that intersect the relative interior of s, and let L_q be the set of lines of $\hat{S}$ that intersect the relative interior of ap; see Figure* 5(i)*. Then the probability of s to be created by* `CutRandomInc` *is bounded by*

$$\frac{8}{(w+1)^2(q+w+3)^2},$$

where $w = |L_w|, q = |L_q|$.

If one of the endpoints of the splitter is p, then the probability of s to be created is $\leq 6/(w+1)^3$, where $w = |L_w|$ and L_w is the set of lines crossing the relative interior of s; see Figure 5(ii).

Proof. Let A denote the event that l_1, l_2 appear in S before all the lines of $L_q \cup L_w \cup \{l_3\}$, and let B denote the event that l_3, l_4 appear in S before all the lines of L_w.

The event A is a necessary and sufficient condition for pb (or a longer segment) to be created when merging is not used. The event B, conditioned on A, is a necessary and sufficient condition for the vertices delimiting s to be created before s is being "killed." Hence s is created by `CutRandomInc` (without merging) if and only if $A \cap B$ occurs for S. (If merging is used, only one implication holds: If s is created, then $A \cap B$ occurs for S.)

To compute $P(A \cap B)$ it suffices to consider permutations of only the $q+w+4$ lines in $L_q \cup L_w \cup \{l_1, l_2, l_3, l_4\}$. We distinguish between two cases.

(i) The first three lines in such a permutation are the lines l_1, l_2, l_4, in any order in which l_4 is not the third line. This ensures the occurrence of A. We now choose the $w+1$ locations of the lines in $L_w \cup \{l_3\}$ in the permutation and place l_3 at the first of the these locations, thus ensuring B. The number of such permutations is $(6-2)\binom{q+w+1}{w+1} w!q! = 4(q+w+1)!/(w+1)$.

(ii) The first two lines in the permutation are l_1, l_2 (in any order). Again, A is ensured. To ensure B, we choose the $w+2$ locations of the lines in $L_w \cup \{l_3, l_4\}$ and place l_3, l_4 as the first two of them (in any order). The number of such permutations is

$$2!\binom{q+w+2}{w+2} 2!w!q! = \frac{4(q+w+2)!}{(w+1)(w+2)}.$$

It is easily verified that these two cases exhaust all possibilities of $A \cap B$ to arise. Hence,

$$\begin{aligned} P(A \cap B) &= \frac{4(q+w+1)!}{(w+1)(q+w+4)!} + \frac{4(q+w+2)!}{(w+1)(w+2)(q+w+4)!} \\ &\le \frac{4}{(w+1)(q+w+2)(q+w+3)^2} + \frac{4}{(w+1)^2(q+w+3)^2} \\ &\le \frac{8}{(w+1)^2(q+w+3)^2}. \end{aligned}$$

The proof of the second part of the lemma follows by observing that ap is created if and only if l_1, l_2, l_3 appear in S before all the lines of L_w. The probability for this to happen is $3!w!/(w+3)! \le 6/(w+1)^3$. ☐

DEFINITION 2.5. Let $\mathcal{T}_{\mathcal{SP}}(S)$ denote the set of splitters in $\bigcup_{i=1}^{n} \mathcal{CT}_{\mathcal{SP}}(S_i)$, and let $\mathcal{T}_{\mathcal{VD}}(S)$ denote the set of trapezoids in $\bigcup_{i=1}^{n} \mathcal{CT}_{\mathcal{VD}}(S_i)$. Let $\mathcal{T}_{\mathcal{SP}}^{\mathcal{A}}(S) = \bigcup_{i=1}^{n} \mathcal{CT}_{\mathcal{SP}}(S_i, n/(2r))$, and let $\mathcal{T}_{\mathcal{VD}}^{\mathcal{A}}(S) = \bigcup_{i=1}^{n} \mathcal{CT}_{\mathcal{VD}}(S_i, n/r)$.

LEMMA 2.6. *Let S be a random permutation of $\hat{S}$. Then*

$$E\left[\sum_{s \in \mathcal{T}_{\mathcal{SP}}^{\mathcal{A}}(S)} (w(s))^c\right] = O\left(n^c r^{2-c}\right)$$

for $c = 0$ or $c = 1$.

Proof. Let p be a vertex of $\mathcal{A}(\hat{S})$. The expected contribution of all the splitters that lie on the vertical line passing through p to the above sum is at most

$$\begin{aligned} &O\left(\sum_{w=n/2r}^{\infty} \sum_{q=0}^{\infty} \frac{w^c}{(w+1)^2(q+w+3)^2} + \sum_{w=n/2r}^{\infty} \frac{w^c}{(w+1)^3}\right) \\ &= O\left(\sum_{w=n/2r}^{\infty} \sum_{q=0}^{\infty} \frac{w^{c-2}}{(q+w+3)^2} + \left(\frac{n}{r}\right)^{c-2}\right) = O\left(\sum_{w=n/2r}^{\infty} w^{c-3} + \left(\frac{n}{r}\right)^{c-2}\right) \\ &= O\left(\left(\frac{n}{r}\right)^{c-2}\right) \end{aligned}$$

for $c = 0, 1$.

Since there are $O(n^2)$ vertices in $\mathcal{A}(\hat{S})$, it follows that

$$E\left[\sum_{s\in\mathcal{T}^{\mathcal{A}}_{\mathcal{SP}}(S)} (w(s))^c\right] = O\left(n^c r^{2-c}\right). \qquad \square$$

Lemma 2.6 implies that the number of "heavy" splitters generated by `CutRandomInc`, with or without merging, is $O(r^2)$, and their total weight is $O(nr)$.

LEMMA 2.7. *Let S be a random permutation of $\hat{S}$. Then*

$$W = E\left[\sum_{\Delta\in\mathcal{T}^{\mathcal{A}}_{\mathcal{VD}}(S)} (w(\Delta))^c\right] = O\left(n^c r^{2-c}\right)$$

for $c = 0, 1$.

Proof. The probability of a trapezoid Δ of weight w to be created during the computation of $\mathcal{CT}_{\mathcal{VD}}(S)$, if it is defined by $d \le 4$ lines, is proportional to $1/w^d$. Let f^d_w denote the number of trapezoids of $\mathcal{T}_{\mathcal{VD}}(S)$ that are defined by d lines of S and have weight w. Let $F^d_{\le w} = \sum_{q=0}^{w} f^d_q$. By the Clarkson–Shor probabilistic technique [CS89], we have $F^d_{\le w} = O((n/w)^2 w^d) = O(n^2 w^{d-2})$. Let W_d denote the contribution to W made by trapezoids defined by d lines. Then

$$\begin{aligned}
W_d &= \sum_{w=n/r}^{n-d} \frac{f^d_w w^c}{w^d} = \sum_{w=n/r}^{n-d} f^d_w w^{c-d} \le \sum_{w=n/r}^{n-d} (F^d_{\le w} - F^d_{\le w-1}) w^{c-d} \\
&\le F^d_{\le n} n^{c-d} + \sum_{w=n/r}^{n-d-1} F^d_{\le w}(w^{c-d} - (w+1)^{c-d}) = O\left(n^c + \sum_{w=n/r}^{n-d-1} F^d_{\le w} w^{c-d-1}\right) \\
&= O\left(n^c + \sum_{w=n/r}^{n-d-1} n^2 w^{d-2} w^{c-d-1}\right) = O\left(n^c + n^2 \sum_{w=n/r}^{\infty} w^{c-3}\right) \\
&= O\left(n^c + n^2 (n/r)^{c-2}\right) = O\left(n^c r^{2-c}\right).
\end{aligned}$$

Overall, $W = \sum_{d=1}^{4} W_i = O(n^c r^{2-c})$. $\square$

By Lemma 2.7, the expected number of trapezoids in $\mathcal{T}^{\mathcal{A}}_{\mathcal{VD}}(S)$ is $O(r^2)$, and their expected total weight is $O(nr)$.

Remark 2.8. Lemmas 2.6 and 2.7 hold for any $0 \le c < 2$, but we only need the results for $c = 0, 1$.

Let $\nabla\mathcal{VD}_i = \mathcal{CT}_{\mathcal{VD}}(S_i, n/r) \setminus \mathcal{CT}_{\mathcal{VD}}(S_{i-1}, n/r)$, let $\nabla\mathcal{SP}_i = \mathcal{CT}_{\mathcal{SP}}(S_i, n/2r) \setminus \mathcal{CT}_{\mathcal{SP}}(S_{i-1}, n/2r)$, and let $\nabla\mathcal{C}_i$ be the set of *active* trapezoids in $\mathcal{C}_i \setminus \mathcal{C}_{i-1}$, namely, the new active trapezoids created in the ith iteration of the algorithm.

LEMMA 2.9. (a) *Each new trapezoid $\tau \in \nabla\mathcal{C}_i$ must be contained in a new trapezoid $\Delta \in \nabla\mathcal{VD}_i$.*

(b) *Let Δ be a $(1/r)$-active trapezoid in $\nabla\mathcal{VD}_i$, and let $\nabla\mathcal{C}_i(\Delta)$ (resp., $\nabla\mathcal{SP}_i(\Delta)$) denote the set of trapezoids in $\nabla\mathcal{C}_i$ (resp., splitters in $\nabla\mathcal{SP}_i$) that are contained in Δ. Then*

$$\sum_{\tau\in\nabla\mathcal{C}_i(\Delta)} w(\tau) = O\left(w(\Delta) + \sum_{s\in\nabla\mathcal{SP}_i(\Delta)} w(s)\right)$$

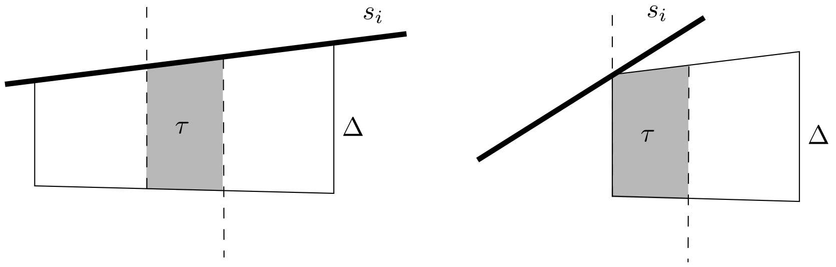

FIG. 6. *A new trapezoid $\tau \in \nabla\mathcal{C}_i$ must lie inside a new trapezoid $\Delta \in \nabla\mathcal{VD}_i$.*

and

$$\left|\nabla\mathcal{C}_i(\Delta)\right| = O\left(\frac{r}{n}w(\Delta) + \left|\nabla\mathcal{SP}_i(\Delta)\right|\right).$$

The lemma holds regardless of whether or not `CutRandomInc` *performs merging.*

Proof. (a) Let $\tau \in \nabla\mathcal{C}_i$ be an active trapezoid created in the ith iteration of `CutRandomInc`, and let Δ be the trapezoid of $\mathcal{CT}_{\mathcal{VD}}(S_i)$ that contains Δ. If the line s_i is the top or bottom line of τ, then clearly Δ is also newly created. Otherwise s_i must delimit one of the vertical sides of τ. This side is also a side of Δ, so Δ is newly created. Hence $\Delta \in \nabla\mathcal{VD}_i$. See Figure 6.

(b) Let τ be a trapezoid in $\nabla\mathcal{C}_i(\Delta)$. We charge the weight of τ either to (a portion of) the weight of the (active) trapezoid of Δ, or to a new "heavy" splitter that bounds τ.

As noted in (a), at least one of the splitters of τ must be new (i.e., created in the ith iteration), and this remains true even if τ was created by merging a few active trapezoids of $\mathcal{C}_{i-1}$.

Consider the lines $l \in \hat{S}$ that cross τ. If at least half of these lines intersect the ceiling and/or floor of Δ, we charge $w(\tau)$ to those intersection points whose number is at least $w(\tau)/2$. Since there are at most $2w(\Delta)$ such intersections on the boundary of Δ, it follows that the sum of the weights $w(\tau)$ of such trapezoids is at most $4w(\Delta)$.

So one can assume that at least half the lines that cross τ do not intersect either the floor or the ceiling of τ. This implies that the new splitter must intersect at least $w(\tau)/2 > n/(2r)$ of these lines, which implies that $s \in \nabla\mathcal{SP}_i$. Thus, we charge $w(\tau)$ to $w(s)$. Since $w(\tau) \leq 2w(s)$, and each such splitter can be charged at most twice, the first inequality of (b) follows.

As for the second inequality, if a $(1/r)$-active trapezoid $\tau \in \nabla\mathcal{C}_i(\Delta)$ does not have a splitter of $\nabla\mathcal{SP}_i$ as one of its sides, then there at least n/r intersections between the lines crossing τ and the bottom and top edges of τ. The number of such trapezoids within Δ is at most $2w(\Delta)/(n/r) = O((r/n)w(\Delta))$. This is easily seen to imply the second inequality. ∎

THEOREM 2.10. *The expected size of the cutting generated by* `CutRandomInc` *(with or without merging) is $O(r^2)$ and the expected running time is $O(nr)$.*

Proof. Since the direct work involved in creating the children of a trapezoid is proportional to the number of lines that cross it, we can bound the overall work performed by `CutRandomInc` by the total weight of the active trapezoids that it generates.

Of course, if we perform merging, there is also additional work associated with merging trapezoids. However, the merging stage can be performed in linear time in the total weight of the split trapezoids. This requires a somewhat careful but routine implementation, so that the running time remains linear even when merging the conflict lists of a potentially large number of trapezoids, during the creation of a single new (merged) trapezoid.

Thus, using Lemma 2.9(a), the expected running time is proportional to

$$E\left[\sum_{i=1}^{n}\sum_{\tau\in\nabla\mathcal{C}_i} w(\tau)\right] = E\left[\sum_{i=1}^{n}\sum_{\Delta\in\nabla\mathcal{VD}_i}\sum_{\tau\in\nabla\mathcal{C}_i(\Delta)} w(\tau)\right].$$

By Lemma 2.9(b), we have

$$\begin{aligned} E\left[\sum_{i=1}^{n}\sum_{\tau\in\nabla\mathcal{C}_i} w(\tau)\right] &= E\left[\sum_{i=1}^{n}\sum_{\Delta\in\nabla\mathcal{VD}_i} O\left(w(\Delta)+\sum_{s\in\nabla\mathcal{SP}_i(\Delta)} w(s)\right)\right] \\ &= O\left(E\left[\sum_{\Delta\in\mathcal{T}^{\mathcal{A}}_{\mathcal{VD}}(S)} w(\Delta)+\sum_{s\in\mathcal{T}^{\mathcal{A}}_{\mathcal{SP}}(S)} w(s)\right]\right) = O(nr) \end{aligned}$$

by Lemmas 2.6, 2.7.

As for the expected size of the cutting,

$$\begin{aligned} E\left[\sum_{i=1}^{n}|\nabla\mathcal{C}_i|\right] &= E\left[\sum_{i=1}^{n}\sum_{\Delta\in\nabla\mathcal{VD}_i}|\nabla\mathcal{C}_i(\Delta)|\right] = O\left(E\left[\sum_{\Delta\in\mathcal{T}^{\mathcal{A}}_{\mathcal{VD}}(S)}\frac{r}{n}w(\Delta)+|\mathcal{T}^{\mathcal{A}}_{\mathcal{SP}}(S)|\right]\right) \\ &= O(r^2), \end{aligned}$$

by Lemma 2.9(b). □

The algorithm `CutRandomInc` works also for planar arrangements of segments and x-monotone curves (such that the number of intersections of any pair of curves is bounded by a constant). This follows by a straightforward adaption of the proof to those cases, which we omit, and it is summarized in the following proposition.

PROPOSITION 2.11. *Let $\hat{\Gamma}$ be a set of x-monotone curves such that each pair intersects in at most a constant number of points. Then the expected size of the $(1/r)$-cutting generated by* `CutRandomInc` *for Γ is $O(r^2)$, and the expected running time is $O(nr)$ for any integer $1 \le r \le n$ in an appropriate model of computation.*[2]

However, the arrangement of a set of n segments or curves might have subquadratic complexity (since the number of intersection points might be subquadratic). This raises the question of whether `CutRandomInc` generates smaller cuttings for such sparse arrangements.

Indeed, an algorithm of [dBS95] generates cuttings of size $O(r+\frac{r^2}{n^2}\kappa)$ in expected time $O\left(n\log r+\frac{r}{n}\kappa\right)$, where κ is the overall complexity of the arrangement. Using `CutRandomInc` for this case, we obtain the following slightly weaker bounds.

PROPOSITION 2.12. *Let $\hat{\Gamma}$ be a set of n curves, such that each pair of curves of $\hat{\Gamma}$ intersect in at most a constant number of points. Then the expectedsize of the*

[2]Namely, the real-RAM model—the intersection of two curves, and the value of a curve at a certain x-coordinate can be computed in $O(1)$ time.

$(1/r)$-cutting generated by `CutRandomInc`*, when applied to $\hat{\Gamma}$, is*

$$O\left(r \log r + \frac{r^2}{n^2}\kappa\right),$$

and the expected running time is $O(n \log^2 r + r\kappa/n)$ for any integer $1 \le r \le n$, where κ is the complexity of $\mathcal{A}(\hat{\Gamma})$.

Since `CutRandomInc` generates superficial splitters, the results for sparse arrangements are slightly worse (by a factor of $\log r$ if κ is relatively small) than those of [dBS95]. We omit any further details. The algorithm of [dBS95] is similar to the algorithm of Chazelle and Friedman [CF90], and we therefore believe that in practice `CutRandomInc` (with merging) will generate much smaller cuttings for $\mathcal{A}(\hat{\Gamma})$, as the results of section 4 might suggest.

Remark 2.13. An interesting question is whether `CutRandomInc` can be extended to higher dimensions. If we execute `CutRandomInc` in higher dimensions, we need to use a more complicated technique in decomposing each of our "vertical trapezoids" whenever it intersects a newly inserted hyperplane. Chazelle and Friedman's algorithm uses bottom vertex triangulation for this decomposition. However, in our case, it is easy to verify that `CutRandomInc` might generate simplices so that the size of their defining set need not be bounded by a constant, if we use bottom vertex triangulation. This implies that the current analysis cannot be extended to this case. We leave the problem of extending `CutRandomInc` to higher (say, three) dimensions as an open problem for further research.

2.1. Cuttings by vertical polygons. In this section, we present another variant of `CutRandomInc` that uses "vertical polygons" instead of vertical trapezoids and establish similar optimal performance bounds for this variant.

Definition 2.14. Let $\hat{S}$ be a set of n lines. A convex polygon P is a *μ-vertical polygon* of $\hat{S}$ if the boundary of P, except for the two vertical sides of P, if any, is contained in $\bigcup \hat{S}$, and the number of nonvertical edges of P is at most μ, where μ is a small positive constant (the case $\mu = 2$ is the case of vertical trapezoids). We denote the set of all such polygons by $\mathcal{VP}_\mu(\hat{S})$. A μ-vertical polygon P is a *μ-corridor* if its two splitters (i.e., vertical sides) are defined by vertices of $\mathcal{A}(\hat{S})$ lying on the boundary of P. Note that the size of the defining set of a μ-corridor is $\le \mu + 2$.

In the following, we consider μ to be a prescribed small constant.

We can use μ-vertical polygons instead of vertical trapezoids in `CutRandomInc`; namely, each region maintained by `CutRandomInc` is a μ-vertical polygon. Whenever a new region is being created, it is split into two subregions if it has more than μ nonvertical edges. This is done by erecting a splitter from an appropriate vertex of the region. Let `CRIVPolygon` denote this variant of `CutRandomInc`. Here too we have the option of performing *merging*. That is, we merge an as-long-as-possible sequence of adjacent μ-vertical polygons within the same face of $\mathcal{A}(S_i)$ into a single vertical polygon, as long as the number of its nonvertical edges does not exceed μ.

The gain in using μ-vertical polygons instead of vertical trapezoids is that the number of splitters generated is much smaller, yielding smaller cuttings. See section 4. The disadvantage is that the regions output by the algorithm are more complex to handle in any subsequent application of the cutting.

Lemma 2.15. *Let $\hat{S}$ be a set of n lines in the plane. The number of μ-corridors of $\mathcal{A}(\hat{S})$ is $O(n^2)$.*

Proof. A vertex p of $\mathcal{A}(\hat{S})$ is the left-bottom vertex of onlya constant number ($O(\mu)$) of μ-corridors. The lemma follows since the number of such vertices is $O(n^2)$. ∎

Note that any μ-vertical polygon is contained in only a constant number of μ-corridors. Let S be a random permutation of the lines of $\hat{S}$, and let $\mathcal{CO}_i$ denote the set of active μ-corridors in $\mathcal{A}(S_i)$ for $i = 1, \dots, n$. Let $\mathcal{T}^{\mathcal{A}}_{\mathcal{CO}} = \bigcup_{i=1}^{n} \mathcal{CO}_i$. Note that those corridors are not necessarily disjoint. Moreover, each active region maintained by `CRIVPolygon` is contained inside at least one active corridor, and the set of splitters generated by `CRIVPolygon` is a subset of the set of splitters generated by `CutRandomInc`. Thus, Lemma 2.6 holds for the active splitters generated by `CRIVPolygon`. As for the corridors, we have the following lemma.

LEMMA 2.16. *Let S be a random permutation of $\hat{S}$; then*

$$W = E\left[\sum_{\tau \in \mathcal{T}^{\mathcal{A}}_{\mathcal{CO}}(S)} (w(\tau))^c\right] = O\left(n^c r^{2-c}\right)$$

for $c = 0, 1$.

Proof. We follow the proof of Lemma 2.7, using Lemma 2.15 to bound the number of "heavy" μ-corridors. This follows by observing that we can apply the Clarkson–Shor technique [CS89] to bound the number of μ-corridors with weight at most k. Indeed, arguing as in the proof of Lemma 2.7, the expected contribution to total weight of μ-vertical corridors having weight at least $n/(2r)$, created by the algorithm and defined by d lines, is $O(n^c r^{2-c})$ for $d = 1, \dots, \mu + 4$. ∎

THEOREM 2.17. *The expected size of the cutting generated by* `CRIVPolygon` *(with or without merging) is $O(r^2)$, and the expected running time is $O(nr)$.*

Proof. We only sketch the proof, since it is similar to the analysis of `CutRandomInc`. Note that the proof of Lemma 2.9 can be adapted to handle active corridors and the active regions maintained by `CRIVPolygon`. Indeed, after the ith iteration of the algorithm, each newly created active μ-vertical polygon is contained in (at least one) newly created active μ-corridor. We assign each such μ-vertical polygon to one of those newly active μ-corridors in an arbitrary manner.

Now, to bound the work associated with such a μ-corridor X, we apply the same charging scheme used in Lemma 2.9, charging the weight of all the active μ-vertical polygons that were assigned to X (all of them are contained inside X) to the weight of X and to the weight of the newly created "heavy" splitters inside X.

Since each splitter is contained in a constant number of μ-corridors, this implies that the overall charge made to a newly created splitter s is $O(w(s))$.

Overall, this implies that the overall expected running time of the algorithm is bounded by the total weight of the active μ-corridors and the heavy splitters that it creates.

By Lemmas 2.6 and 2.16, the expected total weight of the μ-vertical polygons generated by `CRIVPolygon` is $O(nr)$, which implies immediately that the expected running time is $O(nr)$, and the expected size of the cuttings is $O(r^2)$, by following the proof of Theorem 2.10. We omit the details. ∎

Remark 2.18. We can further modify the algorithm `CRIVPolygon` so that it tries to remove inactive regions from the left and right sides of any newly created active region. We call this variant `PolyVertical`. It is easy to verify that the same proof of correctness, with slight modifications, works also for `PolyVertical`.

3. Generating small cuttings. In this section, we present an efficient algorithm that generates cuttings of guaranteed small size. The algorithm is based on

Matoušek's construction of small cuttings [Mat98]. We first review this construction and then show how to modify it for building small cuttings efficiently.

Definition 3.1 (see [Mat98]). Let $\hat{S}$ be a set of n lines in the plane in general position, i.e., every pair of lines intersects in exactly one point, no three have a common point, no line is vertical or horizontal, and the x-coordinates of all intersections are distinct. The *level* of a point in the plane is the number of lines of $\hat{S}$ lying strictly below it. Consider the set E_k of all edges of the arrangement of $\hat{S}$ having level k (where $0 \le k < n$). These edges form an x-monotone connected polygonal line, which is called the *level* k of the arrangement of $\hat{S}$.

Definition 3.2 (see [Mat98]). Let E_k be the level k in the arrangement $\mathcal{A}(\hat{S})$ with edges $e_0, e_1, \dots, e_t$ (from left to right), and let p_i be a point in the interior of the edge e_i, for $i = 0, \dots, t$. The *q-simplification* of the level k for an integer parameter $1 \le q \le t$ is defined as the x-monotone polygonal line containing the part of e_0 to the left of the point p_0, the segments $p_0 p_q$, $p_q p_{2q}, \dots, p_{\lfloor (t-1)/q \rfloor q} p_t$, and the part of e_t to the right of p_t. Let $\mathrm{simp}_q(E_k)$ denote this polygonal line.

Let $\hat{S}$ be a set of n lines in general position, and let $\mathcal{E}_{i,q}$ denote the union of the levels $E_i, E_{i+q}, \dots, E_{n+i-q}$ for $i = 0, \dots, q-1$. Let $\mathrm{simp}_q(\mathcal{E}_{i,q})$ denote the set of edges of the q-simplifications of the levels of $\mathcal{E}_{i,q}$.

Matoušek showed that the vertical decomposition of the plane induced by $\mathrm{simp}_q(\mathcal{E}_{i,q})$, where $q = n/(2r)$ (we assume that n is divisible by $2r$), is a $(1/r)$-cutting of the plane for any $i = 0, \dots, q-1$. Moreover, the following holds.

Theorem 3.3 (see [Mat98]). *Let $\hat{S}$ be a set of n lines in general position, let r be a positive integer, and let $q = n/(2r)$. Then the subdivision of the plane defined by the vertical decomposition of $\mathrm{simp}_q(\mathcal{E}_{m,q})$ is a $(1/r)$-cutting of $\mathcal{A}(\hat{S})$, where $0 \le m < q$ is the index $i \in \{0, \dots, q-1\}$ for which $|\mathcal{E}_{i,q}|$ is minimized. Moreover, the cutting generated has at most $8r^2 + 6r + 4$ trapezoids.*

Remark 3.4. (i) Matoušek's construction can be slightly improved, by noting that the leftmost and rightmost points in a q-simplification of a level can be placed at "infinity"; that is, we replace the first and second edges in the q-simplification by a ray emanating from p_q which is parallel to e_0. We perform a similar shortcut for the two last edges of the simplified level. We denote this improved simplification by simp'_q. It is easy to prove that using this improved simplification also results in a $(1/r)$-cutting of $\mathcal{A}(\hat{S})$ with at most $8r^2 + 6r + 4 - 4 \cdot 2r = 8r^2 - 2r + 4$ vertical trapezoids.

(ii) Inspecting Matoušek's construction, we see that if we can only find an i such that $|\mathcal{E}_{i,q}| \le cn^2/q$, where $c > 1$ is a prescribed constant, then the vertical decomposition induced by $\mathrm{simp}'_q(\mathcal{E}_{i,q})$ is a $(1/r)$-cutting having $\le c(8r^2 - 2r + 4)$ trapezoids.

Let $n_i = |\mathcal{E}_{i,q}|$ for $i = 0, \dots, q-1$. Matoušek's construction is carried out by computing the numbers $n_0, \dots, n_q$ and picking the minimal number n_i, which is guaranteed to be no larger than the average n^2/q. Unfortunately, implementing this scheme explicitly requires computing the whole arrangement $\mathcal{A}(\hat{S})$, so the resulting running time is $O(n^2)$. Let us assume for the moment that one can compute any of the numbers n_i quickly. Then, as the following lemma shows, one can compute a number n_i which is $\le (1+\varepsilon)n^2/q$, without computing all the n_i's.

Lemma 3.5. *Let $n_0, \dots, n_{q-1}$ be q positive integers, whose sum $m = \sum_{i=0}^{q-1} n_i$ is known in advance, and let $\varepsilon > 0$ be a prescribed constant. One can compute an index $0 \le k < q$, such that $n_k \le \lceil (1+\varepsilon)m/q \rceil$, by repeatedly picking uniformly and independently a random index $0 \le i < q$ and by checking whether $n_i \le \lceil (1+\varepsilon)m/q \rceil$. The expected number of iterations required is $\le 1 + 1/\varepsilon$.*

Proof. Let Y_i be the random variable which is the value of n_i picked in the ith iteration. Using Markov's inequality[3], one obtains

$$Pr\left[Y_i \geq (1+\varepsilon)\frac{m}{q}\right] \leq \frac{E\left[Y_i\right]}{(1+\varepsilon)\frac{m}{q}}.$$

Since $E[Y_i] = m/q$, we have that the probability for failure in the ith iteration is

$$Pr\left[Y_i \geq (1+\varepsilon)\frac{m}{q}\right] \leq \frac{1}{1+\varepsilon}.$$

Let X denote the number of iterations required by the algorithm. Then $E[X]$ is bounded by the expected number of trials to the first success in a geometric distribution with probability $p \geq 1 - \frac{1}{1+\varepsilon}$. Thus, the expected number of iterations is bounded by

$$E[X] \leq \frac{1}{p} \leq \frac{1}{1-\frac{1}{1+\varepsilon}} = 1 + \frac{1}{\varepsilon}. \qquad \square$$

To apply Lemma 3.5 in our setting, we need to supply an efficient algorithm for computing the level of an arrangement of lines in the plane.

LEMMA 3.6. *Let $\hat{S}$ be a set of n lines in the plane. Then one can compute, in $O((n+h)\log^2 n)$ time, the level k of $\mathcal{A}(\hat{S})$, where $h = |E_k|$ is the complexity of the level.*

Proof. The technique presented here is well known (see [BDH99] for a recent example); we include it for the sake of completeness of exposition. Let $e_0, \ldots, e_t$ be the edges of the level k from left to right (where e_0, e_t are rays).

Let e be an edge of the level k. Let f be the face of $\mathcal{A}(\hat{S})$ having e on its boundary and lying above e. In particular, all the edges on the bottom part of ∂f belong to the level k.

Let $f_1, \ldots, f_r$ be the faces of $\mathcal{A}(\hat{S})$ having the level k as their "floor," from left to right. The ray e_0 can be computed in $O(n)$ time since it lies on line l_k of $\hat{S}$, with the kth largest slope. Moreover, by intersecting l_k with the other lines of $\hat{S}$, one can compute e_0 in linear time.

Any face of $\mathcal{A}(\hat{S})$ is uniquely defined as an intersection of half-planes induced by the lines of $\hat{S}$. For the face f_1, we can compute the half-planes and their intersection that represents f_1, in $O(n \log n)$ time; see [dBvKOS97]. To carry out the computation of the bottom parts of $f_2, \ldots, f_r$, one can dynamically maintain the intersection representing f_i as we traverse the level k from left to right. To do so, we will use the data structure of Overmars and Van Leeuwen [OvL81] that maintains such an intersection, with $O(\log^2 n)$ time for each update operation. As we move from f_i to f_{i+1} through a vertex v, we have to "flip" the two half-planes associated with the two lines passing through v, at a cost of $O(\log^2 n)$ time per vertex. Similarly, if we are given an edge e on the boundary of f_i we can compute the next edge in $O(\log^2 n)$ time.

Thus, we can compute the level k of $\mathcal{A}(\hat{S})$ in $O((n+h)\log^2 n)$ time. $\square$

Combining Lemmas 3.5 and 3.6, we have the following theorem.

THEOREM 3.7. *Let $\hat{S}$ be a set of n lines in the plane, and let $0 < \varepsilon \leq 1$ be a prescribed constant. Then one can compute a $(1/r)$-cutting of $\mathcal{A}(\hat{S})$, having at*

[3]The inequality asserts that $Pr[Y \geq t] \leq \frac{E[Y]}{t}$ for a random variable Y that assumes only nonnegative values.

most $(1+\varepsilon)(8r^2 - 2r + 4)$ *trapezoids. The expected running time of the algorithm is* $O\left(\left(1+\frac{1}{\varepsilon}\right) nr \log^2 n\right)$.

Proof. By the above discussion, it is enough to find an index $0 \le i \le q-1$, such that $|\mathcal{E}_{i,q}| \le M = (1+\varepsilon)\frac{n^2}{q} \le 2(1+\varepsilon)nr$, where $q = \lceil n/(2r) \rceil$. By Remark 3.4(ii), the vertical decomposition of $\mathrm{simp'}_q(\mathcal{E}_{i,q})$ is a $(1/r)$-cutting of the required size.

Picking i randomly, we have to check whether $|\mathcal{E}_{i,q}| \le M$. We can compute $\mathcal{E}_{i,q}$ by computing the levels $E_i, E_{i+q}, \dots, E_{i+\lfloor (n-i-1)/q \rfloor q}$ in an output-sensitive manner, using Lemma 3.6. Note that if $|\mathcal{E}_{i,q}| > M$, we can abort as soon as the number of edges we computed exceeds M. Thus, we can check if $|\mathcal{E}_{i,q}| \le M$ takes $O(nr \log^2 n)$ time. By Lemma 3.6, the expected number of iterations the algorithm performs until the inequality $|\mathcal{E}_{i,q}| \le M$ will be satisfied is $\le 1 + 1/\varepsilon$. Thus, the expected running time of the algorithm is

$$O\left(\left(1+\frac{1}{\varepsilon}\right) nr \log^2 n\right),$$

since the vertical decomposition of $\mathrm{simp'}_q(\mathcal{E}_{i,q})$ (which is the resulting cutting) can be computed in additional $O(nr)$ time. In fact, one can also compute, in $O(nr)$ time, for each trapezoid in the cutting, the lines of $\hat{S}$ that intersect it. $\square$

4. Empirical results.

In this section, we present the empirical results we got for computing cuttings in the plane using `CutRandomInc` and various related heuristics that we have implemented and experimented with. A program with a GUI demonstrating the algorithms and heuristics presented in the paper is available on the web in source form [HP98].

4.1. The implemented algorithms—using vertical trapezoids.

We have implemented the algorithm `CutRandomInc` presented in section 2 as well as several other algorithms for constructing cuttings. In this section, we report on the experimental results that we obtained.

Most of the algorithms we have implemented are variants of `CutRandomInc`. The algorithms implemented are the following (we denote by $K(\Delta)$ the set of lines that cross a vertical trapezoid Δ).

Classical: This is a variant of the algorithm of Chazelle and Friedman [CF90] for constructing a cutting. We pick a sample $R \subseteq \hat{S}$ of r lines and compute its arrangement $A = \mathcal{A}_{\mathcal{VD}}(R)$. For each active trapezoid $\Delta \in A$, we pick a random sample $R_\Delta \subseteq K(\Delta)$ of size $6k \log k$, where $k = \lceil r|K(\Delta)|/n \rceil$, and compute the arrangement of $\mathcal{A}_{\mathcal{VD}}(R_\Delta)$ inside Δ. If $\mathcal{A}_{\mathcal{VD}}(R_\Delta)$ is not a $(1/r)$-cutting, then the classical algorithm performs resampling inside Δ until it reaches a cutting. Our implementation is more naive, and it simply continues recursively into the active subtrapezoids of $\mathcal{A}_{\mathcal{VD}}(R_\Delta)$.

Cut randomized incremental: This is `CutRandomInc` without merging, as described in Figure 2.

Randomized incremental: This is `CutRandomInc` with merging.

The following four heuristics, for which we currently do not have a proof of any concrete bound on the expected size of the cutting that they generate, also perform well in practice.

Parallel incremental: Let $\mathcal{C}_i$ be the covering generated in the ith iteration of the algorithm. For each active trapezoid $\Delta \in \mathcal{C}_i$, pick a random line from $K(\Delta)$ and insert it into Δ (i.e., split Δ accordingly). Continue until there are no active trapezoids. Note that unlike `CutRandomInc` the insertion operations are performed locally inside each trapezoid, and the line chosen for insertion in each trapezoid is independent of the lines chosen for other trapezoids.

Greedy trapezoid: This is a variant of `CutRandomInc`, where we try to be "smarter" about the line inserted into the partition in each iteration. Let V_i be the set of trapezoids of $\mathcal{C}_i$ with maximal weight. We pick randomly a trapezoid Δ out of the trapezoids of V_i and pick randomly a line s from $K(\Delta)$. We then insert s into $\mathcal{C}_i$.

Greedy line: Similar to *greedy trapezoid*, but here we compute the set $\mathcal{U}$ of lines of $\hat{S}$, for which $w'(s)$ is maximal, where $w'(s)$ is the number of active trapezoids in $\mathcal{C}_i$ that intersect the line s. We pick randomly a line from $\mathcal{U}$ and insert it into the current partition of the plane.

Greedy weighted line: Similar to *greedy line*, but our weight function is

$$w'(s) = \sum_{\Delta \in \mathcal{C}_i, s \cap \Delta \neq \emptyset, w(\Delta) > n/r} \left\lfloor \frac{w(\Delta)}{\left\lfloor \frac{n}{3r} \right\rfloor} \right\rfloor ;$$

namely, we give a higher priority to lines that intersect heavier $(1/r)$-active trapezoids.

4.2. Polygonal cuttings. In judging the quality of cuttings, the size of the cutting is of major concern. However, other factors might also be important. For example we want the regions defining the cutting to be as simple as possible. Furthermore, there are applications where we are not interested directly in the size of the cutting, but rather in the overall number of vertices defining the cutting regions. This is useful when applying cuttings in the dual plane and transforming the vertices of the cutting back to the primal plane, as done in the computation of partition trees [Mat92]. A natural question is the following: Can one compute better cuttings if one is willing to use cutting regions which are different from vertical trapezoids?

For example, if one is willing to cut using nonconvex regions having a nonconstant description complexity, the size of the cutting can be improved to $4r^2+2r+2$ [Mat98]. On the other hand, if one wishes to cut a collection of lines by triangles instead of trapezoids, the situation becomes somewhat disappointing, because the smallest cuttings currently known for this case are generated by taking the cutting of Remark 3.4 and by splitting each trapezoid into two triangles. This results in cuttings having (roughly) $16r^2$ triangles.

In this section, we present a slightly different approach for computing cuttings, suggested to us by Matoušek, that works extremely well in practice. The new approach, a variant of which has already been presented in section 2.1, is based on cuttings using polygonal convex regions with a small number of sides, instead of vertical trapezoids. Namely, we apply `CutRandomInc`, where each region is a convex polygon (of constant complexity). Whenever we insert a new line into an active region, we split the polygon into two new polygons. Of course, it might be that the number of vertices of a new polygon is too large. If so, we split each such polygon into two subpolygons ensuring that the number of vertices of the new polygons is below our threshold.

Intuitively, the benefit in this approach is that the number of superfluous entities (i.e., vertical walls in the case of vertical trapezoids) participating in the definition of the cutting regions is much smaller. Moreover, since the cutting regions are less restrictive, the algorithm can be more flexible in its maintenance of the active regions.

Here are the different methods we tried.

PolyTree: We use `CutRandomInc` where each region is a convex polygon having at most k-sides. When inserting a new line, we first split each of the active regions

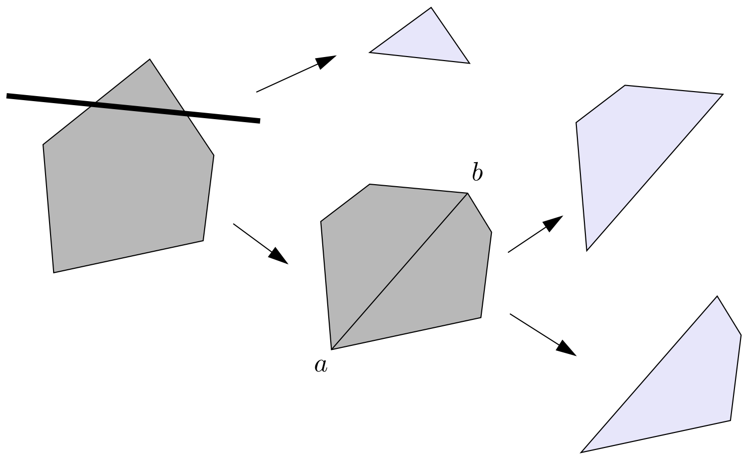

FIG. 7. *In the* `PolyTree` *algorithm, each time a polygon is being split by a line, we might have to further split it because a split region might have too many vertices.*

that intersect it into two subpolygons. If a split region R has more than k sides, we further split it using the diagonal of R that achieves the best balanced partition of R; namely, it is the pair of vertices a, b realizing the following minimum:

$$\min_{a,b \in V(R)} \max\left(w(R \cap H_{ab}^{+}), w(R \cap H_{ab}^{-})\right),$$

where $V(R)$ is the set of vertices of R, $w(R)$ is the number of lines intersecting R, and H_{ab}^{+} (resp., H_{ab}^{-}) is the closed half-plane lying to the right (resp., left) of ab. See Figure 7.

PolyTriangle: Modified `PolyTree` for generating cuttings by triangles. In each stage, we check whether a newly created region R can be triangulated into a set of inactive triangles. To do so, compute an arbitrary triangulation of the region R and check if all the triangles generated in our (arbitrary) triangulation of R are inactive. If so, replace R in our cuttings by its triangulation.[4]

PolyDeadLeaf: Modified `PolyTree` for generating cuttings by triangles. Whenever a region is being created we check whether it has a leaf triangle (a triangle defined by three consecutive vertices of the region) that is inactive. If we find such an inactive triangle, we add it immediately to the final cutting. We repeat this process until the region cannot be further shrunk.

PolyVertical: (This is the variant presented in section 2.1.) We use `PolyTree`, but instead of splitting along a diagonal, we split along a vertical ray emanating from one of the vertices of the region. The algorithm also tries to remove dead regions from the left and right side of the region. Intuitively, each region is now an extended vertical trapezoid having a convex ceiling and floor, with at most two additional vertical walls.

Remark 4.1. Note that for all the polygonal cutting methods, except `CRIVPolygon` (this is `PolyVertical` without the removal of dead regions; see section 2.1) and `PolyVertical`, it is not even clear that the number of regions they maintain in the ith iteration is $O(i^2)$. Thus, the proof of Theorem 2.10 does not work for those methods.

[4]Computing the "best" triangulation (i.e., the weight of the heaviest triangle is minimized) is relatively complicated and requires dynamic programming. It is not clear that it is going to perform better than `PolyDeadLeaf`, described below.

4.3. Implementation details. As an underlying data structure for our testing, we implemented the history-graph data structure [Sei91]. Our random arrangements were constructed by choosing n points uniformly and independently on the left side of the unit square, and similarly on the right side of the unit square. We sorted the points and connected them by lines in a transposed manner. This yields a random arrangement with all the $\binom{n}{2}$ intersections inside the unit square.

We had implemented our algorithm in `C++`. We had encountered problems with floating point robustness at an early stage of the implementation and decided to use exact arithmetic instead, using `LEDA` rational numbers [MN95]. While this solved the robustness problems, we had to deal with a couple of other issues:

- Speed: Using exact arithmetic instead of floating point arithmetic resulted in a slowdown by a factor 20–40. The time to perform an operation in exact arithmetic is proportional to the bit-sizes of the numbers involved. To minimize the size of the numbers used in the computations, we normalized the line equations so that the coefficients are integer numbers (in reduced form). Using more advanced techniques one can get close to floating-point speed with the "security" provided by exact arithmetic. See [AHH+99].
- Memory consumption: A `LEDA` rational is represented by a block of memory dynamically allocated on the heap. In order to save, both in the memory consumed and the time used by the dynamic memory allocator, we observe that in a representation of vertical decomposition the same number appears in several places (i.e., an x-coordinate of an intersection point appears in 6 different vertical trapezoids). We reduce memory consumption, by storing such a number only once. To do so, we use a repository of rational numbers generated so far by the algorithm. Whenever we compute a new x-coordinate, we search it in the repository, and if it does not exist, then we insert it. In particular, each vertical trapezoid is represented by two pointers to its x_{left} and x_{right} coordinates and pointers to its top and bottom lines.
  The repository is implemented using Treaps [SA96].

4.4. Handling degeneracies. Geometric degeneracy is one of the main obstacles when implementing geometric algorithms. To overcome this problem, we used exact arithmetic. While this ensured that the underlining geometric primitives work correctly, it does not tackle the problem of geometric degeneracies directly. Fortunately, in our case the handling of geometric degeneracies is straightforward.

Indeed, the various algorithms we presented for computing cuttings use only two geometric primitives. The first is *split*, which split a region (i.e., vertical trapezoid/convex polygon) Δ by a line l that crosses it (the line might be an input line, or a line connecting two vertices of the region) into a constant number of regions $R_1, \ldots, R_k$. Here, to overcome degeneracy the algorithm throws away regions having an empty interior. If the regions are polygons, an additional step is added to remove superfluous collinear vertices (i.e., a vertex lying on the line induced by its two neighbors) from the newly created regions.

The second primitive checks whether a line l crosses the interior of a region Δ. This is done by checking for each vertex of Δ, on which side of l it lies. If two vertices of Δ lie on opposite sides of l, then l crosses the interior of Δ. Since the program uses exact arithmetic this primitive gives the correct results.

4.5. Results—vertical trapezoids. The empirical results we got for the algorithms/heuristics of subsection 4.1 are depicted in Tables 1–5.

Table 1
Results for 1/2-cuttings. Each entry is the size of the minimal cutting computed, divided by $2^2 = 4$. *The corresponding value in Matoušek's construction* [Mat98] *is smaller than* 12.00.

Lines	Parallel Inc	Classical	Randomized Inc	Greedy trapezoid	Greedy line	Greedy weighted line
4	1.50	1.50	1.50	1.50	1.50	1.50
8	2.00	12.50	2.75	2.25	2.25	2.50
16	4.75	25.75	4.25	4.75	4.00	4.50
32	4.75	24.75	7.00	5.50	6.00	6.25

For each value of r and each value of n, we computed a random arrangement of lines inside the unit square, as described above. For each such arrangement, we performed 10 tests for each algorithm/heuristic. The tables present the size of the minimal cutting computed in those tests. Each entry is the size of the output cutting divided by r^2. In addition, each table caption presents a range containing the size of the cutting that can be obtained by Matoušek's algorithm [Mat98].

It is an interesting question whether using merging by `CutRandomInc` results in practice in smaller cuttings. We tested this empirically, and the results are presented in Table 6. As can be seen in Table 6, using merging does generate smaller cuttings, but the improvement in the cutting size is rather small. The difference in the size of the generated cuttings seems to be less than $2r^2$.

4.6. Implementing Matoušek's construction. In Table 7, we present the empirical results for Matoušek's construction, comparing it with the slight improvement described in Remark 3.4. For small values of r, the improved version yields considerably smaller cuttings than Matoušek's construction, making it the best method we are aware of for constructing small cuttings.

We had implemented Matoušek's algorithm naively, using quadratic space and time. Currently, this implementation cannot be used for larger inputs because it runs out of memory. Implementing the more efficient algorithm described in Theorem 3.7 is nontrivial since it requires the implementation of the rather complex data structure of Overmars and van Leeuwen [OvL81]. However, if it is critical to reduce the size of a cutting for large inputs, the algorithm of Theorem 3.7 seems to be the best available option.

Overall, Matoušek's algorithm gives the best results for cuttings by vertical trapezoids. However, for polygonal cuttings, the results we got are even better, as described below.

4.7. Results—polygonal cuttings. The results for polygonal cuttings are presented in Table 8. As seen in the tables, the polygonal cutting methods perform well in practice. In particular, the `PolyTree` method generated cuttings of average size (roughly) $7.5r^2$, beating all the cutting methods that use vertical trapezoids.

As for triangles, the situation is even better: `PolyDeadLeaf` generates cuttings by triangles of size $\leq 12r^2$. (That is better by an additive factor of about $4r^2$ than the best theoretical bound.)

To summarize, polygonal cutting methods seem to be the clear winner in practice. They generate cuttings of a small size, with a small number of vertices and small number of triangles.

5. Conclusions. In this paper, we have presented a new approach, different from that of [CF90], for constructing cuttings in the plane. The new algorithm is rather simple and easy to implement. We have proved the correctness and bounded the expected output size and expected running time of several variants of the new algorithm and have also demonstrated that the new algorithms perform much better in practice than the algorithm of [CF90]. We believe that the results in this paper show that planar cuttings are practical and might be useful in practice when constructing

data structures for range searching and related applications.

Moreover, the empirical results show that the size of the cutting constructed by the new algorithms is not considerably larger (and in some cases even smaller) than the cuttings that can be computed by the currently best theoretical algorithm (too slow to be useful in practice due to its $O(n^2)$ running time) of Matoušek [Mat98]. The empirical constants that we obtain are generally between 10 and 13 (for vertical trapezoids). For polygonal cuttings we get a constant of 8 by cutting by convex polygons (using `PolyTree`) having at most 6 vertices. Moreover, the various variants of `CutRandomInc` seem to produce constants that are rather close to each other. As noted above, the method described in Remark 3.4 generates the smallest cuttings by vertical trapezoids.

As for running time, the results we got in practice are the following: In computing a (1/8)-cutting of 1024 lines, the fastest algorithm was `PolyTree`, requiring about half a minute on average. The other polygonal methods lagged slightly behind. `CutRandomInc` was the fastest algorithm that produced cuttings by vertical trapezoids, being several times slower. Matoušek's method required several hours due to our naive (i.e., $O(n^2)$) implementation. This information should be taken with reservation, since no serious effort had gone into optimizing the code for speed, and those measurements tend to change from execution to execution. (Recall also that we use exact arithmetic, which slows down the running time significantly.)

Given these results, we recommend for use in practice one of the polygonal cutting methods. They perform well in practice, and they should be used whenever possible.

If we are restricted to a vertical trapezoid, `CutRandomInc` seems like a reasonable algorithm to be used in practice (without merging, as merging is the only "nontrivial" part in the implementation of the algorithm).

There are several interesting open problems for further research:

- Can one obtain provable bounds on the expected size of the cutting generated by the `PolyTree` method, and on its running time? (Remember that in the `PolyTree` method the cutting regions are convex polygons with a constant number of edges.) The same question applies for all the other methods we had implemented.
- Can one prove the existence of a cutting smaller than the one guaranteed by the algorithm in Remark 3.4 for specific values of r? For example, Table 1 suggests a smaller cutting should exist for $r = 2$. In particular, the test results hint that a cutting made out of 32 vertical trapezoids should exist, while the cutting size guaranteed by Matoušek's algorithm [Mat98] is 48.
- Can one generate smaller cuttings by modifying `CutRandomInc` to be smarter in its decision on when to merge trapezoids?
- Is there a simple and practical algorithm for computing cuttings in three and higher dimensions? The current algorithms seems to be far from practical.
- Can the following heuristic improve (substantially) the size of the cuttings in practice? After the cuttings are computed, pass over the cutting regions and merge adjacent regions that are adjacent and compatible, so that the resulting regions are still $(1/r)$-inactive. Inspecting the output of our test program in Figure 1 indicates that this indeed the case.

Acknowledgments. The author wishes to thank Pankaj Agarwal, Boris Aronov, Hervé Brönnimann, Bernard Chazelle, Jiří Matoušek, and Joe Mitchell for helpful discussions and suggestions concerning the problems studied in this paper and related problems.

The author also wishes to thank deeply Micha Sharir for his help and guidance in preparing the paper. He contributed several key ideas to the new simplified analysis of `CutRandomInc`.

ON QUIESCENT RELIABLE COMMUNICATION[*]

MARCOS KAWAZOE AGUILERA[†], WEI CHEN[†], AND SAM TOUEG[†]

Abstract. We study the problem of achieving reliable communication with *quiescent* algorithms (i.e., algorithms that eventually stop sending messages) in asynchronous systems with process crashes and lossy links. We first show that it is impossible to solve this problem in asynchronous systems (with no failure detectors). We then show that, among failure detectors that output lists of suspects, the weakest one that can be used to solve this problem is $\diamond\mathcal{P}$, a failure detector that cannot be implemented. To overcome this difficulty, we introduce an implementable failure detector called *Heartbeat* and show that it can be used to achieve quiescent reliable communication. Heartbeat is novel: in contrast to typical failure detectors, it does not output lists of suspects and it is implementable without timeouts. With Heartbeat, many existing algorithms that tolerate only process crashes can be transformed into quiescent algorithms that tolerate both process crashes and message losses. This can be applied to consensus, atomic broadcast, k-set agreement, atomic commitment, etc.

Key words. algorithms, reliability, reliable communication, quiescence, asynchronous systems, heartbeat, crash failures, link failures, failure detection, fault-tolerance, message passing, processor failures

1. Introduction.

1.1. Motivation.

We focus on the problem of *quiescent* reliable communication in asynchronous message-passing systems with process crashes and lossy links. To illustrate this problem consider a system of two processes, a sender s and a receiver r, connected by an asynchronous bidirectional link. Process s wishes to send some message m to r. Suppose first that no process may crash, but the link between s and r may lose messages (in both directions). If we put no restrictions on message losses it is obviously impossible to ensure that r receives m. An assumption commonly made to circumvent this problem is that the link is *fair*: if a message is sent infinitely often, then it is received infinitely often.

With such a link, s could repeatedly send copies of m forever, and r is guaranteed to eventually receive m. This is impractical, since s never stops sending messages. The obvious fix is the following protocol: (a) s sends a copy of m repeatedly until it receives $ack(m)$ from r, and (b) upon each receipt of m, r sends $ack(m)$ back to s. Note that this protocol is *quiescent*: eventually no process sends or receives messages.

The situation changes if, in addition to message losses, process crashes may also occur. The protocol above still works, but it is not quiescent anymore: for example, if r crashes before sending $ack(m)$, then s will send copies of m forever. Is there a *quiescent* protocol ensuring that if neither s nor r crashes then r eventually receives m? It turns out that the answer is no, even if one assumes that the link can only lose a finite number of messages.

Since process crashes and message losses are common types of failures, this negative result is an obstacle to the design of fault-tolerant distributed systems. In this paper, we explore the use of *unreliable failure detectors* to circumvent this obstacle. Roughly speaking, unreliable failure detectors provide (possibly erroneous) hints on the operational status of processes. Each process can query a local failure detector module that provides some information about which processes have crashed. This information is typically given in the form of a list of *suspects*.

In general, failure detectors can make mistakes: a process that has crashed is not necessarily suspected, and a process may be suspected even though it has not crashed. Moreover, the local lists of suspects dynamically change and lists of different processes do not have to agree (or even eventually agree). Introduced in [12], the abstraction of unreliable failure detectors has been used to solve several important problems such as consensus, atomic broadcast, group membership, nonblocking atomic commitment, and leader election [3, 20, 26, 28, 32, 34].

Our goal is to use unreliable failure detectors to achieve quiescence, but before we do so we must address the following important question. Note that any reasonable implementation of a failure detector in a message-passing system is itself *not* quiescent: a process being monitored by a failure detector must periodically send a message to indicate that it is still alive, and it must do so forever (if it stops sending messages it cannot be distinguished from a process that has crashed). Given that failure detectors are not quiescent, does it still make sense to use them as a tool to achieve quiescent applications (such as quiescent reliable broadcast, consensus, or group membership)?

The answer is yes for two reasons. First, a failure detector is intended to be a basic system service that is *shared* by many applications during the lifetime of the system, and so its cost is amortized over all these applications. Second, failure detection is a service that needs to be active forever—and so it is natural that it sends messages forever. In contrast, many applications (such as a single remote procedure call (RPC) or the reliable broadcast of a single message) should not send messages forever, i.e., they should be quiescent. Thus, there is no conflict between the goal of building quiescent applications and the use of a nonquiescent failure detection service as a tool to achieve this goal.

1.2. Achieving quiescent reliable communication using failure detectors. How can we use an unreliable failure detector to achieve quiescent reliable communication in the presence of process and link failures? This can be done with the *eventually perfect* failure detector $\diamond\mathcal{P}$ [12]. Intuitively, $\diamond\mathcal{P}$ satisfies the following two properties: (a) if a process crashes, then there is a time after which it is permanently suspected, and (b) if a process does not crash, then there is a time after which it is never suspected. Using $\diamond\mathcal{P}$, the following obvious algorithm solves our sender/receiver example: (a) while s has not received $ack(m)$ from r, it periodically does the following: s queries $\diamond\mathcal{P}$ and sends a copy of m to r if r is not currently suspected; (b) upon each receipt of m, r sends $ack(m)$ back to s. Note that this algorithm is *quiescent*: eventually no process sends or receives messages.

So $\diamond\mathcal{P}$ is sufficient to achieve quiescent reliable communication. But is it necessary? In the first part of the paper, we show that among all failure detectors that output lists of suspects, $\diamond\mathcal{P}$ is indeed the *weakest* one that can be used to solve this problem. Unfortunately, $\diamond\mathcal{P}$ is not implementable (this would violate a known impossibility result [17, 12]). Thus, at a first glance, it seems that achieving quiescent reliable communication requires a failure detector that cannot be implemented. In the second part of the paper, we show that this is not so.

In fact, we show that quiescent reliable communication can be achieved with a failure detector that *is implementable* in systems with process crashes and lossy links. This new failure detector, called *Heartbeat* and denoted $\mathcal{HB}$, is very simple. Roughly speaking, the failure detector module of $\mathcal{HB}$ at a process p outputs a vector of counters, one for each neighbor q of p. If neighbor q does not crash, its counter at p increases with no bound. If q crashes, its counter eventually stops increasing. The basic idea behind an implementation of $\mathcal{HB}$ is the obvious one: each process periodically sends an *I-am-alive* message (a "heartbeat") and every process receiving a heartbeat increases the corresponding counter.[1]

$\mathcal{HB}$ should not be confused with existing implementations of failure detectors (some of which have modules that are also called *heartbeat* [35, 10]). Even though existing failure detectors are also based on the repeated sending of a heartbeat, they use timeouts on heartbeats in order to derive lists of processes considered to be up or down, and applications can only see these lists. In contrast, $\mathcal{HB}$ does *not* use timeouts on the heartbeats of a process in order to determine whether this process has failed or not. $\mathcal{HB}$ just counts the *total number of heartbeats* received from each process and outputs these "raw" counters without any further processing or interpretation.

A remark is now in order regarding the practicality of $\mathcal{HB}$. As we mentioned above, $\mathcal{HB}$ outputs a vector of unbounded counters. In practice, these unbounded counters are not a problem for the following reasons. First, they are in *local memory* and not in messages—our $\mathcal{HB}$ implementations use bounded messages. Second, if we bound each local counter to 64 bits and assume a rate of one heartbeat per nanosecond, which is orders of magnitude higher than currently used in practice, then $\mathcal{HB}$ will work for more than 500 years.

1.3. Detailed outline of the results. We focus on two types of reliable communication mechanisms: *quasi-reliable send and receive*, and *reliable broadcast*. Roughly speaking, a pair of send and receive primitives is quasi-reliable if it satisfies the following property: if processes s and r are *correct* (i.e., they do not crash), then r receives a message from s exactly as many times as s sent that message to r. Reliable broadcast [23] ensures that if a correct process broadcasts a message m then all correct processes deliver m; moreover, all correct processes deliver the same set of messages. Our goal is to obtain quiescent implementations of these primitives in networks that do not partition permanently. More precisely, we consider networks in which processes may crash and links may lose messages, but every pair of correct processes are connected through some *fair path*, i.e., a path containing only fair links and correct processes.

We first show that in asynchronous systems (with no failure detectors), there is no quiescent implementation of quasi-reliable send and receive or of reliable broadcast in such networks (even if we assume that links can lose only a finite number of messages). We then show that the weakest failure detector *with bounded output size*[2] that can be used to solve these problems is $\diamond\mathcal{P}$—which is not implementable.

To overcome this difficulty, we introduce $\mathcal{HB}$, a failure detector that outputs unbounded counters, and show that $\mathcal{HB}$ is strong enough to achieve quiescent reliable communication but weak enough to be implementable. We consider two types of networks. In the first type, all links are bidirectional and fair. In the second one, some links are unidirectional, and some links have no restrictions on message losses, i.e.,

[1] As we will see, however, in some types of networks the actual implementation is not as easy.

[2] Note that a list of suspects has bounded size.

they are not fair. Examples of such networks are unidirectional rings that intersect. For the first type of networks, a common one in practice, the implementation of $\mathcal{HB}$ and the reliable communication algorithms are very simple and efficient. The algorithms for the second type are significantly more complex.

We then consider two stronger types of communication primitives, namely, *reliable send and receive* and *uniform reliable broadcast*, and give quiescent implementations that use $\mathcal{HB}$. These implementations assume that a majority of processes are correct (a result in [5] shows that this assumption is necessary).

We conclude the paper by showing how $\mathcal{HB}$ can be used to extend previous work in order to solve problems with algorithms that are both quiescent and tolerant of process crashes and messages losses. First, we explain how $\mathcal{HB}$ can be used to transform many existing algorithms that tolerate process crashes into quiescent algorithms that tolerate both process crashes and message losses (fair links). This transformation can be applied to the algorithms for consensus in [2, 7, 9, 12, 14, 16, 33], for atomic broadcast in [12], for k-set agreement in [13], for atomic commitment in [20], for approximate agreement in [15], etc. Next, we show that $\mathcal{HB}$ can be used to extend the work in [5] to obtain the following result. Let P be a problem. Suppose P is correct-restricted (i.e., its specification refers only to the behavior of correct processes), or a majority of processes are correct. If P is solvable with a quiescent protocol that tolerates only process crashes, then P is also solvable with a quiescent protocol that tolerates process crashes and message losses.[3]

To summarize, in this paper, we do the following.

1. We explore the use of unreliable failure detectors to achieve *quiescent* reliable communication in the presence of process crashes and lossy links—a problem that cannot be solved without failure detection.
2. We show that the weakest failure detector with bounded output size that can be used to solve this problem is $\diamond\mathcal{P}$—which is not implementable.
3. To overcome this obstacle, we introduce $\mathcal{HB}$: this failure detector can be used to achieve quiescent reliable communication, and it *is* implementable. In contrast to common failure detectors [3, 12, 20, 21, 28, 34], $\mathcal{HB}$ does not output a list of suspects, and it can be implemented without timeouts.
4. We show that $\mathcal{HB}$ can be used to extend existing algorithms for many fundamental problems (e.g., consensus, atomic broadcast, k-set agreement, atomic commitment, and approximate agreement) to tolerate message losses. It can also be used to extend the results of [5].

Result (2) above implies that failure detectors with bounded output size are either (a) too weak to achieve quiescent reliable communication, or (b) not implementable. Thus, failure detectors that output lists of processes, which are commonly used in practice, are not always the best ones to solve a problem: their power or applicability is limited. To the best of our knowledge, this is the first work that shows that failure detectors with bounded output size have inherent limitations.

The problem of achieving reliable communication despite failures has been extensively studied, especially in the context of data link protocols (see Chapter 22 of [29] for a compendium). Our work differs from previous results because we seek *quiescent* algorithms in systems where processes *and* links can fail (and this requires the use of unreliable failure detectors). The works that are the closest to ours are due to Moses and Roth [30] and Basu, Charron-Bost, and Toueg [5]. The main goal of [30] is to achieve quiescent reliable communication with algorithms that garbage-collect

[3]The link failure model in [5] is slightly different from the one used here (cf. section 10).

old messages in systems with lossy links (the issue of garbage collection is only briefly considered here). The algorithms in [30], however, are not resilient to process crashes. The protocols in [5] tolerate both process crashes and lossy links, but they are not quiescent (and they do not use failure detectors). In section 10, we use $\mathcal{HB}$ to extend the results of [5] and obtain quiescent protocols.

The paper is organized as follows. Our model is given in section 2. In section 3, we define the reliable communication primitives that we focus on. In section 4, we show that, without failure detectors, quiescent reliable communication is impossible. In section 5, we prove that $\diamond\mathcal{P}$ is the weakest failure detector with bounded output size that can be used to solve this problem (this proof is under a simplifying assumption; the proof without this assumption is given in the appendix). We then define the heartbeat failure detector $\mathcal{HB}$ in section 6. In section 7, we show how to use $\mathcal{HB}$ to achieve quiescent reliable communication. In section 8, we show how to implement $\mathcal{HB}$. In section 9, we consider two stronger types of communication primitives and give quiescent implementations that use $\mathcal{HB}$. In section 10, we explain how $\mathcal{HB}$ can be used to extend several previous results. We conclude the paper with some remarks about message buffering, quiescence versus termination, models of lossy links, and the generalization of our results to partitionable networks.

2. Model.

We consider asynchronous message-passing distributed systems in which there are no timing assumptions. In particular, we make no assumptions on the time it takes to deliver a message, or on relative process speeds. Processes can communicate with each other by sending messages through unidirectional links. We do not assume that the network is completely connected or that the links are bidirectional. The system can experience both process failures and link failures. Processes can fail by crashing, and links can fail by dropping messages. The model, based on the one in [11], is described next.

A network is a directed graph $G = (\Pi, \Lambda)$ where $\Pi = \{1, \dots, n\}$ is the set of processes, and $\Lambda \subseteq \Pi \times \Pi$ is the set of links. If there is a link from process p to process q, we denote this link by $p \rightarrow q$, and if, in addition, $q \neq p$, we say that q is a *neighbor* of p. The set of neighbors of p is denoted by $\mathit{neighbor}(p)$.

We assume the existence of a discrete global clock—this is merely a fictional device to simplify the presentation, and processes do not have access to it. We take the range $\mathcal{T}$ of the clock's ticks to be the set of natural numbers.

2.1. Failures and failure patterns.

Processes can fail by crashing, i.e., by halting prematurely. A *process failure pattern* F_P is a function from $\mathcal{T}$ to 2^{Π}. Intuitively, $F_P(t)$ denotes the set of processes that have crashed through time t. Once a process crashes, it does not "recover," i.e., for all t: $F_P(t) \subseteq F_P(t+1)$. We say p *crashes in* F_P if $p \in F_P(t)$ for some t; otherwise we say p *is correct in* F_P.

Some links in the network are fair. Roughly speaking, a fair link $p \rightarrow q$ may intermittently drop messages and may do so infinitely often, but it must satisfy the following "fairness" property: if p repeatedly sends some message to q and q does not crash, then q eventually receives that message. Link properties are made precise in section 2.5.

A *link failure pattern* F_L is a subset of the set of links Λ. Intuitively, F_L is the set of links that may fail to satisfy the above fairness property. If $p \rightarrow q \notin F_L$, we say that $p \rightarrow q$ *is fair in* F_L.

A *failure pattern* $F = (F_P, F_L)$ combines a process failure pattern and a link failure pattern, and $\mathit{correct\_proc}(F)$ and $\mathit{crashed\_proc}(F)$ denote the set of processes that are correct and crashed in F_P, respectively.

2.2. Network connectivity. The following definitions are with respect to a given failure pattern $F = (F_P, F_L)$. We say that a path $(p_1, \dots, p_k)$ in the network is *fair* if processes $p_1, \dots, p_k$ are correct and links $p_1 \to p_2, \dots, p_{k-1} \to p_k$ are fair. We assume that every pair of distinct correct processes is connected through a fair path. This precludes permanent network partitions.

2.3. Failure detectors. Each process has access to a local failure detector module that provides (possibly incorrect) information about the failure pattern that occurs in an execution. A *failure detector history H with range $\mathcal{R}$* is a function from $\Pi \times \mathcal{T}$ to $\mathcal{R}$. $H(p, t)$ is the output value of the failure detector module of process p at time t. *A failure detector $\mathcal{D}$* is a function that maps each failure pattern F to a *set* of failure detector histories with range $\mathcal{R}_{\mathcal{D}}$ (where $\mathcal{R}_{\mathcal{D}}$ denotes the range of the output of $\mathcal{D}$). $\mathcal{D}(F)$ denotes the set of possible failure detector histories permitted by $\mathcal{D}$ for the failure pattern F.

We now define the *eventually perfect failure detector* $\diamond\mathcal{P}$ [12].[4] Each failure detector module of $\diamond\mathcal{P}$ outputs a *set of processes* that are suspected to have crashed, i.e., $\mathcal{R}_{\diamond\mathcal{P}} = 2^{\Pi}$. For each failure pattern F, $\diamond\mathcal{P}(F)$ is the set of all failure detector histories H with range $\mathcal{R}_{\diamond\mathcal{P}}$ that satisfy the following properties.

1. *Strong completeness*. Eventually, every process that crashes is permanently suspected by every correct process. More precisely,

$$\exists t \in \mathcal{T}\, \forall p \in \mathit{crashed\_proc}(F),\, \forall q \in \mathit{correct\_proc}(F),\, \forall t' \geq t : p \in H(q, t').$$

2. *Eventual strong accuracy*. There is a time after which correct processes are not suspected by any correct process. More precisely,

$$\exists t \in \mathcal{T}\ \forall t' \geq t,\ \forall p, q \in \mathit{correct\_proc}(F) : p \notin H(q, t').$$

Sometimes we need to consider systems without failure detectors. For convenience, we model such systems by assuming that their failure detectors always output nil. More precisely, the *nil failure detector* $\mathcal{D}_{\perp}$ is the one where the failure detector modules of all processes always output $\perp$, independent of the failure pattern. A *system without failure detectors* is one whose failure detector is $\mathcal{D}_{\perp}$.

2.4. Runs of algorithms. An algorithm A is a collection of n deterministic automata, one for each process in the system. Computation proceeds in atomic *steps* of A. In each step, a process may receive a message from a process, get an external input, query its failure detector module, undergo a state transition, send a message to a neighbor, and issue an external output.

A *run of algorithm A using failure detector $\mathcal{D}$* is a tuple $R = (F, H_{\mathcal{D}}, I, S, T)$ where F is a failure pattern, $H_{\mathcal{D}} \in \mathcal{D}(F)$ is a history of failure detector $\mathcal{D}$ for failure pattern F, I is an initial configuration of A, S is an infinite sequence of steps of A, and T is an infinite list of increasing time values indicating when each step in S occurs.

A run must satisfy the following properties for every process p. If p has crashed by time t, i.e., $p \in F_P(t)$, then p does not take a step at any time $t' \geq t$; if p is correct, i.e., $p \in \mathit{correct\_proc}(F)$, then p takes an infinite number of steps; if p takes a step at time t and queries its failure detector, then p gets $H_{\mathcal{D}}(p, t)$ as a response.

2.5. Link properties. Each run $R = (F, H_{\mathcal{D}}, I, S, T)$ must also satisfy some "link properties." First, no link creates or duplicates messages. More precisely, for every link $p \to q \in \Lambda$, the following must hold.

[4]In [12], $\diamond\mathcal{P}$ denotes a *class* of failure detectors.

1. *Uniform integrity*. For all $k \geq 1$, if q receives a message m from p exactly k times by time t, then p sent m to q at least k times before time t.

Moreover, every fair link transports any message that is repeatedly sent through it. More precisely, for every link $p \to q \notin F_L$, the following must hold.

2. *Fairness*. If p sends a message m to q an infinite number of times and q is correct, then q receives m from p an infinite number of times.

Note that any link, whether fair or not, may lose (or not lose) messages arbitrarily during any finite period of time. In particular, a fair link may lose all the messages sent during any finite period of time, while a link that is not fair may behave perfectly during that time.

2.6. Environments and problem solving. The correctness of an algorithm may depend on certain assumptions on the "environment," e.g., the maximum number of processes that may crash. For example, a consensus algorithm may need the assumption that a majority of processes is correct. Formally, an *environment* $\mathcal{E}$ is a set of failure patterns. Unless otherwise stated, the only restriction that we put on the environment in this paper is that every pair of distinct correct processes is connected through a fair path.

A problem P is defined by properties that sets of runs must satisfy. An algorithm A solves problem P using a failure detector $\mathcal{D}$ in environment $\mathcal{E}$ if the set of all runs $R = (F, H_{\mathcal{D}}, I, S, T)$ of A using $\mathcal{D}$, where $F \in \mathcal{E}$ satisfies the properties required by P.

Let $\mathcal{C}$ be a class of failure detectors. An algorithm A solves a problem P using $\mathcal{C}$ in environment $\mathcal{E}$ if for all $\mathcal{D} \in \mathcal{C}$, A solves P using $\mathcal{D}$ in $\mathcal{E}$. An algorithm implements $\mathcal{C}$ in environment $\mathcal{E}$ if it implements some $\mathcal{D} \in \mathcal{C}$ in $\mathcal{E}$.

3. Quiescent reliable communication. In this paper, we focus on quasi-reliable send and receive, and reliable broadcast, because these communication primitives are sufficient to solve many problems (see section 10.1). Stronger types of communication primitives—reliable send and receive, and uniform reliable broadcast—are briefly considered in section 9.

3.1. Quasi-reliable send and receive. Consider any two distinct processes s and r. We define *quasi-reliable send and receive from s to r* in terms of two primitives, $\mathsf{qr\text{-}send}_{s,r}$ and $\mathsf{qr\text{-}receive}_{r,s}$. We say that process s $\mathsf{qr\text{-}sends}$ *message m to process r* if s invokes $\mathsf{qr\text{-}send}_{s,r}(m)$. We assume that if s is correct, it eventually returns from this invocation. We allow process s to $\mathsf{qr\text{-}send}$ the same message m more than once through the same link. We say that process r $\mathsf{qr\text{-}receives}$ *message m from process s* if r returns from the invocation of $\mathsf{qr\text{-}receive}_{r,s}(m)$. Primitives $\mathsf{qr\text{-}send}_{s,r}$ and $\mathsf{qr\text{-}receive}_{r,s}$ satisfy the following properties.

1. *Uniform integrity*. For all $k \geq 1$, if r $\mathsf{qr\text{-}receives}$ m from s exactly k times by time t, then s $\mathsf{qr\text{-}sent}$ m to r at least k times before time t.

2. *Quasi no loss.*[5] For all $k \geq 1$, if both s and r are correct, and s $\mathsf{qr\text{-}sends}$ m to r exactly k times by time t, then r eventually $\mathsf{qr\text{-}receives}$ m from s at least k times.

Intuitively, quasi no loss together with uniform integrity implies that if s and r are correct, then r $\mathsf{qr\text{-}receives}$ m from s exactly as many times as s $\mathsf{qr\text{-}sends}$ m to r.

We want to implement quasi-reliable send and receive primitives using the communication service provided by the network links. Informally, such an implementation is *quiescent* if it sends only a finite number of messages when $\mathsf{qr\text{-}send}_{s,r}$ is invoked a

[5]A stronger property, called *No Loss*, is used in section 9.1 to define *reliable* send and receive.

finite number of times.[6]

3.2. Reliable broadcast. *Reliable broadcast* [9] is defined in terms of two primitives: broadcast(m) and deliver(m). We say that process p *broadcasts message* m if p invokes broadcast(m). We assume that every broadcast message m includes the following fields: the identity of its sender, denoted $sender(m)$, and a sequence number, denoted $seq(m)$. These fields make every message unique. We say that q *delivers message* m if q returns from the invocation of deliver(m). Primitives broadcast and deliver satisfy the following properties [23].

1. *Validity*. If a correct process broadcasts a message m, then it eventually delivers m.

2. *Agreement*. If a correct process delivers a message m, then all correct processes eventually deliver m.

3. *Uniform integrity*. For every message m, every process delivers m at most once, and only if m was previously broadcast by $sender(m)$.

Validity and agreement imply that if a correct process broadcasts a message m, then all correct processes eventually deliver m.

We want to implement reliable broadcast using the communication service provided by the network links. Informally, such an implementation is *quiescent* if it sends only a finite number of messages when broadcast is invoked a finite number of times.

3.3. Relating reliable broadcast and quasi-reliable send and receive. From a quiescent implementation of quasi-reliable send and receive one can easily obtain a quiescent implementation of reliable broadcast, and vice-versa.

Remark 3.1. From any quiescent implementation of reliable broadcast, we can obtain a quiescent implementation of the quasi-reliable primitives $\text{qr-send}_{p,q}$ and $\text{qr-receive}_{q,p}$ for every pair of processes p and q.

Remark 3.2. Suppose that every pair of correct processes is connected through a path of correct processes. If we have a quiescent implementation of quasi-reliable primitives $\text{qr-send}_{p,q}$ and $\text{qr-receive}_{q,p}$ for all processes p and $q \in neighbor(p)$, then we can obtain a quiescent implementation of reliable broadcast.

To implement reliable broadcast from qr-send and qr-receive, one can use a simple diffusion algorithm (e.g., see [23]).

4. Impossibility of quiescent reliable communication. We now show that in a system without failure detectors, quiescent reliable communication cannot be achieved. This holds even if the network is completely connected and only a finite number of messages can be lost.

THEOREM 4.1. *Consider a system without failure detectors where every pair of processes is connected by a fair link and at most one process may crash. Let s and r be any two distinct processes. There is no quiescent implementation of quasi-reliable send and receive from s to r. This holds even if we assume that only a finite number of messages can be lost.*

Proof.[7] Assume, by contradiction, that there exists a quiescent implementation I of quasi-reliable $\text{qr-send}_{s,r}$ and $\text{qr-receive}_{r,s}$. The basic intuition behind the proof

[6] A quiescent implementation of $\text{qr-send}_{s,r}$ and $\text{qr-receive}_{r,s}$ is allowed to send a finite number of messages even if no $\text{qr-send}_{s,r}$ is invoked at all (e.g., some messages may be sent as part of an "initialization phase").

[7] This theorem is actually a corollary of Theorem A.12 and the fact that the eventually perfect failure detector $\diamond\mathcal{P}$ cannot be implemented. The proof of Theorem A.12, however, uses some complex arguments that obscure the intuition behind Theorem 4.1. We prefer to give a self-contained and direct proof that does not use Theorem A.12.

is to construct a run R_1 where s qr-sends a message to r, but r crashes. Since the implementation of qr-send and qr-receive is quiescent, only a finite number of messages are sent to r in R_1. We then construct a similar run R_2 where s qr-sends a message to r, r does not crash, but the finite number of messages sent to r are lost. Runs R_1 and R_2 are indistinguishable from the point of view of r, so r never qr-receives the message—a contradiction. It turns out that to construct run R_1, we need another run R_0. This is because we allow the quiescent implementation of qr-send and qr-receive to send a finite number of "initialization" messages (see footnote 6). We now describe runs R_0, R_1, and R_2 in more detail.

In run R_0, s qr-sends no messages, all processes are correct, processes take steps in round-robin fashion, and every time a process takes a step, it receives the earliest message sent to it that it did not yet receive. Since I is quiescent, there is a time t_0 after which no messages are sent or received. By the uniform integrity property of qr-send and qr-receive, process r never qr-receives any message.

Run R_1 is identical to run R_0 up to time t_0; at time $t_0 + 1$, s qr-sends M to r, and r crashes; after time $t_0 + 1$, no processes crash, and every time a process takes a step, it receives the earliest message sent to it that it did not yet receive. Since I is quiescent, there is a time $t_1 > t_0$ after which no messages are sent or received.

In run R_2, r behaves exactly as in run R_0 (in particular, r does not crash and r receives a message m in R_2 whenever it receives m in R_0); all other processes behave exactly as in run R_1 (in particular, a process $p \neq r$ receives a message m in R_2 whenever it receives m in R_1). Note that, in R_2, if messages are sent to or from r after time t_0, then they are never received.

We now show that in R_2 all links satisfy the uniform integrity property. Assume that for some $k \geq 1$, some process q receives m from some process p k times by time t. There are several cases. (1) If $q = r$, then r receives m from p k times in R_0 by time t (since r behaves in the same way in R_0 and R_2). In R_0, by the uniform integrity property of the links, p sends m to r at least k times before time t. This happens by time t_0, since there are no sends in R_0 after time t_0. Note that by time t_0, p behaves exactly in the same way in R_0, R_1, and R_2. Thus p sends m to r at least k times before time t in R_2. (2) If $q \neq r$ and $p = r$, then q receives m from r k times in R_1 by time t (since q behaves in the same way in R_1 and R_2). In R_1, by the uniform integrity property of the links, r sends m to q at least k times before time t. This happens by time t_0, since r crashes at time t_0+1 in R_1. By time t_0, r behaves exactly in the same way in R_0, R_1, and R_2. Thus r sends m to q at least k times before time t in R_2. (3) If $q \neq r$ and $p \neq r$, then q receives m from p k times in R_1 by time t (since q behaves in the same way in R_1 and R_2). In R_1, by the uniform integrity property of the links, p sends m to q at least k times before time t. Note that p behaves exactly in the same way in R_1 and R_2. Thus p sends m to q at least k times in R_2 before time t. Therefore, in R_2 all links satisfy the uniform integrity property.

We next show that in R_2 all links satisfy the fairness property, and in fact only a finite number of messages are lost. Note that r sends only a finite number of messages in R_0 (since it does not send messages after time t_0), and every process $p \neq r$ sends only a finite number of messages in R_1 (since it does not send messages after time t_1). So, by construction of R_2, all processes send only a finite number of messages in R_2. Therefore, only a finite number of messages are lost, and in R_2 all links satisfy the fairness property.

We conclude that R_2 is a possible run of I in a network with fair links that lose only a finite number of messages. Note that in R_2: (a) both s and r are correct;

(b) s qr-sends M to r; and (c) r does not qr-receive M. This violates the quasi no loss property of qr-send$_{s,r}$ and qr-receive$_{r,s}$, and so I is not an implementation of qr-send$_{s,r}$ and qr-receive$_{r,s}$—a contradiction. □

Theorem 4.1 and Remark 3.1 immediately imply the following corollary.

COROLLARY 4.2. *There is no quiescent implementation of reliable broadcast in a network where a process may crash and links may lose a finite number of messages.*

The above results show that quiescent reliable communication cannot be achieved in a system without failure detectors. The rest of this paper explores the use of failure detectors to solve this problem.

5. The weakest failure detector with bounded output size for quiescent reliable communication.

In practice, and in much of the previous literature, the output of a failure detector is just a set of processes suspected to have failed. One such failure detector, namely $\diamond\mathcal{P}$, can be used to achieve quiescent reliable communication. However, $\diamond\mathcal{P}$ is not implementable in asynchronous systems. Can we achieve quiescent reliable communication with a failure detector that outputs a set of suspects and is implementable?

In this section we show that the answer is no. In fact, we prove a stronger result: Among all failure detectors *with bounded output size* (these include all failure detectors that output a set of suspects), the weakest one for achieving quiescent reliable communication is $\diamond\mathcal{P}$—which is not implementable. In contrast, if we do not bound the output size, quiescent reliable communication can be solved with $\mathcal{HB}$—which is implementable. This shows that failure detectors with bounded output size have some inherent limitations.

We prove our result with respect to a problem that we call *single-shot reliable send and receive.* This problem is weaker than quasi-reliable send and receive, and reliable broadcast, and thus our result immediately applies to those problems as well.

In section 5.1, we explain what it means for a failure detector to be weaker than another one. In section 5.2, we define the single-shot reliable send and receive problem. We then proceed to prove our main result under some reasonable simplifying assumption. We first give a rough outline of this proof (section 5.3) and then the proof itself (sections 5.4 and 5.5). In the appendix, we give the full proof without the simplifying assumption.

5.1. Failure detector transformations.

Failure detectors can be compared via algorithmic transformations [12, 11]. A transformation algorithm $T_{\mathcal{D}\to\mathcal{D}'}$ uses failure detector $\mathcal{D}$ to emulate $\mathcal{D}'$, as we now explain. At each process p, the algorithm $T_{\mathcal{D}\to\mathcal{D}'}$ maintains a variable $\mathcal{D}'_p$ that emulates the output of $\mathcal{D}'$ at p. Let $H_{\mathcal{D}'}$ be the history of all the $\mathcal{D}'$ variables in a run R of $T_{\mathcal{D}\to\mathcal{D}'}$, i.e., $H_{\mathcal{D}'}(p,t)$ is the value of $\mathcal{D}'_p$ at time t in run R. Algorithm $T_{\mathcal{D}\to\mathcal{D}'}$ *transforms* $\mathcal{D}$ *into* $\mathcal{D}'$ *in environment* $\mathcal{E}$ if and only if for every $F \in \mathcal{E}$ and every run $R = (F, H_{\mathcal{D}}, I, S, T)$ of $T_{\mathcal{D}\to\mathcal{D}'}$ using $\mathcal{D}$, we have $H_{\mathcal{D}'} \in \mathcal{D}'(F)$. Intuitively, since $T_{\mathcal{D}\to\mathcal{D}'}$ is able to use $\mathcal{D}$ to emulate $\mathcal{D}'$, $\mathcal{D}$ provides at least as much information about process failures as $\mathcal{D}'$ does, and we say that $\mathcal{D}'$ *is weaker than* $\mathcal{D}$ *in* $\mathcal{E}$.

Note that, in general, $T_{\mathcal{D}\to\mathcal{D}'}$ need not emulate *all* the failure detector histories of $\mathcal{D}'$ (in environment $\mathcal{E}$); what we do require is that all the failure detector histories it emulates be histories of $\mathcal{D}'$ (in that environment).

5.2. Single-shot reliable send and receive.

The single-shot reliable send and receive problem is defined in terms of two communication primitives, called s-send and s-receive. Each process can s-send a single bit once to one process of its choice, if it wishes to do so (but it is also possible that no process in the system ever s-sends any bit). The s-send and s-receive primitives must satisfy the following property. For any two correct processes p and q, and any $b \in \{0, 1\}$, p s-sends b to q if and only if q s-receives b from p.

An implementation $\mathcal{I}$ of s-send and s-receive is quiescent if it sends only a finite number of messages throughout the network.

5.3. Intuitive overview of the simple proof. Let $\mathcal{D}$ be a failure detector with bounded output size, i.e., the range of $\mathcal{D}$ is finite. Suppose $\mathcal{D}$ can be used to solve the single-shot reliable send and receive problem with a quiescent algorithm $\mathcal{I}$ ($\mathcal{I}$ is also called the implementation of s-send and s-receive). We show that $\mathcal{D}$ can be transformed to $\diamond\mathcal{P}$.

The proof that follows makes the simplifying assumption that $\mathcal{I}$ does not have an "initialization phase" that requires the sending of messages. In other words, we assume that $\mathcal{I}$ is such that if no process ever s-sends any bit, then no process ever sends any messages. This reasonable assumption allows us to simplify the proof and illustrate the basic ideas. In the appendix, we give the full proof.

Since the range of $\mathcal{D}$ is finite, then for every failure detector history H of $\mathcal{D}$: (a) each failure detector module outputs some values infinitely often (these are the "limit values"), and (b) there is a time after which it outputs only limit values. Let v be a limit value for process p and H. A crucial observation is that with H it is possible to construct runs such that whenever p takes a step it always gets v from its failure detector module. It is easy to generalize the notion of a limit value for p to a limit vector for a set of processes P: A vector f (with a value for every process in the system) is a limit vector for P and H if, for each process p in P, the failure detector module of p outputs $f(p)$ infinitely often in H. Note that with H it is possible to construct runs such that whenever a process p in P takes a step, it obtains $f(p)$ from its failure detector module. We say that vector f hints that P is the set of all correct processes, if f could occur as a limit vector for P when P is the set of correct processes (more precisely, f is a limit vector for P in a history $H \in \mathcal{D}(F)$ where $\mathit{correct\_proc}(F) = P$).

Consider a failure detector history H that can occur when P is the set of all correct processes. Let f be any limit vector for P and H. Clearly, f hints that P is the set of all correct processes. Can f also hint that a proper subset P' of P is the set of all correct processes? The answer is no. As we argue next, this is because with $\mathcal{D}$, a process in P' should be able to s-send a bit to a process q in $P \setminus P'$ and to do so quiescently using $\mathcal{I}$.

Suppose, for contradiction, that f hints that P' is the set of all correct processes. Then we can construct a run R_1 of $\mathcal{I}$ where (a) P' is indeed the set of all correct processes, (b) processes in P' are scheduled such that whenever they take steps they get f from their failure detector module, (c) some process p in P' s-sends a bit b to some process q in $P \setminus P'$, and (d) processes in $P \setminus P'$ never take a step. Because the implementation $\mathcal{I}$ is quiescent, in R_1 eventually all processes in P' (including p) stop sending messages—they give up on trying to transmit b to q.

Since f also hints that P is the set of correct processes, we can create another run R_2 of $\mathcal{I}$ where (a) P is the set of correct processes, (b) processes in P are scheduled such that whenever they take steps they get f from their failure detector module, (c) p s-sends b to q, and (d) messages sent between processes in P' and processes in $P \setminus P'$ are lost. Note that from the point of view of processes in P', run R_2 is indistinguishable from run R_1. Thus in R_2 eventually all processes in P' stop sending messages—they give up on trying to transmit b to q. So, in R_2 process q never receives any messages, and thus it does not s-receive b from p. Since p and q are correct in R_2, the implementation $\mathcal{I}$ of s-send and s-receive is incorrect—a contradiction. Thus f cannot hint that P' is the set of all correct processes.

Let E_P be the set of all vectors that hint that P is the set of correct processes (this set is determined by $\mathcal{D}$). The algorithm that transforms $\mathcal{D}$ to $\diamond\mathcal{P}$ uses a predetermined "table of hints" containing, for each possible P, the set E_P.

The transformation algorithm works as follows. Each process p periodically sends its current failure detector output to every process and maintains two variables: f and *Order*. Vector f stores the last failure detector value received from each process, and *Order* is an ordered set of processes. Whenever p receives a failure detector value from another process q, it records that value in $f(q)$ and moves q to the front of *Order*. Let P be the set of correct processes in this run. Note that (a) eventually f is a limit vector for P, and (b) the correct processes percolate to the front of *Order* (processes that crash end up at the tail), so that eventually P is some prefix of *Order*.

To satisfy the properties of $\diamond\mathcal{P}$, p must eventually output the complement of P. By (b) above, eventually P is the largest prefix of *Order* that contains correct processes. To find this maximal prefix, p repeatedly uses its current value of f and the predetermined table of hints, as follows. For each prefix P' of *Order*, in order of increasing size, p checks if f hints that P' is the set of all correct processes, i.e., $f \in E_{P'}$, and if so p outputs the complement of P'. This works because, as we argued above, any limit vector f for P: (1) hints that P is the set of all correct processes, and (2) cannot hint that a proper subset P' of P is the set of all correct processes. This concludes the overview of the proof (the reader should understand why the argument above breaks down without the simplifying assumption).

We next give the actual proof. The transformation algorithm $T_{\mathcal{D}\to\diamond\mathcal{P}}$ uses a table which is determined a priori from $\mathcal{D}$ (this is the "table of hints" in our intuitive explanation). We first define this table and show some of its properties (section 5.4). We then describe and prove the correctness of the transformation algorithm $T_{\mathcal{D}\to\diamond\mathcal{P}}$ that uses this table (section 5.5).

5.4. The predetermined table. Let $\mathcal{E}$ be an environment and $\mathcal{D}$ be any failure detector with finite range $\mathcal{R} = \{v_1, v_2, \dots, v_\ell\}$. Let $\mathcal{I}$ be a quiescent implementation of s-send and s-receive that uses $\mathcal{D}$ in environment $\mathcal{E}$. Assume that if no process s-sends any bit, then $\mathcal{I}$ does not send any messages (this simplifying assumption is removed in the appendix).

Given $v_j \in \mathcal{R}$, a process $p \in \Pi$, and a failure detector history H with range $\mathcal{R}$, we say that v_j is *a limit value for p and H* if, for infinitely many t, $H(p,t) = v_j$. Let f be an assignment of failure detector values to every process in Π, i.e., $f : \Pi \longrightarrow \mathcal{R}$. Let P be a nonempty set of processes. We say that *f is a limit vector for P and H* if for all $p \in P$, $f(p)$ is a limit value for p and H. The set of all limit vectors for P and H is denoted $L_P(H)$. Let $E_P^{\mathcal{D},\mathcal{E}} = \{f \mid \exists F \in \mathcal{E}, \exists H \in \mathcal{D}(F) : P = \mathit{correct\_proc}(F) \text{ and } f \in L_P(H)\}$. Roughly speaking, $E_P^{\mathcal{D},\mathcal{E}}$ is the set of limit vectors that could occur when P is the set of correct processes.

The table used by the transformation algorithm $T_{\mathcal{D}\to\diamond\mathcal{P}}$ consists of all the sets $E_P^{\mathcal{D},\mathcal{E}}$ where P ranges over all nonempty subsets of processes. Note that this table is finite. We omit the superscript $\mathcal{D},\mathcal{E}$ from $E_P^{\mathcal{D},\mathcal{E}}$ whenever it is clear from the context.

LEMMA 5.1. *Let $F \in \mathcal{E}$, $P = \mathit{correct\_proc}(F)$, and $H \in \mathcal{D}(F)$. Assume $P \neq \emptyset$. If $f \in L_P(H)$, then $f \in E_P$ and $f \notin E_{P'}$ for every P' such that $\emptyset \subset P' \subset P$.*

Proof. Let $f \in L_P(H)$. The fact that $f \in E_P$ is immediate from the definition of

E_P. Let P' be such that $\emptyset \subset P' \subset P$. Suppose, for contradiction, that $f \in E_{P'}$. Then there exists a failure pattern $F' \in \mathcal{E}$ and $H' \in \mathcal{D}(F')$ such that $P' = \mathit{correct\_proc}(F')$ and $f \in L_{P'}(H')$.

We now obtain a contradiction by using the quiescent implementation $\mathcal{I}$ of s-send and s-receive. Let p be a process in P' and q be a process in $P \setminus P'$. We construct two runs, R_1 and R_2 of $\mathcal{I}$ using $\mathcal{D}$, as follows.

1. Run R_1 has failure pattern F' and failure detector history H'. Initially p s-sends some bit b to q. Processes in P' take steps and those in $\Pi \setminus P'$ do not. Processes in P' take steps in round-robin fashion such that every time a process $r \in P'$ takes a step, it obtains $f(r)$ from its failure detector module (since $f \in L_{P'}(H')$, $f(r)$ is a limit value for r and H'). Moreover, every process in P' receives every message sent to it.

Since $\mathcal{I}$ is quiescent, there is a time t_1 after which no messages are sent or received. Assume without loss of generality that at time t_1 all processes in P' took the same number k of steps (otherwise, choose another time $t'_1 > t_1$). Note that all messages in R_1 are sent within the finite period of time $[0, t_1]$. Thus the fact that all processes in P' receive all the messages sent to them is consistent with the link failure pattern of F' (even if in F' some of the links are not fair).

2. Run R_2 has failure pattern F and failure detector history H. Initially, processes in R_2 behave as in R_1: p s-sends some bit b to q; moreover, each process in P' takes the same k steps as in R_1, and processes in $\Pi \setminus P'$ do not take any steps. More precisely, processes in P' take steps in round-robin fashion such that every time a process $r \in P'$ takes a step, it obtains $f(r)$ from its failure detector module (since $f \in L_P(H)$ and $r \in P' \subset P$, $f(r)$ is a limit value for r and H). Moreover, every process in P' receives every message sent to it, and all messages sent to processes in $\Pi \setminus P'$ are lost. This goes on until each process in P' takes k steps, exactly as in R_1.[8] Let t_2 be the time when this happens. After t_2, processes in P take steps in round-robin fashion such that every time a process $r \in P'$ takes a step, it obtains $f(r)$ from its failure detector module (it does not matter what a process $r \in P \setminus P'$ gets from its failure detector module, as long as it is compatible with H). Moreover, after t_2 no process s-sends any bit. This completes the description of run R_2.

In R_2, at time t_2, each process in P' is in the same state as in run R_1 at time t_1. Moreover, each process in $P \setminus P'$ is in its initial state. By a simple induction argument we can show that after time t_2 in R_2, (a) processes in P' continue to behave as in R_1, (b) processes in $P \setminus P'$ behave as if they were in a run of $\mathcal{I}$ in which no process ever s-sends any bit, and (c) no process sends any message (this induction uses the simplifying assumption that in a run in which there are no s-sends, no process sends any message). Therefore, in R_2, process q (which is in $P \setminus P'$) never receives any messages. This implies that q does not s-receive b from p.

Note that in R_2: (a) both p and q are correct; (b) p s-sends b to q; and (c) q does not s-receive b from p. Thus $\mathcal{I}$ is not a correct implementation of s-send and s-receive—a contradiction. ∎

5.5. The transformation algorithm. The algorithm $T_{\mathcal{D}\to\mathcal{D}'}$ that transforms $\mathcal{D}$ to an eventually perfect failure detector $\mathcal{D}' = \diamond\mathcal{P}$ in environment $\mathcal{E}$ is shown in Figure 5.1. $T_{\mathcal{D}\to\mathcal{D}'}$ uses the table of sets E_P (for all nonempty subsets of processes P) that has been determined a priori from the given $\mathcal{D}$ and $\mathcal{E}$. It also uses an implementation

[8]This behavior of the links is consistent with F because for any finite period of time, any link (whether fair or not in F) may lose or not lose any message.

```
For every process $p$:

    Initialization:
        for all $q \in \Pi$ do $f[q] \leftarrow \perp$
        $Order \leftarrow \emptyset$
        $\mathcal{D}'_p \leftarrow \emptyset$
        { For each $\emptyset \subset P \subseteq \Pi$, the set $E_P^{\mathcal{D},\mathcal{E}}$ is determined a priori from $\mathcal{D}$ and $\mathcal{E}$ }

    cobegin
        || Task 1:
            repeat periodically
                $v \leftarrow \mathcal{D}_p$                                              {query $\mathcal{D}$}
                for all $q \in \Pi$ do qr-send $v$ to $q$

        || Task 2:
            upon qr-receive $w$ from $q$ do {upon receipt of a failure detector value from $q$}
                $f[q] \leftarrow w$
                $Order \leftarrow q \mid\mid (Order \setminus \{q\})$     {process $q$ is moved to the front of $Order$}
                if for some $k \geq 1$, $f \in E_{Order[1..k]}^{\mathcal{D},\mathcal{E}}$ then
                    let $k_0$ be the smallest such $k$
                    $\mathcal{D}'_p \leftarrow \Pi \setminus Order[1..k_0]$         {suspect processes not in $Order[1..k_0]$}
    coend
```

FIG. 5.1. *Transformation of $\mathcal{D}$ to an eventually perfect failure detector $\mathcal{D}'$ in environment $\mathcal{E}$.*

of qr-send and qr-receive between every pair of processes. A simple implementation is by repeated retransmissions and diffusion (it does not have to be quiescent).

All variables are local to each process. Vector f stores the last failure detector value that p qr-received from each process; *Order* is an ordered set that records the order in which the last failure detector value from each process was qr-received; $\mathcal{D}'_p$ denotes the output of the eventually perfect failure detector that p is simulating (a set of processes that p currently suspects).

In Task 1, each process p periodically qr-sends the output of its failure detector module $\mathcal{D}_p$ to every process q. Upon the qr-receipt of a failure detector value from process q in Task 2, process p enters it into $f[q]$ and moves q to the front of *Order*. Then p checks if there is some prefix $Order[1..k]$ of *Order* such that $f \in E_{Order[1..k]}$. If there is, it sets $\mathcal{D}'$ to the complement of the smallest such prefix.

We now show that the failure detector constructed by this algorithm, namely $\mathcal{D}'$, is an eventually perfect failure detector. Consider a run of this algorithm with failure pattern $F \in \mathcal{E}$ and failure detector history $H \in \mathcal{D}(F)$, such that $correct\_proc(F) \neq \emptyset$. Let t be the number of processes that crash in F, i.e., $t = |\Pi \setminus correct\_proc(F)|$. Henceforth, p denotes a correct process in F, and variables f and *Order* are local to p.

LEMMA 5.2. *There is a time after which* (1) $Order\ [1..n-t] = correct\_proc(F)$, *and* (2) $f \in L_{Order[1..n-t]}(H)$.[9]

Proof. Part (1) is clear from the way *Order* is updated, the fact that p keeps qr-receiving failure detector values from every correct process, and the fact that p

[9]This does not mean that eventually the values of variables f and *Order* at p stop changing. It means that, although they may continue to change forever, eventually the predicates (1) and (2) are true forever at p.

eventually stops qr-receiving messages from processes that crash. Part (2) of the lemma follows from part (1) and the fact that the range $\mathcal{R}$ of $\mathcal{D}$ is finite. ∎

COROLLARY 5.3. *There is a time after which* (1) $f \in E_{Order[1..n-t]}$, *and* (2) *for all* $1 \leq k < n-t$, $f \notin E_{Order[1..k]}$.

Proof. By Lemma 5.2, there is a time t_0 after which $f \in L_{Order[1..n-t]}(H)$ and $Order[1..n-t] = correct\_proc(F)$. So after time t_0, by Lemma 5.1, $f \in E_{Order[1..n-t]}$. This shows (1). Let k be such that $1 \leq k < n-t$. After t_0, $\emptyset \subset Order[1..k] \subset correct\_proc(F)$, and $f \in L_{correct\_proc(F)}(H)$. So, by Lemma 5.1, $f \notin E_{Order[1..k]}$. This shows (2). ∎

COROLLARY 5.4. *There is a time after which* $\mathcal{D}'_p = \Pi \setminus correct\_proc(F)$.

Proof. By Corollary 5.3 and the algorithm, there is a time after which the k_0 selected in line 20 is always $n-t$. Now apply Lemma 5.2 part (1). ∎

By Corollary 5.4, we have the following theorem.

THEOREM 5.5. *Consider an asynchronous system subject to process crashes and message losses. Suppose failure detector $\mathcal{D}$ with finite range can be used to solve the single-shot reliable send and receive problem in environment $\mathcal{E}$, and that the implementation is quiescent. Assume further that if no process ever* s-sends *any bit, then this implementation does not send any messages. Then $\mathcal{D}$ can be transformed (in environment $\mathcal{E}$) to the eventually perfect failure detector $\diamond\mathcal{P}$.*

Theorems 5.5 and A.12 imply that if we restrict ourselves to failure detectors that output a set of suspects, we cannot achieve quiescent reliable communication with a failure detector that can be implemented. Thus we next introduce $\mathcal{HB}$, a failure detector that does *not* output a set of suspects. $\mathcal{HB}$ can be used to achieve quiescent reliable communication and it is implementable.

6. Definition of $\mathcal{HB}$.

A *heartbeat failure detector* $\mathcal{D}$ has the following features. The output of $\mathcal{D}$ at each process p is a list $(p_1, n_1), (p_2, n_2), \ldots, (p_k, n_k)$, where $p_1, p_2, \ldots, p_k$ are the neighbors of p, and each n_j is a nonnegative integer. Intuitively, n_j increases while p_j has not crashed, and stops increasing if p_j crashes. We say that n_j is *the heartbeat value of* p_j *at* p. The output of $\mathcal{D}$ at p at time t, namely $H(p,t)$, will be regarded as a vector indexed by the set $\{p_1, p_2, \ldots, p_k\}$. Thus $H(p,t)[p_j]$ is n_j. The *heartbeat sequence of* p_j *at* p is the sequence of the heartbeat values of p_j at p as time increases. $\mathcal{D}$ satisfies the following properties.

- *$\mathcal{HB}$-completeness*. At each correct process, the heartbeat sequence of every neighbor that crashes is bounded:

$$\forall F, \forall H \in \mathcal{D}(F), \forall p \in correct\_proc(F), \forall q \in crashed\_proc(F) \cap neighbor(p),$$
$$\exists K \in \boldsymbol{N}, \forall t \in \mathcal{T} : H(p,t)[q] \leq K.$$

- *$\mathcal{HB}$-accuracy*.
  - At each process, the heartbeat sequence of every neighbor is nondecreasing:

$$\forall F, \forall H \in \mathcal{D}(F), \forall p \in \Pi, \forall q \in neighbor(p), \forall t \in \mathcal{T} : H(p,t)[q] \leq H(p,t+1)[q].$$

  - At each correct process, the heartbeat sequence of every correct neighbor is unbounded:

$$\forall F, \forall H \in \mathcal{D}(F), \forall p \in correct\_proc(F), \forall q \in correct\_proc(F) \cap neighbor(p),$$
$$\forall K \in \boldsymbol{N}, \exists t \in \mathcal{T} : H(p,t)[q] > K.$$

The class of all heartbeat failure detectors is denoted $\mathcal{HB}$. By a slight abuse of notation, we sometimes use $\mathcal{HB}$ to refer to an arbitrary member of that class.

It is easy to generalize the definition of $\mathcal{HB}$ so that the failure detector module at each process p outputs the heartbeat of every process in the system [1], rather than just the heartbeats of the neighbors of p, but we do not need this generality here.

7. Quiescent reliable communication using $\mathcal{HB}$.

The communication networks that we consider are not necessarily completely connected, but we assume that every pair of correct processes is connected through a fair path. We first consider a simple type of such networks, in which every link is assumed to be bidirectional[10] and fair (Figure 7.1a). This assumption, a common one in practice, allows us to give efficient and simple algorithms. We then drop this assumption and treat a more general type of networks, in which some links may be unidirectional and/or not fair (Figure 7.1b). For both network types, we give quiescent reliable communication algorithms that use $\mathcal{HB}$. Our algorithms have the following feature: processes do not need to know the entire network topology or the number of processes in the system; they only need to know the identity of their neighbors.

In our algorithms, $\mathcal{D}_p$ denotes the current output of the failure detector $\mathcal{D}$ at process p.

7.1. The simple network case.

We assume that all links in the network are bidirectional and fair (Figure 7.1a). In this case, the algorithms are very simple. We first give a quiescent implementation of quasi-reliable qr-send$_{s,r}$ and qr-receive$_{r,s}$ for the case $r \in neighbor(s)$. For s to qr-send a message m to r, it repeatedly sends m to r every time the heartbeat of r increases, until s receives $ack(m)$ from r. Process r qr-receives m from s the first time it receives m from s, and r sends $ack(m)$ to s every time it receives m from s.

From this implementation and Remark 3.2, we can obtain a quiescent implementation of reliable broadcast. Then, from Remark 3.1, we can obtain a quiescent implementation of quasi-reliable send and receive for every pair of processes.

7.2. The general network case.

In this case (Figure 7.1b), some links may be unidirectional, e.g., the network may contain several unidirectional rings that intersect with each other. Moreover, some links may not be fair (and processes do not know which ones are fair).

Achieving quiescent reliable communication in this type of network is significantly more complex than before. For instance, suppose that we seek a quiescent implementation of quasi-reliable send and receive. In order for the sender s to qr-send a message m to the receiver r, it has to use a diffusion mechanism, even if r is a neighbor of s (since the link $s \to r$ may not be fair). Because of intermittent message losses, this diffusion mechanism needs to ensure that m is repeatedly sent over fair links. But when should this repeated send stop? One possibility is to use an acknowledgement mechanism. Unfortunately, the link in the reverse direction may not be fair (or may not even be part of the network), and so the acknowledgement itself has to be diffused. But diffusing the acknowledgements quiescently and reliably introduces a "chicken and egg" problem. We now explain how our algorithms avoid this problem.

We give a quiescent implementation of reliable broadcast in Figure 7.2. This implementation can be used to obtain quasi-reliable send and receive between every pair of processes (see Remark 3.1). For each message m that is broadcast, each process p maintains a variable $got_p[m]$ containing a set of processes. Intuitively, a process q

[10]In our model, this means that link $p \to q$ is in the network if and only if link $q \to p$ is in the network. In other words, $q \in neighbor(p)$ if and only if $p \in neighbor(q)$.

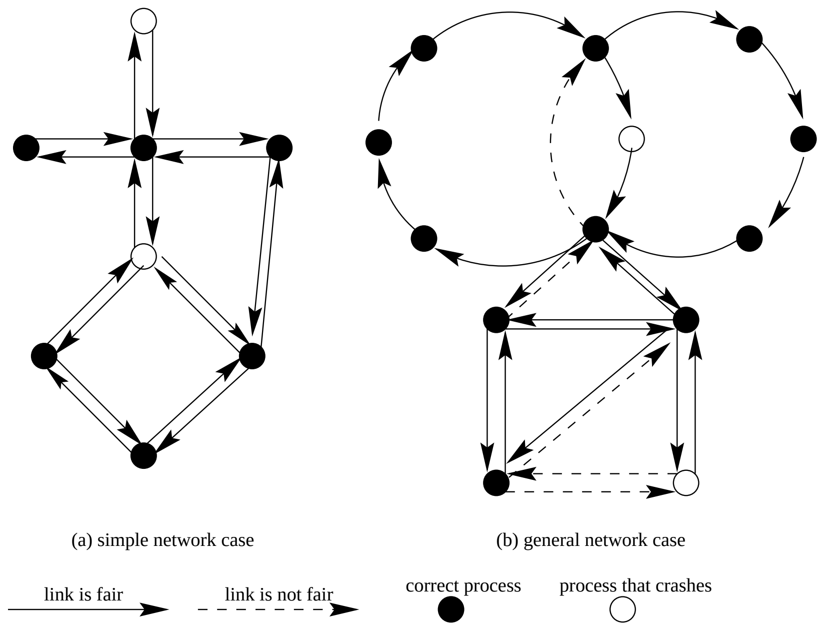

FIG. 7.1. *Examples of the simple and general network cases.*

is in $got_p[m]$ if p has evidence that q has delivered m. All the messages sent by a process p in the reliable broadcast algorithm are of the form $(m, got\_msg, path)$ where got_msg is the current value of $got_p[m]$, and $path$ is the sequence of processes that this copy of $(m, got\_msg, path)$ has traversed so far.

In order to reliably broadcast a message m, p first delivers m; then p initializes variable $got_p[m]$ to $\{p\}$ and forks task $diffuse(m)$; finally p returns from the invocation of broadcast(m). The task $diffuse(m)$ runs in the background. In this task, p periodically checks if, for some neighbor $q \notin got_p[m]$, the heartbeat of q at p has increased, and, if so, p sends $(m, got_p[m], p)$ to all neighbors whose heartbeat increased—even to those who are already in $got_p[m]$.[11] The task terminates when all neighbors of p are contained in $got_p[m]$.

Upon the receipt of a message $(m, got\_msg, path)$, process p first checks if it has already delivered m, and, if not, it delivers m and forks task $diffuse(m)$. Then p adds the contents of got_msg to $got_p[m]$ and appends itself to $path$. Finally, p forwards the new message $(m, got_p[m], path)$ to all its neighbors that appear at most once in $path$.

The code consisting of lines 19 through 27 is executed atomically.[12] Each concurrent execution of the $diffuse$ task (lines 9 to 17) has its own copy of all the local variables in this task.

We now outline the proof that, for the general network case, Figure 7.2 is a

[11]It may appear that p does not need to send this message to processes in $got_p[m]$, since they have already gotten m! But with this "optimization" the algorithm is no longer quiescent; in the proof of Lemma 7.8 we will indicate exactly where the sending to *every* neighbor whose heartbeat increased is necessary.

[12]A process p executes a region of code atomically if at any time there is at most one thread of p in this region.

```
1   For every process $p$:
2
3       To execute broadcast$(m)$:
4           deliver$(m)$
5           $got[m] \leftarrow \{p\}$
6           fork task $diffuse(m)$
7           return
8
9       task $diffuse(m)$:
10          for all $q \in neighbor(p)$ do $prev\_hb[q] \leftarrow -1$
11          repeat periodically
12              $hb \leftarrow \mathcal{D}_p$                    { query the heartbeat failure detector }
13              if for some $q \in neighbor(p)$, $q \notin got[m]$ and $prev\_hb[q] < hb[q]$ then
14                  for all $q \in neighbor(p)$ such that $prev\_hb[q] < hb[q]$ do
15                      send $(m, got[m], p)$ to $q$
16                  $prev\_hb \leftarrow hb$
17          until $neighbor(p) \subseteq got[m]$
18
19      upon receive $(m, got\_msg, path)$ from $q$ do
20          if $p$ has not previously executed deliver$(m)$ then
21              deliver$(m)$
22              $got[m] \leftarrow \{p\}$
23              fork task $diffuse(m)$
24          $got[m] \leftarrow got[m] \cup got\_msg$
25          $path \leftarrow path \cdot p$
26          for all $q$ such that $q \in neighbor(p)$ and $q$ appears at most once in $path$ do
27              send $(m, got[m], path)$ to $q$
```

FIG. 7.2. *General network case—quiescent implementation of* broadcast *and* deliver *using* $\mathcal{HB}$.

quiescent implementation of reliable broadcast that uses $\mathcal{HB}$. The first few lemmas are obvious.

LEMMA 7.1 (uniform integrity). *For every message m, every process delivers message m at most once, and only if m was previously broadcast by sender(m).*

LEMMA 7.2 (validity). *If a correct process broadcasts a message m, then it eventually delivers m.*

LEMMA 7.3. *For any processes p and q,* (1) *if at some time t, $q \in got_p[m]$, then $q \in got_p[m]$ at every time $t' \geq t$;* (2) *when $got_p[m]$ is initialized, $p \in got_p[m]$; and* (3) *if $q \in got_p[m]$, then q delivered m.*

LEMMA 7.4. *For every m and path, there is a finite number of distinct messages of the form $(m, *, path)$.*

LEMMA 7.5. *If some process sends a message of the form $(m, *, path)$, then no process appears more than twice in path.*

LEMMA 7.6. *Suppose link $p \to q$ is fair, and p and q are correct processes. If p delivers a message m, then q eventually delivers m.*

Proof. Suppose, by contradiction, that p delivers m and q never delivers m. Since p delivers m and it is correct, it forks task *diffuse*(m). Since q does not deliver m, by Lemma 7.3 part (3) q never belongs to $got_p[m]$. Since p is correct, this implies that p executes the loop in lines 11–17 an infinite number of times. Since q is a correct neighbor of p, the $\mathcal{HB}$-accuracy property guarantees that the heartbeat sequence of q at p is nondecreasing and unbounded. Thus the condition in line 13 evaluates to true an infinite number of times. Therefore, p executes line 14 an infinite number of times, and so p sends a message of the form $(m, *, p)$ to q an infinite number of times. By Lemma 7.4, there exists a subset $g_0 \subseteq \Pi$ such that p sends message (m, g_0, p) infinitely often to q. So, by the fairness property of link $p \rightarrow q$, q eventually receives (m, g_0, p). Therefore, q delivers m. This contradicts the assumption that q does not deliver m. ∎

LEMMA 7.7 (agreement). *If a correct process p delivers a message m, then every correct process q eventually delivers m.*

Proof (sketch). By successive applications of Lemma 7.6 over any fair path from p to q. ∎

We now show that the algorithm in Figure 7.2 is quiescent. In order to do so, we focus on a single invocation of broadcast and show that it causes the sending of only a finite number of messages. This implies that the implementation sends only a finite number of messages when broadcast is invoked a finite number of times.

Let m be a message and consider an invocation of broadcast(m). This invocation can only cause the sending of messages of form $(m, *, *)$. Thus, all we need to show is that every process eventually stops sending messages of this form.

LEMMA 7.8. *Let p be a correct process and q be a correct neighbor of p. If p forks task diffuse(m), then eventually condition $q \in got_p[m]$ holds forever.*

Proof. By Lemma 7.3 part (1), we only need to show that eventually q belongs to $got_p[m]$. Suppose, by contradiction, that q never belongs to $got_p[m]$. Let $(p_1, p_2, \ldots, p_{k'})$ be a simple fair path[13] from p to q with $p_1 = p$ and $p_{k'} = q$. Let $(p_{k'}, p_{k'+1}, \ldots, p_k)$ be a simple fair path from q to p with $p_k = p$. For $1 \leq j < k$, let $P_j = (p_1, p_2, \ldots, p_j)$. Note that a process can appear at most twice in P_k. Thus, for $1 \leq j < k$, process p_{j+1} appears at most once in P_j.

We claim that for each $j \in \{1, \ldots, k-1\}$, there is a set g_j containing $\{p_1, p_2, \ldots, p_j\}$ such that p_j sends (m, g_j, P_j) to p_{j+1} an infinite number of times. For $j = k-1$, this claim together with the fairness property of link $p_{k-1} \rightarrow p_k$ immediately implies that $p_k = p$ eventually receives (m, g_{k-1}, P_{k-1}). Upon the receipt of such a message, p adds the contents of g_{k-1} to its variable $got_p[m]$. Since g_{k-1} contains $p_{k'} = q$, this contradicts the fact that q never belongs to $got_p[m]$.

We show the claim by induction on j. For the base case note that, since q never belongs to $got_p[m]$ and q is a neighbor of $p_1 = p$, then p_1 executes the loop in lines 11–17 an infinite number of times. Since q is a correct neighbor of p_1, the $\mathcal{HB}$-accuracy property guarantees that the heartbeat sequence of q at p_1 is nondecreasing and unbounded. Thus, the condition in line 13 evaluates to true an infinite number of times. So p_1 executes line 14 infinitely often. Since p_2 is a correct neighbor of p_1, its heartbeat sequence is nondecreasing and unbounded, and so p_1 sends messages of the form $(m, *, p_1)$ to p_2 an infinite number of times.[14] By Lemma 7.4, there is some g_1 such that p_1 sends (m, g_1, p_1) to p_2 an infinite number of times. Note that Lemma 7.3 parts (1) and (2) imply that $p_1 \in g_1$. This shows the base case.

For the induction step, suppose that for $j < k-1$, p_j sends (m, g_j, P_j) to p_{j+1} an infinite number of times for some g_j containing $\{p_1, p_2, \ldots, p_j\}$. By the fairness property of link $p_j \rightarrow p_{j+1}$, p_{j+1} receives (m, g_j, P_j) from p_j an infinite number of times. Since p_{j+2} is a neighbor of p_{j+1} and appears at most once in P_{j+1}, each time p_{j+1} receives (m, g_j, P_j), it sends a message of the form $(m, *, P_{j+1})$ to p_{j+2}. It is easy

[13]A path is *simple* if all processes in that path are distinct.

[14]This is where the proof uses the fact that p sends message containing m to all its neighbors whose heartbeat increased—even to those (such as p_2) that may already be in $got_p[m]$ (cf. line 14 of the algorithm).

to see that each such message is (m, g, P_{j+1}) for some g that contains both g_j and p_{j+1}. By Lemma 7.4, there exists $g_{j+1} \subseteq \Pi$ such that g_{j+1} contains $\{p_1, p_2, \ldots, p_{j+1}\}$ and p_{j+1} sends (m, g_{j+1}, P_{j+1}) to p_{j+2} an infinite number of times. □

COROLLARY 7.9. *If a correct process p forks task diffuse(m), then eventually p stops sending messages in task diffuse(m).*

Proof. For every neighbor q of p, there are two cases. If q is correct, then eventually condition $q \in got_p[m]$ holds forever by Lemma 7.8. If q crashes, then the $\mathcal{HB}$-completeness property guarantees that the heartbeat sequence of q at p is bounded, and so eventually condition $prev\_hb_p[q] \geq hb_p[q]$ holds forever. Therefore, there is a time after which the guard in line 13 is always false. Hence, p eventually stops sending messages in task *diffuse*(m). □

LEMMA 7.10 (quiescence). *Eventually every process stops sending messages of the form $(m, *, *)$.*

Proof. Suppose, for a contradiction, that the lemma is not true. Then there exists a process p such that p never stops sending messages of the form $(m, *, *)$. By Lemma 7.5, the third component of a message of the form $(m, *, *)$ ranges over a finite set of values. Therefore, there is some fixed *path* such that p sends an infinite number of messages of the form $(m, *, path)$.

Now let $path_0$ to be the shortest path such that there exists some process p_0 that sends messages of the form $(m, *, path_0)$ an infinite number of times. Note that p_0 must be correct. Corollary 7.9 shows that there is a time after which p_0 stops sending messages in its task *diffuse*(m). Since p_0 only sends a message in task *diffuse*(m) or in line 27, then p_0 sends messages of the form $(m, *, path_0)$ in line 27 an infinite number of times. For each $(m, *, path_0)$ that p_0 sends in line 27, p_0 must have previously received a message of the form $(m, *, path_1)$ such that $path_0 = path_1 \cdot p_0$. So p_0 receives a message of the form $(m, *, path_1)$ an infinite number of times. By the uniform integrity property of the links, some process p_1 sends a message of form $(m, *, path_1)$ to p_0 an infinite number of times. But $path_1$ is shorter than $path_0$—a contradiction to the minimality of $path_0$. □

From Lemmas 7.1, 7.2, 7.7, and 7.10 we have the following theorem.

THEOREM 7.11. *For the general network case, the algorithm in Figure* 7.2 *is a quiescent implementation of reliable broadcast that uses $\mathcal{HB}$.*

From this theorem and Remark 3.1 we have the following corollary.

COROLLARY 7.12. *In the general network case, quasi-reliable send and receive between every pair of processes can be implemented with a quiescent algorithm that uses $\mathcal{HB}$.*

8. Implementations of $\mathcal{HB}$.

We now give implementations of $\mathcal{HB}$ for the two types of communication networks that we considered in the previous sections. These implementations do not use timeouts.

8.1. The simple network case.

We assume all links in the network are bidirectional and fair (Figure 7.1a). In this case, the implementation is obvious. Each process periodically sends a HEARTBEAT message to all its neighbors; upon the receipt of such a message from process q, p increases the heartbeat value of q.

8.2. The general network case.

In this case some links are unidirectional and/or not fair (Figure 7.1b). The implementation is more complex than before because each HEARTBEAT has to be diffused, and this introduces the following problem: when a process p receives a HEARTBEAT message it has to relay it even if this is not the first time p receives such a message. This is because this message could be a

```
For every process $p$:

    Initialization:
        for all $q \in neighbor(p)$ do $\mathcal{D}_p[q] \leftarrow 0$

    cobegin
        || Task 1:
            repeat periodically
                for all $q \in neighbor(p)$ do send $(\mathsf{HEARTBEAT}, p)$ to $q$

        || Task 2:
            upon receive $(\mathsf{HEARTBEAT}, path)$ from $q$ do
                for all $q$ such that $q \in neighbor(p)$ and $q$ appears in $path$ do
                    $\mathcal{D}_p[q] \leftarrow \mathcal{D}_p[q] + 1$
                $path \leftarrow path \cdot p$
                for all $q$ such that $q \in neighbor(p)$ and $q$ does not appear in $path$ do
                    send $(\mathsf{HEARTBEAT}, path)$ to $q$
    coend
```

FIG. 8.1. *General network case—implementation of $\mathcal{HB}$.*

new "heartbeat" from the originating process. But this could also be an "old" heartbeat that cycled around the network and came back, and p must avoid relaying such heartbeats.

The implementation is given in Figure 8.1. Every process p executes two concurrent tasks. In the first task, p periodically sends message $(\mathsf{HEARTBEAT}, p)$ to all its neighbors. The second task handles the receipt of messages of the form $(\mathsf{HEARTBEAT}, path)$. Upon the receipt of such message from process q, p increases the heartbeat values of all its neighbors that appear in *path*. Then p appends itself to *path* and forwards message $(\mathsf{HEARTBEAT}, path)$ to all its neighbors that do not appear in *path*.

We now show that, for the general network case, the algorithm in Figure 8.1 implements $\mathcal{HB}$.

LEMMA 8.1. *At every process p, the heartbeat sequence of every neighbor q is nondecreasing.*

Proof. The proof is obvious. □

LEMMA 8.2. *At each correct process p, the heartbeat sequence of every correct neighbor q is unbounded.*

Proof (sketch). It is possible that link $q \to p$ is not fair or not even in the network. However, there is a simple fair path $P = (p_1, \ldots, p_k)$ from q to p with $p_1 = q$ and $p_k = p$. Process $p_1 = q$ sends its heartbeat to all its neighbors infinitely often. Since the links $p_1 \to p_2, \ldots, p_{k-1} \to p_k$ are fair and each p_j is correct, the heartbeats of q are relayed infinitely often through that path, and $p_k = p$ receives them infinitely often. □

COROLLARY 8.3 ($\mathcal{HB}$-accuracy). *At each process the heartbeat sequence of every neighbor is nondecreasing, and at each correct process the heartbeat sequence of every correct neighbor is unbounded.*

Proof. The proof follows from Lemmas 8.1 and 8.2. □

The proofs of the next two lemmas are obvious.

LEMMA 8.4. *If some process p sends $(\mathsf{HEARTBEAT}, path)$ then (1) p is the last process in path, and (2) no process appears twice in path.*

LEMMA 8.5. *Let p, q be processes, and let path be a nonempty sequence of processes. If p receives message* $(\mathsf{HEARTBEAT}, path \cdot q)$ *an infinite number of times, then q receives message* $(\mathsf{HEARTBEAT}, path)$ *an infinite number of times.*

LEMMA 8.6 ($\mathcal{HB}$-completeness). *At each correct process, the heartbeat sequence of every neighbor that crashes is bounded.*

Proof (sketch). Let p be a correct process, and let q be a neighbor of p that crashes. Suppose that the heartbeat sequence of q at p is not bounded. Then p increments $\mathcal{D}_p[q]$ an infinite number of times. So, for an infinite number of times, p receives messages of the form $(\mathsf{HEARTBEAT}, *)$ with a second component that contains q. By Lemma 8.4 part (2), the second component of a message of the form $(\mathsf{HEARTBEAT}, *)$ ranges over a finite set of values. Thus there exists a *path* containing q such that p receives $(\mathsf{HEARTBEAT}, path)$ an infinite number of times.

Let $path = (p_1, \dots, p_k)$. Then, for some $j \le k$, $p_j = q$. If $j = k$, then, by the uniform integrity property of the links and by Lemma 8.4 part (1), q sends $(\mathsf{HEARTBEAT}, path)$ to p an infinite number of times. This contradicts the fact that q crashes. If $j < k$, then, by repeated applications of Lemma 8.5, we conclude that p_{j+1} receives message $(\mathsf{HEARTBEAT}, (p_1, \dots, p_j))$ an infinite number of times. Therefore, by the uniform integrity property of the links and Lemma 8.4 part (1), p_j sends $(\mathsf{HEARTBEAT}, (p_1, \dots, p_j))$ to p_{j+1} an infinite number of times. Since $p_j = q$, this contradicts the fact that q crashes. ☐

By Corollary 8.3 and the above lemma, we have the following theorem.

THEOREM 8.7. *For the general network case, the algorithm in Figure* 8.1 *implements $\mathcal{HB}$.*

9. Stronger communication primitives.

Quasi-reliable send and receive and reliable broadcast are sufficient to solve many problems (see section 10.1). However, stronger types of communication primitives, namely, *reliable send and receive* and *uniform reliable broadcast*, are sometimes needed. We now give quiescent implementations of these primitives for systems with process crashes and message losses.

Let t be the number of processes that may crash. [5] shows that if $t \ge n/2$ (i.e., half of the processes may crash), these primitives cannot be implemented, even if we assume that links may lose only a finite number of messages and we do not require that the implementation be quiescent.

We now show that if $t < n/2$, then there are quiescent implementations of these primitives for the two types of network considered in this paper. The implementations that we give here are simple and modular but are inefficient (in terms of number of messages sent). More efficient ones can be obtained by modifying the algorithms in sections 7.1 and 7.2. Hereafter, we assume that $t < n/2$.

9.1. Reliable send and receive.

Consider any two distinct processes s and r. We define *reliable send and receive from s to r* in terms of two primitives: $\mathsf{r\text{-}send}_{s,r}$ and $\mathsf{r\text{-}receive}_{r,s}$. We require that if a correct process invokes r-send, it eventually returns from this invocation. If a process s returns from the invocation of $\mathsf{r\text{-}send}_{s,r}(m)$, we say that *$s$ completes the* r-send *of message m to r.* With quasi-reliable send and receive, it is possible that s completes the qr-send of m to r, then s crashes, and r never qr-receives m (even though it does not crash). In contrast, with reliable send and receive primitives, if s completes the r-send of message m to a correct process r, then r eventually r-receives m (even if s crashes). More precisely, reliable send and receive satisfies the following properties.

1. *Uniform integrity.* For all $k \ge 1$, if r r-receives m from s exactly k times by time t, then s r-sent m to r at least k times before time t.

```
1   For process $s$:
2
3       Initialization:
4           $seq \leftarrow 0$                          { $seq$ is the current sequence number }
5
6       To execute r-send$_{s,r}(m)$:
7           $seq \leftarrow seq + 1$
8           $lseq \leftarrow seq$
9           broadcast$(m, lseq, s, r)$
10          wait until qr-received (ACK, $lseq$) from $t+1$ processes
11          return
12
13  For every process $p$:
14
15      upon deliver$(m, lseq, s, r)$ do
16          qr-send$_{p,s}$(ACK, $lseq$)
17          if $p = r$ then r-receive$_{r,s}(m)$
```

FIG. 9.1. *Quiescent implementation of* r-send$_{s,r}$ *and* r-receive$_{r,s}$ *for* $n > 2t$.

2. *No loss.* For all $k \geq 1$, if r is correct and s completes the r-send of m to r exactly k times by time t, then r eventually r-receives m from s at least k times.[15]

A quiescent implementation of r-send and r-receive can be obtained using a quiescent implementation of reliable broadcast and of qr-send/qr-receive between every pair of processes. Roughly speaking, when s wishes to r-send m to r, it broadcasts a message that contains m, s, r, and a fresh sequence number, and then waits to qr-receive $t+1$ acknowledgements for that message before returning from this invocation of r-send. When a process p delivers this broadcast message, it qr-sends an acknowledgement back to s, and if $p = r$, then it also r-receives m from s. This algorithm is shown in Figure 9.1 (the code consisting of lines 7 and 8 is executed atomically).

9.2. Uniform reliable broadcast. The agreement property of reliable broadcast states that if a *correct* process delivers a message m, then all correct processes eventually deliver m. This requirement allows a *faulty* process (i.e., one that subsequently crashes) to deliver a message that is never delivered by the correct processes. This behavior is undesirable in some applications, such as *atomic commitment* in distributed databases [4, 19, 22]. For such applications, a stronger version of reliable broadcast is more suitable, namely, *uniform reliable broadcast* which satisfies uniform integrity, validity (section 3.2), and the following.

- *Uniform agreement* [31]. If *any* process delivers a message m, then all correct processes eventually deliver m.

A quiescent implementation of uniform reliable broadcast can be obtained using quiescent implementations of reliable broadcast, and of quasi-reliable send and receive between every pair of processes. Roughly speaking, when p wishes to uniform-broadcast m, it broadcasts m. Upon the delivery of m, each process r qr-sends an acknowledgement to every process, waits for the qr-receipt of such acknowledgements from $t+1$ processes, and then uniform-delivers m.

[15]The no loss and quasi no loss properties are very similar to the strong validity and validity properties in section 6 of [23].

10. Using $\mathcal{HB}$ to extend previous work.

$\mathcal{HB}$ can be used to extend previous work in order to solve problems with algorithms that are both quiescent and tolerant of process crashes and messages losses.

10.1. Extending existing algorithms to tolerate link failures.

$\mathcal{HB}$ can be used to transform many existing algorithms that tolerate process crashes into quiescent algorithms that tolerate both process crashes and message losses. For example, consider the randomized consensus algorithms of [7, 14, 16, 33], the failure-detector based ones of [2, 12], the probabilistic one of [9], and the algorithms for atomic broadcast in [12], k-set agreement in [13], atomic commitment in [20], and approximate agreement in [15]. All these algorithms tolerate process crashes. Moreover, it is easy to verify that the only communication primitives that they actually need are quasi-reliable send and receive and/or reliable broadcast. Thus in systems where $\mathcal{HB}$ is available, all these algorithms can be made to tolerate both process crashes and message losses (with fair links) by simply plugging in the quiescent communication primitives given in section 7.[16] The resulting algorithms tolerate message losses and are quiescent.

10.2. Extending results of Basu, Charron-Bost, and Toueg [5].

Another way to solve problems with quiescent algorithms that tolerate both process crashes and message losses is obtained by extending the results of [5]. That work addresses the following question: given a problem that can be solved in a system where the only possible failures are process crashes, is the problem still solvable if links can also fail by losing messages? One of the models of lossy links considered in [5] is called *fair lossy*. Roughly speaking, a fair lossy link $p \to q$ satisfies the following property. If p sends an infinite number of messages to q and q is correct, then q receives an infinite number of messages from p (see section 11.3 for a brief comparison between fair lossy and fair links).

[5] establishes the following result: any problem P that can be solved in systems with process crashes can also be solved in systems with process crashes and fair lossy links, provided P is *correct-restricted*[17] or a majority of processes are correct. For each of these two cases, [5] shows how to transform any algorithm that solves P in a system with process crashes into one that solves P in a system with process crashes and fair lossy links. The algorithms that result from these transformations, however, are not quiescent: each transformation requires processes to repeatedly send messages forever.

Given $\mathcal{HB}$, we can modify the transformations in [5] to ensure that if the original algorithm is quiescent, then so is the transformed one. Roughly speaking, the modification consists of (1) adding message acknowledgements; (2) suppressing the sending of a message from p to q if either (a) p has received an acknowledgement for that message from q, or (b) the heartbeat of q has not increased since the last time p sent a message to q; and (3) modifying the meaning of the operation "append $Queue_1$ to $Queue_2$" so that only the elements in $Queue_1$ that are not in $Queue_2$ are actually appended to $Queue_2$. The results in [5], combined with the above modification, show that if a problem P can be solved with a quiescent algorithm in a system with crash failures only, and either P is correct-restricted or a majority of processes are correct,

[16] This can also be done to algorithms that require reliable send/receive or uniform reliable broadcast by plugging in the implementations given in section 9, provided a majority of processes are correct.

[17] Intuitively, a problem P is correct-restricted if its specification does not refer to the behavior of faulty processes [6, 18].

then P is solvable with a quiescent algorithm that uses $\mathcal{HB}$ in a system with crash failures and fair lossy links.

11. Concluding remarks.

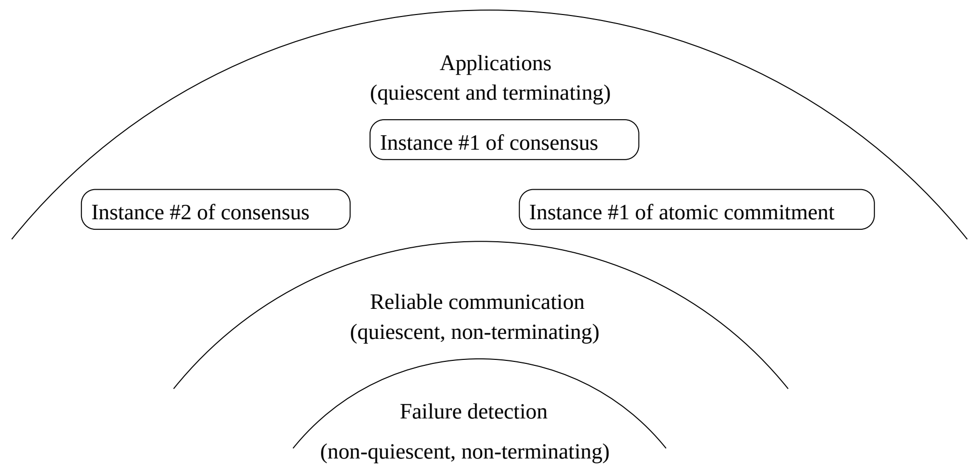
11.1. About message buffering. We now address the issue of message buffering in the implementation of quasi-reliable send and receive, and of reliable broadcast (section 7). Soon after a process p crashes, its heartbeat ceases everywhere and processes stop sending messages to p. However, they do have to keep the messages they intended to send to p, just in case p is merely very slow, and the heartbeat of p resumes later on. In theory, they have to keep these messages forever. In practice, however, the system will eventually decide that p is indeed useless and will "remove" p (e.g., via a group membership protocol). All the stored messages addressed to p can then be discarded. The removal of p may take a long time,[18] but the heartbeat mechanism ensures that processes stop sending messages to p soon after p actually crashes, and much before its removal.

11.2. Quiescence versus termination. In this paper, we considered reliable communication protocols that tolerate process crashes and message losses, and we focused on achieving quiescence. What about achieving termination? A *terminating* protocol guarantees that every process eventually reaches a halting state from which it cannot take further actions. A terminating protocol is obviously quiescent, but the converse is not necessarily true. For example, consider the protocol described at the beginning of section 1. In this protocol, (a) s sends a copy of m repeatedly until it receives $ack(m)$ from r, and then it halts; and (b) upon each receipt of m, r sends $ack(m)$ back to s. In the absence of process crashes this protocol is quiescent. However, the protocol is not terminating because r never halts: r remains (forever) ready to reply to the receipt of a possible message from s.

Can we use $\mathcal{HB}$ to obtain reliable communication protocols that are *terminating*? The answer is no, *even for systems with no process crashes*, as we now explain. Consider a system with message losses (fair links) and no process crashes. [27] proves that for any terminating protocol P and any initial configuration of P, there are runs of P in which all processes halt without receiving any message. This implies that a terminating protocol cannot solve the reliable communication problem (in systems with fair links).

To deal with this problem, we propose a layering that allows *applications* to terminate. This layering, shown in Figure 11.1, separates applications, reliable communication, and failure detection. At the lowest level, there are failure detectors, such as $\mathcal{HB}$. Of course, these are neither quiescent nor terminating. At the middle level, there are reliable communication protocols, such as those that we described in sections 3 and 9. These communication protocols are quiescent (thanks to the failure detectors at the lower level) but not terminating. Finally, at the top level, there are applications, such as concurrent instances of consensus, atomic broadcast, atomic commitment protocols, etc. Applications are both quiescent *and* terminating: they achieve termination thanks to the reliable communication layer. For example, consider an instance of consensus. Once a process decides, it delegates the task of broadcasting the decision value to the reliable communication layer, and then it terminates (without waiting for the broadcast to terminate). Since every correct process eventually decides and terminates, this instance of consensus terminates.

[18]In some group membership protocols, the timeout used to remove a process is on the order of minutes: killing a process is expensive and so timeouts are set conservatively.



Applications
(quiescent and terminating)
Instance #1 of consensus
Instance #2 of consensus
Instance #1 of atomic commitment
Reliable communication
(quiescent, non-terminating)
Failure detection
(non-quiescent, non-terminating)

FIG. 11.1. *Layering that separates applications, reliable communication, and failure detection.*

If necessary, termination in the reliable communication layer can also be achieved in practice, as we now explain. A reliable communication protocol is unable to terminate when processes cannot determine whether a nonresponsive process has crashed or it is only very slow. However, as we mentioned in our discussion of message buffering, a process that actually crashes is eventually removed by the operating system or a group membership protocol (and the remaining processes are notified accordingly). When this happens, the communication protocol can terminate. Note that with the heartbeat mechanism quiescence can be achieved long before termination (this is because when a process crashes, it may take a relatively long time to decide that it actually crashed, but its heartbeat count at other processes stops increasing almost immediately).

As a final remark, we note that some communication protocols, such as standard *data link* protocols, are inherently nonterminating: they are shared communication services that are always "ready" for message transmission. The reliable communication protocols (in our middle level) could also be viewed in the same way, namely, as nonterminating shared services that are always ready for message transmission.

11.3. Fair links versus fair lossy links. Fair links and fair lossy links are two typical models of lossy links considered in the literature.[19] Roughly speaking, a fair link guarantees that for every m, if p sends m to q an infinite number of times, and q is correct, then q receives m an infinite number of times. On the other hand, a fair lossy link guarantees that if p sends an infinite number of messages to q, and q is correct, then q receives an infinite number of messages from p. Fair lossy links and fair links differ in a subtle way. For instance, if process p sends the infinite sequence of distinct messages $m_1, m_2, m_3, \dots$ to q and $p \to q$ is fair lossy, then q is guaranteed to receive an infinite subsequence, whereas if $p \to q$ is fair, q may receive nothing (because each distinct message is sent only once). On the other hand, if p sends the infinite sequence $m_1, m_2, m_1, m_2, \dots$ and $p \to q$ is fair lossy, q may never receive a copy of m_2 (while

[19]In [29], these links correspond to the strong and weak loss limitation properties, respectively.

it receives m_1 infinitely often), whereas if $p \to q$ is fair, q is guaranteed to receive an infinite number of copies of both m_1 and m_2.

In this paper, we chose the fair links model. A natural question is whether our results still hold with fair lossy links instead. It turns out that the answer is yes, as we now explain. First note that Theorems 4.1, 5.5, and A.12 still hold because their proofs rely only on the fact that lossy links may lose (or not lose) messages arbitrarily during any finite period of time—a behavior allowed by fair lossy links. Moreover, the algorithms in sections 7 and 8 can be easily modified to work with fair lossy links through the use of piggybacking; namely, every time a process wishes to send a message, it piggybacks all the messages that it previously sent.[20] Finally, the algorithms in section 9 are still correct because they do not directly use the communication links; rather, they rely only on the communication algorithms of section 7.

11.4. Quiescent versus nonquiescent transformations. We proved that if $\mathcal{D}$ is a failure detector with finite range that can be used to solve quiescent reliable communication, then $\mathcal{D}$ can be transformed to $\diamond\mathcal{P}$. Our transformation is not quiescent: to "extract" $\diamond\mathcal{P}$ out of $\mathcal{D}$, processes keep on sending messages forever. This, however, does not invalidate the two facts that we wanted to show, namely:

1. $\mathcal{D}$ encodes at least as much information as $\diamond\mathcal{P}$.
2. $\mathcal{D}$ *cannot* be implemented (this follows from the transformation from $\mathcal{D}$ to $\diamond\mathcal{P}$, and the fact that $\diamond\mathcal{P}$ cannot be implemented).

This shows that finite-range failure detectors have some inherent limitation (because there is a failure detector with infinite range, namely $\mathcal{HB}$, that can be used to solve quiescent reliable communication such that (1) $\mathcal{HB}$ does not encode $\diamond\mathcal{P}$, and (2) $\mathcal{HB}$ can be implemented).

Even though a nonquiescent transformation was sufficient to establish our results, quiescent transformations are necessary when comparing the power of failure detectors to solve tasks with quiescent algorithms, as we now explain. If $\mathcal{D}$ can be transformed to $\mathcal{D}'$, we can conclude that $\mathcal{D}$ is (at least) as powerful as $\mathcal{D}'$ in terms of task solving (intuitively, a *task* is a relation between inputs and outputs [8, 25]). If the transformation from $\mathcal{D}$ to $\mathcal{D}'$ is not quiescent, however, $\mathcal{D}$ may not be as powerful as $\mathcal{D}'$ in terms of solving tasks *quiescently*: there may be a task that can be solved quiescently with $\mathcal{D}'$ but not with $\mathcal{D}$. On the other hand, if the transformation from $\mathcal{D}$ to $\mathcal{D}'$ *is* quiescent, we can conclude that $\mathcal{D}$ is (at least) as powerful as $\mathcal{D}'$ in terms of solving tasks with quiescent algorithms. The study of quiescent transformations is a new and interesting subject of research.

11.5. Extension to partitionable networks. In this paper, we considered networks that do not partition: we assumed that every pair of correct processes are reachable from each other through fair paths. In a subsequent paper [1], we drop this assumption and consider *partitionable networks.* We first generalize the definition of $\mathcal{HB}$ and show how to implement it in such networks. We then consider generalized versions of reliable communication and of consensus for partitionable networks and use $\mathcal{HB}$ to solve these problems with quiescent protocols (to solve consensus we also use a generalization of the *eventually strong* failure detector [12]).

Appendix. Removing the simplifying assumption from Theorem 5.5.

We now give an extended, more complex proof of Theorem 5.5 without the simplifying assumption.

[20] With the fair links used in this paper, this expensive piggybacking is avoided. We believe that in practice, links that intermittently lose messages are *both* fair and fair lossy.

Let $\mathcal{E}$ be an environment and $\mathcal{D}$ be any failure detector with finite range $\mathcal{R} = \{v_1, v_2, \ldots, v_\ell\}$. Let $\mathcal{I}$ be a quiescent implementation of s-send and s-receive that uses $\mathcal{D}$ in environment $\mathcal{E}$.

As in the simpler proof in section 5, the transformation algorithm $T_{\mathcal{D}\to\diamond\mathcal{P}}$ uses a finite table that is predetermined from $\mathcal{D}$. We first define this table and show some of its properties (section A.1). We then describe and prove the correctness of the transformation algorithm $T_{\mathcal{D}\to\diamond\mathcal{P}}$ that uses this table (section A.2).

A.1. The predetermined table. For the definitions in this proof, let

- v_j be a failure detector value, i.e., $v_j \in \mathcal{R}$,
- p be a process, i.e., $p \in \Pi$,
- F be a failure pattern,
- H be a failure detector history with range $\mathcal{R}$,
- f be an assignment of failure detector values to every process in Π, i.e., $f : \Pi \longrightarrow \mathcal{R}$,
- P and P_0 be a nonempty set of processes,
- $p_0, p_1, \ldots, p_{m-1}$ be the processes in P (where $m = |P|$ and $p_0 < p_1 < \cdots < p_{m-1}$).

DEFINITION A.1. *We say that* v_j *is* a limit value for p and H *if, for infinitely many* t, $H(p,t) = v_j$.

DEFINITION A.2. *We say that* f is a limit vector for P and H *if for all* $p \in P$, $f(p)$ *is a limit value for* p *and* H*. The set of all limit vectors for* P *and* H *is denoted* $L_P(H)$.

DEFINITION A.3. *RRIRounds*(P, f) *is defined as follows.*

Consider the round-robin execution of implementation $\mathcal{I}$ *in which* (a) *processes in* P *take steps forever in a round-robin fashion*[21] *and processes in* $\Pi \setminus P$ *do not take any steps,* (b) *no process ever* s-send*s any bit,* (c) *every time a process* $p \in P$ *queries its failure detector module,* p *gets* $f(p)$, (d) *every time a process* $p \in P$ *takes a step,* p *receives the earliest message sent to it that it did not yet receive (thus, every* $p \in P$ *eventually receives each message sent to it), and* (e) *all messages sent to processes in* $\Pi \setminus P$ *are lost.*[22]

There are two possible cases in the above round-robin execution of $\mathcal{I}$.

1. Every process eventually stops sending messages. *In this case, after some number* k *of round-robin rounds, no process ever receives any messages. We say that "round-robin initialization (r.r.i.) occurs in* k *rounds," and define* *RRIRounds*$(P, f) = k$.
2. Some process never stops sending messages. *In this case, we define* *RRIRounds*$(P, f) = \infty$.

Intuitively, we say that F and H allow r.r.i. for P and f if the following hold: (a) in the above execution with P and f, r.r.i. occurs in k rounds for some k, and (b) there is a schedule compatible with F and H that allows this k-round r.r.i. More precisely, we have the following definition.

DEFINITION A.4. *We say that* F and H allow r.r.i. for P and f *if*

(a) *RRIRounds*$(P, f) = k$ *for some* k, *and*

(b) *there are times* $t_0 < t_1 < \cdots < t_{mk-1}$ *such that for every* $0 \le j \le mk - 1$, (1) $p_{j \bmod m}$ *is not crashed at time* t_j, *i.e.,* $p_{j \bmod m} \notin F(t_j)$, *and* (2)

[21] That is, p_0 takes the first step, then p_1 takes a step, and so on, so that the jth step is taken by process $p_{(j-1) \bmod m}$.

[22] It is possible that this is *not* a valid execution of $\mathcal{I}$ using $\mathcal{D}$ in environment $\mathcal{E}$.

the failure detector module of $p_{j \bmod m}$ *at time* t_j *outputs* $f(p_{j \bmod m})$, *i.e.,* $H(p_{j \bmod m}, t_j) = f(p_{j \bmod m})$.

DEFINITION A.5. $L_{P,P_0}(F,H) = \{f \mid f \in L_P(H)$, *and* F *and* H *allow r.r.i. for* P_0 *and* $f\}$.

DEFINITION A.6. $E^{\mathcal{D},\mathcal{E}}_{P,P_0} = \{f \mid \exists F \in \mathcal{E}, \exists H \in \mathcal{D}(F) : P = \mathit{correct\_proc}(F)$, *and* $f \in L_{P,P_0}(F,H)\}$.

Roughly speaking, $E^{\mathcal{D},\mathcal{E}}_{P,P_0}$ is the set of limit vectors f that could occur when P is the set of correct processes and it is possible to have r.r.i. for P_0 and f.

The table used by the transformation algorithm $T_{\mathcal{D}\to\diamond\mathcal{P}}$ consists of all the sets $E^{\mathcal{D},\mathcal{E}}_{P,P_0}$ where P and P_0 range over all nonempty subsets of processes. Note that this table is finite. We omit the superscript $\mathcal{D},\mathcal{E}$ from $E^{\mathcal{D},\mathcal{E}}_{P,P_0}$ whenever it is clear from the context.

LEMMA A.7. *Let* $F \in \mathcal{E}$, $P = \mathit{correct\_proc}(F)$, $H \in \mathcal{D}(F)$, *and* $f \in L_P(H)$. *Assume* $P \neq \emptyset$. *Then* $\mathit{RRIRounds}(P,f) < \infty$.

Proof. We can construct a run R of implementation $\mathcal{I}$ using $\mathcal{D}$ with $F \in \mathcal{E}$, such that all processes behave exactly as in the round-robin execution of $\mathcal{I}$ that was used to define $\mathit{RRIRounds}(P,f)$. To see this, note that since $F \in \mathcal{E}$, $P = \mathit{correct\_proc}(F)$, $H \in \mathcal{D}(F)$, and $f \in L_P(H)$, we can find times for the round-robin steps of correct processes such that, for each time u at which a process p takes a step, the output $H(p,u)$ of its failure detector module is $f(p)$. Since $\mathcal{I}$ is quiescent, there is a time after which no process sends any message in run R. Thus, $\mathit{RRIRounds}(P,f) < \infty$. ∎

LEMMA A.8. *Let* $F \in \mathcal{E}$, $P = \mathit{correct\_proc}(F)$, *and* $H \in \mathcal{D}(F)$. *Assume* $P \neq \emptyset$ *and let* P_0 *be such that* $P \subseteq P_0 \subseteq \Pi$. *If* $f \in L_{P,P_0}(F,H)$, *then* $f \in E_{P,P_0}$ *and* $f \notin E_{P',P_0}$ *for all* P' *such that* $\emptyset \subset P' \subset P$.

Proof. Let $f \in L_{P,P_0}(F,H)$. The fact that $f \in E_{P,P_0}$ is immediate from the definition of E_{P,P_0}. Let P' be such that $\emptyset \subset P' \subset P$. Suppose, for contradiction, that $f \in E_{P',P_0}$. Then there exists a failure pattern $F' \in \mathcal{E}$ and $H' \in \mathcal{D}(F')$ such that $P' = \mathit{correct\_proc}(F')$ and $f \in L_{P',P_0}(F',H')$.

We now obtain a contradiction by using the quiescent implementation $\mathcal{I}$. Let p be a process in P' and q be a process in $P \setminus P'$. We construct three runs of $\mathcal{I}$, namely, R_0, R_1, and R_2. Roughly speaking, each one of these runs starts with an r.r.i. for P_0 and f. After this initialization, in R_0 nothing else happens, in R_1 process p s-sends some bit to q but q crashes, and in R_2 process p s-sends the same bit to q and q is correct. We will reach a contradiction by arguing that in R_2 process q behaves as in R_0, and thus it never s-receives any bit from p—this violates the defining property of s-send and s-receive.

Runs R_0, R_1, and R_2 are defined as follows.[23]

1. Run R_0 has failure pattern F and failure detector history H. Since $f \in L_{P,P_0}(F,H)$, $f \in L_P(H)$, and F and H allow r.r.i. for P_0 and f. R_0 consists initially of an r.r.i. for P_0 and f. More precisely, initially: (a) processes in P_0 take steps in a round-robin fashion and processes in $\Pi \setminus P_0$ do not take any steps, (b) no process s-sends any bit, (c) every time a process $r \in P_0$ queries its failure detector module, r gets $f(r)$, (d) every time a process $r \in P_0$ takes a step, r receives the earliest message sent to it that it did not yet receive, and (e) all messages sent to processes in $\Pi \setminus P_0$ are lost. This goes on until each process in P_0 has taken $\mathit{RRIRounds}(P_0,f)$ steps. Let

[23]In each one of these runs, we will require that for a certain *finite* period of time, some messages are lost while others are not. As we explained in our model (section 2.5), this behavior is consistent with any link failure pattern.

t_0 be the time when this happens. After t_0, processes in P take steps in a round-robin fashion such that every time a process $r \in P$ takes a step, it obtains $f(r)$ from its failure detector module (this is possible because $f \in L_P(H)$); moreover, no process s-sends any bit. Note that since both p and q are in $P = \mathit{correct\_proc}(F)$, and p does not s-send any bit to q, it must be that q does not s-receive any bit from p. Furthermore, after time t_0, no processes send or receive any messages.

2. Run R_1 has failure pattern F' and failure detector history H'. Since $f \in L_{P',P_0}(F', H')$, $f \in L_{P'}(H')$, and F' and H' allow r.r.i. for P_0 and f. Initially, processes in R_1 behave as in R_0, i.e., R_1 starts with an r.r.i. for P_0 and f. Then, execution proceeds as follows: (a) p s-sends some bit b to q, (b) processes in P' take steps in round-robin fashion and processes in $\Pi \setminus P'$ take no steps, (c) every time a process $r \in P'$ takes a step, it obtains $f(r)$ from its failure detector module, (d) every time a process $r \in P'$ takes a step, r receives the earliest message sent to it that it did not yet receive, and (e) all messages sent to processes in $\Pi \setminus P'$ are lost.

Note that, since implementation $\mathcal{I}$ is quiescent, there is a time t_1 after which no messages are sent or received. Assume without loss of generality that at time t_1 every process in P' took the same number k of steps (otherwise, choose another time $t_1' > t_1$).

3. Run R_2 has failure pattern F and failure detector history H. Initially, processes in R_2 behave as in R_1: R_2 starts with an r.r.i. for P_0 and f, and then p s-sends b to q and execution continues as in R_1, until each process in P' has taken k steps (this is possible because $f \in L_P(H)$ and $P' \subseteq P$). Let t_2 be the time when this happens. After t_2, execution proceeds as follows: (a) no process s-sends any bit, (b) processes in P take steps in round-robin fashion and processes in $\Pi \setminus P$ take no steps, and (c) every time a process $r \in P$ takes a step, it obtains $f(r)$ from its failure detector module (this is possible because $f \in L_P(H)$).

In R_2, at time t_2, each process in P' is in the same state as in run R_1 at time t_1, and each process in $P \setminus P'$ is in the same state as in run R_0 at time t_0. A simple induction on the steps taken shows that, in R_2, (1) processes in P' have the same behavior as in run R_1; (2) processes in $P \setminus P'$ have the same behavior as in run R_0; (3) no messages are sent or received after time t_2. Since $q \in P \setminus P'$ and q does not s-receive any bit from p in R_0, it does not s-receive any bit from p in R_2.

In summary, in R_2: (a) both p and q are correct; (b) p s-sends b to q; and (c) q does not s-receive b from p. Thus, $\mathcal{I}$ is not a correct implementation of s-send and s-receive—a contradiction. ∎

A.2. The transformation algorithm. The algorithm $T_{\mathcal{D}\to\mathcal{D}'}$ that transforms $\mathcal{D}$ to an eventually perfect failure detector $\mathcal{D}' = \diamond\mathcal{P}$ in environment $\mathcal{E}$ is shown in Figure A.1. $T_{\mathcal{D}\to\mathcal{D}'}$ uses the table of sets E_{P,P_0} (for all nonempty subsets P and P_0 of processes) that has been determined a priori from the given $\mathcal{D}$ and $\mathcal{E}$. It also uses an implementation of qr-send and qr-receive between every pair of processes. A simple implementation is by repeated retransmissions and diffusion (it does not have to be quiescent).

All variables are local to each process. *Sequences* is a finite set of finite sequences of pairs (p, v) where $p \in \Pi$ is a process and $v \in \mathcal{R}$ is a failure detector value. It stores possible schedules that could have resulted from F and H. Vector f stores the last failure detector value that p qr-received from each process. *Order* is an ordered set that records the order in which the last failure detector value from each process was qr-received. $\mathcal{D}'_p$ denotes the output of the eventually perfect failure detector that p is simulating (a set of processes that p currently suspects). *AllowsRRI* is a Boolean

```
For every process $p$:

    Initialization:
        for all $q \in \Pi$ do $f[q] \leftarrow \bot$
        $Order \leftarrow \emptyset$
        $Sequences \leftarrow \{\lambda\}$
        $\mathcal{D}'_p \leftarrow \emptyset$
        { For each $\emptyset \subset P, P_0 \subseteq \Pi$, the set $E^{\mathcal{D},\mathcal{E}}_{P,P_0}$ is determined a priori from $\mathcal{D}$ and $\mathcal{E}$ }

    cobegin
        || Task 1:
            repeat periodically
                $v \leftarrow \mathcal{D}_p$                                        {query $\mathcal{D}$}
                append $(p, v)$ to each sequence in $Sequences$
                for all $q \in \Pi$ do qr-send $(Sequences, v)$ to $q$

        || Task 2:
            upon qr-receive $(Sequences', v')$ from $q$ do
                $f[q] \leftarrow v'$
                $Order \leftarrow q \mid\mid (Order \setminus \{q\})$      {process $q$ is moved to the front of $Order$}

FIG. A.1. *Transformation of $\mathcal{D}$ to an eventually perfect failure detector $\mathcal{D}'$.*

function that takes three parameters: a set *Sequences*, a set $P = \{p_0, p_1, \ldots, p_{m-1}\} \subseteq \Pi$ (where $p_0 < p_1 < \cdots < p_{m-1}$), and a vector f. It returns true if and only if for some sequence $s \in Sequences$, there exists a subsequence of s that consists of $RRIRounds(P, f)$ repetitions of $(p_0, f(p_0)), (p_1, f(p_1)), \ldots, (p_{m-1}, f(p_{m-1}))$.

In Task 1, each process p periodically queries its failure detector module, appends a new pair to each sequence in *Sequences*, and then qr-sends *Sequences* and the output of its failure detector module $\mathcal{D}_p$ to every process. Upon the qr-receipt of $(Sequences', v')$ from process q in Task 2, process p enters v' into $f[q]$, moves q to the front of *Order*, and updates *Sequences*. Then, p uses the function *AllowsRRI* to check whether there is some k such that r.r.i. could have occurred for $Order[1..k]$ and f. If there is, it sets k_0 to the *largest* such k and then checks if for some k', $f \in E_{Order[1..k'],Order[1..k_0]}$. If so, it sets k_1 to the *smallest* such k' and sets $\mathcal{D}'$ to the complement of $Order[1..k_1]$.

We now show that the failure detector constructed by this algorithm, namely $\mathcal{D}'$, is an eventually perfect failure detector. Consider a run of this algorithm with failure pattern $F \in \mathcal{E}$ and failure detector history $H \in \mathcal{D}(F)$, such that $correct\_proc(F) \neq \emptyset$. Let t be the number of processes that crash in F, i.e., $t = |\Pi \setminus correct\_proc(F)|$. Henceforth, p denotes a correct process in F, and f, *Order*, and *Sequences* are variables local to p.

LEMMA A.9. *There is a time t_0 after which* (1) $Order[1..n-t] = correct\_proc(F)$, (2) $f \in L_{Order[1..n-t]}(H)$, *and* (3) $AllowsRRI(Sequences, Order[1..n-t], f)$.[24]

[24]This does not mean that eventually the values of variables f, *Sequences*, and *Order* at p stop

Proof. Note that p eventually stops qr-receiving messages from processes that crash, and p never stops qr-receiving messages from correct processes. From the way *Order* is updated, there is a time t_1 after which (1) holds.

Let $P = \mathit{correct\_proc}(F)$. Variable f ranges over a finite number of values, so there are functions $f_1, f_2, \ldots, f_N : \Pi \to \mathcal{R}$ such that (a) for every $1 \le j \le N$, variable f is equal to f_j an infinite number of times, and (b) there is a time t_2 after which the predicate $f \in \{f_1, f_2, \ldots, f_N\}$ holds. We now show that for every $1 \le j \le N$, $f_j \in L_P(H)$, and there is a time τ_j after which $\mathit{AllowsRRI}(\mathit{Sequences}, P, f_j)$ holds. Together with (1) and (b), this implies that after time $t_0 = \max\{t_1, t_2, \tau_1, \tau_2, \ldots, \tau_N\}$, both (2) and (3) hold.

Let $1 \le j \le N$. We first claim that each process $q \in P$ obtains $f_j(q)$ from $\mathcal{D}$ in line 13 an infinite number of times—this immediately implies $f_j \in L_P(H)$. To show the claim, note that process p qr-receives a message from q and updates $f[q]$ an infinite number of times. Together with (a), this implies that p qr-receives a message containing $f_j(q)$ from q an infinite number of times, and this implies the claim.

We now show that there is a time τ_j after which $\mathit{AllowsRRI}(\mathit{Sequences}, P, f_j)$ holds. Since $f_j \in L_P(H)$, by Lemma A.7, $\mathit{RRIRounds}(P, f_j) = k$ for some $k < \infty$. Let $p_0 < p_1 < \cdots < p_{m-1}$ be the processes in P. By the claim, at some time u_0, p_0 obtains $f_j(p_0)$ from $\mathcal{D}$ in line 13. After doing so, p_0 appends $(p_0, f_j(p_0))$ to all sequences in *Sequences* and qr-sends a message containing *Sequences* to all processes. At some time $u_1' > u_0$, p_1 qr-receives this message and updates *Sequences*. By the claim, at some time $u_1 > u_1'$, p_1 obtains $f_j(p_1)$ from $\mathcal{D}$ in line 13. After doing so, p_1 appends $(p_1, f_j(p_1))$ to all sequences in *Sequences* and so p_1 obtains a sequence containing $(p_0, f_j(p_0))$ before $(p_1, f_j(p_1))$. We can repeat this argument for all the processes in P in a round-robin order, for $k+1$ rounds, and conclude that eventually $\mathit{AllowsRRI}(\mathit{Sequences}, P, f_j)$ holds. □

LEMMA A.10. *There is a time t_1 after which for every $m_0 \ge n - t$ such that $\mathit{AllowsRRI}(\mathit{Sequences}, \mathit{Order}[1..m_0], f)$ holds:* (1) $f \in E_{\mathit{Order}[1..n-t], \mathit{Order}[1..m_0]}$ *and* (2) *for all* $1 \le m_1 < n - t$, $f \notin E_{\mathit{Order}[1..m_1], \mathit{Order}[1..m_0]}$.

Proof. By Lemma A.9, there is a time t_0 after which (a) $\mathit{Order}[1..n-t] = \mathit{correct\_proc}(F)$, and (b) $f \in L_{\mathit{Order}[1..n-t]}(H)$. Let $t_1 = t_0$. Suppose that at some time $t_1' > t_1$, $\mathit{AllowsRRI}(\mathit{Sequences}, \mathit{Order}[1..m_0], f)$ holds for some $m_0 \ge n - t$. This implies that F and H allow r.r.i. for $\mathit{Order}[1..m_0]$ and f. From (b), $f \in L_{\mathit{Order}[1..n-t], \mathit{Order}[1..m_0]}(F, H)$ holds at time t_1'. By Lemma A.8, $f \in E_{\mathit{Order}[1..n-t], \mathit{Order}[1..m_0]}$.

Let $1 \le m_1 < n - t$. By (a), $\emptyset \subset \mathit{Order}[1..m_1] \subset \mathit{correct\_proc}(F) \subseteq \mathit{Order}[1..m_0]$ holds at time t_1'. Note that $f \in L_{\mathit{Order}[1..n-t], \mathit{Order}[1..m_0]}(F, H)$ holds at time t_1'. By Lemma A.8, $f \notin E_{\mathit{Order}[1..m_1], \mathit{Order}[1..m_0]}$. □

COROLLARY A.11. *There is a time after which $\mathcal{D}_p' = \Pi \setminus \mathit{correct\_proc}(F)$.*

Proof. By Lemma A.9 part (3), there is a time t_0 after which every time p qr-receives some message, the **if** in line 22 evaluates to true and the k_0 selected in line 23 is at least $n - t$. After time t_0, by Lemma A.10, there is a time after which every time p qr-receives some message, the **if** in line 24 evaluates to true and the k_1 selected in line 25 is $n - t$. Now apply Lemma A.9 part (1). □

By Corollary A.11, we have the following theorem.

THEOREM A.12. *Consider an asynchronous system subject to process crashes and message losses. Suppose that failure detector $\mathcal{D}$ with finite range can be used to*

changing. It means that, although they may continue to change forever, eventually the predicates (1), (2), and (3) are true forever at p.

solve the single-shot reliable send and receive problem in environment $\mathcal{E}$ and that the implementation is quiescent. Then $\mathcal{D}$ can be transformed (in environment $\mathcal{E}$) to the eventually perfect failure detector $\diamond\mathcal{P}$.

Acknowledgments. We are grateful to Anindya Basu and Bernadette Charron-Bost for having provided extensive comments that improved the presentation of this paper. We would also like to thank Tushar Deepak Chandra for suggesting the name Heartbeat and for providing insightful comments regarding the simplifying assumption of Theorem 5.5 which helped us write the appendix. We are also grateful to the anonymous referees for their helpful comments.

GADGETS, APPROXIMATION, AND LINEAR PROGRAMMING[*]

LUCA TREVISAN[†], GREGORY B. SORKIN[‡], MADHU SUDAN[§], AND DAVID P. WILLIAMSON[‡]

Abstract. We present a linear programming-based method for finding "gadgets," i.e., combinatorial structures reducing constraints of one optimization problem to constraints of another. A key step in this method is a simple observation which limits the search space to a *finite* one. Using this new method we present a number of new, computer-constructed gadgets for several different reductions. This method also answers a question posed by Bellare, Goldreich, and Sudan [*SIAM J. Comput.,* 27 (1998), pp. 804–915] of how to prove the optimality of gadgets: linear programming duality gives such proofs.

The new gadgets, when combined with recent results of Håstad [*Proceedings of the* 29*th ACM Symposium on Theory of Computing*, 1997, pp. 1–10], improve the known inapproximability results for MAX CUT and MAX DICUT, showing that approximating these problems to within factors of $16/17+\epsilon$ and $12/13+\epsilon$, respectively, is NP-hard for every $\epsilon > 0$. Prior to this work, the best-known inapproximability thresholds for both problems were 71/72 (M. Bellare, O. Goldreich, and M. Sudan [*SIAM J. Comput.*, 27 (1998), pp. 804–915]). Without using the gadgets from this paper, the best possible hardness that would follow from Bellare, Goldreich, and Sudan and Håstad is 18/19. We also use the gadgets to obtain an improved approximation algorithm for MAX3 SAT which guarantees an approximation ratio of .801. This improves upon the previous best bound (implicit from M. X. Goemans and D. P. Williamson [*J. ACM*, 42 (1995), pp. 1115–1145]; U. Feige and M. X. Goemans [*Proceedings of the Third Israel Symposium on Theory of Computing and Systems*, 1995, pp. 182–189]) of .7704.

Key words. combinatorial optimization, approximation algorithms, reductions, intractability, NP-completeness, probabilistic proof systems

1. Introduction.

A "gadget" is a finite combinatorial structure which translates a given constraint of one optimization problem into a set of constraints of a second optimization problem. A classical example is in the reduction from 3SAT to MAX 2SAT, due to Garey, Johnson, and Stockmeyer [6]. Given an instance of 3SAT on variables $X_1, \ldots, X_n$ and with clauses $C_1, \ldots, C_m$, the reduction creates an instance of MAX 2SAT on the original or "primary" variables $X_1, \ldots, X_n$ along with new or "auxiliary" variables $Y^1, \ldots, Y^m$. The clauses of the MAX 2SAT instance are obtained by replacing each clause of length 3 in the 3SAT instance with a "gadget," in this case a collection of 10 2SAT clauses. For example, the clause $C_k = X_1 \vee X_2 \vee X_3$ would be replaced with the following 10 clauses on the variables X_1, X_2, X_3 and a

new auxiliary variable Y^k:

$$X_1,\ X_2,\ X_3,\ \neg X_1 \vee \neg X_2,\ \neg X_2 \vee \neg X_3,\ \neg X_3 \vee \neg X_1,\\ Y^k,\ X_1 \vee \neg Y^k,\ X_2 \vee \neg Y^k,\ X_3 \vee \neg Y^k.$$

The property satisfied by this gadget is that for any assignment to the primary variables, if clause C_k is satisfied, then 7 of the 10 new clauses can be satisfied by setting Y^k appropriately; otherwise only 6 of the 10 are satisfiable. (Notice that the gadget associated with each clause C_k uses its own auxiliary variable Y^k, and thus Y^k may be set independently of the values of variables not appearing in C_k's gadget.) Using this simple property of the gadget it is easy to see that the maximum number of clauses satisfied in the MAX 2SAT instance by any assignment is $7m$ if and only if the instance of 3SAT is satisfiable. This was used by [6] to prove the NP-hardness of solving MAX 2SAT. We will revisit the 3SAT-to-2SAT reduction in Lemma 6.5.

Starting with the work of Karp [12], gadgets have played a fundamental role in showing the hardness of optimization problems. They are the core of any reduction between combinatorial problems, and they retain this role in the spate of new results on the nonapproximability of optimization problems.

Despite their importance, the construction of gadgets has always been a "black art" with no general methods of construction known. In fact, until recently no one had even proposed a concrete definition of a gadget; Bellare, Goldreich, and Sudan [2] finally did so, with a view to quantifying the role of gadgets in nonapproximability results. Their definition is accompanied by a seemingly natural "cost" measure for a gadget. The more costly the gadget, the weaker the reduction. However, first, finding a gadget for a given reduction remained an ad hoc task. Second, it remained hard to prove that a gadget's cost was optimal.

This paper addresses these two issues. We show that for a large class of reductions, the space of potential gadgets that need to be considered is actually *finite*. This is not entirely trivial, and the proof depends on properties of the problem that is being reduced to. However, the method is very general and encompasses a large number of problems. An immediate consequence of the finiteness of the space is the existence of a search procedure to find an optimal gadget. But a naive search would be impracticably slow, and search-based proofs of the optimality (or the nonexistence) of a gadget would be monstrously large.

Instead, we show how to express the search for a gadget as a linear program (LP) whose constraints guarantee that the potential gadget is indeed valid, and whose objective function is the cost of the gadget. Central to this step is the idea of working with weighted versions of optimization problems rather than unweighted ones. (Weighted versions result in LPs, while unweighted versions would result in integer programs (IPs).) This seemingly helps only in showing hardness of weighted optimization problems, but a result due to Crescenzi, Silvestri, and Trevisan [3] shows that for a large class of optimization problems (including all the ones considered in this paper), the weighted versions are exactly as hard with respect to approximation as the unweighted ones. Therefore, working with a weighted version is as good as working with an unweighted one.

The LP representation has many benefits. First, we are able to search for much more complicated gadgets than is feasible manually. Second, we can use the theory of LP duality to present short(er) proofs of optimality of gadgets and nonexistence of gadgets. Last, we can solve relaxed or constrained versions of the LP to obtain upper and lower bounds on the cost of a gadget, which can be significantly quicker than solving the actual LP. Being careful in the relaxing/constraining process (and with a bit of luck), we can often get the bounds to match, thereby producing optimal gadgets with even greater efficiency!

Armed with this tool for finding gadgets (and an RS/6000, OSL, and often APL2[1]), we examine some of the known gadgets and construct many new ones. (In what follows we often talk of "gadgets reducing problem X to problem Y" when we mean "gadgets used to construct a reduction from problem X to problem Y.") Bellare, Goldreich, and Sudan [2] presented gadgets reducing the computation of a "verifier" for a probabilistically checkable proof system (PCP) to several problems, including MAX 3SAT, MAX 2SAT, and MAX CUT. We examine these in turn and show that the gadgets in [2] for MAX 3SAT and MAX 2SAT are optimal, but their MAX CUT gadget is not. We improve on the efficiency of the last, thereby improving on the factor to which approximating MAX CUT can be shown to be NP-hard. We also construct a new gadget for the MAX DICUT problem, thereby strengthening the known bound on its hardness. Plugging our gadget into the reduction (specifically Lemma 4.15) of [2] shows that approximating MAX CUT to within a factor of 60/61 is NP-hard, as is approximating MAX DICUT to within a factor of 44/45.[2] For both problems, the hardness factor proved in [2] was 71/72. The PCP machinery of [2] has since been improved by Håstad [9]. Our gadgets and Håstad's result show that, for every $\epsilon > 0$, approximating MAX CUT to within a factor of $16/17 + \epsilon$ is NP-hard, as is approximating MAX DICUT to within a factor of $12/13 + \epsilon$. Using Håstad's result in combination with the gadgets of [2] would have given a hardness factor of $18/19 + \epsilon$ for both problems for every $\epsilon > 0$.

Obtaining better reductions between problems can also yield improved approximation algorithms (if the reduction goes the right way!). We illustrate this point by constructing a gadget reducing MAX 3SAT to MAX 2SAT. Using this new reduction in combination with a technique of Goemans and Williamson [7, 8] and the state-of-the-art .931-approximation algorithm for MAX 2SAT due to Feige and Goemans [5] (which improves upon the previous .878-approximation algorithm of [8]), we obtain a .801-approximation algorithm for MAX 3SAT. The best result that could be obtained previously, by combining the technique of [7, 8] and the bound of [5], was .7704. (The best previously published result is a .769 approximation algorithm by Ono, Hirata, and Asano [14].)

Finally, our reductions have implications for PCPs. Let $\mathrm{PCP}_{c,s}[\log, q]$ be the class of languages that admit membership proofs that can be checked by a probabilistic verifier that uses a logarithmic number of random bits, reads at most q bits of the proof, accepts correct proofs of strings in the language with probability at least c, and accepts purported proofs of strings not in the language with probability at most s. We show the following: first, for any $\epsilon > 0$, there exist constants c and s, $c/s > 10/9 - \epsilon$, such that $\mathrm{NP} \subseteq \mathrm{PCP}_{c,s}[\log, 2]$; and second, for all c, s with $c/s > 2.7214$, $\mathrm{PCP}_{c,s}[\log, 3] \subseteq \mathrm{P}$. The best bound for the former result obtainable from [2, 9] is $22/21 - \epsilon$; the best previous bound for the latter was 4 [16].

All the gadgets we use are computer constructed. In the final section, we present an example of a lower bound on the performance of a gadget. The bound is not

[1]Respectively, an IBM RiscSystem/6000 workstation, the IBM Optimization Subroutine Library, which includes an LP package, and (not that we are partisan) IBM's APL2 programming language.

[2]Approximation ratios in this paper for maximization problems are less than 1 and represent the weight of the solution achievable by a polynomial-time algorithm divided by the weight of the optimal solution. This matches the convention used in [18, 7, 8, 5] and is the reciprocal of the measure used in [2].

computer constructed and cannot be, by the nature of the problem. The bound still relies on defining an LP that describes the optimal gadget and extracting the lower bound from the LP's dual.

Subsequent work. Subsequent to the original presentation of this work [17], the approximability results presented in this paper have been superseded. Karloff and Zwick [10] present a 7/8-approximation algorithm for MAX 3SAT. This result is tight unless NP = P [9]. The containment result $\text{PCP}_{c,s}[\log, 3] \subseteq \text{P}$ has also been improved by Zwick [19] and shown to hold for any $c/s \geq 2$. This result is also tight, again by [9]. Finally, the gadget construction methods of this paper have found at least two more applications. Håstad [9] and Zwick [19] use gadgets constructed by these techniques to show hardness results for two problems they consider: MAX 2LIN and MAX NAE3SAT, respectively.

Version. An extended abstract of this paper appeared as [17]. This version corrects some errors, pointed out by Karloff and Zwick [11], in the extended abstract. This version also presents inapproximability results resting on the improved PCP constructions of Håstad [9], while mentioning the results that could be obtained otherwise.

Organization of this paper. The next section introduces precise definitions which formalize the preceding outline. Section 3 presents the finiteness proof and the LP-based search strategy. Section 4 contains negative (nonapproximability) results and the gadgets used to derive them. Section 5 briefly describes our computer system for generating gadgets. Section 6 presents the positive result for approximating MAX 3SAT. Section 7 presents proofs of optimality of the gadgets for some problems and lower bounds on the costs of others. It includes a mix of computer-generated and hand-generated lower bounds.

2. Definitions.

We begin with some definitions we will need before giving the definition of a gadget from [2]. In what follows, for any positive integer n, let $[n]$ denote the set $\{1, \ldots, n\}$.

DEFINITION 2.1. *A* (k-ary) constraint function *is a Boolean function* $f : \{0,1\}^k \to \{0,1\}$.

We refer to k as the arity of a k-ary constraint function f. When it is applied to variables $X_1, \ldots, X_k$ (see the following definitions), the function f is thought of as imposing the constraint $f(X_1, \ldots, X_k) = 1$.

DEFINITION 2.2. *A* constraint family $\mathcal{F}$ *is a collection of constraint functions. The* arity *of* $\mathcal{F}$ *is the maximum of the arity of the constraint functions in* $\mathcal{F}$.

DEFINITION 2.3. *A* constraint C *over a variable set* $X_1, \ldots, X_n$ *is a pair* $C = (f, (i_1, \ldots, i_k))$, *where* $f : \{0,1\}^k \to \{0,1\}$ *is a constraint function and* $i_1, \ldots, i_k$ *are distinct members of* $[n]$. *The constraint* C *is said to be* satisfied *by an assignment* $\vec{a} = a_1, \ldots, a_n$ *to* $X_1, \ldots, X_n$ *if* $C(a_1, \ldots, a_n) \overset{\text{def}}{=} f(a_{i_1}, \ldots, a_{i_k}) = 1$. *We say that constraint* C *is* from $\mathcal{F}$ *if* $f \in \mathcal{F}$.

Constraint functions, constraint families, and constraints are of interest due to their defining role in a variety of NP optimization problems.

DEFINITION 2.4. *For a finitely specified constraint family* $\mathcal{F}$, MAX $\mathcal{F}$ *is the optimization problem given by*

INPUT: *An instance consisting of* m *constraints* $C_1, \ldots, C_m$, *on* n *Boolean variables* $X_1, \ldots, X_n$, *with nonnegative real weights* $w_1, \ldots, w_m$. *(An instance is thus a triple* $(\vec{X}, \vec{C}, \vec{w})$.*)*

GOAL: *Find an assignment* $\vec{b}$ *to the variables* $\vec{X}$ *which maximizes the weight* $\sum_{j=1}^{m} w_j C_j(\vec{b})$ *of satisfied constraints.*

Constraint functions and families and the class $\{\text{MAX } \mathcal{F} \mid \mathcal{F}\}$ allow descriptions of optimization problems and reductions in a uniform manner. For example, if $\mathcal{F} =$ 2SAT is the constraint family consisting of all constraint functions of arity at most 2 that can be expressed as the disjunction of up to 2 literals, then MAX 2SAT is the corresponding MAX $\mathcal{F}$ problem. Similarly MAX 3SAT is the MAX $\mathcal{F}$ problem defined using the constraint family $\mathcal{F} =$ 3SAT consisting of all constraint functions of arity up to 3 that can be expressed as the disjunction of up to 3 literals.

One of the motivations for this work is to understand the "approximability" of many central optimization problems that can be expressed as MAX $\mathcal{F}$ problems, including MAX 2SAT and MAX 3SAT. For $\beta \in [0, 1]$, an algorithm $\mathcal{A}$ is said to be a β-approximation algorithm for the MAX $\mathcal{F}$ problem if on every instance $(\vec{X}, \vec{C}, \vec{w})$ of MAX $\mathcal{F}$ with n variables and m constraints, $\mathcal{A}$ outputs an assignment $\vec{a}$ subject to (s.t.) $\sum_{j=1}^{m} w_j C_j(\vec{a}) \geq \beta \max_{\vec{b}}\{\sum_{j=1}^{m} w_j C_j(\vec{b})\}$. We say that the problem MAX $\mathcal{F}$ is β-approximable if there exists a *polynomial time*-bounded algorithm $\mathcal{A}$ that is a β-approximation algorithm for MAX $\mathcal{F}$. We say that MAX $\mathcal{F}$ is hard to approximate to within a factor β (β-inapproximable) if the existence of a polynomial-time β-approximation algorithm for MAX $\mathcal{F}$ implies NP = P.

Recent research has yielded a number of new approximability results for several MAX $\mathcal{F}$ problems (see [7, 8]) and a number of new results yielding hardness of approximations (see [2, 9]). One of our goals is to construct efficient reductions between MAX $\mathcal{F}$ problems that allow us to translate "approximability" and "inapproximability" results. As we saw in the opening example, such reductions may be constructed by constructing "gadgets" reducing one constraint family to another. More specifically, the example shows how a reduction from 3SAT to 2SAT results from the availability, for every constraint function f in the family 3SAT, of a gadget reducing f to the family 2SAT. This notion of a gadget reducing a constraint function f to a constraint family $\mathcal{F}$ is formalized in the following definition.

Definition 2.5 (gadget [2]). *For $\alpha \in \mathcal{R}^+$, a constraint function $f : \{0,1\}^k \to \{0,1\}$, and a constraint family $\mathcal{F}$, an* α-gadget *(or "gadget with performance α") reducing f to $\mathcal{F}$ is a set of variables $Y_1, \ldots, Y_n$, a finite collection of real weights $w_j \geq 0$, and associated constraints C_j from $\mathcal{F}$ over* primary variables $X_1, \ldots, X_k$ *and* auxiliary variables $Y_1, \ldots, Y_n$, *with the property that, for Boolean assignments $\vec{a}$ to $X_1, \ldots, X_k$ and $\vec{b}$ to $Y_1, \ldots, Y_n$, the following are satisfied:*

$$(\forall \vec{a} : f(\vec{a}) = 1)\ (\forall \vec{b}) : \sum_j w_j C_j(\vec{a}, \vec{b}) \leq \alpha, \tag{2.1}$$

$$(\forall \vec{a} : f(\vec{a}) = 1)\ (\exists \vec{b}) : \sum_j w_j C_j(\vec{a}, \vec{b}) = \alpha, \tag{2.2}$$

$$(\forall \vec{a} : f(\vec{a}) = 0)\ (\forall \vec{b}) : \sum_j w_j C_j(\vec{a}, \vec{b}) \leq \alpha - 1. \tag{2.3}$$

The gadget is strict *if, in addition,*

$$(\forall \vec{a} : f(\vec{a}) = 0)\ (\exists \vec{b}) : \sum_j w_j C_j(\vec{a}, \vec{b}) = \alpha - 1. \tag{2.4}$$

We use the shorthand notation $\Gamma = (\vec{Y}, \vec{C}, \vec{w})$ to denote the gadget described above.

It is straightforward to verify that the introductory example yields a strict 7-gadget reducing the constraint function $f(X_1, X_2, X_3) = X_1 \vee X_2 \vee X_3$ to the family 2SAT.

Observe that an α-gadget $\Gamma = (\vec{Y}, \vec{C}, \vec{w})$ can be converted into an $\alpha' > \alpha$ gadget by "rescaling," i.e., multiplying every entry of the weight vector $\vec{w}$ by α'/α (although strictness is not preserved). This indicates that a "strong" gadget is one with a small α; in the extreme, a 1-gadget would be the "optimal" gadget. This intuition will be confirmed in the role played by gadgets in the construction of reductions. Before describing this, we first list the constraints and constraint families that are of interest to us.

For convenience we now give a comprehensive list of all the constraints and constraint families used in this paper.

DEFINITION 2.6.

- Parity check (PC) *is the constraint family* $\{\mathrm{PC}_0, \mathrm{PC}_1\}$, *where, for* $i \in \{0,1\}$, PC_i *is defined as follows:*

$$\mathrm{PC}_i(a,b,c) = \begin{cases} 1 & \textit{if } a \oplus b \oplus c = i, \\ 0 & \textit{otherwise.} \end{cases}$$

Henceforth we will simply use terms such as MAX PC *to denote the optimization problem* MAX $\mathcal{F}$, *where* $\mathcal{F} = \mathrm{PC}$. MAX PC *(referred to as MAX 3LIN in* [9]*) is the source of all our inapproximability results.*

- *For any* $k \geq 1$, Exactly-k-SAT (EkSAT) *is the constraint family* $\{f : \{0,1\}^k \to \{0,1\} : |\{\vec{a} : f(\vec{a}) = 0\}| = 1\}$, *that is, the set of* k*-ary* disjunctive *constraints.*
- *For any* $k \geq 1$, kSAT *is the constraint family* $\bigcup_{l \in [k]} \mathrm{E}l\mathrm{SAT}$.
- SAT *is the constraint family* $\bigcup_{l \geq 1} \mathrm{E}l\mathrm{SAT}$.

The problems MAX 3SAT, MAX 2SAT, *and* MAX SAT *are by now classical optimization problems. They were considered originally in* [6]*; subsequently their central role in approximation was highlighted in* [15]*; and recently, novel approximation algorithms were developed in* [7, 8, 5]. *The associated families are typically the targets of gadget constructions in this paper. Shortly, we will describe a lemma which connects the inapproximability of* MAX $\mathcal{F}$ *to the existence of gadgets reducing* PC_0 *and* PC_1 *to* $\mathcal{F}$. *This method has so far yielded in several cases tight, and in other cases the best-known, inapproximability results for* MAX $\mathcal{F}$ *problems.*

In addition to 3SAT*'s use as a target, its members are also used as sources; gadgets reducing members of* MAX 3SAT *to* MAX 2SAT *help give an improved* MAX 3SAT *approximation algorithm.*

- 3-Conjunctive SAT (3ConjSAT) *is the constraint family* $\{f_{000}, f_{100}, f_{110}, f_{111}\}$, *where*
  (1) $f_{000}(a,b,c) = a \wedge b \wedge c$,
  (2) $f_{001}(a,b,c) = a \wedge b \wedge \neg c$,
  (3) $f_{011}(a,b,c) = a \wedge \neg b \wedge \neg c$,
  (4) $f_{111}(a,b,c) = \neg a \wedge \neg b \wedge \neg c$.

Members of 3ConjSAT *are sources in gadgets reducing them to* 2SAT. *These gadgets enable a better approximation algorithm for the* MAX 3ConjSAT *problem, which in turn sheds light on the class* $\mathrm{PCP}_{c,s}[\log, 3]$.

- CUT: $\{0,1\}^2 \to \{0,1\}$ *is the constraint function given by* $\mathrm{CUT}(a,b) = a \oplus b$. CUT/0 *is the family of constraints* $\{\mathrm{CUT}, \mathrm{T}\}$, *where* $\mathrm{T}(a) = 0 \oplus a = a$. CUT/1 *is the family of constraints* $\{\mathrm{CUT}, \mathrm{F}\}$, *where* $\mathrm{F}(a) = 1 \oplus a = \neg a$.

MAX CUT *is again a classical optimization problem. It has attracted attention due to the recent result of Goemans and Williamson* [8] *providing a* 0.878 *approximation algorithm. An observation from Bellare, Goldreich, and Sudan* [2] *shows that the approximabilities of* MAX CUT/0, MAX CUT/1, *and* MAX CUT *are all identical; this* *is also formalized in Proposition* 4.1 *below. Hence* MAX CUT/0 *becomes the target of gadget constructions in this paper, allowing us to get inapproximability results for these three problems.*

- DICUT: $\{0,1\}^2 \to \{0,1\}$ *is the constraint function given by* $\text{DICUT}(a,b) = \neg a \wedge b$.

MAX DICUT *is another optimization problem to which the algorithmic results of* [8, 5] *apply. Gadgets whose target is* DICUT *will enable us to get inapproximability results for* MAX DICUT.

- 2CSP *is the constraint family consisting of all* 16 *binary functions, i.e.,* $\text{2CSP} = \{f : \{0,1\}^2 \to \{0,1\}\}$.

MAX 2CSP *was considered in* [5]*, which gives a* 0.859 *approximation algorithm; here we provide inapproximability results.*

- Respect of monomial basis check (RMBC) *is the constraint family* $\{\text{RMBC}_{ij} | i,j \in \{0,1\}\}$, *where*

$$\text{RMBC}_{ij}(a,b,c,d) = \begin{cases} 1 & \textit{if } a = 0 \textit{ and } b = c \oplus i, \\ 1 & \textit{if } a = 1 \textit{ and } b = d \oplus j, \\ 0 & \textit{otherwise.} \end{cases}$$

  RMBC_{00} *may be thought of as the test* $(c,d)[a] \overset{?}{=} b$, RMBC_{01} *as the test* $(c,\neg d)[a] \overset{?}{=} b$, RMBC_{10} *as the test* $(\neg c, d)[a] \overset{?}{=} b$, *and* RMBC_{11} *as the test* $(\neg c, \neg d)[a] \overset{?}{=} b$, *where the notation* $(v_1, \ldots, v_n)[i]$ *refers to the* $(i+1)$*'st coordinate of the vector* $(v_1, \ldots, v_n)$.

Our original interest in RMBC *came from the work of Bellare, Goldreich, and Sudan* [2]*, which derived hardness results for* MAX $\mathcal{F}$ *using gadgets reducing every constraint function in* PC *and* RMBC *to* $\mathcal{F}$. *This work has been effectively superseded by Håstad's* [9]*, which only requires gadgets reducing members of* PC *to* $\mathcal{F}$. *However we retain some of the discussion regarding gadgets with* RMBC *functions as a source, since these constructions were significantly more challenging, and some of the techniques applied to overcome the challenges may be applicable in other gadget constructions. A summary of all the gadgets we found, with their performances and lower bounds, is given in Table* 2.1.

We now put forth a theorem, essentially from [2] (and obtainable as a generalization of its Lemmas 4.7 and 4.15), that relates the existence of gadgets with $\mathcal{F}$ as target to the hardness of approximating MAX $\mathcal{F}$. Since we will not be using this theorem except as a motivation for studying the family RMBC, we do not prove it here.

THEOREM 2.7. *For any family* $\mathcal{F}$, *if there exists an* α_1*-gadget reducing every function in* PC *to* $\mathcal{F}$ *and an* α_2*-gadget reducing every function in* RMBC *to* $\mathcal{F}$, *then for any* $\epsilon > 0$, *MAX* $\mathcal{F}$ *is hard to approximate to within* $1 - \frac{.15}{.6\alpha_1 + .4\alpha_2} + \epsilon$.

In this paper we will use the following, stronger, result by Håstad.

THEOREM 2.8 (see [9]). *For any family* $\mathcal{F}$, *if there exists an* α_0*-gadget reducing* PC_0 *to* $\mathcal{F}$ *and an* α_1*-gadget reducing* PC_1 *to* $\mathcal{F}$, *then for any* $\epsilon > 0$, MAX $\mathcal{F}$ *is hard to approximate to within* $1 - \frac{1}{\alpha_0 + \alpha_1} + \epsilon$.

Thus, using CUT/0, DICUT, 2CSP, EkSAT, and kSAT as the target of gadget constructions from PC_0 and PC_1, we can show the hardness of MAX CUT, MAX DICUT, MAX 2CSP, MAX EkSAT, and MAX kSAT, respectively. Furthermore, minimizing the value of α in the gadgets gives better hardness results.

Table 2.1

All gadgets described are provably optimal and strict. The sole exception (†) is the best possible strict gadget; there is a nonstrict 3-gadget. All "previous" results quoted are interpretations of the results in [2], *except the gadget reducing* 3*SAT to* 2*SAT, which is due to* [6], *and the gadget reducing* PC *to* 3*SAT, which is folklore.*

3. The basic procedure.

The key aspect of making the gadget search spaces finite is to limit the number of auxiliary variables by showing that duplicates (in a sense to be clarified) can be eliminated by means of proper *substitutions.* In general, this is possible if the target of the reduction is a "hereditary" family as defined below.

Definition 3.1. *A constraint family $\mathcal{F}$ is* hereditary *if for any $f \in \mathcal{F}$ of arity k and any two indices $i, j \in [k]$, the function f when restricted to $X_i \equiv X_j$ and considered as a function of $k-1$ variables is identical (up to the order of the arguments) to some other function $f' \in \mathcal{F} \cup \{0, 1\}$ (where 0 and 1 denote the constant functions).*

Definition 3.2. *A family $\mathcal{F}$ is* complementation closed *if it is hereditary and, for any $f \in \mathcal{F}$ of arity k and any index $i \in [k]$, the function f' given by $f'(X_1, \ldots, X_k) = f(X_1, \ldots, X_{i-1}, \neg X_i, X_{i+1}, \ldots, X_k)$ is contained in $\mathcal{F}$.*

Definition 3.3 (partial gadget). *For $\alpha \in \mathcal{R}^+$, $S \subseteq \{0, 1\}^k$, a constraint function $f : \{0, 1\}^k \to \{0, 1\}$, and a constraint family $\mathcal{F}$, an S-*partial α-gadget *(or "S-partial gadget with performance α") reducing f to $\mathcal{F}$ is a finite collection of constraints $C_1, \ldots, C_m$ from $\mathcal{F}$ over primary variables $X_1, \ldots, X_k$ and finitely many auxiliary variables $Y_1, \ldots, Y_n$, and a collection of nonnegative real weights $w_1, \ldots, w_m$, with the property that, for Boolean assignments $\vec{a}$ to $X_1, \ldots, X_k$ and $\vec{b}$ to $Y_1, \ldots, Y_n$, the following are satisfied:*

$$(\forall \vec{a} \in \{0,1\}^k : f(\vec{a}) = 1)\ (\forall \vec{b} \in \{0,1\}^n) : \sum_{j=1}^{m} w_j C_j(\vec{a}, \vec{b}) \le \alpha, \tag{3.1}$$

$$(\forall \vec{a} \in S : f(\vec{a}) = 1)\ (\exists \vec{b} \in \{0,1\}^n) : \sum_{j=1}^{m} w_j C_j(\vec{a}, \vec{b}) = \alpha, \tag{3.2}$$

$$(\forall \vec{a} \in \{0,1\}^k : f(\vec{a}) = 0)\ (\forall \vec{b} \in \{0,1\}^n) : \sum_{j=1}^{m} w_j C_j(\vec{a}, \vec{b}) \le \alpha - 1, \tag{3.3}$$

$$(\forall \vec{a} \in S : f(\vec{a}) = 0)\ (\exists \vec{b} \in \{0,1\}^n) : \sum_{j=1}^{m} w_j C_j(\vec{a}, \vec{b}) = \alpha - 1. \tag{3.4}$$

We use the shorthand notation $\Gamma = (\vec{Y}, \vec{C}, \vec{w})$ *to denote the partial gadget.*

The following proposition follows immediately from the definitions of a gadget and a partial gadget.

PROPOSITION 3.4. *For a constraint function* $f : \{0,1\}^k \to \{0,1\}$, *let* $S_1 = \{\vec{a} \in \{0,1\}^k : f(\vec{a}) = 1\}$ *and let* $S_2 = \{0,1\}^k$. *Then for every* $\alpha \in \mathcal{R}^+$ *and constraint family* $\mathcal{F}$,

(1) *an* S_1*-partial* α*-gadget reducing* f *to* $\mathcal{F}$ *is an* α*-gadget reducing* f *to* $\mathcal{F}$*;*

(2) *an* S_2*-partial* α*-gadget reducing* f *to* $\mathcal{F}$ *is a strict* α*-gadget reducing* f *to* $\mathcal{F}$*.*

DEFINITION 3.5. *For* $\alpha \ge 1$ *and* $S \subseteq \{0,1\}^k$, *let* $\Gamma = (\vec{Y}, \vec{C}, \vec{w})$ *be an* S*-partial* α*-gadget reducing a constraint* $f : \{0,1\}^k \to \{0,1\}$ *to a constraint family* $\mathcal{F}$. *We say that the function* $b : S \to \{0,1\}^n$ *is a* witness *for the partial gadget, witnessing the set* S, *if* $b(\vec{a})$ *satisfies equations* (3.2) *and* (3.4). *Specifically,*

$$(\forall \vec{a} \in S : f(\vec{a}) = 1) : \sum_{j=1}^{m} w_j C_j(\vec{a}, b(\vec{a})) = \alpha \qquad \text{and}$$

$$(\forall \vec{a} \in S : f(\vec{a}) = 0) : \sum_{j=1}^{m} w_j C_j(\vec{a}, b(\vec{a})) = \alpha - 1.$$

The witness function can also be represented as an $|S| \times (k+n)$ *matrix* W_b *whose rows are the vectors* $(\vec{a}, b(\vec{a}))$. *Notice that the columns of the matrix correspond to the variables of the gadget, with the first* k *columns corresponding to primary variables, and the last* n *corresponding to auxiliary variables. In what follows we shall often prefer the matrix notation.*

DEFINITION 3.6. *For a set* $S \subseteq \{0,1\}^k$, *let* M_S *be the matrix whose rows are the vectors* $\vec{a} \in S$, *let* k'_S *be the number of distinct columns in* M_S, *and let* k''_S *be the number of columns in* M_S *distinct up to complementation. Given a constraint* f *of arity* k *and a hereditary constraint family* $\mathcal{F}$ *that is* not *complementation closed, an* $(S, f, \mathcal{F})$-canonical witness matrix *(for an* S*-partial gadget reducing* f *to* $\mathcal{F}$*) is the* $|S| \times (2^{|S|} + k - k'_S)$ *matrix* W *whose first* k *columns correspond to the* k *primary variables and whose remaining columns are all possible column vectors that are distinct from one another and from the columns corresponding to the primary variables. If* $\mathcal{F}$ is *complementation closed, then a canonical witness matrix is the* $|S| \times (2^{|S|-1} + k - k''_S)$ *matrix* W *whose first* k *columns correspond to the* k *primary variables and whose remaining columns are all possible column vectors that are distinct up to complementation from one another and from the columns corresponding to the primary variables.*

The following lemma is the crux of this paper and establishes that the optimal gadget reducing a constraint function f to a hereditary family $\mathcal{F}$ is finite. To motivate the lemma, we first present an example, due to Karloff and Zwick [11], showing that this need not hold if the family $\mathcal{F}$ is not hereditary. Their counterexample has $f(a) = a$ and $\mathcal{F} = \{\mathrm{PC}_1\}$. Using k auxiliary variables, $Y_1, \ldots, Y_k$, one may construct a gadget for the constraint X using the constraints $X \oplus Y_i \oplus Y_j$, $1 \leq i < j \leq k$, with each constraint having the same weight. For an appropriate choice of this weight it may be verified that this yields a $(2 - 2/k)$-gadget for even k; thus the performance tends to 2 in the limit. On the other hand it can be shown that any gadget with k auxiliary variables has performance at most $2 - 2^{1-k}$; thus no finite gadget achieves the limit. It is clear that for this example the lack of hereditariness is critical: any hereditary family containing PC_1 would also contain f, providing a trivial 1-gadget.

To see why the hereditary property helps in general, consider an α-gadget Γ reducing f to $\mathcal{F}$, and let W be a witness matrix for Γ. Suppose two columns of W, corresponding to auxiliary variables Y_1 and Y_2 of Γ, are identical. Then we claim that Γ does not really need the variable Y_2. In every constraint containing Y_2, replace it with Y_1 to yield a new collection of weighted constraints. By the hereditary property of $\mathcal{F}$, all the resulting constraints are from $\mathcal{F}$. And, the resulting instance satisfies all the properties of an α-gadget. (The universal properties follow trivially, while the existential properties follow from the fact that in the witness matrix Y_1 and Y_2 have the same assignment.) Thus this collection of constraints forms a gadget with fewer variables and performance at least as good. The finiteness follows from the fact that a witness matrix with distinct columns has a bounded number of columns. The following lemma formalizes this argument. In addition it also describes the canonical witness matrix for an optimal gadget—something that will be of use later.

LEMMA 3.7. *For $\alpha \geq 1$, set $S \subset \{0,1\}^k$, constraint $f : \{0,1\}^k \to \{0,1\}$, and hereditary constraint family $\mathcal{F}$, if there exists an S-partial α-gadget Γ reducing f to $\mathcal{F}$ with witness matrix W, then for any $(S, f, \mathcal{F})$-canonical witness matrix W' and some $\alpha' \leq \alpha$, there exists an α'-gadget Γ' reducing f to $\mathcal{F}$ with W' as a witness matrix.*

Proof. We first consider the case where $\mathcal{F}$ is not complementation closed. Let $\Gamma = (\vec{Y}, \vec{C}, \vec{w})$ be an S-partial α-gadget reducing f to $\mathcal{F}$ and let W be a witness matrix for Γ. We create a gadget Γ' with $n' = 2^{|S|} - k'$ auxiliary variables $Y'_1, \ldots, Y'_{n'}$, one associated with each column of the matrix W' other than the first k.

With each variable Y_i of Γ we associate a variable Z such that the column corresponding to Y_i in W is the same as the column corresponding to Z in W'. Notice that Z may be one of the primary variables $X_1, \ldots, X_k$ or one of the auxiliary variables $Y'_1, \ldots, Y'_{n'}$. By definition of a canonical witness, such a column and hence variable Z does exist.

Now for every constraint C_j on variables $Y_{i_1}, \ldots, Y_{i_k}$ in Γ with weight w_j, we introduce the constraint C_j on variables $Y'_{i'_1}, \ldots, Y'_{i'_k}$ in Γ' with weight w_j where $Y'_{i'_l}$ is the variable associated with Y_{i_l}. Notice that in this process the variables involved with a constraint do not necessarily remain distinct. This is where the *hereditary property* of $\mathcal{F}$ is used to ensure that a constraint $C_j \in \mathcal{F}$, when applied to a tuple of nondistinct variables, remains a constraint in $\mathcal{F}$. In the process we may arrive at some constraints which are either always satisfied or never satisfied. For the time being, we assume that the constraints $\mathbf{0}$ and $\mathbf{1}$ are contained in $\mathcal{F}$, so this occurrence does not cause a problem. Later we show how this assumption is removed.

This completes the description of Γ'. To verify that Γ' is indeed an S-partial α-gadget, we notice that the universal constraints (conditions (3.1) and (3.3) in Definition 3.3) are trivially satisfied, since Γ' is obtained from Γ by renaming some variables and possibly identifying some others. To see that the existential constraints (conditions (3.2) and (3.4) in Definition 3.3) are satisfied, notice that the assignments to the variables $\vec{Y}$ that witness these conditions in Γ are allowable assignments to the corresponding variables in $\vec{Y}'$ and in fact this is what dictated our association of variables in $\vec{Y}$ to the variables in $\vec{Y}'$. Thus Γ' is indeed an S-partial α-gadget reducing f to $\mathcal{F}$, and, by construction, has W' as a witness matrix.

Last, we remove the assumption that Γ' must include constraints $\mathbf{0}$ and $\mathbf{1}$. Any constraints $\mathbf{0}$ can be safely thrown out of the gadget without changing any of the parameters, since such constraints are never satisfied. On the other hand, constraints $\mathbf{1}$ do affect α. If we throw away a $\mathbf{1}$ constraint of weight w_j, this reduces the total weight of satisfied clauses in every assignment by w_j. Throwing away all such constraints reduces α by the total weight of the $\mathbf{1}$ constraints, producing a gadget of (improved) performance $\alpha' \leq \alpha$.

Finally, we describe the modifications required to handle the case where $\mathcal{F}$ is complementation closed (in which case the definition of a canonical witness changes). Here, for each variable Y_i and its associated column of W, either there is an equal column in W', in which case we replace Y_i with the column's associated variable $Y'_{i'}$, or there is a complementary column in W', in which case we replace Y_i with the negation of the column's associated variable, $\neg Y'_{i'}$, The rest of the construction proceeds as above, and the proof of correctness is the same. □

It is an immediate consequence of Lemma 3.7 that an optimum gadget reducing a constraint function to a hereditary family does not need to use more than an explicitly bounded number of auxiliary variables.

COROLLARY 3.8. *Let f be a constraint function of arity k with s satisfying assignments. Let $\mathcal{F}$ be a constraint family and $\alpha \geq 1$ be such that there exists an α-gadget reducing f to $\mathcal{F}$.*

(1) *If $\mathcal{F}$ is hereditary, then there exists an α'-gadget with at most $2^s - k'$ auxiliary variables reducing f to $\mathcal{F}$, where $\alpha' \leq \alpha$ and k' is the number of distinct variables among the satisfying assignments of f.*

(2) *If $\mathcal{F}$ is complementation closed, then there exists an α'-gadget with at most $2^{s-1} - k''$ auxiliary variables reducing f to $\mathcal{F}$ for some $\alpha' \leq \alpha$, where k'' is the number of distinct variables, up to complementation, among the satisfying assignments of f.*

COROLLARY 3.9. *Let f be a constraint function of arity k. Let $\mathcal{F}$ be a constraint family and $\alpha \geq 1$ be such that there exists a strict α-gadget reducing f to $\mathcal{F}$.*

(1) *If $\mathcal{F}$ is hereditary, then there exists a strict α'-gadget with at most $2^{2^k} - k$ auxiliary variables reducing f to $\mathcal{F}$ for some $\alpha' \leq \alpha$.*

(2) *If $\mathcal{F}$ is complementation closed, then there exists a strict α'-gadget with at most $2^{2^k-1} - k$ auxiliary variables reducing f to $\mathcal{F}$ for some $\alpha' \leq \alpha$.*

We will now show how to cast the search for an optimum gadget as an LP.

DEFINITION 3.10. *For a constraint function f of arity k, constraint family $\mathcal{F}$, and $s \times (k+n)$ witness matrix M,* $\mathrm{LP}(f, \mathcal{F}, M)$ *is an LP defined as follows:*

- *Let $C_1, \ldots, C_m$ be all the possible distinct constraints that arise from applying a constraint function from $\mathcal{F}$ to a set of $n+k$ Boolean variables. Thus for every j, $C_j : \{0,1\}^{k+n} \to \{0,1\}$. The LP variables are $w_1, \ldots, w_m$, where w_j corresponds to the weight of the constraint C_j. Additionally the LP has one more variable α.*
- *Let $S \subseteq \{0,1\}^k$ and $b : S \to \{0,1\}^n$ be such that $M = W_b$ (i.e., M is the witness matrix corresponding to the witness function b for the set S). The LP inequalities correspond to the definition of an S-partial gadget:*

$$(3.5)\quad (\forall \vec{a} \in \{0,1\}^k : f(\vec{a}) = 1)\ (\forall \vec{b} \in \{0,1\}^n) : \sum_{j=1}^{m} w_j C_j(\vec{a}, \vec{b}) \leq \alpha,$$

$$(\forall \vec{a} \in S : f(\vec{a}) = 1) : \sum_{j=1}^{m} w_j C_j(\vec{a}, b(\vec{a})) = \alpha, \tag{3.6}$$

$$(\forall \vec{a} \in \{0,1\}^k : f(\vec{a}) = 0)\ (\forall \vec{b} \in \{0,1\}^n) : \sum_{j=1}^{m} w_j C_j(\vec{a}, \vec{b}) \le \alpha - 1, \tag{3.7}$$

$$(\forall \vec{a} \in S : f(\vec{a}) = 0) : \sum_{j=1}^{m} w_j C_j(\vec{a}, b(\vec{a})) = \alpha - 1. \tag{3.8}$$

Finally the LP has the inequalities $w_j \ge 0$.

- *The objective of the LP is to minimize α.*

PROPOSITION 3.11. *For any constraint function f of arity k, constraint family $\mathcal{F}$, and $s \times (k+n)$ witness matrix M witnessing the set $S \subseteq \{0,1\}^k$, if there exists an S-partial gadget reducing f to $\mathcal{F}$ with witness matrix M, then* LP$(f, \mathcal{F}, M)$ *finds such a gadget with the minimum possible α.*

Proof. The LP-generated gadget consists of k primary variables $X_1, \ldots, X_k$ corresponding to the first k columns of M; n auxiliary variables $Y_1, \ldots, Y_n$ corresponding to the remaining n columns of M; constraints $C_1, \ldots, C_m$ as defined in Definition 3.10; and weights $w_1, \ldots, w_m$ as returned by LP$(f, \mathcal{F}, M)$. By construction the LP solution returns the minimum possible α for which an S-partial α-gadget reducing f to $\mathcal{F}$ with witness M exists. ☐

THEOREM 3.12 (main). *Let f be a constraint function of arity k with s satisfying assignments. Let k' be the number of distinct variables of f and k'' be the number of distinct variables up to complementation. Let $\mathcal{F}$ be a hereditary constraint family with functions of arity at most l. Then*

- *if there exists an α-gadget reducing f to $\mathcal{F}$, then there exists such a gadget with at most v auxiliary variables, where $v = 2^{s-1} - k''$ if $\mathcal{F}$ is complementation closed and $v = 2^s - k'$ otherwise;*
- *if there exists a strict α-gadget reducing f to $\mathcal{F}$, then there exists such a gadget with at most v auxiliary variables, where $v = 2^{2^k - 1} - k''$ if $\mathcal{F}$ is complementation closed and $v = 2^{2^k} - k'$ otherwise.*

Furthermore such a gadget with smallest performance can be found by solving an LP with at most $|\mathcal{F}| \times (v+k)^l$ variables and 2^{v+k} constraints.

Remark 3.12. The sizes given above are upper bounds. In specific instances, the sizes may be much smaller. In particular, if the constraints of $\mathcal{F}$ exhibit symmetries, or are not all of the same arity, then the number of variables of the LP will be much smaller.

Proof. By Proposition 3.11 and Lemma 3.7, we have that LP$(f, \mathcal{F}, W_S)$ yields an optimal S-partial gadget if one exists. By Proposition 3.4 the setting $S = S_1 = \{\vec{a} | f(\vec{a}) = 1\}$ gives a gadget, and the setting $S = S_2 = \{0,1\}^k$ gives a strict gadget. Corollaries 3.8 and 3.9 give the required bound on the number of auxiliary variables; and the size of the LP then follows from the definition. ☐

To conclude this section, we mention some (obvious) facts that become relevant when searching for large gadgets. First, if $S' \subseteq S$, then the performance of an S'-partial gadget reducing f to $\mathcal{F}$ is also a lower bound on the performance of an S-partial gadget reducing f to $\mathcal{F}$. The advantage here is that the search for an S'-partial gadget may be much faster. Similarly, to get upper bounds on the performance of an S-partial gadget, one may use other witness matrices for S (rather than the canonical one), in particular ones with (many) fewer columns. This corresponds to making a choice of auxiliary variables not to be used in such a gadget.

4. Improved negative results.

4.1. MAX CUT. We begin by showing an improved hardness result for the MAX CUT problem. It is not difficult to see that no gadget per Definition 2.5 can reduce any member of PC to CUT: for any setting of the variables which satisfies (2.2), the complementary setting has the opposite parity (so that it must be subject to inequality (2.3)), but the values of all the CUT constraints are unchanged, so that the gadget's value is still α, violating (2.3). Following [2], we use instead the fact that MAX CUT and MAX CUT/0 are equivalent with respect to approximation as shown below.

Proposition 4.1. MAX CUT *is equivalent to* MAX CUT/0. *Specifically, given an instance $\mathcal{I}$ of either problem, we can create an instance $\mathcal{I}'$ of the other with the same optimum and with the feature that an assignment satisfying constraints of total weight W to the latter can be transformed into an assignment satisfying constraints of the same total weight in $\mathcal{I}$.*

Proof. The reduction from MAX CUT to MAX CUT/0 is trivial, since the family CUT/0 contains CUT, and thus the identity map provides the required reduction.

In the reverse direction, given an instance $(\vec{X}, \vec{C}, \vec{w})$ of MAX CUT/0 with n variables and m clauses, we create an instance $(\vec{X}', \vec{C}', \vec{w})$ of MAX CUT with $n+1$ variables and m clauses. The variables are simply the variables $\vec{X}$ with one additional variable called 0. The constraints of $\vec{C}$ are transformed as follows. If the constraint is a CUT constraint on variables X_i and X_j it is retained as is. If the constraint is $T(X_i)$ it is replaced with the constraint $\mathrm{CUT}(X_i, 0)$. Given an assignment $\vec{a}$ to the vector $\vec{X}'$, notice that its complement also satisfies the same number of constraints in $\mathcal{I}'$. We pick the one among the two that sets the variable 0 to 0, and then observe that the induced assignment to $\vec{X}$ satisfies the corresponding clauses of $\mathcal{I}$. □

Thus we can look for reductions to CUT/0. Notice that the CUT/0 constraint family is hereditary, since identifying the two variables in a CUT constraint yields the constant function 0. Thus by Theorem 3.12, if there is an α-gadget reducing PC_0 to CUT/0, then there is an α-gadget with at most 13 auxiliary variables (16 variables in all). Only $\binom{16}{2} = 120$ CUT constraints are possible on 16 variables. Since we only need to consider the cases when $Y_1 = 0$, we can construct an LP as above with $2^{16-1} + 4 = 32{,}772$ constraints to find the optimal α-gadget reducing PC_0 to CUT/0. An LP of the same size can similarly be constructed to find a gadget reducing PC_1 to CUT/0.

Lemma 4.2. *There exists an* 8*-gadget reducing* PC_0 *to* CUT/0, *and it is optimal and strict.*

We show the resulting gadget in Figure 4.1 as a graph. The primary variables are labeled x_1, x_2, and x_3, while 0 is a special variable. The unlabeled vertices are auxiliary variables. Each constraint of nonzero weight is shown as an edge. An edge between the vertex 0 and some vertex x corresponds to the constraint $T(x)$. Any other edge between x and y represents the constraint $\mathrm{CUT}(x, y)$. Note that some of the 13 possible auxiliary variables do not appear in any positive weight constraint and thus are omitted from the graph. All nonzero weight constraints have weight .5.

By the same methodology, we can prove the following.

Lemma 4.3. *There exists a* 9*-gadget reducing* PC_1 *to* CUT/0, *and it is optimal and strict.*

The gadget is similar to the previous one, but the old vertex 0 is renamed Z, and a new vertex labeled 0 is joined to Z by an edge of weight 1.

The two lemmas along with Proposition 4.1 above imply the following theorem.

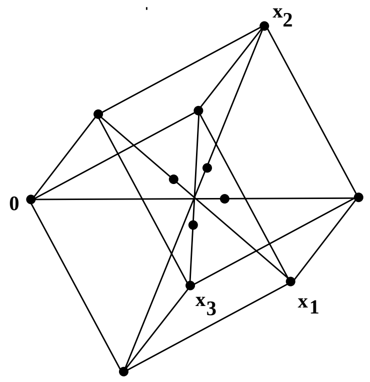

FIG. 4.1. *8-gadget reducing* PC$_0$ *to* CUT. *Every edge has weight .5. The auxiliary variable which is always* 0 *is labeled* 0.

THEOREM 4.4. *For every* $\epsilon > 0$, MAX CUT *is hard to approximate to within* $16/17 + \epsilon$.

Proof. Combining Theorem 2.8 with Lemmas 4.2 and 4.3, we find that MAX CUT/0 is hard to approximate to within $16/17 + \epsilon$. The theorem then follows from Proposition 4.1. ◻

RMBC *gadgets.* Finding RMBC gadgets was more difficult. We discuss this point since it leads to ideas that can be applied in general when finding large gadgets. Indeed, it turned out that we couldn't exactly apply the technique above to find an optimal gadget reducing, say, RMBC$_{00}$ to CUT/0. (Recall that the RMBC$_{00}(a_1, a_2, a_3, a_4)$ is the function $(a_3, a_4)[a_1] \overset{?}{=} a_2$.) Since there are 8 satisfying assignments to the 4 variables of the RMBC$_{00}$ constraint, by Theorem 3.12, we would need to consider $2^8 - 4 = 252$ auxiliary variables, leading to an LP with $2^{252} + 8$ constraints, which is somewhat beyond the capacity of current computing machines. To overcome this difficulty, we observed that for the RMBC$_{00}$ function, the value of a_4 is irrelevant when $a_1 = 0$ and the value of a_3 is irrelevant when $a_1 = 1$. This led us to try only restricted witness functions for which $\vec{b}(0, a_2, a_3, 0) = \vec{b}(0, a_2, a_3, 1)$ and $\vec{b}(1, a_2, 0, a_4) = \vec{b}(1, a_2, 1, a_4)$ (dropping from the witness matrix columns violating the above conditions), even though it is not evident a priori that a gadget with a witness function of this form exists. The number of distinct variable columns that such a witness matrix can have is at most 16. Excluding auxiliary variables identical to a_1 or a_2, we considered gadgets with at most 14 auxiliary variables. We then created an LP with $\binom{18}{2} = 153$ variables and $2^{18-1} + 8 = 131{,}080$ constraints. The result of the LP was that there exists an 8-gadget with constant 0 reducing RMBC$_{00}$ to CUT, and that it is strict. Since we used a restricted witness function, the LP does not prove that this gadget is optimal.

However, lower bounds can be established through construction of optimal S-partial gadgets. If S is a subset of the set of satisfying assignments of RMBC$_{00}$, then its defining equalities and inequalities (see Definition 3.3) are a subset of those for a gadget, and thus the performance of the partial gadget is a lower bound for that of a true gadget.

In fact, we have always been lucky with the latter technique, in that some choice of the set S has always yielded a lower bound and a matching gadget. In particular, for reductions from RMBC to CUT, we have the following result.

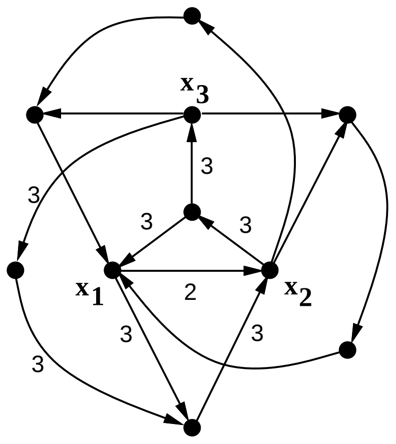

FIG. 4.2. 8*-gadget reducing* PC_0 *to* DICUT*. Edges have weight* 1 *except when marked otherwise.*

THEOREM 4.5. *There is an* 8*-gadget reducing* RMBC_{00} *to* CUT/0*, and it is optimal and strict; there is an* 8*-gadget reducing* RMBC_{01} *to* CUT/0*, and it is optimal and strict; there is a* 9*-gadget reducing* RMBC_{10} *to* CUT/0*, and it is optimal and strict; and there is a* 9*-gadget reducing* RMBC_{11} *to* CUT/0*, and it is optimal and strict.*

Proof. In each case, for some set S of satisfying assignments, an optimal S-partial gadget also happens to be a true gadget, and strict. In the same notation as in Definition 2.6, the appropriate sets S of 4-tuples (a, b, c, d) are, for RMBC_{00}, $S = \{0001, 1101, 0110, 1010\}$; for RMBC_{01}, $S = \{0000, 1100, 0111, 1011\}$; for RMBC_{10}, $S = \{0100, 1000, 0011, 1111\}$; and for RMBC_{11}, $S = \{0101, 1001, 0010, 1110\}$. □

4.2. MAX DICUT. As in the previous subsection, we observe that if there exists an α-gadget reducing an element of PC to DICUT, there exists an α-gadget with 13 auxiliary variables. This leads to LPs with $16 \cdot 15$ variables (one for each possible DICUT constraint, corresponding to a directed edge) and $2^{16} + 4 = 65{,}540$ linear constraints. The solution to the LPs gives the following.

LEMMA 4.6. *There exist* 6.5*-gadgets reducing* PC_0 *and* PC_1 *to* DICUT*, and they are optimal and strict.*

The PC_0 gadget is shown in Figure 4.2. Again x_1, x_2, and x_3 refer to the primary variable and an edge from x to y represents the constraint $\neg x \wedge b$. The PC_1 gadget is similar but has all edges reversed.

THEOREM 4.7. *For every* $\epsilon > 0$, MAX DICUT *is hard to approximate to within* $12/13 + \epsilon$.

RMBC *gadgets.* As with the reductions to CUT/0, reductions from the RMBC family members to DICUT can be done by constructing optimal S-partial gadgets, and again (with fortuitous choices of S) these turn out to be true gadgets, and strict.

THEOREM 4.8. *There is a* 6*-gadget reducing* RMBC_{00} *to* DICUT*, and it is optimal and strict; there is a* 6.5*-gadget reducing* RMBC_{01} *to* DICUT*, and it is optimal and strict; there is a* 6.5*-gadget reducing* RMBC_{10} *to* DICUT*, and it is optimal and strict; and there is a* 7*-gadget reducing* RMBC_{11} *to* DICUT*, and it is optimal and strict.*

Proof. Using, case by case, the same sets S as in the proof of Theorem 4.5, again yields in each case an optimal S-partial gadget that also happens to be a true, strict gadget. □

4.3. MAX 2-CSP. For reducing an element of PC to the 2CSP family we need consider only four auxiliary variables, for a total of seven variables. There are two nonconstant functions on a single variable, and twelve nonconstant functions on pairs of variables, so that there are $2\cdot 7+12\cdot\binom{7}{2}=266$ functions to consider overall. We can again set up an LP with a variable per function and $2^7+4=132$ linear constraints. We obtain the following lemma.

LEMMA 4.9. *There exist* 5*-gadgets reducing* PC_0 *and* PC_1 *to* 2CSP, *and they are optimal and strict.*

The gadget reducing PC_0 to 2CSP is the following:

$$\begin{array}{rrrr} X_1\wedge\neg Y_1, & X_1\wedge Y_2, & \neg X_1\wedge Y_3, & \neg X_1\wedge Y_4,\\ X_2\wedge\neg Y_1, & \neg X_2\wedge Y_2, & X_2\wedge Y_3, & \neg X_2\wedge Y_4,\\ \neg X_3\wedge Y_1, & X_3\wedge\neg Y_2, & X_3\wedge\neg Y_3, & \neg X_3\wedge\neg Y_4. \end{array}$$

The gadget reducing PC_1 to 2CSP can be obtained from this one by complementing all the occurrences of X_1.

THEOREM 4.10. *For every* $\epsilon>0$, MAX 2CSP *is hard to approximate to within* $9/10+\epsilon$.

MAX 2CSP can be approximated to within .859 [5]. The above theorem has implications for probabilistically checkable proofs. Reversing the well-known reduction from constraint-satisfaction problems to probabilistically checkable proofs (see [1]),[3] Theorem 4.10 yields the following theorem.

THEOREM 4.11. *For any* $\epsilon>0$, *constants* c *and* s *exist such that* $\mathrm{NP}\subseteq\mathrm{PCP}_{c,s}[\log,2]$ *and* $c/s>10/9-\epsilon$.

The previously known gap between the completeness and soundness achievable reading two bits was 74/73 [2]. It would be $22/21-\epsilon$ using Håstad's result [9] in combination with the argument of [2]. Actually the reduction from constraint-satisfaction problems to probabilistically checkable proofs is reversible, and this will be important in section 7.

RMBC *gadgets.*

THEOREM 4.12. *For each element of* RMBC, *there is a* 5*-gadget reducing it to* 2CSP, *and it is optimal and strict.*

Proof. Using the same selected assignments as in Theorems 4.5 and 4.8 again yields lower bounds and matching strict gadgets. □

5. Interlude: Methodology. Despite their seeming variety, all the gadgets in this paper were computed using a single program (in the language APL2) to generate an LP and call upon OSL (the IBM Optimization Subroutine Library) to solve it. This "gadget-generating" program takes several parameters.

The *source function* f is specified explicitly by a small program that computes f.

The *target family* $\mathcal{F}$ is described by a single function, implemented as a small program, and applied to all possible clauses of specified lengths and symmetries. The symmetries are chosen from among the following: whether clauses are unordered or ordered; whether their variables may be complemented; and whether they may include the constants 0 or 1. For example, a reduction to MAX CUT/0 would take as $\mathcal{F}$ the function $x_1\oplus x_2$, applied over unordered binomial clauses, in which complementation is not allowed but the constant 0 is allowed. This means of describing $\mathcal{F}$ is relatively intuitive and has never restricted us, even though it is not completely general. Finally,

[3]The reverse connection is by now a folklore result and may be proved along the lines of [2, Proposition 10.3, Part (3)].

we specify an arbitrary set S of selected assignments, which allows us to search for S-partial gadgets (recall Definition 3.3). From (3.2) and (3.4), each selected assignment $\vec{a}$ generates a constraint that $(\exists\vec{b}) : \sum_j w_j C_j(\vec{a},\vec{b}) = \alpha - (1 - f(\vec{a}))$. Selecting all *satisfying* assignments of f reproduces the set of constraints (2.2) for an α-gadget, while selecting *all* assignments reproduces the set of constraints (2.2) and (2.4) for a strict α-gadget.

Selected assignments are specified explicitly; by default, to produce an ordinary gadget, they are the satisfying assignments of f. The canonical witness for the selected set of assignments is generated by our program as governed by Definition 3.6. Notice that the definition of the witness depends on whether $\mathcal{F}$ is complementation closed or not, and this is determined by the explicitly specified symmetries.

To facilitate the generation of restricted witness matrices, we have also made use of a "don't-care" state (in lieu of 0 or 1) to reduce the number of selected assignments. For example, in reductions from RMBC_{00}, we have used selected assignments of $(00*0)$, $(011*)$, $(10*0)$, and $(11*1)$. The various LP constraints must be satisfied for both values of any don't-care, while the witness function must not depend on the don't-care values. So in this example, use of a don't-care reduces the number of selected assignments from 8 to 4, reduces the number of auxiliary variables from about 2^8 to 2^4 (ignoring duplications of the 4 primary variables, or any symmetries), and reduces the number of constraints in the LP from 2^{2^8} (about 10^{77}) to 2^{2^4} (a more reasonable 65,536). Use of don't-cares provides a technique complementary to selecting a subset of all satisfying assignments in that if the LP is feasible it provides an upper bound and a gadget, but the gadget may not be optimal.

In practice, selecting a subset of satisfying assignments has been by far the more useful of the two techniques; so far we have always been able to choose a subset which produces a lower bound and a gadget to match.

After constructing and solving an LP, the gadget-generating program uses brute force to make an independent verification of the gadget's validity, performance, and strictness.

The hardest computations were those for gadgets reducing from RMBC; on an IBM Risc System/6000 model 43P-240 workstation, running at 233MHz, these took up to half an hour and used 500 MB or so of memory. However, the strength of [9] makes PC virtually the sole source function of contemporary interest, and all the reductions from PC are easy; they use very little memory, and run in seconds on an ordinary 233MHz Pentium processor.

6. Improved positive results.

In this section we show that we can use gadgets to improve approximation algorithms. In particular, we look at MAX 3SAT, and a variation, MAX 3ConjSAT, in which each clause is a conjunction (rather than a disjunction) of three literals. An improved approximation algorithm for the latter problem leads to improved results for probabilistically checkable proofs in which the verifier examines only three bits. Both of the improved approximation algorithms rely on strict gadgets reducing the problem to MAX 2SAT. We begin with some notation.

DEFINITION 6.1. *A* (β_1, β_2) approximation algorithm *for* MAX 2SAT *is an algorithm which receives as input an instance with unary clauses of total weight* m_1 *and binary clauses of total weight* m_2, *and two reals* $u_1 \leq m_1$ *and* $u_2 \leq m_2$, *and produces reals* $s_1 \leq u_1$ *and* $s_2 \leq u_2$ *and an assignment satisfying clauses of total weight at least* $\beta_1 s_1 + \beta_2 s_2$. *If there exists an optimum solution that satisfies unary clauses of weight no more than* u_1 *and binary clauses of weight no more than* u_2, *then there is a guarantee that no assignment satisfies clauses of total weight more than* $s_1 + s_2$.

That is, supplied with a pair of "upper bounds" u_1, u_2, a (β_1, β_2) approximation algorithm produces a single upper bound of $s_1 + s_2$, along with an assignment respecting a lower bound of $\beta_1 s_1 + \beta_2 s_2$.

LEMMA 6.2 (Feige and Goemans [5]). *There exists a polynomial-time* $(.976, .931)$-*approximation algorithm for* MAX 2SAT.

6.1. MAX 3SAT. In this section we show how to derive an improved approximation algorithm for MAX 3SAT. By restricting techniques in [8] from MAX SAT to MAX 3SAT and using a .931-approximation algorithm for MAX 2SAT due to Feige and Goemans [5], one can obtain a .7704-approximation algorithm for MAX 3SAT. The basic idea of [8] is to reduce each clause of length 3 to the three possible subclauses of length 2, give each new length-2 clause one-third the original weight, and then apply an approximation algorithm for MAX 2SAT. This approximation algorithm is then "balanced" with another approximation algorithm for MAX 3SAT to obtain the result. Here we show that by using a strict gadget to reduce 3SAT to MAX 2SAT, a good (β_1, β_2)-approximation algorithm for MAX 2SAT leads to a .801-approximation algorithm for MAX 3SAT.

LEMMA 6.3. *If for every $f \in$* E3SAT *there exists a strict α-gadget reducing f to* 2SAT, *there exists a (β_1, β_2)-approximation algorithm for* MAX 2SAT, *and $\alpha \geq 1 + \frac{(\beta_1 - \beta_2)}{2(1-\beta_2)}$, then there exists a ρ-approximation algorithm for* MAX 3SAT *with*

$$\rho = \frac{1}{2} + \frac{(\beta_1 - 1/2)(3/8)}{(\alpha - 1)(1 - \beta_2) + (\beta_1 - \beta_2) + (3/8)}.$$

Proof. Let ϕ be an instance of MAX 3SAT with length-1 clauses of total weight m_1, length-2 clauses of total weight m_2, and length-3 clauses of total weight m_3. We use the two algorithms listed below, getting the corresponding upper and lower bounds on the number of satisfiable clauses:

- Random: We set each variable to 1 with probability 1/2. This gives a solution of weight at least $m_1/2 + 3m_2/4 + 7m_3/8$.
- Semidefinite programming: We use the strict α-gadget to reduce every length-3 clause to length-2 clauses. This gives an instance of MAX 2SAT. We apply the (β_1, β_2)-approximation algorithm with parameters $u_1 = m_1$ and $u_2 = m_2 + \alpha m_3$ to find an approximate solution to this problem. The approximation algorithm gives an upper bound $s_1 + s_2$ on the weight of any solution to the MAX 2SAT instance and an assignment of weight $\beta_1 s_1 + \beta_2 s_2$. When translated back to the MAX 3SAT instance, the assignment has weight at least $\beta_1 s_1 + \beta_2 s_2 - (\alpha - 1)m_3$. Furthermore, $s_1 \leq m_1$, $s_2 \leq m_2 + \alpha m_3$, and the maximum weight satisfiable in the MAX 3SAT instance is at most $s_1 + s_2 - (\alpha - 1)m_3$.

The performance guarantee of the algorithm which takes the better of the two solutions is at least

$$\rho_1 \overset{\text{def}}{=} \min_{\substack{s_1 \leq m_1 \\ s_2 \leq m_2 + \alpha m_3}} \frac{\max\{m_1/2 + 3m_2/4 + 7m_3/8, \quad \beta_1 s_1 + \beta_2 s_2 - (\alpha - 1)m_3\}}{s_1 + s_2 - (\alpha - 1)m_3}.$$

We now define a sequence of simplifications which will help prove the bound:

$$\rho_2 \overset{\text{def}}{=} \min_{\substack{t_1 \leq m_1 \\ t_2 \leq m_2 + m_3}} \frac{1}{t_1 + t_2} \max\{ \begin{array}{l} m_1/2 + 3m_2/4 + 7m_3/8, \\ \beta_1 t_1 + \beta_2 t_2 - (1 - \beta_2)(\alpha - 1)m_3\}, \end{array}$$

$$\rho_3 \overset{\text{def}}{=} \min_{\substack{t_1 \le m_1 \\ t_2 \le m_2 + m_3}} \frac{1}{t_1+t_2} \max\{ \begin{array}{l} t_1/2 + 3t_2/4 + m_3/8, \\ t_1/2 + 7m_3/8, \\ \beta_1 t_1 + \beta_2 t_2 - (1-\beta_2)(\alpha-1)m_3\}, \end{array}$$

$$\rho_4 \overset{\text{def}}{=} \min_{t_2 \le t} \frac{1}{t} \max\{ \begin{array}{l} t/2 + t_2/4 + m_3/8, \\ t/2 - t_2/2 + 7m_3/8, \\ \beta_1 t - (\beta_1 - \beta_2)t_2 - (1-\beta_2)(\alpha-1)m_3\}, \end{array}$$

$$\rho_5 \overset{\text{def}}{=} \frac{1}{2} + \left(\frac{\frac{3}{8}(\beta_1 - \frac{1}{2})}{(1-\beta_2)(\alpha-1) + (\beta_1-\beta_2) + \frac{3}{8}} \right).$$

To finish the proof of the lemma, we claim that

$$\rho_1 \ge \rho_2 \ge \cdots \ge \rho_5.$$

To see this, notice that the first inequality follows from the substitution of variables $t_1 = s_1$, $t_2 = s_2 - (\alpha-1)m_3$. The second follows from the fact that setting m_1 to t_1 and m_2 to $\max\{0, t_2 - m_3\}$ only reduces the numerator. The third inequality follows from setting $t = t_1 + t_2$. The fourth is obtained by substituting a convex combination of the arguments instead of max and then simplifying. The convex combination takes a θ_1 fraction of the first argument, θ_2 of the second, and θ_3 of the third, where

$$\theta_1 = \frac{\frac{2}{3}(1-\beta_2)(\alpha-1) + \frac{7}{6}(\beta_1-\beta_2)}{(1-\beta_2)(\alpha-1) + (\beta_1-\beta_2) + \frac{3}{8}},$$

$$\theta_2 = \frac{\frac{1}{3}(1-\beta_2)(\alpha-1) - \frac{1}{6}(\beta_1-\beta_2)}{(1-\beta_2)(\alpha-1) + (\beta_1-\beta_2) + \frac{3}{8}},$$

and

$$\theta_3 = \frac{\frac{3}{8}}{(1-\beta_2)(\alpha-1) + (\beta_1-\beta_2) + \frac{3}{8}}.$$

Observe that $\theta_1 + \theta_2 + \theta_3 = 1$ and that the condition on α guarantees that $\theta_2 \ge 0$. ☐

Remark 6.4. The analysis given in the proof of the above lemma is tight. In particular for an instance with m clauses such that

$$m_3 \overset{\text{def}}{=} m \frac{\beta_1 - 1/2}{(1-\beta_2)(\alpha-1) + (\beta_1-\beta_2) + 3/8},$$

$m_1 \overset{\text{def}}{=} m - m_3$, $m_2 \overset{\text{def}}{=} 0$, $s_1 = m_1$, and $s_2 = \alpha m_3$, it is easy to see that $\rho_1 = \rho_5$.

The following lemma gives the strict gadget reducing functions in E3SAT to 2SAT. Notice that finding strict gadgets is almost as forbidding as finding gadgets for RMBC, since there are eight existential constraints in the specification of a gadget. This time we relied instead on luck. We looked for an S-partial gadget for the set $S = \{111, 100, 010, 001\}$ and found an S-partial 3.5-gadget that turned out to be a gadget! Our choice of S was made judiciously, but we could have afforded to run through all $\binom{8}{4}$ sets S of size 4 in the hope that one would work.

LEMMA 6.5. *For every function $f \in$ E3SAT, there exists a strict (and optimal) 3.5-gadget reducing f to* 2SAT.

Proof. Since 2SAT is complementation closed, it is sufficient to present a 3.5-gadget reducing $(X_1 \vee X_2 \vee X_3)$ to 2SAT. The gadget is $X_1 \vee X_3, \neg X_1 \vee \neg X_3, X_1 \vee \neg Y, \neg X_1 \vee Y, X_3 \vee \neg Y, \neg X_3 \vee Y, X_2 \vee Y$, where every clause except the last has weight 1/2, and the last clause has weight 1. □

Combining Lemmas 6.2, 6.3, and 6.5 we get a .801-approximation algorithm.

THEOREM 6.6. MAX 3SAT *has a polynomial-time .801-approximation algorithm.*

6.2. MAX 3-ConjSAT. We now turn to the MAX 3ConjSAT problem. The analysis is similar to that of Lemma 6.3.

LEMMA 6.7. *If for every $f \in$ 3ConjSAT there exists a strict $(\alpha_1 + \alpha_2)$-gadget reducing f to 2SAT composed of α_1 length-1 clauses and α_2 length-2 clauses and there exists a (β_1, β_2) approximation algorithm for MAX 2SAT, then there exists a ρ approximation algorithm for MAX 3ConjSAT with*

$$\rho = \frac{\frac{1}{8}\beta_1}{\frac{1}{8} + (1-\alpha_1)(\beta_1 - \beta_2) + (1-\beta_2)(\alpha_1 + \alpha_2 - 1)}$$

provided $\alpha_1 + \alpha_2 > 1 + 1/8(1-\beta_2)$.

Proof. Let ϕ be an instance of MAX 3ConjSAT with constraints of total weight m. As in the MAX 3SAT case, we use two algorithms and take the better of the two solutions:

- Random: We set every variable to 1 with probability half. The total weight of satisfied constraints is at least $m/8$.
- Semidefinite programming: We use the strict α-gadget to reduce any constraint to 2SAT clauses. This gives an instance of MAX 2SAT and we use the (β_1, β_2)-approximation algorithm with parameters $u_1 = \alpha_1 m$ and $u_2 = \alpha_2 m$. The algorithm returns an upper bound $s_1 + s_2$ on the total weight of satisfiable constraints in the MAX 2SAT instance, and an assignment of measure at least $\beta_1 s_1 + \beta_2 s_2$. When translated back to the MAX 3ConjSAT instance, the measure of the assignment is at least $\beta_1 s_1 + \beta_2 s_2 - (\alpha_1 + \alpha_2 - 1)m$. Furthermore, $s_1 \le \alpha_1 m$, $s_2 \le \alpha_2 m$, and the total weight of satisfiable constraints in the MAX 3ConjSAT instance is at most $s_1 + s_2 - (\alpha_1 + \alpha_2 - 1)m$.

Thus we get that the performance ratio of the algorithm which takes the better of the two solutions above is at least

$$\rho_1 \overset{\text{def}}{=} \min_{\substack{s_1 \le \alpha_1 m \\ s_2 \le \alpha_2 m}} \frac{\max\{m/8, \quad \beta_1 s_1 + \beta_2 s_2 - (\alpha_1 + \alpha_2 - 1)m\}}{s_1 + s_2 - (\alpha_1 + \alpha_2 - 1)m}.$$

We now define a sequence of simplifications which will help prove the bound:

$$\rho_2 \overset{\text{def}}{=} \min_{\substack{t_1 \le \alpha_1 m \\ t_2 \le (1-\alpha_1) m}} \frac{1}{t_1 + t_2} \max\{m/8, \quad \beta_1 t_1 + \beta_2 t_2 - (1-\beta_2)(\alpha_1 + \alpha_2 - 1)m\},$$

$$\rho_3 \overset{\text{def}}{=} \min_{\substack{t \le m \\ t_2 \le (1-\alpha_1) m}} \frac{1}{t} \max\{m/8, \quad \beta_1 t - (\beta_1 - \beta_2) t_2 - (1-\beta_2)(\alpha_1 + \alpha_2 - 1)m\},$$

$$\rho_4 \overset{\text{def}}{=} \min_{t \le m} \frac{1}{t} \max\{m/8, \quad \beta_1 t - ((1-\alpha_1)(\beta_1 - \beta_2) + (1-\beta_2)(\alpha_1 + \alpha_2 - 1))m\},$$

$$\rho_5 \stackrel{\text{def}}{=} \frac{\frac{1}{8}\beta_1}{\frac{1}{8} + (1-\alpha_1)(\beta_1 - \beta_2) + (1-\beta_2)(\alpha_1 + \alpha_2 - 1)}.$$

In order to prove the lemma, we claim that

$$\rho_1 \geq \rho_2 \geq \cdots \geq \rho_5.$$

To see this, observe that the first inequality follows from the substitution of variables $t_1 = s_1$ and $t_2 = s_2 - (\alpha_1 + \alpha_2 - 1)m$. The second follows from setting $t = t_1 + t_2$. The third inequality follows from the fact that setting t_2 to $(1-\alpha_1)m$ only reduces the numerator. The fourth is obtained by substituting a convex combination of the arguments instead of max and then simplifying. $\square$

The following gadget was found by looking for an S-partial gadget for $S = \{111, 110, 101, 011\}$.

Lemma 6.8. *For any $f \in$ 3ConjSAT there exists a strict (and optimal) 4-gadget reducing f to 2SAT. The gadget is composed of one length-1 clause and three length-2 clauses.*

Proof. Recall that 2SAT is complementation closed, and thus it is sufficient to exhibit a gadget reducing $f(a_1, a_2, a_3) = a_1 \wedge a_2 \wedge a_3$ to 2SAT. Such a gadget is Y, $(\neg Y \vee X_1)$, $(\neg Y \vee X_2)$, $(\neg Y \vee X_3)$, where all clauses have weight 1. The variables X_1, X_2, X_3 are primary variables and Y is an auxiliary variable. $\square$

Theorem 6.9. MAX 3ConjSAT *has a polynomial-time* .367*-approximation algorithm.*

It is shown by Trevisan [16, Theorem 18] that the above theorem has consequences for $\text{PCP}_{c,s}[\log, 3]$. This is because the computation of the verifier in such a proof system can be described by a decision tree of depth 3 for every choice of random string. Further, there is a 1-gadget reducing every function which can be computed by a decision tree of depth k to kConjSAT.

Corollary 6.10. $\text{PCP}_{c,s}[\log, 3] \subseteq \text{P}$ *provided that $c/s > 2.7214$.*

The previous best trade-off between completeness and soundness for polynomial-time PCP classes was $c/s > 4$ [16].

7. Lower bounds for gadget constructions.

In this section we shall show that some of the gadget constructions mentioned in this paper and in [2] are optimal, and we shall prove lower bounds for some other gadget constructions.

The following result is useful to prove lower bounds for the RMBC family.

Lemma 7.1. *If there exists an α-gadget reducing an element of* RMBC *to a complementation-closed constraint family $\mathcal{F}$, then there exists an α-gadget reducing all elements of* PC *to $\mathcal{F}$.*

Proof. If a family $\mathcal{F}$ is complementation closed, then an α-gadget reducing an element of PC (respectively, RMBC) to $\mathcal{F}$ can be modified (using complementations) to yield α-gadgets reducing all elements of PC (respectively RMBC) to $\mathcal{F}$. For this reason, we will restrict our analysis to PC_0 and RMBC_{00} gadgets. Note that, for any $a_1, a_2, a_3 \in \{0,1\}^3$, $\text{PC}_0(a_1, a_2, a_3) = 1$ if and only if $\text{RMBC}_{00}(a_1, a_2, a_3, \overline{a_3}) = 1$. Let Γ be an α-gadget over primary variables $x_1, \ldots, x_4$ and auxiliary variables $y_1, \ldots, y_n$ reducing RMBC to 2SAT. Let Γ' be the gadget obtained from Γ by imposing $x_4 \equiv \overline{x_3}$: it is immediate to verify that Γ' is an α-gadget reducing PC_0 to $\mathcal{F}$. $\square$

7.1. Reducing PC and RMBC to 2SAT.

Theorem 7.2. *If Γ is an α-gadget reducing an element of* PC *to* 2SAT, *then $\alpha \geq 11$.*

Proof. It suffices to consider PC_0. We prove that the optimum of (LP1) is at least 11. To this end, consider the dual program of (LP1). We have a variable $y_{\vec{a},\vec{b}}$ for any $\vec{a} \in \{0,1\}^3$ and any $\vec{b} \in \{0,1\}^4$, plus additional variables $\hat{y}_{\vec{a},\vec{b}^{opt}(\vec{a})}$ for any $\vec{a} : \mathrm{PC}(\vec{a}) = 1$, where $\vec{b}^{opt}$ is the "optimal" witness function defined in section 3. The formulation is

$$\begin{array}{ll}
\text{maximize} \quad \sum_{\vec{a},\vec{b}:\mathrm{PC}(\vec{a})=0} y_{\vec{a},\vec{b}} & \\
\text{subject to} & \\
\sum_{\vec{a},\vec{b}} y_{\vec{a},\vec{b}} \leq 1 + \sum_{\vec{a}:\mathrm{PC}(\vec{a})=1} y_{\vec{a},\vec{b}^{opt}(\vec{a})}, & \\
\sum_{\vec{a},\vec{b}} y_{\vec{a},\vec{b}} C_j(\vec{a},\vec{b}) \geq \sum_{\vec{a}:\mathrm{PC}(\vec{a})=1} \hat{y}_{\vec{a},\vec{b}^{opt}(\vec{a})} C_j(\vec{a},\vec{b}^{opt}(\vec{a})) & \forall j \in [98], \\
y_{\vec{a},\vec{b}} \geq 0 & (\forall \vec{a} \in \{0,1\}^3)\ (\forall \vec{b} \in \{0,1\}^4), \\
\hat{y}_{\vec{a},\vec{b}^{opt}(\vec{a})} \geq 0 & (\forall \vec{a} : \mathrm{PC}(\vec{a}) = 1),
\end{array}$$

(DUAL1).

There exists a feasible solution for (DUAL1) whose cost is 11. ∎

COROLLARY 7.3. *If* Γ *is an* α*-gadget reducing an element of* RMBC *to* 2SAT*, then* $\alpha \geq 11$.

7.2. Reducing PC and RMBC to SAT.

THEOREM 7.4. *If* Γ *is an* α*-gadget reducing an element of* PC *to* SAT*, then* $\alpha \geq 4$.

Proof. As in the proof of Theorem 7.2 we give a feasible solution to the dual to obtain the lower bound. The LP that finds the best gadget reducing PC_0 to SAT is similar to (LP1), the only difference being that a larger number N of clauses are considered, namely, $N = \sum_{i=1}^{7} \binom{7}{i} 2^i$. The dual program is then

$$\begin{array}{ll}
\text{maximize} \quad \sum_{\vec{a},\vec{b}:\mathrm{PC}(\vec{a})=0} y_{\vec{a},\vec{b}} & \\
\text{subject to} & \\
\sum_{\vec{a},\vec{b}} y_{\vec{a},\vec{b}} \leq 1 + \sum_{\vec{a}:\mathrm{PC}(\vec{a})=1} y_{\vec{a},\vec{b}^{opt}(\vec{a})}, & \\
\sum_{\vec{a},\vec{b}} y_{\vec{a},\vec{b}} C_j(\vec{a},\vec{b}) \geq \sum_{\vec{a}:\mathrm{PC}(\vec{a})=1} \hat{y}_{\vec{a},\vec{b}^{opt}(\vec{a})} C_j(\vec{a},\vec{b}^{opt}(\vec{a})) & \forall j \in [N], \\
y_{\vec{a},\vec{b}} \geq 0 & (\forall \vec{a} \in \{0,1\}^3)\ (\forall \vec{b} \in \{0,1\}^4), \\
\hat{y}_{\vec{a},\vec{b}^{opt}(\vec{a})} \geq 0 & (\forall \vec{a} : \mathrm{PC}(\vec{a}) = 1),
\end{array}$$

(DUAL2).

Consider now the following assignment of values to the variables of (DUAL2) (the unspecified values have to be set to zero):

$$\begin{array}{l}
(\forall \vec{a} : \mathrm{PC}(\vec{a}) = 1)\ \hat{y}_{\vec{a},\vec{b}^{opt}(\vec{a})} = \frac{3}{4}, \\
(\forall \vec{a} : \mathrm{PC}(\vec{a}) = 1)(\forall \vec{a}' : d(\vec{a},\vec{a}') = 1)\ y_{\vec{a}',\vec{b}^{opt}(\vec{a})} = \frac{1}{3},
\end{array}$$

where d is the Hamming distance between binary sequences. It is possible to show that this is a feasible solution for (DUAL2) and it is immediate to verify that its cost is 4. ∎

COROLLARY 7.5. *If* Γ *is an* α*-gadget reducing an element* RMBC *to* SAT*, then* $\alpha \geq 4$.

7.3. Reducing *k*SAT to *l*SAT.

Let k and l be any integers $k > l \geq 3$. The standard reduction from EkSAT to lSAT can be seen as a $\lceil (k-2)/(l-2) \rceil$-gadget. In this section we shall show that this is asymptotically the best possible. Note that since lSAT is complementation closed we can restrict ourselves to considering just one constraint function of EkSAT, say $f(a_1, \ldots, a_k) \equiv \bigvee_i a_i$.

THEOREM 7.6. *For any $k > l > 2$, if Γ is an α-gadget reducing f to $lSAT$, then $\alpha \geq k/l$.*

Proof. We can write an LP whose optimum gives the smallest α such that an α-gadget exists reducing f to lSAT. Let b be the witness function used to formulate this LP. We can assume that b is 2^{2^k}-ary and we let $K = 2^{2^k}$. Also let N be the total number of constraints from lSAT that can be defined over $k + K$ variables. Assume some enumeration $C_1, \ldots, C_N$ of such constraints. The dual LP is

$$\begin{array}{ll}
\text{maximize} & \sum_{\vec{a},\vec{b}:\mathrm{PC}(\vec{a})=0} y_{\vec{a},\vec{b}} \\
\text{subject to} & \\
 & \sum_{\vec{a},\vec{b}} y_{\vec{a},\vec{b}} \leq 1 + \sum_{\vec{a}:f(\vec{a})=1} y_{\vec{a},\vec{b}^{kSAT-lSAT}(\vec{a})}, \\
\forall j \in [N] & \sum_{\vec{a},\vec{b}} y_{\vec{a},\vec{b}} C_j(\vec{a},\vec{b}) \geq \sum_{\vec{a}:f(\vec{a})=1} \hat{y}_{\vec{a},\vec{b}^{kSAT-lSAT}(\vec{a})} C_j(\vec{a}, \\
 & \vec{b}^{kSAT-lSAT}(\vec{a})), \\
\forall \vec{a} \in \{0,1\}^k,\ \forall \vec{b} \in \{0,1\}^K & y_{\vec{a},\vec{b}} \geq 0, \\
\forall \vec{a} : f(\vec{a}) = 1 & \hat{y}_{\vec{a},\vec{b}^{kSAT-lSAT}(\vec{a})} \geq 0
\end{array}$$

(DUAL3).

The witness function $\vec{b}^{kSAT-lSAT}$ is an "optimal" witness function for gadgets reducing kSAT to lSAT.

Let $A_k \subset \{0,1\}^k$ be the set of binary k-ary strings with exactly one nonzero component (note that $|A_k| = k$). Also let $\vec{0}$ (respectively, $\vec{1}$) be the k-ary string all of whose components are equal to 0 (respectively, 1). The following is a feasible solution for (DUAL3) whose cost is k/l. We only specify nonzero values:

$$\begin{array}{ll}
(\forall \vec{a} \in A_k) & \hat{y}_{\vec{a},\vec{b}^{kSAT-lSAT}(\vec{a})} = 1/l, \\
(\forall \vec{a} \in A_k) & y_{\vec{0},\vec{b}^{kSAT-lSAT}(\vec{a})} = 1/l, \\
(\forall \vec{a} \in A_k) & y_{\vec{1},\vec{b}^{kSAT-lSAT}(\vec{a})} = 1/k\ . \qquad \square
\end{array}$$

In view of the above lower bound, a gadget cannot provide an approximation-preserving reduction from MAX SAT to MAX kSAT. More generally, there cannot be an approximation-preserving gadget reduction from MAX SAT to, say, MAX $(\log n)$SAT. In partial contrast with this lower bound, Khanna et al. [13] have given an approximation-preserving reduction from MAX SAT to MAX 3SAT and Crescenzi and Trevisan [4] have provided a *tight* reduction between MAX SAT and MAX $(\log n)$SAT, showing that the two problems have the same approximation threshold.

Acknowledgments. We thank Pierluigi Crescenzi and Oded Goldreich for several helpful suggestions and remarks. We are grateful to John Forrest and David Jensen for their assistance in efficiently solving large LPs. We thank Howard Karloff and Uri Zwick for pointing out the error in the earlier version of this paper and the counterexample to our earlier claim. We thank the anonymous referees for their numerous comments and suggestions leading to the restructuring of section 3.
