MULTIPLE NONINTERACTIVE ZERO KNOWLEDGE PROOFS UNDER GENERAL ASSUMPTIONS[*]

URIEL FEIGE[†], DROR LAPIDOT[†], AND ADI SHAMIR[†]

Abstract. In this paper we show how to construct noninteractive zero knowledge proofs for any NP statement under general (rather than number theoretic) assumptions, and how to enable polynomially many provers to give polynomially many such proofs based on a single random string. Our constructions can be used in cryptographic applications in which the prover is restricted to polynomial time.

Key words. Hamiltonian cycle, witness indistinguishability

1. Introduction.

1.1. Background. Blum, Feldman, and Micali [BFM] suggested the intriguing concept of *noninteractive zero knowledge* (NIZK) *proofs*, aimed at eliminating the interaction between prover and verifier in zero knowledge interactive proof systems [GMR]. The prover P writes down a zero knowledge proof that an input x belongs to a prespecified language L, and any verifier V can check the validity of this written proof against a universal publicly available random string (such as the RAND string of one million random digits), called the *common reference string*. NIZK has become an important primitive for cryptographic protocols, with applications such as signature schemes [BG] and encryption schemes secure against chosen ciphertext attack [NY].

NIZK proof systems for any NP statement were constructed in [BFM] and [DMP87], under specific number theoretic assumptions (namely, that it is difficult to distinguish products of two primes from products of three primes, or that it is difficult to decide quadratic residuosity modulo products of two primes). The main disadvantage of these *bounded* NIZK proofs is that the prover can prove only one statement of size bounded by the length of the common reference string: if polynomially many proofs are given using the same reference string, the zero knowledge property breaks down.[1] In [BDMP] it was finally shown how a single prover can give polynomially many proofs using the same reference string, but the scheme is still based on a specific number theoretic assumption: deciding quadratic residuosity (modulo composite integers whose factorization is not known) is computationally hard. Moreover, their scheme cannot support polynomially many provers.

A variation of the NIZK model was suggested by De Santis, Micali, and Persiano [DMP88]. In their *noninteractive with preprocessing* model, the verifier and prover create a common reference string (which need not look like a random string) during an interactive preliminary stage. Based on this common reference string (CRS), the prover can then prove any single NP statement (of bounded length). Unlike

[1]The method suggested in [BFM] for overcoming this difficulty was found to be flawed.

the original NIZK model, in the noninteractive with preprocessing model, the proof should look convincing only to the verifier who takes part in the initial preprocessing stage, which makes this model unsuitable for applications such as signature schemes. [DMP88] showed an implementation of this idea based on the general assumption that one-way functions exist. Under the stronger cryptographic assumption that *oblivious transfer* protocols exist, [KMO] shows how after an initial preprocessing stage, the prover can noninteractively prove polynomially many NP statements, but again the proof is verifiable only by its original recipient. [BeMi] show how to do oblivious transfer without interaction (and hence NIZK proofs, by [KMO]) in a model where the verifier is first given a special public key.

1.2. Our results. In this paper we answer the two major open questions associated with the concept of NIZK, as presented by Blum, De Santis, Micali, and Persiano [BDMP]: how to construct NIZK proof systems for any NP statement under general (rather than number theoretic) assumptions and how to enable polynomially many provers to share the same random reference string in giving such proofs.

As a preliminary result leading to our solution of the first open question, we construct (under the assumption that one-way functions exist) a very simple zero knowledge *noninteractive with preprocessing* proof for Hamiltonicity, whose efficiency is comparable with the efficiency of the interactive proofs presented by Blum [Blum] and Goldreich, Micali, and Wigderson [GMW]. In contrast, all the previously known constructions of *NIZK with preprocessing* proofs [DMP88] are more complex and less efficient than their interactive counterparts. Then, under the assumption that one-way permutations exist, we show that if the prover and verifier initially share a common random string (which we call a common reference string), then the initial preprocessing stage of our protocol can be discarded, yielding a NIZK proof for any NP statement in the original noninteractive model of Blum, Feldman, and Micali. This noninteractive protocol is the only known implementation which relies on general computational assumptions and is conceptually simpler than the number-theoretic protocols[2] presented by Blum, De Santis, Feldman, Micali, and Persiano. Under the stronger assumption that certified trapdoor permutations exist (i.e., that the prover can demonstrate that his chosen function is indeed a permutation without revealing its trapdoor), our NIZK protocol can be carried out by probabilistic polynomial time provers and thus can be used in cryptographic applications which require NIZK protocols.

As a solution to the second open problem, we show how to transform any *bounded* NIZK proof system for an *NP complete* language into a *general* NIZK proof system in which polynomially many independent provers can share the same reference string and use it to prove polynomially many statements of polynomial length. The transformation is based on the general assumption that one-way functions exist.

Independent of our work, De Santis and Yung [DY] also show how to transform bounded NIZK proof systems into general ones, although their transformation produces noninteractive proofs which are longer than ours.

In order to use NIZK proof systems in cryptographic applications it is often necessary to extend the security conditions imposed on NIZKs to withstand adaptive attacks (see [BG], [NY]). The original definitions of NIZK proof systems assume that the statements to be proved are chosen independently of the CRS, whereas the

[2]This is based on the assumption that deciding quadratic residuosity (modulo composite integers whose factorization is not known) is computationally hard.

adaptive setting allows for the possibility that statements to be proven are chosen after the CRS is given, and may depend upon the CRS. In the last section of this paper we show that our constructions also satisfy the more stringent conditions imposed by the adaptive setting.

1.3. Definitions. $A(x)$ denotes the random variable describing the output of a probabilistic algorithm A on input x. Informally, $\nu(n)$ denotes functions vanishing faster than the inverse of any polynomial; i.e., $f(n) \leq \nu(n)$ is shorthand notation for

$$\forall d\ \exists N \text{ s.t. } \forall n > N\ \ 0 \leq f(n) < \frac{1}{n^d}$$

and $f(n) \geq 1 - \nu(n)$ is shorthand notation for

$$\forall d\ \exists N \text{ s.t. } \forall n > N\ \ 1 \geq f(n) > 1 - \frac{1}{n^d}.$$

DEFINITION 1.1. *A binary relation R is* polynomially bounded *if it is decidable in polynomial time and also there is a polynomial p such that for all $(x, w) \in R$ it is the case that $|w| \leq p(|x|)$. For any such relation and any x we let $w(x) = \{w : (x, w) \in R\}$ denote the witness set of x. We let $L_R = \{x \mid \exists w \text{ s.t. } (x, w) \in R\}$.*

R will denote a polynomially bounded relation in what follows. Note that if R is polynomially bounded, then L_R is in NP.

A NIZK proof system for NP allows a prover P to use a publicly available random string (the *CRS*) in order to prove in writing (without interaction) any NP theorem, without revealing any knowledge besides the validity of the theorem. Any polynomial time verifier V with access to the CRS can verify the validity of the proof.

The input of P is a triple (x, ω, σ) where $(x, \omega) \in R$, R is a polynomially testable relation, and σ is the CRS. Its output $P(x, \omega, \sigma)$ is a noninteractive proof (based on the witness ω, with respect to the CRS σ) that $x \in L_R$. The initial input of V (before receiving P's proof) is the pair (x, σ). Let $|x| = n$ denote the size of the common input x. Let $V(x, \sigma, P(x, \omega, \sigma))$ denote the output of the verifier V, after receiving the noninteractive proof $P(x, \omega, \sigma)$. This output may be either "accept" or "reject." For brevity of notation, we sometimes do not explicitly specify x and σ as inputs to V, when x and σ are clear from the context.

As in the case of interactive proofs, noninteractive proofs satisfy the *completeness* and the *soundness* conditions: if $x \in L_R$ then P's proof causes V to accept, and if $x \notin L_R$ the probability that V accepts P's output is negligible. The following is the formal definition of a noninteractive proof.

DEFINITION 1.2. *A noninteractive proof system for an NP language L_R is a pair of probabilistic algorithms (P, V) (where V is polynomial time) satisfying the following conditions.*

There exist two integers $b, c \geq 1$ such that the following hold:

(1) Completeness. $\forall (x, \omega) \in R$, $\forall \sigma$ *of length* $n^b k^c$ $V(x, \sigma, P(x, \omega, \sigma)) = \textit{accept}$.

(2) Soundness. *If σ is a random string, then the probability of succeeding in proving a false statement is negligible, even if the theorem is chosen by P after seeing σ.*[3] *Formally, $\forall n \geq 1$ at least $(1 - \nu(k))$ of the strings σ of length $n^b k^c$ satisfy*

$$\forall x \in (\{0,1\}^n - L_R) \qquad \forall y \quad V(x, \sigma, y) = \textit{reject}.$$

[3]In nonadaptive definitions of soundness, the prover could produce a false statement based on the choice of the random string, whose proof (associated with this particular string) will be accepted. Our definition of soundness disallows this possibility.

Remark. In the definition above (and in Definition 1.3 below), k is a security parameter (known to all parties) that quantifies how "sound" a noninteractive proof must be (or quantifies the "zero knowledge" property in Definition 1.3). More formally, we assume that the value of k (represented in unary notation as 1^k) is an additional input provided to all the algorithms, but we do not make this dependence explicit in order to simplify our notation. It is often convenient (and is the practice of most other papers on zero knowledge) to choose $k = n$ and require the desired properties of noninteractive proof systems to hold for "large enough n."

As in the case of interactive proofs (see [GMR]), the formal definition of NIZK proofs involves the notion of a probabilistic expected polynomial time simulator M, whose input is just the common input x of P and V (without an appropriate witness ω), and its output $M(x)$ consists of two strings: one of them simulates the common (random) reference string, and the other one simulates the real noninteractive proof (sent by P). Informally, a noninteractive proof is zero knowledge if such a pair of strings is computationally indistinguishable from what V sees in the actual noninteractive proof which is $(\sigma, P(x, \omega, \sigma))$. The following is the formal definition of NIZK.

DEFINITION 1.3. *A noninteractive proof system for an NP-language L_R is zero knowledge if there exists a probabilistic machine M (called a simulator) such that for any $x \in L_R$, $M(x)$ terminates in expected polynomial time and the two ensembles $\{(\sigma, P(x, \omega, \sigma))\}$[4] and $\{M(x)\}$[5] are computationally indistinguishable on L_R by any nonuniform polynomial time distinguisher $D = \{D_l\}_{l \geq 1}$:*

$$\exists b, c \geq 1 \quad \exists M \, \forall D = \{D_l\}_{l \geq 1} \, \forall (x, \omega) \in R \, \forall d \geq 1 \quad \exists K \geq 1 \, \forall k > \ \mathrm{Max}(K, |x|),$$

$$|Pr(D_k(M(x)) = 1) - Pr(D_k(\sigma, P(x, \omega, \sigma)) = 1)| < \frac{1}{k^d},$$

where the probability space is taken over the random choices of $\sigma \in_R \{0,1\}^{|x|^b k^c}$ and over the random tapes of P and M.

Remark. A nonuniform algorithm $D = \{D_l\}_{l \geq 1}$ is an algorithm that for every input length l gets an auxiliary input ("advice") of length polynomial in l. These algorithms are equivalent to polynomial size circuit families.

In cryptographic applications we would like to use efficient protocols for both P and V. The term *NIZK proof systems with efficient provers* denotes NIZK proof systems in which the truthful prover (in the *completeness* condition) is probabilistic polynomial time (in n, the length of the input x, and in k, the security parameter). "Cheating" provers (in the *soundness* condition) are never required to be computationally bounded.

2. NIZKs under general cryptographic assumptions.

2.1. A NIZK proof with preprocessing. In this subsection we present a protocol for a different model which is called a NIZK proof with preprocessing. This is not the final protocol: it is presented here just as an intermediate step in order to facilitate the understanding of the final NIZK proof system.

Consider a prover who wants to prove the Hamiltonicity of an arbitrary graph G with n nodes. We assume that the prover and the verifier are allowed to execute a

[4]Every element in this ensemble is uniquely determined by the choice of $\sigma \in_R \{0,1\}^{|x|^b k^c}$ and the prover's random tape.

[5]Here, every element is uniquely determined by the value of the random tape of the probabilistic machine M.

preliminary interactive stage which is independent of G (i.e., at this stage they know that in the noninteractive stage the prover will prove the Hamiltonicity of an n node graph, but they don't know which graph it will be). Only after the termination of this interactive stage they get G and execute the noninteractive move in which the prover sends a written message to the verifier in order to convince him in zero knowledge that G is Hamiltonian. The verifier is not allowed to ask the prover any questions and should be convinced just by reading this message.

The basic step. Let H be a randomly chosen directed Hamiltonian cycle on n nodes. We call such a graph a *good graph.* Note that this is a cyclic list without any starting point. The adjacency matrix of H is a matrix in which each row and each column contains exactly one entry that is set to 1, and the locations of the entries that are 1 define a permutation with a single cycle. Let S be the adjacency matrix of a good graph in which each entry is replaced by a string that hides it (for example, by the hard bit construction of [GL] or by a probabilistic encryption), so that a polynomially bounded observer cannot determine the locations of the ones.

Assume now that S is given to both P and V, and that P wants to prove to V that some n-nodes graph G is Hamiltonian. Since P is infinitely powerful, he can recover (to himself) the hidden 0/1 values of S which define the Hamiltonian cycle H in the good graph and determine a permutation π on the nodes of G such that H is a Hamiltonian cycle in $\pi(G)$ (i.e., $H \subseteq \pi(G)$).

In order to convince V that G is Hamiltonian, P just sends it a message which consists of the permutation π and the decryptions of all entries $S_{i,j}$ in the good matrix S for which $(i,j) \notin E(\pi(G))$. V accepts the proof iff all the revealed entries are 0. The proof system is *complete* since P can carry it out and V will accept it when G is indeed Hamiltonian. The proof system is *sound* because V's acceptance implies that all the n ones that remain unrevealed in S (and define a Hamiltonian cycle) correspond to edges of $\pi(G)$, which means that $\pi(G)$ contains a Hamiltonian cycle and thus the common input graph G is Hamiltonian.

We informally argue that the proof is *zero knowledge.* All that the verifier receives is a random permutation π and a collection of random encryptions (the entries of S) along with the decryption of those $S_{i,j}$ for which $(i,j) \notin E(\pi(G))$. All these decrypted values are 0. Since the original good matrix H (which defines the 0/1 values of S) is randomly chosen with uniform distribution (among the $(n-1)!$ possibilities), then so is $\pi \in_R Sym(n)$ (the permutation group on $[1 \ldots n]$). This follows from the fact that any two different Hamiltonian cycles H and H' determine two disjoint sets A_H and $A_{H'}$ of n permutations, where each permutation in A_H ($A_{H'}$) maps the Hamiltonian cycle of G onto H (H').[6] Therefore, for any permutation in $Sym(n)$, the probability that V receives it is $\frac{1}{n!}$. Therefore, this protocol can be easily simulated: the simulator (whose input is just the graph G) chooses a random permutation $\pi \in_R Sym(n)$ with uniform distribution, chooses random 0/1 values for all entries $S'_{i,j}$ for which $(i,j) \in E(\pi(G))$, fixes all the others to be 0, and produces random encryptions for all entries of S'. Then the simulator outputs π and the decryptions of all entries $S'_{i,j}$ for which $(i,j) \notin E(\pi(G))$. Since π is uniformally chosen in $Sym(n)$ and all the above encryptions are randomized, this simulation is computationally indistinguishable from the real proof.

Based on the above, we construct a NIZK proof system with preprocessing (regardless of whether P is efficient or not): In the preliminary interactive stage P sequentially sends k (= security parameter) good random matrices $S_1, S_2, \ldots, S_k$ to

[6]There may be several Hamiltonian cycles in G, but we concentrate on any one of them.

V and receives k random bits $b_1, b_2, \ldots, b_k$ from V. In the noninteractive move it reveals all entries of those S_i's for which $b_i = 0$ and executes the above basic step for those S_i for which $b_i = 1$. If all the S_i with $b_i = 0$ are good (i.e., hidden adjacency matrices of Hamiltonian cycles), then V can conclude with high probability that at least one of the other S_i is also good, in which case G is guaranteed to be Hamiltonian.

In order to compare this protocol with Blum's protocol for Hamiltonicity [Blum], let us recall that in the first move of Blum's scheme P randomly permutes G and sends V the encrypted adjacency matrix of this isomorphic copy. V then sends a random bit to P and according to that bit P either reveals all the entries in the matrix and the permutation or reveals only the entries which correspond to the edges of the Hamiltonian cycle. Our protocol resembles Blum's protocol, with one major difference: in Blum's protocol all the moves depend on G, while in our protocol only the last move depends on G. As a result, Blum's protocol cannot be split into a preprocessing stage and a noninteractive proof as we did in our protocol.

Remark. This particular NIZK proof with preprocessing can be extended for *directly* proving (without reduction to the Hamiltonian problem) a variety of graph theoretic problems which are satisfied by a single minimal (or maximal) graph (under isomorphism). This family includes clique, graph coloring, graph partition into k-cliques, three-dimensional matching, etc. We don't know how to extend our proof technique directly to other NP-complete problems.

2.2. A NIZK proof with a common reference string. In this subsection we show that under the assumption that (strong) one-way permutations exist, if the prover and the verifier initially share a random string (or CRS) σ, then the initial preprocessing stage of the protocol described in section 2.1 can be discarded, yielding a NIZK proof for any NP statement in the noninteractive model of Blum, Feldman, and Micali.

DEFINITION 2.1. *A permutation f is a (strong)* one-way function *if for any x ($|x| = n$), $f(x)$ (which is also of length n) can be computed in polynomial time, but for any nonuniform polynomial time algorithm A,*

$$Prob(A(y) = f^{-1}(y)) \leq \nu(n),$$

where the probability is computed over the random choices of $y \in_R \{0,1\}^n$.

We remark that strong one-way permutations exist if "weak" one-way permutations (i.e., the probability of not inverting y is nonnegligible) exist [Yao], [GILVZ].

In our NIZK construction we want to guarantee the hardness of inverting the one-way permutation f at the single bit level. This idea is captured in the notion of *a hard-core predicate* of a one-way function. A hard-core predicate of a function f is a predicate $B : \{0,1\}^* \longrightarrow \{0,1\}$, which is efficiently computable but such that given only $f(x)$ it is hard to guess $B(x)$ with a probability significantly better than 1/2.

DEFINITION 2.2. *We call the predicate $B : \{0,1\}^* \longrightarrow \{0,1\}$ a* hard-core predicate *of the function $f : \{0,1\}^* \longrightarrow \{0,1\}^*$ if the following conditions are satisfied:*

1. *B is computable in deterministic polynomial time.*
2. *For every nonuniform polynomial time probabilistic algorithm A, for every integer $c > 0$, and for every large enough n,*

$$Prob\{A(f(x)) = B(x)\} < \frac{1}{2} + \frac{1}{n^c},$$

where the probability is taken over the coin tosses of A and for x uniformly chosen in $\{0,1\}^n$.

The idea of hard-core predicates was introduced and first implemented (based on a specific one-way permutation) by [BM]. [Yao] presented a general transformation of any (strong) one-way function into one which has a hard-core predicate, but the transformation was impractical. Goldreich and Levin [GL] provided an alternative transformation which was much more efficient. Our NIZK construction uses such a hard-core predicate in order to extract hard-to-guess bits from any given one-way function.

2.2.1. Informal description. Assume that P and V possess a CRS σ, and P wants to send V a NIZK proof based on σ (rather than on an interactive preprocessing stage) that an arbitrary n node graph G is Hamiltonian. Basically, the proof technique consists of two stages.

1. Interpretation of the CRS as an encoding of a string of "secret" bits—a hidden random string (HRS). Only the unbounded prover can initially read the hidden bits, but he can later selectively reveal the value of some of the hidden bits to the polynomially bounded verifier without revealing any information on the other hidden bits.
2. Interpretation of the HRS as a sequence of $n \times n$ matrices in such a way that at least one of them represents a good graph with overwhelming probability. For each matrix the prover P is allowed to do one of two things: to prove to V that the matrix is not good by revealing all its entries, or to use it as if it is a good matrix in the Hamiltonicity testing protocol of section 2.1. Note that the prover can claim that a bad matrix is good, but he cannot successfully claim that a good matrix is bad, and thus he will be forced to use all the good matrices in the protocol. If the input G is non-Hamiltonian, P will fail to convince V except in the extremely unlikely case in which all the matrices defined by the HRS are bad.

The first stage is implemented by considering the CRS as a concatenation of polynomially many blocks $u_1, u_2, \ldots$, where each block contains k (= security parameter) random bits. We define a corresponding intermediate random string (IRS) by concatenating the values of $w_1, w_2, \ldots$, where each w_i is equal to $f^{-1}(u_i)$. The ith bit s_i in the HRS is a hard-core bit defined by the ith block u_i in the CRS. By revealing s_i we mean that P sends to V the bit s_i along with w_i from the IRS. By checking s_i we mean that V checks that $f(w_i) = u_i$ and $B(w_i) = s_i$. Note that $f^{-1}(u_i)$ exists and is uniquely defined by our assumption that f is a one-way permutation, and thus even the unbounded prover cannot "flip" the value of this bit without being caught by the verifier.

The second stage is implemented by interpreting the HRS as a sequence of $n \times n$ 0/1 matrices which with overwhelming probability contain at least one good matrix. Notice that if we naively interpret each block of n^2 consecutive bits from the HRS as an $n \times n$ 0/1 matrix, then the probability that even one of these polynomially many matrices is good is exponentially low. Therefore, we have to encode our matrices in a more complicated way.

Assume that the HRS can be partitioned into equal size segments $z_1, z_2, z_3, \ldots$, each of which defines (in some way) an $n^2 \times n^2$ matrix B_i of zeros and ones, such that for each i and each (j, l) the probability that the (j, l)th entry in B_i is 1 equals $\frac{1}{n^3}$ (i.e., $Pr\{B_i(j, l) = 1\} = \frac{1}{n^3}$). Therefore, for any segment z_i the expected number of 1-entries in the corresponding matrix B_i is n, and we will later prove that every B_i contains, with nonnegligible probability, exactly n rows and n columns, each of which contains a single 1-entry and the $n \times n$ permutation matrix induced by these rows and columns is Hamiltonian. Therefore, if the length of the HRS is large enough (polynomial in n and k), then, with high probability, at least one of its segments defines a good matrix.

All we have to show is how to transform a given random string into a sequence of matrices, each of which has the property of B_i. Consider the given random string as a concatenation of polynomially many consecutive blocks of m bits where $m = \log(n^3)$ (w.l.o.g. we can assume that it is an integer). We interpret a block as 1 if all its m bits are 1, and 0 otherwise. Therefore, for every m-bit block, the probability of being interpreted as 1 is $\frac{1}{n^3}$ and thus we can pack each consecutive segment of n^4m random bits into the desired $n^2 \times n^2$ 0/1 matrix B_i discussed above.

Informally, the proof technique is the following: for each matrix B_i, the prover must either prove that it contains no good $n \times n$ submatrix or execute the basic step (described in section 2.1) on a good matrix derived from B_i. In order to construct a good matrix from a given matrix $B = B_i$ and to prove that the input n-node graph G is Hamiltonian, P executes the following.

1. If the number of ones in B is different from n or there exists a row or a column which contains at least two ones, then P proves this fact by revealing all entries in B. Otherwise (i.e., B contains an $n \times n$ permutation submatrix), P reveals all entries in the n^2-n rows and the n^2-n columns which contain only zeros, and removes them from B. If the resulting $n \times n$ Boolean matrix does not represent a permutation with a single cycle (i.e., it is not an adjacency matrix of some Hamiltonian cycle), then P proves this fact by revealing all entries of the remaining $n \times n$ matrix.
2. Otherwise (i.e., the remaining $n \times n$ matrix forms an adjacency matrix of some Hamiltonian cycle), P must execute the basic protocol (described in the previous section) on the resulting $n \times n$ good matrix.

In order to formally describe the scheme and prove its correctness, we introduce some notation and definitions.

2.2.2. Notation and definitions. Let

$$\sigma = r_1 \dots r_{poly(k,n)} \qquad r_i \in_R \{0,1\}$$

$$= u_1 \dots u_{poly(k,n)} \qquad u_i \in_R \{0,1\}^k$$

be the CRS, shared by P and V. Let f be a (strong) one-way permutation, and let s_i be the hard bit that corresponds to the k-bit string u_i (with respect to f).

We associate with the CRS an IRS defined by $(f^{-1}(u_1), \dots, f^{-1}(u_{poly(k,n)}))$. According to the definition of a hard bit (see [GL]) each s_i (of the HRS) is polynomially computable from the corresponding $f^{-1}(u_i)$ (of the IRS) which acts as its "witness."

For each $i \geq 1$ let

$$b_i = \bigwedge_{j=1}^{m} s_{(i-1)m+j},$$

where $m = \log(n^3)$.

Let B_i be an $n^2 \times n^2$ matrix which is defined as follows: $B_i(j,l) = b_{(i-1)n^4+(j-1)n^2+l}$ for every $1 \leq i, j, l$.

DEFINITION 2.3. *We say that B_i is a proper matrix if it contains exactly n ones and each column and row contains at most a single one.*

If B_i is a proper matrix let N_i be the $n \times n$ matrix obtained by removing all the $n^2 - n$ columns and $n^2 - n$ rows which contain only zeros. Otherwise N_i is undefined.

DEFINITION 2.4. *A Boolean $n \times n$ matrix is called good if it is the adjacency matrix of a graph which consists of a single directed cycle passing through all the n vertices.*

With some abuse of notation, we also call the large $n^2 \times n^2$ matrix B_i good if it is proper, and if the (unique) $n \times n$ submatrix N_i it defines is good.

2.2.3. The scheme. Assume that P and V have a CRS with $2n^7k^2m$ bits and fix some one-way permutation f.

P's protocol. For each $1 \leq i \leq kn^3$ do the following:

1. If the matrix B_i is not good then reveal all its entries.
2. Otherwise (B_i contains a good $n \times n$ submatrix N_i), reveal and remove (the entries of) all the $n^2 - n$ columns and all the $n^2 - n$ rows which contain only zeros, and execute the noninteractive stage (of the protocol described in section 2.1) on the remaining good matrix N_i.

V's protocol. For each $1 \leq i \leq kn^3$ do the following:

1. If P reveals all entries of B_i then check that the revealed bits are correct and that the matrix they define is not a good matrix.
2. Otherwise, P should reveal $n^2 - n$ columns and $n^2 - n$ rows: check that the revealed bits are correct and that all entries they define in these rows and columns are zeros; in addition, P should execute in this case the basic protocol (described in section 2.1) on the remaining hidden $n \times n$ matrix: check that this proof is carried out correctly.

Accept the proof iff each of these kn^3 checks is successful.

2.3. Correctness.

2.3.1. Completeness. If the input graph is indeed Hamiltonian, then the prover can execute correctly the proof with respect to each one of the good matrices (if they exist). In each $n^2 \times n^2$ matrix that does not yield a good submatrix, P is just required to reveal the entire matrix and V will accept its proof as valid. As a result, an honest prover never fails.

2.3.2. Soundness.

CLAIM 2.5. *For every i, the probability that exactly n entries of B_i are 1 is at least $\frac{1}{4\sqrt{n}}$.*

Proof. The bits of the HRS are unbiased and independent, and for each j the probability that $b_j = 1$ is $1/n^3$. Therefore, the probability that B_i has exactly n ones is

$$\binom{n^4}{n} \left(\frac{1}{n^3}\right)^n \left(1 - \frac{1}{n^3}\right)^{n^4 - n} > \frac{1}{4\sqrt{n}}$$

for all sufficiently large n. □

The size of B_i is $n^2 \times n^2$ and the 0/1 value of each entry is determined independently of the others since these bits are determined by nonoverlapping blocks from the random CRS. Assume now that B_i has exactly n ones. Its entries are independent of each other, and thus the locations of the n ones in the n^2 rows of B_i can be viewed as the result of placing n balls in n^2 buckets. The same argument holds also for the columns. By the birthday paradox, with constant probability, the n ones are located in n distinct rows and n distinct columns, and thus with constant probability a matrix B_i with n ones is proper.

The number of permutations in $Sym(n)$ which consist of a single cycle (of length n) is $(n-1)!$. Therefore, the probability that N_i is a good matrix, given that it is a permutation matrix, is n^{-1}.

We conclude that, for every i, the probability that B_i is good is at least $\geq dn^{-3/2}$, where d is a constant. Thus if the length of the CRS is $\Omega(n^{13/2}k^2m)$ bits, then with probability $(1-e^{-nk})$ at least one of the B_i's yields a good matrix. Any such matrix will expose a cheating P, since it cannot prove that B_i is bad and cannot use it in the basic step, and these are its only two options.

Remark. If $\log(n^3)$ is not an integer, set $m = \lceil \log(n^3) \rceil$ and choose B_i as a $\lceil bn^2 \rceil \times n^2$ matrix where $b = \frac{2^m}{n^3}$ $(1 < b < 2)$.

2.3.3. Zero knowledge. We construct a random polynomial time simulator M which generates a "random string" and a "proof" of Hamiltonicity which are polynomially indistinguishable (by nonuniform distinguishers) from those generated by a real execution of the protocol.

Consider the task of M. Compared with the real prover P, it is handicapped in two respects: It cannot invert one-way functions (and thus cannot expose the HRS defined by the given CRS), and it may not know a Hamiltonian cycle in G. We solve one problem at a time and use the transitivity of indistinguishability to prove that the two solutions can be combined into one. First we construct a random polynomial time algorithm P' that cannot invert one-way functions, but does have access to the Hamiltonian cycle of G. P' uniformally generates a CRS in such a way that it can recover its associated HRS. Since the original CRS (appended to a proof of the real prover) is also uniformally chosen, these two strings are identically distributed. Next we construct a probabilistic expected polynomial time simulator M whose input is the Hamiltonian graph G (without its Hamiltonian cycle) and whose output is polynomially indistinguishable from that of P'. Therefore, these constructions imply that our scheme is zero knowledge.

Let P' be the random polynomial time algorithm whose input consists of the graph G along with its Hamiltonian cycle. The instructions of the original P and the definition of the one-way permutation f (which is fixed in the original proof) are parts of P'. P' executes the real protocol with the following exception: instead of using the given random CRS to compute its associated IRS, it chooses a truly random IRS and computes its associated CRS by applying the one-way permutation f (in the forward direction) to each consecutive block of k bits in the IRS. Namely, for each segment v_i ($v_i \in_R \{0,1\}^k$) in the IRS, P' evaluates $f(v_i)$ and set $f(v_i)$ to be the ith k-segment of the new CRS. The output of P' consists of his CRS accompanied by a noninteractive proof for the Hamiltonicity of G (which is performed exactly according to the instructions of the real P). Since both the original CRS (which is used by P) and that produced by P' are uniformally distributed random strings, and P' and P behave identically once the CRS is determined, we conclude that the output of P' is indistinguishable from the original CRS followed by the real prover's proof.

We now change P' further to get the simulator M. This simulator accepts a Hamiltonian graph G and the security parameter k as inputs but is not given any Hamiltonian cycle in G. Its output is a string σ_k of length n^7k^2m bits and a "proof" of Hamiltonicity based on this CRS. The basic idea behind the simulator is that it tries to execute the protocol and changes the CRS in an indistinguishable way whenever it encounters difficulties. To do this, it leaves unchanged all the bits of the HRS which were part of bad matrices but changes to zero all the bits of the HRS which were part of good matrices. This would allow the simulator to successfully carry out both stages of the proof (namely, demonstrating the unsuitability of the bad matrices by revealing all their entries and revealing the required zero entries in all the presumably good remaining matrices). To change an HRS bit to zero, the simulator repeatedly tries new random IRS values until it finds one which makes the corresponding HRS bit zero and then replaces the corresponding CRS block by f applied to the new IRS value (which remains random and indistinguishable from the original value). More precisely, the simulator M performs the following steps:

1. M randomly chooses a sequence of n^7k^2m truly random bits and uses them as the IRS. Every segment in this IRS that yields a good matrix M changes all entries whose value is 1 to zeros. This is done in the following way: for each i for which N_i is a good matrix and for each j, l such that $N_i(j,l) = 1$, M executes the following trial: it replaces all bits in the IRS which give rise to this $N_i(j,l)$ by new random km bits. M repeatedly executes this trial until $N_i(j,l) = 0$ (the probability of success is $1 - \frac{1}{n^3}$).
2. M computes the CRS σ_k from the modified IRS by applying f in the forward direction and then computes the HRS from the IRS in exactly the same way as it is done by P.
3. For each i such that B_i has not been changed in the first step, M reveals all entries of B_i. For each of the other B_i's, M reveals $n^2 - n$ random rows and $n^2 - n$ random columns. Since the resulting $n \times n$ matrix contains only zeros, M can easily simulate the basic step by choosing a random permutation $\psi \in_R Sym(n)$ and revealing every $B_i(j,l)$ such that there is no edge between j and l in $\psi(G)$.

The output of M is denoted by $(\sigma_k, proof'(\sigma_k, G))$, where the first component plays the role of the CRS and the second one includes all revealed bits and permutations. Let τ_k be a string of length n^7k^2m bit which is produced by P' as a CRS and denote by $proof(\tau_k, G)$ a proof of P' based on G and τ_k.

For any nonuniform distinguisher D, let $D(x)$ denote the 0/1 output of D on input x. Let

$$\rho^D_{P',k,G} = Pr\{D((\tau_k, proof(\tau_k, G)), G) = 1\},$$

$$\rho^D_{M,k,G} = Pr\{D((\sigma_k, proof'(\sigma_k, G)), G) = 1\},$$

where the probabilities are taken over the random tapes of P' and M and thus also over the random choices of τ_k and σ_k (which are chosen by P' and M, respectively).

LEMMA 2.6. *For any polynomial Q and any positive integer t, there exists a positive integer K, such that for any Hamiltonian graph G of size n, for any nonuniform distinguisher D, and for any $k \geq \max(K, n)$,*

$$|\rho^D_{P',k,G} - \rho^D_{M,k,G}| < \frac{1}{Q(k)},$$

where the running time of D is bounded by k^t.

Proof. The proof is based on the well-known hybrid argument of [GM]. We assume the existence of some efficient distinguisher D, a polynomial Q, and an infinite subset of security parameters $\mathcal{I} \subset \mathcal{N}$ such that for every $k \in \mathcal{I}$,

$$(*) \quad |\rho^D_{P',k,G} - \rho^D_{M,k,G}| \geq \frac{1}{Q(k)}.$$

Our goal is to show how to use the existence of these entities in order to successfully predict some hard-core bit, in violation of the assumption that f is a one-way permutation. More precisely, we would like to construct a probabilistic polynomial time nonuniform algorithm C which, given as input $f(x)$ for a randomly chosen x, predicts its hard-core predicate $B(x)$ with nonnegligible probability of success. This C chooses a Hamiltonian graph G and constructs a proof of Hamiltonicity whose CRS is a mixture of an initial segment corresponding to a real proof by P' and a final segment corresponding to a simulated proof by M. (Note that both P' and M are polynomial time, and thus their behavior can be replicated by C.) It is not difficult to show that for some location of this boundary, our assumption implies that the distinguisher's probability of outputting 1 jumps nonnegligibly when the CRS boundary moves by a single block. If C embeds its input $f(x)$ at this crucial location in the CRS, it can use the success of the distinguisher to predict the value of the hard-core bit of its input. This will lead to a contradiction, and thus the probability distributions generated by P' and by M are polynomially indistinguishable.

From here on we omit the superscript D and the subscript G. Let k be an element in $\mathcal{I}$. Let $\alpha = (i_1, \ldots, i_t, \psi_1, \ldots, \psi_u)$ $(1 \leq i_1 < \cdots < i_t \leq n^7 km$ and for each $1 \leq i \leq u$ $\psi_i \in Sym(n))$ and let $\rho_{\alpha,k}$ $(\rho'_{\alpha,k})$ denote the probability that the hidden bits which are revealed by P' (respectively, M) are those which are indexed (in the HRS) by $i_1, \ldots, i_t$ and $\psi_1, \ldots, \psi_u$ are the permutations associated with good matrices chosen by P' (respectively, M). Since M and P' follow exactly the same procedure for choosing the locations of the revealed bits (M may change the *value* of some revealed bits from 1 to 0 by replacing their corresponding CRS blocks but does not try to move their *location*), and both of them choose truly random permutations to apply to G, we conclude that for any α,

$$\rho_{\alpha,k} = \rho'_{\alpha,k}.$$

Let $proof(\tau_k, G, \alpha)$ and $proof'(\sigma_k, G, \alpha)$ denote proofs of P' and M based on τ_k and σ_k, respectively, in which the locations of the revealed bits and the random permutations (in $Sym(n)$) are identical and are defined by $\alpha = (i_1, \ldots, i_t, \psi_1, \ldots, \psi_u)$. Denote by $\rho_{P',\alpha,k}$ the probability that D outputs 1 on $(\tau_k, proof(\tau_k, G, \alpha))$ (produced by P') and by $\rho_{M,\alpha,k}$ the probability that D outputs 1 on $(\sigma_k, proof'(\sigma_k, G, \alpha))$ (produced by M).

It is obvious that

$$(**) \quad \rho_{P',k} = \sum_{\alpha} \rho_{\alpha,k} \rho_{P',\alpha,k}$$

and

$$(***) \quad \rho_{M,k} = \sum_{\alpha} \rho_{\alpha,k} \rho_{M,\alpha,k}.$$

We now want to show that for any fixed choice of α, D is unable to distinguish between $(\tau_k, proof(\tau_k, G, \alpha))$ and $(\sigma_k, proof'(\sigma_k, G, \alpha))$.

CLAIM 2.7. *For every α,*

$$|\rho_{P',\alpha,k} - \rho_{M,\alpha,k}| < \frac{1}{Q(k)}.$$

Proof. Assume that this is not true; namely, there is α for which w.l.o.g.

$$\rho_{P',\alpha,k} - \rho_{M,\alpha,k} \geq \frac{1}{Q(k)}.$$

We now use the hybrid argument by scanning across the list of locations of revealed bits and defining a sequence of associated probabilities. For every $1 \leq j \leq n^7km$, $\rho^j_{\alpha,k}$ denotes the probability that D outputs 1 on the following (string, proof): the first $k(j-1)$ bits in the string are a prefix of a CRS generated by P' from a randomly chosen IRS, while the remaining bits in the string are generated by M from a random IRS which was modified to force zeros to appear in certain HRS revealed positions. The proof following the string is the implied combination of a prefix produced by P' and a suffix produced by M, where both parts are based on the vector α. By the hybrid argument we conclude that there is $1 \leq i \leq n^7km$ for which

$$\rho^{i+1}_{\alpha,k} - \rho^i_{\alpha,k} \geq \frac{1}{Q(k)n^7km}.$$

We'll now describe the formal construction of the probabilistic polynomial time nonuniform algorithm C_k whose auxiliary input is the graph G, including the definition of a Hamiltonian cycle, α, i, and the auxiliary input needed for D. This algorithm uses the polynomial time P', M, and D as subroutines and on input $f(x)$ (where x is randomly chosen) outputs a bit b which is the hard bit of $f(x)$ with probability $\geq \frac{1}{2} + \frac{1}{poly(k)}$. This is a contradiction to the assumption that f is oneway.

The algorithm C_k executes the following steps.

1. Run P' so that the indices of the hidden bits which are revealed and the permutations associated with the Hamiltonian matrices are according to α.
2. Run M according to the same rule.
3. Erase from the output of P' all the bits coming after the $(i-1)$th block of the CRS (call this prefix S_P).
4. Erase from the output of M the first i blocks; namely, keep the last n^7k^2m-ik bits of the CRS and append the revealed bits and the permutations associated with the Hamiltonian matrices (which are based on α and thus are identical for P' and M). Call this suffix S_M.
5. Feed D with $S_P \circ f(x) \circ S_M$.
6. If $D(S_P \circ f(x) \circ S_M) = 1$, then $b = 1$ else $b = 0$.

Without loss of generality, assume that the bit defined by the ith block of P' is 1, and M changes it to 0 (these are the only changes made by M, and unchanged locations cannot possibly trigger a reaction by the distinguisher). It is easy to verify that with probability $\geq \frac{1}{2} + \frac{1}{poly(k)}$, b is the hard bit of $f(x)$ and this is a contradiction to the assumption that f is oneway. $\square$

This claim together with $(**)$ and $(***)$ contradicts $(*)$ which completes the proof of the Lemma. $\square$

2.4. Efficient provers.

2.4.1. The scheme. If the truthful prover is restricted to be a random polynomial time machine (namely, it has the same computational power as V) then it can not invert the one-way permutation in the protocol described in the previous section. In order to overcome this difficulty we use the notion of *families of certified trapdoor permutations.* Therefore, our assumption in this section is that such families exist. Informally, a permutation is trapdoor if its values can be computed in polynomial time and it is hard to compute its inverse, but there exists an auxiliary information (which is called the trapdoor) such that there is an algorithm which gets this trapdoor information as an auxiliary input and computes the inverse of this function in polynomial time. Such a family is certified if it is easy to verify that a given function does belong to this family. The following is the formal definition of a family of certified trapdoor permutations.

DEFINITION 2.8. *Let I be an infinite set of indices. A set of functions $F = \bigcup_{k\geq 1} F_k$ where*

$$F_k = \{f_i : D_i \longrightarrow D_i \quad : \quad i \in I \bigcap \{0,1\}^k\}$$

is a family of certified trapdoor permutations *if for every $i \in I$, f_i is a permutation over the finite domain $D_i \subseteq \{0,1\}^k$ and the following conditions are satisfied:*

1. *There exists a random polynomial time generating algorithm G that on input k (in unary representation) generates a random pair $(i, t(i))$, where $i \in I \bigcap \{0,1\}^k$ (defines the function f_i) and $t(i)$ is a trapdoor information for f_i.*
2. *There exists a probabilistic polynomial time algorithm that on input i determines whether $f_i \in F$ (in particular whether f_i is a permutation).*
3. *There exists a random polynomial time algorithm that on input $i \in I$ chooses a random element $x \in D_i$ with uniform distribution over D_i. There exists a polynomial time algorithm that for any $i \in I$ and any x checks whether $x \in D_i$.*
4. *There exists a polynomial time algorithm A such that*
$$\forall i \in I \quad \forall x \in D_i \qquad A(i,x) = f_i(x).$$
5. *For any random polynomial time algorithm B, for every constant $c > 0$, and for every large enough integer k,*
$$Prob\{B(i, f_i(x)) = x\} < \frac{1}{k^c}$$
where the probability space is taken over the random tape of B combined with the distribution of i as generated by $G(1^k)$ and a random uniform choice of $x \in D_i$.
6. *There exists a polynomial time algorithm C such that*
$$C(i, t(i), f_i(x)) = x \qquad \forall x \in D_i, \quad \forall i \in I.$$

For simplicity, we assume that there exists a family of certified trapdoor permutations in which each of the domains $D_i = \{0,1\}^{n_i}$, where n_i is some integer that depends on i. (However, we emphasize that this assumption can be relaxed in several ways, such as allowing the domains D_i to cover a nonnegligible fraction of $\{0,1\}^{n_i}$, or using one-to-one functions rather than permutations. In particular, the number theoretic assumptions used in [BDMP]'s construction of NIZKs are a special case of our relaxed assumptions.) Under this assumption, the scheme described in section 2.2 can be modified to accommodate probabilistic polynomial time provers. Efficient P randomly chooses a trapdoor permutation $f \in F_k$, sends its index i (of length k) to V, and keeps the trapdoor information $t(i)$ secret. The ability of P to invert f efficiently is due to its knowledge of the trapdoor information.

The proof of *completeness* remains unchanged. The proof of *soundness* has to be modified for the following reason. In contrast to the scheme described in section 2.2 in which the (unbounded) prover does not choose the one-way permutation, in the efficient scheme a cheating prover may choose a particularly useful trapdoor permutation after seeing the CRS. Namely, he can choose a trapdoor permutation for which the corresponding hidden string HRS (determined by the given CRS and this particular trapdoor permutation) does not yield any Hamiltonian matrix. Such a string enables a cheating prover to "prove" the Hamiltonicity of *any* graph, in particular non-Hamiltonian graphs, without getting caught by the verifier.

To overcome this difficulty, we only have to extend the length of the CRS. Recall (see section 2.3.2) that for any fixed (either trapdoor or one-way) permutation, if the length of the CRS is $\Omega(n^{13/2}k^2m)$ bits, then the fraction of bad CRSs (those which do not yield any Hamiltonian matrix) is e^{-nk}. Since all random bits of the CRS are independent, we conclude that if the length of the CRS is twice as long, then the fraction of bad CRSs with respect to any fixed trapdoor permutation is less than e^{-2nk}. But recall that in the new scheme the prover can choose any trapdoor permutation he wishes, out of a family of at most 2^k trapdoor permutations. Therefore, $\frac{2^k}{e^{2nk}} < 2^{-k}$ is an upper bound on the fraction of random strings which can be bad relative to some trapdoor permutation.

The proof of the zero knowledge property of our new scheme resembles its counterpart for the original scheme (with an unbounded prover), except that we have to consider a family of certified trapdoor permutations rather than a fixed one-way permutation. Namely, the probability distribution over all pairs (CRS , proof) includes now also the uniform distribution over all trapdoor permutations in this family, rather than just the uniform distribution over all random strings. Now, the intermediate simulator P' (which has an access to a Hamiltonian cycle in G) should uniformly choose a random trapdoor permutation f (without its trapdoor information) in order to have an output's distribution identical to that of the real prover. The main simulator M (which does not know any Hamiltonian cycle in G) uses the same random f, and both P' and M should apply f in the forward direction. The rest of the proof (regarding the indistinguishability between the outputs of M and P') goes exactly as introduced in section 2.3.3.

We remark that the certification assumption (part 2 of Definition 2.8) can be relaxed. It states that *there exists a polynomial time algorithm that on input i determines whether* $f_i \in F$. This item is included to guarantee that a cheating prover cannot choose a function which does not belong to the prespecified family F of trapdoor permutations. In particular, if P sends to V a definition of a trapdoor function which is not a permutation at all, *soundness* does not necessarily hold, as the opening of the hard-core bits is not unique. Recently, Bellare and Yung [BY] constructed a NIZK proof system for proving that a given function (whose description is of polynomial size) is "almost permutation" (permutation on all but a small fraction of the domain). They showed that this implies that part 2 of the definition is not necessary for the construction of efficient NIZK proof systems for NP.

2.4.2. Public-key cryptosystems secure against chosen ciphertext attacks. The existence of public-key cryptosystems which are secure against passive eavesdropping under the assumption that certified trapdoor permutations exist is well known [GM, Yao, GL]. Naor and Yung [NY] show how to construct a public-key cryptosystem which is provably secure against chosen ciphertext attacks (CCS-PKC), given a public-key cryptosystem which is secure against passive eavesdropping and a NIZK proof system in the shared string model. Using their result together with our construction (for polynomial time provers) we have the following corollary.

COROLLARY 2.9. *CCS-PKC exist under the general assumption that certified trapdoor permutations exist.*

This is the first known CCS-PKC which does not rely on the hardness of specific computational number-theoretic problems.

3. Multiple NIZK proofs based on a single random string.

3.1. Introduction. In the previous section we constructed a *bounded* NIZK proof system, in which the prover can prove a single statement. In this section we construct a *general* NIZK proof system, in which polynomially many statements can be proven by polynomially many provers independently. Our main concern will be to control the length of the common random string σ. Recall that in the case of bounded NIZKs, the length of σ is some explicit polynomial in n (the length of the statement to be proved) and k (a security parameter). One may attempt to transform a bounded NIZK proof system into a general one by reusing the bits of σ over and over again each time a new statement is proved. Unfortunately, it is not known whether the zero knowledge property is preserved if the number of statements proven exceeds $O(\log n)$. If there is an a-priori bound m on the number of statements to be proved, then an alternative approach may be to extend σ by a factor of m. However, this solution is extremely wasteful in the length of σ (and even more if m turns out to be an overestimate). Thus throughout this paper we make the requirement that *the length of σ depends on n and k alone, but not on the number of statements to be proven, which can be an arbitrary polynomial in n.*

Notation and conventions. Throughout the following sections, n denotes the size of a single input statement, whereas m denotes the number of input statements to be proved, each of length n. The value of m is a function of n (typically, some polynomial in n), though we do not introduce special notation to denote this fact. To avoid excessive use of parameters, we identify the security parameter k with the length n of a single input statement (see the remark following Definition 1.2). We use the $\nu(n)$ notation of section 1.3 whenever it is not a source for confusion. We assume that outputs of provers (denoted by $P(x, w, \sigma)$) include explicitly the input x and the CRS σ. Recall our nonstandard use of *ensembles* (see section 1.3) in which the ensemble for the simulator is indexed by inputs $x \in L_R$, whereas the ensemble for the truthful prover is indexed by inputs $x \in L_R$, together with a valid witness w for each input. The two ensembles were said to be indistinguishable if, for any (large enough) input $x \in L_R$, the corresponding distributions (the prover's proofs and the simulator's simulated proofs) were indistinguishable, regardless of the witness w used by the truthful prover. We extend this concept of ensembles to accommodate multiple noninteractive proofs. The ensemble for the simulator is indexed by sequences of equal length inputs in L_R, where, for each sequence, its length m is bounded by some polynomial in the length n of single input statements in the sequence. The ensemble for the truthful prover is indexed by a sequence of equal length inputs in L_R, together with a sequence of corresponding valid witnesses. The two ensembles are indistinguishable if for any sequence of equal length inputs in L_R the corresponding distributions (the prover's sequence of proofs and the simulator's simulated proofs) are indistinguishable, regardless of the sequence of witnesses used by the truthful prover. For computational indistinguishability, the probability of distinguishing between the two ensembles must decrease as fast as $\nu(n)$, which is equivalent to $\nu(mn)$, by our requirement that m is polynomial in n. The distinguishing algorithm is denoted by D and runs in nonuniform polynomial time. Hence $\forall D$ quantifies over all nonuniform polynomial time algorithms. D will typically receive the output of the prover as input, which by our convention regarding $P(x, w, \sigma)$ implies that D also sees x and σ.

DEFINITION 3.1. *A noninteractive proof systems for the language L_R is* general zero knowledge *if there exists a random polynomial time simulator M such that for* *any positive constant c, for any $m \leq n^c$, the two ensembles $\{(\sigma, P(x_1, w_1, \sigma), \ldots, P(x_m, w_m, \sigma))\}$ and $\{M(x_1, x_2, \ldots, x_m)\}$ are computationally indistinguishable. In any sequence of instances that indexes the ensembles, all x_i are of the same length (denoted by n), and for all $1 \leq i \leq m$, $(x_i, w_i) \in R$.*

Remark. An important feature of our definition of general zero knowledge noninteractive proof systems is that each of the statements x_j is proven independently. Consequently, polynomially many provers can share the same random reference string σ and prove polynomially many statements independently. A somewhat weaker definition, in which the proof of statement x_j may depend on the proof of previous statements, is given in [BDMP]. Their definition applies only to the case that a single prover uses σ to prove polynomially many statements. The construction that they propose does not support polynomially many independent provers (i.e., our stronger definition).

In this section we show how to transform any bounded NIZK proof system for an NP complete language L_R into a general NIZK proof system for the same language L_R. Our transformation uses the NP-completeness of L_R in an essential way, and does not handle cases in which L_R is not NP-complete. Our transformation applies only to NIZK proof systems with efficient provers (and does not apply to NIZK proof systems such as that of section 2.2 in which P inverts one-way permutations).

We now give a quick overview of our construction. It is based on the concept of *witness indistinguishability* [FS], which informally means that it is intractable to distinguish which of two possible witnesses P is using in his proof of an NP statement. We prove that any NIZK proof system with efficient provers is also witness indistinguishable. Furthermore, the witness indistinguishability property is preserved even if polynomially many noninteractive witness indistinguishable proofs are given using the same reference string (again, provided that the prover in each individual proof is efficient).

If one could argue that any sequence of noninteractive witness indistinguishable proofs is also zero knowledge then we would be done. It is not true that in general witness indistinguishability implies zero knowledge, but there are special cases where this implication holds. We show, under the assumption that one-way functions exist, that any NIZK proof system for any NP-complete language can be modified to a new noninteractive proof system for which witness indistinguishability always implies zero knowledge.

3.2. Noninteractive witness indistinguishability. In this subsection we define the concept of noninteractive witness indistinguishability and prove some of its important properties.

DEFINITION 3.2. *A noninteractive proof system (P, V) is* bounded witness indistinguishable *over R if for any large enough input x, any $w_1, w_2 \in w(x)$, and for a randomly chosen reference string σ, the ensembles which differ only in the witness that P is using, but not in x or σ, are computationally indistinguishable. In more detail,*

$\forall D \; \exists N \; \forall n > N \; \forall x \in L_R \bigcap \{0,1\}^n \; \forall w_1, w_2 \in w(x)$,

$$\sum_{\sigma} 2^{-|\sigma|} \cdot |\ \text{Prob}(D(P(x, w_1, \sigma)) = 1), -\ \text{Prob}(D(P(x, w_2, \sigma)) = 1)| \ < \ \nu(n).$$

The probability space is that of P's random coin tosses.

We remark that there are two plausible ways of defining noninteractive witness indistinguishability. In the first alternative, the proofs that use different witnesses need to look similar when both use the same CRS σ. In the second alternative, each proof may use a different σ (that is, for each witness we first average the output of the distinguisher over all choices of σ, and only then compare between the use of different witnesses). The first alternative is stronger, and we adopted it in Definition 3.2. The second alternative is also useful, as it relates more naturally to noninteractive zero knowledge, where σ produced by the simulator M is not required to be identical to σ used by the prover. For the case of efficient provers, the following lemma shows the equivalence of the two alternatives.

LEMMA 3.3. *Noninteractive proof system* (P, V) *with efficient provers is* bounded witness indistinguishable *over* R *if and only if*

$\forall D\ \exists N\ \forall n > N\ \forall x \in L_R \bigcap \{0,1\}^n\ \forall w_1, w_2 \in w(x)$,

$$\left|\sum_{\sigma} 2^{-|\sigma|}(Prob(D(P(x,w_1,\sigma)) = 1) - Prob(D(P(x,w_2,\sigma)) = 1))\right| < \nu(n).$$

Proof. The "only if" direction is obvious. We prove only the "if" direction.

Assume that for some infinite sequence $\mathcal{I}$ of triplets (x, w_1, w_2) of inputs together with their respective witnesses, some nonuniform polynomial time algorithm D can distinguish between P using witness w_1 and P using witness w_2. Formally, for some $k > 0$,

$$\sum_{\sigma} 2^{-|\sigma|} \cdot |Prob(D(P(x,w_1,\sigma)) = 1) - Prob(D(P(x,w_2,\sigma)) = 1)| > \frac{1}{(|x|)^k},$$

where $(x, w_1, w_2) \in \mathcal{I}$, and the probabilities are taken over the random choices of P. We construct a new nonuniform *random* polynomial time distinguisher D', which uses "knowledge" of both w_1 and w_2 and contradicts the condition of the lemma. (D' can be transformed into a *deterministic* nonuniform distinguisher by standard averaging techniques.) The distinguisher D' essentially simulates the behavior of D but with the following modification: on public random strings σ for which $Prob(D(P(x,w_1,\sigma)) = 1) < Prob(D(P(x,w_2,\sigma)) = 1)$, algorithm D' inverts the output of D so as to prevent a cancelation effect between σ with the above property and σ for which $Prob(D(P(x,w_1,\sigma)) = 1) > Prob(D(P(x,w_2,\sigma)) = 1)$.

On input z, a noninteractive proof for x using the public random string σ, D' operates as follows. First, ignoring z, algorithm D' performs the following *bias test* for σ, obtaining a "bias indicator" b. Algorithm D' generates $|x|^{k+1}$ independent strings from each of the distributions $P(x, w_1, \sigma)$ and $P(x, w_2, \sigma)$ (we note that this is possible because P is polynomial time, and D' can simulate P with the relevant auxiliary input). D' feeds these strings to D, obtaining from D two sequences of output bits, each of length $|x|^{k+1}$. If the first such sequence (corresponding to w_1) contains less 1 entries than the second (corresponding to w_2), then b is set to 1. Otherwise b is set to 0. Then D' feeds D with z and flips the output of D if and only if $b = 1$.

It is a simple matter to show that

$$\left|\sum_{\sigma} 2^{-|\sigma|}(Prob(D'(P(x,w_1,\sigma)) = 1) - Prob(D'(P(x,w_2,\sigma)) = 1))\right| > \frac{1}{2(|x|)^k}. \qquad \square$$

Remark. The above proof uses the fact that P is efficient (i.e., polynomial time). The equivalence between definitions might not hold if the prover is nonpolynomial.

Consider for example the zero knowledge proof system of section 2.2 in which the prover inverts one-way functions. It is witness indistinguishable in the sense of Lemma 3.3—this can be proved in a way similar to the proof of Lemma 3.4 below. However, it is not witness indistinguishable in the sense of Definition 3.2: the prover is deterministic, and hence for any particular σ, the use of different witnesses by the prover is distinguishable by examining a single bit location (that may depend on σ) of the prover's output. An averaging argument shows that there is some bit location that (for a polynomial fraction of the possible choices of σ) distinguishes between the two witnesses that the prover may be using.

LEMMA 3.4. *Any bounded NIZK proof system with polynomial time prover is also a bounded noninteractive witness indistinguishable proof system.*

Proof. Assume that the proof system is not witness indistinguishable. By Lemma 3.3, for some constant k and an infinite sequence of inputs there exists a distinguisher D that satisfies

$$\left|\sum_{\sigma} 2^{-|\sigma|}(Prob(D(P(x,w_1,\sigma))=1) - Prob(D(P(x,w_2,\sigma))=1))\right| > \frac{1}{(|x|)^k}.$$

Now the proof system cannot be zero knowledge. For consider any proposed simulator M. No matter what value $Prob(D(M(x))=1)$ takes on, it differs either from $Prob(D(P(x,w_1))=1)$ or from $Prob(D(P(x,w_1))=1)$ by at least $\frac{1}{2(|x|)^k}$. Since both the latter cases are valid distributions of noninteractive proofs for x, we conclude that D is a distinguisher which fails any simulator. ◻

DEFINITION 3.5. *A noninteractive proof system is* general witness indistinguishable *over R if for any positive constant c, for any $m \le n^c$, we have that the two ensembles $\{(P(x_1,w_1^1,\sigma), P(x_2,w_2^1,\sigma),\ldots,P(x_m,w_m^1,\sigma))\}$ and $\{(P(x_1,w_1^2,\sigma), P(x_2,w_2^2,\sigma),$ $\ldots,P(x_m,w_m^2,\sigma))\}$ are computationally indistinguishable (in the sense of Definition* 3.2*, where σ is identical in the two ensembles). In more detail,*

$$\forall D\ \forall c\ \exists N\ \forall n > N\ \forall m < n^c$$

whenever $x_i \in L_R \bigcap \{0,1\}^n$ and $w_i^1, w_i^2 \in w(x_i)$ for all $1 \le i \le m$, then

$$\sum_{\sigma} 2^{-|\sigma|} \cdot |Prob(D(P(x_1,w_1^1,\sigma),\ldots,P(x_m,w_m^1,\sigma))=1)$$

$$-Prob(D(P(x_1,w_1^2,\sigma),\ldots,P(x_m,w_m^2,\sigma))=1)| \ < \ \nu(n).$$

The probability space is that of P's random coin tosses.

LEMMA 3.6. *Any bounded noninteractive witness indistinguishable proof system with efficient provers is also general witness indistinguishable.*

Proof. Assume that for some constant c and infinitely many n the following holds: there exists a distinguisher D of size at most n^c, a positive integer m, where $m \le n^c$, a sequence $\mathcal{X} = (x_1, x_2, \ldots, x_m)$ of inputs (each of size n), and two sequences, $\mathcal{W}^1 = (w_1^1,\ldots,w_m^1)$ and $\mathcal{W}^2 = (w_1^2,\ldots w_m^2)$, of witnesses for the respective $x_i \in \mathcal{X}$, such that

$$\sum_{\sigma} 2^{-|\sigma|} \cdot |Prob(D(P(x_1,w_1^1,\sigma),\ldots,P(x_m,w_m^1,\sigma))=1)$$

$$-Prob(D(P(x_1,w_1^2,\sigma),\ldots,P(x_m,w_m^2,\sigma))=1)| \ > \ n^{-c},$$

where probabilities are taken over the random coin tosses of P. Then by the "hybrid" argument of [GM] (also known as "probability walk" argument), there must be a "polynomial jump" somewhere in the execution: there exists k, where $1 \leq k \leq m$, such that

$$\sum_{\sigma} 2^{-|\sigma|} \cdot |Prob(D(P(x_1, w_1^1, \sigma), \ldots, P(x_k, w_k^1, \sigma), \ldots, P(x_m, w_m^2, \sigma)) = 1)$$

$$-Prob(D(P(x_1, w_1^1, \sigma), \ldots, P(x_k, w_k^2, \sigma), \ldots, P(x_m, w_m^2, \sigma)) = 1)| \;>\; \frac{1}{mn^c}.$$

We now use the nonuniformity of the distinguishers to derive a contradiction. Since the proof system has efficient provers, the whole set of proofs $(P(x_1, w_1^1, \sigma), \ldots, P(x_{k-1}, w_{k-1}^1, \sigma), P(x_{k+1}, w_{k+1}^2, \sigma), \ldots, P(x_m, w_m^2, \sigma))$ can be simulated by a modified D', who has as auxiliary input $((x_1, w_1^1), \ldots, (x_{k_1}, w_{k-1}^1), (x_{k+1}, w_{k+1}^2), \ldots, (x_m, w_m^2))$. This random nonuniform polynomial time D' can now distinguish between proofs for x_k in which the prover uses w_k^1 and proofs in which the prover uses w_k^2. This contradicts our assumption that the original protocol was witness indistinguishable. □

3.3. The transformation. We assume the existence of pseudorandom bit generators (see [BM], [Yao]), which extend n-bit random seeds to $2n$-bit pseudorandom strings, computationally indistinguishable from strings of truly random $2n$ bits. The existence of pseudorandom generators follows from the assumption that one-way functions exist [ILL], [Ha].

Let (P, V) be any bounded NIZK proof system with polynomial time prover for the NP-complete language L_R. We construct $(\bar{\text{P}}, \bar{\text{V}})$, a general NIZK proof system for L_R, under the sole assumption that one-way functions exist.

Let $g : \{0,1\}^n \longrightarrow \{0,1\}^{2n}$ be a pseudorandom bit generator. We introduce two new NP languages. L_{R_g} is the NP language corresponding to the relation $R_g(y, s)$ iff $g(s) = y$. $L_{R_\#}$ is the NP language corresponding to the relation $R_\#(x\#y, w)$ iff *either* $R(x, w)$ *or* $R_g(y, w)$, where # is used as a special delimiting character in the alphabet of the inputs to $L_{R_\#}$.

We now describe the algorithm of $\bar{\text{P}}$ on input $(x, w) \in R$ and reference string σ.

1. Divide the CRS σ into two segments: the first $2n$ bits, denoted by y, and called the *reference statement*; the rest of the CRS is denoted by σ'.
2. Construct the instance $x\#y \in L_{R_\#}$. Observe that w, the witness that $\bar{\text{P}}$ has for $x \in L_R$, is a witness for $x\#y \in L_{R_\#}$.
3. Reduce $x\#y$ to an instance X of the NP-complete language L_R, using a publicly known reduction with efficient transformation of witnesses. (That is, any witness for the original instance can be efficiently transformed into a witness for the target instance, and vice versa. Known reductions to NP-complete languages have this property.) Reduce w, the witness for $x\#y \in L_{R_\#}$, to W, a witness for $X \in L_R$.
4. Send x, X, and $P(X, W, \sigma')$. (The last term, $P(X, W, \sigma')$, is a random variable that denotes the NIZK proof that the prover P from the system (P, V) would produce on input X, witness W, and reference string σ', depending on P's private random string.)

The verifier $\bar{\text{V}}$ accepts if the publicly known reduction (from $L_{R_\#}$ to L_R) gives X when applied to $x\#y$, and if furthermore V would have accepted $P(X, W, \sigma')$.

THEOREM 3.7. *Under the assumptions that (P, V) is a bounded NIZK proof system with efficient provers for L_R, that L_R is NP-complete, and that g is a pseudo-*

random generator, the above transformed scheme is a general NIZK proof system for L_R.

Proof. We first give an intuitive introduction to the full proof. The completeness, soundness, and zero knowledge properties of ($\bar{\mathrm{P}}$, $\bar{\mathrm{V}}$) are based on the corresponding properties of (P, V). Efficiency is preserved in the completeness property since from a witness to x, prover $\bar{\mathrm{P}}$ can derive a witness to X, and thus execute the bounded NIZK proof system (P, V). The soundness property follows from the fact that y is chosen as a truly random (rather than pseudorandom) string. Thus, for almost all possible choices of y, it is not in the range of g, and consequently $X \in L_R$ if and only if $x \in L_R$. The zero knowledge property requires more subtle analysis. The simulation of ($\bar{\mathrm{P}}$, $\bar{\mathrm{V}}$) is done by replacing the reference statement y by a pseudorandom string y'. This y' is generated by selecting at random an n bit seed s and computing $y' = g(s)$. Since g is a pseudorandom bit generator, this replacement is indistinguishable to polynomial time observers. Now any statement x with witness w is transformed into a statement X which also has s, the seed of y', as its witness. The simulator uses s instead of w in order to prove X. The concept of witness indistinguishability can now be used to show that this change of witnesses in the proof of X is indistinguishable to polynomial time observers, even if it is done polynomially many times. We now give a more detailed proof.

Completeness (while preserving efficiency). The reduction of $L_{R_\#}$ to L_R allows efficient transformation of witnesses. Thus $\bar{\mathrm{P}}$, who knows a witness for $x \in L_R$, and hence for $x\#y \in L_{R_\#}$, can also compute in polynomial time a witness for X and use it in order to perform the protocol. The reduction is also publicly known, and so $\bar{\mathrm{V}}$ can check that it was followed correctly. The completeness property then follows from the completeness property of (P, V).

Soundness. From the soundness property of (P, V) it follows that either $x \in L_R$ or y is in the range of the generator g (i.e., there is an s such that $y = g(s)$). But simple counting shows that the probability that the random string y of length $2n$ is in the range of g (i.e., has a seed of length n) is at most 2^{-n}, and thus with overwhelming probability indeed $x \in L_R$.

The completeness and soundness property trivially continue to hold even if polynomially many statements are proved.

Zero knowledge. For any large enough value of n, consider any sequence (x_1, w_1), (x_2, w_2), $\ldots$, (x_m, w_m), of inputs together with their respective witnesses, where m is polynomial in n. Assume that $\bar{\mathrm{P}}$ proves for these inputs membership in L_R (by using private coin tosses, the associated witnesses, and the CRS σ). We construct a simulator M which creates an ensemble indistinguishable from the ensemble that $\bar{\mathrm{P}}$ produces. M receives as input only the sequence of instances $\{x_i\}$, without their respective witnesses.

M randomly selects an n bit seed s and computes the $2n$-bit string $y' = g(s)$, to be used as the reference statement (instead of a random y used in reality). M generates a truly random reference string σ'. For each $1 \le j \le m$, M reduces $x_j\#y'$ to an instance X_j of L_R and derives from s a witness w' for this instance. Then M uses the proof system (P, V) and the reference string σ' to simulate a proof that $X \in L_R$, by using its knowledge of the seed s (rather than a witnesses it does not have to the statements x_j).

In order to prove that M's simulation is indistinguishable from $\bar{\mathrm{P}}$'s proofs, we construct a hybrid $\bar{\mathrm{M}}$, which constructs y' pseudorandomly as M does, but simulates the proofs using w_1, w_2, $\ldots$ as $\bar{\mathrm{P}}$ does.

LEMMA 3.8. *For any positive constant c, for any $m \leq n^c$, the two ensembles $\{(\sigma, \bar{P}(x_1, w_1, \sigma), \ldots, \bar{P}(x_m, w_m, \sigma))\}$ and $\{\bar{M}((x_1, w_1), (x_2, w_2), \ldots, (x_m, w_m))\}$ are computationally indistinguishable. In any sequence of instances that indexes the ensembles, all x_i are of the same length (denoted by n), and for all $1 \leq i \leq m$, $(x_i, w_i) \in R$.*

Proof. Assume otherwise, and let D be a distinguisher that distinguishes between $\bar{\text{M}}$'s output and $\bar{\text{P}}$'s output. We construct a distinguisher D' that distinguishes between truly random strings, and outputs of the generator g, contradicting its pseudorandomness. For infinitely many values of n, nonuniform algorithm D' has as auxiliary input the corresponding sequence (x_1, w_1), (x_2, w_2), $\ldots$, (x_m, w_m) for which D distinguishes between the two ensembles. In order to test whether a string y of length $2n$ was generated from the distribution of outputs of the generator g, D' generates a random reference string σ' and simulates $\bar{\text{P}}$'s action on the sequence (x_1, w_1), (x_2, w_2), $\ldots$, (x_m, w_m), with respect to the reference string composed of y and σ'. Now the verdict of D of whether the output was produced by $\bar{\text{P}}$ (which uses truly random y) or by $\bar{\text{M}}$ (which uses pseudorandom y) forms a statistical test as to whether y was truly random or generated by g. □

The proof of the following lemma is the heart of our argument that the transformed scheme is general zero knowledge.

LEMMA 3.9. *For any positive constant c, for any $m \leq n^c$, the two ensembles $\{\bar{M}((x_1, w_1), (x_2, w_2), \ldots, (x_m, w_m))\}$ and $\{M(x_1, x_2, \ldots, x_m)\}$ are computationally indistinguishable. In any sequence of instances that indexes the ensembles, all x_i are of the same length (denoted by n), and for all $1 \leq i \leq m$, $(x_i, w_i) \in R$.*

Proof. Consider what the simulators $\bar{\text{M}}$ and M actually do. They are giving NIZK proofs for a sequence of statements $X_1, \ldots, X_m$, derived from the sequence $x_1, \ldots, x_m$, by taking into account a reference statement y'. In more detail, they first generate a reference statement y', and thereafter each of them uses the truly random reference string σ' to execute NIZK protocols for the sequence $X_1, \ldots, X_m$, in the same way as a true prover in (P, V) would execute such protocols. The only difference between $\bar{\text{M}}$ and M is in the sequence of witnesses that they are using, where $\bar{\text{M}}$ uses the sequence $w_1, \ldots, w_m$, and M repeatedly uses s as a witness for each of the X_i (recall that s is the seed that was used in order to generate y').

Protocol (P, V) is zero knowledge. By Lemma 3.4 it is witness indistinguishable. By Lemma 3.6, even polynomially many executions of (P, V) on the same reference string σ' are witness indistinguishable. Hence the ensembles that $\bar{\text{M}}$ and M create are indistinguishable. □

From the two lemmas above it follows that the outputs of M and $\bar{\text{P}}$ are computationally indistinguishable, which completes the proof that the protocol is zero knowledge. □

Remarks.

1. In giving multiple NIZK proofs, the prover reuses public randomness (the CRS) over and over again. However, the prover must use "fresh" private randomness (internal random coin tosses) in each execution of the protocol. Otherwise, zero knowledge might not be preserved. In particular, when applying our transformation to the efficient bounded NIZK described in section 2.4, the truthful prover is expected to use a different trapdoor permutation for each input statement being proved.
2. The complexity of the pseudorandom bit generator g has major impact on the overall complexity of our transformation. The choice of g (and, in par-

ticular, the time required for a nondeterministic Turing machine to accept the language L_{R_g}) influences the size of X, the statement that the truthful prover eventually proves (which may be much larger than the size of x, the original statement that the prover wants to prove). There is a spectrum of constructions of pseudorandom bit generators, where the complexity of the construction typically depends on the strength of the underlying computational complexity assumptions (e.g., compare [BM] with [ILL, Ha]). In applying our transformation, one should first determine the computational complexity assumptions that were made in the construction of the particular bounded NIZK proof system, and based on them, select the simplest pseudorandom bit generator.

3. The term *bounded* NIZK proof systems indicates that the length of the CRS bounds the size of the (single) NP statement that can be proven. We have seen that using *general* NIZK proof systems, polynomially many NP statements, each of bounded length, can be proved. [BDMP] show that under the assumption that one-way functions (and hence encryption schemes) exist, general NIZK proof systems can be used in order to prove statements that are longer than the bound implied by the length of the CRS. For completeness, we sketch how this is done.
   On input of a satisfiable 3-SAT formula Φ (any other NP-statement can be reduced to 3-SAT, if necessary), the prover encrypts separately the satisfying value of each variable and for each clause $C \in \Phi$ constructs the string composed of the concatenation of the encrypted values of the three variables in C. Observe that the length of each such string does not depend on the length of Φ. Each string is treated as an NP-statement: "there exists a decryption of the encrypted values that would show that clause C is satisfiable." The prover gives a NIZK for each such statement separately, and the verifier verifies that each of the NIZK proofs is acceptable.

4. Security against adaptive attacks.

4.1. Definitions. NIZK proof systems are useful design primitives in the construction of cryptographic schemes, such as signature schemes [BG] and encryption schemes [NY]. It is often required that the cryptographic scheme will be robust against attacks of adaptive nature, which are the strongest types of attack. For example, a standard security requirement of signature schemes is that even after requesting signatures of polynomially many messages of his choice, the adversary is not able to forge a signature to any new message. In order to treat adaptive attacks we extend the security requirements of NIZK proof systems.

In a typical adaptive scenario, a polynomial time adversary A repeatedly selects statements and observes their noninteractive proofs. His goal is to come up with a statement x on which one of the three basic properties of NIZK proof systems is violated: either x is true but P cannot produce a noninteractive proof for it (violating the *completeness* condition) or x is false but there exists a noninteractive "proof" that convinces V to accept x (violating the *soundness* condition), or x is true and the adversary can extract useful information from the noninteractive proof that P gives (violating the *zero knowledge* property).

Definition 1.2 is strong enough to serve as the definition of *completeness* and *soundness* for the adaptive scenario. However, Definition 3.1 of *zero knowledge* needs to be modified. We define the concept of *adaptive zero knowledge* in a way similar to Bellare and Goldwasser [BG] (see also [GGM]'s test for pseudorandom functions).

We call this test *adaptive indistinguishability*, or the AI test (partially because of its origins as Turing's test for artificial intelligence). In our AI test, an adversary A is confronted with a blackbox B. His goal is to determine whether B contains a real prover P or whether it contains a simulator M. A first requests the random reference string σ from B. If P is inside the box, it replies with a truly random string. If M is inside the box, it replies with a string of its choice. Now, possibly based on σ, A generates a pair $(x, w) \in R$ and sends it to B. If P is inside the box, it produces a noninteractive proof $P(x, w, \sigma)$. If M is inside the box, w is "magically" filtered away, and M must simulate a noninteractive proof for x. This procedure of adaptively choosing theorems and receiving noninteractive proofs for them is repeated polynomially many times until A is ready to pass a decision: $'0'$ or $'1'$. (M, P) are said to pass the AI test if the probabilities that A outputs $'1'$ when M is inside the box and when P is inside the box are equal up to negligible additive terms.

DEFINITION 4.1. *A noninteractive adaptive proof system* (P, V) *is* adaptive zero knowledge *if there exists a random polynomial time simulator* M *such that* (M, P) *pass the AI test for any nonuniform polynomial time adversary* A.

We remark that in [BG]'s definition, A is not required to supply witnesses for $x \in L_R$ to the blackbox. This leaves open the question of how the real prover P (which is assumed to be efficient) comes up with a witness w for $x \in L_R$, to be used in producing a NIZK proof for this fact. One possibility is that some computationally unbounded agent produces this witness for P. Another is that A has to produce the witness. In our definition we choose the latter possibility, with the intention of using it only in applications where all parties are (nonuniform) polynomial time. We do not know if the theorems to follow (and, in particular, Theorem 4.4) hold also with respect to the stronger definition of zero knowledge, in which a computationally unbounded agent produces the witnesses.

PROPOSITION 4.2. *Any noninteractive proof system which is adaptive zero knowledge (Definition* 4.1*) is also general zero knowledge (Definition* 3.1*).*

Proof. The proof follows directly from the nonuniformity of the adversary in Definition 4.1. If there is a sequence of inputs with respective witnesses that serves to defeat the general zero knowledge property (according to Definition 3.1), then the adversary A (of Definition 4.1) can hold this same sequence as auxiliary input and defeat the adaptive zero knowledge property. ◻

A somewhat weaker condition than adaptive zero knowledge is *single statement adaptive zero knowledge*. For such proof systems, the adversary of the AI test is allowed to request only one noninteractive proof from B before passing his judgment as to what is inside the box.

PROPOSITION 4.3. *Any noninteractive proof system which is single statement adaptive zero knowledge is also bounded zero knowledge (Definition* 1.3*).*

Proof. The proof follows directly from the nonuniformity of the adversary. ◻

Remark. The converse of the above proposition is probably not true. For example, consider the NIZK proposed in [BDMP] for the language NQR. [BDMP] prove that the noninteractive proof system for this language is zero knowledge by producing a simulator M that constructs a CRS only after it sees the input x. In contrast, adaptive zero knowledge postulates that σ is generated first, and x is chosen only later. Despite the fact that [BDMP]'s NIZK proof system for the language NQR is bounded zero knowledge, it is not known to be single statement adaptive zero knowledge.

4.2. Robustness of our protocols. All theorems and lemmas that deal with the adaptive zero knowledge scenario are straightforward modifications of their counterparts that dealt with the nonadaptive scenario. For this reason, we only state our theorems, and give some "hints" to help the reader in modifying the proofs in previous sections so that they also apply to the adaptive case.

THEOREM 4.4. *The NIZK of section* 2 *is single statement adaptive zero knowledge.*

Proof. There are two parts to a proof that a certain protocol is zero knowledge. One part is to construct the simulator M. The other part is to prove that its output is indistinguishable from the output of the real prover.

We first address the problem of constructing the "adaptive" simulation. Consider the simulator M described in section 2. This simulator generates a reference string σ' independently of the common input x. This σ' can be used to simulate a noninteractive proof for any input x. Consequently, the same simulator can be used even if the input statement is chosen adaptively after the CRS is chosen.

The proof of indistinguishability follows the same arguments as those which are used in the proof of subsection 2.3.3. Recall that it was shown that if the proof system is not zero knowledge on input $(x, w) \in R$, then one could construct an efficient algorithm (denoted by C) that predicts the hard bits of the one-way permutation (or trapdoor permutation, if the prover is required to be efficient). This algorithm had (x, w) as auxiliary input and constructed a reference string σ in the course of its operation. For the case of adaptive zero knowledge, the end result would again be an efficient algorithm C that predicts the hard bits of the one-way permutation. However, this algorithm would not explicitly receive any $(x, w) \in R$ as auxiliary input. The reason for this is that in the adaptive scenario, the adversary A need not have a prespecified (x, w) that it uses in foiling the zero knowledge property. Instead, A may generate (x, w) only after observing σ. Likewise, we must allow C to generate (x, w) only after constructing σ, in a way similar to A. Hence, instead of supplying C with explicit (x, w) as auxiliary input, we supply it with the auxiliary input of A, which C can later use to generate (x, w) that depend on σ. $\square$

In the rest of this section we consider only NIZK proofs with efficient provers.

THEOREM 4.5. *The transformation of section* 3.3 *transforms efficient noninteractive single statement adaptive zero knowledge proof systems into efficient (general) noninteractive adaptive zero knowledge proof systems.*

Proof. Theorem 4.5 is proved in the same way as Theorem 3.7, which is its nonadaptive counterpart. We only sketch the modifications that are necessary.

The proof of the *completeness* and *soundness* conditions is straightforward. The main emphasis is on the proof of the *adaptive zero knowledge* property. Recall that in order to prove Theorem 3.7, we used the concept of *witness indistinguishability.* In order to prove Theorem 4.5, we define a corresponding notion of *adaptive witness indistinguishability.* Once this concept is defined, and its main properties are established (see Lemmas 4.7 and 4.8 below), the proof of Theorem 4.5 can be carried out in a way similar to the proof of Theorem 3.7.

In the AI test for witness indistinguishability a nonuniform polynomial time adversary A is confronted with a blackbox B that may contain one of two possible provers, denoted by P_1 and P_2. The provers differ in the witnesses that they select to use in producing NIZK proofs, and the goal of A is to determine whether B contains P_1 or P_2. A first requests the random reference string σ from B. Now, possibly based on σ, A generates a triplet (x, w^1, w^2), where $(x, w^1) \in L_R$ and $(x, w^2) \in L_R$ and sends the triplet to B. If P_1 is inside B, it uses only the first of the given witnesses for x to generate the noninteractive proof $P(x, w^1, \sigma)$. If P_2 is inside B, it uses only the second of the given witnesses to generate $P(x, w^2, \sigma)$. This procedure of adaptively choosing theorems and receiving noninteractive proofs for them is repeated polynomially many times until A is ready to pass a decision: $'0'$ or $'1'$. (P_1, P_2) are said to pass the AI test for witness indistinguishability if the probabilities that A outputs $'1'$ when P_1 is inside the box and when P_2 is inside the box are equal up to negligible additive terms.

Definition 4.6. *A noninteractive adaptive proof system* (P, V) *is* adaptive witness indistinguishable *if* (P_1, P_2) *pass the AI test for witness indistinguishability.*

In *single statement adaptive witness indistinguishability*, the adversary A is allowed to request only one noninteractive proof from B before passing his judgment of whether P_1 or P_2 is inside the box.

Lemma 4.7. *Any noninteractive proof system which is single statement adaptive zero knowledge is also single statement adaptive witness indistinguishable.*

The proof of Lemma 4.7 is similar to the proof Lemma 3.4 and is omitted.

The following lemma shows that adaptive witness indistinguishability is preserved under repeated applications of the noninteractive proof system with the same random reference string.

Lemma 4.8. *Any noninteractive proof system which is single statement adaptive witness indistinguishable is also adaptive witness indistinguishable.*

Proof. Assume that there exists an adversary A which adaptively generates triplets (x_i, w_i^1, w_i^2) (for $i \geq 1$) and can distinguish between P_1 and P_2. By the "hybrid" argument of [GM], there must be a "polynomial jump" somewhere in the execution: there exists k, such that if for $i < k$ the adversary uses the first of the two generated witnesses of each instance to produce $P(x_i, w_i^1, \sigma)$ by itself, then generates (x_k, w_k^1, w_k^2) and gives it to the blackbox, and finally (for $i > k$) uses the second of the two generated witnesses of each instance to produce $P(x_i, w_i^2, \sigma)$ by itself, then A can distinguish between the case that P_1 is inside the box and the case that P_2 is inside the box. This contradicts our assumption that the original protocol was single statement adaptive witness indistinguishable. □

The rest of the proof of Theorem 4.5 can be carried out in a way similar to the proof of Theorem 3.7. The details are omitted. □

5. Conclusions. We show how one can construct general NIZK proof systems under general computational complexity assumptions. Theoretically, NIZK proof systems have numerous cryptographic applications ([BG], [NY], and we are confident that more will follow). However, to be useful in practice, the efficiency of NIZK proof systems must be greatly improved. One parameter that deserves special attention is the length of the CRS. To prove Hamiltonicity of n-node graphs, our NIZK proof system requires $|\sigma| = \Omega(n^{11/2})$. Recently, Kilian [K94] presented considerably more efficient NIZK proof systems for circuit satisfiability, and this was further simplified and improved by Kilian and Petrank [KP], to a point where the complexity of NIZK proof systems for NP statements almost matches that of the most efficient known *interactive* zero knowledge proof systems.

The following question remains open: what are the minimal computational complexity assumptions that support bounded NIZK proof systems?

Recall that once bounded NIZK proof systems with efficient provers are constructed, the transformation to general NIZK proof systems requires only the assumption that one-way functions exist and are relatively efficient. Since the transformation to general NIZK proof systems requires only bounded noninteractive witness indistinguishable proof systems as a starting point, the above question can be reformulated with NIZK replaced by noninteractive witness indistinguishability.

Acknowledgments. We thank Moni Naor for helpful discussions, Oded Goldreich for his useful remarks on an early version of this manuscript, and the referees of this paper for greatly improving its readability.

TIGHT ANALYSES OF TWO LOCAL LOAD BALANCING ALGORITHMS [*]

BHASKAR GHOSH[†], F. T. LEIGHTON[‡], BRUCE M. MAGGS[§], S. MUTHUKRISHNAN[¶], C. GREG PLAXTON[‖][††], R. RAJARAMAN[‖][††], ANDRÉA W. RICHA[§], ROBERT E. TARJAN[#], AND DAVID ZUCKERMAN[‖][‡‡]

Abstract. This paper presents an analysis of the following load balancing algorithm. At each step, each node in a network examines the number of tokens at each of its neighbors and sends a token to each neighbor with at least $2d+1$ fewer tokens, where d is the maximum degree of any node in the network. We show that within $O(\Delta/\alpha)$ steps, the algorithm reduces the maximum difference in tokens between any two nodes to at most $O((d^2 \log n)/\alpha)$, where Δ is the global imbalance in tokens (i.e., the maximum difference between the number of tokens at any node initially and the average number of tokens), n is the number of nodes in the network, and α is the edge expansion of the network. The time bound is tight in the sense that for any graph with edge expansion α, and for any value Δ, there exists an initial distribution of tokens with imbalance Δ for which the time to reduce the imbalance to even $\Delta/2$ is at least $\Omega(\Delta/\alpha)$. The bound on the final imbalance is tight in the sense that there exists a class of networks that can be locally balanced everywhere (i.e., the maximum difference in tokens between any two neighbors is at most $2d$), while the global imbalance remains $\Omega((d^2 \log n)/\alpha)$. Furthermore, we show that upon reaching a state with a global imbalance of $O((d^2 \log n)/\alpha)$, the time for this algorithm to locally balance the network can be as large as $\Omega(n^{1/2})$. We extend our analysis to a variant of this algorithm for dynamic and asynchronous networks. We also present tight bounds for a randomized algorithm in which each node sends at most one token in each step.

1. Introduction. A natural way to balance the workload in a distributed system is to have each workstation periodically poll the other stations to which it is connected and send some of its work to stations with less work pending. This paper analyzes the effectiveness of this local load balancing strategy in the simplified scenario in which each workstation has a collection of independent unit-size jobs (called *tokens*) that can be executed on any other workstation. We model a distributed system as a graph, where nodes correspond to workstations and edges correspond to connections between stations, and we assume that in one unit of time, at most one token can be transmitted across an edge of the graph in each direction. Our analysis addresses only the static load balancing aspect of this problem: we assume that each processor has an initial collection of tokens and that no tokens are created or destroyed while the tokens are being balanced.

We analyze the algorithms in this paper in terms of the initial *imbalance* of tokens, i.e., the maximum difference between the number of tokens at any node and the average number of tokens, which we denote Δ; the number of nodes in the graph, which we denote n; the maximum degree of the graph, d; and the node and edge expansion of the graph. We define the *node expansion* μ of a graph G to be the largest value such that every set S of $n/2$ or fewer nodes in G has at least $\mu|S|$ neighbors outside of S. We define the *edge expansion* α of a graph G to be the largest value such that for every set S of $n/2$ or fewer nodes in G, there are at least $\alpha|S|$ edges in G with one endpoint in S and the other not in S.

The performance of an algorithm is characterized by the time that it takes to balance the tokens and by the final balance that it achieves. We say that an algorithm *globally balances* (or just *balances*) to within t tokens if the maximum difference in the number of tokens between any two nodes in the graph is at most t. We say that an algorithm *locally balances* to within t tokens if the maximum difference in the number of tokens between any two neighboring nodes in the graph is at most t.

We analyze two different types of algorithms in this paper: single-port and multiport. In the *single-port* model, a node may send and/or receive at most one token in one unit of time. In the *multiport* model, a node may send and/or receive a token across all of its edges (there may be as many as d) in a single unit of time. Not surprisingly, the load balancing algorithms run faster in the multiport model. In practice, however, single-port nodes may be preferred to multiport nodes because they are easier and less costly to build.

1.1. Our results. This paper analyzes the simplest and most natural local algorithms in both the single-port and multiport models.

In the single-port algorithm, a matching is randomly chosen at each step. First, each (undirected) edge in the network is independently selected to be a *candidate* with probability $1/(4d)$. Then each candidate edge (u, v) for which there is another candidate edge (u, x) or (y, v) is removed from the set of candidates. The remaining candidates form a matching M in the graph. For each edge (u, v) in M, u sends a token to v if at the beginning of the step node u contains at least two more tokens than v. This algorithm was first analyzed in [14].

We analyze the performance of the single-port algorithm in terms of both the edge expansion and the node expansion of the graph. In terms of edge expansion, we show that the single-port algorithm balances to within $O((d \log n)/\alpha)$ tokens in $O(d\Delta/\alpha)$ steps with high probability. In terms of node expansion, the final imbalance is $O((\log n)/\mu)$ and the time is $O(d\Delta/\mu)$ with high probability. (To compare these bounds, note that $\mu \leq \alpha \leq d\mu$.) The time bounds are tight in the sense that for many values of n, d, α, μ, and Δ, there is a graph with n nodes, maximum degree d, edge expansion α or node expansion μ, and an initial placement of tokens with imbalance Δ such that the time (for any algorithm) to balance to within even $\Delta/2$ tokens is at least $\Omega(d\Delta/\alpha)$. Similarly, in terms of node expansion, there exist classes of graphs where the time to balance to within even $\Delta/2$ tokens is at least $\Omega(d\Delta/\mu)$.

The multiport algorithm is simpler and deterministic. At each step, a token is sent from node u to node v across edge (u, v) if at the beginning of the step node u contains at least $2d + 1$ more tokens than node v. This algorithm was first analyzed in [2].

As in the single-port case, we analyze the multiport algorithm in terms of both edge expansion and node expansion. In terms of edge expansion, the algorithm balances to within $O((d^2 \log n)/\alpha)$ tokens in $O(\Delta/\alpha)$ steps. This bound is tight in the sense that for any network with edge expansion α, and any value Δ, there exists an initial distribution of tokens with imbalance Δ such that the time to reduce the imbalance to even $\Delta/2$ is $\Omega(\Delta/\alpha)$. In terms of node expansion, the algorithm balances to within $O((d \log n)/\mu)$ tokens in $O(\Delta/\mu)$ time. This bound is tight in the sense that for many values of d, n, and μ, and any value Δ, there exists an n-node, maximum degree d graph with node expansion μ and an initial distribution of tokens with imbalance Δ for which the time to balance to within $\Delta/2$ tokens is $\Omega(\Delta/\mu)$.

Both the single-port and the multiport algorithms will eventually locally balance the network, the single-port algorithm to within one token and the multiport algorithm to within $2d$ tokens. However, even after reducing the global imbalance to a small value, the time for either of these algorithms to reach a locally balanced state can be quite large. In particular, we show that after reaching a state that is globally balanced to within $O((d \log n)/\mu)$ tokens, the multiport algorithm may take another $\Omega(n^{1/2})$ steps to reach a state that is locally balanced to within $2d$ tokens. For networks with large node expansion and small degree, e.g., $\mu = \Omega(1)$ and $d = O(1)$, and small initial imbalance, e.g., $\Delta = O((d \log^2 n)/\mu)$, the time to locally balance the network, $\Omega(n^{1/2})$, may be much larger than the time, $O(\Delta/\mu) = O((d \log^2 n)/\mu^2) = O(\log^2 n)$, to reach a state that is globally balanced to within $O((d \log n)/\mu)$ tokens. Moreover, there exist networks with diameter $\Theta(\log n/\mu)$ for which even after reducing the global imbalance to the asymptotically best possible value of $O(d \log n/\mu)$ tokens in optimal time, the multiport algorithm can still take a long time to locally balance to within d tokens. We prove similar bounds for the single-port algorithm.

Thus far we have described a network model in which the nodes are synchronized by a global clock (i.e., a *synchronous* network) and in which the edges are assumed not to fail. With minor modifications, however, the load balancing algorithms can be made to work in both asynchronous and dynamic networks. In a *dynamic* network, the set of edges in the network may vary at each time step. In any time step, a *live* edge is one that can transmit one message in each direction. We assume that at each time step, each node in a synchronous dynamic network knows which of its edges are live. In an *asynchronous* network, the topology is fixed, but an adversary determines the speed at which each edge operates at every instant of time. For every undirected edge between two nodes, we allow at most two messages to be in transit at any instant in time. These messages may travel in opposite directions across the edge, or both may travel in one direction while no message travels in the opposite direction. An edge is said to be *live* for a unit interval of time if every message that was in transit across the edge (in either direction) at the beginning of the interval is guaranteed to reach the end of the edge by the end of the interval. We analyze the performance of the multiport load balancing algorithm under the assumption that at each time step, the set of live edges has some edge expansion α or node expansion μ.

We also study the off-line load balancing problem, in which every node has knowledge of the global state of the network. This problem has been studied on static synchronous networks in [29]. We use their results to obtain tight bounds on off-line load balancing in terms of edge expansion and node expansion. For the single-port model, we prove that any network can be balanced off-line in $\lceil(1+\mu)\Delta/\mu\rceil$ steps so that no node has more than two tokens more than the average. This result can be used to show that any network can be balanced off-line to within three tokens in at most $2\lceil(1+\mu)\Delta/\mu\rceil$ steps in the single-port model. Moreover, there exists a network and an initial token distribution for which any single-port off-line algorithm takes more than $\lceil(1+\mu)\Delta/\mu\rceil$ steps to balance the network to within one token. Similarly, in the multiport model, any network can be balanced off-line in at most $\lceil\Delta/\alpha\rceil$ steps so that no node contains more than d tokens more than the average. Using this result, we show that any network can be balanced to within $d+1$ tokens in at most $2\lceil\Delta/\alpha\rceil$ steps. It is easy to observe that for any network there exists an initial token distribution such that any algorithm will take at least $\lceil\Delta/\alpha\rceil$ steps to balance the network to within one token.

1.2. Previous and related work. Load balancing has been studied extensively because it comes up in a wide variety of settings, including adaptive mesh partitioning [17, 39], fine-grain functional programming [16], job scheduling in operating systems [13, 25], and distributed tree searching [22, 26]. A number of models have been proposed for load balancing, differing chiefly in the amount of global information used by the load balancing algorithm [2, 11, 12, 14, 27, 31]. In these models, algorithms have been proposed for specific applications; also, proposed heuristics and algorithms have been analyzed using simulations and queueing-theoretic techniques [28, 35, 37]. In what follows, we focus on models that allow only local algorithms and on prior work that takes an analytical approach to the load balancing problem.

Local algorithms restricted to particular networks have been studied on counting networks [4, 23], hypercubes [20, 34], and meshes [17, 29]. Another class of networks on which load balancing has been studied is the class of expanders. Peleg and Upfal [32] pioneered this study by identifying certain small-degree expanders as being suitable for load balancing. Their work has been extended in [9, 18, 33]. These algorithms use either strong expanders to approximately balance the network or the AKS sorting network [3] to perfectly balance the network. Thus, they do not work on networks of arbitrary topology. Also, these algorithms work by setting up fixed paths through the network on which load is moved and therefore cannot cope with changes in the network topology. In contrast, our local algorithm works on any arbitrary dynamic network that remains connected.

On arbitrary topologies, load balancing has been studied under two models. In the first model, any amount of load can be moved across a link in any time step [8, 12, 14, 15, 19, 36]. The second model is the one that we adopt here, namely, one in which at most one unit load can be moved across a link in each time step. Load balancing algorithms for the second model were first proposed and analyzed in [2] for the multiport variant and in [14] for the single-port variant. The upper bounds established by them are suboptimal by a factor of $\Omega(\log(n\Delta))$ or $\Omega(\sqrt{n})$, respectively. We improve these results for both single-port and multiport variants.

As remarked earlier, our multiport results (and those in [2]) hold even for dynamic or asynchronous networks. In general, work on dynamic and asynchronous networks has been limited. In work related to load balancing, for instance, an end-to-end communication problem, namely, one in which messages are routed from a single source to a single destination, has been studied in [1, 7] on dynamic networks. Our scenario is substantially more involved since we are required to move load between several sources and destinations simultaneously. Another result on dynamic networks is the recent analysis of a local algorithm for the approximate multicommodity flow problem [5, 6]. While their result has several applications including the end-to-end communication problem mentioned above, it does not seem to extend to load balancing. Our result on load balancing is related to their work in the technique; however, our algorithm and analysis are simpler and we obtain optimal bounds for our problem.

The convergence of local load balancing algorithms is related to that of random walks on Markov chains. Indeed the convergence bounds in both cases depend on the expansion properties of the underlying graph, and they are established using potential function arguments. There are, however, two important differences. First, the analysis of the rapid convergence of random walks [21, 30] relies on averaging arbitrary probabilities across any edge. This corresponds to sending an arbitrary (possibly nonintegral) load along an edge, which is forbidden in our model. In this sense, the analysis in [12] (and all references in the unbounded capacity model) are similar to the random walk analysis. Second, our argument uses an exponential potential function. The analyses in [12, 21, 30], in contrast, use quadratic potential functions. Our potential function and our amortized analysis were necessary, since a number of previous attempts using quadratic potential functions yielded suboptimal results [2, 14] for local load balancing.

As mentioned earlier, we consider only the static aspect of load balancing. For a recent survey on the dynamic aspect of this problem (i.e., when tokens can be created or destroyed while the tokens are being balanced), see [40].

1.3. Outline. The remainder of this paper is organized as follows. Section 2 contains some definitions. Section 3.1 analyzes the performance of the single-port algorithm. Section 3.2 analyzes the performance of the multiport algorithm. In section 4, we show that the time to reach a locally balanced state can be quite large, even if the network starts in a state that is well balanced globally. Section 5 describes extensions to dynamic and asynchronous networks. Finally, section 6 presents tight bounds on off-line load balancing.

2. Preliminaries.

For any network $G = (V, E)$ with n nodes and edge expansion α, we denote the number of tokens at $v \in V$ by $w(v)$. We denote the average number of tokens by ρ, i.e., $\rho = (\sum_{v \in V} w(v))/n$. For simplicity, throughout this paper we assume that ρ is an integer. We assign a unique *rank* from $[1, w(v)]$ to every token at v. The *height* of a token is its rank minus ρ. The height of a node is the maximum among the heights of all its tokens.

Consider a partition of V given by $\{S_i\}$, where the index i is any integer (positive, negative, or zero) and S_i may be empty for any i. Let $S_{>j}$ be $\cup_{i>j} S_i$. Similarly, we define $S_{\geq j}$, $S_{<j}$, and $S_{\leq j}$. We define index i to be *good* if $|S_i| \leq \alpha|S_{>i}|/2d$. An index that is not good is called a *bad* index. Thus, index i is good if there are at least $\alpha|S_{>i}|/2$ edges from nodes in $S_{>i}$ to nodes in $S_{<i}$. To observe this, note that the number of edges out of $S_{>i}$ is at least $\alpha|S_{>i}|$. On the other hand, the number of edges coming out of S_i is at most $d|S_i|$, which is at most $\alpha|S_{>i}|/2$ if i is good. Therefore, at least $\alpha|S_{>i}|/2$ edges go from nodes in $S_{>i}$ to nodes in $S_{<i}$.

For any bad index i, it follows from the equality $|S_i| = |S_{>i-1}| - |S_{>i}|$ that $|S_{>i}| < |S_{>i-1}|/(1+\alpha/(2d))$. Consider the reduction in $|S_{>i}|$ as i increases. For each bad index, there is a reduction by a factor of $1/(1+\alpha/(2d))$. Hence, there can be at most $\lceil \log_{(1+\alpha/(2d))} n \rceil$ bad indices because $(1+\alpha/(2d))^{\log_{(1+\alpha/(2d))} n} \geq n$. It follows that at least half of the indices in $[1, 2\lceil \log_{(1+\alpha/(2d))} n \rceil]$ are good.

Finally, we note that for $0 \leq a \leq 1$, $1+a \geq e^{a-a^2/2} \geq e^a/2$. Thus $\ln(1+a) \geq a/2$, implying $\log(1+a) = \Theta(a)$. We will use this result several times in the sections to follow, without further justification.

3. Analysis for static synchronous networks.

3.1. The single-port model.

In this section, we analyze the single-port load balancing algorithm that is described in section 1.1.

THEOREM 3.1. *For an arbitrary network G with n nodes, maximum degree d, edge expansion α, and initial imbalance Δ, the single-port algorithm balances within $O((d \log n)/\alpha)$ tokens in $O((d\Delta)/\alpha)$ steps, with high probability.*

For the sake of analysis, before every step we partition the set of nodes according to how many tokens they contain. For every integer i, we denote the set of nodes having $\rho + i$ tokens as S_i. Consider the first T steps of the algorithm, with T to be specified later. It holds that either $|S_{>0}| \leq n/2$ at the start of at least half the steps, or $|S_{\leq 0}| \leq n/2$ at the start of at least half the steps. Without loss of generality, assume the former is true. Thus, every subset of nodes in $S_{>0}$ expands, and we will use this expansion property to show that the number of nodes that have at least $\rho + 2\log_{(1+\alpha/(2d))} n$ tokens rapidly goes to zero.

Recall that at least half of the indices in $[1, 2\lceil \log_{(1+\alpha/(2d))} n \rceil]$ are good in any time step. Therefore, there exists an index j in $[1, 2\lceil \log_{(1+\alpha/(2d))} n \rceil]$ that is good in at least half of those time steps in which $|S_{>0}| \leq n/2$. Hence j is good in at least $T/4$ steps.

With every token at height x we associate a potential of $\phi(x)$, where $\phi : N \to R$ is defined as follows:

$$\phi(x) = \begin{cases} 0 & \text{if } x \leq j, \\ (1+\nu)^x & \text{otherwise,} \end{cases} \tag{3.1}$$

where $\nu = \alpha/(cd)$ and $c > 1$ is a real constant to be specified later. The potential of the network is the sum of the potentials of all tokens in the network. While transmitting a token, every node sends its token with maximum height. Similarly, any token arriving at a node with height h is assigned height $h+1$. It follows from the definition of the potential function, and the fact that the height of a token never increases, that the potential of the network never increases. In the following, we show that during any step when j is good, the expected decrease in the potential of the network is at least an $\varepsilon\nu^2$ fraction of the potential before the step, where $\varepsilon > 0$ is a real constant to be specified later.

Before proving Theorem 3.1, we present an informal outline of the proof. For simplicity, let us assume that G is a constant-degree expander, i.e., $d = O(1)$ and $\mu = \Omega(1)$. Consider the scenario in which all of the indices greater than j are bad. In this situation, for indices greater than j, the size of the set $S_{\geq i}$ decreases exponentially with increasing i, and hence the number of tokens with height i decreases exponentially with increasing i. If the rate of growth of $\phi(x)$ with increasing x is smaller than the rate of decrease of $|S_{\geq i}|$ with increasing i, then the total potential due to tokens at height i dominates the total potential due to tokens at height greater than i. In such a case the potential of $S_{>j}$ is essentially a constant times the potential of tokens at height $j+1$. In addition, if the potential of tokens at height at most j is zero, then in every step when j is good, there is a constant fraction potential drop because a constant fraction of the nodes in $S_{>j}$ send tokens to $S_{<j}$ in such a step. The exponential function we have defined in (3.1) satisfies the properties described above for c sufficiently large.

In general, the indices greater than j may form any sequence of good and bad indices, provided that the upper bound on the number of bad indices is respected. We consider the indices greater than j in reverse order and show by an amortized analysis that for each index i we can view all indices greater than or equal to i as bad. If i is bad, then this view is trivially preserved; otherwise, the number of edges from $S_{>i}$ to $S_{<i}$ is at least $\alpha|S_{>i}|/2$ and hence there is a significant potential drop across the cut $(S_{\leq i}, S_{>i})$. This drop can be used to rearrange the potential of $S_{>i}$ in order to maintain the view that all indices greater than i are bad. We then invoke the argument for the case in which all indices greater than j are bad, and complete the proof.

Consider step t of the algorithm. Let Φ_t denote the potential of the network after step $t > 0$. Let M_i be the set of tokens that are sent from a node in $S_{>i}$ to a node in $S_{<i}$. Note that a token may appear in several different sets M_i. Let $m_i = |M_i|$. We say that a token p has an *i-drop* of $\phi(i+1) - \phi(i)$ if p moves from a node in $S_{>i}$ to a node in $S_{<i}$. Thus, the potential drop due to a token moving on an edge from node $u \in S_i$ to node $v \in S_{i'}$, $i > i'+1$, can be expressed as the sum of k-drops for $i' < k < i$. In Lemma 3.2, we use this notion of i-drops to relate the total potential drop in step t, Ψ, to the m_i's.

LEMMA 3.2.

$$\Psi = \left(\sum_{i>j} m_i \nu (1+\nu)^i\right) + m_j (1+\nu)^{j+1}.$$

Proof. Let M be the set of tokens that are moved from a node in $S_{>j}$. (Note that tokens that start from and end at nodes in $S_{>j}$ also belong to M.) For any token p, let $a(p)$ (resp., $b(p)$) be the height of p after (resp., before) step t.

$$\begin{aligned}
\Psi &= \sum_{p \in M} (\phi(b(p)) - \phi(a(p))) \\
&= \sum_{p \in M} \sum_{a(p) \leq i < b(p)} (\phi(i+1) - \phi(i)) \\
&= \sum_{i \geq j} \sum_{p \in M_i} (\phi(i+1) - \phi(i)) \\
&= \left(\sum_{i>j} \sum_{p \in M_i} (\phi(i+1) - \phi(i))\right) + \sum_{p \in M_j} (\phi(j+1) - \phi(j)) \\
&= \left(\sum_{i>j} \sum_{p \in M_i} \nu (1+\nu)^i\right) + \sum_{p \in M_j} (1+\nu)^{j+1} \\
&= \left(\sum_{i>j} m_i \nu (1+\nu)^i\right) + m_j (1+\nu)^{j+1}.
\end{aligned}$$

(The second equation holds since the sum of $\phi(i+1)-\phi(i)$ over i telescopes. For the third equation, we interchange the order of summation and use the fact that $\phi(i)$ is zero for all $i \le j$. The fourth equation is obtained by separating the case $i \ge j$ into two cases $i > j$ and $i = j$. For deriving the fifth equation, we use (i) for all $i > j$, $\phi(i+1) - \phi(i) = \nu(1+\nu)^i$, and (ii) $\phi(j) = 0$. The last equation follows from the definition of m_i.) $\square$

We now describe the amortized analysis, which we alluded to earlier in this section, that we use to prove Theorem 3.1. We associate a charge of $\varepsilon\nu^2\phi(h)$ with each token at height h. We show that we can pay for all of the charges using the expected potential drop $E[\Psi]$, which implies a lower bound on $E[\Psi]$. We consider the indices in $[j+1,\ell]$ in reverse order, where ℓ is the maximum token height. For every i in $[j,\ell]$, we maintain a "debt" term, given by Γ_i below, which is the difference between the charges due to tokens at height greater than i and the sum of i'-drops for $i' > i$. We will place an upper bound on $E[\Gamma_i]$ that lets us view all of the indices in $[i+1,\ell]$ as bad indices. In other words, we upper bound $E[\Gamma_i]$ by $\varepsilon\nu|S_{\ge i}|(1+\nu)^i$. It follows from this upper bound and the informal argument outlined earlier in this section that the expected total debt can be paid for by the expected drop across index j.

Formally, for any $i > j$, we define

$$\Psi_i = \sum_{k \ge i} m_k \nu (1+\nu)^k,$$

$$\Gamma_i = (\varepsilon\nu^2)\left(\sum_{p:b(p)\ge i} (1+\nu)^{b(p)}\right) - \Psi_i.$$

We also define

$$\Gamma = (\varepsilon\nu^2)\left(\sum_{p:b(p)>j} (1+\nu)^{b(p)}\right) - \Psi.$$

Note that $\Phi_{t-1} = \sum_{p:b(p)>j}(1+\nu)^{b(p)}$ is the total potential of $S_{>j}$ prior to step t.

In order to prove the upper bound on $E[\Gamma_i]$, we place a lower bound on $E[m_i]$ that is obtained from the following lemma of [14].

LEMMA 3.3 (see [14]). *For any edge $e \in E$, the probability that e is selected in the matching is at least* $1/(8d)$. $\square$

LEMMA 3.4. *There exists a real constant $\varepsilon > 0$ such that for all $i > j$, we have* $E[\Gamma_i] \le (\varepsilon\nu)|S_{\ge i}|(1+\nu)^i$.

Proof. The proof is by reverse induction on i. If $i > \ell$, then the claim holds trivially since Γ_i and $|S_{\ge i}|$ are both equal to zero. (Recall that ℓ denotes the maximum token height.) Therefore, for the base case we consider $i = \ell$. Since $m_\ell = 0$, we have $\Psi_\ell = 0$. Thus, $\Gamma_\ell = (\varepsilon\nu^2)|S_\ell|(1+\nu)^\ell \le (\varepsilon\nu)|S_{\ge \ell}|(1+\nu)^\ell$, since $\nu = \alpha/(cd) \le 1/c \le 1$ by our choice of c.

For the induction step we consider two cases, depending on whether i is good or bad. We begin with the case when i is good. By the definition of a good index, we have $|S_i| \le \alpha|S_{>i}|/2d$. Since each node has at most d adjacent edges, there are at most $\alpha|S_{>i}|/2$ edges adjacent to nodes in S_i. Therefore, there are at most $\alpha|S_{>i}|/2$ edges from $S_{>i}$ to S_i. By the expansion property of the graph, $S_{<i}$ has at least $\alpha|S_{<i}|$ edges to nodes in $S_{\ge i}$, so there are at least $\alpha|S_{>i}|/2$ edges from $S_{>i}$ to $S_{<i}$. By Lemma 3.3, we have $E[m_i] \ge \alpha|S_{>i}|/(16d)$.

We are now ready to place a bound on $E[\Gamma_i]$. By definition, Γ_i can be calculated by subtracting the sum of i-drops from Γ_{i+1} and adding the charges due to tokens at height i. Therefore, we have

$$\begin{aligned}
E[\Gamma_i] &= E[\Gamma_{i+1}] + (\varepsilon\nu^2)|S_{\geq i}|(1+\nu)^i - E[m_i]\nu(1+\nu)^i \\
&\leq E[\Gamma_{i+1}] + (\varepsilon\nu^2)|S_{\geq i}|(1+\nu)^i - c\nu^2|S_{>i}|(1+\nu)^i/16 \\
&\leq E[\Gamma_{i+1}] - (\nu^2)|S_{\geq i}|(1+\nu)^i(f(c,\alpha,d) - \varepsilon) \\
&\leq (\varepsilon\nu)|S_{>i}|(1+\nu)^{i+1} - (\nu^2)|S_{\geq i}|(1+\nu)^i(f(c,\alpha,d) - \varepsilon) \\
&\leq (\varepsilon\nu)|S_{\geq i}|(1+\nu)^i((1+\nu) - \nu(f(c,\alpha,d) - \varepsilon)/\varepsilon),
\end{aligned}$$

where $f(c,\alpha,d) = c/(16(1+\alpha/(2d)))$. (In the first equation, we use the fact the number of tokens p such that $b(p) = i$ is $|S_{\geq i}|$. The second equation follows from the lower bound on $E[m_i]$. The third equation follows from the fact that $|S_{>i}| \geq |S_{\geq i}|/(1+\alpha/(2d))$ whenever i is a good index. The fourth equation follows from the induction hypothesis. The last equation follows from the fact that $|S_{>i}| \leq |S_{\geq i}|$.)

The second case is when i is bad. Thus $|S_i| > \alpha|S_{>i}|/(2d)$. We now place an upper bound on $E[\Gamma_i]$ as follows.

$$\begin{aligned}
E[\Gamma_i] &\leq E[\Gamma_{i+1}] + (\varepsilon\nu^2)|S_{\geq i}|(1+\nu)^i \\
&\leq (\varepsilon\nu)|S_{>i}|(1+\nu)^{i+1} + (\varepsilon\nu^2)|S_{\geq i}|(1+\nu)^i \\
&\leq (\varepsilon\nu)|S_{\geq i}|(1+\nu)^i((1+\nu)/(1+c\nu/2) + \nu).
\end{aligned}$$

(In the first equation, we use the fact the number of tokens p such that $b(p) = i$ is $|S_{\geq i}|$. The second equation follows from the induction hypothesis. The third equation follows from the fact that $|S_{\geq i}| > (1+\alpha/(2d))|S_{>i}|$ whenever i is a bad index.)

We now complete the induction step by determining values for c and ε such that the following equations hold:

$$((1+\nu) - \nu(f(c,\alpha,d) - \varepsilon)/\varepsilon) \leq 1, \tag{3.2}$$

$$(1+\nu)/(1+c\nu/2) + \nu \leq 1. \tag{3.3}$$

We set c to be any constant greater than or equal to $(\alpha/d) + 4$ (e.g., $c = 5$). For this choice of c, $\nu = \alpha/(cd) \leq (c-4)/c$, and hence $2\nu + c\nu^2/2 \leq c\nu/2$. Therefore, we have

$$\begin{aligned}
(1+\nu)/(1+c\nu/2) + \nu &= (1 + 2\nu + c\nu^2/2)/(1+c\nu/2) \\
&\leq (1+c\nu/2)/(1+c\nu/2) \\
&= 1.
\end{aligned}$$

Thus, (3.3) is satisfied. Since $\alpha \leq d$, we find that $f(c,\alpha,d) \geq c/24$. We now set $\varepsilon = c/48$ to establish (3.2). (For example, $c = 5$ and $\varepsilon = 5/48$.) □

We are now in a position to bound $E[\Gamma]$ on those steps in which j is good. By applying Lemma 3.4 with $i = j+1$, we obtain that $E[\Gamma_{j+1}] \leq (\varepsilon\nu)|S_{\geq j+1}|(1+\nu)^{j+1}$. If j is good, then by the definitions of Γ, Γ_{j+1}, and Ψ, we have

$$\begin{aligned}
E[\Gamma] &= E[\Gamma_{j+1}] - E[m_j](1+\nu)^{j+1} \\
&\leq E[\Gamma_{j+1}] - \alpha|S_{>j}|(1+\nu)^{j+1}/(16d) \\
&\leq (\varepsilon\nu)|S_{>j}|(1+\nu)^{j+1} - \alpha|S_{>j}|(1+\nu)^{j+1}/(16d) \\
&= \nu|S_{>j}|(1+\nu)^{j+1}(\varepsilon - c/16) \\
&\leq 0.
\end{aligned}$$

(The second equation follows from the fact that $E[m_j] \geq \alpha|S_{>j}|/16d$ whenever j is good. The third equation follows from the upper bound on $E[\Gamma_{j+1}]$. The fifth equation holds since $c/16 \geq \varepsilon$.)

We now derive a lower bound on the expected drop in the potential of the network during a sequence of T steps. By the definitions of Ψ and Γ, we have $\Phi_t = \Phi_{t-1} - \Psi$ and $\Gamma = \varepsilon\nu^2\Phi_{t-1} - \Psi$. If j is good during step t, we have $E[\Gamma] \leq 0$, and therefore $E[\Phi_t] \leq \Phi_{t-1}(1 - \varepsilon\nu^2)$, where the expectation is taken over the random matching selected in step t. Since j is good in at least $T/4$ steps, we obtain that $E[\Phi_{t+T}] \leq \Phi_t(1 - \varepsilon\nu^2)^{T/4}$, where the expectation is taken over all the random matchings in the T steps. By setting $T = \lceil(4\ln 4)/(\varepsilon\nu^2)\rceil$, we obtain $E[\Phi_{t+T}] \leq \Phi_t/4$. By Markov's inequality, the probability that $\Phi_{t+T} \geq \Phi_t/2$ is at most $1/2$. Therefore, using standard Chernoff bounds [10], we can show that in $T' = 8aT\lceil(\log\Phi_0 + \log n)\rceil$ steps, $\Phi_{T'} > 1$ with probability at most $O(1/(\Phi_0)^a + 1/n^a)$ for any constant $a > 0$.

If Δ is at most $2\log_{(1+\alpha/(2d))} n$, then the claim of the theorem holds trivially. Accordingly, we assume that Δ is greater than $2\log_{(1+\alpha/(2d))} n$ in what follows. Since Φ_0 is at least $(1+\nu)^{\Delta}$, Φ_0 is at least $n^{2/c}$. Therefore, $1/(\Phi_0)^a$ is inverse-polynomial in n. Since $\Phi_0 \leq n(1+\nu)^{\Delta+1}/\nu$, we have $\log\Phi_0 \leq (\Delta+1)(\nu) + \log n - \log\nu$. Therefore, for $T' = O(\Delta d/\alpha + d^2\log n/\alpha^2)$, we have $\Phi_{T'} < 1$ with high probability, which implies that after T' steps $|S_{>2\log_{(1+\alpha/(2d))} n}| = 0$ with high probability.

To establish balance in the number of tokens below the average, we use an averaging argument to show that after T' steps $|S_{<-2\log_{(1+\alpha/(2d))} n}| \leq n/2$ with high probability and then repeat the above arguments with the potential redefined appropriately. This proves Theorem 3.1.

3.2. The multiport model. In this section, we analyze the deterministic multiport algorithm described in section 1.1.

THEOREM 3.5. *For an arbitrary network G with n nodes, maximum degree d, edge expansion α, and initial imbalance Δ, the multiport algorithm load balances to within $O((d^2\log n)/\alpha)$ tokens in $O(\Delta/\alpha)$ steps.*

The proof of Theorem 3.5 is similar to that of Theorem 3.1. We assign a potential to every token, where the potential is exponential in the height of the token. We then show by means of an amortized analysis that a suitable rearrangement of the potential reduces every instance of the problem to a special instance that we understand well.

For the sake of analysis, before every step we partition the set of nodes according to how many tokens they contain. For every integer i, we denote the set of nodes having between $\rho - d + 2id$ and $\rho + d - 1 + 2id$ tokens as S_i. (Recall that ρ is the average number of tokens per node.) Consider the first T steps of the algorithm with T to be specified later. Without loss of generality, we assume that $|S_{>0}| \leq n/2$ holds in at least half of these steps. As shown in section 2, there exists an index j in $[1, 2\lceil\log_{(1+\alpha/(2d))} n\rceil]$ that is good in at least half of those steps in which $|S_{>0}| \leq n/2$. Hence in T steps of the algorithm, j is good in at least $T/4$ steps.

With every token at height h we associate a potential of $\phi(h)$, where $\phi : N \to R$ is defined as follows:

$$\phi(x) = \begin{cases} 0 & \text{if } x \leq 2jd, \\ (1+\nu)^x & \text{otherwise,} \end{cases}$$

where $\nu = \alpha/(cd^2)$ and $c > 0$ is a constant to be specified later. The potential of the network is the sum of the potentials of all tokens in the network.

While transmitting some number (say, m) of tokens in a particular step, a node sends the m highest-ranked tokens. Similarly, if m tokens arrive at a node during a step, they are assigned the m highest ranks within the node. Thus, tokens that do not move retain their ranks after the step. We now describe what specific ranks we assign to tokens that move during any step t. Let u be a node in $S_{<i}$ with height h at the start of step t. Let A (resp., B) be the set of tokens that u receives from nodes in $S_{>i}$ (resp., $S_{\leq i}$). We assign new ranks to tokens in A and B such that the rank of every token in A is less than that of every token in B. Let C be the set of tokens in A that attain height at most $h + (d/2)$ after the step. Since $|A| \leq d$, by the choice of our ranking, we have $|C| \geq |A|/2$. We call C the set of *primary* tokens. We also note that for any node v with height h all tokens leaving v during a step are at height at least $h - d + 1$ prior to the step.

It follows from the definition of the potential function and the fact that the height of a token never increases that the network potential never increases. In the following we show that whenever j is good the potential of $S_{>j}$ decreases by a factor of $\varepsilon\nu^2 d^2$, where $\varepsilon > 0$ is a real constant to be specified later. (For the sake of simplicity, we assume that d is even. If d is odd, we can replace d by $d+1$ in our argument without affecting the bounds by more than constant factors.)

For any token p, let $a(p)$ (resp., $b(p)$) be the index i such that S_i contains p after (resp., before) the step. (Note that the indexing is done prior to the step.) Let M_i be the set of primary tokens received by nodes in $S_{<i}$. Let $m_i = |M_i|$. Note that m_i is at least half the number of edges connecting nodes in $S_{<i}$ and nodes in $S_{>i}$. This is because a token is sent along every one of the edges connecting $S_{<i}$ and $S_{>i}$ and at least half the tokens received by any node in $S_{<i}$ from nodes in $S_{>i}$ are primary tokens. Lemma 3.6 establishes the relationship between the total potential drop Ψ in step t and the m_i's.

LEMMA 3.6.

$$\Psi \geq \left(\frac{1}{2} \sum_{i>j} m_i \nu d (1+\nu)^{(2i-1)d} \right) + m_j (1+\nu)^{2jd+1}.$$

Proof. Let M be the set of primary tokens that are moved from nodes in $S_{>j}$. (Note that primary tokens that start from a node in $S_{>j}$ and end at a node in $S_{>j}$ are in M.) Let p be a token in M. By the definition of a primary token, the height of p prior to the step is at least $2b(p)d - 2d + 1$ and the height after the step is at most $2a(p)d + 3d/2$. Moreover, p belongs to M_i for all i such that $a(p) < i < b(p)$.

$$\begin{aligned}
\Psi &\geq \sum_{p \in M} [\phi(2b(p)d - 2d + 1) - \phi(2a(p)d + 3d/2)] \\
&\geq \sum_{p \in M} \sum_{a(p) < i < b(p)} [\phi(2(i+1)d - 2d + 1) - \phi(2(i-1)d + 3d/2)] \\
&= \sum_{i \geq j} \sum_{p \in M_i} [\phi(2(i+1)d - 2d + 1) - \phi(2(i-1)d + 3d/2)] \\
&= \sum_{i > j} \sum_{p \in M_i} [\phi(2(i+1)d - 2d + 1) - \phi(2(i-1)d + 3d/2)] \\
&\quad + \sum_{p \in M_j} [\phi(2(j+1)d - 2d + 1) - \phi(2(j-1)d + 3d/2)] \\
&\geq \left(\frac{1}{2} \sum_{i>j} \sum_{p \in M_i} \nu d (1+\nu)^{2id-d} \right) + \sum_{p \in M_j} (1+\nu)^{2jd+1}
\end{aligned}$$

$$\geq \left(\frac{1}{2} \sum_{i>j} m_i \nu d (1+\nu)^{2id-d} \right) + m_j (1+\nu)^{2jd+1}.$$

(The first equation follows from the lower bound (resp., upper bound) on the height of a token p in M before (resp., after) the step. For the second equation, note that $2id - 2d + 1 \leq 2(i-1)d + 3d/2$. Therefore, $\phi(2id - 2d + 1) \leq \phi(2(i-1)d + 3d/2)$. The second equation now follows since the sum telescopes. The third equation is obtained by interchanging the sums and noting that $\phi(x)$ is 0 for $x \leq 2jd$. The fourth equation is obtained by partitioning M into the subsets $M \setminus M_j$ and M_j. The fifth equation is derived using the following calculations: (i) $\phi(2id+1) - \phi(2id - d/2) \geq ((1+\nu)^{d/2} - 1)(1+\nu)^{2id-d/2} \geq \nu d (1+\nu)^{2id-d}/2$, (ii) $\phi(2jd+1) = (1+\nu)^{2jd+1}$, and (iii) $\phi(2jd - d/2) = 0$. The last equation follows from the definition of m_i.) □

We establish Theorem 3.5 by means of an amortized analysis similar to the one used in section 3.1. We associate a charge of $\varepsilon \nu^2 d^2 \phi(h)$ with every token at height h. We show that we can pay for all of the charges using the potential drop Ψ and thus place a lower bound on Ψ. We consider the sets S_i in reverse order and maintain a "debt" term Γ_i for each i. Informally, Γ_i indicates the difference between the total charges due to tokens at height at least $2id - d$ and the current upper bound on the potential drop. Our amortized analysis terminates by showing that the total debt Γ is at most zero.

We now formally define Γ_i and Γ. For any token p, let $h(p)$ denote the height of p prior to the step. Thus $2b(p)d - d \leq h(p) \leq 2b(p)d + d - 1$. For $i > j$ and for a suitable constant $\varepsilon > 0$ to be specified later, we define

$$\Psi_i = \frac{1}{2} \sum_{k \geq i} m_k \nu d (1+\nu)^{2kd-d} \text{ and}$$

$$\Gamma_i = (\varepsilon \nu^2 d^2) \left(\sum_{p: h(p) \geq 2id-d} (1+\nu)^{h(p)} \right) - \Psi_i.$$

We also define

$$\Gamma = (\varepsilon \nu^2 d^2) \left(\sum_{p: h(p) > 2jd} (1+\nu)^{h(p)} \right) - \Psi.$$

For any step t', let $\Phi_{t'}$ denote the total potential after step t'. Thus, $\Phi_{t-1} = \sum_{p:h(p)>2jd} (1+\nu)^{h(p)}$ is the total potential prior to step t.

Lemma 3.7. *There exists a real constant $\delta > 0$ such that for all $i > j$, we have*

$$\Gamma_i \leq (\delta \nu d^2) |S_{\geq i}| (1+\nu)^{2id-d}.$$

Proof. The proof is by reverse induction on i. Let ℓ be the maximum token height. Consider first the case when $i > \lfloor (\ell + d)/2d \rfloor$. Since $2id - d > \ell$, there is no token with height at least $2id - d$. Hence $\Gamma_i \leq 0$ and $|S_{\geq i}| = 0$. Thus, the desired claim holds. We now consider $i = \lfloor (\ell + d)/2d \rfloor$. Since $\Psi_i = 0$, we have

$$\begin{aligned}\Gamma_i &\leq (2\varepsilon \nu^2 d^3) |S_{\geq i}| (1+\nu)^{\ell} \\ &\leq (2\varepsilon \nu^2 d^3) |S_{\geq i}| (1+\nu)^{2d(i+1)-d} \\ &\leq (\delta \nu d^2) |S_{\geq i}| (1+\nu)^{2id-d}.\end{aligned}$$

(The first equation holds because (i) each node in S_i has at most $2d$ tokens with height at least $2id-d$, and (ii) $h(p) \leq \ell$ for each token p. The second equation follows from the fact that $\ell < 2(i+1)d-d$. The third equation is obtained by choosing δ and ε such that $\delta > 2\varepsilon\nu d(1+\nu)^{2d}$. Note that for c sufficiently large, $(1+\nu)^{2d}$ can be set to an arbitrarily small constant.)

For the induction step we consider two cases. If i is good, then $|S_i| \leq \alpha|S_{>i}|/(2d)$ and $m_i \geq \alpha|S_{>i}|/4$. Therefore, we have

$$\begin{aligned}\Gamma_i &\leq \Gamma_{i+1} + (2\varepsilon\nu^2 d^3)|S_{\geq i}|(1+\nu)^{2id+d-1} - m_i\nu d(1+\nu)^{2id-d}/2\\ &\leq \Gamma_{i+1} + (2\varepsilon\nu^2 d^3)|S_{\geq i}|(1+\nu)^{2id+d-1} - c\nu^2 d^3|S_{>i}|(1+\nu)^{2id-d}/8\\ &\leq \Gamma_{i+1} - (\nu^2 d^3)|S_{\geq i}|(1+\nu)^{2id-d}(f(c,\alpha,d) - 2\varepsilon(1+\nu)^{2d})\\ &\leq (\delta\nu d^2)|S_{>i}|(1+\nu)^{2(i+1)d-d} - (\nu^2 d^3)|S_{\geq i}|(1+\nu)^{2id-d}(f(c,\alpha,d)-4\varepsilon)\\ &\leq (\delta\nu d^2)|S_{\geq i}|(1+\nu)^{2id-d}((1+\nu)^{2d} - \nu d(f(c,\alpha,d)-4\varepsilon)/\delta),\end{aligned}$$

where $f(c,\alpha,d) = c/(8(1+\alpha/(2d)))$. (The first equation holds because (i) each node in S_i has at most $2d$ tokens with height at least $2id-d$, and (ii) $h(p) \leq 2id+d-1$ for each token p that contributes to Γ_i and not to Γ_{i+1}. The third equation follows from the fact that $|S_{>i}| \geq |S_{\geq i}|/(1+\alpha/(2d))$. The fourth equation follows from the induction hypothesis and the equation $(1+\nu)^{2d} \leq 2$ for c sufficiently large. The last equation is derived using straightforward algebra.)

The second case is when i is bad. Thus $|S_i| > \alpha|S_{>i}|/(2d)$. We have

$$\begin{aligned}\Gamma_i &\leq \Gamma_{i+1} + (2\varepsilon\nu^2 d^3)|S_{\geq i}|(1+\nu)^{2id+d-1}\\ &\leq (\delta\nu d^2)|S_{>i}|(1+\nu)^{2(i+1)d-d} + 2\varepsilon\nu^2 d^3|S_{\geq i}|(1+\nu)^{2id+d-1}\\ &\leq (\delta\nu d^2)|S_{\geq i}|(1+\nu)^{2id-d}((1+\nu)^{2d}/(1+\alpha/(2d)) + 2\varepsilon\nu d(1+\nu)^{2d}/\delta).\end{aligned}$$

We now set c, δ, and ε such that $c > 4$, $c/12 - 4\varepsilon \geq 4\delta$, and $c/4 - 2\varepsilon/\delta \geq 4$. (One set of choices is $c = 50$, $\delta = 1$, and $\varepsilon = 1/24$.) Since $\alpha \leq d$, we have $f(c,\alpha,d) \geq c/12$. Since $c > 4$, we have $2\nu d < 1/2$, and hence $(1+\nu)^{2d} \leq 1 + \sum_{i>0}(2\nu d)^i = 1 + 2\nu d/(1-2\nu d) \leq 1 + 4\nu d$. Thus,

$$((1+\nu)^{2d} - \nu d(f(c,\alpha,d)-4\varepsilon)/\delta) \leq 1 + 4\nu d - 4\nu d \leq 1.$$

Since $\alpha/(2d) \leq 1/2$, we have $1/(1+\alpha/(2d)) \leq 1 - \alpha/2d + (\alpha/2d)^2 \leq 1 - \alpha/(2d) + \alpha/(4d) = 1 - \alpha/(4d)$, and hence

$$\begin{aligned}(1+\nu)^{2d}/(1+\alpha/(2d)) + 2\varepsilon\nu d(1+\nu)^{2d}/\delta &= (1+\nu)^{2d}(1/(1+\alpha/(2d)) + 2\varepsilon\nu d/\delta)\\ &\leq (1+\nu)^{2d}(1 - \alpha/4d + 2\varepsilon\nu d/\delta)\\ &= (1+\nu)^{2d}(1 - c\nu d/4 + 2\varepsilon\nu d/\delta)\\ &\leq (1+4\nu d)(1-4\nu d) < 1.\end{aligned}$$

(The second equation follows from the upper bound on $1/(1+\alpha/(2d))$. The fourth equation follows from the upper bound of $(1+4\nu d)$ on $(1+\nu)^{2d}$.)

Thus, in both cases, $\Gamma_i \leq (\delta\nu d^2)|S_{\geq i}|(1+\nu)^{2id-d}$. This completes the induction step. ▯

COROLLARY 3.8. *If j is good in step t, then we have $\Psi \geq \varepsilon\nu^2 d^2 \Phi_{t-1}$.*

Proof. Applying Lemma 3.7 with $i = j+1$, it follows that $\Gamma_{j+1} \leq (\delta\nu d^2)|S_{\geq j+1}|(1+\nu)^{2(j+1)d-d}$. If j is good, then $|S_{\geq j}| \leq (1+\alpha/(2d))|S_{>j}| \leq 3|S_{>j}|/2$ and $m_j \geq$

$\alpha|S_{>j}|/2$. Therefore,

$$\begin{aligned}\Gamma &\leq \Gamma_{j+1} + \varepsilon\nu^2 d^3 |S_{\geq j}|(1+\nu)^{2jd+d-1} - \alpha|S_{>j}|(1+\nu)^{2jd+1}/2 \\ &\leq (\delta\nu d^2)|S_{>j}|(1+\nu)^{2(j+1)d-d} \\ &\quad + (3\varepsilon\nu^2 d^3)|S_{>j}|(1+\nu)^{2jd+d-1}/2 - \alpha|S_{>j}|(1+\nu)^{2jd+1}/2 \\ &\leq (\nu d^2)|S_{>j}|(1+\nu)^{2(j+1)d-d}(\delta + 3\varepsilon\alpha/(2cd) - c/4) \\ &\leq 0\end{aligned}$$

for c, δ, and ε as chosen in the proof of Lemma 3.7. (In the first equation, the term $\varepsilon\nu^2 d^3|S_{\geq j}|(1+\nu)^{2jd+d-1}$ is an upper bound on the contribution to Γ_j by tokens in $S_{\geq j}$ since (i) tokens with height at least $2jd+d$ contribute to Γ_{j+1}, and (ii) each node in $S_{\geq j}$ has $d-2 \leq d$ tokens with height in the interval $[2jd+1, 2jd+d-1]$. Also, the third term in the first equation is the second term in the right-hand side of the equation of Lemma 3.6. In the second equation, we use the upper bounds on Γ_{j+1} and $|S_{\geq j}|$. The third equation follows from the choice of c, δ, and ε and the fact that for $c > 4$, we have $(1+\nu)^d \leq (1+\alpha/(cd^2))^d \leq (1+1/(cd))^d < (1+1/(4d))^d \leq e^{1/4} \leq 2$.)

By the definitions of Γ and Ψ, we have $\Phi_t \leq \Phi_{t-1} - \Psi$ and $\Gamma = \varepsilon\nu^2 d^2 \Phi_{t-1} - \Psi$. If j is good during step t, then $\Gamma \leq 0$ and the desired claim follows. ◻

By Corollary 3.8, if j is good during step t, then we have

$$\Phi_t \leq \Phi_{t-1}(1 - \varepsilon\nu^2 d^2).$$

After $T = \lceil 4 \ln \Phi_0/(\varepsilon\nu^2 d^2)\rceil$ steps, we have $\Phi_T \leq \Phi_0(1-\varepsilon\nu^2 d^2)^{T/4} < 1$. Since the height of each node is at most Δ initially, $\Phi_0 \leq n\sum_{2jd<i\leq\Delta}(1+\nu)^i \leq n(1+\nu)^{\Delta+1}/\nu$, $\ln \Phi_0 = O(\Delta\nu + \log n)$. Substituting $\alpha/(cd^2)$ for ν, we obtain that within $O(\Delta/\alpha + d^2 \ln n/\alpha^2)$ steps, $|S_{>2\log_{(1+\alpha/(2d))} n}| \leq |S_{>j}| = 0$.

We use an averaging argument to show that after T steps, $|S_{<-2\log_{(1+\alpha/(2d))} n}| \leq n/2$. By redefining the potential function and repeating the above analysis in the other direction, we obtain that in another T steps $|S_{<-4\log_{(1+\alpha/(2d))} n}| = 0$. This completes the proof of Theorem 3.5.

3.3. Results in terms of node expansion. The proofs of Theorems 3.1 and 3.5 can be easily modified to analyze the algorithm in terms of the node expansion μ of the graph instead of the edge expansion α. Recall that μ and α are related by the following inequalities: $\alpha/d \leq \mu \leq \alpha$. The primary modifications that need to be done to obtain bounds in terms of node expansion are to change the definition of a good index and to set ν appropriately. We call index i good if $|S_i| \leq \mu|S_{>i}|/2$. We set $\nu = \mu/c$ (resp., $\nu = \mu/(cd)$) for the single-port model (resp., multiport model).

By an argument similar to the one used in section 2, we obtain that the number of bad indices is at most $\lceil \log_{(1+\mu)} n\rceil$. (In fact, the argument in section 2 uses α/d as a lower bound on μ.) This bound on the number of bad indices leads to an upper bound of $O((\log n)/\mu)$ (resp., $O(d(\log n)/\mu)$) on the final imbalance obtained by the single-port algorithm (resp., multiport algorithm). For a bound on the number of steps, note that while deriving a bound on the potential drop in sections 3.1 and 3.2, we use the edge expansion α to obtain a lower bound on the number of tokens leaving sets $S_{>i}$. Since the best lower bound on α in terms of node expansion is μ, our time bounds here are obtained by substituting μ for α in the time bounds of Theorems 3.1 and 3.5, respectively. We thus obtain Theorems 3.9 and 3.11. Finally, Corollary 3.10 (resp., Corollary 3.12) follows from Theorems 3.1 and 3.9 (resp., Theorems 3.5 and 3.11).

THEOREM 3.9. *For an arbitrary network G with n nodes, maximum degree d, node expansion μ, and initial imbalance Δ, the single-port algorithm balances to within $O((\log n)/\mu)$ tokens in $O(d\Delta/\mu)$ steps with high probability.*

COROLLARY 3.10. *If $\Delta \geq (d \log n)/\mu$, the single-port algorithm balances to within $O(\log n/\mu)$ tokens in $O((d\Delta)/\alpha)$ steps with high probability. If $\Delta < (d \log n)/\mu$, the single-port algorithm balances to within $O(\log n/\mu)$ tokens in $O((d\Delta)/\mu)$ steps with high probability.*

THEOREM 3.11. *For an arbitrary network G with n nodes, maximum degree d, node expansion μ, and initial imbalance Δ, the multiport algorithm balances to within $O((d \log n)/\mu)$ tokens in $O(\Delta/\mu)$ steps.*

COROLLARY 3.12. *If $\Delta \geq (d^2 \log n)/\mu$, the multiport algorithm balances to within $O((d \log n)/\mu)$ tokens in $O(\Delta/\alpha)$ steps. If $\Delta < (d^2 \log n)/\mu$, the multiport algorithm balances to within $O((d \log n)/\mu)$ tokens in $O(\Delta/\mu)$ steps.*

4. Local load balancing can be expensive.

Here we show that upon reaching a state with small global imbalance, the algorithms presented in this paper may still take many steps until they reach a locally balanced state. More specifically, in section 4.1, we show that locally load balancing to within $2d$ tokens using the multiport algorithm of [2] described in section 1.1 can take $\Omega(\sqrt{n})$ more time than globally load balancing to within $O((d \log n)/\mu)$ tokens. We extend this bound to the single-port algorithm presented in [14]; i.e., upon reaching a state where the network is globally balanced to within $O((\log n)/\mu)$ tokens, the expected number of additional steps this algorithm may take to perform local balancing to within one token is $\Omega(d\sqrt{n})$. Furthermore, in section 4.2, we show that in the single-port case, the network may be one step away from being locally balanced to within one token but have an expected running time of $\Omega(\mu\sqrt{n})$ for reaching a locally balanced state. Finally, we prove upper bounds on the time each algorithm takes to reach a locally balanced state in section 4.3.

All results in this section are stated in terms of the node expansion of the network, rather than in terms of its edge expansion. This is done for the sake of making our arguments more intuitive and clear. Similar bounds can be derived in terms of edge expansion.

For any positive n and any μ, $0 < \mu < 1/72$, we present an example of a graph $G = (V, E)$ on n nodes with node expansion at least μ and with maximum degree d that depends on μ, where, given some initial distribution of tokens, locally balancing is difficult.

First, we define the node set V of G. Let μ_0 be equal to $\sqrt{8\mu}$ (note that $0 < \mu_0 < 1/3$). Let V be equal to $(\cup_{i=0}^{k} L_i) \cup (\cup_{i=0}^{k-1} R_i)$, where L_i and R_i are disjoint sets of $(1+\mu_0)^i$ nodes each and k will be specified shortly. For simplicity, we shall ignore integrality constraints on the number of nodes in each set. We could be more formal by setting the size of each set L_i or R_i to be $\lceil (1+\mu_0)^i \rceil$, but this would only make the calculations in this section more involved without changing the asymptotic results. For convenience, let L_{-1} (resp., R_{-1}) denote R_0 (resp., L_0) and R_k denote L_k. Note that each L_i and each R_i has size $(1+\mu_0)^i = \mu_0(\sum_{j=0}^{i-1} |L_j|)+1 = \mu_0(\sum_{j=0}^{i-1} |R_j|)+1$. Thus, setting $n = \sum_{j=0}^{k} |L_j| + \sum_{j=0}^{k-1} |R_j|$ and solving for k, we have $k = \Theta((\log n)/\log(1 + \mu_0)) = \Theta((\log n)/\log(1 + \mu)) = \Theta((\log n)/\mu)$. For simplicity, we assume that $k = (\log n)/\log(1 + \mu)$ and that k is even.

Given μ, we can choose the maximum degree d of G, independent of n, such that the following construction of the edges in G is possible. We obtain a similar structure for the R_i's by replacing L_j by R_j below. Let the only node in L_0 be adjacent to

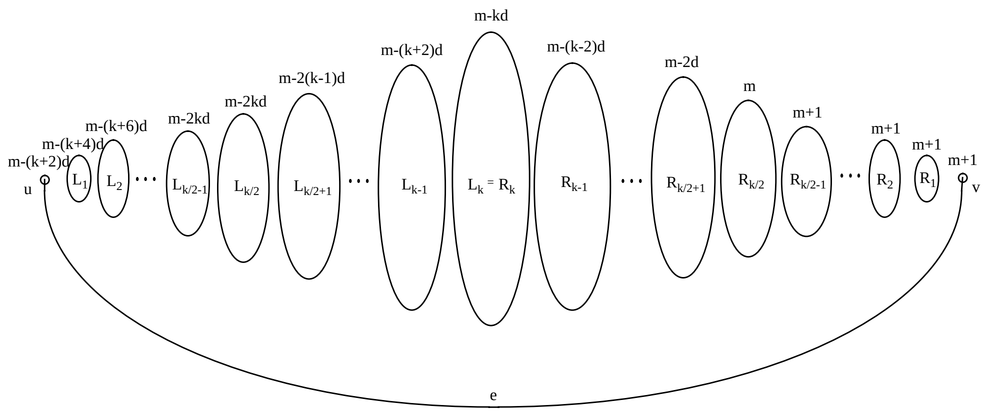

FIG. 4.1. *The initial distribution of tokens on G for the first case.*

every node in L_1. For all i, $0 \le i \le k$, we insert the edges between nodes in L_i such that (i) there are at most $d/2$ such edges adjacent to any node in L_i, and (ii) every subset S of L_i of size less than or equal to $2|L_i|/3$ has at least $\mu_0|S|$ neighbors in $L_i \setminus S$ (see [24, 38] for a proof that such a construction is possible). Also, let each node in L_i have $d(1+\mu_0)/(2(2+\mu_0))$ neighbors in L_{i+1} and each node in L_{i+1} have $d/(2(2+\mu_0))$ neighbors in L_i, $0 < i \le k-1$. For simplicity, we again ignore integrality constraints. Let S be any subset of L_i. There are $(|S|d(1+\mu_0))/(2(2+\mu_0))$ edges between S and L_{i+1}, and each node in L_{i+1} has $d/(2(2+\mu_0)$ neighbors in L_i. Thus, S has at least $(1+\mu_0)|S|$ neighbors in L_{i+1}.

Now we consider how L_{i+1} "expands" into L_i. We can use an approach similar to that of [24, 38] to show that we can choose the edges between L_i and L_{i+1}, respecting the degree constraints, such that any subset S of L_{i+1} of size less than or equal to $3|L_{i+1}|/(4(1+\mu_0))$ has at least $(1+\mu_0)|S|$ neighbors in L_i. This construction is possible since $(1+\mu_0)3|L_{i+1}|/(4(1+\mu_0)) = 3(1+\mu_0)|L_i|/4 < |L_i|$. The same analysis as in [24], but for a bipartite graph with node sets of sizes $|L_{i+1}|$ and $|L_{i+1}|/(1+\mu_0)$ and of regular node degrees $d/(2(2+\mu_0))$ and $d(1+\mu_0)/(2(2+\mu_0))$, respectively, applies here.

To complete the edge construction of G, let u be the only node in L_0, let v be the only node in R_0, and add the edge $e = (u, v)$ to the set E. Note that the diameter of G is $\Theta(k) = \Theta((\log n)/\mu)$.

We give a pictorial representation of the sets R_i's and L_i's in Figure 4.1. The initial distribution of tokens in Figure 4.1 (given by the quantities above the ovals representing each set L_i or R_i) may be ignored for the moment.

We still need to show that the graph G has node expansion at least μ, as claimed.

THEOREM 4.1. *The graph G, constructed as described, has node expansion at least μ.*

Proof. We will show how to account for the node expansion of any subset of G of at most $n/2$ nodes. Let U be a subset of V of size at most $n/2$. We will show that there exists a set of at least $\mu|U| = \mu_0^2|U|/8$ nodes outside of U that are all adjacent to nodes in U. For any subsets X and Y of V, we define the neighborhood of X in Y, $N_Y(X)$, as the subset of nodes in Y, but not in X, that are adjacent to some node in X, i.e., $N_Y(X) = \{y \in (Y \setminus X) \ : \ (x,y) \in E, x \in X\}$. If the set Y is not specified, assume $Y = V$. Let $U_i^L = U \cap L_i$ and $U_i^R = U \cap R_i$ for all $0 \le i \le k$. We consider two cases, according to whether the size of U_k^L is greater than $2|L_k|/3$ or not.

Case 1. If $|U_k^L| > 2|L_k|/3$, then let W^L (resp., W^R) be the union of the sets U_j^L (resp., U_j^R) of size greater than $2|L_j|/3$ (resp., $2|R_j|/3$) such that there is no U_q^L (resp., U_q^R), $q > j$, of size less than or equal to $2|L_q|/3$ (resp., $2|R_q|/3$). Let ℓ (resp., r) be the minimum index of a set U_j^L in W^L (resp., U_t^R in W^R). In case no such j (resp., t) exists, let $\ell = 0$ (resp., $r = 0$). Let $\mathcal{S}$ denote $(\cup_{j=\ell}^{k} L_j) \cup (\cup_{j=r}^{k-1} R_j)$, and let $W = W^L \cup W^R$. Note that since $|U_j^L| > 2|L_j|/3$ for all $j \geq \ell$ and $|U_j^R| > 2|R_j|/3$ for all $j \geq r$, there are at most $3|W|/2$ nodes in $\mathcal{S}$. Furthermore, since the set U has at most $n/2$ nodes, there are at most $3n/4$ nodes in $\mathcal{S}$. Hence, there are at least $n/4$ nodes that are not in $\mathcal{S}$, and so we must have either $\sum_{i=0}^{\ell-1} |L_i| \geq n/8$ or $\sum_{i=0}^{r-1} |R_i| \geq n/8$. Assume without loss of generality that the former is true. This implies that $|L_\ell| > \mu_0 n/8$.

We will account for the node expansion of U using the neighborhood of U_ℓ^L in $L_{\ell-1} \setminus U_{\ell-1}^L$. If $|U_\ell^L| < 3|L_\ell|/(4(1+\mu_0))$ (implying that $\mu_0 < 1/8$, since $|U_\ell^L| > 2|L_\ell|/3$), then

$$\begin{aligned}|N_{L_{\ell-1}}(U_\ell^L) \setminus U_{\ell-1}^L| &\geq \frac{(1+\mu_0)2|L_\ell|}{3} - \frac{2|L_{\ell-1}|}{3} = \frac{2|L_\ell|}{3}\left((1+\mu_0) - \frac{1}{(1+\mu_0)}\right)\\ &> \frac{2|L_\ell|\mu_0(2+\mu_0)}{3(1+\mu_0)} > \mu_0|L_\ell| > \frac{\mu_0^2 n}{8}\end{aligned}$$

(the second-to-last inequality follows from $(2+\mu_0)/(1+\mu_0) > 3/2$). Otherwise, any subset of $|U_\ell^L|$ of size $3|L_\ell|/(4(1+\mu_0))$ has at least $(1+\mu_0)3|L_\ell|/(4(1+\mu_0))$ neighbors in $L_{\ell-1}$. Thus

$$\begin{aligned}|N_{L_{\ell-1}}(U_\ell^L) \setminus U_{\ell-1}^L| &\geq \frac{(1+\mu_0)3|L_\ell|}{4(1+\mu_0)} - \frac{2|L_{\ell-1}|}{3} = |L_\ell|\left(\frac{3}{4} - \frac{2}{3(1+\mu_0)}\right)\\ &> \frac{9\mu_0|L_\ell|}{12(1+\mu_0)} > \frac{\mu_0|L_\ell|}{2} > \frac{\mu_0^2 n}{16}.\end{aligned}$$

We obtained the second-to-last inequality by substituting $1+\mu_0$ by $4/3$ in the denominator of the left-hand side of the inequality.

Hence, in Case 1 we have at least $\mu_0^2 n/16 \geq \mu_0^2|U|/8$ nodes not in U that are adjacent to the nodes in U.

Case 2. If $|U_k^L| \leq 2|L_k|/3$, then each set U_i^L and each set U_j^R is considered in exactly one of the following subcases. We prove the results that follow for the sets U_j^L's only. Similar results hold if we replace U_j^L by U_j^R and L_j by R_j in the two subcases below.

Case 2.1. Let i be the maximum index such that $|U_i^L| > 2|L_i|/3$ and $|U_{i+1}^L| \leq 2|L_{i+1}|/3$. If $|U_{i+1}^L| \leq |L_{i+1}|/3$, then the neighbors of U_i^L in L_{i+1} that are not in U_{i+1}^L can account for the node expansion of $\cup_{j=0}^{i+1} U_j^L$, because

$$\begin{aligned}|N_{L_{i+1}}(U_i^L) \setminus U_{i+1}^L| &> \frac{(1+\mu_0)2|L_i|}{3} - \frac{|L_{i+1}|}{3} = \frac{|L_{i+1}|}{3}\\ &> \frac{\mu_0}{3}\left(\sum_{j=0}^{i}|L_j|\right) \geq \frac{\mu_0}{4}\left(\left(\sum_{j=0}^{i}|L_j|\right) + |L_{i+1}| - 1\right)\\ &\geq \frac{\mu_0}{4}\left(\sum_{j=0}^{i+1}|U_j^L|\right)\end{aligned}$$

(the second-to-last inequality follows from the fact that $|L_{i+1}| = \mu_0(\sum_{j=0}^{i} |L_j|) + 1 \leq [(\sum_{j=0}^{i} |L_j|)/3] + 1$, since $\mu_0 < 1/3$). Otherwise, $|L_{i+1}|/3 < |U_{i+1}^L| \leq 2|L_{i+1}|/3$, and the neighborhood of U_{i+1}^L in L_{i+1} can account for the node expansion of $\cup_{j=0}^{i+1} U_j^L$, since

$$|N_{L_{i+1}}(U_{i+1}^L)| \geq \mu_0 |U_{i+1}^L| > \frac{\mu_0 |L_{i+1}|}{3} > \frac{\mu_0^2}{3}\left(\sum_{j=0}^{i} |L_j|\right)$$
$$\geq \frac{\mu_0^2}{4}\left(\sum_{j=0}^{i} |L_j| + |L_{i+1}| - 1\right) \geq \frac{\mu_0^2}{4}\left(\sum_{j=0}^{i+1} |U_j^L|\right).$$

Case 2.2. Now we consider every U_j^L, $i+2 \leq j \leq k$, that we did not account for in Case 2.1. Any set U_j^L that was not considered in Case 2.1 has size less than or equal to $2|L_j|/3$ by the choice of i in Case 2.1. Thus the neighborhood of each U_j^L in L_j, $i < j \leq k$, has size at least $\mu_0 |U_j^L|$, and so it accounts for the node expansion of U_j^L.

It follows from Cases 1 and 2 that U has at least $(\mu_0^2 |U|)/8 = \mu|U|$ neighbors outside of U in G. ◻

We group the sets R_i's and L_i's into $\mathcal{L}$ and $\mathcal{R}$, groups of $k/2$ consecutive sets, and $\mathcal{M}$, a group of $k+1$ consecutive sets (note that we have $2k+1$ distinct sets). Let $\mathcal{L} = \{L_0, L_1, \ldots, L_{k/2-1}\}$, $\mathcal{R} = \{R_0, R_1, \ldots, R_{k/2-1}\}$, and $\mathcal{M} = \{L_{k/2}, L_{k/2+1}, \ldots, L_{k-1}, L_k\ (= R_k), R_{k-1}, \ldots, R_{k/2}\}$. Our choice for $\mathcal{L}$, $\mathcal{M}$, and $\mathcal{R}$ is such that the number of sets in $\mathcal{L}$ is close to half the number of sets in $\mathcal{M}$.

4.1. It may be expensive to locally balance *G*. We give an initial distribution of tokens on G that has global imbalance of $\Theta((d \log n)/\mu)$. Then we show that the multiport algorithm will take $\Omega(\sqrt{n})$ steps to locally balance G to within $2d$ tokens. Suppose we have the following initial distribution of tokens on G: For every node z in $\mathcal{R}$, $w(z) = m+1$, where m is an integer such that $m \geq 2kd$; for all z in R_i, R_i in $\mathcal{M}$, let $w(z) = m - 2(i-k/2)d$; for all z in L_i, L_i in $\mathcal{M}$, let $w(z) = m - 2(3k/2 - i)d$; for all z in L_i, L_i in $\mathcal{L}$, let $w(z) = m - 2(i + k/2 + 1)d$. Then w is globally balanced to within $\Theta(dk) = \Theta((d \log n)/\mu)$ tokens, but it is not locally balanced to within $2d$ tokens, since $w(v) - w(u) = (k+2)d + 1 \geq 2d + 1$. See Figure 4.1.

We will maintain the invariant that at any step of the multiport algorithm, every node in L_i (resp., R_i) has the same number of tokens for all $0 \leq i \leq k$. The following lemma shows that this invariant holds.

LEMMA 4.2. *Suppose every node in L_i (resp., R_i) had the same number of tokens at the start of the multiport algorithm for all $0 \leq i \leq k$. Then every node in L_i (resp., R_i) has the same number of tokens at any step of the algorithm for all $0 \leq i \leq k$.*

Proof. We prove this lemma using induction, and without loss of generality, we will prove it for the sets L_i only. Suppose that every node in L_i had the same number of tokens at time step $t-1$. A node x in L_i sends a token to one of its neighbors y in L_{i+1} only if it has at least $2d+1$ more tokens than y. Thus if at time t, x sends a token to some y in L_{i+1}, then it sends a token to all of its neighbors in L_{i+1}, since all of them had the same number of tokens at time $t-1$. Note that x has at least $2d+1$ tokens and x has at most d neighbors. Hence at time t, every edge between L_i and L_{i+1} is traversed by a token. Since every node in L_{i+1} is adjacent to the same number of nodes in L_i, they all receive the same number of tokens from L_i. We can use a similar argument for tokens that move from L_i to L_{i-1}. For $i = k$, consider only tokens moving from L_k ($= R_k$) to L_{k-1} (and R_{k-1}). No token moves between any two nodes in L_i, since all nodes in L_i had the same number of tokens at time $t-1$ (thus we can ignore the edges inside each set L_i and R_i). □

Now we prove the main theorem in this section for the multiport model.

THEOREM 4.3. *The multiport algorithm may take $\Omega(\sqrt{n})$ steps to locally balance G, even if G is globally balanced to within $\Theta((d \log n)/\mu)$ tokens initially.*

Proof. Assume we have a initial token distribution on G as defined above. The number of nodes in $\mathcal{R}$, as well as in $\mathcal{L}$, is proportional to $|R_{k/2-1}| = (1+\mu_0)^{k/2-1} = (1+\mu_0)^{\frac{\log n}{2\log(1+\mu)}-1} > \sqrt{n}/(1+\mu_0) > \sqrt{n}/2$. We claim that in order for G to be locally balanced to within $2d$ tokens, we need to move at least $\sqrt{n}/2$ tokens from $\mathcal{R}$ to $\mathcal{L}$ across edge e. Since at most one token at a time can traverse e, this will require time $\Omega(\sqrt{n})$. Our proof proceeds as follows.

(1) Since every node in R_j (resp., L_j) for $0 \le j \le k/2-1$ is identical with respect to both the number of tokens it has (by Lemma 4.2) and the number of neighbors it sees in R_{j-1} and R_{j+1} (resp., L_{j-1} and L_{j+1}), we observe that the tokens in G flow as follows. Tokens will be sent from v to u across edge e until u has $2d+1$ more tokens than a node in L_1. Then, every node in L_1 receives a token from u. This process continues until the nodes in L_1 each have at least $2d+1$ more tokens than a node in L_2. Then every node in L_1 will send a token to each of its neighbors in L_2 (by Lemma 4.2, every node in L_2 receives the same number of tokens from the nodes in L_1). Continuing in this fashion, the flow of tokens in $\mathcal{L}$ will proceed only from left to right, i.e., tokens never move from L_i to L_{i-1}, or inside L_i, for all L_i in $\mathcal{L}$. In parallel, as the number of tokens in v gets small, the nodes in R_1 will all send a token to v. When the nodes in R_1 have each sent $2d+1$ tokens to v, the nodes in R_2 will all send a token to each of its neighbors in R_1, etc. Thus, as in $\mathcal{L}$, the tokens also flow only from left to right in $\mathcal{R}$ (i.e., tokens never move from R_i to R_{i+1}, or inside R_i, for all R_i in $\mathcal{R}$). Thus, no token ever moves from $\mathcal{R}$ to $\mathcal{M}$ or from $\mathcal{M}$ to $\mathcal{L}$.

(2) Now we show that only after $\sqrt{n}/2$ steps have elapsed can we have (i) $w(x) - w(y) \le 2d$ for all x in L_i for all y in L_{i+1} for all L_i in $\mathcal{L}$, i.e., $\mathcal{L}$ is locally balanced, and (ii) $w(u) > m - (k+2)d$. Suppose we reach such a configuration at some time t. Then every node in $\mathcal{L}$ has at least one more token than it had initially (since $w(u) = m-(k+2)d$ and $w(x) - w(y) = 2d$ for all x in L_i, y in L_{i+1}, and L_i in $\mathcal{L}$, initially). That is, we have at least $|\mathcal{L}| \ge \sqrt{n}/2$ "extra" tokens in $\mathcal{L}$ at time t, all of which have reached $\mathcal{L}$ by traversing e from v to u, since no token moves from $\mathcal{M}$ to $\mathcal{L}$. Hence $t \ge \sqrt{n}/2$.

(3) We also show that only after $\sqrt{n}/2$ steps have elapsed can we have (i) $w(y) - w(x) \le 2d$ for all x in R_i for all y in R_{i+1} for all R_i in $\mathcal{R}$, i.e., $\mathcal{R}$ is locally balanced, and (ii) $w(v) \le m - kd$. A counting argument (similar to the one above) on the number of tokens in $\mathcal{R}$ and the fact that no token is ever sent from $\mathcal{R}$ to $\mathcal{M}$ is sufficient to show this.

From (2) and (3), we conclude that on each of the first $\sqrt{n}/2$ steps the following holds: Either $w(u) \le m-(k+2)d$ and $w(v) > m - kd$, and so v sends a token to u, or the subnetwork induced by $\mathcal{L} \cup \mathcal{R}$ is not $2d$-locally balanced. Thus G is not locally balanced before the first $\sqrt{n}/2$ steps. Hence the algorithm takes $\Omega(\sqrt{n})$ time to locally balance G. □

A similar result holds for the single-port model. Assume we have the following initial distribution of tokens: for every node z in $\mathcal{R}$, $w(z) = m+1$, where m is an integer such that $m \ge k$; for all z in R_i, R_i in $\mathcal{M}$, let $w(z) = m+k/2-i$; for all z in L_i,

L_i in $\mathcal{M}$, let $w(z) = m-(3k/2-i)$; for all z in L_i, L_i in $\mathcal{L}$, let $w(z) = m-(i+k/2+1)$.

The arguments used in the proof of Theorem 4.3 can be easily modified to hold for the single-port model with the initial distribution of tokens defined above, since the lower bound on the number of steps required to reach a locally balanced state is given only in terms of how many tokens traverse the edge e. Lemma 4.2, which is used to show that no token moves from $\mathcal{M}$ to $\mathcal{L}$ without traversing edge e, no longer holds in the single-port model. Instead, we prove Lemma 4.4, which implies that no token moves from $\mathcal{M}$ to $\mathcal{L}$ without traversing edge e, as stated in Corollary 4.5. Recall that in the single-port algorithm, a token moves from node x to node y at some step only if edge (x, y) is selected to be in the matching, and x has at least two more tokens than y, at that step.

We first prove Lemma 4.4, from which we derive Corollary 4.5. Let M denote the set of tokens in $\mathcal{M}$ either that were initially in $\mathcal{M}$ or that moved from $\mathcal{R}$ to $\mathcal{M}$ without using the edge e (i.e., tokens that moved from $\mathcal{R}$ to $\mathcal{M}$ through some node in $R_{k/2}$) at any step of the single-port algorithm. Without loss of generality, assume that if a node in $\mathcal{M}$ sends a token at step t of the algorithm, it will send a token that is not in M if it has one for all t.

LEMMA 4.4. *At any step of the single-port algorithm for any node x in $\mathcal{M}$, the number of tokens on x that belong to M is at most the total number of tokens on x initially.*

Proof. By definition, a token in M is either a token that was in $\mathcal{M}$ initially or a token that moved from $\mathcal{R}$ to $\mathcal{M}$ through some node in $R_{k/2}$. Suppose, for the sake of contradiction, that at step t, a node x in $\mathcal{M}$ has one more token in M than it had initially. Assume x had b tokens initially. There exists a sequence of nodes $x = x_1, \ldots, x_p$ such that (i) x_i is adjacent to x_{i+1} in G, (ii) x_i had at least $b+i$ tokens at time t_i, (iii) $t_p < \cdots < t_1 = t$, and (iv) x_p is in $R_{k/2}$ and x_i, $i \neq p$, is not in $R_{k/2}$. There are two cases to consider.

(1) If no x_i is in $\mathcal{L}$ (i.e., every node x_i is in $\mathcal{M}$), then let q be the distance in $\mathcal{M}$ from x to x_p. Thus x_p has at least $b+p \geq b+q+1 = m+1$ tokens at time t_p. But no node in $R_{k/2}$ can have $m+1$ tokens, since $m+1$ is the maximum number of tokens in G initially, and no node in $R_{k/2}$ had that many tokens initially.

(2) Otherwise, let x_j (resp., $x_{j'}$) be the first (resp., last) node in the sequence that is not in $\mathcal{M}$. Then x_{j-1} and $x_{j'+1}$ belong to $L_{k/2}$. Let q be the distance from v to x_{j-1} in $\mathcal{M}$. Then $x_{j'+1}$ has at least $b+p \geq b+q+2 \geq (m-k)+q+1$ tokens at step $t_{j'+1}$. Thus x_p has at least $b+q+k+2 \geq m+q+1 \geq m+1$ tokens at step t_p, a contradiction (see item (1)). □

COROLLARY 4.5. *No token initially in $\mathcal{M} \cup \mathcal{R}$ ever moves from $\mathcal{M}$ to $\mathcal{L}$ without traversing edge e.*

Proof. By Lemma 4.4, no node x in $L_{k/2}$ will ever have more tokens in M than it had initially. Since the number of tokens on x at the beginning of the algorithm, $m-k$, is minimal (over the entire network), it follows that x will have exactly $m-k$ tokens that belong to M at any step of the algorithm. Thus x will never send a token that belongs to M to any other node in G. Since a token can move from $\mathcal{M}$ to $\mathcal{L}$ only through some node in $L_{k/2}$, the corollary follows. □

Any edge is selected independently with probability $O(1/d)$ at each iteration of the single-port algorithm. Thus an edge e is selected, on average, an $O(1/d)$ fraction of the time. Hence, we can show that it will take $\Omega(d\sqrt{n})$ expected time for G to be locally balanced to within one token in the single-port model, even if initially G is globally balanced to within $O((\log n)/\mu)$ tokens, as stated in the theorem below.

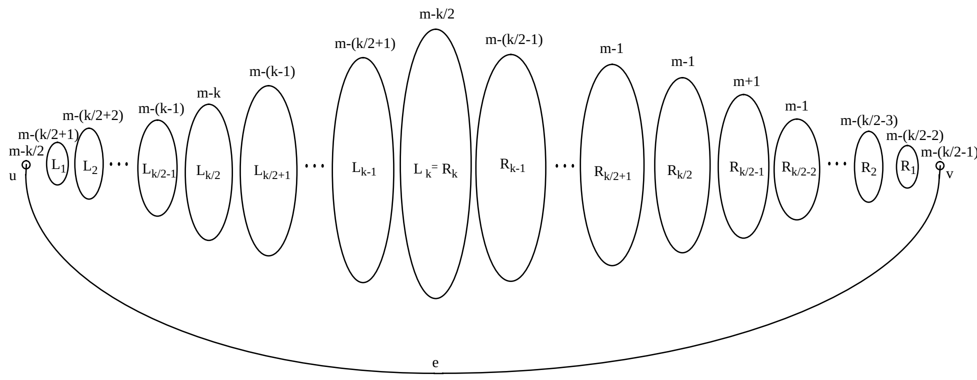

FIG. 4.2. *The initial distribution of tokens on G for the second case.*

THEOREM 4.6. *The single-port algorithm may take $\Omega(d\sqrt{n})$ expected number of steps to locally balance G to within one token, even if G is globally balanced to within $O((\log n)/\mu)$ tokens initially.*

4.2. The single-port algorithm may diverge from an almost locally balanced state. In this section we consider the single-port model only. Suppose we have the following distribution of tokens on G: for all z in $R_{k/2-1}$, let $w(z) = m + 1$ (where m is an integer such that $m \geq k$), and for all z in R_i, $i \leq k/2 - 2$ (note that $R_i \in \mathcal{R}$), let $w(z) = m - (k/2 - i - 1)$; for all z in $R_{k/2}$, let $w(z) = m - 1$; for all z in R_i, $i \geq k/2 + 1$ (note that $R_i \in \mathcal{M}$), let $w(z) = m - (i - k/2)$; for all z in L_i, L_i in $\mathcal{M}$, let $w(z) = m - (3k/2 - i)$; for all z in L_i, L_i in $\mathcal{L}$, let $w(z) = m - (k/2 + i)$. Thus w is globally balanced to within $O((\log n)/\mu)$ tokens but it is not locally balanced to within one token, since $w(x) - w(y) = 2$, for any x in $R_{k/2-1}$ and y in $R_{k/2} \cup R_{k/2-2}$. See Figure 4.2.

The intuition for this case is that if all tokens move in the "right direction" initially, we reach a locally balanced state in a single time step. Otherwise, if a large number of tokens move in the "wrong direction" in the first step, it will take many steps until we reach such a state. If every node in $R_{k/2-1}$ is matched with some node in $R_{k/2}$ (we can construct G such that every node in $R_{k/2-1}$ has a distinct neighbor in $R_{k/2}$), G reaches local balance in a single time step. On the other hand, if some tokens move across a matching between the nodes in $R_{k/2-1}$ and $R_{k/2-2}$, then these tokens will continue moving "down" (nondecreasing indices of R_i) and will never move "up." The expected size of such a matching will be $\Omega(|R_{k/2-1}|/d)$ (each node in $R_{k/2-1}$ has $d/(2(2 + \mu_0)) \geq d/5$ neighbors in $R_{k/2-2}$). Using an analysis similar to that of section 4.1 for the single-port model, we see that no token that was initially in $\mathcal{M} \cup \mathcal{R}$ moves from $\mathcal{M}$ to $\mathcal{L}$ without traversing edge e and that either $w(v) > m - k/2 + 1$ and $w(u) \leq m - k/2$ or $\mathcal{L} \cup \mathcal{R}$ is not locally balanced for each of the $\Omega(|R_{k/2-1}|/d)$ initial steps. Thus, once any of the tokens that moved from $R_{k/2-1}$ to $R_{k/2-2}$ in the first step reaches v, it will eventually traverse e onto u.

Hence, eventually all tokens that moved from $R_{k/2-1}$ to $R_{k/2-2}$ in the initial step will reach u. Since $|R_{k/2-1}| \geq \mu\sqrt{n}/((1 + \mu_0)^2)$ and $1 < (1 + \mu_0)^2 < 2$, the expected number of edges between nodes in $R_{k/2-1}$ and nodes in $R_{k/2-2}$ in a selected matching is $\Omega(|R_{k/2-1}|/d) = \Omega(\mu\sqrt{n}/d)$. The expected time for edge e to be in a selected matching is at least d. Thus the expected time for G to be locally balanced to within one token is $\Omega(\mu\sqrt{n})$. This result is stated in the following theorem.

THEOREM 4.7. *There exists an initial distribution of tokens from which the network G can be locally balanced to within one token in one step, but for which the expected number of steps required by the single-port algorithm to locally balance G to within one token is $\Omega(\mu\sqrt{n})$.*

4.3. Convergence to a locally balanced state. We now prove that if the graph G is globally balanced to within Δ tokens, in $O(n\Delta^2/d)$ subsequent steps the multiport algorithm locally balances G to within $2d$ tokens. Define the potential Φ of the network as $\sum_{v\in V}(w(v)-\rho)^2$. If the network is globally balanced to within Δ tokens, then $\Phi = O(n\Delta^2)$. At any step, if there exists an edge (u,v) such that $|w(u)-w(v)| \geq 2d+1$, then a token is transmitted along (u,v) resulting in a potential drop of at least d. Thus, within $O(n\Delta^2/d)$ steps the network is globally balanced. Similarly, it is not difficult to show that if the graph G is globally balanced to within Δ tokens, then the single-port algorithm locally balances to within one token in $O(nd\Delta^2)$ subsequent steps with high probability, since a token transmitted along an edge results in a potential drop of at least one and an edge is selected with probability at least $1/(8d)$.

5. Extension to dynamic and asynchronous networks. In this section, we extend our results of section 3.2 for the multiport model to dynamic and asynchronous networks. We first prove that a variant of the local multiport algorithm is optimal on dynamic synchronous networks in the same sense as for static synchronous networks. We then use a result of [2] that relates the dynamic synchronous and asynchronous models to extend our results to asynchronous networks.

In the dynamic synchronous model, the edges of the network may fail or succeed dynamically. An edge $e \in E$ is *live* during step t if e can transmit a message in each direction during step t. We assume that in each step each node knows which of its adjacent edges are live. The local load balancing algorithm for static synchronous networks can be modified to work on dynamic synchronous networks. The algorithm presented here is essentially the same as in [2].

Since edges may fail dynamically, a node u may have no knowledge of the height of a neighboring node v and hence may be unable to decide whether to send a token to v. In our algorithm, which we call **DS**, every node u maintains an estimate $e^u(v)$ of the number of tokens at v for every neighbor v of u. (The value of $e^u(v)$ at the start of the algorithm is arbitrary.) In every step of the algorithm, each node u performs the following operations:

(1) For each live neighbor v of u, if $w(u) - e^u(v) > 12d$, u sends a message consisting of $w(u)$ and a token; otherwise, u sends a message consisting only of $w(u)$. Next, $w(u)$ is decreased by the number of tokens sent.

(2) For each message received from a live neighbor v, $e^u(v)$ is updated according to the message, and if the message contains a token, $w(u)$ is increased by one.

Unlike the algorithm for static networks, the above algorithm may (temporarily) worsen the imbalance since a node may have an old estimate of the height of one of its neighbors. Two anomalies may occur while executing **DS**: (i) a token sent by u to v may gain height as it is possible for $w(u)-e^u(v)$ to be greater than $12d$ even if $w(u)$ is at most $w(v)$, and (ii) node u may not send a token to v as it is possible for $w(u)-e^u(v)$ to be at most $12d$ even if $w(u) - w(v)$ is much larger than $12d$. Consequently, the analysis for dynamic networks is more difficult than for static networks. We employ a more complicated amortized analysis to account for the above anomalies.

For every integer i, let S_i denote the set of nodes that have at least $\rho - 12d + 24id$ and at most $\rho + 12d - 1 + 24id$ tokens. Consider T steps of **DS**. We assume without loss of generality that $|S_{>0}| \leq n/2$ at the start of at least $T/2$ steps. As shown in section 2, there exists an index j in $[1, 2\lceil \log_{(1+\alpha/(2d))} n \rceil]$ that is good in at least half of those steps in which $|S_{>0}| \leq n/2$. (Recall that index i is good if $|S_i| \leq \alpha |S_{>i}|/2d$.) If index j is good at the start of step t, we call t a *good* step. For any token p, let $h_t(p)$ denote the height of p after step t, $t > 0$. For convenience, we denote the height of p at the start of **DS** by $h_0(p)$. Similarly, for $t \geq 0$, we define $h_t(u)$ for every node u and $e_t^u(v)$ for every edge (u, v).

With every token at height h, we associate a potential of $\phi(h)$, where $\phi : N \to R$ is defined as follows:

$$\phi(x) = \begin{cases} 0 & \text{if } x \leq 24jd - 11d, \\ (1+\nu)^x & \text{otherwise,} \end{cases}$$

where $\nu = \alpha/(cd^2)$ and $c > 0$ is a constant to be specified later. Let Φ_t denote the total potential of the network after step t. Let Ψ_t denote the potential drop during step t.

We analyze **DS** by means of an amortized analysis over the steps of the algorithm. Let E_t be the set $\{(u, v) : (u, v) \text{ is live during step } t,\ u \in S_{>j}, \text{ and } h_{t-1}(u) - h_{t-1}(v) \geq 24d\}$. For every step t, we assign an amortized potential drop of

$$\hat{\Psi}_t = \frac{1}{50} \sum_{\substack{(u,v)\in E_t \\ h_{t-1}(u) > h_{t-1}(v)}} (\phi(h_{t-1}(u) - d) - \phi(h_{t-1}(v) + d)).$$

The definition of $\hat{\Psi}_t$ is analogous to the amount of potential drop that we use in step t in the argument of section 3.2 for the static case. By modifying that argument slightly and choosing appropriate values for the constants c and ε, we show the following lemma.

LEMMA 5.1. *If the live edges of G have an edge expansion of α during every step of* **DS**, *then for every good step t we have $\hat{\Psi}_t \geq \varepsilon \nu^2 d^2 \Phi_{t-1}$, where ε is an appropriately chosen constant.*

Proof (sketch). Let M_i denote the set of live edges between nodes in $S_{<i}$ and nodes in $S_{>i}$. Let $m_i = |M_i|$. For any node u, let $g(u)$ represent the group to which u belongs prior to step t. We now place a lower bound on $\hat{\Psi}_t$ which is analogous to that on Ψ in Lemma 3.6 of section 3.2. By the definition of $\hat{\Psi}_t$, we have

$$\begin{aligned}
\hat{\Psi}_t &= \frac{1}{50} \sum_{\substack{(u,v)\in E_t \\ h_{t-1}(u) > h_{t-1}(v)}} (\phi(h_{t-1}(u) - d) - \phi(h_{t-1}(v) + d)) \\
&\geq \frac{1}{50} \sum_{\substack{(u,v)\in E_t \\ h_{t-1}(u) > h_{t-1}(v)}} \sum_{g(v)<i<g(u)} (\phi(24(i+1)d - 13d) - \phi(24(i-1)d + 13d)) \\
&= \frac{1}{50} \sum_{i\geq j} \sum_{\substack{(u,v)\in M_i \\ h_{t-1}(u) > h_{t-1}(v)}} (\phi(24(i+1)d - 13d) - \phi(24(i-1)d + 13d)) \\
&= \frac{1}{50} \sum_{i>j} \sum_{\substack{(u,v)\in M_i \\ h_{t-1}(u) > h_{t-1}(v)}} (\phi(24(i+1)d - 13d) - \phi(24(i-1)d + 13d)) \\
&\quad + \frac{1}{50} \sum_{\substack{(u,v)\in M_j \\ h_{t-1}(u) > h_{t-1}(v)}} \phi(24(j+1)d - 13d)
\end{aligned}$$

$$\geq \frac{22}{50}\sum_{i>j}\sum_{\substack{(u,v)\in M_i\\ h_{t-1}(u)>h_{t-1}(v)}} \nu d(1+\nu)^{24id-11d} + \frac{1}{50}\sum_{\substack{(u,v)\in M_j\\ h_{t-1}(u)>h_{t-1}(v)}} (1+\nu)^{24jd+11d}$$

$$\geq \frac{22}{50}\sum_{i>j} m_i \nu d(1+\nu)^{24id-11d} + \frac{1}{50} m_j (1+\nu)^{24jd+11d}.$$

(For the second equation, note that $24id-13d \leq 24(i-1)d+13d$. Therefore, $\phi(24id-13d) \leq \phi(24(i-1)d+13d)$. The second equation now follows since the sum telescopes. The third equation is obtained by interchanging the sums and noting that $\phi(x)$ is zero for $x \leq 24jd-11d$. The fourth equation is obtained by partitioning the set M into subsets $M \setminus M_j$ and M_j. The fifth equation uses the following calculations: (i) $\phi(24id+11d)-\phi(24id-11d) \geq ((1+\nu)^{22d}-1)(1+\nu)^{24id-11d} \geq 22d(1+\nu)^{24id-11d}$, (ii) $\phi(24jd+11d)=(1+\nu)^{24jd+11d}$, and (iii) $\phi(24jd-11d)=0$. The last equation follows from the definition of m_i.)

We next establish claims similar to Lemma 3.7 and Corollary 3.8 of section 3.2 by modifying the constants in the proofs. Thus we have $\hat{\Psi}_t \geq \varepsilon\nu^2 d^2 \Phi_{t-1}$ for an appropriately chosen constant ε. □

The following lemma relates the amortized potential drops to the actual potential drops.

Lemma 5.2. *For any initial load distribution and any step $t' > 0$, we have*

$$\sum_{t\leq t'} \Psi_t \geq \left(\sum_{t\leq t'} \hat{\Psi}_t\right) - 2\Phi_0 - n^2\phi(24jd). \tag{5.1}$$

In order to prove Lemma 5.2, we need to address two issues that arise in the dynamic setting: (i) potential gains, i.e., when a token gains height, and (ii) the lack of a potential drop across edges that join nodes differing by at least $24d$ tokens. We show that for any of the above events to occur, "many" tokens should have lost height in previous steps. We use a part of this prior potential drop to account for (i) and (ii). At a high level, our proof follows the lines of Lemma 3 of [2]. However, since the potential functions involved are different, the two proofs differ considerably in the details. We have included a complete proof of Lemma 5.2 in Appendix B.

The main result follows from Lemmas 5.1 and 5.2. We first show that within $O(1/(\varepsilon\nu^2 d^2))$ steps, there is a step when the actual potential of the network either decreases by a factor of 2 or falls below a threshold value.

Lemma 5.3. *Let t be any integer such that at least $7/(\varepsilon\nu^2 d^2)$ of the first t steps are good. There exists $t' \leq t$ such that $\Phi_{t'} \leq \max\{\Phi_0/2, n^2\phi(24jd)\}$.*

Proof. If $\Phi_0 \leq n^2\phi(24jd)$, then the claim is proved for $t=0$. For the remainder of the proof, we assume that $\Phi_0 \geq n^2\phi(24jd)$. If $\Phi_{t'} \leq \Phi_0/2$ for any $t' < t$, the claim is proved. Otherwise, for all $t' < t$, we have $\Phi_{t'} > \Phi_0/2$. In this case, we obtain

$$\begin{aligned}\Phi_t &= \Phi_0 - \sum_{t'<t}\Psi_{t'}\\ &\leq 3\Phi_0 + n^2\phi(24jd) - \sum_{t'<t}\hat{\Psi}_{t'}\\ &\leq 4\Phi_0 - \sum_{\substack{t'<t\\ t'\text{good}}} (\varepsilon\nu^2 d^2)\Phi_{t'}\\ &\leq \Phi_0/2.\end{aligned}$$

(To obtain the second equation, we invoke Lemma 5.2. For the third equation, we invoke Lemma 5.1 and use the inequalities $\Phi_0 \geq n^2\phi(24jd)$ and $\hat{\Psi}_{t'} \geq 0$ for every t'. For the last equation, we use the fact that at least $7/(\varepsilon\nu^2 d^2)$ of the t steps are good and the equation $\Phi_{t'} > \Phi_0/2$ for every $t' < t$.) ∎

THEOREM 5.4. *For an arbitrary network G with n nodes, degree d, and initial imbalance Δ, if the live edges at every step t of G have edge expansion α, then the dynamic synchronous multiport algorithm load balances to within $O(d^2(\log n)/\alpha)$ tokens in $O(\Delta/\alpha)$ steps.*

Proof. We first place an upper bound on the number t of steps such that the height of each node at the end of step t is $O(d^2(\log n)/\alpha^2)$. If Δ is at most $d^2(\log n)/\alpha^2$, then a trivial bound is 0.

We now consider the case when Δ is at least $d^2(\log n)/\alpha^2$. By repeatedly invoking Lemma 5.3, we obtain that within $T = \lceil(7/(\varepsilon\nu^2 d^2))\rceil\lceil\log\Phi_0\rceil$ good steps, there exists a step after which the potential of the network is at most $n^2\phi(24jd)$. (Note that the fact that Lemma 5.2 holds for arbitrary initial values of the estimates, the $e^u(v)$'s, is crucial here.) Since at least $T/4$ of the first T steps are good, there exists $t \leq 4\lceil(7/(\varepsilon\nu^2 d^2))\rceil\lceil\log\Phi_0\rceil$ such that $\Phi_t \leq n^2\phi(24jd)$. Since $\Phi_0 \leq n(1+\nu)^{(\Delta+1)}/\nu$, we have $\log\Phi_0 \leq \log n + (\Delta+1)\log(1+\nu) - \log\nu$. Since $\nu = \alpha/(cd^2)$ and $\log(1+\nu) < \nu$, we have $t = O((\Delta/\alpha) + d^2(\log n)/\alpha^2) = O(\Delta/\alpha)$.

Let h be the maximum height of any node after step t. We thus have

$$\begin{aligned}\phi(h) &\leq \Phi_t\\ &\leq n^2(1+\nu)^{24jd}.\end{aligned}$$

Therefore, if $\phi(h) > 0$, then $h \leq \log_{(1+\nu)}(n^2(1+\nu)^{24jd})$. If $\phi(h) = 0$, then $h \leq 24jd - 11d$. In either case,

$$\begin{aligned}h &\leq 24jd + (2\log n)/\log(1+\nu)\\ &\leq 24jd + (4\log n)/\nu\\ &= O((d^2\log n)/\alpha).\end{aligned}$$

(The right-hand side of the first equation is an expansion of $\log_{(1+\nu)}(n^2(1+\nu)^{24jd})$. The second equation holds since $\log(1+\nu) < \nu/2$ for c appropriately large. The final inequality follows from the relations $\nu = \alpha/(cd^2)$ and $j = O((d\log n)/\alpha)$.)

Thus, at the end of step t, no node has more than $a = \rho + h$ tokens. We now prove by contradiction that for every step after step t, no node has more than $a + d$ tokens. Let t' be the first step after step t such that there exists some node u with more than $a + d$ tokens. (If no such t' exists, the claim holds trivially.) Of the $d+1$ highest tokens received by u after step t, at least 2 tokens (say p and q) were last sent by the same neighbor v of u. Without loss of generality, we assume that p arrived at u before q. Let t_1 be the step when p was last sent by v to u. Therefore, we have $e^v_{t_1}(u) \geq h_{t_1}(p) - d \geq a - d$. Hence q can be sent to u only when v has height at least $a + 11d$, which contradicts our choice of t'.

We have shown that after $O(\Delta/\alpha)$ steps, no node ever has more than $\rho + O((d^2\log n)/\alpha)$ tokens. An easy averaging argument shows that there exists $k = O((d\log n)/\alpha)$ such that after every step $t' \geq t$, $|S_{<-k}| \leq n/2$. By defining an appropriate potential function for tokens with heights below the average and repeating the analysis done for $S_{>j}$, we show that in another $O(\Delta/\alpha)$ steps, all nodes have more than $\rho - O(d^2(\log n)/\alpha)$ tokens. ∎

As suggested in [2], a simple variant of **DS** can be defined for asynchronous networks. As shown in [2], the analysis for the dynamic synchronous case can be used for asynchronous networks to yield the same time bounds. Hence, the multiport local load balancing algorithm balances to within $O(d^2 \log n/\alpha)$ tokens in time $O(\Delta/\alpha)$ on asynchronous networks.

6. Tight bounds on off-line load balancing. In this section, we analyze the load balancing problem in the off-line setting for both single-port and multiport models. We derive nearly tight bounds on the minimum number of steps required to balance on arbitrary networks in terms of the node and edge expansion of the networks. We assume that the network is synchronous.

We first consider the network $G = (V, E)$ under the single-port model. For any subset X of V, let $\overline{X}$ denote $V \setminus X$, $m(X)$ denote the number of edges in a maximum matching between X and $\overline{X}$, $A(X)$ denote the set $\{v \in \overline{X} : \exists x \in X \text{ such that } (x, v) \in E\}$, and $B(X)$ denote the set $\{x \in X : \exists y \in A(X) \text{ such that } (x, y) \in E\}$. For subsets X and Y of V, let $M(X, Y)$ denote the set of edges with one endpoint in X and the other in Y.

LEMMA 6.1. *For any network $G = (V, E)$ with node expansion μ and any subset X of V, we have $m(X) \le \mu \min\{|X|, |\overline{X}|\}/(1 + \mu)$. Moreover, for any subset X of V, $m(X \cup A(X)) \le |A(X)|$.*

Proof. Without loss of generality, assume that $|X| \le |\overline{X}|$. Consider the bipartite graph $H = (B(X), A(X), M(X, \overline{X}))$. A maximum matching in H is equal to a maximum flow in the graph $I = (B(X) \cup A(X) \cup \{s, t\}, M(X, \overline{X}) \cup \{(s, x) : x \in B(X)\} \cup \{(x, t) : x \in A(X)\})$ from source s to sink t. (All of the edges of I have unit capacity.) We will show that every cut C of I separating s and t is of cardinality at least $\mu|X|/(1 + \mu)$.

Consider any cut $C = (S, T)$ with $s \in S$ and $t \in T$. The set of edges in C is $M(S, T)$. Let $Y = T \cap B(X)$ and $Z = T \cap A(X)$. The capacity of C, given by $|M(S, T)|$, can be lower bounded as follows.

$$\begin{aligned}
|M(S,T)| &= |Y| + |M(Y, A(X) \setminus Z)| + |M(B(X) \setminus Y, Z)| + |A(X) \setminus Z| \\
&\ge |Y| + |M(B(X) \setminus Y, Z)| + |A(X) \setminus Z| \\
&\ge |A(X \setminus Y)| \\
&\ge \mu |X \setminus Y| \\
&= \mu(|X| - |Y|) \\
&\ge \mu|X|/(1 + \mu).
\end{aligned}$$

(For the third equation, see Figure 6.1. Three subsets of nodes contribute to the set $A(X \setminus Y)$: (i) the set of nodes in Y that have an edge to a node in $X \setminus Y$, (ii) the set of nodes in Z that have an edge to a node in $X \setminus Y$, and (iii) the set of nodes in $A(X) \setminus Z$ that have an edge to a node in $X \setminus Y$. The size of the three sets is bounded by $|Y|$, $|M(B(X) \setminus Y, Z)|$, and $|A(X) \setminus Z|$, respectively. The fourth equation follows from the definition of $A(X \setminus Y)$. The fifth equation holds since Y is a subset of X. The last equation holds since $|Y| \le |M(S, T)|$.)

For the second part of the lemma, we note that since all of the neighbors of X are in $A(X)$, any node in $X \cup A(X)$ that connects to some node outside of $X \cup A(X)$ is in $A(X)$. Therefore, $m(X \cup A(X)) \le |A(X)|$. $\square$

Theorem 1 of [29] obtains tight bounds on the off-line complexity of load balancing in terms of the function m. We restate the theorem using our notation and

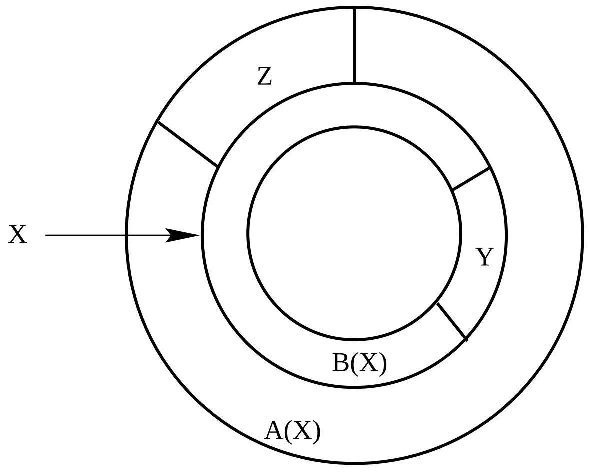

FIG. 6.1. *The sets X, Y, Z, $A(X)$, and $B(X)$ in the proof of Lemma* 6.1.

terminology. Before stating the theorem, we need one additional notation. For any subset X of nodes of any network, let $I(X)$ denote the number of tokens held by nodes in X in the initial distribution.

THEOREM 6.2 (see [29]). *Consider a network $G = (V, E)$ in the single-port model. The network G can be balanced in at most $\max_{\emptyset \subsetneq X \subsetneq V} \lceil (I(X) - \rho|X|)/m(X) \rceil$ steps so that every node has at most $\lceil \rho \rceil + 1$ tokens. Moreover, any algorithm takes at least $\max_{\emptyset \subsetneq X \subsetneq V} \lceil (I(X) - \rho|X|)/m(X) \rceil$ steps to balance the network so that every node has at most $\lceil \rho \rceil$ tokens.* $\square$

Theorem 6.2 and Lemma 6.1 imply the following result.

LEMMA 6.3. *Assume the single-port model. Any network G with node expansion μ and initial imbalance Δ can be balanced in at most $\lceil \Delta(1+\mu)/\mu \rceil$ steps so that every node has at most $\lceil \rho \rceil + 1$ tokens. Moreover, there exist a network G and an initial load distribution with imbalance Δ such that any algorithm takes at least $\lceil \Delta(1+\mu)/\mu \rceil$ steps to balance G such that every node has at most $\lceil \rho \rceil$ tokens.*

Proof. If $I(X)$ is the total number of tokens belonging to nodes in X in the initial distribution, then we have $-\Delta|X| \leq I(X) - \rho|X| \leq \Delta|X|$ for all X. Moreover, $|I(X) - \rho|X|| = |I(\overline{X}) - \rho|\overline{X}||$. Therefore, for all X, $|I(X) - \rho|X|| = \Delta \min\{|X|, |\overline{X}|\}$. By Lemma 6.1, $m(X)$ is at least $\mu \min\{|X|, |\overline{X}|\}/(1 + \mu)$ for all X. Thus, the first claim of Theorem 6.2 establishes the first claim of the desired lemma.

For the second claim of the lemma, given any μ, we construct the following network $G = (V, E)$ with node expansion μ. The node set V is partitioned into three sets X, Y, and Z such that (i) $|Y| = \mu|X|$ and (ii) $|Z| = |X|(1 + \mu)^2/(1 - \mu)$. Let n and x denote $|V|$ and $|X|$, respectively. Thus, n equals $x(1 + \mu + (1 + \mu)^2/(1 - \mu)) = 2x(1 + \mu)/(1 - \mu)$. The edge set E is the union of the sets $X \times X$, $X \times Y$, $Y \times Y$, $Y \times Z$, and $Z \times Z$.

We now show that the node expansion of G is μ. Consider any nonempty subset U of V of size at most $n/2$, and let X', Y', and Z' denote $U \cap X$, $U \cap Y$, and $U \cap Z$, respectively. Let $n(U)$ denote the number of neighbors of U that lie outside of U. We need to show that $n(U)$ is at least $\mu|U|$.

We consider two cases: (i) Y' and Z' are both empty, and (ii) Y' is nonempty or Z' is nonempty. In the first case, $U = X'$. Therefore, $n(U) \geq |Y| = \mu x \geq \mu|U|$. In the second case, we have

$$\begin{aligned} n(U) &\geq |Z| - |Z'| \\ &\geq |Z| - |U| \\ &\geq x((1+\mu)^2/(1-\mu) - (1+\mu)/(1-\mu)) \\ &= x\mu(1+\mu)/(1-\mu) \\ &\geq \mu|U|. \end{aligned}$$

(The second equation holds since Z' is a subset of U. For the third equation, note that $|U| \leq n/2 = x(1+\mu)/(1-\mu)$. The last equation follows from the upper bound of $x(1+\mu)/(1-\mu)$ on $|U|$.)

We now apply the second claim of Lemma 6.1 to the subset X. Since $A(X) = Y$, $m(X \cup Y) = \mu x = \mu|X \cup Y|/(1+\mu)$. Given any Δ, consider the initial token distribution in which each node in $X \cup Y$ has $\rho + \Delta$ tokens and each node in Z has $\rho - \Delta(1-\mu)/(1+\mu)$ tokens, where ρ is any integer that is at least $\Delta(1-\mu)/(1+\mu)$. (Note that the average number of tokens is ρ.) By applying the second claim of Theorem 6.2, we obtain that the number of steps to balance G so that each node has at most ρ tokens is at least $(I(X \cup Y) - \rho|X \cup Y|)/m(X \cup Y) \geq \Delta|X \cup Y|/m(X \cup Y) \geq \Delta(1+\mu)/\mu$. Since the number of steps is an integer, the desired claim follows. □

By using the techniques of [29], we can modify the proof of Lemma 6.3 to show that any network G with node expansion μ and initial imbalance Δ can be globally balanced to within 3 tokens in at most $2\lceil\Delta(1+\mu)/\mu\rceil$ steps. The extra factor of 2 is required because even after balancing the network so that each node has at most $\lceil\rho\rceil + 1$ tokens, there may exist a node with considerably fewer than ρ tokens. It takes an additional $\lceil\Delta(1+\mu)/\mu\rceil$ steps to bring the network to a state in which the global imbalance is at most 3.

Lemma 6.3 implies that the time bound achieved by the single-port algorithm (see Theorems 3.1 and 3.9) is not optimal for all networks. An example of a network for which the single-port algorithm is not optimal is the hypercube, which has maximum degree $\log n$, edge expansion 1, and node expansion $\Theta(1/\sqrt{\log n})$. The local algorithm balances in $\Omega(\Delta \log n)$ time, while there exists an $O(\Delta\sqrt{\log n} + \log^2 n)$ time load balancing algorithm for the hypercube [34] which is optimal for Δ sufficiently large. For the class of constant-degree networks, however, the time taken by the single-port algorithm to reduce the global imbalance to $O(\log n/\mu)$ (see Theorem 3.9) is within a constant factor of the time taken by any algorithm to completely balance the network (see Lemma 6.3).

The proofs of Theorem 1 of [29] and Lemma 6.3 can be modified to establish the following result for the multiport model.

LEMMA 6.4. *Assume the multiport model. Any network G with edge expansion α and initial imbalance Δ can be balanced in at most $\lceil\Delta/\alpha\rceil$ steps so that every node has at most $\lceil\rho\rceil + d$ tokens. Moreover, for every network G, there exists an initial load distribution with imbalance Δ such that any algorithm takes at least $\lceil\Delta/\alpha\rceil$ steps to balance G so that every node has at most $\lceil\rho\rceil$ tokens.*

Proof (sketch). We prove that there exists an off-line algorithm that balances to within d tokens in at most $T = \max_{\emptyset \subset X \subset V} \lceil \frac{|I(X) - \rho|X||}{|M(X,\overline{X})|} \rceil$ steps. For all $X \subseteq V$, we have (i) $|I(X) - \rho|X|| \leq \Delta \min\{|X|, |\overline{X}|\}$ (see proof of Lemma 6.3), and (ii) $|M(X,\overline{X})| \geq \alpha \min\{|X|, |\overline{X}|\}$. It follows from (i) and (ii) that $T \leq \lceil\Delta/\alpha\rceil$.

We modify the proofs of Theorem 1 and Lemma 4 of [29] (where the single-port model was assumed) to establish the desired claims for the multiport model. We transform the load balancing problem on G to a network flow problem on a directed graph $H = (V', E')$, which is constructed as follows. Let V_i be $\{\langle v, i\rangle : v \in V\}$, $0 \le i \le T$. Let E_i be $\{(\langle u, i\rangle, \langle v, i+1\rangle) : (u, v) \in E \text{ or } u = v\}$, $0 \le i < T$. We set V' to $\{s\} \cup \bigcup_{0 \le i \le T} V_i \cup \{t\}$ and E' to $\{(s, \langle v, 0\rangle) : v \in V\} \cup \bigcup_{0 \le i < T} E_i \cup \{(\langle v, T\rangle, t) : v \in V\}$. For any v in V, the capacity of the edge $(s, \langle v, 0\rangle)$ is $w(v)$. For any (u, v) in E, the capacity of any edge $(\langle u, i\rangle, \langle v, i+1\rangle)$, $0 \le i < T$, is 1. For any v in V, the capacity of any edge $(\langle v, i\rangle, \langle v, i+1\rangle)$, $0 \le i < T$, is ∞. For any v in V, the capacity of the edge $(\langle v, T\rangle, t)$ is $\lceil \rho \rceil + d$.

We show that the value of the maximum integral flow in H is equal to the total number of tokens N in V, from which it follows that there exists an off-line algorithm that balances to within d tokens in T steps. Consider any cut $C = (S, T)$ of H separating $s \in S$ and $t \in T$. Let $S_i = S \cap V_i$ and $D(S_i) = \{v \in V : \langle v, i\rangle \in S_i\}$. If $S_0 = \emptyset$, or $S_T = V_T$, or there is an edge of infinite capacity, then the capacity of C is at least N. Otherwise, the number of edges from V_i to V_{i+1} that belong to the cut is at least $|M(D(S_i), \overline{D(S_i)})| - d(|S_{i+1}| - |S_i|)$. Moreover, since there is no edge with infinite capacity in C, $D(S_i)$ is a subset of $D(S_{i+1})$. Thus the capacity of C is at least

$$\begin{aligned}
&I(D(V_0) \setminus D(S_0)) + \left(\sum_{i=0}^{T-1} \Big(|M(D(S_i), \overline{D(S_i)})| - d(|S_{i+1}| - |S_i|)\Big)\right) + (\lceil \rho \rceil + d)|S_T| \\
&\ge I(D(V_0) \setminus D(S_0)) + \left(\sum_{i=0}^{T-1} ((I(D(S_i)) - \rho|S_i|)/T - d(|S_{i+1}| - |S_i|))\right) + (\lceil \rho \rceil + d)|S_T| \\
&\ge I(D(V_0) \setminus D(S_0)) + \left(\sum_{i=0}^{T-1} ((I(D(S_0)) - \rho|S_T|)/T - d(|S_T| - |S_0|))\right) + (\lceil \rho \rceil + d)|S_T| \\
&\ge I(D(V_0) \setminus D(S_0)) + I(D(S_0)) - \rho|S_T| + d|S_0| + \lceil \rho \rceil |S_T| \\
&\ge N.
\end{aligned}$$

(In the first equation, (i) $I(D(V_0) \setminus D(S_0))$ is the capacity of the edges from s to V_0 that belong to the cut, (ii) $|M(D(S_i), \overline{D(S_i)})| - d(|S_{i+1}| - |S_i|)$ is the capacity of the edges from V_i to V_{i+1} that belong to the cut, and (iii) $(\lceil \rho \rceil + d)|S_T|$ is the capacity of the edges from S_T to t that belong to the cut. The second equation follows from the definition of T and the fact that $|D(S_i)| = |S_i|$. For the third equation, note that $D(S_0)$ is a subset of $D(S_i)$ for all i and $|S_T| \ge |S_i|$ for all i. The fourth equation holds since the sum of $|S_{i+1}| - |S_i|$ telescopes. The final equation is obtained since $I(D(V_0)) = N$.) Since the capacity of the cut $(\{s\}, V' \setminus \{s\})$ equals N, the maximum flow in H is N.

To prove the second part of the lemma, given any network G with a partition (V_1, V_2) of its nodes such that $|V_1| \le n/2$ and $|M(V_1, V_2)| = \alpha|V_1|$, we define an initial load distribution with average ρ in which each node in V_1 has $\rho + \Delta$ tokens and each node in V_2 has $\rho - \Delta|V_1|/|V_2|$ tokens. The desired claim holds since at least $\Delta|V_1|$ tokens need to leave the set V_1. $\square$

Lemma 6.4 implies that the local multiport algorithm is asymptotically optimal for *all* networks. As in the single-port case, we can modify the above proof to obtain upper bounds on the off-line complexity of globally balancing a network. We can show that any network G with edge expansion α and initial imbalance Δ can be globally balanced to within $d + 1$ tokens in at most $2\lceil \Delta/\alpha \rceil$ steps.

Appendix A. Some technical inequalities. Let ν equal $\alpha/(cd^2)$. For the following we set c large enough so that $(1 + \nu)^{12d} \le 3/2$. The function ϕ is defined in section 5.

LEMMA A.1. *For any integer x, if $\phi(x) > 0$, then $\phi(x+12d) \le 3\phi(x)/2$.*

Proof. Since $\phi(x) > 0$, we have $\phi(x+12d) = (1+\nu)^{12d}\phi(x) \le 3\phi(x)/2$. (Note that if $\phi(x) = 0$, then $\phi(x+12d)$ may not equal $(1+\nu)^{12d}\phi(x)$.) ∎

LEMMA A.2. *For any integer x we have*

$$\max\{\phi(24jd), \phi(x-12d)\} \ge 2\phi(x)/3.$$

Proof. If $\phi(x-12d) > 0$, then $2\phi(x)/3 \le \phi(x-12d)$ by Lemma A.1. Otherwise, $x - 12d \le 24jd - 11d$, which implies that $x \le 24jd + d$. Therefore, $\phi(x) \le \phi(24jd+d) \le \phi(24jd)(1+\nu)^d \le 3\phi(24jd)/2$. ∎

LEMMA A.3. *For any integers x and y, if $\phi(x) > 0$ and $x - y \ge 11d$, then we have $\phi(x) - \phi(y) \ge 2(\phi(x+11d) - \phi(y))/5$.*

Proof.

$$\begin{aligned}
2(\phi(x+11d) - \phi(y))/5 &= 2(\phi(x+11d) - \phi(x))/5 \\
&\quad +2(\phi(x) - \phi(y))/5 \\
&\le 2(1+\nu)^{11d}(\phi(x) - \phi(x-11d))/5 \\
&\quad +2(\phi(x) - \phi(y))/5 \\
&\le 2(1+\nu)^{11d}(\phi(x) - \phi(y))/5 \\
&\quad +2(\phi(x) - \phi(y))/5 \\
&\le \phi(x) - \phi(y).
\end{aligned}$$

(In the second equation we use $x - 11d \ge y$. In the last equation we use $(1+\nu)^{11d} \le 3/2$.) ∎

Appendix B. Proof of Lemma 5.2. We define a notion of "goodness" of the tokens. Initially, all tokens are unmarked. After any step t, for every token p that is moved along an edge, p is marked *good* if $h_{t-1}(p) - h_t(p) \ge 6d$; otherwise, p is marked *bad*. The marking of tokens that do not move is unchanged.

LEMMA B.1. *For any two bad tokens p_1 and p_2 present at any node v at the start of any step t, if p_1 and p_2 are last sent to v by the same neighbor u of v, then $|h_t(p_1) - h_t(p_2)| > 4d$.*

Proof. Let t_1 (resp., t_2) be the step during which p_1 (resp., p_2) is last sent to v. Without loss of generality, we assume $t_1 < t_2 < t$. Thus we have $h_t(p_1) < h_t(p_2)$. Since u's estimate of the number of tokens at v is updated in step t_1, we have $e^u_{t_1}(v) \ge \rho + h_{t_1}(p_1) - d$. (Note that $e^u_{t_1}(v)$ is u's estimate of the number of tokens at v after step t_1.) Since p_1 remains at v during the interval $[t_1, t_2)$, we find that $e^u_{t'}(v) \ge \rho + h_{t'}(p_1) - d$ for every step t' in $[t_1, t_2)$. In particular, we have $e^u_{t_2-1}(v) \ge \rho + h_{t_2-1}(p_1) - d$. Since u sends p_2 to v in step t_2, $h_{t_2-1}(p_2) \ge h_{t_2-1}(u) - d \ge e^u_{t_2-1}(v) - \rho + 11d \ge h_{t_2-1}(p_1) + 10d$. Since p_2 is bad, we also have $h_{t_2}(p_2) > h_{t_2-1}(p_2) - 6d \ge h_{t_2-1}(p_1) + 4d$. Since $h_t(p_2) = h_{t_2}(p_2)$ and $h_t(p_1) = h_{t_2-1}(p_1)$, the lemma follows. ∎

COROLLARY B.2. *At any time, for any node u and integer $i > 0$, there are at most d bad tokens with heights in $(i, i+4d]$.* ∎

Proof of Lemma 5.2. Consider an arbitrary step t of the algorithm. For every token p transferred from u to v in step t, we assign some credit to every edge adjacent to u or v. Specifically, if p is marked good after step t we assign an *outgoing credit* of $9(\phi(h_{t-1}(p)) - \phi(h_t(p)))/(20d)$ units to every edge adjacent to u and an *incoming credit* of the same amount to every edge adjacent to v. If p is marked bad we assign an outgoing credit of $(\phi(h_t(p)+d) - \phi(h_t(p)))/(20d) + (\phi(h_{t-1}(p)) - \phi(h_{t-1}(p)-d))$

units to every edge adjacent to u and an incoming credit of the same amount to every edge adjacent to v. Also, for each edge (u, v), we assign an *initial credit* of $2\max\{\phi(24jd), \phi(h_0(u) - d) + \phi(h_0(v) - d)\}$ units at the start of the analysis. The total initial credit I is bounded as follows:

$$\begin{aligned} I &\le 2\binom{n}{2}\phi(24jd) + \sum_{(u,v)\in E} 2(\phi(h_0(u) - d) + \phi(h_0(v) - d)) \\ &\le n^2\phi(24jd) + \sum_{u\in V}\sum_{0\le \ell<d} 2\phi(h_0(u) - \ell) \\ &\le n^2\phi(24jd) + 2\Phi_0. \end{aligned}$$

(The first equation follows from the fact that the maximum of two quantities is at most the sum of the particular quantities. We also note that each undirected edge (u, v) appears at most once in the summation. For the second equation, we note that each node has at most d edges. Hence for any node u, the term $2\phi(h_0(u)-d)$ appears in at most d terms of the sum. We complete the derivation of the second equation by observing that $\phi(h_0(u) - \ell)$ is at least $\phi(h_0(u) - d)$ for $0 \le \ell < d$. The third equation is obtained by the fact that $\sum_{0\le\ell<d} \phi(h_0(u) - \ell)$ is at most $\phi(u)$.) The above bound on I corresponds to the negative term in (5.1).

We now show that by using the above accounting method we can account for the amortized potential drop of $(\phi(h_{t-1}(u) - d) - \phi(h_{t-1}(v) + d))/50$ units at step t for every edge $(u, v) \in E_t$. To accomplish this, for every live edge (u, v) ((u, v) not necessarily in E_t), we consider three cases: (i) a token p sent from u to v is marked good, (ii) a token p sent from u to v is marked bad, (iii) no token is sent from u to v.

We first consider case (i). When a token p is marked good after being sent along (u, v), we use the actual potential drop of p to pay for the amortized drop D_1 associated with (u, v) as well as the total credit D_2 assigned to the edges adjacent to u or v due to the transfer of a good token.

$$\begin{aligned} D_1 + D_2 &\le (\phi(h_{t-1}(u) - d) - \phi(h_{t-1}(v) + d))/50 + 2d[9(\phi(h_{t-1}(p)) - \phi(h_t(p)))]/(20d) \\ &\le (\phi(h_{t-1}(p)) - \phi(h_t(p)))/50 + 9(\phi(h_{t-1}(p)) - \phi(h_t(p)))/10 \\ &\le \phi(h_{t-1}(p)) - \phi(h_t(p)). \end{aligned}$$

(The first term in the right-hand side of the first equation is the amortized potential drop. The second term is an upper bound on D_2, since the number of edges adjacent to either u or v is at most $2d$. The second equation follows from the fact that $h_{t-1}(p)$ is at least $h_{t-1}(u) - d$ and $h_t(p)$ is at most $h_t(u) + d$.)

We now consider case (ii). In this case we need to account for (1) if $h_t(p) > h_{t-1}(p)$, an amount equal to the potential increase of $D_1 = \phi(h_t(p))-\phi(h_{t-1}(p))$ units, and (2) a credit of at most $(\phi(h_t(p) + d) - \phi(h_t(p)))/10 + (\phi(h_{t-1}(p)) - \phi(h_{t-1}(p) - d))/10$ units. We pay for $(\phi(h_{t-1}(p)) - \phi(h_t(p)))/10$ units of the credit using the potential change. The remainder of the credit we need to account for is at most the sum of $D_2 = (\phi(h_t(p) + d) - \phi(h_t(p)))/10$ and $D_3 = (\phi(h_t(p)) - \phi(h_{t-1}(p) - d))/10$. (Note that this is true regardless of whether the potential of p decreases in step t.)

We have two subcases, depending on whether t is the first step in which (u, v) is live (subcase (a)) or not (subcase (b)). In subcase (a), if $h_0(u) \ge h_t(p) - d$, the initial credit C_0 associated with (u, v) is at least $2\max\{\phi(24jd), \phi(h_t(p) - 2d)\}$. Since $\phi(h_t(p) - 2d) \ge \phi(h_t(p) - 12d)$, it follows from Lemma A.2 that $3C_0/4 \ge \phi(h_t(p)) \ge D_1$. Since $\phi(h_t(p) - 2d) \ge \phi(h_t(p) - 11d)$, $C_0/4 \ge \phi(h_t(p) + d)/3 \ge \phi(h_t(p) + d)/10 + \phi(h_t(p))/10 \ge D_2 + D_3$. Therefore, we have $C_0 \ge D_1 + D_2 + D_3$.

We now consider subcase (a) under the assumption that $h_0(v) \le h_t(p) - d$. In order to do the accounting, we use part of the incoming credit associated with the edge (u, v) due to the set X of good tokens of v with heights in the interval $(h_0(v), h_t(p) - d]$. (Note that each token in X is marked and thus has contributed incoming credit to all edges adjacent to v.) Since each token x in X is good, the height of the token before the transfer to node v was at least $h_t(q) + 6d$. Therefore, the incoming credit assigned to (u, v) by a token x in X is at least $9(\phi(h_t(q) + 6d) - \phi(h_t(q)))/(20d)$ units. For each token x in X, we use $c_x = 8(\phi(h_t(q) + 6d) - \phi(h_t(q)))/(20d)$ units of this incoming credit. Let C_1 denote $\sum_{x \in X} c_x$. We obtain the following lower bound C_1. By invoking Corollary B.2, we obtain

$$\begin{aligned}
C_1 &\ge \frac{8}{20d} \sum_{1 \le i \le \lfloor \frac{h_t(p) - d - h_0(v)}{4d} \rfloor} \sum_{1 \le k \le 3d} (\phi(h_t(p) - d - 4id + k + 6d) \\
&\qquad\qquad - \phi(h_t(p) - d - 4id + k + d)) \\
&\ge \frac{8}{20d} \sum_{1 \le k \le 3d} \sum_{1 \le i \le \lfloor \frac{h_t(p) - d - h_0(v)}{4d} \rfloor} (\phi(h_t(p) - d - 4id + k + 6d) \\
&\qquad\qquad - \phi(h_t(p) - 4id + k)) \\
&\ge \frac{8}{20d} \sum_{1 \le k \le 3d} \Bigg(\phi(h_t(p) - d - 4d + k + 6d) \\
&\qquad\qquad - \phi(h_t(p) - 4d \left\lfloor \frac{h_t(p) - d - h_0(v)}{4d} \right\rfloor + k) \Bigg) \\
&\ge \frac{8}{20d} \sum_{1 \le k \le 3d} (\phi(h_t(p) + d) - \phi(h_0(v) + 8d)) \\
&= 6(\phi(h_t(p) + d) - \phi(h_0(v) + 8d))/5.
\end{aligned}$$

(In the first equation we partition the interval $(h_0(v), h_t(p) - d]$ into subintervals of $4d$ consecutive integers starting from $h_t(p) - d$. The last subinterval may have fewer than $4d$ integers; if so, we ignore the last subinterval in the sum. The second summation in the first equation is a lower bound on the sum of c_x over each good token x in each subinterval. To obtain the second summation, we invoke Corollary B.2, which implies that there are at least $3d$ good tokens in every subinterval of $4d$ tokens. The second equation is obtained by interchanging the order of summation. For the third equation, we use the fact that $\phi(h_t(p) - d - 4(i-1)d + k + 6d) \ge \phi(h_t(p) - 4id + k)$ and then note that the sum telescopes. For the fourth inequality, note that (i) the index k is at least 0 and at most $3d$, and (ii) $h_t(p) - 4d\lfloor \frac{h_t(p) - d - h_0(v)}{4d} \rfloor \le h_0(v) + 5d$.)

Since p is marked bad after step t, we have $h_t(p) > h_{t-1}(p) - 6d$. Therefore,

$$\begin{aligned}
C_0 + C_1 &\ge 2 \max\{\phi(24jd), \phi(h_0(v) - d)\} + 6(\phi(h_t(p) + d) - \phi(h_0(v) + 8d))/5 \\
&\ge 6\phi(h_t(p) + d)/5 \\
&\ge \phi(h_t(p)) - \phi(h_{t-1}(p)) + (\phi(h_t(p) + d) - \phi(h_t(p)))/10 \\
&\quad + (\phi(h_t(p)) - \phi(h_{t-1}(p) - d))/10 \\
&\ge D_1 + D_2 + D_3.
\end{aligned}$$

(The first equation states the lower bounds on C_0 and C_1 obtained above. For the second equation, we invoke Lemma A.2 as follows: $2 \max\{\phi(24jd), \phi(h_0(v) - d)\} \ge 4\phi(h_0(v) + 11d)/3 \ge 6\phi(h_0(v) + 8d)/5$. The third equation is obtained from the following three observations: (i) $\phi(h_t(p)+d) \geq \phi(h_t(p)) - \phi(h_{t-1}(p))$, (ii) $\phi(h_t(p)+d)/10 \geq (\phi(h_t(p)+d) - \phi(h_t(p)))/10$, and (iii) $\phi(h_t(p)+d)/10 \geq (\phi(h_t(p)) - \phi(h_{t-1}(p) - d))/10$.)

We use a similar argument as above to handle subcase (b), where t is not the first step in which (u, v) is live. The set X is the set of good tokens of v with heights in the interval $(e^u_{t-1}(v) - \rho, h_t(p) - d]$. Let c_x and C_1 be defined as in subcase (a). That is, c_x equals $8(\phi(h_t(x)+6d) - \phi(h_t(x)))/(20d)$ units of the incoming credit assigned to (u, v) by a token x in X, and C_1 equals $\sum_{x \in X} c_x$. We will show that $11C_1/12 \geq D_1 + D_3$ and $C_1/12 \geq D_2$, and hence obtain that $C_1 \geq D_1 + D_2 + D_3$.

We first show that $11C_1/12 \geq D_1 + D_3$. If $h_t(p) \leq h_{t-1}(p) - d$, then D_1 and D_3 are both nonpositive and hence the desired claim holds trivially. We now assume that $h_t(p) > h_{t-1}(p) - d$. Let y denote $e^u_{t-1}(v) - \rho + 8d$. We observe that since u sent a token to v during step t, $y = e^u_{t-1}(v) - \rho + 8d \leq h_{t-1}(u) - 4d \leq h_{t-1}(p) - 3d$. Since p is a bad token, we have $y \leq h_{t-1}(p) - 3d < h_t(p) - 2d$. As in subcase (a), we divide the interval $(e^u_{t-1}(v) - \rho, h_t(p) - d]$ into subintervals consisting of $4d$ consecutive integers. Note that $e^u_{t-1}(v) - \rho \leq h_t(p) - 11d$ and hence the number of subintervals is at least 1. We obtain the following lower bound on $11C_1/12$.

$$\begin{aligned}
11C_1/12 &\geq (11/12) \cdot 6(\phi(h_t(p)+d) - \phi(y))/5 \\
&\geq 11(\phi(h_t(p)+d) - \phi(h_{t-1}(p) - 2d))/10 \\
&\geq (\phi(h_t(p)) - \phi(h_{t-1}(p))) + (\phi(h_t(p)) - \phi(h_{t-1}(p) - d))/10 \\
&= D_1 + D_3.
\end{aligned}$$

(The first equation is obtained in the same manner as the upper bound on C_1 in subcase (a). While the interval considered in subcase (a) is $(h_0(v), h_t(p) - d]$, we consider here the interval $(e^u_{t-1}(v) - \rho, h_t(p) - d] = [y - 8d, h_t(p) - d]$. Hence, the term $\phi(h_0(v) + 8d)$ obtained in the lower bound on C_1 in subcase (a) is replaced by $\phi(y)$ above. The second equation is obtained from the upper bound on y.)

We now show that $C_1/12 \geq D_2$. Since a token is sent by u to v in step t, $e^u_{t-1}(u) - \rho \leq h_{t-1}(u) - 12d \leq h_{t-1}(p) - 11d$. Moreover, since p is a bad token, $h_{t-1}(p) \leq h_t(p) - 6d$. Therefore, $e^u_{t-1}(u) - \rho \leq h_t(p) - 5d$. It follows that $(h_t(p) - 5d, h_t(p) - d]$ is a subinterval of $(e^u_{t-1}(u) - \rho, h_t(p) - d]$. Hence, C_1 can be lower bounded by adding c_x over all good tokens x whose height is in $(h_t(p) - 5d, h_t(p) - d]$. By Corollary B.2, at least $3d$ of the tokens in $[h_t(p) - 5d, h_t(p) - d]$ are good. We thus obtain

$$\begin{aligned}
C_1/12 &\geq (3d/12) \cdot 8(\phi(h_t(p)+d) - \phi(h_t(p) - d))/(20d) \\
&= (\phi(h_t(p)+d) - \phi(h_t(p)))/10 \\
&\geq D_2.
\end{aligned}$$

(For the first equation, note that $c_x = 8(\phi(h_t(x)+6d) - \phi(h_t(x)))/(20d) \geq 8(\phi(h_t(p)+d) - \phi(h_t(p) - d))/(20d)$ for $h_t(x)$ in $[h_t(p) - 5d, h_t(p) - d]$. The last equation follows from the definition of D_2.)

To complete the proof for case (ii), we show that for any token x of v, any incoming credit assigned by x to edge (u, v) that is used at step t for case (ii) is not used again for case (ii). To prove this, we note that for any x in X, for every further step $t' > t$ until x is transferred by u, we have $h_{t'}(x) \geq e^u_{t'-1}(v) - \rho$. While establishing case (ii) for step t, we use only the incoming credit assigned by tokens in $(e^u_{t'-1}(v) - \rho, h_{t'}(p) - d]$. Hence the incoming credit assigned by x to edges adjacent to u that is used at step t will never be used again.

We need to consider case (iii) only under the assumption that $(u, v) \in E_t$, i.e., (u, v) is live in step t. In this case we account for $D = (\phi(h_{t-1}(u) - d) - \phi(h_{t-1}(v) + d))/50$ units of potential. Again we consider two subcases depending on whether t is the last step in which (u, v) is live (subcase (a)) or not (subcase (b)). We first consider subcase (a). If $h_0(u) \geq h_{t-1}(u) - 12d$, then we use $C_0 = 2\max\{\phi(24jd), \phi(h_0(u) - d)\}$ units of the initial credit associated with (u, v). Since $h_{t-1}(u) - d \leq h_0(u) - d + 12d$, it follows from Lemma A.2 that $C_0 \geq 4\phi(h_{t-1}(u) - d)/3 \geq \phi(h_{t-1}(u) - d)/50 \geq D$.

We now consider subcase (a) of case (iii) under the assumption that $h_0(u) < h_{t-1}(u) - 12d$. In addition to C_0, we also use part of the incoming credit associated with the set of tokens $Y = \{y : y \text{ is a token of } u \text{ and } h_0(u) < h_t(y) \leq h_{t-1}(u)\}$. Specifically, for every token y in Y, we use $(\phi(h_t(y) + d) - \phi(h_t(y)))/(20d)$ units of incoming credit that is assigned to (u, v) by y. Note that since $h_t(y) > h_0(u)$, token y has moved and hence has assigned some incoming credit to (u, v). If y is good, this credit is at least $9(\phi(h_t(y) + 6d) - \phi(h_t(y)))/(20d)$ units; otherwise, this credit is at least $(\phi(h_t(y) + d) - \phi(h_t(y)))/(20d)$. Moreover, if y is a good token, at most $8(\phi(h_t(y) + 6d) - \phi(h_t(y)))/(20d)$ units of incoming credit were used in the analysis of case (ii). If y is a bad token, none of the incoming credit was used in the analysis of case (ii). In either case, at least $(\phi(h_t(y) + d) - \phi(h_t(y)))/(20d)$ units of incoming credit still remain. Let this credit be denoted C_1. We obtain the following lower bound on $C_0 + C_1$:

$$\begin{aligned}
C_0 + C_1 &\geq C_0 + \sum_{h_0(u) < k \leq h_{t-1}(u)} (\phi(k + d) - \phi(k))/(20d) \\
&= C_0 + \frac{1}{20d} \sum_{1 \leq i \leq d} (\phi(h_{t-1}(u) + i) - \phi(h_0(u) + i)) \\
&\geq C_0 + (\phi(h_{t-1}(u)) - \phi(h_0(u) + d))/20 \\
&\geq \phi(h_{t-1}(u))/20 \\
&\geq D.
\end{aligned}$$

(The second equation holds since the sum in the first equation can be expressed as a sum of d telescoping sums. For the third equation we invoke Lemma A.2 and obtain that $C_0 \geq 2\phi(h_0(u) + 11d)/3 \geq \phi(h_0(u) + d)/20$.)

We now consider subcase (b) of (iii). Recall that by the definition of E_t, u is in $S_{>j}$ at the start of step t. Therefore, $h_{t-1}(u) \geq 24(j+1)d - 12d \geq 24jd + 12d$. Since no token was sent along (u, v) in step t, we have $e^u_{t-1}(v) - \rho > h_{t-1}(u) - 12d$ ($\geq 24jd$). By the definition of E_t, we also have $h_{t-1}(u) \geq h_{t-1}(v) + 24d$. It follows that $e^u_{t-1}(v) - \rho > h_{t-1}(v) + 12d$. Since the last step in which (u, v) was live, at least $e^u_{t-1}(v) - \rho - h_{t-1}(v)$ tokens have left v. We use the outgoing credit assigned to (u, v) due to these token transmissions. Consider a token x that is transmitted by v in step t'. If x is marked good after the step, then the outgoing credit assigned by x to (u, v) is at least $9(\phi(h_{t'-1}(p)) - \phi(h_{t'}(p)))/(20d) \geq 9(\phi(h_{t'-1}(p)) - \phi(h_{t'-1}(p) - 6d))/(20d)$ units. Otherwise, the outgoing credit assigned by x to (u, v) is at least $(\phi(h_{t'-1}(p)) - \phi(h_{t'-1}(p) - d))/(20d)$ units. In either case, the outgoing credit is at least $(\phi(h_{t'-1}(p)) - \phi(h_{t'-1}(p) - d))/(20d)$ units. We thus obtain the following lower bound on the total outgoing credit C_2 assigned to (u, v) by at least $e^u_{t-1}(v) - \rho - h_{t-1}(v)$ tokens.

$$C_2 \geq \sum_{h_{t-1}(v) < k \leq e^u_{t-1}(v) - \rho} (\phi(k) - \phi(k - d))/(20d)$$

$$\begin{aligned}
&= \frac{1}{20d} \sum_{1 \le i \le d} (\phi(e^u_{t-1}(v) - \rho - d + i) - \phi(h_{t-1}(v) - d + i)) \\
&\ge (\phi(e^u_{t-1}(v) - \rho - d) - \phi(h_{t-1}(v)))/20 \\
&\ge (\phi(e^u_{t-1}(v) - \rho + 11d) - \phi(h_{t-1}(v) + d))/50 \\
&\ge (\phi(h_{t-1}(u) - d) - \phi(h_{t-1}(v) + d))/50 \\
&= D.
\end{aligned}$$

(The second equation holds since the sum in the first equation can be expressed as a sum of d telescoping sums. For the third and fourth inequalities, we first note that since no token is sent by u to v in step t, we have $e^u_{t-1}(v) - \rho > h_{t-1}(u) - 12d \ge 24jd - d$. The third equation now follows from Lemma A.3 and the fact that $\phi(e^u_{t-1}(v) - \rho - d) > 0$. The fourth equation follows directly from the lower bound on $e^u_{t-1}(v) - \rho$.)

We note that the outgoing credit assigned to edge (u, v) in the above analysis of case (iii) is used at most once in case (iii). To prove this, we observe that after step t, the value of $e^u(v)$ is updated by u to $h_{t-1}(v) + \rho$. Therefore, if case (iii) of the analysis subsequently uses any outgoing credit assigned by a token x that leaves v and whose height in v is in $(h_{t-1}(v), e^u_{t-1}(v)]$, then x reached v after step t. Hence, the outgoing credit assigned by the $e^u_{t-1}(v) - h_{t-1}(v)$ tokens that are used in the analysis for step t are not used again for a later step. $\square$

AN ALGORITHM FOR SHORTEST PATHS IN BIPARTITE DIGRAPHS WITH CONCAVE WEIGHT MATRICES AND ITS APPLICATIONS*

XIN HE† AND ZHI-ZHONG CHEN‡

Abstract. The traveling salesman problem on an n-point convex polygon and the minimum latency tour problem for n points on a straight line are two basic problems in graph theory and have been studied in the past. Previously, it was known that both problems can be solved in $O(n^2)$ time. However, whether they can be solved in $o(n^2)$ time was left open by Marcotte and Suri [*SIAM J. Comput.*, 20 (1991), pp. 405–422] and Afrati et al. [*Informatique Theorique Appl.*, 20 (1986), pp. 79–87], respectively.

In this paper we show that both problems can be solved in $O(n \log n)$ time by reducing them to the following problem: Given an edge-weighted complete bipartite digraph $G = (X, Y, E)$ with $X = \{x_0, \ldots, x_n\}$ and $Y = \{y_0, \ldots, y_m\}$, we wish to find the shortest path from x_0 to x_n in G. This new problem requires $\Omega(nm)$ time to solve in general, but we show that it can be solved in $O(n + m \log n)$ time if the weight matrices A and B of G are both concave, where for $0 \le i \le n$ and $0 \le j \le m$, $A[i, j]$ and $B[j, i]$ are the weights of the edges (x_i, y_j) and (y_j, x_i) in G, respectively. As demonstrated in this paper, the new problem is a powerful tool and we believe that it can be used to solve more problems.

1. Introduction.

The traveling salesman problem (TSP) is a classical problem of combinatorial optimization. It has been the testing ground of many new algorithmic ideas during the past half-century: dynamic programming, linear programming, genetic algorithms, etc. The TSP is NP-hard and even nonapproximatable. This has motivated researchers to look at its special cases. It turns out that various special cases of the TSP remain NP-hard but are approximatable. Among the special cases solvable in polynomial time, the TSP for points on a convex polygon is well known. In this special case, we are given a set S of n points on the boundary of a convex polygon C and two points x and y in S and are requested to compute a shortest tour starting at x, visiting all the points in $S - \{x, y\}$, and ending at y. Here, the distance between two points in S is the Euclidean distance between them. This special case can be solved in $O(n^2)$ time via dynamic programming [10], but whether it can be solved in $o(n^2)$ time was an open question (posed in [10]). In this paper, we give an affirmative answer to this open question. More specifically, we show that the TSP for points on a convex polygon can be solved in $O(n \log n)$ time.

The minimum latency problem (MLP) is as follows: We are given a metric space M on n points $\{x_1, \ldots, x_n\}$ and are requested to compute a tour in M starting at x_1

which minimizes the sum of the arrival times at the n points. More precisely, if T is a tour starting at x_1 we say that the *latency* of x_i with respect to T is the distance traveled in T before reaching x_i; and the latency of T is the sum of the latencies of the n points. The goal is then to find a tour of minimum latency. The MLP is a well-studied problem in the operations research literature, where it is also known as the "delivery-man problem" and the "traveling repairman problem" (see [5] for more discussions and references). Although it looks similar to the TSP, the MLP is very different from the TSP in nature [5]. Generally, the MLP is NP-complete [5]. Even for points on a tree or on a convex polygon, it is not known whether the MLP is in P or NP-complete [5]. The case where points are on a straight line was considered in [1, 5]. This case is interesting since it is exactly the following *disk head scheduling problem*: A disk head moves along a straight line L. The head must visit a set of n points on L in order to satisfy disk access requests. The time needed to travel is proportional to the distance being traveled. Once the head reaches a point, the disk access time can be ignored (since the disk rotating speed is much higher than the head moving speed). We want to find a tour of the head such that the average delay (or equivalently, the total delay) of all requests is minimized. The MLP for this special case can be solved in $O(n^2)$ time via dynamic programming [1, 5]. However, whether it can be solved in $o(n^2)$ time was an open question [1]. In this paper, we answer this question in the affirmative by giving an $O(n \log n)$-time algorithm for it.

We obtain the two results mentioned above by efficient reductions to a *single* problem called the *shortest path in bipartite digraph* (SPBD) problem, which is defined as follows. Let $G = (X, Y, E)$ be a complete bipartite digraph with $X = \{x_0, x_1, \ldots, x_n\}$ and $Y = \{y_0, y_1, \ldots, y_m\}$. Each edge $e \in E$ is associated with a real-valued weight $w(e)$. We use $x_i \to y_j$ and $y_j \to x_i$ to denote the edges. Let $A[0..n, 0..m]$ be the matrix with $A[i,j] = w(x_i \to y_j)$ and $B[0..m, 0..n]$ be the matrix with $B[i,j] = w(y_i \to x_j)$. The weight of a (directed) path P in G is defined as $w(P) = \sum_{e \in P} w(e)$. Given such a digraph G, the SPBD problem is to find a path P in G from x_0 to x_n such that $w(P)$ is minimized. For arbitrary weight matrices, we must examine all the edges of G in order to find the shortest path. Thus we need at least $\Omega(nm)$ time to solve the problem. A matrix $M[0..n, 0..m]$ is called *concave* if the following hold:

$$M[i_1, j_1] + M[i_2, j_2] \le M[i_2, j_1] + M[i_1, j_2] \quad \text{for} \quad 0 \le i_1 \le i_2 \le n \quad \text{and} \quad 0 \le j_1 \le j_2 \le m. \tag{1.1}$$

Concave matrices were first discussed in [12] and have been very successfully used in solving various problems (see [2, 3, 4, 6, 7, 8, 9, 11, 12, 13] and the references cited within). Given two matrices $A[0..n, 0..m]$ and $B[0..m, 0..n]$, the product matrix $W[0..n, 0..n] = A \times B$ is defined by

$$W[i,j] = \min_{0 \le k \le m} (A[i,k] + B[k,j]). \tag{1.2}$$

For the SPBD problem we require that G contains no negative cycles since otherwise the shortest path of G is not well defined. If both A and B are concave, as we will prove later, this requirement is satisfied if all the entries on the main diagonal of the product matrix $W = A \times B$ are nonnegative. In section 4 we will prove the following theorem.

THEOREM 1.1. *Given two concave matrices A and B such that all the entries on the main diagonal of the product matrix $W = A \times B$ are nonnegative, the SPBD problem defined by A and B can be solved in $O(n + m \log n)$ time.*

Even for this special case, no algorithm with $o(nm)$ running time was previously known. In this theorem we assume that the matrices A and B are not explicitly given. Rather, an entry is computed in constant time when it is needed. This is true when we apply our SPBD algorithm to solve the TSP and the MLP.

The rest of this paper is organized as follows. In section 2 we present the reduction from the TSP for points on a convex polygon to the SPBD problem. In section 3 we reduce the MLP for points on a straight line to the SPBD problem. In section 4 we prove Theorem 1 by giving an $O(n + m \log n)$-time algorithm for the SPBD problem. Section 5 concludes the paper.

2. The TSP for points on a convex polygon.

Let C be a convex polygon and Z be the set of the corner vertices of C. The members of Z will be called *points*. For two points z_1 and z_2 in Z, let $d(z_1, z_2)$ denote the Euclidean distance between z_1 and z_2. The points in Z induce an edge-weighted complete graph G_Z, where the weight on each edge $\{z_1, z_2\}$ is $d(z_1, z_2)$. We identify each edge $\{z_1, z_2\}$ with the line segment whose endpoints are z_1 and z_2. The weight of a path P in G_Z is the sum of the weights on the edges in P and is denoted by $w(P)$. Fix two points x and y in Z. Hereafter, a Hamiltonian path in G_Z always means one from x to y. Our goal is to compute an optimal Hamiltonian path in G_Z, i.e., a Hamiltonian path in G_Z of minimum weight. An easy geometric argument shows that every optimal path P must be simple, i.e., no two edges of P cross each other.

Let $x = x_0, x_1, \ldots, x_n = y$ be the points in Z that lie on the boundary of C from x to y in the clockwise order. Let C_X be the portion of the boundary of C which starts at x, includes $x_1, \ldots, x_{n-1}$, and ends at y. Similarly, let $x = y_0, y_1, \ldots, y_m = y$ be the points in Z that lie on the boundary of C from x to y in the counterclockwise order. Let C_Y be the portion of the boundary of C which starts at x, includes $y_1, \ldots, y_{m-1}$, and ends at y. For $0 \le i < j \le n$ let $x_i \overset{X}{\rightarrow} x_j$ denote the portion of C_X from x_i to x_j. For $0 \le i < j \le m$ let $y_i \overset{Y}{\rightarrow} y_j$ denote the portion of C_Y from y_i to y_j.

Let P be an optimal Hamiltonian path from $x_0 = y_0$ to $x_n = y_m$ in G_Z. Depending on whether the first and the last edges of P are in C_X or in C_Y, there are four possibilities. We assume that both the first and the last edges of P are in C_Y. Then P must be of the following form:

$$\begin{aligned} x_{i_0} = x_0 = y_0 \overset{Y}{\rightarrow} y_{j_1} \rightarrow x_1 \overset{X}{\rightarrow} x_{i_1} \rightarrow y_{j_1+1} \overset{Y}{\rightarrow} y_{j_2} \rightarrow x_{i_1+1} \overset{X}{\rightarrow} \cdots \overset{X}{\rightarrow} x_{i_t} \\ = x_{n-1} \rightarrow y_{j_t+1} \overset{Y}{\rightarrow} y_m = x_n \end{aligned}$$

for some $0 < j_1 < j_2 < \cdots < j_t < m-1$ and $0 = i_0 < i_1 < i_2 < \cdots < i_t = n-1$. (See Figure 2.1. In Figure 2.1(b) the points in C_X and C_Y are drawn on two vertical lines for the sake of clarity.) We use the following *dummy path* P' to represent P (the edges of P' are shown as dashed lines in Figure 2.1(b)):

$$P' : \ x_{i_0}(= x_0) \rightarrow y_{j_1} \rightarrow x_{i_1} \rightarrow y_{j_2} \rightarrow x_{i_2} \rightarrow \cdots \rightarrow y_{j_{t-1}} \rightarrow x_{i_{t-1}} \rightarrow y_{j_t} \rightarrow x_{i_t}(= x_{n-1}).$$

The edges $x_{i_{l-1}} \rightarrow y_{j_l}$ and $y_{j_l} \rightarrow x_{i_l}$ in P' are called *dummy edges*. P is completely specified by P'.

For each dummy edge $x_{i_{l-1}} \rightarrow y_{j_l}$ in P', the edge $x_{i_{l-1}} \rightarrow x_{i_{l-1}+1}$ is not in P, while the edge $y_{j_l} \rightarrow x_{i_{l-1}+1}$ is in P. For each dummy edge $y_{j_l} \rightarrow x_{i_l}$ in P', the edge $y_{j_l} \rightarrow y_{j_l+1}$ is not in P, while the edge $x_{i_l} \rightarrow y_{j_l+1}$ is in P. This motivates the following definition of the weights of dummy edges $x_i \rightarrow y_j$ and $y_j \rightarrow x_i$ given in the matrices $A[0..n-1, 0..m-1]$ and $B[0..m-1, 0..n-1]$:

$$A[i, j] = w(x_i \rightarrow y_j) = d(x_{i+1}, y_j) - d(x_i, x_{i+1}), \tag{2.1}$$

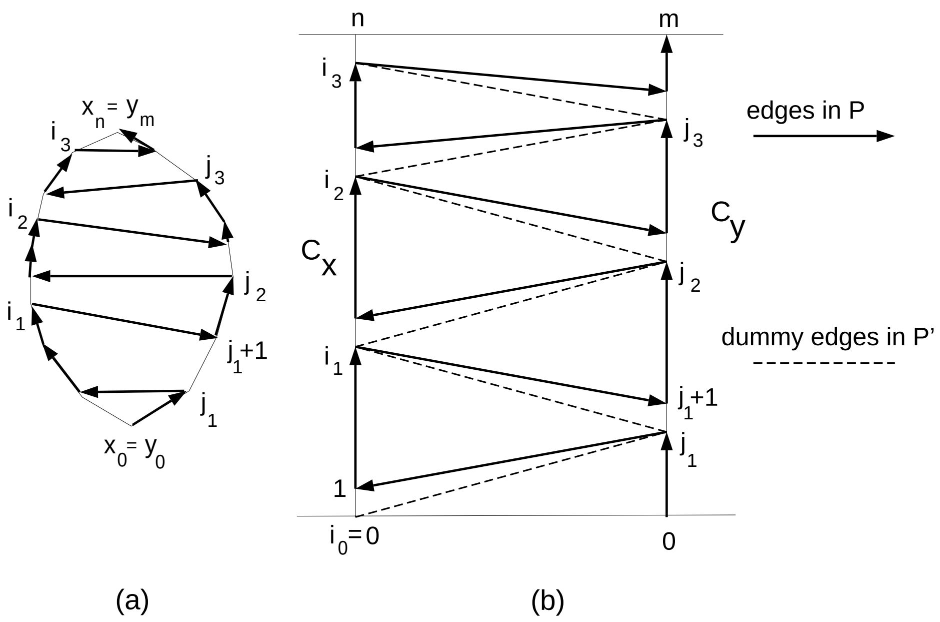

FIG. 2.1. (a) *An optimal path* P *in a convex polygon;* (b) *a simplified representation of* P.

$$B[j,i] = w(y_j \to x_i) = d(y_{j+1}, x_i) - d(y_j, y_{j+1}). \tag{2.2}$$

Note that $A[0,0] = B[0,0] = 0$. Let $S_X = \sum_{i=1}^{n-1} d(x_{i-1}, x_i)$ and $S_Y = \sum_{j=1}^{m} d(y_{j-1}, y_j)$. It is easy to verify that the total weight of P is

$$w(P) = S_X + S_Y + \sum_{l=1}^{t} A[i_{l-1}, j_l] + \sum_{l=1}^{t} B[j_l, i_l]. \tag{2.3}$$

Although the above discussion is carried out by assuming that the first and the last edges of P are in C_Y, it also applies to other cases. For example, if the first edge of P is in C_X, we let $j_1 = 0$. If the last edge of P is in C_X, we let $j_t = m-1$. It is easy to verify that (2.3) is valid for these cases, too.

Since the term $S_X + S_Y$ in (2.3) is fixed for any P, to minimize $w(P)$ we need only to minimize the *reduced weight* $w(P')$ defined as follows:

$$w(P') = \sum_{l=1}^{t} A[i_{l-1}, j_l] + \sum_{l=1}^{t} B[j_l, i_l]. \tag{2.4}$$

Let $G = (X, Y, E)$ be the complete bipartite digraph with $X = \{x_0, x_1, \ldots, x_{n-1}\}$ and $Y = \{y_0, y_1, \ldots, y_{m-1}\}$ and the weight matrices A and B. Then a dummy path P' with minimum reduced weight $w(P')$ is exactly a shortest path in G from x_0 to x_{n-1}.

For $0 \le i < i' \le n-1$ and $0 \le j < j' \le m-1$, by the definition of A and the fact that C is a convex polygon, we have $A[i,j] + A[i',j'] - A[i,j'] - A[i',j] = d(x_{i+1}, y_j) + d(x_{i'+1}, y_{j'}) - d(x_{i+1}, y_{j'}) - d(x_{i'+1}, y_j) < 0$.

Thus A is concave. Similarly, we can show that B is also concave. Let $W = A \times B$. Then

$$W[i,i] = \min_{0 \le j \le m-1} [d(x_{i+1}, y_j) - d(x_i, x_{i+1}) + d(y_{j+1}, x_i) - d(y_j, y_{j+1})].$$

By the quadrangle inequality the expression within the min sign is > 0 for each j. Thus $W[i,i] > 0$ for all $0 \le i \le n-1$. By Theorem 1.1 we have the following theorem.

THEOREM 2.1. *The traveling salesman problem for points on an N-point convex polygon can be solved in $O(N \log N)$ time.*

3. The MLP for points on a straight line. Consider a set S of $n+1$ points, a symmetric distance matrix $d[0..n, 0..n]$, and a tour T which visits the points of S in some order. The *latency* of a point $p \in S$ with respect to T is the length of the tour from the starting point to the first occurrence of p. More precisely, suppose that T visits the points in S in the order $p_0, p_1, \ldots, p_n$ starting at p_0. Let $d(p_{i-1}, p_i)$ be the distance traveled along T between p_{i-1} and p_i. Then the latency of p_i is $w(p_i) = \sum_{j=1}^{i} d(p_{j-1}, p_j)$. The *total latency* $w(T)$ of T is the sum of the latencies of all the points in S: $w(T) = \sum_{i=1}^{n} w(p_i)$. Or, equivalently,

$$w(T) = \sum_{k=1}^{n} d(p_{k-1}, p_k)(n-k+1). \tag{3.1}$$

We wish to find a tour T with minimum $w(T)$. In this section we show that the MLP for points on a straight line can be reduced to the SPBD problem and solved in $O(n \log n)$ time.

Let $S = \{x_n, x_{n-1}, \ldots, x_1, x_0 = y_0 = 0, y_1, y_2, \ldots, y_m\}$ be a set of $N = n+m+1$ distinct points on the real line from left to right. We overload x_i (and y_j) to denote both a point and the distance from it to the origin. The tour starts at the point 0. Define

$$\begin{aligned} w(T_X) &= \sum_{k=1}^{n} (x_k - x_{k-1})(n-k+1), \\ w(T_Y) &= \sum_{k=1}^{m} (y_k - y_{k-1})(m-k+1). \end{aligned}$$

$w(T_X)$ is the total latency of the tour T_X that starts at $x_0 = 0$ and travels the points $x_1, x_2, \ldots, x_n$ in this order. $w(T_Y)$ is the total latency of the tour T_Y that starts at $y_0 = 0$ and travels the points $y_1, y_2, \ldots, y_m$ in this order.

Consider an optimal tour T for S. Depending on whether the first and the last edges of T are to the left or to the right, there are four possibilities. If, for example, the first edge is to the right and the last edge is to the left, then T must be of the following form (see Figure 3.1):

$$x_{i_0} = y_{j_0} = x_0 = y_0 \overset{\Delta}{\rightarrow} y_{j_1} \overset{\Delta}{\rightarrow} x_{i_1} \overset{\Delta}{\rightarrow} y_{j_2} \overset{\Delta}{\rightarrow} x_{i_2} \overset{\Delta}{\rightarrow} \cdots \overset{\Delta}{\rightarrow} x_{i_{t-1}} \overset{\Delta}{\rightarrow} y_{j_t} = y_m \overset{\Delta}{\rightarrow} x_{i_t} = x_n$$

for some $0 = j_0 < j_1 < j_2 < \cdots < j_{t-1} < j_t = m$ and $0 = i_0 < i_1 < \cdots < i_{t-1} < i_t = n$. (The notation $x_i \overset{\Delta}{\rightarrow} y_j$ denotes the straight line segment whose end points are x_i and y_j consisting of several edges.) We use the following *dummy tour* T' to represent T:

$$T' : \ x_{i_0} (= x_0) \rightarrow y_{j_1} \rightarrow x_{i_1} \rightarrow \cdots \rightarrow x_{i_{t-1}} \rightarrow y_{j_t} (= y_m) \rightarrow x_{i_t} (= x_n).$$

T is completely specified by T'. Define the *reduced weight* of the dummy tour T' to be

$$w(T') = \sum_{l=1}^{t} y_{j_l} [n+m-j_l-i_{l-1}] + \sum_{l=1}^{t} x_{i_l} [n+m-j_l-i_l]. \tag{3.2}$$

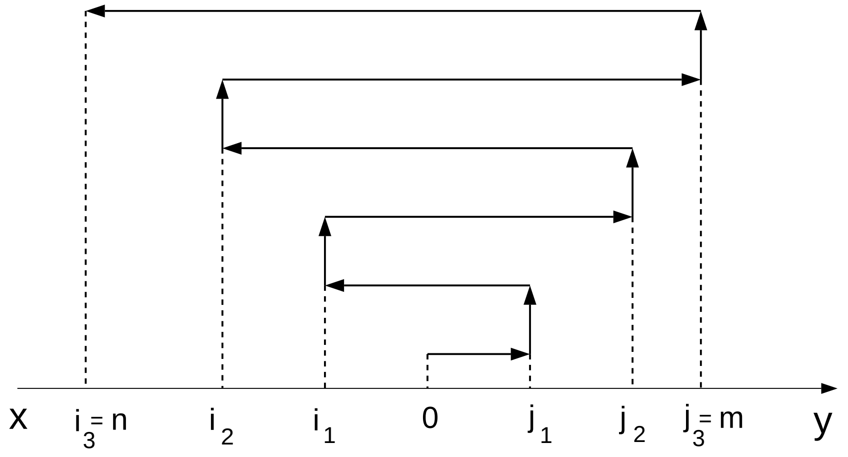

FIG. 3.1. *Optimal tour for points on a straight line.*

LEMMA 3.1. *The weight of T and the reduced weight of T' satisfies*

$$w(T) = w(T_X) + w(T_Y) + 2w(T'). \tag{3.3}$$

Proof. First we note that $w(T_X) + w(T_y)$ is the sum of the shortest-path distances from $x_0 = y_0$ to the points x_i $(1 \le i \le n)$ and y_j $(1 \le j \le m)$. In the tour T, the latency of each point will be the shortest-path distance plus some additional delay (caused by the zigzag-shaped detour). We need to compute this additional delay. Each "loop" of the form "from y_0 to y_{j_l} and back" contributes a delay of $2y_{j_l}$ to each point that is as yet unvisited when this loop is traversed; there are $(n + m - j_l - i_{l-1})$ such points. So the additional delay contributed by this loop is

$$2y_{j_l}(n + m - j_l - i_{l-1}).$$

Similarly, the additional delay contributed by a loop of the form "from x_0 to x_{i_l} and back" is

$$2x_{i_l}(n + m - j_l - i_l).$$

Summing up all these additional delay terms, we have $w(T) = w(T_X) + w(T_Y) + \sum_{l=1}^{t} 2y_{j_l}[n + m - j_l - i_{l-1}] + \sum_{l=1}^{t} 2x_{i_l}[n + m - j_l - i_l] = w(T_X) + w(T_Y) + 2w(T')$. $\square$

Although Lemma 3.1 is proved by assuming that the first edge of T is to the right and the last edge of T is to the left, it also applies to other cases. For example, if the first edge of T is to the left, we can let $j_1 = 0$. If the last edge of T is to the right, we can let $i_{t-1} = n$ and delete from T the subpath from y_m to x_n. It can be verified that (3.3) is valid for those cases, too. Since the term $w(T_X) + w(T_Y)$ is fixed for all T, in order to minimize $w(T)$ we need only to minimize $w(T')$.

Let $G = (X, Y, E)$ be the complete bipartite digraph with $X = \{x_0, x_1, \ldots, x_n\}$, $Y = \{y_0, y_1, \ldots, y_m\}$, and the weight matrices $A[0..n, 0..m]$ and $B[0..m, 0..n]$ defined as follows:

$$A[i,j] = w(x_i \to y_j) = y_j(n+m-i-j),$$
$$B[j,i] = w(y_j \to x_i) = x_i(n+m-i-j).$$

Note that $A[0,0] = B[0,0] = 0$. It is easy to check that a dummy tour T' with minimum reduced weight $w(T')$ is exactly a shortest path in G from x_0 to x_n. By the definition of A, for $0 \leq i < i' \leq n$ and $0 \leq j < j' \leq m$, we have $(A[i,j] + A[i',j']) - (A[i,j'] + A[i',j]) = (i'-i)(y_j - y_{j'}) < 0$. Thus A is concave. Similarly, we can show that B is also concave. Since all the entries of A and B are nonnegative, all the entries of $W = A \times B$ are nonnegative. Thus by Theorem 1.1 we have the following.

THEOREM 3.2. *The minimum latency problem for a set of N points on straight line can be solved in $O(N \log N)$ time.*

4. Solving the SPBD problem.

Our algorithm for solving the SPBD problem is a reduction to an enhanced version of the *least weight subsequence* (LWS) problem. In section 4.1 we describe the LWS problem and its enhanced version. The reduction from the SPBD problem to the enhanced LWS problem is discussed in section 4.2. An algorithm for solving the enhanced LWS problem is given in section 4.3. In section 4.4 we give a complete description of our algorithm for the SPBD problem and analyze its time complexity.

4.1. The LWS problem and the enhanced LWS problem.

The following LWS problem was introduced in [8]. Given a sequence $\{x_0, x_1, \ldots, x_n\}$ and a real-valued weight function $w(x_i, x_j)$ defined for indices $0 \leq i < j \leq n$, find an integer $k \geq 1$ and a sequence $S = \{0 = i_0 < i_1 < \cdots < i_{k-1} < i_k = n\}$ such that the total weight $w(S) = \sum_{l=1}^{k} w(x_{i_{l-1}}, x_{i_l})$ is minimized. The LWS problem can also be formulated as a graph problem: Given an acyclic digraph G with vertex set $V = \{x_0, \ldots, x_n\}$, the edge set $E = \{x_i \to x_j \mid 0 \leq i < j \leq n\}$, and the weight function w, we wish to find a shortest path in G from x_0 to x_n. For an arbitrary weight function w, the LWS problem requires $\Omega(n^2)$ time to solve. The weight function w is *concave* if the following hold:

$$w(x_{i_1}, x_{j_1}) + w(x_{i_2}, x_{j_2}) \leq w(x_{i_2}, x_{j_1}) + w(x_{i_1}, x_{j_2}) \quad \text{for } 0 \leq i_1 \leq i_2 \leq j_1 \leq j_2 \leq n. \tag{4.1}$$

If the weight function is concave, then we have an instance of the concave LWS problem. Hirschberg and Larmore showed that the concave LWS problem can be solved in $O(n \log n)$ time [8]. Similar algorithms were developed in [6, 7]. Wilber discovered an elegant linear-time algorithm for solving this problem [11]. All these algorithms assume that each entry $w(i,j)$ can be computed in constant time. In this paper we consider only the concave LWS problem. From now on the phrase "LWS problem" always means the concave LWS problem.

The *enhanced* version of the LWS problem is defined as follows. An instance of the enhanced LWS problem is a sequence $\{x_0, x_1, \ldots, x_n\}$ and a real-valued concave weight function $w(x_i, x_j)$ defined on *all* $0 \leq i, j \leq n$ such that $w(x_i, x_i) \geq 0$ for all $0 \leq i \leq n$. We want to find a sequence $S = \{0 = i_0, i_1, \ldots, i_k = n\}$ ($i_0, i_1, \ldots, i_k$ are not necessarily in increasing order, as in the ordinary LWS problem), such that the total weight $w(S) = \sum_{l=1}^{k} w(x_{i_{l-1}}, x_{i_l})$ is minimized. In terms of the graph formulation, given a complete digraph G with vertex set $V = \{x_0, x_1, \ldots, x_n\}$ and a weight function w, we wish to find a shortest x_0 to x_n path in G. Let $e = x_i \to x_j$

be an edge of G. If $i < j$, e is called a *forward* edge. If $i = j$, e is called a *selfloop*. If $i > j$, e is called a *backward* edge. We require that the weight of the selfloops of G be nonnegative since otherwise the weight of the shortest path in G would be $-\infty$.

LEMMA 4.1. *For any instance of the enhanced LWS problem there exists a shortest x_0 to x_n path consisting of only forward edges.*

Proof. Let P be a shortest path from x_0 to x_n in G such that the number of edges in P is minimum. Since $w(x_i, x_i) \geq 0$ for all i, we may assume that P contains no selfloops. Toward a contradiction, suppose that P contains a backward edge. Let $x_{i_l} \to x_{i_{l+1}}$ be the first backward edge of P. Then $i_l > i_{l+1}$ and $i_l > i_{l-1}$. By the concavity of w and the assumption that $w(x_i, x_i) \geq 0$ for all x_i, we have $w(x_{i_{l-1}}, x_{i_{l+1}}) \leq w(x_{i_{l-1}}, x_{i_{l+1}}) + w(x_{i_l}, x_{i_l}) \leq w(x_{i_{l-1}}, x_{i_l}) + w(x_{i_l}, x_{i_{l+1}})$. Thus replacing the two edges $x_{i_{l-1}} \to x_{i_l} \to x_{i_{l+1}}$ in P by a single edge $x_{i_{l-1}} \to x_{i_{l+1}}$, we get a path P' such that $w(P') \leq w(P)$ and the number of edges in P' is one less than that in P. This contradicts the choice of P. $\square$

Lemma 4.1, together with the concavity of w, implies that there are no negative cycles in any instance of the enhanced LWS problem. It also implies that we can ignore all the backward edges and selfloops when solving the enhanced LWS problem.

4.2. Reduction. In this section we show that the SPBD problem can be reduced to the enhanced LWS problem. First we need several technical lemmas. The following lemma was proved in [12].

LEMMA 4.2. *If both A and B are concave, then the product matrix $W = A \times B$ is also concave.*

For $0 \leq i \leq n$ and $0 \leq j \leq n$, let $I(i, j)$ denote the smallest index k that realizes the minimum value in definition (1.2). Namely, $I(i, j)$ is the smallest index such that $W[i, j] = A[i, I(i, j)] + B[I(i, j), j]$. The following lemma was proved in [12].

LEMMA 4.3. *For any i, j ($0 \leq i < n$, $0 \leq j < n$), we have $I(i, j) \leq I(i, j + 1) \leq I(i + 1, j + 1)$.*

Remark. The definitions of concavity and the matrix product in [12] are slightly different from the definitions used here. In [12] a concave matrix is an upper triangular matrix such that the condition (1.1) is true for $i_1 \leq i_2 \leq j_1 \leq j_2$. In the matrix product definition (1.2) the minimum is taken over $i \leq k \leq j$. Under these definitions, Yao proved Lemmas 4.2 and 4.3. Under our definitions, Lemmas 4.2 and 4.3 can be proved via similar methods.

Let (i, j) and (i', j') be two pairs of indices. If $i \leq i'$ and $j \leq j'$, we write $(i, j) \prec (i', j')$. By Lemma 4.3, $(i, j) \prec (i', j')$ implies $I(i, j) \leq I(i', j')$.

LEMMA 4.4. *Let $(i_1, j_1), (i_2, j_2), \ldots, (i_p, j_p)$ be p pairs of indices such that $(i_l, j_l) \prec (i_{l+1}, j_{l+1})$ for all $1 \leq l < p$. Then $I(i_1, j_1), I(i_2, j_2), \ldots, I(i_p, j_p)$ can be computed in $O(m \log p)$ time.*

Proof. This can be done in a binary search fashion. More specific, we find $I_{p/2} = I(i_{p/2}, j_{p/2})$ in the first stage, find $I(i_{p/4}, j_{p/4})$ (by searching the range $0..I_{p/2}$) and $I(i_{3p/4}, j_{3p/4})$ (by searching the range $I_{p/2}..m$) in the second stage, and so on. In total, there are $\log p$ stages. Since each stage can be done in $O(m)$ time, the lemma holds. $\square$

Consider an instance of the SPBD problem defined by a complete bipartite digraph $G = (X, Y, E)$ and two concave weight matrices A and B. Let $G' = (X, E')$ be the complete digraph on X with the concave weight matrix $w = A \times B$. If $w(x_i, x_i) \geq 0$ for all $0 \leq i \leq n$, then G' and w define an instance of the enhanced LWS problem.

Let $P' :\ x_0 = x_{i_0} \to x_{i_1} \to \cdots \to x_{i_k} = x_n$ be a shortest path in G' from x_0 to x_n. For each l ($0 \leq l \leq k$), let $j_l = I(i_{l-1}, i_l)$. Then $P :\ x_0 = x_{i_0} \to y_{j_1} \to x_{i_1} \to$

$y_{j_2} \to \cdots \to y_{j_k} \to x_{i_k} = x_n$ is a path in G from x_0 to x_n. Let $w(P')$ denote the weight of P' in G' and $w(P)$ the weight of P in G. Clearly, $w(P) = w(P')$. We will show that $w(P)$ is minimum among all paths from x_0 to x_n in G.

Let Q be a shortest path in G from x_0 to x_n. Since G is bipartite, Q is a concatenation of subpaths $Q_1, Q_2, \ldots, Q_p$ for some $p \geq 1$, where each Q_l $(1 \leq l \leq p)$ consists of two edges $x_{i'_{l-1}} \to y_{j'_l} \to x_{i'_l}$ ($i'_0 = 0$ and $i'_p = n$). For each $1 \leq l \leq p$, if $j'_l \neq I(i'_{l-1}, i'_l)$, we can replace Q_l by the subpath $x_{i'_{l-1}} \to y_{I(i'_{l-1}, i'_l)} \to x_{i'_l}$ without increasing the total weight $w(Q)$. Therefore, without loss of generality, we may assume that $j'_l = I(i'_{l-1}, i'_l)$ for all $1 \leq l \leq p$. Hence the weight of Q_l is $w[i'_{l-1}, i'_l]$. Thus Q corresponds to a path $Q' = \{x_0 = x_{i'_0} \to x_{i'_1} \to \cdots \to x_{i'_p} = x_n\}$ from x_0 to x_n in G' with $w(Q') = w(Q)$. Since the weight of P' is minimum among all such paths in G', we have $w(P) = w(P') \leq w(Q') = w(Q)$. Thus P is a shortest path in G from x_0 to x_n.

LEMMA 4.5. *Let A and B be two concave matrices such that all the entries on the main diagonal of the product matrix $w = A \times B$ are nonnegative. If the enhanced LWS problem defined by the matrix w can be solved in $T(n,m)$ time, then the SPBD problem defined by A and B can be solved in $O(T(n,m) + m \log n)$ time.*

Proof. In order to solve the SPBD problem defined by matrices A and B, we first solve the enhanced LWS problem defined by the matrix $w = A \times B$. Let P' : $x_0 = x_{i_0} \to x_{i_1} \to \cdots \to x_{i_k} = x_n$ be the solution path found. We compute $j_1, j_2, \ldots, j_k$, where $j_l = I(i_{l-1}, i_l)$. Since $(i_0, i_1) \prec (i_1, i_2) \prec \cdots \prec (i_{k-1}, i_k)$, this can be done in $O(m \log n)$ time by Lemma 4.4. The path $x_0 = x_{i_0} \to y_{j_1} \to x_{i_1} \to \cdots \to y_{j_k} \to x_{i_k} = x_n$ is the solution for the SPBD problem. ∎

We want to use Wilber's algorithm in [11] to solve our enhanced LWS problem. In order to do this, however, we have to overcome two difficulties. First, Wilber's algorithm is for solving the (ordinary) LWS problem which is defined by an upper triangle matrix while our problem is defined by a full matrix. Second, Wilber's algorithm assumes that each entry $w(i,j)$ can be evaluated in $O(1)$ time. In our case, an entry of the matrix $w = A \times B$ may need $\Theta(m)$ time to evaluate. We will address these two issues in the next section.

4.3. An algorithm for the enhanced LWS problem. Our algorithm for the enhanced LWS problem is a modification of Wilber's algorithm for the LWS problem. First, we briefly review Wilber's algorithm. (We assume that the reader is familiar with [11].) Then we show how to modify Wilber's algorithm to solve our problem.

Consider an instance of the LWS problem with the sequence $\{x_0, x_1, \ldots, x_n\}$ and the weight matrix $w(x_i, x_j)$. Recall that w is an $(n+1) \times (n+1)$ upper triangular matrix. Let $f(0) = 0$ and, for $1 \leq j \leq n$, let $f(j)$ be the weight of the lowest weight subsequence between x_0 and x_j. For $0 \leq i < j \leq n$ let $g(i,j)$ be the weight of the lowest-weight subsequence between x_0 and x_j whose next-to-last element is x_i. Then we have

$$(4.2) \qquad \begin{cases} f(j) = \min_{0 \leq i < j} g(i,j) & \text{for } 1 \leq j \leq n, \\ g(i,j) = f(i) + w(x_i, x_j) & \text{for } 0 \leq i < j \leq n. \end{cases}$$

To solve the LWS problem it is enough to compute $f(1), f(2), \ldots, f(n)$. Adding $f(i_1) + f(i_2)$ to both sides of inequality (4.1) and applying definition (4.2), we get

$$g(i_1, j_1) + g(i_2, j_2) \leq g(i_1, j_2) + g(i_2, j_1) \quad \text{for } 0 \leq i_1 \leq i_2 \leq j_1 \leq j_2 \leq n.$$

Consider a matrix $M[0..n, 0..m]$. For each column index $0 \leq j \leq m$ let $i(j)$ be the smallest row index such that $M(i(j), j)$ equals the minimum value in the jth column of M. The *column minima searching* problem for M is to find the $i(j)$'s for all $0 \leq j \leq m$. M is called *monotone* if $i(j_1) \leq i(j_2)$ for all $0 \leq j_1 < j_2 \leq m$. M is *totally monotone* if every 2×2 submatrix of M is monotone [3]. If M is concave, then it is easy to check that M is totally monotone. (The reverse is not necessarily true.) For a totally monotone matrix M, the column minima searching problem for M can be solved in $O(n+m)$ time, assuming that each entry of M can be evaluated in $O(1)$ time [3]. Following [8], we will refer to the algorithm in [3] as the SMAWK algorithm.

We extend the definition of g by setting $g(i,j) = +\infty$ for $0 \leq j \leq i \leq n$. Then g becomes a full $(n+1) \times (n+1)$ matrix. It is easy to verify that the extended matrix g is totally monotone. (The only role of the $+\infty$ entries is to make g a full matrix for convenience. These entries otherwise have no effect on the computation.) Our goal is to determine the row index of the minimum value in each column of g (which gives $f(1), \ldots, f(n)$). One might simply want to apply the SMAWK algorithm to g. But we cannot, because for $i < j$, the value of $g(i,j)$ depends on $f(i)$ and $f(i)$ depends on $g(0,i), g(1,i), \ldots, g(i-1,i)$. Thus we cannot compute the value of g in $O(1)$ time as required by the SMAWK algorithm.

Wilber's algorithm starts in the upper left corner of g and works rightward and downward, at each iteration learning enough new values of f to be able to compute enough new values of g to continue with the next iteration. Actually, during one step of each iteration, the algorithm might "pretend" to know values of f that it really does not have. At the end of the iteration, the assumed value of f is checked for validity.

We use $f(j)$ and $g(i,j)$ to refer to the correct values of f and g, respectively. The currently computed value of $f(j)$ is denoted by $F(j)$ and sometimes will be incorrect. The currently computed value of $g(i,j)$ is denoted by $G[i,j]$ and is always computed as $F[i] + w(i,j)$. Therefore $G[i,j] = g(i,j)$ iff $F(i) = f(i)$. The algorithm does not explicitly store the matrices w, g, G. Rather, their entries are calculated when needed. Let $G[i_1, i_2; j_1, j_2]$ denote the submatrix of G consisting of the intersection of rows i_1 through i_2 and columns j_1 through j_2. $G[i_1, i_2; j]$ denotes the intersection of rows i_1 through i_2 with column j. The rows of G are indexed from 0 and the columns are indexed from 1. Wilber's algorithm is as follows.

```
WILBER'S ALGORITHM.
$F[0] \leftarrow c \leftarrow r \leftarrow 0$.
**while** $(c < n)$ do
    1. $p \leftarrow \min\{2c - r + 1, n\}$.
    2. Apply the SMAWK algorithm to find the minimum in each column of sub-
       matrix $S = G[r, c; c+1, p]$. For $j \in [c+1, p]$, let $F[j]$ = the minimum value
       found in $G[r, c; j]$.
    3. Apply the SMAWK algorithm to find the minimum in each column of the
       submatrix $T = G[c+1, p-1; c+2, p]$. For $j \in [c+2, p]$, let $H[j]$ = the
       minimum value found in $G[c+1, p-1; j]$.
    4. If there is an integer $j \in [c+2, p]$ such that $H[j] < F[j]$, then set $j_0$ to the
       smallest such integer. Otherwise set $j_0 \leftarrow p+1$.
    5. **if** $(j_0 = p+1)$ **then** $c \leftarrow p$;
       **else** $F[j_0] \leftarrow H[j_0]$; $r \leftarrow c+1$; $c \leftarrow j_0$.
**end**.
```

Figure 4.1 shows the submatrices S and T during a typical iteration of the algorithm. (This figure is taken from [11].) Each time we are at the beginning of the

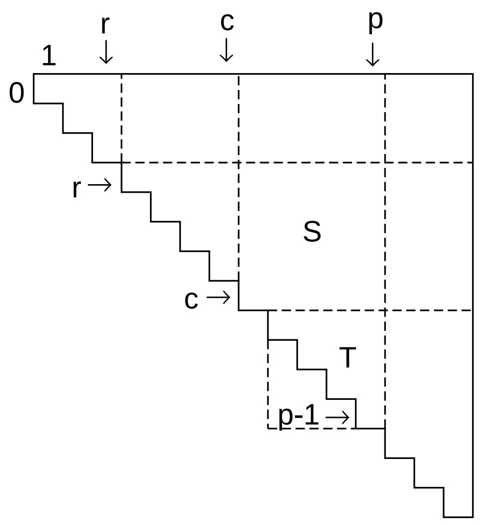

FIG. 4.1. *A typical iteration of Wilber's algorithm.*

loop, the following invariants hold:

(a) $r \geq 0$ and $c \geq r$.

(b) For each $j \in [0, c]$, $F[j] = f(j)$.

(c) All the minima in columns $c + 1$ through n of g are in rows $\geq r$.

These invariants are clearly satisfied at the beginning when $r = c = 0$.

Invariant (b) implies that $G[i, j] = g(i, j)$ for all j and all $i \in [0, c]$. So the entries of the submatrix S are the same as the corresponding entries of g. Therefore S is totally monotone, and for each $j \in [c + 1, p]$ step 2 sets $F[j]$ to the minimum value of the subcolumn $g(r, c; j)$. Also, since S contains all the finite-valued cells in column $c + 1$ of g that are in rows $\geq r$, we have $F[c + 1] = f(c + 1)$ at the end of step 2. On the other hand, we do not necessarily have $F[j] = f(j)$ for any $j \in [c + 2, p]$, since g has finite-valued cells in those columns that are in rows $\geq r$ and not in S.

In step 3 we proceed as if $F[j] = f(j)$ for all $j \in [c + 1, p - 1]$. Since this may be false, some of the values in T may be bogus. However, T is always totally monotone because if we add $F[i_1] + F[i_2]$ to both sides of (4.1) we get $G[i_1, j_1] + G[i_2, j_2] \leq G[i_1, j_2] + G[i_2, j_1]$. Thus the SMAWK algorithm works correctly and $H[j]$ is set to the minimum value of the subcolumn $G[c + 1, p - 1; j]$ (which is not necessarily the same as the minimum value of the subcolumn $g(c + 1, p - 1; j)$). Note that since all the entries on and below the main diagonal of g are $+\infty$, they cannot be $H[j]$ for any j and hence have no effect on the computation.

In step 4 we either verify that $F[j] = f(j)$ for all $j \in [c + 2, p]$ (this is the case if $H[j] \geq F[j]$ for all $j \in [c + 2, p]$) or we find the smallest j where this condition fails (this is the case when there exists $j \in [c+2, p]$ such that $H[j] < F[j]$). In either case, the values of c and r are set accordingly at step 5 so that the loop invariants hold. This completes the description of Wilber's algorithm.

Next we discuss how to use Wilber's algorithm to solve the enhanced LWS problem. Let $w[0..n, 0..n]$ be the weight matrix of an instance of the enhanced LWS problem. Let L denote the portion of w consisting of the entries on and below the main diagonal of w. Let w' be the matrix obtained from w by replacing all the entries in L by $+\infty$. Then w' defines an instance of the (ordinary) LWS problem. By

Lemma 4.1, the solution for the problem defined by w' is identical to the solution for the problem defined by w. If each entry of w can be computed in $O(1)$ time, we can use Wilber's algorithm on w' to solve the problem. However, if the enhanced LWS problem is derived from an instance of the SPBD problem, the entries of the matrix $w = A \times B$ cannot be computed in $O(1)$ time. In this case we cannot afford to change w to w' since doing so will destroy some properties of w that are crucial for obtaining a fast algorithm. Fortunately, we will show that Wilber's algorithm can be applied directly to w to solve the enhanced LWS problem.

It is enough to show that the entries in L have no effect on the computation of Wilber's algorithm. The only place where Wilber's algorithm needs the entries in L is step 3, where the SMAWK algorithm is applied to the submatrix T. For each $j \in [c+2, p]$ let $F[j]$ and $H[j]$ be the minimum value of column j in S and T, respectively. There are three cases:

(a) $F[j] \leq H[j]$.

(b) $F[j] > H[j]$ and $H[j]$ is not in L. Namely, $H[j] = G[i,j]$ for some $i < j$.

(c) $F[j] > H[j]$ and $H[j]$ is in L. Namely, $H[j] = G[i,j]$ for some $i \geq j$.

In cases (a) and (b) the values in L do not affect the computation. In the following we show that case(c) cannot occur. Toward a contradiction, assume that there exist indices $j \in [c+2, p]$ and i such that $i \geq j$ and $H[j] = G[i,j] < F[j]$.

Case 1: If $i = j$, then $H[j] = G[j,j] = F[j] + w(j,j) \geq F[j]$. This is impossible.

Case 2: If $i > j$, then $H[j] = G[i,j] = F[i] + w(i,j)$. Recall that $F[i]$ is the minimum value of the subcolumn $G[r,c;i]$. Suppose that $F[i] = G[t,i] = F[t] + w(t,i)$ for some $r \leq t \leq c$. Note that $t \leq c < i$ and $j < i$. By the concavity of w we have $w(t,j) + w(i,i) \leq w(t,i) + w(i,j)$. Since $w(i,i) \geq 0$ for all i, we have $H[j] = F[i] + w(i,j) = F[t] + w(t,i) + w(i,j) \geq F[t] + w(t,j) + w(i,i) \geq F[t] + w(t,j) = G[t,j] \geq F[j]$. This contradicts the assumption that $H[j] < F[j]$.

Since case (c) cannot occur, the entries in L do not affect the computation of Wilber's algorithm, regardless of whether they are changed to $+\infty$ or not. Hence we have proved the following lemma.

LEMMA 4.6. *An instance of the enhanced LWS problem defined by a (full) concave matrix w can be correctly solved by applying Wilber's algorithm to the matrix w.*

Next we address the second difficulty mentioned at the end of section 4.2. If the instance of the enhanced LWS problem is derived from an instance of the SPBD problem (defined by matrices A and B), the weight matrix w of the enhanced LWS problem is the product matrix $w = A \times B$. Therefore the key assumption of Wilber's algorithm that each entry $w[i,j]$ can be evaluated in $O(1)$ time is not valid.

During each stage of Wilber's algorithm (steps 2 and 3) we need to find column minima of the submatrices S and T. Both S and T have the form $C'[r,c;q,p]$ where $C'[i,j] = F[i] + w[i,j]$ for some known value $F[i]$. Since the values $C'[i,j]$ cannot be computed in $O(1)$ time, we cannot use the SMAWK algorithm directly. Instead, we use the algorithm given in the following lemma.

LEMMA 4.7. *The column minima searching problem for the submatrix $C'[r,c;q,p]$ with $r \leq q$ and $c \leq p$ can be solved in $O((c-r) + (p-q) + (k_2 - k_1))$ time, where $k_1 = I(r,r)$ and $k_2 = I(p,p)$.*

Proof. By Lemma 4.3, for each $i \in [r,c]$ and $j \in [q,p]$, $w[i,j] = \min_{0 \leq k \leq m}(A[i,k] + B[k,j])$ can be computed by searching k in the range $k \in [k_1, k_2]$. For $j \in [q,p]$ let $d(j)$ denote the column minimum of $C'[r,c;j]$. Then $d(j) = \min_{r \leq i \leq c}\{F[i] + w[i,j]\} = \min_{r \leq i \leq c}\{F[i] + \min_{k_1 \leq k \leq k_2}(A[i,k] + B[k,j])\} = \min_{k_1 \leq k \leq k_2}\{B[k,j] + \min_{r \leq i \leq c}(F[i] + A[i,k])\}$.

For $i \in [r, c]$ and $k \in [k_1, k_2]$ let $A'[i, k] = F[i] + A[i, k]$. Then A' is totally monotone. For each $k \in [k_1, k_2]$ let $J[k]$ be the minimum of the subcolumn $A'[r, c; k]$.

For $k \in [k_1, k_2]$ and $j \in [q, p]$ let $B'[k, j] = B[k, j] + J[k]$. Then B' is totally monotone. Clearly, $d(j)$ is the minimum of the subcolumn $B'[k_1, k_2; j]$. Thus the column minima $d(j)$'s of $C'[r, c; q, p]$ can be found by two applications of the SMAWK algorithm, once on A' and once on B'. Each entry of A' and B' can be evaluated in $O(1)$ time. Thus the total time needed is $O((c-r)+(k_2-k_1))+O((k_2-k_1)+(p-q)) = O((c-r)+(p-q)+(k_2-k_1))$. $\square$

4.4. The SPBD algorithm and its complexity. The following is the complete description of our SPBD algorithm.

SPBD ALGORITHM.

```
Input: An instance of the SPBD problem defined by two concave matrices $A$ and $B$.
  1. Compute $I(0,0), I(1,1), \ldots, I(n,n)$ (cf. Lemma 4.4).
  2. Solve the enhanced LWS problem defined by the matrix $w = A \times B$ by ap-
     plying Wilber's algorithm on $w$. But instead of using the SMAWK algorithm
     we use the algorithm given in Lemma 4.7 to search the column minima of the
     submatrix $S$ and $T$ during the execution.
  3. Using the method described in Lemma 4.5, convert the solution of the en-
     hanced LWS problem defined by $w$ to the solution of the original SPBD
     problem.
end.
```

The correctness of the algorithm follows from the discussion of the last subsection. Next we analyze the running time of the SPBD algorithm. We concentrate on step 2 since this is the nontrivial part of the algorithm. Each iteration of Wilber's algorithm is completely specified by three parameters: r, c, p. Let r_i, c_i, p_i be the values of these parameters in the ith iteration. The parameters for the next iteration are calculated in step 5 as follows:

Case 1: "then" part of step 5 is executed. In this case, $r_{i+1} = r_i$, $c_{i+1} = p_i$, and

Case 1a: $p_{i+1} = 2c_{i+1} - r_{i+1} + 1$, if it is $\leq n$, or

Case 1b: $p_{i+1} = n$, otherwise.

Case 2: "else" part is executed. In this case, $r_{i+1} = c_i + 1$, $c_{i+1} = j_0$ (where $c_i + 2 \leq j_0 \leq p_i$), and

Case 2a: $p_{i+1} = 2c_{i+1} - r_{i+1} + 1$, if it is $\leq n$, or

Case 2b: $p_{i+1} = n$, otherwise.

If Case 1a (or 1b, 2a, 2b, respectively) applies to the ith iteration, we call it a type 1a (or 1b, 2a, 2b, respectively) iteration. We call $[r_i, p_i]$ the ith *span*; r_i and p_i are the left and the right ends of the ith span, respectively. Note that after a type 1a or 1b iteration, the left end is not changed and the right end increases. After a type 2a or 2b iteration, the left end increases and the right end may increase, decrease, or remain unchanged. For an interval $[t, t+1]$ $(0 \leq t < n)$ we say that a span $[r_i, p_i]$ *covers* $[t, t+1]$, written as $[t, t+1] \in [r_i, p_i]$, if $r_i \leq t$ and $t+1 \leq p_i$. Since the left end of spans never decreases, the spans "move" from left to right during the execution of the algorithm. Once the left end of a span is $\geq t+1$, $[t, t+1]$ will never be covered by any subsequent spans. First we make the following obvious observations:

(a) If a type 1a or 1b iteration follows a type 1b or 2b iteration, the algorithm terminates immediately.

(b) If the ith iteration is of type 1a, then $p_{i+1} - r_{i+1} = (2c_{i+1} - r_{i+1} + 1) - r_{i+1} = 2(p_i - r_i) + 1$. Namely, the length of the $(i+1)$th span is $1 + 2 \times$ (the length of the ith span).

(c) Suppose that the ith iteration is of type 2a or 2b. Since $p_i \leq 2c_i - r_i + 1$, we have $c_i \geq (p_i + r_i - 1)/2$. Hence $r_{i+1} = c_i + 1 \geq (p_i + r_i - 1)/2 + 1$.

(d) Suppose that an interval $[t, t+1]$ is covered by the ith span $[r_i, p_i]$. If the ith iteration is of type 1a or 1b, and the $(i+1)$st iteration is of type 2a or 2b, then $r_{i+2} = c_{i+1} + 1 = p_i + 1 > t + 1$. Hence $[t, t+1]$ is not covered by $[r_{i+2}, p_{i+2}]$ nor by any subsequent spans.

The following lemma gives an upper bound on the number of times an interval $[t, t+1]$ can be covered by spans. This bound is needed in the analysis of our algorithm.

LEMMA 4.8. *Any interval* $[t, t+1]$ $(0 \leq t < n)$ *is covered by at most* $2 \log n + 2$ *spans.*

Proof. Let $[r_{i_1}, p_{i_1}], [r_{i_2}, p_{i_2}], \ldots, [r_{i_k}, p_{i_k}]$ be all the spans covering $[t, t+1]$, where $i_1 < i_2 < \cdots < i_k$. Then $r_{i_l} \leq t$ and $t + 1 \leq p_{i_l}$ for all $1 \leq l \leq k$.

Let l be the first index such that the i_lth iteration is of type 1a or type 1b. (If no such l exists, let $l = k$.) We first show that $k - l \leq \log n + 2$.

Case 1: The i_lth iteration is of type 1b. If the $(i_l + 1)$st iteration is of type 1a or 1b, then the algorithm terminates by observation (a). If the $(i_l + 1)$st iteration is of type 2a or 2b, then by observation (d) $[t, t+1]$ is not covered by $[r_{i_l+2}, p_{i_l+2}]$ nor by any subsequent spans.

Case 2: The i_lth iteration is of type 1a. Let s (possibly $s = 0$) be the largest integer such that the iterations $i_l, i_l + 1, \ldots, i_l + s$ are all of type 1a. Clearly, $[t, t+1]$ is covered by the spans $[r_{i_l+1}, p_{i_l+1}], \ldots, [r_{i_l+s}, p_{i_l+s}]$. By observation (b) each type 1a iteration doubles the length of the span. Since the length of a span is at most n, we have $s \leq \log n$. The $(i_l + s + 1)$st iteration is of type 1b, 2a, or 2b. If it is of type 2a or 2b, then by observation (d) $[t, t+1]$ is not covered by the $(i_l + s + 2)$nd span nor by any subsequent spans. If the $(i_l + s + 1)$st iteration is of type 1b, then, similar to Case 1, either the algorithm terminates at the $(i_l + s + 2)$nd iteration, or $[t, t+1]$ is not covered by the $(i_l + s + 2)$nd span nor by any subsequent spans.

In either case, the number of spans following the i_lth iteration that cover $[t, t+1]$ is at most $\log n + 2$. So $k - l \leq \log n + 2$. Next we show $l \leq \log n$ and this will complete the proof of the lemma.

For each $1 \leq h < l$ the i_hth iteration is of type 2a or 2b. Fix an index h. For each $j \geq i_h$ let $L_j = (t+1) - r_j$. Note that if $L_j \leq 0$, then the span $[r_j, p_j]$ cannot cover the interval $[t, t+1]$. By the fact that $t + 1 \leq p_{i_h}$ and observation (c), we have

$$\begin{aligned} L_{i_h+1} &= (t+1) - r_{i_h+1} \leq (t+1) - ((p_{i_h} + r_{i_h} - 1)/2 + 1) \\ &= (2t - p_{i_h} - r_{i_h} + 1)/2 \leq (t - r_{i_h})/2 < L_{i_h}/2. \end{aligned}$$

Since the left end of the spans never decreases, we now have that $L_{i_{h+1}} \leq L_{i_h+1} < L_{i_h}/2$. This is true for all $1 \leq h < l$. Hence $L_{i_l} < L_{i_1}/2^l$. If $l > \log n$, then L_{i_l} becomes 0 and the interval $[t, t+1]$ is not covered by $[r_{i_l}, p_{i_l}]$ nor by any subsequent spans. So we must have $l \leq \log n$. This establishes the lemma. ☐

We are now ready to prove Theorem 1.1.

Proof of Theorem 1.1. Step 1 of the SPBD algorithm takes $O(m \log n)$ time by Lemma 4.4. In step 2 we use Wilber's algorithm to solve the enhanced LWS problem defined by the matrix $w = A \times B$. But instead of using the SMAWK algorithm we use the subroutine in Lemma 4.7 for finding column minima in S and T. Note that all the other steps of Wilber's algorithm take $O(n + m)$ time. Thus if we can show that the time needed by these subroutine calls is bounded by $O(n + m \log n)$, the theorem will follow from Lemma 4.5.

Consider the ith iteration. We need to find the column minima of the submatrices $S_i = G[r_i, c_i; c_i + 1, p_i]$ and $T_i = G[c_i + 1, p_i - 1; c_i + 2, p_i]$. Let $k_1 = I(r_i, r_i)$, $k_2 = I(p_i, p_i)$, and $k_3 = I(c_i + 1, c_i + 1)$. Since $r_i < c_i + 1 \leq p_i$ we have $k_1 \leq k_3 \leq k_2$ by Lemma 4.3.

By Lemma 4.7 the searching of S_i needs $O((c_i - r_i) + (p_i - c_i - 1) + (k_2 - k_1)) = O((p_i - r_i) + (k_2 - k_1))$ time. The searching of T_i needs $O((p_i - 1 - c_i - 1) + (p_i - c_i - 2) + (k_2 - k_3))$ time. Since $p_i \leq 2c_i - r_i + 1$ and $k_3 \geq k_1$, this is bounded by $O((p_i - r_i) + (k_2 - k_1))$. Thus the total time needed to search S_i and T_i in all the iterations is $\sum_{i=1}^{K} O((p_i - r_i) + (I(p_i, p_i) - I(r_i, r_i)))$, where K is the total number of iterations of the algorithm. Since Wilber's original algorithm takes $O(n)$ time, the term $\sum_{i=1}^{K} O(p_i - r_i)$ is bounded by $O(n)$. On the other hand,

$$\begin{aligned}\sum_{i=1}^{K}(I(p_i, p_i) - I(r_i, r_i)) &= \sum_{i=1}^{K}\sum_{t=r_i}^{p_i-1}(I(t+1, t+1) - I(t, t)) \\ &= \sum_{t,i \text{ where } [t,t+1]\in[r_i,p_i]} (I(t+1, t+1) - I(t, t)). \qquad (4.3)\end{aligned}$$

By Lemma 4.8 each interval $[t, t + 1]$ is covered by at most $2 \log n + 2$ spans. Thus the above sum is bounded by $O(\log n \sum_{t=0}^{n-1}(I(t + 1, t + 1) - I(t, t))) = O(m \log n)$ as to be shown. $\square$

5. Conclusion.

We introduced the SPBD problem and showed that if the weight matrices are concave, then the SPBD problem can be reduced to the enhanced LWS problem and solved in $O(n+m \log n)$ time. As applications, we showed that the MLP for points on a straight line and the TSP for points on a convex polygon can be reduced to the SPBD problem and solved in $O(n \log n)$ time, which substantially improves the previously known $O(n^2)$-time algorithms. The setting of the SPBD problem is quite general. It is interesting to find other applications of the SPBD problem.

We tried (but failed) to use this technique to solve the MLP for points on a convex polygon. (To our knowledge, the MLP for this special case is not known to be in P.) In the two applications discussed in this paper, the optimal paths are simple (i.e., no two edges of the path cross). Unfortunately, the optimal tour in the MLP for points on a convex polygon does not have this crucial property. It would be interesting to find a polynomial-time algorithm for solving the MLP for this case.

Another open problem is to solve the MLP for an *r-arm star graph* G, which has a center vertex c and r "arms" connected to c, and each arm is a straight line with several vertices on it. (Thus the straight line discussed in section 3 is a two-arm star graph.) If each arm of G contains at most k vertices, then the MLP problem for G can be solved in $O(r \times k^r)$ time by using dynamic programming, which is not a polynomial in terms the number of vertices of G. Is it possible to solve this problem in polynomial time using ideas similar to the SPBD algorithm? This would seem to require, at the very least, solving r-partite generalization of the SPBD problem.

Acknowledgments. The authors would like to thank the referees for pointing out the much simplified proof of Lemma 3.1, for mentioning the last open problem in section 5, and for suggestions that considerably improved the exposition.

REGULAR CLOSURE OF DETERMINISTIC LANGUAGES[*]

EBERHARD BERTSCH[†] AND MARK-JAN NEDERHOF[‡]

Abstract. We recall the notion of regular closure of classes of languages. We present two important results. The first result is that all languages which are in the regular closure of the class of deterministic (context-free) languages can be recognized in linear time. This is a nontrivial result, since this closure contains many inherently ambiguous languages. The second result is that the class of deterministic languages is contained in the closure of the class of deterministic languages with the prefix property or, stated in an equivalent way, all LR(k) languages are in the regular closure of the class of LR(0) languages.

Key words. context-free languages, regular languages

1. Introduction.

Despite important insights in applying sophisticated matrix operations to recognition techniques [16], the known upper bound on the time complexity of context-free language recognition still exceeds $\mathcal{O}(n^2)$, measured in the length of the input string. However, there are many languages whose time complexity has been shown to be linear by means of *specialized* algorithms but which are not recognized in linear time by *general* recognition algorithms. The frontier of knowledge in this area is advanced by the results presented in this article.

We introduce a special class of two-level automata. Their upper level is constituted by a (classical) finite automaton whose transitions are, however, not enabled by a single terminal symbol but by any element of a given (lower-level) language. All languages at the lower level are assumed to have the restrictive LR(k)-property. Due to the well-known correspondence between regular expressions and finite automata, the new class of languages may thus be stated to result from the set of deterministic (i.e., LR(k)) languages by recursively applying concatenation, union, and Kleene star to given languages in that class.

The new class contains some notorious specimens such as $\{a^m b^m c^n\} \cup \{a^m b^n c^n\}$, an inherently ambiguous language [8]. As will be developed in the body of this article, a linear upper time bound on recognizing such languages can be established.

The results are related to our previous work [13] on efficient recognition of language suffixes. It had in turn been motivated by practical syntax error detection (more precisely, by noncorrecting error recovery [15]).

The article may be outlined as follows. After introducing the definitional framework in section 2, we show that all deterministic context-free languages can be constructed from prefix-free deterministic languages by regular operations (section 3).

This follows from a detailed decomposition of pushdown computations into sequences of moves that do not discard more than one element of the stack they started with.

The most important proposition of section 4 is that each deterministic pushdown automaton can be transformed into an equivalent one which is "loop-free." This requires a fairly deep discussion of individual pushing and popping moves. In essence, automata are changed in such a way that the stack contents after certain moves must reflect the *amount* of processed input. Using tabulation, the transformed pushdown automata can be simulated at all input positions in linear time. This result is part of a proof of the fact that languages in the regular closure of the deterministic languages can be recognized in linear time by means of a two-level device, to be defined in section 5.

Section 6 deals with various syntheses and applications of the obtained results. In particular, "on-line" and "off-line" variants of the two-level device are presented and compared. The difference between these notions is rather similar to the one between Earley's recognition algorithm [7] and the Cocke–Kasami–Younger technique [8]. With the latter approach, partial recognition results are collected without reference to their left context.

Although the parse tree concept is less immediate for the new kind of language description than for ordinary grammars, we are able to sketch an efficient transduction procedure yielding representations of the syntactic structure of given inputs (section 7).

Two applications are presented in section 8. First we prove that suffix recognition is possible in linear time. This new proof is much shorter than recently published proofs of this fact. We then describe an application in pattern matching.

2. Notation. A finite automaton $\mathcal{F}$ is a 5-tuple (S, Q, q_s, F, T), where S and Q are finite sets of input symbols and states, respectively; $q_s \in Q$ is the *initial* state and $F \subseteq Q$ is the set of *final* states; and the transition relation T is a subset of $Q \times S \times Q$.

An input string $b_1 \cdots b_m \in S^*$ is *recognized* by the finite automaton if there is a sequence of states $q_0, q_1, \ldots, q_m$ such that $q_0 = q_s$, $(q_{k-1}, b_k, q_k) \in T$ for $1 \leq k \leq m$, and $q_m \in F$. For a certain finite automaton $\mathcal{F}$, the set of all such strings w is called the language *accepted by* $\mathcal{F}$, denoted $L(\mathcal{F})$. The languages accepted by finite automata are called the *regular* languages.

In the following, we describe a type of pushdown automaton without internal states and with very simple kinds of transition. This is a departure from the standard literature (e.g., [9]), but simplifies considerably our definitions and proofs in the remainder of the paper. That the generative capacity of this type of pushdown automaton is not affected with respect to any of the more traditional types can be argued by the fact that every context-free language is accepted by a nondeterministic LR recognizer of a form very similar to our type of pushdown automaton [14]. See also [13].

Thus, we define a pushdown automaton (PDA) $\mathcal{A}$ to be a 5-tuple $(\Sigma, \Delta, X_{initial}, F, T)$, where Σ, Δ, and T are finite sets of input symbols, stack symbols and transitions, respectively; $X_{initial} \in \Delta$ is the *initial* stack symbol, and $F \subseteq \Delta$ is the set of *final* stack symbols.

We consider a fixed input string $a_1 \cdots a_n \in \Sigma^*$. A *configuration* of the automaton is a pair (δ, v) consisting of a stack $\delta \in \Delta^*$ and the remaining input v, which is a suffix of the original input string $a_1 \cdots a_n$.

The *initial* configuration is of the form $(X_{initial}, a_1 \cdots a_n)$, where the stack is formed by the initial stack symbol $X_{initial}$. A *final* configuration is of the form $(\delta X, \epsilon)$, where the element on top of the stack is some final stack symbol $X \in F$.

The transitions in T are of the form $X \overset{z}{\mapsto} XY$, where $z = \epsilon$ or $z = a$, or of the form $XY \overset{\epsilon}{\mapsto} Z$.

The application of such a transition $\delta_1 \overset{z}{\mapsto} \delta_2$ is described as follows. If the topmost symbols on the stack are δ_1, then these may be replaced by δ_2, provided either $z = \epsilon$ or $z = a$ and a is the first symbol of the remaining input. If $z = a$ then furthermore a is removed from the remaining input.

Formally, for a fixed PDA we define the binary relation $\vdash$ on configurations as the least relation satisfying $(\delta\delta_1, v) \vdash (\delta\delta_2, v)$ if there is a transition $\delta_1 \overset{\epsilon}{\mapsto} \delta_2$ and $(\delta\delta_1, av) \vdash (\delta\delta_2, v)$ if there is a transition $\delta_1 \overset{a}{\mapsto} \delta_2$.

In the case that we consider more than one PDA at the same time we use symbols $\overset{z}{\mapsto}_{\mathcal{A}}$ and $\vdash_{\mathcal{A}}$ instead of $\overset{z}{\mapsto}$ and $\vdash$ if these refer to one particular PDA $\mathcal{A}$.

The recognition of a certain input v is obtained if, starting from the initial configuration for that input, we can reach a final configuration by repeated application of transitions, or, formally, if $(X_{initial}, v) \vdash^* (\delta X, \epsilon)$, with some $\delta \in \Delta^*$ and $X \in F$, where $\vdash^*$ denotes the reflexive and transitive closure of $\vdash$ (and $\vdash^+$ denotes the transitive closure of $\vdash$). For a certain PDA $\mathcal{A}$, the set of all such strings v which are recognized is called the language *accepted by* $\mathcal{A}$, denoted $L(\mathcal{A})$. A PDA is called *deterministic* if, for all possible configurations, at most one transition is applicable. The languages accepted by deterministic PDAs (DPDAs) are called *deterministic languages*.

We may restrict DPDAs such that no transitions apply to final configurations, by imposing $X \notin F$ if there is a transition $X \overset{z}{\mapsto} XY$ and $Y \notin F$ if there is a transition $XY \overset{\epsilon}{\mapsto} Z$. We call such a DPDA *prefix-free*. The languages accepted by such DPDAs are obviously *prefix-free*, which means that no string in the language is a prefix of any other string in the language. Conversely, any prefix-free deterministic language is accepted by some prefix-free DPDA, the proof being that in a DPDA, all transitions of the form $X \overset{z}{\mapsto} XY$, $X \in F$, and $XY \overset{\epsilon}{\mapsto} Z$, $Y \in F$, can be removed without consequence to the accepted language if this language is prefix-free.

In compiler design, the deterministic languages are better known as LR(k) languages, and the prefix-free deterministic languages as LR(0) languages [9].

A prefix-free DPDA is in normal form if, for all input v, $(X_{initial}, v) \vdash^* (\delta X, \epsilon)$, with $X \in F$, implies $\delta = \epsilon$, and furthermore F is a singleton $\{X_{final}\}$. Any prefix-free DPDA can be put into normal form. (See [9, Theorem 5.1] for a proof of a related result.) We define a *normal PDA* (NPDA) to be a prefix-free deterministic PDA in normal form.

We define a subrelation $\models^+$ of $\vdash^+$ as $(\delta, vw) \models^+ (\delta\delta', w)$ if and only if $(\delta, vw) = (\delta, z_1 z_2 \cdots z_m w) \vdash (\delta\delta_1, z_2 \cdots z_m w) \vdash \cdots \vdash (\delta\delta_m, w) = (\delta\delta', w)$, for some $m \geq 1$, where $|\delta_k| > 0$ for all k, $1 \leq k \leq m$. Informally, we have $(\delta, vw) \models^+ (\delta\delta', w)$ if configuration $(\delta\delta', w)$ can be reached from (δ, vw) without the bottommost part δ of the intermediate stacks being affected by any of the transitions; furthermore, at least one element is pushed on top of δ. Note that $(\delta_1 X, vw) \models^+ (\delta_1 X\delta', w)$ implies $(\delta_2 X, vw') \models^+ (\delta_2 X\delta', w')$ for any δ_2 and any w', since the transitions neither address the part of the stack below X nor read the input following v.

3. Metadeterministic languages.

In this section we define a new subclass of the context-free languages, which results from combining deterministic languages by the operations used to specify regular languages.

We first define the concept of *regular closure* of a class of languages.[1] Let $\mathcal{L}$ be a

[1]This notion was called *rational closure* in [3].

class of languages. The regular closure of $\mathcal{L}$, denoted $C(\mathcal{L})$, is defined as the smallest class of languages such that

(i) $\emptyset \in C(\mathcal{L})$,
(ii) if $l \in \mathcal{L}$ then $l \in C(\mathcal{L})$,
(iii) if $l_1, l_2 \in C(\mathcal{L})$ then $l_1 l_2 \in C(\mathcal{L})$,
(iv) if $l_1, l_2 \in C(\mathcal{L})$ then $l_1 \cup l_2 \in C(\mathcal{L})$, and
(v) if $l \in C(\mathcal{L})$ then $l^* \in C(\mathcal{L})$.

Note that a language in $C(\mathcal{L})$ may be described by a regular expression over symbols representing languages in $\mathcal{L}$.

Let $\mathcal{D}$ denote the class of deterministic languages. Then the class of *metadeterministic* languages is defined to be its regular closure, $C(\mathcal{D})$. This class is obviously a subset of the class of context-free languages, since the class of context-free languages is closed under concatenation, union, and Kleene star, and it is a *proper* subset, since, for example, the context-free language $\{ww^R \mid w \in \{a,b\}^*\}$ is not in $C(\mathcal{D})$. (w^R denotes the mirror image of w.)

Finite automata constitute a computational representation for regular languages; DPDAs constitute a computational representation for deterministic languages. By combining these two mechanisms we obtain the metadeterministic automata, which constitute a computational representation for the metadeterministic languages.

Formally, a metadeterministic automaton $\mathcal{M}$ is a triple $(\mathcal{F}, A, \mu)$, where $\mathcal{F} = (S, Q, q_s, F, T)$ is a finite automaton, A is a finite set of DPDAs with identical alphabets Σ, and μ is a mapping from S to A.

The language accepted by such a device is composed of languages accepted by the DPDAs in A according to the transitions of the finite automaton $\mathcal{F}$. Formally, a string v is *recognized by* automaton $\mathcal{M}$ if there is some string $b_1 \cdots b_m \in S^*$, a sequence of PDAs $\mathcal{A}_1, \mathcal{A}_2, \ldots, \mathcal{A}_m \in A$, and a sequence of strings $v_1, \ldots, v_m \in \Sigma^*$ such that

(i) $b_1 \cdots b_m \in L(\mathcal{F})$,
(ii) $\mathcal{A}_k = \mu(b_k)$ for $1 \leq k \leq m$,
(iii) $v_k \in L(\mathcal{A}_k)$ for $1 \leq k \leq m$, and
(iv) $v = v_1 \cdots v_m$.

The set of all strings recognized by automaton $\mathcal{M}$ is called the language *accepted by* $\mathcal{M}$, denoted $L(\mathcal{M})$.

EXAMPLE 3.1. *As a simple example of a language accepted by a metadeterministic automaton, consider $L = L_1 \cup L_2$, where $L_1 = \{a^m b^n c^n \mid n, m \in \{0, 1, \ldots\}\}$ and $L_2 = \{a^m b^m c^n \mid n, m \in \{0, 1, \ldots\}\}$. It is well established that L is not a deterministic language* [9, *Example* 10.1]. *However, it is the union of two languages L_1 and L_2, which are by themselves deterministic. Therefore, L is accepted by a metadeterministic automaton $\mathcal{M}$ which uses two DPDAs $\mathcal{A}_1$ and $\mathcal{A}_2$, accepting L_1 and L_2, respectively.*

We may, for example, define $\mathcal{M}$ as $(\mathcal{F}, \{\mathcal{A}_1, \mathcal{A}_2\}, \mu)$ with $\mathcal{F} = (S, Q, q_s, F, T)$, where

(i) $S = \{b_1, b_2\}$,
(ii) $Q = \{q_s, q_f\}$,
(iii) $F = \{q_f\}$,
(iv) $T = \{(q_s, b_1, q_f),\ (q_s, b_2, q_f)\}$, *and*
(v) $\mu(b_1) = \mathcal{A}_1$ *and* $\mu(b_2) = \mathcal{A}_2$.

A graphic representation for $\mathcal{M}$ is given in Figure 3.1. *States $q \in Q$ are represented by vertices labeled q and triples $(q, b, p) \in T$ are represented by arrows from q to p labeled $\mu(b)$.* □

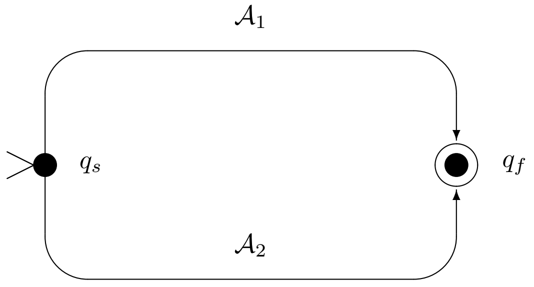

FIG. 3.1. *A metadeterministic automaton.*

That the metadeterministic automata precisely accept the metadeterministic languages is reflected by the following equation

$$C(\mathcal{D}) = \{L(\mathcal{M}) \mid \mathcal{M} \text{ is a metadeterministic automaton}\}.$$

This equation straightforwardly follows from the equivalence of finite automata and regular expressions and the equivalence of DPDAs and deterministic languages.

Let $\mathcal{N}$ denote the class of prefix-free deterministic languages. In the same vein, we have

$$C(\mathcal{N}) = \{L(\mathcal{M}) \mid \mathcal{M} = (\mathcal{F}, A, \mu) \text{ is a metadeterministic automaton where } A \text{ is a set of NPDAs}\}.$$

In the following discussion, we set out to prove a number of properties of languages in $C(\mathcal{D})$, represented by their metadeterministic automata (i.e., their corresponding recognition devices). The DPDAs in an arbitrary such device cause some technical difficulties which may be avoided if we restrict ourselves to metadeterministic automata which use only normal PDAs, as opposed to arbitrary DPDAs. Fortunately, this restriction does not reduce the class of languages that can be described, or in other words, $C(\mathcal{N}) = C(\mathcal{D})$. We prove this equality below.

Since $C(\mathcal{N}) \subseteq C(\mathcal{D})$ is vacuously true, it is sufficient to argue that $\mathcal{D} \subseteq C(\mathcal{N})$, from which $C(\mathcal{D}) \subseteq C(C(\mathcal{N})) = C(\mathcal{N})$ follows, using the closure properties of C—in particular, monotonicity and idempotence.

We prove that $\mathcal{D} \subseteq C(\mathcal{N})$ by showing how for each DPDA $\mathcal{A}$ a metadeterministic automaton $\rho(\mathcal{A}) = (\mathcal{F}, A, \mu)$ may be constructed such that A consists only of prefix-free DPDAs and $L(\rho(\mathcal{A})) = L(\mathcal{A})$. This construction follows.

CONSTRUCTION 1 (DPDA to metadeterministic automaton). *Let* $\mathcal{A} = (\Sigma, \Delta, X_{initial}, F_{\mathcal{A}}, T_{\mathcal{A}})$ *be a deterministic PDA. Construct the metadeterministic automaton* $\rho(\mathcal{A}) = (\mathcal{F}, A, \mu)$, *with* $\mathcal{F} = (S, Q, q_s, F_{\mathcal{F}}, T_{\mathcal{F}})$, *where*

(i) $S = \{b_{X,Y} \mid X, Y \in \Delta\} \cup \{c_{X,Y} \mid X, Y \in \Delta\}$,
(ii) $Q = \Delta$,
(iii) $q_s = X_{initial}$,
(iv) $F_{\mathcal{F}} = F_{\mathcal{A}}$,
(v) $T_{\mathcal{F}} = \{(X, b_{X,Y}, Y) \mid X, Y \in \Delta\} \cup \{(X, c_{X,Y}, Y) \mid X, Y \in \Delta\}$.

The set A *consists of (prefix-free deterministic) PDAs* $\mathcal{B}_{X,Y}$ *and* $\mathcal{C}_{X,Y}$ *for all* $X, Y \in \Delta$, *defined as follows.*

Each $\mathcal{B}_{X,Y}$ is defined to be $(\Sigma, \{X^{in}, Y^{out}\}, X^{in}, \{Y^{out}\}, T)$, where X^{in} and Y^{out} are fresh symbols and the transitions in T are

$$X^{in} \overset{z}{\mapsto}_{\mathcal{B}_{X,Y}} X^{in}Y^{out} \quad \textit{for all } X \overset{z}{\mapsto}_{\mathcal{A}} XY, \textit{some } z.$$

Each $\mathcal{C}_{X,Y}$ is defined to be $(\Sigma, \Delta \cup \{X^{in}, Y^{out}\}, X^{in}, \{Y^{out}\}, T)$, where X^{in} and Y^{out} are fresh symbols and the transitions in T are those in $T_{\mathcal{A}}$ plus the extra transitions

$$\begin{array}{lll} X^{in} & \overset{z}{\mapsto}_{\mathcal{C}_{X,Y}} X^{in}Z & \textit{for all } X \overset{z}{\mapsto}_{\mathcal{A}} XZ, \textit{ some } z \textit{ and } Z; \\ X^{in}Z & \overset{\epsilon}{\mapsto}_{\mathcal{C}_{X,Y}} Y^{out} & \textit{for all } XZ \overset{\epsilon}{\mapsto}_{\mathcal{A}} Y, \textit{ some } Z. \end{array}$$

The function μ maps the symbols $b_{X,Y}$ to automata $\mathcal{B}_{X,Y}$ and the symbols $c_{X,Y}$ to automata $\mathcal{C}_{X,Y}$.

Each automaton $\mathcal{B}_{X,Y}$ mimics a single transition of $\mathcal{A}$ of the form $X \overset{z}{\mapsto}_{\mathcal{A}} XY$. Formally, $\mathcal{B}_{X,Y}$ recognizes a string z if and only if $(X, z) \vdash_{\mathcal{A}} (XY, \epsilon)$.

Each automaton $\mathcal{C}_{X,Y}$ mimics a computation of $\mathcal{A}$ that replaces stack element X with stack element Y. Formally, $\mathcal{C}_{X,Y}$ recognizes a string v if and only if $(X, v) \models^{+}_{\mathcal{A}} (XZ, \epsilon) \vdash_{\mathcal{A}} (Y, \epsilon)$ for some $Z \in \Delta$.

For the proof, consider that recognition of v by $\mathcal{C}_{X,Y}$ means that $(X^{in}, v) \models^{+}_{\mathcal{C}_{X,Y}} (X^{in}Z, \epsilon) \vdash_{\mathcal{C}_{X,Y}} (Y^{out}, \epsilon)$ for some Z, due to the nature of its transitions. This is equivalent to $(X^{in}, z) \vdash_{\mathcal{C}_{X,Y}} (X^{in}W, \epsilon)$, $(W, v') \vdash^{*}_{\mathcal{C}_{X,Y}} (Z, \epsilon)$, $(X^{in}Z, \epsilon) \vdash_{\mathcal{C}_{X,Y}} (Y^{out}, \epsilon)$, and $v = zv'$, for some z, v', and W, due to the definition of $\models^{+}$. This is again equivalent to $(X, z) \vdash_{\mathcal{A}} (XW, \epsilon)$, $(W, v') \vdash^{*}_{\mathcal{A}} (Z, \epsilon)$, $(XZ, \epsilon) \vdash_{\mathcal{A}} (Y, \epsilon)$, and $v = zv'$, by virtue of the construction of $\mathcal{C}_{X,Y}$ from $\mathcal{A}$. Finally, this conjunction is equivalent to $(X, v) \models^{+}_{\mathcal{A}} (XZ, \epsilon) \vdash_{\mathcal{A}} (Y, \epsilon)$.

Note that the languages recognized by some of the $\mathcal{B}_{X,Y}$ and $\mathcal{C}_{X,Y}$ may be the empty set.

That all $\mathcal{B}_{X,Y}$ and $\mathcal{C}_{X,Y}$ are deterministic follows from the fact that by assumption $\mathcal{A}$ is deterministic. That all $\mathcal{B}_{X,Y}$ and $\mathcal{C}_{X,Y}$ are prefix-free follows from the fact that no transitions apply when a final stack symbol is on top of the stack.

To prove that $L(\rho(\mathcal{A})) = L(\mathcal{A})$ we have to show the following.

1. Any sequence of transitions of the form $(X_{initial}, a_1 \cdots a_n) \vdash^{*}_{\mathcal{A}} (\delta X, \epsilon)$, with $X \in F_{\mathcal{A}}$, can be decomposed into a list of m sequences of transitions $(X^{in}_{k-1}, v_k) \vdash^{*}_{\mathcal{A}_k} (\delta_k X^{out}_k, \epsilon)$, $1 \leq k \leq m$, $X_0 = X_{initial}$ and $X_m = X$, using a list of m automata $\mathcal{A}_1, \ldots, \mathcal{A}_m \in A$ that recognize strings $v_1, \ldots, v_m$, respectively, where $a_1 \cdots a_n = v_1 \cdots v_m$ and such that the string $b_1 \cdots b_m$ with $\mu(b_k) = \mathcal{A}_k$ for $1 \leq k \leq m$ is recognized by $\mathcal{F}$.

2. Conversely, if we have a string $b_1 \cdots b_m$ recognized by $\mathcal{F}$, then we must show that any list of m sequences of transitions $(X^{in}_{k-1}, v_k) \vdash^{*}_{\mathcal{A}_k} (\delta_k Y^{out}_k, \epsilon)$ for automata $\mathcal{A}_k = \mu(b_k)$, $1 \leq k \leq m$, can be composed into a single sequence $(X_0, v_1 \cdots v_m) \vdash^{*}_{\mathcal{A}} (\delta Y_m, \epsilon)$, with $X_0 = X_{initial}$ and $Y_m \in F_{\mathcal{A}}$, using $X_k = Y_k$, $1 \leq k \leq m$.

The intuition behind decomposing a sequence of transitions for DPDA $\mathcal{A}$ is conveyed by Figure 3.2. We see the development of the stack, of which the height alternately increases and decreases during performance of the transitions. We assume the input is recognized at t9, where some final stack symbol X_9 is on top of the stack. We now locate the point in time t8 where the stack was of the same height for the last time before t9. Assume that at t8 some stack symbol X_8 is on top of the stack. The sequence of transitions from t8 to t9 is of the form $(X_8, v) \models^{+}_{\mathcal{A}} (X_8 Z, \epsilon) \vdash_{\mathcal{A}} (X_9, \epsilon)$ for some $Z \in \Delta$, which means that the stack development can be mimicked by the PDA

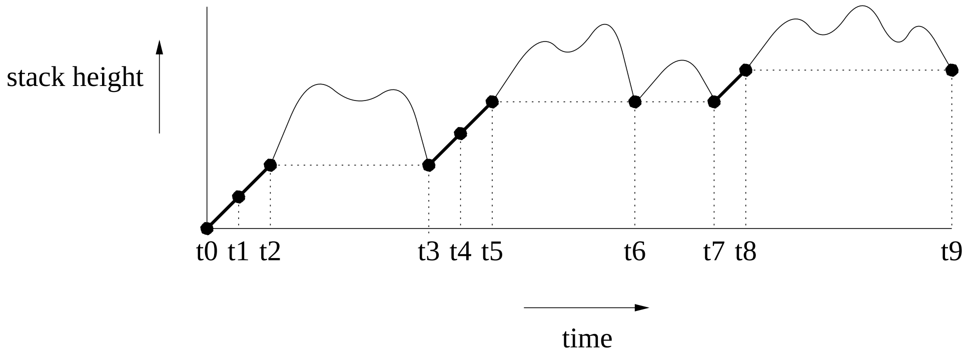

FIG. 3.2. *A stack development of a DPDA $\mathcal{A}$ on input $v_1 \cdots v_9$.*

$\mathcal{C}_{X_8,X_9}$. In Figure 3.2 the step between t7 and t8 is of the form $(X_7, z) \vdash_{\mathcal{A}} (X_7X_8, \epsilon)$, which is mimicked by the PDA $\mathcal{B}_{X_7,X_8}$.

This can be continued until the complete sequence of transitions has been decomposed into a list of nine sequences which are mimicked by PDAs of the form $\mathcal{B}_{X_{k-1},X_k}$ or $\mathcal{C}_{X_{k-1},X_k}$. The corresponding string $b_1 \cdots b_9$, where $b_k = b_{X_{k-1},X_k}$ or $b_k = c_{X_{k-1},X_k}$, $1 \leq k \leq 9$, then allows state $X_9 \in F_{\mathcal{F}} = F_{\mathcal{A}}$ to be reached from state q_s, or, in other words, this string is recognized by finite automaton $\mathcal{F}$.

The proof of the general case uses induction on t. We show that if we have a sequence of transitions

$$(X_0, z_1z_2 \cdots z_t) \vdash_{\mathcal{A}} (\delta_1X_1, z_2 \cdots z_t) \vdash_{\mathcal{A}} \cdots \vdash_{\mathcal{A}} (\delta_{t-1}X_{t-1}, z_t) \vdash_{\mathcal{A}} (\delta_tX_t, \epsilon),$$

then for some m there is

(i) a list $Y_0, \ldots, Y_m \in \Delta$, with $Y_0 = X_0$ and $Y_m = X_t$,

(ii) a list $b_1, \ldots, b_m \in S$, such that (Y_0, b_1, Y_1), (Y_1, b_2, Y_2), ..., $(Y_{m-1}, b_m, Y_m) \in T$, and

(iii) a list $v_1, \ldots, v_m \in \Sigma^*$, such that $v_1 \cdots v_m = z_1 \cdots z_t$ and v_k is recognized by PDA $\mu(b_k)$, for $1 \leq k \leq m$.

The case that $t = 0$ can trivially be solved with $m = 0$; for $t > 0$ we distinguish between two cases:

(i) $|\delta_{t-1}X_{t-1}| < |\delta_tX_t|$, or, in other words, the last step used a pushing transition; or

(ii) $|\delta_{t-1}X_{t-1}| > |\delta_tX_t|$, or, in other words, the last step used a popping transition.

In the first case we may assume by definition that the automaton $\mathcal{B}_{X_{t-1},X_t}$ recognizes z_t. The induction hypothesis for $t-1$, applied to $(X_0, z_1z_2 \cdots z_{t-1}) \vdash_{\mathcal{A}}^* (\delta_{t-1}X_{t-1}, \epsilon)$, provides the required three lists with some $m-1$ instead of m. We set $Y_m = X_t$, $b_m = b_{X_{t-1},X_t}$ (so that $\mu(b_m) = \mathcal{B}_{X_{t-1},X_t}$), $v_m = z_t$, which gives us the required three lists for t. Note that $(X_0, z_1 \cdots z_{t-1}) \vdash_{\mathcal{A}}^* (\delta_{t-1}X_{t-1}, \epsilon)$ and $(X_0, z_1 \cdots z_{t-1}z_t) \vdash_{\mathcal{A}}^* (\delta_{t-1}X_{t-1}, z_t)$ are equivalent.

In the second case we may assume that there is a maximal $t' < t$ such that $|\delta_{t'}X_{t'}| = |\delta_tX_t|$. Note that then $|\delta_{t''}X_{t''}| > |\delta_tX_t|$, for $t' < t'' < t$, which means we have $(\delta_{t'}X_{t'}, z_{t'+1} \cdots z_t) \models_{\mathcal{A}}^+ (\delta_{t'}X_{t'}X_{t-1}, \epsilon) \vdash_{\mathcal{A}} (\delta_{t'}X_t, \epsilon)$, which is equivalent to $(X_{t'}, z_{t'+1} \cdots z_t) \models_{\mathcal{A}}^+ (X_{t'}X_{t-1}, \epsilon) \vdash_{\mathcal{A}} (X_t, \epsilon)$. By definition we get that the automaton $\mathcal{C}_{X_{t'},X_t}$ recognizes $z_{t'+1} \cdots z_t$. The induction hypothesis for t', applied to

$(X_0, z_1z_2\cdots z_{t'}) \vdash^*_{\mathcal{A}} (\delta_{t'}X_{t'}, \epsilon)$, provides the required three lists with some $m-1$ instead of m. We set $Y_m = X_t$, $b_m = c_{X_{t'},X_t}$ (so that $\mu(b_m) = \mathcal{C}_{X_{t'},X_t}$), $v_m = z_{t'+1}\cdots z_t$, which gives us the required three lists for t. Note that $(X_0, z_1\cdots z_{t'}) \vdash^*_{\mathcal{A}} (\delta_{t'}X_{t'}, \epsilon)$ and $(X_0, z_1\cdots z_{t'}z_{t'+1}\cdots z_t) \vdash^*_{\mathcal{A}} (\delta_{t'}X_{t'}, z_{t'+1}\cdots z_t)$ are equivalent.

We now give a proof of the converse, viz. that, if we have a string $b_1\cdots b_m \in L(\mathcal{F})$, then a list of m sequences of transitions for automata $\mathcal{A}_k = \mu(b_k)$ recognizing strings v_k, $1 \leq k \leq m$, can be composed into a single sequence for $\mathcal{A}$ recognizing $v_1\cdots v_m$.

Because of the definition of $\rho(\mathcal{A})$, this list of m sequences consists of sequences of the form $(X^{in}_{k-1}, v_k) \vdash^*_{\mathcal{A}_k} (\delta'_k X^{out}_k, \epsilon)$, $k = 1, 2, \ldots, m$, where $\delta'_k = X^{in}_{k-1}$ if $\mathcal{A}_k$ is of the form $\mathcal{B}_{X_{k-1},X_k}$ and $\delta'_k = \epsilon$ if $\mathcal{A}_k$ is of the form $\mathcal{C}_{X_{k-1},X_k}$. The existence of these sequences implies the existence of sequences $(X_{k-1}, v_k) \vdash^*_{\mathcal{A}} (\delta_k X_k, \epsilon)$, where $\delta_k = X_{k-1}$ if $\mathcal{A}_k$ is of the form $\mathcal{B}_{X_{k-1},X_k}$ and $\delta_k = \epsilon$ if $\mathcal{A}_k$ is of the form $\mathcal{C}_{X_{k-1},X_k}$.

We can place these m sequences after one another to obtain $(X_0, v_1\cdots v_m) \vdash^*_{\mathcal{A}} (\delta_1\cdots\delta_m X_m, \epsilon)$, making use of the fact that $(X_{k-1}, v_k) \vdash^*_{\mathcal{A}} (\delta_k X_k, \epsilon)$ implies $(\delta_1\cdots\delta_{k-1}X_{k-1}, v_k v_{k+1}\cdots v_k) \vdash^*_{\mathcal{A}} (\delta_1\cdots\delta_{k-1}\delta_k X_k, v_{k+1}\cdots v_k)$. Since $b_1\cdots b_m \in L(\mathcal{F})$ and therefore $X_0 = q_s = X_{initial}$ and $X_m \in F_{\mathcal{F}} = F_{\mathcal{A}}$, this sequence recognizes $v_1\cdots v_k$.

This discussion yields the following theorem.

THEOREM 3.2. $C(\mathcal{N}) = C(\mathcal{D})$

This theorem can be paraphrased as "The class of LR(k) languages is contained in the regular closure of the class of LR(0) languages."[2]

EXAMPLE 3.3. *We demonstrate Construction* 1 *by means of an example. Consider the language* $L_{Pal} = \{wcw^R \mid w \in \{a,b\}^*\}$, *where* w^R *denotes the mirror image of string* w. *This language consists of palindromes in which a symbol* c *occurs as the center of each palindrome.*

Now consider the language $L_{PrePal} = \{v \mid \exists w[vw \in L_{Pal}]\}$, *consisting of all prefixes of palindromes. This language, which is obviously not prefix-free, is accepted by the PDA* $\mathcal{A}_{PrePal} = (\Sigma, \Delta, I, F, T)$, *with* $\Sigma = \{a,b,c\}$, $\Delta = \{I, A, B, C, \overline{A}, \overline{\overline{A}}, \overline{B}, \overline{\overline{B}}\}$, $F = \{I, A, B, C\}$, *and* T *consists of the following transitions:*

$$\begin{array}{lcll}
X & \overset{a}{\mapsto} & XA & for\ X \in \{I, A, B\}, \\
X & \overset{b}{\mapsto} & XB & for\ X \in \{I, A, B\}, \\
X & \overset{c}{\mapsto} & XC & for\ X \in \{I, A, B\}, \\
C & \overset{a}{\mapsto} & C\overline{A}, & \\
C\overline{A} & \overset{\epsilon}{\mapsto} & \overline{\overline{A}}, & \\
A\overline{\overline{A}} & \overset{\epsilon}{\mapsto} & C, & \\
C & \overset{b}{\mapsto} & C\overline{B}, & \\
C\overline{B} & \overset{\epsilon}{\mapsto} & \overline{\overline{B}}, & \\
B\overline{\overline{B}} & \overset{\epsilon}{\mapsto} & C. &
\end{array}$$

The automaton operates by pushing each a *or* b *it reads onto the stack in the form of* A *or* B *until it reads* c, *and then the symbols read are matched against the occurrences of* A *and* B *on the stack. Note that* F *is* $\{I, A, B, C\}$, *which means that a recognized string may be the prefix of a palindrome instead of being a palindrome itself.*

[2]Not all definitions of LR(0) in the literature are equivalent. For example, [8] allows some LR(0) languages that are not prefix-free. Theorem 13.3.1 in [8] implies that the alternative class of LR(0) languages is contained in the regular closure of the class of what we call LR(0) languages.

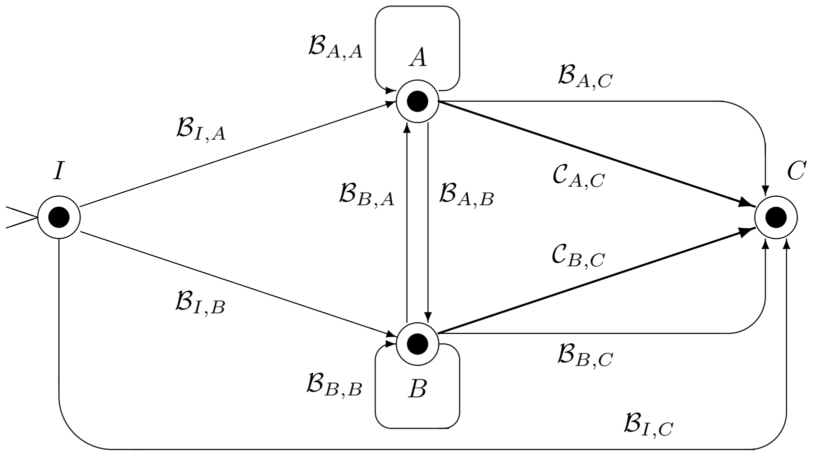

FIG. 3.3. *Metadeterministic automaton* $\rho(\mathcal{A}_{PrePal})$.

The upper level of the metadeterministic automaton $\rho(\mathcal{A}_{PrePal})$ *is shown in Figure* 3.3. *(Automata accepting the empty language have been omitted from this representation, as have vertices which after this omission do not occur on any path from I to any other final state.)*

The automaton $\mathcal{B}_{A,B}$ *accepts the language* $\{b\}$*, since the only pushing transition of* $\mathcal{A}_{PrePal}$ *which places B on top of A reads b. As another example of a lower level automaton, automaton* $\mathcal{C}_{A,C}$ *accepts the language* $\{wa \mid w \in L_{Pal}\}$*, since* $(A, v) \models^{+}_{\mathcal{A}} (AZ, \epsilon) \vdash_{\mathcal{A}} (C, \epsilon)$*, some Z, holds only for v of the form wa, with* $w \in L_{Pal}$*; for example,* $(A, bcba) \vdash_{\mathcal{A}} (AB, cba) \vdash_{\mathcal{A}} (ABC, ba) \vdash_{\mathcal{A}} (ABC\overline{B}, a) \vdash_{\mathcal{A}} (AB\overline{\overline{B}}, a) \vdash_{\mathcal{A}} (AC, a) \vdash_{\mathcal{A}} (AC\overline{A}, \epsilon) \vdash_{\mathcal{A}} (A\overline{\overline{A}}, \epsilon) \vdash_{\mathcal{A}} (C, \epsilon)$.

Note that Construction 1 *together with a mechanical transformation from finite automata to regular expressions (e.g.,* [9, *Theorem* 2.4]) *gives us a method for obtaining a regular expression over LR(0) languages, given an LR(k) language. For example, the equation* $L_{PrePal} = \{a, b\}^*(\epsilon \cup L_{Pal})$ *may be derived from Figure* 3.3. □

4. Recognizing fragments of a string. In this section we investigate the following problem. Given an input string $a_1 \cdots a_n$ and an NPDA $\mathcal{A}$, find all pairs of input positions (j, i) such that substring $a_{j+1} \cdots a_i$ is recognized by $\mathcal{A}$; or in other words, such that $(X_{initial}, a_{j+1} \cdots a_i) \vdash^* (X_{final}, \epsilon)$. It will be proved that this problem can be solved in linear time.

For technical reasons we have to assume that the stack always consists of at least two elements. This is accomplished by assuming that a fresh stack symbol $\perp$ occurs below the bottom of the actual stack and that the actual initial configuration is created by an imaginary extra step $(\perp, v) \vdash (\perp X_{initial}, v)$.

The original problem stated above is now generalized to finding all 4-tuples (X, j, Y, i), with $X, Y \in \Delta$ and $0 \leq j \leq i \leq n$, such that $(X, a_{j+1} \cdots a_i) \models^+ (XY, \epsilon)$. In words, this condition states that if a stack has an element labeled X on top, then the pushdown automaton can, by reading the input between j and i and without ever popping X, obtain a stack with one more element, labeled Y, which is on top of X. Such 4-tuples are henceforth called *items*.

The items are computed by a dynamic programming algorithm based on work from [1, 11, 6, 12].

Algorithm 1 (dynamic programming). Consider an NPDA and an input string $a_1 \cdots a_n$.

```
1. Let the set $\mathcal{U}$ be $\{(\bot, i, X_{initial}, i) \mid 0 \leq i \leq n\}$.
2. Perform one of the following two steps as long as one of them is applicable.
push  1. Choose a pair, not considered before, consisting of a transition $X \overset{z}{\mapsto} XY$
         and an input position $j$, such that $z = \epsilon \vee z = a_{j+1}$.
      2. If $z = \epsilon$ then let $i = j$, else let $i = j + 1$.
      3. Add item $(X, j, Y, i)$ to $\mathcal{U}$.
pop   1. Choose a triple, not considered before, consisting of a transition $XY \overset{\epsilon}{\mapsto} Z$
         and items $(W, h, X, j), (X, j, Y, i) \in \mathcal{U}$.
      2. Add item $(W, h, Z, i)$ to $\mathcal{U}$.
3. Finally, define the set $\mathcal{V}$ to be $\{(j, i) \mid (\bot, j, X_{final}, i) \in \mathcal{U}\}$.
```

It can be proved [1, 11] that Algorithm 1 eventually adds an item (X, j, Y, i) to $\mathcal{U}$ if and only if $(X, a_{j+1} \cdots a_i) \models^+ (XY, \epsilon)$. Specifically, $(\bot, j, X_{final}, i) \in \mathcal{U}$ is equivalent to $(\bot, a_{j+1} \cdots a_i) \vdash (\bot X_{initial}, a_{j+1} \cdots a_i) \vdash^* (\bot X_{final}, \epsilon)$. Therefore, the existence of such an item $(\bot, j, X_{final}, i) \in \mathcal{U}$, or, equivalently, the existence of $(j, i) \in \mathcal{V}$, indicates that substring $a_{j+1} \cdots a_i$ is recognized by $\mathcal{A}$, which solves the original problem stated at the beginning of this section.

If no restrictions apply, the number of 4-tuples computed in $\mathcal{U}$ can be quadratic in the length of the input. The central observation is this: It is possible that items $(X, j, Y, i) \in \mathcal{U}$ are added for several (possibly linearly many) i, with fixed X, j, and Y. This may happen if $(\bot, a_h \cdots a_j \cdots a_{i_m}) \vdash^* (\delta X, a_{j+1} \cdots a_{i_m}) \models^+ (\delta XY, a_{i_1+1} \cdots a_{i_m})$ and $(Y, a_{i_1+1} \cdots a_{i_m}) \vdash^+ (Y, a_{i_2+1} \cdots a_{i_m}) \vdash^+ \cdots \vdash^+ (Y, a_{i_{m-1}+1} \cdots a_{i_m}) \vdash^+ (Y, \epsilon)$, which leads to m items $(X, j, Y, i_1), \ldots, (X, j, Y, i_m)$. Such a situation can in the most trivial case be caused by a pair of transitions $X \overset{z}{\mapsto} XY$ and $XY \overset{\epsilon}{\mapsto} X$; the general case is more complex, however.

However, whenever it can be established that for all X, j, and Y there is at most one i with (X, j, Y, i) being constructed, the number of entries computed in $\mathcal{U}$ is linear in the length of the input string, and we get a linear time bound by the reasoning presented at the end of this section.

The following definition identifies the intermediate objective for obtaining a linear complexity. We define a PDA to be *loop-free* if $(X, v) \vdash^+ (X, \epsilon)$ does not hold for any X and v. The intuition is that reading some input must be reflected by a change in the stack.

Our solution to linear-time recognition for automata which are not loop-free is the following: We define a language-preserving transformation from an arbitrary NDPA to a loop-free NDPA. (A similar transformation for the purpose of recognizing suffixes of strings in linear time was described in [13].) Intuitively, this is done by pushing extra elements $\overline{X}$ on the stack so that we have $(X, v) \vdash^+ (\overline{X}X, \epsilon)$ instead of $(X, v) \vdash^+ (X, \epsilon)$, where $\overline{X}$ is a special stack symbol to be defined shortly.

As a first step we remark that for an NPDA we can divide the stack symbols into two sets *PUSH* and *POP*, defined by

$$\begin{aligned} PUSH &= \{X \mid \text{there is a transition } X \overset{z}{\mapsto} XY\}, \\ POP &= \{Y \mid \text{there is a transition } XY \overset{\epsilon}{\mapsto} Z\} \cup \{X_{final}\}. \end{aligned}$$

It is straightforward to show that determinism of the PDA requires that *PUSH* and *POP* be disjoint. We may further assume that each stack symbol belongs to either *PUSH* or *POP*, provided we assume that the PDA is *reduced*, meaning that there are no transitions or stack symbols which are useless for obtaining the final configuration from an initial configuration.[3]

CONSTRUCTION 2 (NPDA transformation). *Consider an NPDA* $\mathcal{A} = (\Sigma, \Delta, X_{initial}, \{X_{final}\}, T)$*, of which the set of stack symbols* Δ *is partitioned into* $PUSH$ *and* POP*, as explained above. From this NPDA a new PDA* $\tau(\mathcal{A}) = (\Sigma, \Delta', X'_{initial}, \{X'_{final}\}, T')$ *is constructed,* $X'_{initial}$ *and* X'_{final} *being fresh symbols, where* $\Delta' = \Delta \cup \{X'_{initial}, X'_{final}\} \cup \{\overline{X} \mid X \in PUSH\}$*,* $\overline{X}$ *being fresh symbols, and the transitions in* T' *are given by*

$$\begin{array}{lll}
XY & \overset{\epsilon}{\mapsto}_{\tau(\mathcal{A})} & Z \quad \textit{for } XY \overset{\epsilon}{\mapsto}_{\mathcal{A}} Z \textit{ with } Z \in POP,\\
XY & \overset{\epsilon}{\mapsto}_{\tau(\mathcal{A})} & \overline{Z} \quad \textit{for } XY \overset{\epsilon}{\mapsto}_{\mathcal{A}} Z \textit{ with } Z \in PUSH,\\
\overline{X} & \overset{\epsilon}{\mapsto}_{\tau(\mathcal{A})} & \overline{X}X \quad \textit{for } X \in PUSH,\\
\overline{X}Y & \overset{\epsilon}{\mapsto}_{\tau(\mathcal{A})} & Y \quad \textit{for } X \in PUSH, Y \in POP,\\
X & \overset{z}{\mapsto}_{\tau(\mathcal{A})} & XY \quad \textit{for } X \overset{z}{\mapsto}_{\mathcal{A}} XY,
\end{array}$$

and the two transitions $X'_{initial} \overset{\epsilon}{\mapsto}_{\tau(\mathcal{A})} X'_{initial}X_{initial}$ *and* $X'_{initial}X_{final} \overset{\epsilon}{\mapsto}_{\tau(\mathcal{A})} X'_{final}$*.*

To provide an intuitive explanation of this construction, we observe that the unwanted sequences of transitions have the property of replacing a push symbol X by itself without affecting the part of the stack under it in the course of doing so. The transformation has the effect that instead of X, a padded form of it consisting of two symbols $\overline{X}X$ is produced by the corresponding new transition sequence. Thus, for example, a sequence $(X, v_1v_2) \models^+ (XY_1, v_2) \vdash (X, v_2) \models^+ (XY_2, \epsilon) \vdash (X, \epsilon)$ in the original automaton is turned into a sequence $(X, v_1v_2) \models^+ (XY_1, v_2) \vdash (\overline{X}, v_2) \vdash (\overline{X}X, v_2) \models^+ (\overline{X}XY_2, \epsilon) \vdash (\overline{X}\,\overline{X}, \epsilon) \vdash (\overline{X}\,\overline{X}X, \epsilon)$ in the transformed automaton.

The padding has to be gotten rid of later, viz. when some genuine pop symbol is on top of it. We could, for example, obtain $(\overline{X}\,\overline{X}X, z) \vdash (\overline{X}\,\overline{X}XY, \epsilon) \vdash (\overline{X}\,\overline{X}Z, \epsilon) \vdash (\overline{X}Z, \epsilon) \vdash (Z, \epsilon)$, where the original automaton would do $(X, z) \vdash (XY, \epsilon) \vdash (Z, \epsilon)$, assuming $Z \in POP$.

EXAMPLE 4.1. *We demonstrate this construction further by means of a more elaborate example.*

Consider the NPDA $\mathcal{A} = (\{a, b\}, \{X, Y, Z, P\}, X, \{P\}, T)$*, where* T *contains the transitions given in the left half of Figure* 4.1*. It is clear that* $\mathcal{A}$ *is not loop-free: we have* $(X, a) \vdash (XY, \epsilon) \vdash (X, \epsilon)$*. If the input* $a_1 \cdots a_n$ *to Algorithm* 1 *is* a^n*, then* $(\perp, a_{j+1} \cdots a_i) \models^+ (\perp X, \epsilon)$ *and therefore* $(\perp, j, X, i) \in \mathcal{U}$ *for* $0 \leq j \leq i \leq n$*. This explains why the time complexity is quadratic.*

We divide the stack symbols into $PUSH = \{X\}$ *and* $POP = \{Y, Z, P\}$*. Of the transformed automaton* $\tau(\mathcal{A}) = (\{a, b\}, \{X, Y, Z, P, X', P', \overline{X}\}, X', \{P'\}, T')$*, the transitions are given in the right half of Figure* 4.1*. That the complexity of Algorithm* 1 *is no longer quadratic but linear for the transformed PDA is proved in the remainder of this section.*

The recognition of aab by $\mathcal{A}$ *and* $\tau(\mathcal{A})$ *is compared in Figure* 4.2. □

We now set out to prove that τ has the required properties.

LEMMA 4.2. *If* $\mathcal{A}$ *is an NPDA, then* $\tau(\mathcal{A})$ *is an NPDA.*

Proof. To check the NPDA property, we must establish that $\tau(\mathcal{A})$ is deterministic, prefix-free, and in normal form. We discuss these points in sequence.

Determinism in the case of $X'_{initial}$ is obvious since only one transition applies. This also holds for X_{final}, for which there were no applicable transitions in $\mathcal{A}$ because

[3]Note that each PDA may be turned into a reduced PDA accepting the same language by just omitting the useless transitions.

$\mathcal{A}$	$\tau(\mathcal{A})$
	$X' \overset{\epsilon}{\mapsto} X'X$
$X \overset{a}{\mapsto} XY$	$X \overset{a}{\mapsto} XY$
$XY \overset{\epsilon}{\mapsto} X$	$XY \overset{\epsilon}{\mapsto} \overline{X}$
	$\overline{X} \overset{\epsilon}{\mapsto} \overline{X}X$
$X \overset{b}{\mapsto} XZ$	$X \overset{b}{\mapsto} XZ$
$XZ \overset{\epsilon}{\mapsto} P$	$XZ \overset{\epsilon}{\mapsto} P$
	$\overline{X}P \overset{\epsilon}{\mapsto} P$ (Some other transitions of this form have been omitted, because they are useless.)
	$X'P \overset{\epsilon}{\mapsto} P'$

it is prefix-free by assumption. No transitions apply when X'_{final} is on top of the stack.

For each symbol $\overline{X}$ on top of the stack, exactly one pushing transition may be applied. For each pair of symbols $\overline{X}\,Y$ on top of the stack, with $Y \in \mathit{POP}$, exactly one popping transition may be applied.

The other cases of XY on top with pop symbol Y produce either Z or $\overline{Z}$ deterministically, depending on whether Z is a push or pop symbol.

For push symbols $X \in \Delta$ on top of the stack, the unique push move also available in $\mathcal{A}$ is the only possibility.

Prefix-freeness follows from the fact that no transitions with a final stack symbol on top of the stack are possible. On the same line, the property of being in normal form means that the unique final stack symbol can only be at the bottom. This is guaranteed by producing it only from the initial stack symbol which is itself not produced by any transition. □

LEMMA 4.3. *If $\mathcal{A}$ is an NPDA, then $\mathcal{A}$ and $\tau(\mathcal{A})$ accept the same language.*

Proof. We first prove that for all stack symbols $X_1, \ldots, X_m$ from Δ we have $(X_{initial}, v) \vdash^*_{\mathcal{A}} (X_1 \cdots X_m, \epsilon)$ if and only if $(X_{initial}, v) \vdash^*_{\tau(\mathcal{A})} (\alpha_1 X_1 \alpha_2 \cdots \alpha_m X_m, \epsilon)$, where, for all i, $1 \leq i \leq m$, we have $\alpha_i = \overline{Y_{i,1}}\,\overline{Y_{i,2}} \cdots \overline{Y_{i,r_i}}$ for some $r_i \geq 0$.

only if. The proof is given by induction on the number of steps used in $(X_{initial}, v) \vdash^*_{\mathcal{A}} (X_1 \cdots X_m, \epsilon)$.

1. If zero steps are involved then we have $(X_{initial}, \epsilon) \vdash^*_{\mathcal{A}} (X_{initial}, \epsilon)$. By definition we have also $(X_{initial}, \epsilon) \vdash^*_{\tau(\mathcal{A})} (X_{initial}, \epsilon)$.

2. Suppose that the last step is a push. Then we have $(X_{initial}, v) \vdash^*_{\mathcal{A}} (X_1 \cdots X_{m-1}, z) \vdash_{\mathcal{A}} (X_1 \cdots X_m, \epsilon)$, where the last transition used is $X_{m-1} \overset{z}{\mapsto}_{\mathcal{A}} X_{m-1} X_m$. The induction hypothesis informs us that $(X_{initial}, v) \vdash^*_{\tau(\mathcal{A})} (\alpha_1 X_1 \alpha_2 \cdots \alpha_{m-1} X_{m-1}, z)$. Also, because $X_{m-1} \overset{z}{\mapsto}_{\tau(\mathcal{A})} X_{m-1} X_m$, we have $(X_{initial}, v) \vdash^*_{\tau(\mathcal{A})} (\alpha_1 X_1 \alpha_2 \cdots \alpha_{m-1} X_{m-1} X_m, \epsilon)$.

3. Suppose that the last step is a pop. Then we have $(X_{initial}, v) \vdash^*_{\mathcal{A}} (X_1 \cdots X_{m-1} X'_m X_{m+1}, \epsilon) \vdash_{\mathcal{A}} (X_1 \cdots X_{m-1} X_m, \epsilon)$, where the last transition used is $X'_m X_{m+1} \overset{\epsilon}{\mapsto}_{\mathcal{A}} X_m$. The induction hypothesis informs us that $(X_{initial}, v) \vdash^*_{\tau(\mathcal{A})} (\alpha_1 X_1 \alpha_2 \cdots \alpha_m X'_m \alpha_{m+1} X_{m+1}, \epsilon)$, with $\alpha_{m+1} = \overline{Y_1} \cdots \overline{Y_r}$, for some $r > 0$. We first have $(\alpha_1 X_1 \alpha_2 \cdots \alpha_m X'_m \overline{Y_1} \cdots \overline{Y_r} X_{m+1}, \epsilon) \vdash_{\tau(\mathcal{A})} (\alpha_1 X_1 \alpha_2 \cdots \alpha_m X'_m \overline{Y_1} \cdots \overline{Y_{r-1}} X_{m+1}, \epsilon) \vdash_{\tau(\mathcal{A})} \cdots \vdash_{\tau(\mathcal{A})} (\alpha_1 X_1 \alpha_2 \cdots \alpha_m X'_m X_{m+1}, \epsilon)$, using the transitions $\overline{Y_j} X_{m+1} \overset{\epsilon}{\mapsto}_{\tau(\mathcal{A})} X_{m+1}$, $1 \leq j \leq r$, which exist since $X_{m+1} \in POP$. Subsequently, there are two possibilities:

(i) If $X_m \in PUSH$ then $X'_m X_{m+1} \overset{\epsilon}{\mapsto}_{\tau(\mathcal{A})} \overline{X_m}$ and $(\alpha_1 X_1 \alpha_2 \cdots \alpha_m X'_m X_{m+1}, \epsilon) \vdash_{\tau(\mathcal{A})} (\alpha_1 X_1 \alpha_2 \cdots \alpha_m \overline{X_m}, \epsilon) \vdash_{\tau(\mathcal{A})} (\alpha_1 X_1 \alpha_2 \cdots \alpha_m \overline{X_m} X_m, \epsilon)$. In the last configuration, $\alpha_m \overline{X_m}$ is a sequence of "barred" symbols, as desired.

(ii) If $X_m \in POP$ then $X'_m X_{m+1} \overset{\epsilon}{\mapsto}_{\tau(\mathcal{A})} X_m$ and $(\alpha_1 X_1 \alpha_2 \cdots \alpha_m X'_m X_{m+1}, \epsilon) \vdash_{\tau(\mathcal{A})} (\alpha_1 X_1 \alpha_2 \cdots \alpha_m X_m, \epsilon)$.

if. Analogously to the "only if" part, the proof is given by induction on the number of steps used in $(X_{initial}, v) \vdash^*_{\tau(\mathcal{A})} (\alpha_1 X_1 \alpha_2 \cdots \alpha_m X_m, \epsilon)$. The following cases are possible.

1. Suppose that the last transition used was $\overline{X_m} \overset{\epsilon}{\mapsto}_{\tau(\mathcal{A})} \overline{X_m} X_m$. Then we have $(X_{initial}, v) \vdash^*_{\tau(\mathcal{A})} (\alpha_1 X_1 \alpha_2 \cdots X_{m-1} \alpha'_m XY, \epsilon) \vdash_{\tau(\mathcal{A})} (\alpha_1 X_1 \alpha_2 \cdots X_{m-1} \alpha'_m \overline{X_m}, \epsilon) \vdash_{\tau(\mathcal{A})} (\alpha_1 X_1 \alpha_2 \cdots X_{m-1} \alpha'_m \overline{X_m} X_m, \epsilon)$, where $\alpha_m = \alpha'_m \overline{X_m}$, and the second-to-last transition used was $XY \overset{\epsilon}{\mapsto}_{\tau(\mathcal{A})} \overline{X_m}$ for some X and Y. The induction hypothesis informs us that $(X_{initial}, v) \vdash^*_{\mathcal{A}} (X_1 \cdots X_{m-1} XY, \epsilon)$. From $XY \overset{\epsilon}{\mapsto}_{\tau(\mathcal{A})} \overline{X_m}$ we conclude the existence of $XY \overset{\epsilon}{\mapsto}_{\mathcal{A}} X_m$. Therefore, $(X_1 \cdots X_{m-1} XY, \epsilon) \vdash_{\mathcal{A}} (X_1 \cdots X_{m-1} X_m, \epsilon)$.

2. Suppose that the last transition used was $\overline{X} X_m \overset{\epsilon}{\mapsto}_{\tau(\mathcal{A})} X_m$. Then we have $(X_{initial}, v) \vdash^*_{\tau(\mathcal{A})} (\alpha_1 X_1 \alpha_2 \cdots \alpha_m \overline{X_m} X_m, \epsilon) \vdash_{\tau(\mathcal{A})} (\alpha_1 X_1 \alpha_2 \cdots \alpha_m X_m, \epsilon)$. Since $\alpha_m \overline{X_m}$ is a sequence of barred symbols, the induction hypothesis informs us that $(X_{initial}, v) \vdash^*_{\mathcal{A}} (X_1 \cdots X_m, \epsilon)$.

3. Suppose that the last transition used was $XY \overset{\epsilon}{\mapsto}_{\tau(\mathcal{A})} X_m$ for X and Y from Δ. Then we have $(X_{initial}, v) \vdash^*_{\tau(\mathcal{A})} (\alpha_1 X_1 \alpha_2 \cdots X_{m-1} \alpha_m XY, \epsilon) \vdash_{\tau(\mathcal{A})} (\alpha_1 X_1 \alpha_2 \cdots X_{m-1} \alpha_m X_m, \epsilon)$. From the induction hypothesis, $(X_{initial}, v) \vdash^*_{\mathcal{A}} (X_1 \cdots X_{m-1} XY, \epsilon)$. The transition $XY \overset{\epsilon}{\mapsto}_{\mathcal{A}} X_m$ is identically available in $\mathcal{A}$, thus providing the desired sequence of transitions.

4. The argument for a transition $X \overset{z}{\mapsto}_{\tau(\mathcal{A})} XY$, $X \in \Delta$, is analogous to case 3 because again the transition is available also in the old automaton.

From the definition of τ it is clear that $(X'_{\mathit{initial}}, v) \vdash^*_{\tau(\mathcal{A})} (X'_{\mathit{final}}, \epsilon)$ is possible only if $(X_{\mathit{initial}}, v) \vdash^*_{\tau(\mathcal{A})} (X_{\mathit{final}}, \epsilon)$. From the "if" part we conclude that $(X_{\mathit{initial}}, v) \vdash^*_{\tau(\mathcal{A})} (X_{\mathit{final}}, \epsilon)$ implies $(X_{\mathit{initial}}, v) \vdash^*_{\mathcal{A}} (X_{\mathit{final}}, \epsilon)$.

From the "only if" part we conclude that $(X_{\mathit{initial}}, v) \vdash^*_{\mathcal{A}} (X_{\mathit{final}}, \epsilon)$ implies $(X'_{\mathit{initial}}, v) \vdash_{\tau(\mathcal{A})} (X'_{\mathit{initial}} X_{\mathit{initial}}, v) \vdash^*_{\tau(\mathcal{A})} (X'_{\mathit{initial}} \alpha X_{\mathit{final}}, \epsilon) \vdash^*_{\tau(\mathcal{A})} (X'_{\mathit{initial}} X_{\mathit{final}}, \epsilon) \vdash_{\tau(\mathcal{A})} (X'_{\mathit{final}}, \epsilon)$, for some $\alpha = \overline{Y_1} \cdots \overline{Y_r}$, using the transitions $\overline{Y_j} X_{\mathit{final}} \overset{\epsilon}{\mapsto}_{\tau(\mathcal{A})} X_{\mathit{final}}$, $1 \leq j \leq r$, which exist since $X_{\mathit{final}} \in \mathit{POP}$.

This proves the equivalence of the two accepted languages. □

LEMMA 4.4. *If $\mathcal{A}$ is an NPDA, then $\tau(\mathcal{A})$ is loop-free.*

Proof. Consider the set of stack symbols of $\tau(\mathcal{A})$. We define a partial ordering $<$ on these symbols as the least ordering satisfying

$$\begin{aligned}
X'_{\mathit{final}} &< X'_{\mathit{initial}}, \\
X &< \overline{Y} \quad \text{for all } X \in \mathit{POP}, Y \in \mathit{PUSH}, \\
\overline{Y} &< Z \quad \text{for all } Y, Z \in \mathit{PUSH}, \\
X &< Z \quad \text{for all } X \in \mathit{POP}, Z \in \mathit{PUSH}.
\end{aligned}$$

Note that this relation is transitive and irreflexive. Below we prove that if $(X, v) \vdash^+_{\tau(\mathcal{A})} (Z, \epsilon)$ then $Z < X$. This is sufficient to prove that $\tau(\mathcal{A})$ is loop-free, since $<$ is irreflexive.

Consider $(X, v) \models^+_{\tau(\mathcal{A})} (XY, \epsilon) \vdash_{\tau(\mathcal{A})} (Z, \epsilon)$, using some transition $XY \overset{\epsilon}{\mapsto}_{\tau(\mathcal{A})} Z$ for the last step. It is obvious that $X \notin \mathit{POP}$ since otherwise Y could not have been on top of X. There are three remaining cases.

(i) If $X = X'_{\mathit{initial}}$ then Z must be X'_{final}. Therefore, $Z < X$.

(ii) If $X \in \mathit{PUSH}$ then either $Z \in \mathit{POP}$ or Z is of the form $\overline{Z'}$, with $Z' \in \mathit{PUSH}$, according to the definition of τ. Therefore, in either case $Z < X$.

(iii) If X is of the form $\overline{X'}$, with $X' \in \mathit{PUSH}$, then the transition $XY \overset{\epsilon}{\mapsto}_{\tau(\mathcal{A})} Z$ must be of the form $\overline{X'} Y \overset{\epsilon}{\mapsto}_{\tau(\mathcal{A})} Y$, with $Y = Z \in \mathit{POP}$. Therefore, $Z < X$.

Since each sequence $(X, v) \vdash^+_{\tau(\mathcal{A})} (Z, \epsilon)$ can be split up into smaller sequences (in this case at most two, leading from a symbol in PUSH to a barred symbol and then to a symbol in POP) of the form $(X, v) \models^+_{\tau(\mathcal{A})} (XY, \epsilon) \vdash_{\tau(\mathcal{A})} (Z, \epsilon)$ and since $<$ is transitive, the required result follows. □

We now return to the issue of the time complexity of Algorithm 1. We start with a minor result.

LEMMA 4.5. *Let $\mathcal{U}$ be computed, using Algorithm 1, for a loop-free NPDA and certain input. There can be at most one item of the form $(X, j, Y, i) \in \mathcal{U}$ for each X, Y, and j.*

Proof. The existence of an item $(X, j, Y, i) \in \mathcal{U}$ requires that $(X, a_{j+1} \cdots a_i) \models^+ (XY, \epsilon)$. Because the NPDA is (by definition) deterministic, the existence of two items $(X, j, Y, i_1), (X, j, Y, i_2) \in \mathcal{U}$ (say, $i_1 < i_2$) requires that $(X, a_{j+1} \cdots a_{i_1}) \models^+ (XY, \epsilon)$ and $(Y, a_{i_1+1} \cdots a_{i_2}) \vdash^+ (Y, \epsilon)$, because of the definition of $\models^+$. However, $(Y, a_{i_1+1} \cdots a_{i_2}) \vdash^+ (Y, \epsilon)$ is not possible if the NPDA is loop-free. □

THEOREM 4.6. *For a loop-free NPDA, Algorithm 1 has linear time demand, measured in the length of the input.*

Proof. Let the input be $a_1 \cdots a_n$. Let $|\Delta|$ denote the number of stack symbols. We investigate how many steps are applied in the process of computing $\mathcal{U}$.

push. Since the PDA is deterministic, there are $\mathcal{O}(|\Delta| \cdot n)$ combinations of a stack symbol X and an input position i such that there is a transition $X \overset{z}{\mapsto} XY$ with $z = \epsilon \vee z = a_i$. Therefore, the pushing step is applied $\mathcal{O}(|\Delta| \cdot n)$ times.

pop. There are $\mathcal{O}(|\Delta|^2 \cdot n)$ items of the form $(W, h, X, j) \in \mathcal{U}$ because of Lemma 4.5. For each of these, there are $\mathcal{O}(|\Delta|)$ items of the form $(X, j, Y, i) \in \mathcal{U}$, again because of Lemma 4.5. The popping step is therefore applied $\mathcal{O}(|\Delta|^3 \cdot n)$ times.

Together, they yield $\mathcal{O}(|\Delta|^3 \cdot n)$ steps. Computing $\mathcal{V}$ from $\mathcal{U}$ can be done straightforwardly within $|\Delta|^2 \cdot n$ steps, since there are at worst that many elements in $\mathcal{U}$ according to Lemma 4.5. $\square$

COROLLARY 4.7. *For any NPDA $\mathcal{A}$ and input $a_1 \cdots a_n$, the set $\{(j, i) \mid a_{j+1} \cdots a_i \in L(\mathcal{A})\}$ can be computed in linear time.*

Proof. From Lemmas 4.2 and 4.4 and Theorem 4.6 we conclude that $\{(j, i) \mid a_{j+1} \cdots a_i \in L(\tau(\mathcal{A}))\}$ can be computed in linear time. According to Lemma 4.3, this is the same set as $\{(j, i) \mid a_{j+1} \cdots a_i \in L(\mathcal{A})\}$. $\square$

5. Metadeterministic recognition. With the results from the preceding section, we can prove that the recognition problem for metadeterministic languages can be solved in linear time by giving a tabular algorithm simulating metadeterministic automata.

Consider a metadeterministic automaton $\mathcal{M} = (\mathcal{F}, A, \mu)$. Because of Theorem 3.2, we may assume without loss of generality that the DPDAs in A are all NPDAs. Because of the existence of transformation τ, we may furthermore assume that those NPDAs are all loop-free.

For deciding whether some input string $a_1 \cdots a_n$ is recognized by $\mathcal{M}$, we first determine which substrings of the input are recognized by which NPDAs in A. Then, we traverse the finite automaton, identifying the input symbols of $\mathcal{F}$ with automata which recognize consecutive substrings of the input string. In order to obtain linear time complexity, we again use tabulation, this time by means of pairs (q, i), which indicate that state q has been reached at input position i.

The following is the complete algorithm.

ALGORITHM 2 (metadynamic programming). Consider a metadeterministic automaton $\mathcal{M} = (\mathcal{F}, A, \mu)$, where $\mathcal{F} = (S, Q, q_s, F, T)$ and A is a finite set of loop-free NPDAs, and consider an input string $a_1 \cdots a_n$.

```
1. Construct the tables $\mathcal{V}_{\mathcal{A}}$ as the sets $\mathcal{V}$ in Algorithm 1 for the respective $\mathcal{A} \in A$ and
input $a_1 \cdots a_n$.
2. Let the set $\mathcal{W}$ be $\{(q_s, 0)\}$. Perform the following as long as it is applicable.
    1. Choose a quadruple, not considered before, consisting of
           (i) a pair $(q, j) \in \mathcal{W}$,
          (ii) a PDA $\mathcal{A} \in A$,
         (iii) a pair $(j, i) \in \mathcal{V}_{\mathcal{A}}$, and
          (iv) a state $p \in Q$,
       such that $(q, b, p) \in T$ for some $b$ with $\mu(b) = \mathcal{A}$.
    2. Add $(p, i)$ to $\mathcal{W}$.
3. Recognize the input when $(q, n) \in \mathcal{W}$, for some $q \in F$.
```

THEOREM 5.1. *Algorithm 2 recognizes $a_1 \cdots a_n$ if and only if $a_1 \cdots a_n \in L(\mathcal{M})$.*

Proof. First we prove that Algorithm 2 eventually adds an item (q, i) to $\mathcal{W}$ if and only if there is some string $b_1 b_2 \cdots b_m \in S^*$, a sequence of states $q_0, \ldots, q_m \in Q$, a sequence of PDAs $\mathcal{A}_1, \mathcal{A}_2, \ldots, \mathcal{A}_m \in A$, and a sequence of strings $w_1, \ldots, w_m \in \Sigma^*$ such that

(i) $q_0 = q_s$, $(q_{k-1}, b_k, q_k) \in T$ for $1 \le k \le m$, and $q_m = q$,
(ii) $\mathcal{A}_k = \mu(b_k)$ for $1 \le k \le m$,
(iii) $w_k \in L(\mathcal{A}_k)$ for $1 \le k \le m$, and
(iv) $a_1 \cdots a_i = w_1 \cdots w_m$.

The "if" part of the proof is by induction on m: Suppose that the above four conditions hold. Then in particular $(q_{m-1}, b_m, q_m) \in T$, $\mathcal{A}_m = \mu(b_m)$, and $w_m = a_{j+1} \cdots a_i \in L(\mathcal{A}_m)$, some j. This last condition is equivalent to $(j, i) \in \mathcal{V}_{\mathcal{A}_m}$. The above four conditions for m imply the same conditions for $m-1$ with j instead of i, and therefore we may use the induction hypothesis to derive that (q_{m-1}, j) is added to $\mathcal{W}$. We conclude that the conditions are fulfilled under which the algorithm adds (q_m, i) to $\mathcal{W}$.

The "only if" part of the proof is very similar. Proof by induction can be applied here if we assume that each item is given a "time stamp," identifying the point in time when that item is (first) added to $\mathcal{W}$.

From the above characterization, the correctness of $(q, n) \in \mathcal{W}$ as criterion for recognition of the input immediately follows. A similar property is proved in full detail in [4]. $\square$

We now get the main theorem of this article.

THEOREM 5.2. *Recognition can be performed in linear time for all metadeterministic languages.*

Proof. It is sufficient to prove that Algorithm 2 operates in linear time. Because of Theorem 4.6 and since there is a finite number of NPDAs in A, the tables $\mathcal{V}_{\mathcal{A}}$, $\mathcal{A} \in A$, can be constructed in linear time.

Furthermore, the table $\mathcal{W}$ is constructed in a linear number of steps, since each step corresponds with one quadruple $((q, j),\ \mathcal{A},\ (j, i),\ p)$, with $(j, i) \in \mathcal{V}_{\mathcal{A}}$, of which there are at most $|Q|^2 \cdot |A| \cdot n$. Note that prefix-freeness of each $\mathcal{A}$ implies that for any j there is at most one i such that $(j, i) \in \mathcal{V}_{\mathcal{A}}$. $\square$

6. On-line simulation. The nature of Algorithm 2 as simulation of metadeterministic automata is such that it could be called an *off-line* algorithm. A case in point is that it simulates steps of PDAs at certain input positions, which can never be useful for recognition of the input if the preceding input were taken into account. By processing the input strictly from left to right and by computing the table elements in a demand-driven way, we obtain an *on-line* algorithm, which leads to fewer table elements, although the *order* of the time complexity is not reduced.

The realization of this on-line algorithm consists of two steps: first, we adapt the pushing step so that the PDAs by themselves are simulated on-line; second, we merge Algorithm 1 and Algorithm 2 such that they cooperate by passing control back and forth concerning (1) where a PDA should start to try to recognize a subsequent substring according to the finite automaton and (2) at what input position a PDA has succeeded in recognizing a substring. Conceptually, the finite automaton and the PDAs operate in a routine–subroutine relation.

ALGORITHM 3 (on-line metadynamic programming). Consider a metadeterministic automaton $\mathcal{M} = (\mathcal{F}, A, \mu)$, with $\mathcal{F} = (S, Q, q_s, F, T)$ and A is a finite set of loop-free NPDAs, and consider an input string $a_1 \cdots a_n$.

1. Let the set $\mathcal{W}$ be $\{(q_s, 0)\}$.
2. Let the sets $\mathcal{U}_{\mathcal{A}}$ be $\emptyset$ for all $\mathcal{A} \in A$.
3. Perform one of the following four steps as long as one of them is applicable.

```
down   1. Choose a pair, not considered before, consisting of
                (i)  a pair $(q, i) \in \mathcal{W}$ and
                (ii) a PDA $\mathcal{A} \in A$,
          such that $(q, b, p) \in T$ for some $b$ with $\mu(b) = \mathcal{A}$ and some $p$.
       2. Add $(\perp, i, X_{initial}, i)$ to $\mathcal{U}_{\mathcal{A}}$.
```

push 1. For some PDA $\mathcal{A} \in A$, choose a pair, not considered before, consisting of a transition $X \overset{z}{\mapsto}_{\mathcal{A}} XY$ and an input position j, such that there is an item $(W, h, X, j) \in \mathcal{U}_{\mathcal{A}}$, for some W and h, and such that $z = \epsilon \vee z = a_{j+1}$.
2. If $z = \epsilon$ then let $i = j$, else let $i = j + 1$.
3. Add item (X, j, Y, i) to $\mathcal{U}_{\mathcal{A}}$.

pop 1. For some PDA $\mathcal{A} \in A$, choose a triple, not considered before, consisting of a transition $XY \overset{\epsilon}{\mapsto}_{\mathcal{A}} Z$ and items $(W, h, X, j), (X, j, Y, i) \in \mathcal{U}_{\mathcal{A}}$.
2. Add item (W, h, Z, i) to $\mathcal{U}_{\mathcal{A}}$.

up 1. Choose a quadruple, not considered before, consisting of
(i) a pair $(q, j) \in \mathcal{W}$,
(ii) a PDA $\mathcal{A} \in A$,
(iii) an item $(\perp, j, X_{\mathit{final}}, i) \in \mathcal{U}_{\mathcal{A}}$, and
(iv) a state $p \in Q$,
such that $(q, b, p) \in T$ for some b with $\mu(b) = \mathcal{A}$.
2. Add (p, i) to $\mathcal{W}$.

4. The input is recognized when $(q, n) \in \mathcal{W}$ for some $q \in F$.

The popping and pushing steps, simulating the PDA steps, operate much as in Algorithm 1. An important difference is that the pushing step no longer operates irrespective of preceding input: It simulates only a push on some stack element X if it has been established with regard to previously processed input that such an element may indeed appear on top of the stack.

A second difference is that the PDA steps are simulated by starting at input positions computed by the "down" step, which adds $(\perp, i, X_{\mathit{initial}}, i)$ to $\mathcal{U}_{\mathcal{A}}$ only if recognition of a substring recognized by $\mathcal{A}$ is needed from position i in order to enable a transition to a next state in the finite automaton.

The "up" step constitutes a shift of control back to the finite automaton after some PDA has succeeded in recognizing a substring.[4]

The characterization of the elements in $\mathcal{W}$ we gave after Algorithm 2 is still valid for Algorithm 3. The characterization of the elements in the sets $\mathcal{U}_{\mathcal{A}}$ is more restricted than before, however. Relying on a standard result for on-line tabular simulation of PDAs [11], one can prove that Algorithm 3 eventually adds an item (X, j, Y, i) to $\mathcal{U}_{\mathcal{A}}$ for some $\mathcal{A} \in A$ if and only if there is some $h \leq j$ and some state q such that
1. $(q, h) \in \mathcal{W}$ for some q with $(q, b, p) \in T$, some b with $\mu(b) = \mathcal{A}$ and some p,
2. $(\perp, a_{h+1} \cdots a_j) \vdash^*_{\mathcal{A}} (\delta X, \epsilon)$, for some δ, and
3. $(X, a_{j+1} \cdots a_i) \models^+_{\mathcal{A}} (XY, \epsilon)$.

The first condition states that the finite automaton is in need of a substring recognized by PDA $\mathcal{A}$ starting from position h. The second condition states that some configuration can be reached from an initial configuration by reading the input from position h up to position j, and in this configuration an element labeled X is on top of the stack. The third condition is as before.

A device which recognizes some language by reading input strings from left to right is said to satisfy the *correct-prefix property* if it cannot read past the first incorrect symbol in an incorrect input string. A different way of expressing this is that if it has

[4]If μ is bijective and $(q, b, p) \in T$ is unique for each b, then the condition $(\perp, j, X_{\mathit{final}}, i) \in \mathcal{U}_{\mathcal{A}}$ may be replaced with $(Y, j, X, i) \in \mathcal{U}_{\mathcal{A}}$, with X final in $\mathcal{A}$, and mention of $(q, j) \in \mathcal{W}$ may be omitted. This generalization allows arbitrary PDAs as opposed to NPDAs. In particular, nondeterministic PDAs may be used. For deterministic, loop-free (but not necessarily normal or prefix-free) PDAs the on-line algorithm then still has a linear time complexity. We do not pursue this option because the resulting recognition algorithm cannot be turned into a parsing algorithm; see also section 7.

succeeded in processing a prefix w of some input string wv, then w is a prefix of some input string wv' which can be recognized.

A consequence of the on-line property of Algorithm 3 is that it satisfies the correct-prefix property, provided that both the finite automaton $\mathcal{F}$ and the PDAs in A satisfy the correct-prefix property. A straightforward proof can be obtained from the characterizations of the elements in $\mathcal{W}$ and $\mathcal{U}_{\mathcal{A}}$, $\mathcal{A} \in A$, given above.

7. Producing parse trees. We have shown that metadeterministic recognition can be done efficiently. The next step is to investigate how the recognition algorithms can be extended to become parsing algorithms.

The approach to tabular context-free parsing in [11, 6] is to start with pushdown transducers. A pushdown transducer can be seen as a PDA of which the transitions produce certain *output symbols* when they are applied. The *output string*, which is a list of all output symbols which are produced while successfully recognizing an input, is then seen as a representation of the parse.

If the pushdown transducers are to be realized using a tabular algorithm such as Algorithm 1, then we may apply the following to compute all output strings without impairing the time complexity of the recognition algorithm. The idea is that a context-free grammar, the *output grammar*, is constructed as a side effect of recognition. For each item (X, j, Y, i) added to the table, the grammar contains a nonterminal $A_{(X,j,Y,i)}$. This nonterminal is to generate all lists of output symbols which the pushdown transducer produces while computing $(X, a_{j+1} \cdots a_i) \models^+ (XY, \epsilon)$. The rules of the output grammar are created when items are computed from others. For example, if we compute an item (W, h, Z, i) from two items $(W, h, X, j), (X, j, Y, i) \in \mathcal{U}$, using a popping transition $XY \overset{\epsilon}{\mapsto} Z$ which produces output symbol a, then the output grammar is extended with rule $A_{(W,h,Z,i)} \to A_{(W,h,X,j)}\ A_{(X,j,Y,i)}\ a$.

The start symbol of the output grammar is $A_{(\perp,0,X_{\mathit{final}},n)}$, for recognition of the complete input. For Algorithm 1, however, which recognizes fragments of the input, we have several output grammars, of which the start symbols are of the form $A_{(\perp,j,X_{\mathit{final}},i)}$. The sets of rules of these grammars may overlap.

The languages generated by output grammars consist of all output strings which may be produced by the pushdown transducer while successfully recognizing the corresponding substrings. In the case of DPDAs, these are of course singleton languages.

In a straightforward way this method may be extended to off-line simulation of a metadeterministic automaton $\mathcal{M} = (\mathcal{F}, A, \mu)$, where A is now a set of pushdown transducers, as follows.

1. We create subgrammars for v and the respective automata in A separately, following the ideas above.
2. We merge all grammar rules constructed for the different automata $\mathcal{A} \in A$. We assume that the sets of stack symbols from the respective automata are pairwise disjoint in order to avoid name clashes.
3. For each automaton $\mathcal{A} \in A$ we add rules $A_{(\mathcal{A},j,i)} \to A_{(\perp,j,X_{\mathit{final}},i)}$ if $A_{(\perp,j,X_{\mathit{final}},i)}$ is a nonterminal found while constructing $\mathcal{U}_{\mathcal{A}}$.
4. While constructing table $\mathcal{W}$, we may extend the output grammar with a rule $A_{(p,i)} \to A_{(q,j)}\ A_{(\mathcal{A},j,i)}$ when a pair (p, i) is derived from a pair $(q, j) \in \mathcal{W}$ and a pair $(j, i) \in \mathcal{V}_{\mathcal{A}}$.
5. We extend the output grammar with all rules of the form $S \to (q, n)$, where $q \in F$. S is the start symbol of the grammar.

(For on-line processing similar considerations apply.)

In this way, we may produce a context-free grammar reflecting the structure of the input string without impairing the time complexity of the recognition algorithm.

8. Applications.

8.1. Suffix recognition. For a language L we define the language $\mathit{suffix}(L) = \{v \mid \exists w[wv \in L]\}$. A member of $\mathit{suffix}(L)$ will be called a *suffix*. In this section we will assume that L is a deterministic language.

Only recently [2] has it been shown that suffixes can be recognized in linear time. In [13] it was shown furthermore that *parsing* of suffixes is possible in linear time. Here we give an alternative proof of this result as a corollary to the previous sections. This we do by providing a transformation from a deterministic language L, specified in the form of a deterministic PDA $\mathcal{A}$, to a metadeterministic automaton $\sigma(\mathcal{A})$ recognizing suffixes.

For technical reasons, we assume that the PDA $\mathcal{A}$ satisfies a property called *pop-realistic*, which means that if it can pop a number of elements off a stack, then those elements may indeed occur on top of a stack in a configuration reachable from an initial configuration. Formally, we say that a PDA is *pop-realistic* if $(\delta, v) \vdash^* (X, \epsilon)$, some δ, v, X, implies $(X_{\mathit{initial}}, w) \vdash^* (\delta'\delta, \epsilon)$ for some w and δ'.

The assumption that $\mathcal{A}$ is pop-realistic is not a theoretical restriction, since any PDA can be mechanically transformed into one that is pop-realistic and that accepts the same language [5]; nor is it a practical restriction, since many naturally occurring PDAs realizing top-down or LR recognition, for example, already satisfy this property.

CONSTRUCTION 3 (suffix recognition). *Let $\mathcal{A} = (\Sigma, \Delta, X_{\mathit{initial}}, F_{\mathcal{A}}, T_{\mathcal{A}})$ be a DPDA which is pop-realistic. Construct the metadeterministic automaton $\sigma(\mathcal{A}) = (\mathcal{F}, A, \mu)$, with $\mathcal{F} = (S, Q, q_s, \{q_f\}, T_{\mathcal{F}})$, where*

(i) $S = \{e\} \cup \{b_{X,Y} \mid X, Y \in \Delta\} \cup \{c_X \mid X \in \Delta\}$,

(ii) $Q = \Delta \cup \{q_s, q_f\}$,

(iii) q_s *and* q_f *are fresh symbols,*

(iv) $T_{\mathcal{F}} = \{(q_s, e, X) \mid X \in \Delta\} \cup \{(X, b_{X,Y}, Y) \mid X, Y \in \Delta\} \cup \{(X, c_X, q_f) \mid X \in \Delta\}$.

As the set of PDAs we take $A = \{\mathcal{E}\} \cup \{\mathcal{B}_{X,Y} \mid X, Y \in \Delta\} \cup \{\mathcal{C}_X \mid X \in \Delta\}$. These PDAs are defined as follows.[5]

$\mathcal{E}$ is defined to be $(\Sigma, \{\diamond\}, \diamond, \{\diamond\}, \emptyset)$, where $\diamond$ is a fresh symbol.

Each $\mathcal{B}_{X,Y}$ is defined to be $(\Sigma, \Delta \cup \{X^{in}, X^{out}\}, X^{in}, \{X^{out}\}, T)$, where X^{in} and X^{out} are fresh symbols and the transitions in T are those in $T_{\mathcal{A}}$ plus the extra transitions

$$\begin{array}{lll} X^{in} & \overset{\epsilon}{\mapsto}_{\mathcal{B}_{X,Y}} & X^{in}X, \\ X^{in}X' & \overset{\epsilon}{\mapsto}_{\mathcal{B}_{X,Y}} & X^{out} \qquad \textit{for all } ZX' \overset{\epsilon}{\mapsto}_{\mathcal{A}} Y, \textit{ some } X' \textit{ and } Z. \end{array}$$

Each $\mathcal{C}_X$ is defined to be $(\Sigma, \Delta, X, F_{\mathcal{A}}, T_{\mathcal{A}})$.

The function μ maps the symbol e to automaton $\mathcal{E}$, the symbols $b_{X,Y}$ to automata $\mathcal{B}_{X,Y}$, and the symbols c_X to automata $\mathcal{C}_X$.

The automaton $\mathcal{E}$ accepts the singleton language containing the empty string. Its use at a transition $(q_s, e, X) \in T_{\mathcal{F}}$ is to mimic an arbitrary computation of $\mathcal{A}$, leading to a configuration where X is on top of the stack. During this computation an unknown input string is read, and the rest of the stack is composed of an unknown combination of stack symbols.

[5]Note that the languages recognized by some of these automata may be the empty set.

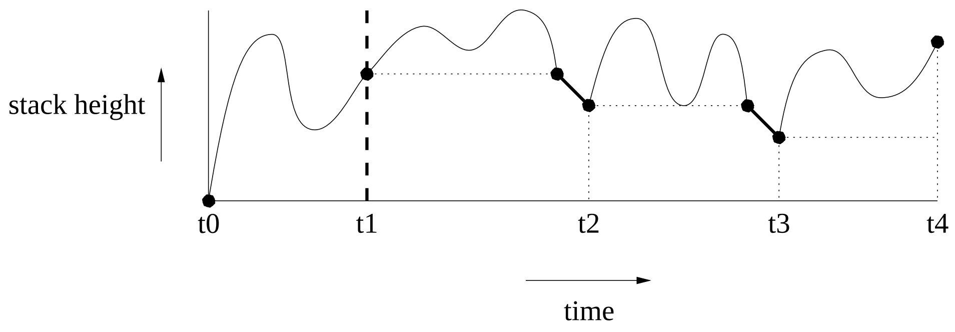

FIG. 8.1. *A stack development of a DPDA $\mathcal{A}$, divided into recognition of a prefix and recognition of the remaining suffix.*

Each automaton $\mathcal{B}_{X,Y}$ mimics all computations beginning with X on top of the stack and ending with the first configuration where the stack shrinks to below the original height; at that point Y is on top. Formally, $\mathcal{B}_{X,Y}$ recognizes a string v if and only if there are X' and Z such that $(X, v) \vdash^* (X', \epsilon)$ and $(ZX', \epsilon) \vdash (Y, \epsilon)$; first, the stack may grow and shrink while reading v, replacing X by some element X', and then X' and an element Z beneath it in the stack are replaced by Y.

Each automaton $\mathcal{C}_X$ mimics all computations of $\mathcal{A}$ that start with X on top of the stack and eventually reach a final configuration without ever having a stack of which the height is 1 less than that of the original stack. Formally, $\mathcal{C}_X$ recognizes a string v if and only if $(X, v) \vdash^*_{\mathcal{A}} (\delta Y, \epsilon)$ for some $Y \in F_{\mathcal{A}}$.

For a complete proof that $L(\sigma(\mathcal{A})) = \mathit{suffix}(L(\mathcal{A}))$, which is similar to the proof in section 3, see [5]. In this article we merely convey the intuition.

Figure 8.1 suggests how the stack may alternately grow and shrink while $\mathcal{A}$ recognizes some input. From t0 to t1 some prefix of the input is read. Acceptance of the remainder of the input, the suffix, is achieved between t1 and t4. Suppose that the stack shrinks to maximally two elements below the height it had at t1: at t2 the stack shrinks to one element below the original height, and at t3 the stack shrinks one element farther. The stack development between t1 and t2 is mimicked by automaton $\mathcal{B}_{X_1,X_2}$, where we assume that X_1 and X_2 are on top of the stack at t1 and t2, respectively. Similarly, the development between t2 and t3 is mimicked by $\mathcal{B}_{X_2,X_3}$. The final part, between t3 and t4, is mimicked by $\mathcal{C}_{X_3}$.

Conversely, if we have consecutive segments of the input recognized by a sequence of automata $\mathcal{B}_{X_1,X_2}$, $\mathcal{B}_{X_2,X_3}$ and $\mathcal{C}_{X_3}$, then composition of the three sequences of transitions leads to a development of the stack as suggested between t1 and t4 in Figure 8.1. The existence of the required sequence of transitions between t0 and t1 follows from the assumption that $\mathcal{A}$ is pop-realistic.

The preceding discussion and Theorem 5.2 together imply the following corollary.

COROLLARY 8.1. *Recognition of suffixes can be performed in linear time for all deterministic languages.*

8.2. Generalized pattern matching. In [10] the following problem is treated. Given are a finite set of input symbols Σ, an input string $a_1 \cdots a_n \in \Sigma^*$ and a pattern $b_1 \cdots b_m \in \Sigma^*$. To be decided is whether $a_1 \cdots a_n = vb_1 \cdots b_m w$ for some $v, w \in \Sigma^*$, or in words, whether $b_1 \cdots b_m$ is a substring of $a_1 \cdots a_n$.

This problem can also be stated as follows. To be decided is whether $a_1 \cdots a_n$ is a member of the language $\Sigma^*\{b_1 \cdots b_m\}\Sigma^*$. This language is described as a regular expression over deterministic languages, i.e., Σ and $\{b_1 \cdots b_m\}$, and therefore this language is metadeterministic. Consequently, the algorithms in this article apply.

The time demand can then be shown to be $\mathcal{O}(n \cdot m)$, which is, of course, $\mathcal{O}(n)$ if n is taken as sole parameter. This is in contrast to the algorithm in [10], which provides a complexity of $\mathcal{O}(n + m)$. This seems a stronger result if time complexity is the only matter under consideration. From a broader perspective, however, our approach allows a larger class of problems to be solved.

For example, the substring problem can be generalized as follows. Given are a finite set of input symbols Σ, an input string $a_1 \cdots a_n \in \Sigma^*$, and a deterministic language $L \subseteq \Sigma^*$. To be decided is whether $a_1 \cdots a_n = uvw$, some $u, w \in \Sigma^*$ and $v \in L$, or in words, whether some substring of $a_1 \cdots a_n$ is in L. As before, the problem can be translated into a membership problem of some string in a metadeterministic language, and therefore our approach allows this problem to be solved in $\mathcal{O}(n)$ time.

9. Conclusions. We have introduced a new subclass of the context-free languages, the metadeterministic languages, which include the deterministic languages properly. We have given recognition algorithms for this class and shown that they have a linear time complexity. Our results are nontrivial since this class contains inherently ambiguous languages. It is still an open problem whether a constructive definition exists for *all* context-free languages which can be recognized in linear time.

Acknowledgments. The second author has had fruitful discussions with Joop Leo about linear-time recognizability of subclasses of context-free languages.

The authors acknowledge help from two referees. The presentation of several proofs was improved by their suggestions.

CONSTRUCTING EVOLUTIONARY TREES IN THE PRESENCE OF POLYMORPHIC CHARACTERS*

MARIA BONET†, CYNTHIA PHILLIPS‡, TANDY WARNOW§, AND SHIBU YOOSEPH¶

Abstract. Most phylogenetics literature and construction methods based upon characters presume monomorphism (one state per character per species), yet polymorphism (multiple states per character per species) is well documented in both biology and historical linguistics. In this paper we consider the problem of inferring evolutionary trees for polymorphic characters. We show efficient algorithms for the construction of perfect phylogenies from polymorphic data. These methods have been used to help construct the evolutionary tree proposed by Warnow, Ringe, and Taylor for the Indo-European family of languages and presented by invitation at the National Academy of Sciences in November 1995.

1. Introduction.

Determining the evolutionary history of a set S of objects (taxa or species) is a problem with applications in a number of domains such as biology, comparative linguistics, and literature. Primary data used to compare different taxa (whether biological species, populations, or languages) can be described using *characters*, where a character is a function $\alpha : S \rightarrow Z$, where Z denotes the integers and thus represents the set of possible *states* of α. In this paper we consider tree construction when characters are permitted to have more than one state on a given object. We call this the *polymorphism problem.* A character that is permitted to have more than one state on a given object will be called a *polymorphic character*, and one that can have only one state for every object is referred to as a *monomorphic* character.

Polymorphism is well documented in both the molecular genetics and comparative linguistics domains [8, 33]. For example, the population geneticist Masatoshi Nei writes: "The study of protein polymorphism has indicated that the extent of genetic variation in natural populations is enormous. However, the total amount of genetic variation cannot be known unless it is studied at the DNA level. The study of DNA polymorphism is still in its infancy, but the results so far obtained indicate that the extent of DNA polymorphism is far greater than that of protein polymorphism" [28, p. 254]. Polymorphism also arises in the comparison of languages. The Indo-Europeanist Donald Ringe writes: "In choosing lexical characters we try to work with

basic meanings (semantic slots), choosing from each language the word that most usually expresses each basic meaning. Languages typically have one word for each basic semantic slot, but instances of two (or even more) words apparently filling the same basic slot are not rare" [30].

Thus polymorphic data is a reality when working with evolutionary tree construction for both linguistic analysis and biological taxa, and methods appropriate for such construction must be devised. In the phylogenetics literature and programs (such as Phylip, PAUP, and MacClade), algorithms and software to *evaluate* fixed leaf-labeled tree topologies for polymorphic data have explicitly required that the number of states be kept quite small because the evaluation requires time exponential in the number of states. This is the first algorithmic study of this problem to go beyond fixed topology problems for bounded number of states.

The concept of an idealized evolutionary tree was introduced by LeQuesne in a series of articles (see, for example, [24, 25]), and later termed "Perfect Phylogenies" by Gusfield in [18], and studied in several papers (see, for example, [13, 14]). The major contribution of this paper is a methodology for inferring perfect phylogenies from monomorphic and polymorphic characters. Recent work in historical linguistics [39] has shown that perfect phylogenies should be obtainable from properly selected and encoded linguistic characters. Algorithms for constructing perfect phylogenies from monomorphic characters were used in [39] to analyze the Indo-European family of languages, whose first-order subgrouping had been argued for decades without resolution. The methodology we propose here significantly extends the range of the data that can be analyzed in historical linguistics. We have applied this methodology to the data set studied by Warnow, Ringe, and Taylor. Detection and resolution of polymorphism led to a modification of their initially proposed phylogeny, which was based only on monomorphic characters. Our methodology and its results were presented at the Symposium on the Frontiers of Science at the National Academy of Sciences in November 1995 [38].

The structure of the rest of the paper is as follows. In section 2 we discuss the causes of polymorphism in linguistics and biology and define the problem of inferring trees from polymorphic characters in these two domains. We show that a perfect phylogeny is an appropriate objective when working with linguistic data as well as some biological data. In section 3 we present two algorithms, one graph theoretic and one combinatorial, for the problem of inferring perfect phylogenies from polymorphic data. In section 4.3 we present a methodology for inferring perfect phylogenies from data which combine monomorphic and polymorphic data. In section 5 we present our analysis of the Indo-European data studied by Warnow, Ringe, and Taylor [39]. In section 6 we consider the problem of inferring evolutionary trees from polymorphic data when a perfect phylogeny is an unlikely outcome. We conclude in section 7.

2. Foundations.

The causes of polymorphism in biology and linguistics differ, and within biology, polymorphism has more than one cause as well. In linguistics, convergence of meanings over time, borrowing of synonyms from other languages, and the inability of modern-day linguists to detect subtle differences of meaning in words from ancient languages can all produce polymorphic characters. Some such cases, like English *little* and *small,* arise by the convergence of meanings over time; others, like American English *stone* and *rock* (to describe a small chunk of the substance that can be thrown), are instances of replacement in progress (*rock* is replacing *stone* in that basic meaning in America). It can be shown that the different manifestations of polymorphism in linguistics each can be described by the conflation of two or more distinct linguistic characters. Often we are able to determine the precise number of monomorphic characters that have merged into the polymorphic character. In linguistics it has been observed that monomorphic characters are *convex*, by which we mean that the nodes sharing any state of any character form a connected set in the tree.

DEFINITION 2.1. *Given a set S of taxa defined by a set C of characters ($|C| = k$), where each $\alpha_j \in C$ is a function $\alpha_j : S \to (2^Z - \{\emptyset\})$, let T be a tree that is leaf-labeled by the taxa in S and with each internal node v labeled with a vector from $(2^Z - \{\emptyset\})^k$ such that the value of $\alpha_j(v)$ is given by the jth component of this vector. A character (polymorphic or monomorphic) $\alpha_j \in C$ is* convex *on T if for all $i \in Z$ the set $X_{i,\alpha_j} = \{v \in V(T) : i \in \alpha_j(v)\}$ is connected. T is a* perfect phylogeny *if every character is convex.*

For polymorphism caused by convergence of convex monomorphic characters, polymorphism can be considered a *separation* problem.

DEFINITION 2.2. *Let α be a character defined on a species set S and let i be a character state of α. Then we define $\alpha^{-1}(i) = \{s \in S : i \in \alpha(s)\}$.*

DEFINITION 2.3. *Let β be a polymorphic character with character states $0, \dots, r-1$, and for each $s \in S$ suppose $|\beta(s)| \le l'$. Then β is* separated *into l monomorphic characters $\alpha_1, \dots, \alpha_l$, where $l \ge l'$, if there is a function $f : \{0, \dots, r-1\} \to \{1, \dots, l\}$, such that if $f(i) = j$ then i is a character state of α_j and in addition, for every $s \in \alpha_j^{-1}(i)$, we have $i \in \beta(s)$.*

Example. Let $S = \{A, B, C, D\}$ and let $\beta(A) = \{0, 1\}, \beta(B) = \{2, 1\}, \beta(C) = \{0\}$, and $\beta(D) = \{2\}$. Then β is separated into two monomorphic characters α_1 and α_2 by setting $f(0) = 1, f(1) = 2, f(2) = 1$. Thus $\alpha_1(A) = \{0\}, \alpha_1(B) = \{2\}, \alpha_1(C) = \{0\}, \alpha_1(D) = \{2\}, \alpha_2(A) = \{1\}$, and $\alpha_2(B) = \{1\}$. In addition, we set $\alpha_2(C) = \{4\}$ and $\alpha_2(D) = \{5\}$.

In the example note that $\alpha_2(C)$ and $\alpha_2(D)$ are set to previously unused values. Thus *if for some $j' \in \{1, 2, \dots, l\}$ $\alpha_{j'}(s)$ is undetermined, then $\alpha_{j'}(s)$ can be set to a previously unused state.*

Problem 1 (separation into l convex characters).

Input. Set S of taxa (defined by set C of characters) and an integer l.

Question. Can we separate each character into at most l monomorphic characters, so that a perfect phylogeny exists for the derived set of monomorphic characters?

Due to inadequate historical evidence, input data may not reflect the actual degree of polymorphism. Separation may be necessary to obtain convexity even if all input characters appear monomorphic. For example, consider four languages with three characters: $A = (1, 2, 1), B = (1, 2, 2), C = (1, 2, 1), D = (1, 2, 2)$. Suppose the first two characters convolve (meanings merge) and linguists detect only one of these characters for each language. This polymorphic character appears monomorphic: $A = (1, 1), B = (1, 2), C = (2, 1), D = (2, 2)$. There is no perfect phylogeny for this set, but we can separate the first character into two such that there is a perfect phylogeny: $A = (1, a, 1), B = (1, b, 2), C = (c, 2, 1)$, and $D = (d, 2, 2)$. Because of lost information, we cannot completely determine the *inferred* characters α_i (hence the use of singletons or previously unused states).

We note that an r-state character can always be separated into r monomorphic *single state* characters which are each convex on all phylogenies. Thus $l = r$ is an easy instance of Problem 1.

In biology, polymorphic characters can arise when dealing with allozyme data [26] and morphological data [40]. In coding allozyme data, each locus is assumed to be a character (as opposed to a character being defined as the presence or absence of individual alleles) and the set of character states can then be defined by the combination of alleles present at the locus. When dealing with sequence data, alternative encodings of the same amino acid sequence can also lead to the presence of polymorphic characters. In each of these cases, the number of different forms that the character can take on a given taxon may be bounded, in which case we may reasonably seek a tree in which every node has no more than some prespecified bound of states for each character. This bound may be character dependent.

Definition 2.4. *Let T be a phylogeny. A character α is said to have* load l *if, for every $v \in V(T)$, $|\alpha(v)| \leq l$. The load of T is defined to be the maximum load on any character.*

Problem 2 (l-load perfect phylogeny).

Input. Set S of taxa (defined by set C of polymorphic characters) and an integer l.

Question. Does an l-load perfect phylogeny exist?

For many morphological characters in biology, convexity is a reasonable assumption (e.g., consider *vertebrate-invertebrate*). Although the causes of polymorphism in biology and linguistics differ, when convexity can be assumed the different problem formulations are equivalent.

Theorem 2.5. *Given a set of taxa defined by a set C of polymorphic characters, T is an l-load perfect phylogeny for C iff we can separate each polymorphic character into at most l monomorphic characters such that T is also a perfect phylogeny for the derived set C'.*

Proof. One direction is easy. For the converse, let T be a perfect phylogeny with load l, let $\alpha \in C$ be given, and assume α has r states present on S. Let T_i be the subgraph of T induced by the vertices labeled i by α. Since T is a perfect phylogeny, each T_i is a subtree. Define G_α to be the graph whose vertices are in one-to-one correspondence with the subtrees $T_i, i = 1, 2, \ldots, r$, and where $(T_i, T_j) \in E$ iff $T_i \cap T_j \neq \emptyset$. Note that since T has load l, G_α has max clique size at most l. G_α is triangulated since it is the intersection graph of subtrees of a tree [7], and hence G_α is perfect [17]. Since G_α is perfect, the chromatic number of G_α equals the max clique size and hence is bounded by l. Hence we can partition the nodes of G_α into at most l independent sets, $V_1, V_2, \ldots, V_l$. Each V_i thus defines a monomorphic character (filled in with singletons), and hence T is a perfect phylogeny for each of these monomorphic characters. ◻

Polymorphism in characters that are based upon columns of molecular sequences behaves differently than polymorphism in morphological characters; for these characters, variations on the parsimony criterion are more appropriate optimization criteria. We discuss the computational complexity of these problems in section 6.

3. Inferring perfect phylogenies from polymorphic characters.

When the maximum permissible load for each character is not given, the problem of inferring perfect phylogenies is best stated as a *minimum load* problem. This is addressed in section 3.1. When the maximum permissible load for each character is given, we have two algorithms which can construct perfect phylogenies; both are efficient when the number of characters is small. These algorithms are presented in section 4. When the character set includes a sufficient number of monomorphic characters, we have a third algorithm which combines techniques for monomorphic and polymorphic characters. This algorithm is presented in section 4.3.

The various parameters to the problem are n (the number of species), k (the number of characters), r (the maximum number of states per character), and l (maximum load for each character).

3.1. Minimum load problems. When convexity of the monomorphic constituents of the polymorphic characters is a reasonable request, we may seek a tree with a prespecified load bound, or else we may seek a tree with a minimum possible load bound. We call the latter problem the *minimum* (or *min*) *load problem.*

We note that the min load problem is NP-hard since the question of whether a 1-load perfect phylogeny exists is NP-complete [4, 36]. However, although the 1-load perfect phylogony problem is NP-complete, the natural fixed parameter versions of the problem are solvable in polynomial time; see [1, 2, 5, 12, 19, 21, 22, 23, 37]. The 2-load perfect phylogeny problem is the next question to consider.

THEOREM 3.1.

(i) *The min load problem can be solved in polynomial time for all fixed n.*
(ii) *The min load problem can be solved in polynomial time when $r = 2$.*
(iii) *The min load problem is NP-hard for all fixed k.*
(iv) *The min load problem is NP-hard for all fixed $r \geq 3$.*
(v) *Determining whether a 2-load perfect phylogeny exists is solvable in polynomial time for all fixed n.*
(vi) *Determining whether a 2-load perfect phylogeny exists is solvable in polynomial time for $r = 2$.*
(vii) *Determining whether a 2-load perfect phylogeny exists is solvable in polynomial time for all fixed k.*
(viii) *Determining whether a 2-load perfect phylogeny exists is NP-complete for all fixed $r \geq 3$.*

Proof. Parts (i) and (v): When n is fixed, the number of possible leaf-labeled topologies is bounded, so we need only consider the min load problem on a fixed topology. Determining the minimum load on a fixed leaf-labeled topology is trivial, since for each internal node $v \in V(T)$ and each character $\alpha \in C$ we simply set $\alpha(v) = \{i : \exists x, y \text{ leaves of } T \text{ with } v \text{ on the path from } x \text{ to } y, \text{ and } i \in \alpha(x) \cap \alpha(y)\}$. This determines the minimum load for the topology. The same argument can be used to show that 2-load perfect phylogeny is solvable in polynomial time when n is fixed.

Parts (ii) and (vi): If $r = 2$, then clearly the min load problem and thus the 2-load perfect phylogeny problem can be solved in polynomial time by observing that 1-load perfect phylogeny on binary characters is solvable in polynomial time [18] and that there is always an r-load perfect phylogeny on any input set containing characters with at most r states.

Part (iii): We now show that the min load problem is NP-hard for all fixed k by showing that the l-load perfect phylogeny problem with fixed number of characters $k \geq 1$, where each character has input load 2 (i.e., two states for every species), is NP-complete. The reduction is from the following problem involving partial t-tree recognition. See section 4.2.3 for definitions of t-trees and partition intersection graphs.

Problem 3 (partial t-tree recognition).

Input. A graph $G = (V, E)$ and an integer $t \leq (n-1)$, where $|V| = n$.

Question. Is G a partial t-tree, i.e., does there exist $G' = (V, E')$ such that $E \subseteq E'$ and G' is a t-tree?

The above problem was shown to be NP-complete by Arnborg, Corneil, and Proskurowski [3].

The reduction is as follows. Let $(G = (V, E), t)$ be an instance of the partial t-tree problem. The corresponding instance of the load problem consists of the species set

$S = \{s_e | e \in E\}$ and one character α, with $\alpha(s_e) = \{i, j\}$, where $e = (i, j)$. Also, set $l = t + 1$. We claim that the instance to the partial t-tree problem has a solution iff the corresponding instance to the load problem has a solution. This can be seen by observing that G is the partition intersection graph of the instance of the load problem and thus we can use Theorems 4.8 and 4.9.

Parts (iv) and (viii): Next we show that the 2-load perfect phylogeny problem, where each of the input characters is monomorphic, is NP-complete for fixed $r \geq 3$. This will also imply that the min load problem is NP-hard for fixed $r \geq 3$. The reduction is from the partial binary characters problem (PBCP), which is defined as follows.

Problem 4 (partial binary character perfect phylogeny).

Input. An $n \times k$ matrix M, of n species and k characters, in which each entry of M is an element of the set $\{0, 1, *\}$.

Question. Can each $*$ entry be set to 0 or 1 so that there exists a 1-load perfect phylogeny with the new matrix ?

The above problem is just a reformulation of the quartet consistency problem, which was shown to be NP-complete by [36].

Given an instance I of PBCP, the instance of the 2-load problem is constructed as follows. Replace each $*$ entry in the matrix defined by I with a 2. Let C be the set of k characters and let S be the set of n species defined by this new matrix. We will add $2k$ new characters and $9k$ new species as follows ($s^i_\alpha = (x, y, z)$ indicates that $\alpha(s^i_\alpha) = x, \alpha^1(s^i_\alpha) = y, \alpha^2(s^i_\alpha) = z$):

1. Initialize $S' = S$ and $C' = C$.
2. For each $\alpha \in C$, do the following:
    a. Define two new characters α^1 and α^2 and nine new species $s^1_\alpha, \ldots, s^9_\alpha$ as follows:
        i. For each $\beta \in C'$ (where $\beta \neq \alpha$) set $\beta(s^i_\alpha) = 2$, where $1 \leq i \leq 9$.
        ii. For each $s \in S'$ set $\alpha^1(s) = 2$ and $\alpha^2(s) = 2$.
        iii. Set $s^1_\alpha = (0, 0, 2)$, $s^2_\alpha = (0, 1, 2)$, $s^3_\alpha = (0, 2, 2)$, $s^4_\alpha = (2, 0, 0)$, $s^5_\alpha = (2, 1, 1)$, $s^6_\alpha = (2, 2, 2)$, $s^7_\alpha = (1, 2, 0)$, $s^8_\alpha = (1, 2, 1)$, $s^9_\alpha = (1, 2, 2)$.
    b. Update $S' = S' \cup \{s^1_\alpha, \ldots, s^9_\alpha\}$ and $C' = C' \cup \{\alpha^1, \alpha^2\}$.

$I' = (S', C')$ is the instance of the load problem. We claim that I has a solution iff I' has a perfect phylogeny with load 2. The proof follows. Let T be a perfect phylogeny which is a solution to instance I of PBCP. Each vertex in T is a k-tuple binary vector. We will first construct the solution for the load problem when restricted to the initial species set S. Identify the species which initially had a $*$ entry for that character and replace the state for that character by a 2. It can be verified that by doing this for every character in C and then relabeling the internal vertices so that the convexity property still holds, we get a solution to the load problem for the initial species S and character set C. Extend the character set C to C' by adding the new characters, which consist entirely of character state 2. This is still a solution to the load problem for S with C'. Let T' be the tree obtained as a result of the above modifications. We will now show how to add the additional $9k$ species. We define $\alpha^{-1}(i) = \{s : \alpha(s) = i\}$. For each $\alpha \in C$ note that there is some edge in T' which separates $\alpha^{-1}(0)$ from $\alpha^{-1}(1)$. For each character $\alpha \in C$, identify an edge e which separates $\alpha^{-1}(0)$ from $\alpha^{-1}(1)$. Attach the 9 new species, associated with α, as shown in Figure 3.1. We note that $\alpha^{-1}(0) \subseteq A$ and $\alpha^{-1}(1) \subseteq B$.

Let T'' be the tree finally obtained after the addition of the $9k$ new species as described above. It can be easily verified that T'' is a solution to instance I' of the

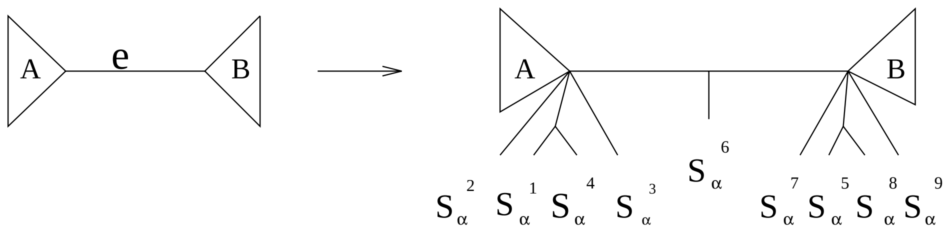

FIG. 3.1. *Adding the* 9 *new species associated with* α.

2-load problem.

For the other direction of the proof, let T be a solution to instance I' of the load problem. We first observe that in any solution to an instance of the 2-load problem involving 3-state monomorphic characters in the input, every character α has associated with it an edge, which splits $\alpha^{-1}(0)$ from $\alpha^{-1}(1)$, or $\alpha^{-1}(0)$ from $\alpha^{-1}(2)$, or $\alpha^{-1}(1)$ from $\alpha^{-1}(2)$. Observe that in I', for each $\alpha \in C$, the only partition possible is $\alpha^{-1}(0)$ from $\alpha^{-1}(1)$. This follows as a result of the constraints imposed by α^1 and α^2. Thus, to get a solution to the PBCP for instance I, we restrict T to the original set of species S and characters C, and then for each character in C we replace the 2's that appear on the 0's side of the partition by 0's and the 2's that appear on the 1's side of the partition by 1's.

This completes the proof.

Part (vii): If k is fixed, then the 2-load perfect phylogeny problem can be solved in polynomial time using the algorithms from section 4. $\square$

This theorem shows that *any* polynomial time algorithm *requires* both k and l bounded (under $P \neq NP$ assumption).

4. Algorithms for perfect phylogenies from polymorphic characters.

In this section we present the two algorithms for inferring perfect phylogenies from polymorphic data when we know the load bound. Although the algorithms we will present assume a universal load bound, these algorithms can be easily modified to allow individual load bounds for each character and will achieve comparable running times. For the sake of clarity, we will present these algorithms as though the load bound is the same for each character; the run times of these algorithms when implemented to handle variable constraints are given within their respective sections.

4.1. A combinatorial algorithm for fixed k and l.

The algorithm we present is an extension and simplification of the algorithm of Agarwala and Fernández-Baca [2]. For the remainder of this section the term *perfect phylogeny* refers to an l-load perfect phylogeny.

Because each character has only r states and each node can choose at most l of these in an l-load perfect phylogeny, the number of possible labels for nodes in the tree is $O(r^{lk})$. Let us call this set S^* and note that $S \subseteq S^*$ (since otherwise some node in S has load greater than l). In contrast to the algorithm in [2], we do not require that the internal nodes be labeled distinctly from the species in S, and instead we will permit species in S to be internal nodes because we can transform any perfect phylogeny in which some species in S label internal nodes into a perfect phylogeny in which all species label leaves by attaching a leaf for s to the internal node labeled by s.

We need some preliminary definitions and facts.

DEFINITION 4.1. $\sum_{\alpha \in C} |\alpha(x) \triangle \alpha(y)|$ *is the* extended Hamming distance *of* $e = (x, y)$*, where* $\triangle$ *denotes the symmetric difference. However, we will call this the* Hamming distance*, understanding this to refer to the extended Hamming distance.*

We note that if a perfect phylogeny exists for S, then one exists where the Hamming distance on any edge is exactly one. We will seek a perfect phylogeny with this property. Working with such perfect phylogenies allows us to quickly solve subproblems because it limits the number of ways a (maximally refined) perfect phylogeny can be constructed.

DEFINITION 4.2 (see [23]). *Given* $x \in S^*$*, the equivalence relation* E_x *is the transitive closure of the following relation* E'_x *on* $S - \{x\}$*:* aE'_xb *if there exists character* α *such that* $(\alpha(a) \cap \alpha(b)) - \alpha(x) \neq \emptyset$*. We denote this set of equivalence classes by* $(S - \{x\})/x$*.*

An observation that follows immediately from this definition is that if T is a perfect phylogeny on S and x an internal node in T, then two species in S which are in the same equivalence class of $(S - \{x\})/x$ must be in the same component of $T - \{x\}$. We also make the following observation.

LEMMA 4.3. *Let* T *be a perfect phylogeny on* S *and* x *be an internal node in* T*. Consider* T *as rooted at* x*. Let* G *be an equivalence class of* $(S - \{x\})/x$ *and let* $y = lca_T(G)$*. Let* v *be a node of* T *on the path from* x *and* y *(thus* $v = x$ *or* $v = y$ *is also possible). Then there exist* $H_1, \ldots, H_t$ *in* $(S - \{v\})/v$ *such that* $H_1 \cup \cdots \cup H_t = G$*.*

Proof. Let T be a perfect phylogeny for S, and x, G, y, and v are as stated. Let $H_1, \ldots, H_t$ be equivalence classes of $(S - \{v\})/v$ containing species from G. Clearly, to prove the lemma it will suffice to prove that all H_i are either disjoint from G or contained in G.

Suppose, by way of contradiction, that for some $i, 1 \leq i \leq t$, H_i contains species from G and from $S - G$. We will show that this implies the existence of a character $\alpha \in C$ and a state a of α such that $a \notin \alpha(v)$, yet $a \in \alpha(x) \cap \alpha(z)$ for some leaf z below v; such a character is not convex on T, contradicting our assumption that T is a perfect phylogeny. This will show that all equivalence classes H_i are either disjoint from or contained in G and will establish our claim.

Since H_i contains species in G and in $S - G$, and is an equivalence class of $(S - \{v\})/v$, there are species $z_1 \in H_i \cap G$ and $z_2 \in H_i - G$ and character α such that $(\alpha(z_1) \cap \alpha(z_2)) - \alpha(v) \neq \emptyset$ (this follows from $(S - \{v\})/v$ being the transitive closure of E_v). Let $a \in \alpha(z_1) \cap \alpha(z_2) - \alpha(v)$. Since z_1 and z_2 are in different equivalence classes of $(S - \{x\})/x$, $a \in \alpha(x)$. Now let $z = lca_T(z_1, z_2)$. This node z is in the subtree rooted at v and satisfies $a \in \alpha(z)$ because T is a perfect phylogeny and z is on the path between z_1 and z_2. This is the character α and state a we stated we would demonstrate, proving our claim. ∎

We now present a dynamic programming algorithm for constructing perfect phylogenies from polymorphic data. We define the *search graph* $SG = (V, E)$ as follows. Each vertex in V is associated with a pair $[G, x]$, where $G = S$ or $G \in (S - \{x\})/x$, and represents the question, Does $G \cup \{x\}$ have a perfect phylogeny? The edges of the search graph are of the form $([G, x][S, x])$, and all pairs of the form $([G_1, x_1], [G_2, x_2])$ where $G_1 \subseteq G_2$ and x_1 and x_2 satisfy $\sum_{\alpha \in C} |\alpha(x_1) \triangle \alpha(x_2)| = 1$. There are $O(r^{lk})$ nodes of type $[S, x]$, and $O(nr^{lk})$ of type $[G, x]$ (because there are at most n equivalence classes in $(S - \{x\})/x$). Also, there are $O(nr^{lk})$ edges of type $([G, x][S, x])$ and $O(nlkr^{lk+1})$ of type $([G_1, x_1], [G_2, x_2])$, since the outdegree of every node is at most lkr.

DEFINITION 4.4. *Given a node* $[G, x]$*, a set of nodes* $[H_1, y], [H_2, y], \ldots, [H_p, y]$

such that (a) Hamming(x,y)= 1 *and (b)* $\cup_i H_i = G$ *is called a* bundle.

There can be multiple bundles going into $[G, x]$, corresponding to the maximally refined perfect phylogenies of $G \cup \{x\}$. If $[H_1, y], [H_2, y], \ldots, [H_p, y]$ is a bundle for $[G, x]$, and all the subproblems have perfect phylogenies, then there is a perfect phylogeny for $G \cup \{x\}$ with subtrees T_i labeled by H_i. We can also have a bundle of just one edge (i.e., ([G,y],[G,x])); such a bundle indicates the existence of a perfect phylogeny T for $G \cup \{y\}$ in which the node corresponding to y has only one child. This is necessary if we require all edges to have Hamming distance 1.

ALGORITHM PHYLOGENY(S). *First create the search graph* G_S*. For each node* $[G, x]$*, determine its bundles. Note that some incoming edges* $([G_1, x_1], [G, x])$ *may not correspond to any bundle because* $(S - \{x_1\})/x_1$ *does not have the proper form (i.e.,* G *may not be the union of a subset of the components of* $(S - \{x_1\})/x_1$*). Remove such edges. Now for each bundle compute the size of the bundle (number of edges)* b_i *and set a counter* $\mathbf{count}_i$ *equal to* b_i*. Each node* $[G_1, x_1]$ *that is a predecessor of node* $[G_2, x_2]$ *is given a pointer to the counter for its bundle. We initialize a queue of "true" nodes as empty.*

We locate each node $[G, x]$ *with* $|G| = 1$*, mark it as true, and place it in the queue. We then pull a node* $[G_1, x_1]$ *out of the queue and process it as follows. For each edge in the search graph* $([G_1, x_1], [G_2, x_2])$ *we decrement the counter for the appropriate bundle into* $[G_2, x_2]$*. If the counter is decremented to* 0*, then all edges of the bundle have been set to true and node* $[G_2, x_2]$ *is added to the queue. When we have processed all edges out of node* $[G_1, x_1]$ *we choose another node from the queue and continue. If we ever try to enqueue a node of the form* $[S, x]$*, then the instance has a perfect phylogeny. If the queue is emptied without ever labeling a node of this form as true, then there is no perfect phylogeny.*

As we enqueue true nodes, we build a topology for a perfect phylogeny for the subproblem represented by that node, ultimately building one for the whole problem if it exists. We denote the topology of the perfect phylogeny for $[G, x]$ *by* $T[G, x]$*. We enqueue* $[G, x]$ *when a bundle* $[H_1, y], [H_2, y], \ldots, [H_p, y]$ *is found such that each* $[H_i, y]$ *has been determined to be true, and hence a topology* $T[H_i, y]$ *for each subproblem has already been determined. We create a new node* v*. If* $x \in S$*, then we label the node* x*. Otherwise it remains unlabeled for now. A method for labeling these nodes is given in the proof of Theorem* 4.6*. We take each of the trees* $T[H_1, y], T[H_2, y], \ldots, T[H_p, y]$*, merge the roots into a single node, and make this node a child of node* v*. Once* $[G, x]$ *has been enqueued, we construct the tree* $T[G, x]$ *and we do not consider any more edges entering* $[G, x]$*. Thus we compute only one topology per true subproblem.*

LEMMA 4.5. *If there exists a perfect phylogeny for* $S \cup \{x\}$*, then the algorithm PHYLOGENY(S) assigns true to* $[G, x]$*, for each* $G \in (S - \{x\})/x$*.*

Proof. The proof is by induction on $|G|$. The base case is trivial. Suppose that the claim holds for all nodes $[G', x']$ where $|G'| < k$. Consider now the node $[G, x]$ where $|G| = k$. Let T be a perfect phylogeny for $S \cup \{x\}$. Assume that T is a perfect phylogeny where the Hamming distance between every pair of adjacent nodes in the tree is one. Consider T as rooted at x, and let $y = lca_T(G)$. From Lemma 4.3, for each node v in the path between x and y, there is a set of equivalence classes of $(S - \{v\})/v$ whose union equals G. Because $y = lca_T(G)$, y is the first node below x for which there are classes $H_1, H_2, \ldots, H_p$, $p > 1$, of $(S - \{y\})/y$ such that $\cup H_i = G$. For all i, $H_i \cup \{y\}$ has a perfect phylogeny. Since $|H_i| < |G|$ it follows that the algorithm has already determined (correctly) that $[H_i, y]$ is true for each $i = 1, 2, \ldots, p$.

We now need to show that for every node z on the path from y to x, $[G, z]$ is set to true. This will prove that $[G, x]$ is true.

Consider the node $z = parent(y)$. We have two cases to consider, depending upon whether z and x are distinct. We consider the first case, where $z = x$. The edges $([H_j, y], [G, x]), j = 1, 2, \ldots, p$ constitute a bundle for $[G, x] = [G, z]$ so that $[G, x] = [G, z]$ is also set to true. We now consider the second case, where $z \neq x$. In this case, G is an equivalence class of $(S - \{z\})/z$, so that $[G, z]$ is also a subproblem, and $([G, y], [G, z])$ is an edge in the search graph. Since $[G, y]$ is set to true (by the above analysis) the algorithm also sets $[G, w]$ to true for all w such that $[G, w]$ is a vertex in the search graph. Thus, for each node w on the path from y to x, $[G, w]$ is set to true; setting $w = x$ yields the result. □

THEOREM 4.6. *The algorithm PHYLOGENY(S) runs in time $O(r^{lk+1}lkn)$ and returns "yes" iff S has a perfect phylogeny.*

Proof. If S has a perfect phylogeny, then there is some species x that can be an internal node of the tree. By Lemma 4.5 the algorithm will return "yes." Suppose now that the algorithm returns the answer yes, and suppose the leaf-labeled tree produced is D. We now show that the internal nodes of this tree can be labeled so as to create a perfect phylogeny T with load l. Given a character α and an unlabeled node v, we assign $\alpha(v)$ to be the states i such that for some pair of leaves x and y in different subtrees of $D - \{v\}$, $i \in \alpha(x) \cap \alpha(y)$. This clearly creates a perfect phylogeny, and we now need to show that the load is bounded by l. Suppose for some node v the load exceeds l, so that (without loss of generality) for each of the first $l+1$ states, $1, 2, \ldots, l+1$, of α, there are at least two subtrees of v with that state. The node v represents a node $[G, y]$ in the search graph, and since it appears in D there is a bundle $[G_1, z], [G_2, z], \ldots, [G_t, z]$ such that all nodes in the bundle are set to true and z and y have distance one. By the construction of D, the subtrees of v have leaf sets $G_1, G_2, \ldots, G_t, S - G$, where $G_i \in (S - \{z\})/z$ for $i = 1, 2, \ldots, t$ (from which it also follows that $S - G$ is the union of the remaining equivalence classes of $(S - \{z\})/z)$. Also by construction, z had load at most l, so that z is labeled with at most l α-states. Thus at least one of the states $1, 2, 3, \ldots, l+1$ is missing from z; without loss of generality let it be $l+1$. It is easy to see that if G_i and G_j (for $i \neq j$) both have leaves with state $l+1$, then they would not be separate equivalence classes in $(S - \{z\})/z$, and similarly if some G_i and $S - G$ both have leaves with state $l+1$. Hence, this labeling has load bounded by l.

The search graph can be constructed in time $O(nlkr^{lk+1})$ by noting that there are $O(r^{kl})$ nodes in the graph, and for each node the maximum number of incoming edges is $O(nrlk)$ and the maximum number of outgoing edges is $O(rlk)$. The rest of the algorithm can be made to run in $(O(nlkr^{lk+1}))$ time, which is linear in the size of the graph. This can be done by sorting the nodes $[G, x]$ according to the size of G and then processing the nodes $[G, x]$ in terms of increasing $|G|$ values. □

Comment. When individual load bounds l_α are given, the algorithm can be modified to run in $O(r^{L+1}Ln)$, where $L = \sum_{\alpha \in C} l_\alpha$.

4.2. A graph-theoretic algorithm for fixed *k* and *l*. In this section we give a graph-theoretic algorithm for the l-load perfect phylogeny problem. The algorithm we present is based upon a characterization of intersection graphs derived from l-load perfect phylogenies as a particular kind of vertex-colored triangulated (i.e., chordal) graphs. On the basis of this characterization we will derive an efficient algorithm for the l-load perfect phylogeny problem when we can fix both l and k.

4.2.1. Preliminary definitions. Let $G = (V, E)$ be a graph. A *vertex coloring* of G is a function color: $V \to Z$. We do not require that color be a *proper* coloring (a coloring function is proper iff $\forall(v,u) \in E$, color$(v) \neq$ color(u)).

The *neighbor set* $\Gamma(v)$ of a vertex v is the set of all vertices in the graph adjacent to v. A vertex v is *simplicial* if $\Gamma(v)$ is a clique.

Given a graph $G = (V, E)$ and a vertex coloring $c : V \to Z$, a *monochromatic clique* in G is a clique with vertex set $V_0 \subset V$ such that color(v)=color(w) for all $v, w \in V_0$. A graph $G = (V, E)$ is *triangulated* if it has no induced cycles of size four or greater. Given a vertex-colored graph $G = (V, E)$, we say that G is *l-triangulated* if G is both triangulated and has no monochromatic cliques of size greater than l. We say that G has an *l-triangulation* $G' = (V, E')$ if $E \subseteq E'$ and G' is l-triangulated.

Let $I = (S, C)$ be an input to the phylogeny problem. For $\alpha \in C$ we define $\alpha_i = \{s \in S : i \in \alpha(s)\}$. The *partition intersection graph* of I is the vertex-colored graph ($G_I = (V, E)$, color) defined by $V = \{\alpha_i : \alpha \in C\}, E = \{(\alpha_i, \beta_j) : \alpha_i \cap \beta_j \neq \emptyset$, where $i \neq j$ if $\alpha = \beta\}$ and for $\alpha \neq \beta$, color$(\alpha_i) =$ color$(\alpha_j) \neq$ color(β_s). Note that because the input I can have load greater than one, the coloring function color may not be proper.

The main results leading to the algorithm can be paraphrased as follows:

- Let I be an input to the l-load perfect phylogeny problem. Then there is an l-load perfect phylogeny for I iff the partition intersection graph G_I has an l-triangulation.
- Given a graph G which is vertex-colored using k colors (not necessarily properly colored) we can determine in time polynomial in fixed k and l whether G has an l-triangulation and construct the l-triangulation when it does.
- Given an l-triangulation G' of G_I we can construct an l-load perfect phylogeny in polynomial time.

As a consequence, we will provide an algorithm for determining if an l-load perfect phylogeny exists for k polymorphic characters defined on n species in $O((rk^3l^2)^{kl+1} + n(kl)^2)$ time.

4.2.2. Characterization of l-triangulated graphs. There is a well-known characterization of triangulated graphs as intersection graphs of subtrees of a tree [7]. In this section we will look at an extension of this particular characterization for l-triangulated graphs.

The following lemma will be useful in the proof of the characterization and also in later theorems. It describes the number of simplicial vertices in a triangulated graph. The proof is simple and is discussed in [17].

LEMMA 4.7. *Let G be a triangulated graph which is not a clique. Then G has at least two nonadjacent simplicial vertices.*

We can make a similar statement about l-triangulated graphs since these graphs are, by definition, also triangulated.

We now present the characterization of l-triangulated graphs.

THEOREM 4.8. *Let $G = (V(G), E(G))$ be a vertex-colored graph. Then G is l-triangulated iff $\exists$ a tree $T = (V(T), E(T))$ together with functions $\varphi : V(G) \to \{$subtrees of $T\}$ and $\phi : V(T) \overset{\text{bijection}}{\to} \{$maximal cliques of $G\}$ such that*

1. *$(v, w) \in E(G)$ iff $\varphi(v) \cap \varphi(w) \neq \emptyset$,*
2. *$\varphi(v) = \{u \in V(T) : v \in \phi(u)\}$,*
3. *$\forall v \in V(T), \phi(v)$ has at most l vertices of the same color.*

Proof. Suppose a tree T exists together with the functions φ and ϕ. We will first show that this, together with conditions 1 and 2, implies that G is triangulated. Let $\Lambda = a_1a_2 \cdots a_ia_1, i \geq 4$, be a simple cycle in G. We will show that Λ has a chord.

Working in *mod i* arithmetic, it can be seen that $\varphi(a_j) \cap \varphi(a_{j+1}) \neq \emptyset\ \forall 1 \leq j \leq i$. Let $\varphi(a_j) = T_j$. Thus $V(T_j) \cap V(T_{j+1}) \neq \emptyset\ \forall 1 \leq j \leq i$. It can be seen that $\exists j$ such that $V(T_{j-1}) \cap V(T_j) \cap V(T_{j+1}) \neq \emptyset$, as otherwise T will contain a cycle. Let $u \in V(T_{j-1}) \cap V(T_j) \cap V(T_{j+1})$. Thus $\phi(u)$ contains a_{j-1}, a_j and a_{j+1} and so $(a_{j-1}, a_{j+1}) \in E(G)$. Hence Λ contains a chord and so G is triangulated.

From condition 3, G can have maximum monochromatic clique size l. Thus G is l-triangulated.

We now prove the converse by induction on $|V(G)|$. Suppose the statement is true for all graphs having less than n vertices. Let G be a connected graph with n vertices and suppose G is l-triangulated. Now if G is complete, then T is a single vertex and the result is trivial. Assume that G is connected but not complete. Since G is l-triangulated, from Lemma 4.7, it contains a simplicial vertex v. Let $A = \{v\} \cup \Gamma(v)$. Note that A is a maximal clique of G and contains monochromatic cliques of size at most l. Let $B = \{u \in A : \Gamma(u) \subset A\}$ and let $X = A - B$. Note that B, X, and $V(G) - A$ are nonempty since G is connected but not complete. Observe that $G' = G|(V(G) - B)$ is l-triangulated and has fewer vertices than G. Applying the induction hypothesis, let T' be the tree and φ' and ϕ' be the functions satisfying the conditions of the theorem for G'. There are two cases to handle here. Case 1 is when X is a maximal clique in G' and Case 2 is when it is not (note that X is a clique in both G and G'):

Case 1. We can obtain T, ϕ, and φ from T', ϕ', and φ' as follows: Identify that vertex $v' \in V(T')$ such that $\phi'(v') = X$. Define $\phi(w) = \phi'(w)\ \forall w \neq v'$ and $\phi(v') = A$. Define $\varphi(y) = \varphi'(y)\ \forall y \notin B$ and $\varphi(y) = \{v'\}\ \forall y \in B$.

Case 2. Identify that vertex $v' \in V(T')$ such that $\phi'(v') \supset X$. Create a new vertex v and connect it to v'. Define $\phi(w) = \phi'(w)\ \forall w \neq v$ and $\phi(v) = A$. Define $\varphi(y) = \{v\} \cup \varphi'(y)\ \forall y \in X$ and $\varphi(y) = \{v\}\ \forall y \in B$.

Note that in both cases A contains at most l vertices from the same color class and that T, ϕ, and φ satisfy the stated conditions. □

THEOREM 4.9. *Given an instance I of the l-load perfect phylogeny problem, let G_I be the corresponding partition intersection graph. Then I has a solution iff G_I has an l-triangulation.*

Proof. Let T be the solution to the instance I of the l-load perfect phylogeny problem. By Theorem 4.8 there is a graph G which is l-triangulated and is related to T as mentioned in that theorem. It can be seen that G is a supergraph of G_I. Thus G_I can be l-triangulated.

Suppose G_I can be l-triangulated. Let G be the l-triangulation of G_I. Then there is a tree T associated with G satisfying the conditions of Theorem 4.8. It can be seen that in T all the character states are convex and each vertex in T has a label set containing at most l vertices of the same color. Thus T is a solution to the instance I of the l-load perfect phylogeny problem. □

4.2.3. *l*-triangulating a vertex-colored graph. In this section we turn to the problem of l-triangulating a vertex-colored graph. The solution to this problem makes use of several properties of triangulated graphs and also of a particular class of triangulated graphs called k-trees.

Further definitions. Triangulated graphs admit orderings $v_1, v_2, \ldots, v_n$ on the vertex set such that for each i, $N_i = \Gamma(v_i) \cap \{v_{i+1}, v_{i+2}, \ldots, v_n\}$ is a clique [17]. These orderings are called *perfect elimination schemes.*

Consider a graph $G = (V, E)$ with $|V| = n \geq k$ that contains at least one k-clique. Such a graph G is a *k-tree* if the nodes of G can be ordered $v_1, v_2, \ldots, v_n$, whereby $\Gamma_G(v_i) \cap \{v_{i+1}, v_{i+2}, \ldots, v_n\}$ is a k-clique for all i with $1 \leq i \leq n - k$. A k-tree also has the following recursive definition: The complete graph on k vertices is a k-tree; if $G = (V, E)$ is a k-tree, and $S \subset V$ is a k-clique, then the graph formed by adding a new vertex v and attaching it to each vertex in S is also a k-tree. Each k-tree may be constructed using several different sequences of these operations. The initial set $S \subset V$ is called a *basis* for the k-tree.

For a graph $G = (V, E)$ and vertex-separator $S \subset V$ with C a component of $G - S$, we define C ∪ cl(S) to be the graph formed by adding to the subgraph of G induced by $C \cup S$ sufficient edges to make S into a clique. Let $G = (V, E)$ be a k-colored graph. We say that G is a *(k,l)-partition intersection graph* if (a) the maximum monochromatic clique size is l, and (b) G is edge covered by kl-cliques. Note that the maximum clique size in a (k, l)-partition intersection graph is kl.

The algorithm we present for l-triangulating a vertex-colored graph is based on dynamic programming. We will need the following lemmas in our algorithm.

LEMMA 4.10. *Let $G = (V, E)$ be a connected graph which is vertex-colored (not necessarily properly colored) using k colors with $|V| \geq kl$, where l is the maximum monochromatic clique size in G. Let the maximum clique size in G be kl. Then G has an l-triangulation iff it has an l-triangulation that is a $(kl - 1)$-tree.*

Proof. Clearly, if G has an l-triangulation that is a $(kl - 1)$-tree, then G has an l-triangulation.

Now suppose that G has an l-triangulation. We will use induction to show that G has an l-triangulation that is a $(kl - 1)$-tree. Base case is when $|V(G)| = kl$, i.e., G is a clique. This is already a $(kl - 1)$-tree and it is l-triangulated.

Suppose the statement is true for all graphs with less than n vertices ($n > kl$) and containing maximum monochromatic clique size l and maximum clique size kl.

Let G be a graph with $|V(G)| = n$. Since G can be l-triangulated, let G' be the l-triangulation of G. From Lemma 4.7 there are at least two nonadjacent simplicial vertices in G'. Pick that simplicial vertex $v \in V(G')$ such that $G' - \{v\}$ still has maximum clique size kl. Let $\Gamma_{G'}(v)$ denote the neighbor set of v in G'. Observe that $G' - \{v\}$ is an l-triangulation of $G - \{v\}$. Thus, by the induction hypothesis, $G' - \{v\}$ can be l-triangulated into a $(kl-1)$-tree. Let G'' be the $(kl-1)$-tree. Let σ be a perfect elimination scheme for G''. Look at x which is the first vertex in $\Gamma_{G'}(v)$ to appear in σ. There are two cases to handle here. Case 1 is when x is within the sequence of last kl vertices appearing in σ. In this case make v adjacent to all vertices in the last kl positions of σ, except with some vertex $u \notin \Gamma_{G'}(v)$ and $\text{color}(u) = \text{color}(v)$. The resulting graph is an l-triangulated $(kl - 1)$-tree. Case 2 is when x is not within the sequence of the last kl vertices appearing in σ. Let A be the set of vertices following x which are neighbors of x. Clearly, $(\Gamma_{G'}(v) - x) \subset A$. Make v adjacent to all vertices in $\Gamma_{G'}(v)$ and also to all except the one vertex u appearing in $A - \Gamma_{G'}(v)$ such that $\text{color}(v) = \text{color}(u)$. The resulting graph is an l-triangulated $(kl - 1)$-tree.

Thus we have that if G has an l-triangulation then it has an l-triangulation which is a $(kl - 1)$-tree. ▯

LEMMA 4.11. *Let G be a (k, l)-partition intersection graph. Then G can be l-triangulated iff there exists a set $K \subseteq V$ of size $(kl - 1)$ which is a separator for G such that for all components C of $G - K$, $C \cup cl(K)$ can be l-triangulated.*

Proof. In Lemma 4.10 it was shown that G has an l-triangulation iff it has an l-triangulation G' which is a $(kl-1)$-tree. If such a G' exists, then G' has a separator of size $kl - 1$ which is a clique by [31]. The converse is straightforward. ▯

We are thus motivated to make the following definition.

DEFINITION 4.12. *Let $G = (V, E)$ be a vertex-colored graph with k colors and with* *maximum monochromatic clique size l. A potential basis for G', the l-triangulation of G, is a subset $V_0 \subseteq V$ such that* (a) $|V_0| = kl - 1$ *and* (b) V_0 *is a vertex separator for G. If $V_0 \subset V$ satisfies both these conditions then we say that V_0 is a* potential basis *for G, and call V_0 a pb-set.*

Our dynamic programming algorithm will solve the l-load problem when the input is a (k, l)-partition intersection graph. Because our input graphs may not be (k, l)-partition intersection graphs, we need the following result.

LEMMA 4.13. *Let $G = (V, E)$ be vertex-colored with a coloring function color (using k colors) and assume that the maximum monochromatic clique size is l. Then there exists a (k, l)-partition intersection graph $G' = (V', E')$ such that the following is true:*

- *For every pb-set $S \subseteq V'$ containing $(k - 1)$ colors and every component C of $G' - S$, $C \cup S$ has all k colors present.*
- *G can be l-triangulated iff G' can be l-triangulated.*
- *The number of vertices in G' is $|V| + |E|(kl - 2)$.*

Proof. For each edge $e = (v, w)$ in E, add $kl - 2$ vertices and sufficient edges so that the kl vertices together form a clique with k color classes of size l. Call the resultant graph G'.

Clearly, $|V(G')| = |V| + |E|(kl - 2)$. Also, since G' is now a (k, l)-partition intersection graph, every edge in G' is part of some kl-clique. Thus, for every *pb*-set S of G' containing $(k - 1)$ colors and for every component C of $G' - S$, $C \cup S$ will have all k colors present.

Finally, suppose G' has an l-triangulation G'_1. Then the subgraph of G'_1 induced by the vertex set $V(G)$ is also l-triangulated [17]. Thus G can be l-triangulated. For the other direction, suppose G has an l-triangulation G_1. Identify the edges in G_1 which were present in G and make each of the edges a part of a new kl-clique. This defines a graph G_1^* which can be verified to be a supergraph of G^* and is also l-triangulated. Thus G can be l-triangulated iff G' can be l-triangulated. □

We now have the basis for an algorithm for computing l-triangulations of vertex-colored graphs:

ALGORITHM B (l-triangulating k-colored graphs).

Step 1. Embed G in a (k, l)-partition intersection graph, G'.

Step 2. Compute all *pb*-sets $V_0 \subseteq V(G')$ and all components C of $G' - V_0$. The subproblems $C \cup cl(V_0)$ are then bucket sorted by size.

Step 3. Use dynamic programming to determine the answers for each subproblem in turn.

Step 4. If there is a *pb*-set V_0 such that for all components C of $G' - V_0$, $C \cup cl(V_0)$ is has an l-triangulation, then return (Yes), else return (No).

It is clear that we need to indicate how we implement Step 3.

Solving subproblems using dynamic programming. We have thus reduced the problem of determining whether the graph G can be l-triangulated to looking at graphs of the form $C \cup cl(S)$, where S is a *pb*-set, C is one of the components of $G' - S$, and we presume G' to be a (k, l)-partition intersection graph.

Rose, Tarjan, and Lueker [32] proved the following lemma about triangulated graphs.

LEMMA 4.14. *Let G be a triangulated graph, σ a perfect elimination scheme for G, and a, b vertices in G. If there is a path P from a to b in G such that every vertex in $P - \{a, b\}$ comes before a and b in the ordering σ, then (a, b) is an edge in G.*

We also observe the following lemma about $(kl - 1)$-trees.

LEMMA 4.15. *If G can be l-triangulated into a $(kl-1)$-tree G', then any $(kl-1)$-clique in G' can be a basis for G'.*

We now prove the following theorem. The proof for this theorem is along the same lines as the proof for Theorem 1 appearing in [27].

THEOREM 4.16. *Let $G = (V, E)$ be a (k, l)-partition intersection graph containing at least $kl+1$ vertices, S_0 pb-set of G, and C a component of $G - S_0$. Then $C \cup cl(S_0)$ can be l-triangulated iff there exists a family $\mathcal{F}$ of l-triangulated $(kl-1)$-trees and a vertex $v \in C$ such that*

1. *For every $F \in \mathcal{F}$ there exists a vertex $x \in S_0$ such that $V(F) = C' \cup cl(S)$, where $S = S_0 \cup \{v\} - \{x\}$ and C' is a component of both $G - S$ and $C \cup cl(S_0) - S$.*
2. *$|V(F)| < |V(C \cup cl(S_0))|$, for every $F \in \mathcal{F}$.*
3. *Every two graphs in $\mathcal{F}$ intersect only on $S_0 \cup \{v\}$.*
4. *$G|(C \cup S_0)$ is contained in $\bigcup_{F \in \mathcal{F}} F$.*

Proof. It is easy to see that if these conditions hold we can combine the l-triangulated $(kl-1)$-trees in $\mathcal{F}$ into one l-triangulated $(kl-1)$-tree covering $C \cup cl(S_0)$ since they intersect only on $S_0 \cup \{v\}$.

For the converse, suppose that $G_1 = C \cup cl(S_0)$ can be l-triangulated. Let G' be an l-triangulation of $C \cup cl(S_0)$. By Lemma 4.15 the $(kl-1)$-clique S_0 can be a basis for G'. Let v be the vertex added to the basis S_0 in the construction of G' and let $S' = S_0 \cup \{v\}$. Thus there is a perfect elimination scheme for G' in which the vertices of S' occur at the end. We will show that we can decompose $C \cup cl(S_0)$ into the union of l-triangulated $(kl-1)$-trees, T_K, each of which is based upon a $(kl-1)$-clique subset $K \subset S'$. We will then show that each such K forming the basis of one of these l-triangulated $(kl-1)$-trees will be a separator for G, so that $T_K - K$ has components $C_1, \ldots, C_r$. We can then in turn write each T_K as the union of possibly smaller $(kl-1)$-trees, $T_K^i = T_K|(C_i \cup K)$. These l-triangulated $(kl-1)$-trees are the ones of interest.

G' is built by adding vertices, one at a time, and making each new vertex adjacent to every vertex in some $(kl-1)$-clique. We will define G_i to be the subgraph of G' induced by the vertex set $\{v_i, v_{i+1}, \ldots, v_{|V|}\}$. Thus $G_{|V|-kl+2}$ is a $(kl-1)$-clique, and to form G_i we make vertex v_i adjacent to every vertex in some $(kl-1)$-clique in G_{i+1}. We will show that we can assign to each added vertex v_i (with $i < (|V| - kl + 1)$) a label $L(v_i)$ the *name* of a $(kl-1)$-clique $K \subset S'$, so that for each $K \subset S'$ the subgraph $T_K = G|V_K$, where $V_K = \{v : L(v) = K \text{ or } v \in K\}$, is an l-triangulated $(kl-1)$-tree. We will also show that every edge e in $G|(C - \{v\})$ is in one of these $(kl-1)$-trees and that the $(kl-1)$-cliques K forming the basis of the $(kl-1)$-trees T_K are separators of G. We will also need to show that the component C' of $C \cup cl(S_0) - L(v)$ containing v is a component of $G - L(v)$. This will prove our assertions.

We first need to show how we assign vertices to $(kl-1)$-clique subsets of S'. Let L be the assignment function we wish to define for every vertex not in S'. Suppose we have constructed the graph G_{i+1} and are now adding v_i to the graph and making it adjacent to every vertex in some $(kl-1)$-clique, R. If $R \subset S'$, then we set $L(v_i) = R$. Otherwise, the vertices in R will consist of (perhaps) some unlabeled vertices (these will be in S') and at least one labeled vertex. If all of the labels in R agree, then this is the label that we will assign to v_i. On the other hand, suppose for our construction that when we make v_i adjacent to every vertex in the $(kl-1)$-clique R not all the labels are the same and that this is the first vertex in this construction for which this happens. In this case, for some vertices v_j and v_k in R, $L(v_j) = X$

and $L(v_k) = Y$, for distinct subsets $X, Y \subset S'$. Without loss of generality we can assume that $i < j < k$. In constructing G_j we made v_j adjacent to every vertex in some $(kl-1)$-clique $C \subset G_{j+1}$. Note that $v_k \in C$ since v_j and v_k are adjacent and $k > j$. Since we were able to set $L(v_j) = X$ unambiguously, this means that either every vertex in C was unlabeled, and thus $X = C$, or that the labeled vertices were all labeled X. Since we have assumed v_k was labeled, we can infer that $L(v_k) = X$ and hence $X = Y$. Thus this assignment of vertices to $(kl-1)$-clique bases is well defined, and each label denotes a subset K of S'. It is easy to see that the subgraph $T_K = G'|V_K$ (for $V_K = \{v : L(v) = K \text{ or } v \in K\}$) is an l-triangulated $(kl-1)$-tree and that T_K is based upon the set K.

By our construction of the labeling function, it is also clear that no edge in G has different labels at its endpoints, so that every edge in $G|(C - \{v\})$ is in exactly one l-triangulated $(kl-1)$-tree, T_K.

We now show that each $(kl-1)$-clique $K \subset S'$ forming the basis of an l-triangulated $(kl-1)$-tree in $\mathcal{F}$ is a separator for $C \cup cl(S_0)$ and for G. We first show that K is a separator for $C \cup cl(S_0)$. Suppose to the contrary, so that for some set $K \subset S$ forming the basis of an l-triangulated $(kl-1)$-tree T_K, $C \cup cl(S_0) - K$ is connected. Let $K = S - \{x\}$. We will show that there is no path from x to any vertex in $C \cup cl(S_0) - K$. Let σ' be a perfect elimination scheme for $T_K \cup \{x\}$. Clearly, we can assume that x is the last vertex in σ' to occur before the vertices of K. Let a be the vertex immediately preceding x. If there is a path from x to a in $C \cup cl(S) - K$, then the edge (a, x) is in G by Lemma 4.14. But then $S \cup \{a\}$ is a $(kl+1)$-clique, contradicting that G has a supergraph which is a $(kl-1)$-tree. The proof can be modified to show that K is a separator for G as well. Hence the $(kl-1)$-trees T^i_K each contain fewer vertices than G.

We now complete our proof by showing that the components of $C \cup cl(S_0) - K$ are also components of $G - K$, where K is the basis of a $(kl-1)$-tree $F \in \mathcal{F}$. Recall that by our construction each such basis K is a set $L(a)$ for some $a \in V(F) - K$. So let C' be a component of $C \cup cl(S_0) - L(a)$, for some $a \in C$. It is easy to see that $L(a) = S_0 \cup \{v\} - \{x\}$ is a separator for $C \cup cl(S_0)$ and that every component X of $C \cup cl(S_0) - L(a)$, such that $x \notin X$, is also a component of $G - L(a)$. Thus we will show that $x \notin C'$, so that C' is a component of $G - L(a)$.

Suppose $x \in C'$. Then x is adjacent to at least one vertex z of $C' - \{x\}$. When we labeled the vertex z we labeled it with $L(a)$ implying that $x \in L(a)$, and yet, by our construction, $x \notin L(a)$. Hence the component C' of $C \cup cl(S_0) - L(a)$ containing a is a component of $G - L(a)$. This completes our proof. □

We can now state the following theorem.

THEOREM 4.17. *Let $G = (V, E)$ be a (k, l)-partition intersection graph with $|V| \geq kl + 1$. Let S_0 be a pb-set and let C be a component of $G - S_0$. Then $C \cup cl(S_0)$ can be l-triangulated iff there exists some vertex v in C and a family of pb-sets $\mathcal{M}$ such that the following is true:*

1. *For each $M \in \mathcal{M}$, $M \subset S_0 \cup \{v\}$ and M is a separator for $C \cup cl(S_0)$ and for G.*
2. *For each vertex $x \in S_0$ there is an $M_x \in \mathcal{M}$ and a component C_x of $G - M_x$ and of $C \cup cl(S_0) - M_x$ such that $|C_x| < |C|$ and $C_x \cup cl(M_x)$ can be l-triangulated.*
3. *Every edge in C is in exactly one C_x given above.*

Proof. Suppose that $C \cup cl(S_0)$ can be l-triangulated and let G' be a l-triangulation of $C \cup cl(S_0)$. From Theorem 4.16 we infer that there is a vertex $v \in C$ such that the subgraph of G' induced by the vertices of $C \cup cl(S_0)$ can be written as the union of the l-triangulated $(kl-1)$-trees T_K based upon *pb*-sets $K \subset S' = S_0 \cup \{v\}$. We will let $\mathcal{M}$ consist of these subsets K, which form the bases of the $(kl-1)$-trees T_K. From Theorem 4.16 it can be seen that $\mathcal{M}$ satisfies the conditions above.

For the converse, if such a family $\mathcal{M} = \{M_i : i \in I\}$ of *pb*-sets exists, then there exists $v \in C$ such that the graph $C \cup cl(S_0)$ is contained in the union of l-triangulatable graphs of the form $C_x \cup cl(M)$, where each $M \in \mathcal{M}$ is a *pb*-set and a subset of $S_0 \cup \{v\}$ and C_x is a component of $G - M$ and a proper subset of C. Since G is a (k,l)-partition intersection graph, these graphs each have all k colors and have monochromatic cliques of maximum size l and also have cliques of maximum size kl. Hence they can be completed to l-triangulated $(kl-1)$-trees T_x, where $V(T_x) = V(C_x \cup M)$. This family of $(kl-1)$-trees $\mathcal{F} = \{T_x : x \in C - \{v\}\}$ shows that $C \cup cl(S_0)$ can be l-triangulated. ∎

THEOREM 4.18. *Let $G = (V,E)$ be a (k,l)-partition intersection graph, $S \subset V$ be a pb-set, and C be a component of $G - S$. Then we can determine whether $C \cup cl(S)$ can be l-triangulated simply by knowing the "answer" for each smaller graph of the form $C' \cup cl(S')$, where S' is a pb-set and C' is a component of $G - S'$.*

Implementation details of the dynamic programming algorithm (Step 3 of Algorithm B). Data structure: A family $\mathcal{X} = \{M_i\}$ of *pb*-sets. For each set M_i in $\mathcal{X}$, and for each of the r_i components C_j of $G - M_i$, we denote by M_i^j, $j = 1, 2, \ldots, r_i$, the subgraph of G induced by $C_j \cup M_i$ with the addition of edges required to make M_i into a clique. Each such M_i^j either can be l-triangulated or cannot be. This will be determined during the algorithm, in order of increasing size of the M_i^j's, and an appropriate answer (yes or no) will be stored for each.

Recall that Step 2 of Algorithm B sorts the subproblems $C_j \cup M_i$ using bucket sort.

ALGORITHM. (the statements in italics denote comments).

```
(* Examine the $M_i^j$ in turn by order of number of vertices,

                **RETURN** (Yes)
            **ELSE RETURN** (No)
    **END-DO**
end of algorithm.
```

The above algorithm can be modified easily to give back an l-triangulation, if it exists.

Run time analysis of Algorithm B. Let $G = (V, E)$ be the (k, l)-partition intersection graph which is given as input to Step 2 of Algorithm B. Then, in Step 2, in the worst case the algorithm checks all subsets of size $kl - 1$ of which there are $O(|V|^{kl-1})$. Each of these is checked for being a pb-set, which involves checking the set to see if it is a vertex separator. This takes $O(|V|^2)$ for each subset. Bucket sorting the subproblems takes a total of $O(|V|^{kl})$. Step 3, which involves checking to see if a subgraph satisfies the conditions of Theorem 4.17, takes time linear in the number of vertices in the subgraph. Thus the overall complexity is $O(|V|^{kl+1})$.

We summarize with the following.

THEOREM 4.19. *Let $G = (V, E)$ be a (k, l)-partition intersection graph. We can in $O(|V|^{kl+1})$ time determine whether G can be l-triangulated and produce the l-triangulation when it exists.*

4.2.4. Summary of the algorithm to solve the l-load perfect phylogeny problem. Given I, compute the partition intersection graph, G_I, and embed G_I in a (k, l)-partition intersection graph G'_I. Use Algorithm B to determine if G'_I can be l-triangulated, and compute the triangulation $G = (V, E)$ if it exists. If there is no l-triangulation, return No. Else, use G to compute the l-load perfect phylogeny T.

We now briefly discuss how T can be constructed from the l-triangulated graph $G = (V, E)$. Recall that T is related to G by Theorem 4.8.

Let $\sigma = v_1 v_2 \dots v_{|V|}$ be a perfect elimination scheme for G. We will construct the tree inductively where T_i is the tree corresponding to $G|\{v_i, v_{i+1}, \dots, v_{|V|}\}$. Thus $T_1 = T$ is the tree we seek.

Let $A_p = \Gamma(v_p) \cap \{v_{p+1}, v_{p+2}, \dots, v_{|V|}\}$. Inductively, assume we are at vertex v_j in σ and assume we have the tree T_{j+1}. Let v_i be the first vertex following v_j (i.e., $j < i$) in σ which is in $\Gamma(v_j)$. Note that $(A_i \cup \{v_i\}) \supseteq A_j$. Since v_j and v_i are simplicial in $G|\{v_j, v_{j+1}, v_{j+2}, \dots, v_{|V|}\}$ and $G|\{v_i, v_{i+1}, v_{i+2}, \dots, v_{|V|}\}$, respectively, it follows that $|\{v_i\} \cup A_i| > |A_j|$ iff, in $G|\{v_j, v_{j+1}, v_{j+2}, \dots, v_{|V|}\}$, the subgraph induced by $\{v_i\} \cup A_i$ is a maximal clique.

Case 1. If the subgraph induced by $\{v_i\} \cup A_i$ is a maximal clique then it follows that $\{v_j\} \cup A_j$ also induces a maximal clique in $G|\{v_j, v_{j+1}, v_{j+2}, \dots, v_{|V|}\}$. Thus from Theorem 4.8 in T_j there will be a vertex which corresponds to $\{v_j\} \cup A_j$. To get T_j from T_{j+1}, we add a new vertex u to $V(T_{j+1})$ and add an edge from u to the vertex $u' \in V(T_{j+1})$ which corresponds to the maximal clique $\{v_i\} \cup A_i$.

Case 2. If $|\{v_i\} \cup A_i| = |A_j|$, then the subgraph induced by $\{v_i\} \cup A_i$ in $G|\{v_j, v_{j+1}, v_{j+2}, \ldots, v_{|V|}\}$ is not a maximal clique. Let v_q $(j \leq q)$ be the first vertex to the left of v_i in σ such that $v_i \in \Gamma(v_q)$ and $|\{v_i\} \cup A_i| = |A_q|$. If $q = j$, then to get T_j we relabel the vertex $u \in V(T_{j+1})$ corresponding to the maximal clique $\{v_i\} \cup A_i$ to now correspond to $\{v_j\} \cup A_j$. If $q \neq j$, then to get T_j from T_{j+1} we create a new vertex corresponding to $\{v_j\} \cup A_j$ and connect it to the vertex $u' \in V(T_{j+1})$ which corresponds to $\{v_q\} \cup A_q$.

It can be seen that the above operations of obtaining T_j from T_{j+1} can be implemented in $O(deg(v_j))$, where $deg(v)$ is the degree of vertex v. This can be achieved by associating two variables with every vertex $v_r \in \sigma$ $(j < r)$, one that corresponds to the vertex $u \in V(T_r)$ such that u represents the maximal clique $\{v_r\} \cup A_r$ in $G|\{v_r, v_{r+1}, \ldots, v_{|V|}\}$ and one that corresponds to a vertex v_s in σ such that v_s is the first vertex to the left of v_r for which $v_s \in \Gamma(v_r)$ and $|\{v_r\} \cup A_r| = |A_s|$.

The time taken for producing a perfect elimination scheme for G is $O(|V| + |E|)$ [17]. From the discussion above, it can be seen that T can then be constructed in $O(|V| + |E|)$. Hence we have the following theorem.

THEOREM 4.20. *Let $G = (V, E)$ be a vertex-colored graph which is l-triangulated. Then the tree T which satisfies the conditions in Theorem* 4.8 *can be constructed in $O(|V| + |E|)$.*

THEOREM 4.21. *The l-load perfect phylogeny problem for n species and k polymorphic characters can be solved and the l-load perfect phylogeny constructed (when it exists) in $O(nk^2l^2 + (rk^3l^2)^{kl+1})$ time.*

Proof. Let I be the input to the l-load perfect phylogeny problem and $G_I = (V, E)$ be the partition intersection graph. Then $|V| = rk$, and it can be shown that if $|E| > kl|V|$ then there is no l-triangulation [27]. Hence $|E| \leq k^2lr$. Let $G'_I = (V', E')$ be the (k, l)-partition intersection graph embedding of G_I, and note that $|V'| = |V| + |E|(kl - 2) \leq rk + k^3l^2r$. The rest follows. □

Comment. In the case where individual load bounds l_α are given, the algorithm can be modified to run in $O(nL^2 + (rkL^2)^{L+1})$, where $L = \sum_{\alpha \in C} l_\alpha$.

4.3. Inferring perfect phylogenies from mixed data. In the previous section we presented two algorithms for inferring perfect phylogenies from polymorphic character data; these algorithms had running times which were exponential in L, where $L = \sum_{\alpha \in C} l_\alpha$ and l_α is the load bound for the character α. We can use these algorithms directly for sets of characters when some of the characters are monomorphic and some are polymorphic, but the expense would be too large. This follows since in typical data sets the number of characters k is the largest parameter, often in the hundreds or thousands; since $L > k$, algorithms that are exponential in L are prohibitively costly. Instead, we propose a method that should be efficient when the number of monomorphic characters is sufficient to reduce the number of minimal perfect phylogenies to a small number. In practice, as the majority of the characters will be monomorphic, this is likely to be very efficient. The method we propose involves two steps and is efficient when the number of minimal perfect phylogenies generated from the monomorphic characters is small.

ALGORITHM C.

Step 1. Infer all minimal perfect phylogenies from the monomorphic characters, using [23].

Step 2. Determine whether any of the minimal perfect phylogenies obtained in Step 1 can be refined so that each polymorphic character is convex on it within the specified load bound.

Discussion of Step 1. The algorithm by Kannan and Warnow [23] has running time of $O(2^{2r+r^2}k_m^{r+3}+Mk_mn)$, where M is the number of minimal perfect phylogenies and k_m is the number of monomorphic characters. This is theoretically expensive if r, the number of states, is too large; however, in practice the algorithm works quickly as long as not too many of the characters have a large number of states. Also, in practice, as long as the monomorphic characters are independent of each other and comprise a suitably large set, there will be very few perfect phylogenies. Thus we expect Step 1 to be very fast and to produce very few minimal perfect phylogenies.

Discussion of Step 2. We consider the following problem.

Problem. Refining a tree.

Input. Leaf-labeled tree T and set C of polymorphic characters, each with an individual load bound.

Question. Does a perfect phylogeny T' exist for the polymorphic characters, subject to the constraint that T' is a refinement of T?

ALGORITHM D.

```
For each internal $v \in T$ which has degree greater than 3, do
  1. Let $\Gamma(v) = \Gamma_1(v) \cup \Gamma_2(v)$, where $\Gamma_1(v)$ consists of all the neighbors of $v$
     which are leaves and $\Gamma_2(v)$ consists of all the nonleaf neighbors of $v$. For each
     $u_j \in \Gamma_2(v)$ add a new node $w_j$ on the edge $(v, u_j)$. Compute the labeling of
     $w_j$ so as to make every character convex (each character must contain every
     state that appears on both sides of $w_j$).
  2. If some new node has a load for a character that exceeds the stated load
     bound for that character, RETURN(NO). Let $S_v = \Gamma_1(v) \cup \{w_j | w_j$ is a new
     node and $w_j$ is a neighbor of $v\}$. Use any of the algorithms from section 3
     to determine if there is a perfect phylogeny for $(S_v, C)$ satisfying the load
     bounds. If any $(S_v, C)$ fails to have a perfect phylogeny meeting the load
     bounds then RETURN(NO), else RETURN(YES).
```

Example. Consider $S = \{a, b, c, d, e, f, g\}$ and $C = \{\alpha, \beta\}$. Let α be a monomorphic character and β be a polymorphic character with load bounded by three. Also, let $\alpha(a) = \{0\}, \alpha(b) = \{0\}, \alpha(c) = \{1\}, \alpha(d) = \{1\}, \alpha(e) = \{1\}, \alpha(f) = \{1\}$, and $\alpha(g) = \{1\}$. In addition, let $\beta(a) = \{0\}, \beta(b) = \{3\}, \beta(c) = \{2, 4\}, \beta(d) = \{2, 3\}, \beta(e) = \{1, 4\}, \beta(f) = \{1, 3\}$, and $\beta(g) = \{0, 4\}$. Figure 4.1(i) shows the phylogeny T obtained by applying the perfect phylogeny algorithm to the monomorphic character α. Let $S' = \{h, c, d, e, f, g\}$ be the species set obtained at the end of step 1 of Algorithm D. Then $\beta(h) = \{0, 3\}$. The instance $(S', \{\beta\})$ has a perfect phylogeny with load bounded by three. This is shown in Figure 4.1. From this phylogeny it is possible to obtain the solution to the instance (S, C), and this is shown in Figure 4.1(iii).

THEOREM 4.22. *Algorithm D correctly determines whether a perfect phylogeny T' exists refining T within the stated load bounds, and it can be modified to produce the perfect phylogeny T' in time* $min\{O(r^{L+1}Ln^2), O(n^2L^2 + n(rkL^2)^{L+1})\}$.

Proof. If the algorithm returns NO, it is clear that no perfect phylogeny within the constraints of the problem exists. If it returns YES, then the perfect phylogenies refining each of the stars can be hooked up via the new nodes. The refinement can be done by using the algorithms in section 4. It can be shown that the algorithm takes $min\{O(r^{L+1}Ln^2), O(n^2L^2 + n(rkL^2)^{L+1})\}$. □

In Algorithm D, if $|S_v|$ is small then it may be cheaper in practice to look at all

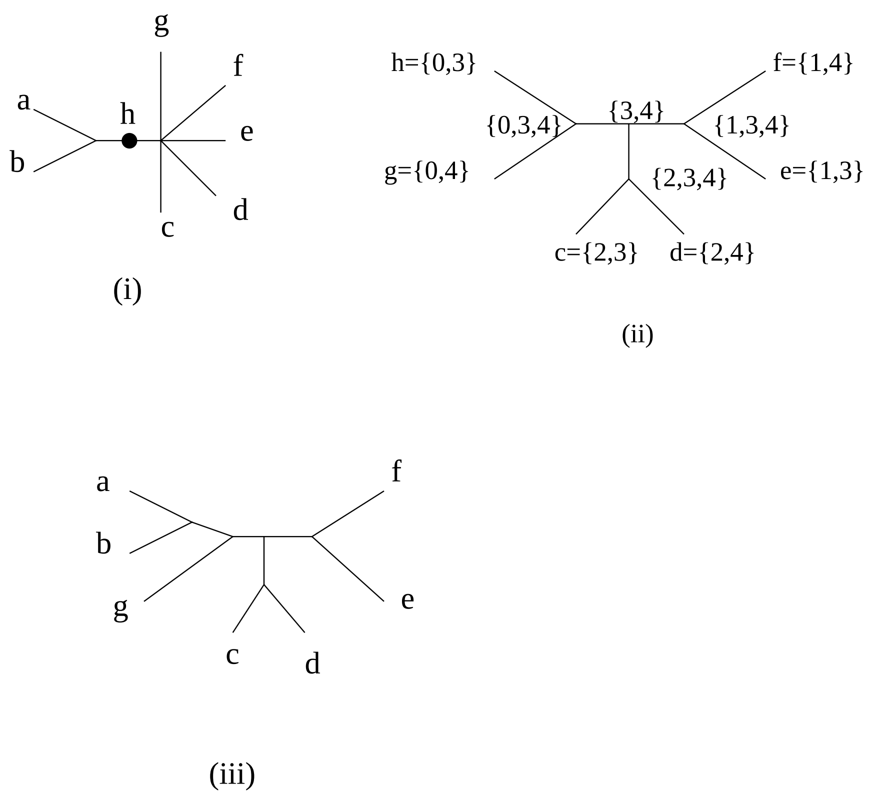

FIG. 4.1. *Example for* Algorithm D.

possible leaf-labeled topologies on S_v rather than use the algorithms of section 4 to determine the existence of perfect phylogenies on S_v.

5. Polymorphism in linguistics. Properly chosen and encoded characters in linguistics have been shown to be convex on the true tree, so that with proper scholarship we should be able to infer a *perfect phylogeny.* In recent work on an Indo-European data set, Warnow, Ringe, and Taylor [39] found that there was extensive presence of polymorphic characters. The degree of polymorphism for each polymorphic character could be determined from the data with high confidence, so that the question of inferring the correct tree amounted to determining if a perfect phylogeny existed in which each character was permitted a maximum degree of polymorphism (i.e., load) on the tree. Figure 5.1 shows the tree that they now posit. This was obtained using Algorithm D. This tree is in fact different from their earlier hypothesis and from the tree that was presented in [6]. This tree has been obtained as a result of using more data. This tree shows a limited support for Indo-Hittite, moderate support for the Italo-Celtic hypothesis, and significant support for a subgroup of Greek and Armenian.

6. Polymorphism in biology. The evolution of biological polymorphic characters can be modeled using the following operations [28]. A *mutation* changes one state into another. A *loss* drops a state from a polymorphic character from parent to child. A *duplication* replicates a state which subsequently mutates. This allows children to have higher load on a polymorphic character than their parents. We con-

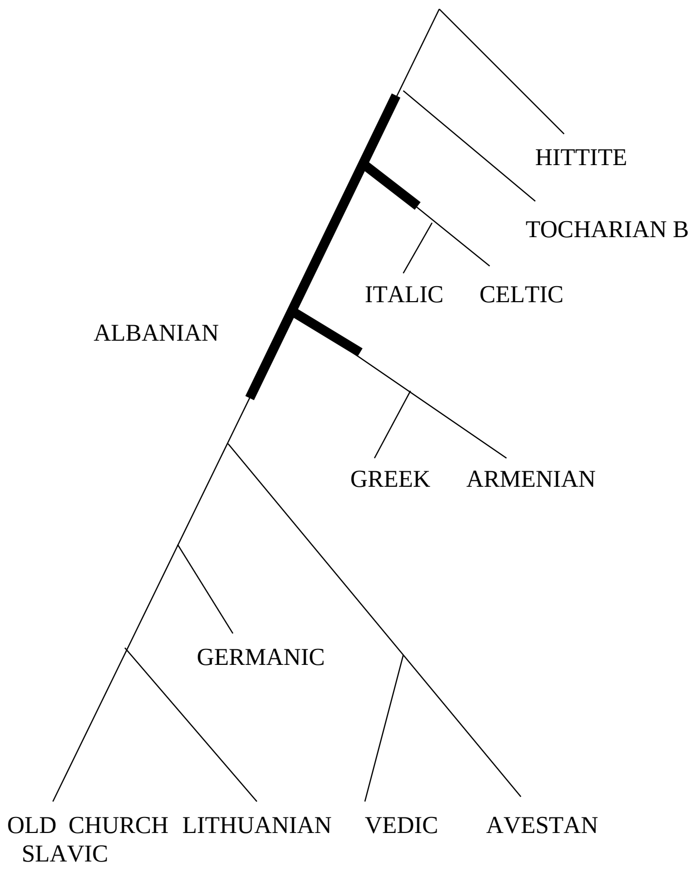

FIG. 5.1. *The tree on the Indo-European data set. Albanian can be on any of the thick edges. The tree indicates only a rooted topology without any edge lengths.*

sider two types of costs: (a) state-independent costs, in which any loss costs $cost_\ell$, any mutation costs $cost_m$, any duplication costs $cost_d$, and any match costs 0; and (b) state-dependent costs, in which the costs are dependent on the states involved.

Parsimony is a popular criterion for evaluating evolutionary trees from biomolecular data. A most parsimonious tree T minimizes $\sum_{e \in E(T)} cost(e)$. Traditionally, for monomorphic characters $cost(e)$ is the Hamming distance of the labels at the two endpoints of e. For unknown topology, the traditional parsimony problem is *NP-hard* [9, 10], but for fixed topology it is in P [16].

Consider the case where costs $cost_\ell, cost_m$, and $cost_d$ are not state-dependent. Let (u, v) be an edge in T with u above v. We define the cost $cost(\alpha, (u, v))$ of $\alpha \in C$ on (u, v) as follows: Let $X = \alpha(u) - \alpha(v), Y = \alpha(v) - \alpha(u)$, and $Z = \alpha(u) \cap \alpha(v)$.

- If $|X| = |Y|$ then $cost(\alpha, (u, v)) = cost_m|X|$ (all events are mutations, but shared states do not change).
- If $|X| > |Y|$ then $cost(\alpha, (u, v)) = cost_\ell[|X| - |Y|] + cost_m|Y|$.
- If $|X| < |Y|$ then $cost(\alpha, (u, v)) = cost_d[|Y| - |X|] + cost_m|X|$.

The cost of the edge (u, v) is then $\sum_{\alpha \in C} cost(\alpha, (u, v))$. For state-dependent costs we must also match states in the parents to states in the child for mutation and duplication events.

We consider the following problem: Given a fixed leaf-labeled topology and a maximum load l, what is the most parsimonious labeling of the internal nodes?

The problem is NP-complete for arbitrary loss, mutation, and duplication cost functions. If $cost_\ell = 0$, such as when we wish to maximize convexity, the problem becomes even harder.

THEOREM 6.1. *The following problems are NP-complete:*

- *Given a tree with leaves labeled by species each with load at most l and a value P, determine if the internal nodes can be labeled to create a phylogeny with load at most l and parsimony cost at most P for arbitrary $cost_\ell < cost_m < cost_d$.*
- *If $cost_\ell = 0$ and $cost_m \leq cost_d$ are arbitrary then given a tree with leaves labeled by species and values l and P, determine if the internal nodes can be labeled to create a phylogeny with load at most l and parsimony cost at most P. This problem remains NP-complete even if the tree is binary, no edges of weight 0 are allowed, and the input load is $1 \leq l_i \leq l$.*

Proof. In the fixed-topology setting, characters are independent. Therefore we consider only the case of a single character with r states.

Clearly the problem is in NP. We now show it is NP-hard. Our reduction is from the *three-dimensional matching problem* (3DM), known to be NP-complete [20], which is defined as follows. We are given three disjoint sets, A, B, and C, each with n elements, and a set X of m *triples*, $X = \{(a_i, b_j, c_k) : a_i \in A, b_j \in B, \text{and } c_k \in C\}$. We say that triple (a_i, b_j, c_k) *covers* a_i, b_j, and c_k. We wish to find a set of n triples that covers every element of A, B, and C exactly once. This set of n triples is called a *perfect matching*.

Given an instance of 3DM, we construct a tree T with leaves labeled by species each with load at most $m-n$. The internal nodes of T can be labeled with load $m-n$ and parsimony $(3mn - 3n^2)cost_m$ iff the instance of 3DM has a perfect matching.

We construct the tree T as follows. We begin by creating an internal *root* node. This root has $3n$ children, $a_1, \dots, a_n$, $b_1, \dots, b_n$, and $c_1, \dots, c_n$, which are all internal nodes. Let $n(a_i)$ for $1 \leq i \leq n$ be the number of triples that contain a_i. We have the following states for our character: m states $x_1, x_2, \dots, x_m$ corresponding to the m triples $x_j \in X$, and $d(a_i) \equiv m - n - n(a_i) + 1$ *dummy states* associated with each a_i (similarly we have $d(b_j) \equiv m - n - n(b_j) + 1$ dummy states for each b_j and $d(c_k) \equiv m - n - n(c_k) + 1$ dummy states for each c_k). Let $D(a_i)$ be the set of dummy states associated with a_i ($|D(a_i)| = d(a_i)$). Let $X(a_i)$ be the set of triples that contain a_i ($|X(a_i)| = n(a_i)$). For the remainder of this discussion we will concentrate on nodes a_i. The nodes b_j and c_k are treated symmetrically.

Node a_i has $n(a_i)$ leaf children. Let $x_1, x_2, \dots, x_{n(a_i)}$ be the states associated with the triples that contain a_i. The ith leaf under node a_i has all the dummy states $D(a_i)$ associated with a_i and all of $x_1, x_2, \dots, x_{n(a_i)}$ *except for* state x_i. Each child thus has load $m-n$.

It can be shown that we can label the internal nodes of this tree with load at most $m-n$ and cost at most $(3mn - 3n^2)cost_m$ iff the instance of 3DM has a perfect matching.

First suppose that $X_s \subset X$ is a set of n triples that forms a perfect matching. Label the root with states from the set $X - X_s$ and label a_i with all the leaves below it except x_q, where $x_q \in X_s$ and $a_i \in x_q$. Each internal node has load $m-n$ as required. The edge from the root to node a_i has cost $d(a_i)cost_m$ since none of the dummy states in $D(a_i)$ are in the root, all of the remaining states in a_i's label are in the root and the root has the same load as a_i (thus we have mutation rather than duplication or loss). Since $\sum_{i=1}^{n} d(a_i) = mn - n^2 + n - m$, we have (since the edges from the root to the b_j and c_k nodes are of similar cost) that the total cost of the edges from the root to its $3n$ children is $3mn - 3n^2 + 3n - 3m$. Now consider the cost of the edges from node a_i to its $n(a_i)$ children. If x_q is the triple in X_s that contains a_i, then the edge to the child missing x_q will have cost 0. All other edges have cost $cost_m$. Summing over all edges from a_i, b_j, or c_k nodes to their children, we have a cost of $(3m-3n)cost_m$. Thus the total cost is $(3mn-3n^2)$ and the parsimony bound is met.

Suppose instead that there is a labeling of the internal nodes of T so that the maximum load is $m-n$ and the total cost is at most $3mn-3n^2$.

We need the following lemma.

LEMMA 6.2. *If $cost_m < cost_d$, then in any optimal solution an internal node will always have load at least as high as the minimum load of any of its children.*

Proof. Consider a node p that is the parent of k children. Suppose there is a labeling of the nodes such that node p has a load smaller than all of its children. Thus in the cost of the tree there are at least k duplications associated with edges from p to its children. If we add to the label of p another state found in at least one of its children (such a state always exists since all children have more labels than p), then regardless of the labeling of p's parent we will decrease the cost of the tree. Adding the label costs at most $cost_d$ along the edge from node p to its parent. However, it saves at least $cost_d + (k-1)(cost_d - cost_m)$. Since $cost_d > cost_m$, adding the label always results in a net savings. Therefore we can assume that in the labeling we are given all internal nodes have load $m-n$, or we can add labels to these internal nodes and only reduce the cost. □

Thus from Lemma 6.2 all internal nodes of the input tree will have load $m-n$. Looking at the root, each state x_i is contained in the leaves of exactly three children. Each dummy state is contained in the leaves of only one child. Therefore a lowest-cost labeling of the root will have $m-n$ states x_i. If all the a_i, b_j, and c_k are also labeled by the states chosen by the root, then the minimum possible cost of the edges from the root to its children is $3mn - 3n^2 - 3m + 3n$. This is because each child a_i must mismatch on at least $m - n - n(a_i)$ labels. Summing over all children of the root, this give $3mn - 3n^2 - 3m$, but since n triples could not be in the label of the root, there is an additional cost of $3n$. Looking at the parsimony bound, even if the cost of the edges from the root to its children is minimum, the total cost of the a_i, b_j, and c_k nodes to their children can be at most $3m - 3n$. Consider a node a_i and its children. The minimum possible cost of the edges between these nodes is $n(a_i) - 1$, which comes from labeling a_i with all its dummy states and all but one of the triple states associated with it. If a_i is instead labeled with all of its triple states and all but one of its dummy states, the cost is $n(a_i)$. To achieve a total remaining cost of $3m - 3n$, however, the cost of each a_i to its children must be the minimum and therefore one of the triple states is missing from each a_i, b_j, and c_k. These must be the n triple states missing in the root or there will be higher cost associated with the edges from the root to its children and the parsimony bound will be exceeded. Thus the n triple states missing from the label of the root cover each of the a_i, b_j, and c_k and correspond to a perfect matching for the 3DM instance.

We now prove the second part of Theorem 6.1. Clearly the problem is in NP. We now show it is NP-hard. We again use a reduction from 3DM as in the proof of the first part of Theorem 6.1. We construct the tree as above with the following modifications. Each node a_i now has two children. For the case of load-1 input, each child is the root of a binary tree. Each of these trees has all the dummies in $D(a_i)$ represented in the leaf set and the states of $X(a_i)$ are arbitrarily divided among the children, appearing as a leaf just once in the subtree rooted at a_i. For other input loads, the labels of the leaves vary. For instance, for load L there are only two leaf children of a_i, one labeled with all the dummies in $D(a_i)$ and all but one state in $X(a_i)$, the other labeled with all the dummy states and the single state $x_q \in X(a_i)$ missing in the label of its sibling. For other loads, the children of a_i can also be made into binary trees where the input load is met by at least one leaf, all dummy states are represented in each child of a_i, and each state in $X(a_i)$ is represented exactly once. To make the whole tree binary, we form an arbitrary binary tree with the a_i as "leaves." (The two children of a_i will be attached.) We call this tree (without the children of a_i) the *A tree*. We make the root of the A tree a child of the global root. Similarly we form a B tree and a C tree and make them children of the global root.

Again, it can be shown that we can find labels for the internal nodes of this tree with load at most $m-n$ and cost at most $(3mn+6n-3n^2-3m)cost_m$ iff the instance of 3DM has a perfect matching.

First suppose that $X_s \subset X$ is a set of n triples that forms a perfect matching. Label the root with states from the set $X - X_s$ and label a_i with all the leaves below it except x_q where $x_q \in X_s$ and $a_i \in x_q$. Each internal node in the A tree is labeled with all of the x_q states appearing in the labels of its two children. It then picks an arbitrary set of the dummy states appearing in its two children so that its final load is $m - n$. Thus each internal node has load at most $m - n$. We now calculate the cost of this labeling. Each dummy state associated with a_i arises once in the A tree by mutation since all internal nodes in the A tree have load $m-n$, as does the global root, and the global root is not labeled with any dummy states. The total cost of all dummies is $(3mn + 3n - 3n^2 - 3m)cost_m$. In addition each of the n triple states not represented in the root arise three times in the tree by mutation for a total cost of $3ncost_m$. Thus the tree costs $(3mn + 6n - 3n^2 - 3m)cost_m$ and the parsimony bound is met.

Suppose instead that there is a labeling of the internal nodes of the tree so that the maximum load is $m-n$ and the total cost is at most $(3mn-+6n-3n^2-3m)cost_m$.

We need the following lemma.

LEMMA 6.3. *If $cost_\ell = 0$, then there exists an optimal solution where each internal node contains all the states in the subtree rooted at it or has maximum load.*

Proof. Suppose we are given a labeling where a node p has load l_p which is not the maximum load but its label does not contain a state r represented in the label of one of its children. Let P be the set of all nodes on the path from p to its first ancestor with load at least $l_p + 1$ or up to the root if no such ancestor exists. Add state r to the label of p. Choose some state that is in node p that is not in its parent (one always exists if the parent has load at most l_p) and add it to the label of its parent, and so on so that each node in set P has its load increased by 1. This increase in labeling costs at most $cost_m$ on the label from the highest node in P to its parent (nothing if the highest node in P is the root), and it saves $cost_m$ on the edge (p, c). Thus we have not increased the cost of the tree. Starting this process with internal nodes lowest in the tree gives us the above claim. ∎

Therefore we can assume that every internal node is labeled with all states in its subtree or has maximum load. In particular, we can assume that the root has maximum load $m - n$. Since each triple state x_q is represented in the leaves of all three children and the dummy states in only one child each, then the minimum possible cost associated with dropping states at the root is $(3mn+6n-3n^2-3m)cost_m$ (all the dummy states must arise somewhere in the tree and the n triple states not present in the root label must arise three times in the tree). Therefore, to meet the parsimony bounds, there can be no additional cost throughout the remainder of the tree. Considering a single node a_i, there are $m-n+1$ states in the subtree rooted at a_i. Since it can have load at most $m-n$, one of these states must be missing from the label at a_i. If one of the dummy states is dropped, then there will be an extra cost of $cost_m$ beyond what is forced by the root (the root allowed each dummy state to arise once and each dummy state appears in the subtrees rooted in both children of node a_i). Therefore node a_i must be labeled with all its dummy states and all but one of the $x_q \in X(a_i)$. These triple states must be passed up the A tree to the root, but there is sufficient capacity to do so (the states that are dropped at internal nodes of the A tree of dummy states, which ultimately had to be dropped anyway). To achieve the parsimony bound, this x_q missing from the label of node a_i must be one of the triples not represented at the root. Therefore the n triple states missing from the root label correspond to the perfect matching in the 3DM instance. ◻

We now consider algorithms for fixed load l. Since the topology is given, characters can be solved independently. We first give the algorithm for the most general possible cost function and then consider special cases which can be solved more efficiently. All the algorithms are standard bottom-up dynamic programming. A final pass downward from the root produces an optimal labeling of the tree in time $O(nlk)$.

THEOREM 6.4. *Given a tree on n species with k characters where r is the maximum number of states for any character,*

1. *there exists an $O(nkr^{2l})$-time algorithm to compute the most parsimonious load-l labeling for the tree for arbitrary state-dependent costs;*
2. *there exists an $O(nkl(2r)^l)$-time algorithm to compute the most parsimonious load-l labeling for the tree for arbitrary fixed costs $cost_\ell \leq cost_m \leq cost_d$;*
3. *there exists an $O(nk(2r)^l)$-time algorithm to compute the most parsimonious load-l labeling for the given tree when $cost_\ell = 0$.*

Proof. When the cost function is state-dependent, we convert our input to a weighted monomorphic parsimony problem. We define a new set of $O(r^l)$ states, one for each possible label of a node. Given two labels l_p and l_c, we can determine the cost of a parent-child edge with labels l_p and l_c. We must match states for mutations and duplications. We thus compute a matrix of edge costs. Because loss and duplication costs are not the same, this matrix is not symmetric in general. We then use the algorithm of Sankoff and Cedergren [34] for weighted parsimony which runs in time $O(nkj^2)$ for n species, k characters, and j states/characters. In our case we have r^l states, where r was the original number of states in the polymorphic character. Thus this algorithm has time $O(nkr^{2l})$.

The bottom-up dynamic programming algorithm for weighted parsimony proceeds as follows. For an internal node v, let $c(v, l_v)$ be cost of the best labeling of the subtree rooted at v provided that node v is labeled l_v. Then we have $c(v, l_v) = \sum_{v' \text{child of } v}(\min_{l_{v'}} c(v', l_{v'}) + w(l_v, l_{v'}))$, where $w(l_v, l_{v'})$ is the cost of the edge with parent label l_v and child label $l_{v'}$. Thus we consider every possible label for an internal node and compare it against every possible label for its children. For arbitrary weight function w, this will cost r^{2l} for each parent-child interaction.

For the case of arbitrary $cost_\ell \leq cost_m \leq cost_d$ (not state-dependent), we can reduce the overall time to $O(nkl(2r)^l)$. Again, we wish to consider every possible label for node v but we need not consider every possible label for its children. Suppose that for each child we know the best choice of label for each of load $1, 2, \ldots, l$, where some specific subset (possibly empty) of the label is specified. For example, we know the best load-3 labeling of the child where a and b are two of the three states. This is $O(lr^l)$ information. To find the best labeling of the subtree rooted at v provided v is labeled by l_v, the only labels we need to consider for the children of v are the best ones for each possible subset of l_v and each possible load. For example, if $l_v = \{a, b\}$, $l = 3$, and $*$ can be any state, then the only labels that must be considered for a child are $*$ (best tree with load-1 label), $**$, $***$, a, $a*$, $a**$, b, $b*$, $b**$, ab, and $ab*$. More formally, let $c(v, L, x)$ be the cost of the best subtree rooted at v where the label of v contains state set L and x other states. Then the cost of label l_v and node v is

$$c(v, l_v) = \sum_{\text{children } v'} \min_{L \subseteq l_v} \min_{0 \le l' \le l - |L|} (c(v', L, l') + w(l_v, L, l')),$$

where

$$w(l_v, L, l') = \begin{cases} l' cost_m + (|l_v| - |L| - l') cost_\ell & \text{if } |L| + l' \le |l_v| \\ (|l_v| - L) cost_m + (|L| + l' - |l_v|) cost_d & \text{otherwise.} \end{cases}$$

Thus to compute the cost of a label, each parent must check $O(l2^l)$ labels in each child. Once the label l_v is computed, it contributes to $O(2^l)$ minimizations used by its parent (each subset of l_v with load $|l_v|$). Since each of the $O(n)$ edges is checked $O(l2^l)$ times for each of the r^l possible parent labels, the overall cost is $O(nkl(2r)^l)$.

To prove the final part of the theorem, when $cost_\ell = 0$ (for example when we wish to maximize convexity), we note that whenever we have $cost_\ell = 0$ there exists an optimal solution where each internal node contains all the states in the subtree rooted at it or has maximum load. We begin by locating the highest internal nodes v with at most l states in the subtree rooted at them. We label node v by these states and make it a leaf by removing all its children. Now we can assume all internal nodes have load l. This saves a factor of l using the preceding algorithm since there is now only one value of l'. $\square$

7. Discussion. In this paper we introduced an algorithmic study of the problem of inferring the evolutionary tree in the presence of polymorphic data. We considered parsimony analysis for polymorphic data on fixed topologies and presented algorithms as well as hardness results. We also presented algorithms for inferring perfect phylogenies from such data, and we note that it is reasonable to seek perfect phylogenies for certain types of data. The results of our analysis of the an expanded Indo-European data set studied by Warnow, Ringe, and Taylor has led to a new hypothesis for the evolution of Indo-European languages.

THE COMPLEXITY OF TREE AUTOMATA AND LOGICS OF PROGRAMS*

E. ALLEN EMERSON† AND CHARANJIT S. JUTLA‡

Abstract. The complexity of testing nonemptiness of finite state automata on infinite trees is investigated. It is shown that for tree automata with the pairs (or complemented pairs) acceptance condition having m states and n pairs, nonemptiness can be tested in deterministic time $(mn)^{O(n)}$; however, it is shown that the problem is in general NP-complete (or co-NP-complete, respectively). The new nonemptiness algorithm yields exponentially improved, essentially tight upper bounds for numerous important modal logics of programs, interpreted with the usual semantics over structures generated by binary relations. For example, it follows that satisfiability for the full branching time logic CTL* can be tested in deterministic double exponential time. Another consequence is that satisfiability for propositional dynamic logic (PDL) with a repetition construct (PDL-delta) and for the propositional Mu-calculus ($L\mu$) can be tested in deterministic single exponential time.

1. Introduction.

There has been a resurgence of interest in automata on infinite objects [1] due to their intimate relation with temporal and modal logics of programs. They provide an important and uniform approach to the development of decision procedures for testing satisfiability of the propositional versions of these logics [43, 33]. Such logics and their corresponding decision procedures are not only of inherent mathematical interest, but are also potentially useful in the specification, verification, and synthesis of concurrent programs (cf. [27, 8, 25, 21]).

In the case of branching time temporal logic, the standard paradigm nowadays for testing satisfiability is the reduction to the nonemptiness problem for finite state automata on infinite trees; i.e., one builds a tree automaton which accepts essentially all models of the candidate formula and then tests nonemptiness of the tree automaton. Thus in order to improve the complexity there are two issues: (1) the size of the tree automaton and (2) the complexity of testing nonemptiness of the tree automaton.

In this paper we obtain new, improved, and essentially tight bounds on testing nonemptiness of tree automata that allow us to close an exponential gap which has existed between the upper and lower bounds of the satisfiability problem of numerous important modal logics of programs. These logics include CTL* (the full branching time logic [9]), PDL-delta (propositional dynamic logic with an infinite repetition construct [33]), and the propositional Mu-calculus ($L\mu$) (a language for characterizing temporal correctness properties in terms of extremal fixpoints of predicate transformers [19] (cf. [7, 2])).

To obtain these improvements, we focus on the complexity of testing nonemptiness of tree automata. We first note, however, that the size of an automaton has two parameters: the number of states in the automaton's transition diagram and the number of pairs in its acceptance condition. We next make the following important observation: for most logics of programs, the number of pairs is logarithmic in the number of states.

We go on to analyze the complexity of testing nonemptiness of pairs tree automata [30] and show that it is NP-complete. However, a multiparameter analysis shows that there is an algorithm that runs in time $(mn)^{O(n)}$ which is polynomial in the number of states m and exponential in the number of pairs n in the acceptance condition of the automaton. The algorithm is based on a type of "pseudomodel checking" for certain restricted Mu-calculus formulae. Moreover, since the problem is NP-complete, it is unlikely to have a better algorithm which is polynomial in both parameters. The previous best known algorithm was in NP [6, 41].

The above nonemptiness algorithm now permits us to obtain a deterministic double exponential time decision procedure for CTL*, by using the reduction from CTL* to tree automata obtained in [13], in which the size of the automaton is double exponential in the length of the formula and the number of pairs is only exponential in the length of the formula. The bound follows by simple arithmetic, since a double exponential raised to a single exponential power is still a double exponential.

This amounts to an exponential improvement over the best previously known algorithm which was in nondeterministic double exponential time [6, 41], i.e., three exponentials when determinized. It is also essentially tight, since CTL* was shown to be double exponential time hard [41]; thus CTL* is deterministic double exponential time complete.

The above result has been obtained using only the classical pairs tree automata of Rabin [30]. However, we also consider the complemented pairs tree automata of Streett [33], which were specifically introduced to facilitate formulation of temporal decision procedures. We show that the nonemptiness problem of complemented pairs automata is co-NP-complete by reducing the complement of the problem to nonemptiness of the pairs automata and vice versa. The reduction employs the fact that infinite Borel games are determinate (Martin's theorem [22]). This reduction also gives a deterministic algorithm which is polynomial in the number of states and exponential in the number of pairs. We can thus reestablish the above upper bound for CTL* using complemented pairs automata as well.

Using the recent single exponential general McNaughton [23] construction of Safra [32] (i.e., construction for determinizing a Büchi finite automaton on infinite strings), our new nonemptiness algorithm also gives us a deterministic single exponential time decision procedure for both PDL-delta and the Mu-calculus, since the Safra construction allows us to reduce satisfiability of these logics to testing nonemptiness of a tree automaton with exponentially many states and polynomially many pairs. This represents an exponential improvement over the best known deterministic algorithms for these logics, which took deterministic double exponential time, corresponding to the nondeterministic exponential time upper bounds of [41]. The bounds are essentially tight also, since the exponential time lower bound follows from that established for ordinary PDL by Fischer and Ladner [14].

It is interesting to note that for most logics (including PDL-delta and the Mu-calculus but excluding CTL*), our nonemptiness algorithm(s) and Safra's construction both play a crucial role. Each is independent of the other. Moreover, each is needed and neither alone suffices. Our algorithm improves the complexity of testing nonemptiness by an exponential factor, while Safra's construction independently applies to reduce the size of the automaton by an exponential factor. For example, the "traditional" result of Streett [33] gave a deterministic triple exponential algorithm for PDL-delta. Our algorithm alone improves it to deterministic double exponential time. Alternatively, Safra's construction alone improves it to deterministic double exponential time. As shown in this paper, the constructions can be applied together to get a cumulative double exponential speedup for PDL-delta. In the case of CTL*, we already had the effect of Safra's construction, because [13] gave a way to determine with only a single exponential blowup the Büchi string automaton corresponding to a linear temporal logic formula by using the special structure of such automata (unique accepting run). Thus Safra's construction provides no help for the complexity of the CTL* logic.

The remainder of the paper is organized as follows. In section 2 we give preliminary definitions and terminology. In section 3 we establish a "small model theorem" for (pairs) tree automata. In section 4 we give the main technical results on testing nonemptiness of pairs tree automata. In section 5 we give the main results on nonemptiness of complemented pairs tree automata. Applications of the algorithms to testing satisfiability of modal logics of programs, including CTL*, PDL-delta, and the Mu-calculus, are described in section 6. Some concluding remarks are given in section 7.

2. Preliminaries.

2.1. Logics of programs.

2.1.1. Full branching time logic. The *full branching time logic* CTL* [9] derives its expressive power from the freedom of combining modalities which quantify over paths and modalities which quantify states along a particular path. These modalities are A, E, F, G, X_s, and U_w ("for all futures," "for some future," "sometime," "always," "strong nexttime," and "weak until," respectively), and they are allowed to appear in virtually arbitrary combinations. Formally, we inductively define a class of state formulae (true or false of states) and a class of path formulae (true or false of paths):

(S1) Any atomic proposition P is a state formula.
(S2) If p, q are state formulae, then so are $p \wedge q$, $\neg p$.
(S3) If p is a path formula, then Ep is a state formula.
(P1) Any state formula p is also a path formula.
(P2) If p, q are path formulae, then so are $p \wedge q$, $\neg p$.
(P3) If p, q are path formulae, then so are $X_s p$ and $p U_w q$.

The semantics of a formula are defined with respect to a structure $M = (S, R, L)$, where S is a nonempty set of states, R is a nonempty binary relation on S, and L is a labeling which assigns to each state a set of atomic propositions true in the state. A *fullpath* $(s_1, s_2, \ldots)$ is a maximal sequence of states such that $(s_i, s_{i+1}) \in R$ for all i. A fullpath is infinite unless for some s_k there is no s_{k+1} such that $(s_k, s_{k+1}) \in R$. We write $M, s \models p$ ($M, x \models p$) to mean that state formula p (path formula p) is true in structure M at state s (of fullpath x, respectively). When M is understood, we write simply $s \models p$ ($x \models p$). We define $\models$ inductively using the convention that $x = (s_1, s_2, \ldots)$ denotes a fullpath and x^i denotes the suffix fullpath $(s_i, s_{i+1}, \ldots)$, provided $i \leq |x|$, where $|x|$, the length of x, is ω when x is infinite and k when x is finite and of the form $(s_1, \ldots, s_k)$; otherwise x^i is undefined.

For a state s,

(S1) $s \models P$ iff $P \in L(s)$ for atomic proposition P,

(S2) $s \models p \wedge q$ iff $s \models p$ and $s \models q$,

$s \models \neg p$ iff not $(s \models p)$,

(S3) $s \models Ep$ iff for some fullpath x starting at s, $x \models p$.

For a fullpath $x = (s_1, s_2, \ldots)$,

(P1) $x \models p$ iff $s_1 \models p$ for any state formula p,

(P2) $x \models p \wedge q$ iff $x \models p$ and $x \models q$,

$x \models \neg p$ iff not $(x \models p)$,

(P3) $x \models X_s p$ iff x^2 is defined and $x^2 \models p$,

$x \models (p\, U_w\, q)$ iff for all $i \in [1 : |x|]$, if for all $j \in [1 : i]$ $x^j \models \neg q$, then $x^i \models p$.

We say that state formula p is *valid*, and write $\models p$, if for every structure M and every state s in M, $M, s \models p$. We say that state formula p is *satisfiable* iff for some structure M and some state s in M, $M, s \models p$. In this case we also say that M defines a *model* of p. We define validity and satisfiability for path formulae similarly.

We write $f \doteq g$ to mean that formula f abbreviates formula g. Other connectives can then be defined as abbreviations in the usual way: $p \vee q \doteq \neg(\neg p \wedge \neg q)$, $p \Rightarrow q \doteq \neg p \vee q$, $p \Leftrightarrow q \doteq (p \Rightarrow q) \wedge (q \Rightarrow p)$, $Ap \doteq \neg E \neg p$, $Gp \doteq p\, U_w\, false$, and $Fp \doteq \neg G \neg p$. Further operators may also be defined as follows:

$X_w p \doteq \neg X_s \neg p$ is the weak nexttime,

$p U_s q \doteq (p U_w q) \wedge Fq$ is the strong until,

$\overset{\infty}{F} p \doteq GFX_s p$ means infinitely often p,

$\overset{\infty}{G} p \doteq FGX_s p$ means almost everywhere p,

$inf \doteq GX_s true$ means the path is infinite, and

$fin \doteq FX_w false$ means the path is finite.

2.1.2. Propositional dynamic logic plus repeat. As opposed to CTL*, in which the models represent behaviors of the programs, in PDL-delta the programs are explicit in the models. The modalities in PDL-delta quantify the states reachable by programs explicitly stated in the modality. Thus, for a program B (which is obtained from atomic programs and tests using regular expressions), $\langle B \rangle p$ ($[B]p$) states that there is an execution of B leading to p (after all executions of B, p holds). Also included is the infinite repetition construct *delta* ($\triangle$) which makes PDL-delta much more expressive than PDL. $\triangle B$ states that it is possible to execute B repetitively infinitely many times. PDL-delta formulae are interpreted over structures $M = (S, R, L)$, where S is a set of states, $R : Prog \to 2^{S \times S}$ is a transition relation, $Prog$ is the set of atomic programs, and L is a labeling of S with propositions in $Prop$. For more details see [33].

2.1.3. Propositional Mu-calculus. A *least fixpoint* construct can be used to increase the power of simple modal logics. Thus, by adding this construct to PDL, we get $L\mu$, the *propositional Mu-calculus* [19], a logic which subsumes PDL-delta. A variant formulation of the Mu-calculus, which we use here, adds the least fixpoint construct to a simple subset of CTL*, including just nexttime (AX_s), the boolean connectives, and propositions (cf. [7]). The least fixpoint construct has the syntax $\mu Y.f(Y)$, where $f(Y)$ is any formula syntactically monotone in the propositional variable Y, i.e., all occurrences of Y in $f(Y)$ fall under an even number of negations. It is interpreted as the smallest set S of states such that $S = f(S)$. By the well-known Tarski–Knaster theorem, $\mu Y.\, f(Y) = \bigcup_i f^i(\text{false})$, where i ranges over all ordinals and f^i (intuitively) denotes the i-fold composition of f with itself; when the domain is finite we may take i as ranging over just the natural numbers. Its dual, the greatest fixpoint, is denoted $\nu Y.f(Y)$ ($\equiv \neg\mu Y.\neg f(\neg Y)$). Thus, e.g., $\mu Y.[B]Y$ is equivalent to $\neg \triangle B$ of PDL-delta. Similarly, using temporal logic, $\mu Y.P \vee AX_sY$ is equivalent to AFP (i.e., along all paths P eventually holds). Many correctness properties of concurrent programs can be characterized in terms of the Mu-calculus, including all those expressible in CTL* and PDL-delta. For more details, see, for example, [7, 19, 35, 12].

The *formulae* of the (propositional) Mu-calculus are

(1) propositional constants $P, Q, \dots,$

(2) propositional variables $Y, Z, \dots,$

(3) $\neg p$, $p \vee q$, and $p \wedge q$, where p and q are any formulae,

(4) EX_sp and AX_sp, where p is any formula,

(5) $\mu Y.f(Y)$ and $\nu Y.f(Y)$, where $f(Y)$ is any formula syntactically monotone in the propositional variable Y, i.e., all occurrences of Y in $f(Y)$ fall under even number of negations.

In what follows, we will use σ as a generic symbol for μ or ν. In a fixed point expression $\sigma Y.f(Y)$, we say that each occurrence of Y is *bound* to σY. If an occurrence of Y is not bound, then it is *free*. A *sentence* (or *closed formula*) is a formula containing no free propositional variables, i.e., no variables unbound by a μ or a ν operator.

Sentences are interpreted over structures $M = (S, R, L)$ as for CTL*. As usual we will write $M, s \models p$ to mean that in structure M at state s sentence p holds true. To give the technical definition of $\models$ we need some preliminaries.

The power set of S, 2^S, may be viewed as the complete lattice $(2^S, S, \phi, \subseteq, \cup, \cap)$. Intuitively, we identify a proposition with the set of states which make it true. Thus, $false$, which corresponds to the empty set, is the bottom element, $true$, which corresponds to S, is the top element, $\cup$ is join, $\cap$ is meet, and implication (for all $s \in S(P(s) \Rightarrow Q(s))$), which corresponds to simple set-theoretic containment ($P \subseteq Q$), provides the partial ordering on the lattice.

Let $\tau : 2^S \rightarrow 2^S$ be given; then we say that τ is *monotonic* provided $P \subseteq Q$ implies $\tau(P) \subseteq \tau(Q)$. A monotonic functional τ always has both a least fixpoint $\mu X.\tau(X)$ and a greatest fixpoint $\nu X.\tau(X)$.

For a formula or function $p(Y)$, we write $p^0(Y) = false$, $p^1(Y) = p(Y)$, $p^{i+1}(Y) = p(p^i)(Y)$ for successor ordinal $i+1$, and $p^j(Y) = \bigcup_{k<j} p^k(Y)$ for limit ordinal j.

THEOREM 2.1 (Tarski–Knaster). *Let $\tau : 2^S \rightarrow 2^S$ be a given monotonic functional. Then*

(a) $\mu Y.\tau(Y) = \bigcap\{Y : \tau(Y) = Y\} = \bigcap\{Y : \tau(Y) \subseteq Y\}$,

(b) $\nu Y.\tau(Y) = \bigcup\{Y : \tau(Y) = Y\} = \bigcup\{Y : \tau(Y) \supseteq Y\}$,

(c) $\mu Y.\tau(Y) = \bigcup_{i \leq |S|} \tau^i(false)$, *and*

(d) $\nu Y.\tau(Y) = \bigcap_{i \leq |S|} \tau^i(true)$.

A formula p with free variables $Y_0, Y_1, \dots, Y_n$ is thus interpreted as a mapping p^M from $(2^S)^{n+1}$ to 2^S, i.e., it is interpreted as a predicate transformer. We write $p(Y_0, Y_1, \dots, Y_n)$ to denote that all free variables of p are among $Y_0, Y_1, \dots, Y_n$. Let $V_0, V_1, \dots, V_n$ be subsets of S; then a *valuation* $\Upsilon = V_0, V_1, \dots, V_n$ is an assignment of $V_0, V_1, \dots, V_n$ to the free variables $Y_0, Y_1, \dots, Y_n$, respectively. $\Upsilon[Y_i \leftarrow V_i']$ denotes the valuation identical to Υ, except that Y_i is assigned V_i'. We use $p^M(\Upsilon)$ to denote the value of p in structure M on the arguments $V_0, V_1, \dots, V_n$. We drop M when it is understood from context. We then let $M, s \models p(\Upsilon)$ iff $s \in p^M(\Upsilon)$, and we define $\models$ inductively as follows:

(1) $s \models P(\Upsilon)$ iff $P \in L(s)$,

(2) $s \models Y(\Upsilon)$ iff $s \in \Upsilon(Y)$,
(3) $s \models (\neg p)(\Upsilon)$ iff $s \not\models p(\Upsilon)$,
$s \models (p \vee q)(\Upsilon)$ iff $s \models p(\Upsilon)$ or $s \models q(\Upsilon)$,
$s \models (p \wedge q)(\Upsilon)$ iff $s \models p(\Upsilon)$ and $s \models q(\Upsilon)$,
(4) $s \models (EX_s p)(\Upsilon)$ iff $\exists t(s,t) \in R$ and $t \models p(\Upsilon)$,
$s \models (AX_s p)(\Upsilon)$ iff (a) $\exists u\ (s,u) \in R$ and $u \models p$ and (b) for all $t\ (s,t) \in R$ implies $t \models p(\Upsilon)$,
(5) $s \models\ (\mu Y.f(Y))(\Upsilon)$ iff $s \in \bigcap\{S' \subseteq S | S' = \{t : t \models f(Y)(\Upsilon[Y \leftarrow S'])\}\}$,
$s \models\ (\nu Y.f(Y))(\Upsilon)$ iff $s \in \bigcup\{S' \subseteq S | S' = \{t : t \models f(Y)(\Upsilon[Y \leftarrow S'])\}\}$.

2.1.4. Conventions. To avoid a proliferation of unnecessary parentheses, we order the connectives from greatest to lowest *binding power* as follows: $\neg$ binds tighter than $F, G, X_w, X_s, \overset{\infty}{F}, \overset{\infty}{G}$, which bind tighter than $\wedge$, which binds tighter than $\vee$, which binds tighter than $\Rightarrow$, which binds tighter than U_w, U_s, which bind tighter than A, E, which bind tighter than μ, ν, which bind tighter than $\Leftrightarrow$.

If we write $M, s \models p$, it is implicit that s is a state of M. That is, $s \in S$ where $M = (S, R, L)$. A convenient abuse of notation is to write $s \in M$ in some places.

If p is a formula, then p^M denotes $\{s : M, s \models p\}$, the set of states s in M at which p is true.

We can write $M, s_1, \ldots, s_k \models p$ to abbreviate $M, s_1 \models p$ and $\ldots$ and $M, s_k \models p$.

We write $p \equiv q$ for $\models p \Leftrightarrow q$. In the context of a structure M, we can also write $p \equiv_M q$ for $p^M = q^M$. If M is understood, then we can drop the M and write just $p \equiv q$. It should be clear from context whether equivalence over all structures or over M is meant. We use $p_1 \equiv p_2 \equiv \cdots \equiv p_k$ as shorthand for $p_1 \equiv p_2$ and $\ldots$ and $p_{k-1} \equiv p_k$.

Technically, we distinguish between an atomic proposition symbol P and the associated set, viz., P^M, of states which are labeled with it in structure M. It is often convenient notation to use the uppercase sans serif symbol P corresponding to P to denote the set of states that are labeled with P.

Remark: We note the following identities:

$EX_w false \equiv AX_w false$ and asserts that a state has no successors.

$EX_s true \equiv AX_s true$ and asserts that a state has one or more successors.

2.2. Automata on infinite trees. We consider finite automata on labeled, infinite binary trees.[1] The set $\{0,1\}^*$ may be viewed as an infinite binary tree, where the empty string λ is the root node and each node u has two successors: the 0-successor $u0$ and the 1-successor $u1$. A finite (infinite) path through the tree is a finite (respectively, infinite) sequence $x = u_0, u_1, u_2, \ldots$ such that each node u_{i+1} is a successor of node u_i. If Σ is an alphabet of symbols, an infinite binary Σ-*tree* is a labeling L which maps $\{0,1\}^* \longrightarrow \Sigma$.

A *finite automaton* $\mathcal{A}$ on infinite binary Σ-trees consists of a tuple $(\Sigma, Q, \delta, q_0, \Phi)$, where

Σ is the finite, nonempty input alphabet labeling the nodes of the input tree,
Q is the finite, nonempty set of states of the automaton,
$\delta : Q \times \Sigma \rightarrow 2^{Q \times Q}$ is the nondeterministic transition function,

[1]We consider here only binary trees to simplify the exposition and for consistency with the classical theory of tree automata. CTL* and the other logics we study have the property that their models can be unwound into an infinite tree. In particular, in [13] it was shown that a CTL* formula of length k is satisfiable iff it has an infinite tree model with finite branching bounded by k, i.e., iff it is satisfiable over a k-ary tree. Our results on tree automata apply to such k-ary trees as explained at the end of the proof of Theorem 4.1.

$q_0 \in Q$ is the start state of the automaton, and

Φ is an acceptance condition described subsequently.

A *run* of $\mathcal{A}$ on the input Σ-tree L is a function $\rho : \{0,1\}^* \to Q$ such that for all $v \in \{0,1\}^*$, $(\rho(v0), \rho(v1)) \in \delta(\rho(v), L(v))$ and $\rho(\lambda) = q_0$. We say that $\mathcal{A}$ *accepts* input tree L iff there exists a run ρ of $\mathcal{A}$ on L such that for all infinite paths x starting at the root of L if $r = \rho \circ x$ is the sequence of states $\mathcal{A}$ goes through along path x, then the acceptance condition Φ holds along r.

For a *pairs* automaton (cf. [23, 30]) acceptance is defined in terms of a finite list $((\mathsf{RED}_1, \mathsf{GREEN}_1), \ldots, (\mathsf{RED}_k, \mathsf{GREEN}_k))$ of pairs of sets of automaton states (which may be thought of as pairs of colored lights where $\mathcal{A}$ flashes the red light of the first pair upon entering any state of the set RED_1, etc.): r satisfies the pairs condition iff there exists a pair $i \in [1..k]$ such that RED_i flashes finitely often and GREEN_i flashes infinitely often. We assume the pairs acceptance condition is given formally by a temporal logic formula $\Phi = \bigvee_{i \in [1..k]} (GF\ \mathrm{GREEN}_i \wedge \neg GF\ \mathrm{RED}_i)$.[2] Similarly, a *complemented pairs* (cf. [33]) automaton has the negation of the pairs condition as its acceptance condition; i.e., for all pairs $i \in [1..k]$, GREEN_i flashes infinitely often implies that RED_i flashes infinitely often, too. The complemented pairs acceptance condition is given formally by a temporal logic formula $\Phi = \bigwedge_{i \in [1:k]} GF\ \mathrm{GREEN}_i \Rightarrow GF\ \mathrm{RED}_i$.

3. Small model theorems.

3.1. Tree automata running on graphs.

Note that an infinite binary tree L' may be viewed as a "binary" structure $M = (S, R, L)$, where $S = \{0,1\}^*$, $R = R_0 \cup R_1$ with $R_0 = \{(s, s0) : s \in S\}$ and $R_1 = \{(s, s1) : s \in S\}$, and $L = L'$. We could alternatively write $M = (S, R_0, R_1, L)$.

We can also define a notion of a tree automaton running on certain appropriately labeled binary, directed graphs that are not binary trees. Such graphs, if accepted, are witnesses to the nonemptiness of tree automata. We make the following definitions.

A *binary structure* $M = (S, R_0, R_1, L)$ consists of a state set S and labeling L as before, plus a transition relation $R_0 \cup R_1$ decomposed into two partial functions: $R_0 : S \longrightarrow S$, where $R_0(s)$, when defined, specifies the 0-successor of s, and $R_1 : S \longrightarrow S$, where $R_1(s)$, when defined, specifies the 1-successor of s. We say that M is a *full binary structure* iff R_0 and R_1 are total.

A *run* of automaton $\mathcal{A}$ on binary structure $M = (S, R_0, R_1, L)$, if it exists, is a mapping $\rho : S \to Q$ such that for all $s \in S$, $(\rho(R_0(s)), \rho(R_1(s))) \in \delta(\rho(s), L(s))$, and $\rho(s_0) = q_0$. Intuitively, a run is a labeling of M with states of $\mathcal{A}$ consistent with the local structure of $\mathcal{A}$'s transition diagram. It will turn out that if an automaton accepts some binary tree, there does exist some finite binary graph on which there is a run that is *accepting*: all of the paths through the graph define state sequences of the automaton meeting its acceptance condition.

3.2. The transition diagram of a tree automaton.

The transition diagram of $\mathcal{A}$ can be viewed as an AND/OR-graph, where the set Q of states of $\mathcal{A}$ comprises the set of OR-nodes, while the AND-nodes define the allowable moves of the automaton. Intuitively, OR-nodes indicate that a nondeterministic choice has to be made (depending on the input label), while the AND-nodes force the automaton along all directions. For example, suppose that for automaton $\mathcal{A}$, $\delta(s, a) = \{(t_1, u_1), \ldots, (t_m, u_m)\}$ and $\delta(s, b) = \{(v_1, w_1), \ldots, (v_n, w_n)\}$; then the transition diagram contains the portion shown in Figure 3.1.

[2]We are assuming that each proposition symbol, such as GREEN_i, of formula Φ is associated

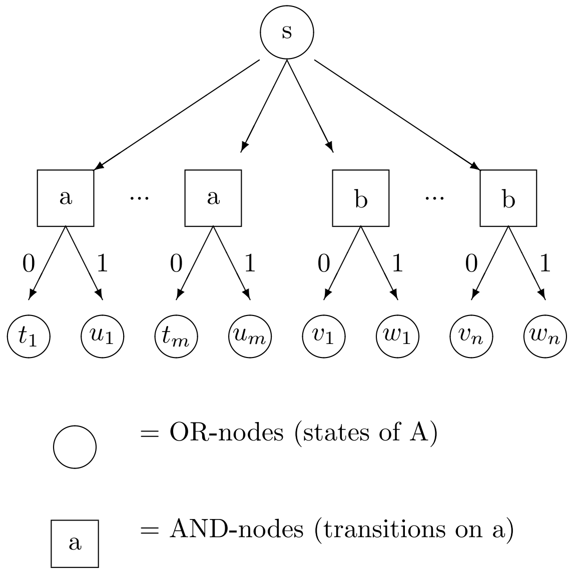

FIG. 3.1.

Formally, given a tree automaton $\mathcal{A} = (\Sigma, Q, \delta, q_0, \Phi)$ with transition function $\delta : Q \times \Sigma \longrightarrow 2^{Q \times Q} : (q, a) \longmapsto \{(r_1, s_1), \ldots, (r_k, s_k)\}$, we may view it as defining a transition diagram T, which is an AND/OR-graph $(D, C, R_{DC}, R_{CD0}, R_{CD1}, L)$, where

$D = Q$ is the set of OR-nodes;

$C = \bigcup_{q \in D} \bigcup_{a \in \Sigma} \{((q, a), (r, s)) : (r, s) \in \delta(q, a)\}$ is the set of AND-nodes. Each AND-node corresponds to a transition. If $\delta(q, a) = \{(r_1, s_1), \ldots, (r_k, s_k)\}$, then the corresponding AND-nodes are essentially the pairs $(r_1, s_1), \ldots, (r_k, s_k)$. However, since each transition is associated with a unique current state/input symbol pair (q, a), we formally define the corresponding AND-nodes to be pairs of pairs: $((q, a), (r_1, s_1)), \ldots, ((q, a), (r_k, s_k))$.

$R_{DC} \subseteq D \times C$ specifies the AND-node successors of each OR-node. For each $q \in D$ as above, $R_{DC}(q) = \bigcup_{a \in \Sigma} \{((q, a), (r, s)) : (r, s) \in \delta(q, a)\}$;[3]

$R_{CD0}, R_{CD1} : C \longrightarrow D$ are partial[4] functions giving the 0-successor and 1-successor states, respectively:

$$R_{CD0}(((q, a), (r, s))) = r \quad \text{and} \quad R_{CD1}(((q, a), (r, s))) = s;$$

L is a labeling of nodes. For an AND-node $L(((q, a), (r, s))) = \{a\}$, where $a \in \Sigma$. For an OR-node, the labeling assigns propositions associated with the acceptance condition Φ so that all OR-nodes in the set GREEN_i (respectively, RED_i) are labeled with the corresponding proposition GREEN_i (respectively, RED_i).

with exactly the set of states of the corresponding name, in this case GREEN_i.

[3]We identify a relation such as $R_{DC} \subseteq D \times C$ with the corresponding function $R'_{DC} : D \longrightarrow 2^C$ defined by $R'_{DC}(d) = \{c \in C : (d, c) \in R_{DC}\}$ for each $d \in D$.

[4]For classically defined tree automata, the functions R_{CD0}, R_{CD1} are total so that there is always a 0-successor and 1-successor automaton state. For technical reasons it is convenient to allow R_{CD0}, R_{CD1} to be partial.

Thus, we may write a tree automaton A in the form (T, d_0, Φ), where T is the diagram, d_0 is the start state, and Φ is an acceptance condition.

3.3. One symbol alphabets. For purposes of testing nonemptiness, without loss of generality, we can restrict our attention to tree automata over a single letter alphabet and, thereby, subsequently ignore the input alphabet. Let $\mathcal{A} = (Q, \Sigma, \delta, q_0, \Phi)$ be a tree automaton over input alphabet Σ. Let $\mathcal{A}' = (Q, \Sigma', \delta', q_0, \Phi)$ be the tree automaton over one letter input alphabet $\Sigma' = \{c\}$ obtained from $\mathcal{A}$ by, intuitively, taking the same transition diagram but now making all transitions on symbol c. Formally, $\mathcal{A}'$ is identical to $\mathcal{A}$ except that the input alphabet is Σ' and the transition function δ' is defined by $\delta'(q, c) = \bigcup_{a \in \Sigma} \delta(q, a)$.

Observation 3.1. The set accepted by $\mathcal{A}$ is nonempty iff the set accepted by $\mathcal{A}'$ is nonempty.

Henceforth, we shall therefore assume that we are dealing with tree automata over a one symbol alphabet.

3.4. Generation and containment. It is helpful to reformulate the notion of run to take advantage of the AND/OR-graph organization of the transition diagram of an automaton. Intuitively, there is a run of diagram T on structure M provided M is "generated" from T by unwinding T so that each state of M is a copy of an OR-node of T.

Formally, we say that a binary structure $M = (S, R_0, R_1, L)$ is *generated by* a transition diagram $T = (D, C, R_{DC}, R_{CD0}, R_{CD1}, L_T)$ (starting at $s_0 \in S$ and $d_0 \in D$) iff $\exists$ is a total function $h : S \longrightarrow D$ such that for all $s \in S$

```
    if $s$ has any successors in $M$, then
        $\exists c \in R_{DC}(h(s))$
            for all $i \in \{0, 1\}$  $R_{CDi}(c)$ is defined iff $R_i(s)$ is defined and
                                      $R_{CDi}(c) = h(R_i(s))$ when both are defined
    and $L(s) = L_T(h(s))$
    (such that $h(s_0) = d_0$).
```

We say that a binary structure $M = (S, R_0, R_1, L)$ is *contained in* transition diagram T (starting at $s_0 \in M$ and $q_0 \in T$) provided M is generated by T (starting at $s_0 \in M$ and $q_0 \in T$), where the generation function h is the natural injection $h : S \longrightarrow D : s \in S \longmapsto s \in D$, so that all states of M are OR-nodes of T.

Note that if M is a structure generated by (respectively, contained in) T, there is an associated AND/OR-graph H generated by (respectively, contained in) T obtained from M by inserting between each state and its successors in M a copy of the AND-node that determines the successors of state via the generation function for M. We write $H = ao(M)$. Conversely, if H is an AND/OR-graph generated by (respectively, contained in) T, there is an associated structure M generated by (respectively, contained in) T obtained from H by eliding AND-nodes. Here we write $M = o(H)$.

3.5. Linear size model theorems. The following theorem (cf. [6]) is the basis of our method of testing nonemptiness of pairs automata. It shows that there is a small binary structure contained in the transition diagram and accepted by the automaton.

THEOREM 3.2 (linear size model theorem). *Let $\mathcal{A}$ be a tree automaton over a one symbol alphabet with pairs acceptance condition $\Phi = \bigvee_{i \in [1:k]} (\overset{\infty}{F} Q_i \wedge \overset{\infty}{G} P_i)$. Then automaton $\mathcal{A}$ accepts some tree T iff $\mathcal{A}$ accepts some binary model M of size linear in the size of $\mathcal{A}$, which is a structure contained in the transition diagram of $\mathcal{A}$.*

Proof. ($\Rightarrow$) For Φ a pairs condition, by the Hossley–Rackoff [18] finite model theorem, if $\mathcal{A}$ accepts some tree M_0, then it accepts some finite binary model M_1 starting at some state $s_0 \in M_1$. Thus, $M_1, s_0 \models A\Phi$ and M_1 is a structure generated by $\mathcal{A}$.

Given any such finite structure M_1 of $A\Phi$ generated by $\mathcal{A}$, we can obtain a finite structure M contained in $\mathcal{A}$ as follows. Let h be the generation function. If two distinct nodes s and t of M_1 have the same labeling with states of $\mathcal{A}$, i.e., $h(s) = h(t)$, then we can eliminate one of them as follows. Attempt to delete s by redirecting all its predecessors u to have t as a successor instead. More precisely, delete all edges of the form (u, s) and replace them by edges of the form (u, t). If the resulting structure, call it M^t, is a model of $A\Phi$, we have reduced the number of "duplicates," such as s and t, by one. If not, try replacing t by s instead. If M^s, the resulting structure is a model of $A\Phi$ and we are done.

However, if both of these replacements fail to yield a model of $A\Phi$, each must introduce a (not necessarily simple) bad cycle where the acceptance condition Φ fails. In M^t the bad cycle is of the form (where u is a predecessor of s in M_1) $u \rightarrow t \rightarrow \cdots \rightarrow u$, where except for the first transition (u, t) the suffix path from t to u is in the original M_1. In M^s the bad cycle is of the form (where v is a predecessor of t in M_1) $v \rightarrow s \rightarrow \cdots \rightarrow v$, where except for the first transition (v, s) the suffix path from s to v is in the original M_1.

However, these two suffix paths in M_1 together with the edges (u, s) and (v, t) in M_1 form a bad cycle in M_1: $u \rightarrow s \rightarrow \cdots \rightarrow v \rightarrow t \rightarrow \cdots \rightarrow u$. This contradicts that M_1 was a model of $A\Phi$.

By repeatedly eliminating duplicates in this way we eventually get the desired model M contained in $\mathcal{A}$.

($\Leftarrow$) Any model M contained in $\mathcal{A}$ such that $M, s_0 \models A\Phi$ can plainly be unwound into a tree that is accepted by $\mathcal{A}$. $\square$

A helpful generalization follows.

THEOREM 3.3 (generalized linear sized model theorem). *Let $s_0, s_1, \ldots, s_k$ ($k \geq 0$) be distinct elements of T and formula $g = P \wedge A(\Phi \vee FR)$, where $\Phi = \bigvee_{i \in [1:k]} (\overset{\infty}{F} Q_i \wedge \overset{\infty}{G} P_i)$ is a pairs acceptance condition and P, R are atomic propositions. Then,*

$\exists M'$ generated by T such that $M', s_0, s_1, \ldots, s_k \models g$

iff

$\exists M$ contained in T such that $M, s_0, s_1, \ldots, s_k \models g$.

Proof. ($\Rightarrow$) Assume the existence of M'. We first show that this implies the existence of M'' generated by T such that

$$M'', s_0, s_1, \ldots, s_k \models P \wedge A(\Phi \vee FR) \text{and for all} \quad s \in M'',\ M'', s \models A(\Phi \vee FR)$$

.

Intuitively, M'' is obtained by deleting spurious nodes from M', retaining just those nodes which are in the "cone" from some s_i until some R-node, if any, is encountered. Technically, let $S = \{t \in M'$: there exists a path from some s_i to t in M', all of whose nodes except (possibly) t itself satisfy $\neg R\}$. Let $S' = M' \setminus S$.

Thus, S' consists of all nodes that can be reached only from any s_i by going through some R-node. Now, delete all successor arcs of R-nodes, and then delete all nodes no longer reachable from some s_i. Note that the deleted nodes are exactly S'. Call the resulting substructure of M' so obtained M''. Note that the nodes retained in M'' are exactly S and that M'' is still generated by T.

Now observe that $A(\Phi \vee FR) \equiv A(A(\Phi \vee FR)\, U_w\, R)$. Therefore, for all $t \in S$, $M', t \models A(\Phi \vee FR)$. Hence, for all $t \in S$, $M'', t \models A(\Phi \vee FR)$, as the only nodes deleted in M'' are the ones which are reached from any s_i by going through some R-node. Thus, $M'', s_0, s_1, \ldots, s_k \models A(\Phi \vee FR) \wedge P$, and for all $s \in M''$, $M'', s \models A(\Phi \vee FR)$.

Any fullpath starting at any node in M'' either

(i) is infinite and satisfies Φ, or

(ii) is finite, terminating in an R-node.

We can now argue, just as in the linear size model theorem, that duplicates can be eliminated. If u and v are duplicates, we can attempt to replace u by v. The only problem is that it may introduce a "bad" cycle satisfying $\neg\Phi$. In that case, it must be possible to replace v by u, for otherwise there would be a bad cycle, i.e., an infinite fullpath satisfying $\neg\Phi$ in the original M''. Continuing in this fashion, we get a structure M with no duplicates. It is isomorphic to a structure contained in T with the desired properties, i.e., $M, s_0, s_1, \ldots, s_k \models P \wedge A(\Phi \vee FR)$.

($\Leftarrow$) By definition, any model M contained in T is also generated by T. ◻

3.6. Pseudomodels. The linear size model theorem also suggests the following.

DEFINITION 3.4. *Let $T = (D, C, R_{DC}, R_{CD0}, R_{CD1}, L_T)$ be the transition diagram of a tree automaton $\mathcal{A}$, let s be a state of $\mathcal{A}$, and let p be a formula.*

- We say that diagram T at state s is a *pseudomodel* of p (or that p is *satisfiable* in T at s) and write $T, s \,\|\!-_{con}\, p$ iff there exists a structure M contained in T such that $M, s \models p$. We also write $p^{T,con}$ for $\{s \in T : T, s \|\!-_{con} p\}$.
- We say p is *generable* in T at s and write $T, s \|\!-_{gen} p$ iff there exists a structure M generated by T such that $M, s \models p$. We also write $p^{T,gen}$ for $\{s \in T : T, s \|\!-_{gen} p\}$.
- We say p is *true* (or *modeled*) in T at s, considered simply as a structure with state set $D \cup C$ and transition relation $R_{CD} \cup R_{DC0} \cup R_{DC1}$ iff $T, s \models p$. We also write $p^{T,\mathrm{mod}}$ for $\{s \in T : T, s \models p\}$.

Remark. For a proposition symbol P we have $P^{T,\mathrm{mod}} = P^{T,con} = P^{T,gen}$.

Our overall approach to testing nonemptiness can now be summarized in the following rephrasing of the linear size model theorem.

THEOREM 3.5. *Automaton $\mathcal{A}$ with diagram T and pairs acceptance condition Φ is nonempty iff $q_0 \in A\Phi^{T,con}$.*

We will check nonemptiness by calculating $A\Phi^{T,con}$ by a process of "pseudomodel checking" (cf. [4]*).*

4. Complexity of pairs tree automata. In this section we prove that nonemptiness of pairs tree automata can be tested in time polynomial in the number of states and exponential in the number of pairs, even though, as we show, the problem is NP-complete in general.

THEOREM 4.1. *Nonemptiness of a pairs automaton $\mathcal{A}$ having m states and n pairs can be tested in deterministic time $(mn)^{O(n)}$.*

Proof. Let $\mathcal{A}$ be a tree automaton with transition diagram T of size m states and pairs acceptance condition $\Phi_\Gamma = \bigvee_{\gamma \in \Gamma} (GFQ_\gamma \wedge FGP_\gamma)$, where Γ is the index set $[1:n]$ of pairs. Here, Q_γ and P_γ stand for GREEN$_\gamma$ and $\neg$RED$_\gamma$, respectively. When Γ is understood from context we can drop it and write just Φ for Φ_Γ. We also let $\Phi_{-\gamma}$ denote $\Phi_{\Gamma \setminus \{\gamma\}}$.

The basic idea of the algorithm is to inductively compute the set of states in T at which $A\Phi$ is satisfiable, viz., $A\Phi^{T,con} = \{s \in T : T, s \|\!-_{con} A\Phi\}$. For this purpose, we use the fixpoint characterization $\mu Y.\tau(Y)$ of $A\Phi$ from Lemma 4.2 below and evaluate it iteratively using the Tarski–Knaster theorem specialized to pseudomodel checking in Lemma 4.3 below. To compute each $Y^{i+1} = \tau(Y^i)$ we evaluate the body $\tau(Y)$ compositionally,[5] using Lemmas 4.2–4.9 as appropriate. This in turn entails the recursive calculation of (essentially) $A\Phi_{-\gamma}$ with one fewer pair. The recursion terminates when $\Phi_{-\gamma} \equiv false$ has 0 pairs, in which case Lemma 4.4 is used instead of Lemma 4.3. For technical reasons, we actually pseudomodel check a modified pairs condition of the form $A(\Phi \vee FR)$, which specializes to the ordinary pairs conditions when $R \equiv false$.

If each OR-node in T had a unique successor, then the pseudomodel checking of $A(\Phi \vee FR)$ would simply amount to model checking in the Mu-calculus [12]. But in general, each OR-node has more than one successor. Therefore, our algorithm must simultaneously exhaust the search space of all structures contained in T and check if one of these structures is a model of the pairs condition. Lemmas 4.2–4.9 below permit both steps to be done together, thereby performing the desired pseudomodel checking. The proofs of the lemmas are given in Appendix A.

LEMMA 4.2 (fixpoint characterization for modified pairs condition). *Let* $\Phi = \vee_\gamma(\overset{\infty}{G}P_\gamma \wedge \overset{\infty}{F}Q_\gamma)$ *denote the pairs condition where* $\Gamma = [1:n]$*; let R be propositional. Then* $A(\Phi \vee FR) \equiv \mu Y.\tau(Y)$, *where* $\tau(Y) = R \vee \vee_\gamma AX_sA(g_\gamma U_w R)$ *and* $g_\gamma = A(\Phi_{-\gamma} \vee F(R \vee Q_\gamma)) \wedge (P_\gamma \vee Y) \wedge AX_s true$.

LEMMA 4.3 (pseudomodel checking via Tarski–Knaster approximation[6]). *Set* $\mathsf{Y}^0 := false^{T,con}$*; set* $\mathsf{Y}^{i+1} := \tau(Y^i)^{T,con}$. *Then* $A(\Phi \vee FR)^{T,con} = \mu Y.\tau(Y)^{T,con} = \bigcup_{i \le |T|} \mathsf{Y}^i$.

LEMMA 4.4 (pseudomodel checking inevitability).

$$AFR^{T,con} = (\mu V.R \vee EX_sAX_sV)^{T,\mathrm{mod}}.$$

Observation 4.5 (pseudomodel checking of disjunctions).

$$(R \vee \bigvee_\gamma (AX_sA[g_\gamma U_w R]))^{T,con} = R^{T,con} \cup \bigcup_\gamma (AX_sA[g_\gamma U_w R])^{T,con}.$$

Observation 4.6 (pseudomodel checking of nexttime).

$$(AX_sA[g_\gamma U_w R])^{T,con} = \{s \in T : T, s \models EX_sAX_sW\}, \mathrm{where} \mathsf{W} = A[g_\gamma U_w R]^{T,con}.$$

DEFINITION 4.7. *Let U be a transition diagram for an automaton, and let Z be a set of OR-nodes of U. We define the AND/OR-graph denoted $U|\mathsf{Z}$, called U* restricted to Z, *to be the result of deleting from U all OR-nodes not in Z and incident arcs, and then deleting all AND-nodes, which do not have all successors in Z, along with all incident arcs. By a convenient abuse of notation, we shall write Z for $U|\mathsf{Z}$ when it is clear that an AND/OR-subgraph of U is intended. In particular, if f is a temporal formula, we write $f^{\mathsf{Z},con}$ for $f^{U|\mathsf{Z},con}$.*

LEMMA 4.8 (pseudomodel checking of weak until). *Set* $\mathsf{Z}^0 := true^{T,con}$*; set* $\mathsf{Z}^{i+1} := ((g_\gamma \wedge AX_sZ^i) \vee R)^{\mathsf{Z}^i,con}$. *Then for some least k,* $\mathsf{Z}^k = \mathsf{Z}^{k+1}$ *is the fixpoint of the descending chain* $\mathsf{Z}^i \supseteq \mathsf{Z}^{i+1}$ *and* $A[g_\gamma U_w R]^{T,con} = \mathsf{Z}^k$.

[5]That is, by induction on formula structure.

[6]It is to be understood below that "set $\mathsf{Y}^{i+1} := \tau(Y^i)^{T,con}$," for example, means to assign to the set Y^{i+1} exactly the set of states in $\tau(Y^i)^{T,con}$ and label the resulting states in the set Y^{i+1} with the symbol Y^{i+1}

LEMMA 4.9 (pseudomodel checking of conjunctions in g_γ). $g_\gamma^{T,con} = A(\Phi_{-\gamma} \vee F(R \vee Q_\gamma))^{T,con} \cap (P_\gamma \vee Y)^{T,con} \cap AX_s true^{T,con}$.

Finally, we analyze the complexity as follows. Let $Com(T, f)$ stand for the complexity of computing $\{s|T, s \,\|\!- f\}$. For size of the transition diagram $|T| = m$, and number of pairs $|\Gamma| = n$, let $C(m, n)$ denote $Com(T, A(\Phi_\Gamma \ \vee \ R))$.

$$\begin{aligned} Com(T, A(\Phi_\Gamma \ \vee \ FR)) &\leq O(m) \cdot Com(T, Y^i), \\ Com(T, Y^i) &\leq n \cdot Com(T, R \vee AX_s A(g_\gamma U_w R)), \\ Com(T, R \vee AX_s A(g_\gamma U_w R)) &\leq O(m) + O(m) \cdot Com(Z^i, g_\gamma \ \wedge \ AX_s Z^i), \\ Com(Z^i, g_\gamma \ \wedge \ AX_s Z^i) &\leq O(m) + Com(U, A(\Phi_{\Gamma \setminus \{\gamma\}} \ \vee FR')), \end{aligned}$$

where $|Z^i|, |U| \ \leq \ |T|$. Thus, for some constant $k > 0$ we have

$$\begin{aligned} C(m, n) &\leq kmn(km + km(km + C(m, n-1))) \\ &= kmn(km + k^2m^2 + kmC(m, n-1)) \\ &= k^2m^2n + k^3m^3n + k^2m^2nC(m, n-1) \\ &\leq 2k^3m^3n + k^2m^2nC(m, n-1). \end{aligned}$$

The above accounts for the cost for 1 or more pairs ($n > 0$). Lemma 4.4 implies $n = 0$ pairs can be handled in $O(m)$ time. Hence, for some sufficiently large constant $c \geq 2k^3$ we have

$$\begin{aligned} &C(m, n) \leq cm^3n + cm^2nC(m, n-1), \\ &C(m, 0) \leq cm. \end{aligned}$$

We must thus solve a recurrence of the form

$$\begin{aligned} &C(m, n) = x + yC(m, n-1), \\ &C(m, 0) = z, \end{aligned}$$

which is readily expanded to show that its solution is $x(y^n - 1) + y^n z \leq y^n(x + z)$. It follows that $C(m, n)$ is at most

$$\begin{aligned} &= (cm + cm^3n)(cm^2n)^n \\ &\leq (dm^3n)(dm^2n)^n \text{ for some constant } d > 2c \\ &= d^{n+1}m^{2n+3}n^{n+1} \\ &\leq n^{n+1}m^{2n+3}n^{n+1} \text{ for all } n \geq d \\ &\leq (mn)^{2n+3} \\ &= (mn)^{O(n)} \text{ for all } n, m \geq 1. \end{aligned}$$

Note that m is the size of the transition diagram, which for an automaton on binary trees can be cubic in the number of states, m_0, i.e., $m = O(m_0^3)$. As a function of the number of states, however, we still get the same order of growth, i.e., $(mn)^{O(n)} = (m_0^3 n)^{O(n)} = (m_0 n)^{3 \cdot O(n)} = (m_0 n)^{O(n)}$. In general, for k-ary trees, the size of the transition diagram m can be $O(m_0^{k+1})$. Thus we get time $(m_0 n)^{(k+1)O(n)}$. This is still $(m_0 n)^{O(n)}$ for fixed k. Moreover, if k grows linearly with n, the bound is still $(m_0 n)^{O(n^2)}$, which is sufficient for obtaining the complexity bounds on logics of programs of section 6. $\square$

THEOREM 4.10. *Pairs tree automaton nonemptiness is NP-complete.*

Proof. Pairs automaton nonemptiness was shown to be in NP in [6]: a nondeterministic Turing machine can guess a linear size model M contained in the automaton diagram and verify that it satisfies the acceptance condition using the model checking algorithm for fairness of [11b] (cf. [41]).

To show NP-hardness we reduce from 3-SAT. Let f be a 3-CNF formula with m clauses $C_1, C_2, \ldots, C_m$ over n variables $v_1, \ldots, v_n$. We will reduce satisfiability of f to the nonemptiness problem of a pairs tree automaton $\mathcal{A}$ with number of states and pairs polynomial in $|f|$.

We will describe $\mathcal{A}$ in terms of its AND/OR-graph transition diagram as usual and pairs acceptance condition.[7] Since we are only concerned about the nonemptiness problem, $\mathcal{A}$ is assumed to have a one symbol alphabet. Corresponding to each clause C_i of f, $\mathcal{A}$ will have an OR-node of the same name, C_i. For each possible literal x, i.e., for each variable v_j and its negation $\neg v_j$, there is an AND-node of the same name, x. If clause C_i contains literal x, then there is an edge $C_i \to x$ in the diagram. If clause C_i contains the literal $\neg x$, then there is an edge $x \to C_i$ in the diagram. Here we identify $\neg\neg x$ with x. We also let S_0 be the start state OR-node with a single AND-node successor which has as its successors $C_1, \ldots, C_m$. Finally, for each literal x there is a pair of lights (GREEN_x, RED_x) such that GREEN_x colors AND-node x and RED_x colors AND-node $\neg x$. Let Φ be the corresponding pairs condition.

The basic idea is that a structure M contained in (the diagram of) $\mathcal{A}$ specifies a choice of literal for each clause. From these literals we can try to recover a satisfying truth assignment for f and vice versa. However, there may be conflicts with one clause using x, another $\neg x$. The following argument shows that there is a conflict-free choice of literals when there is an M satisfying $A\Phi$.

The following claims are equivalent:

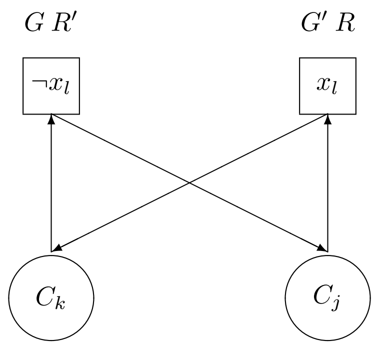
(i) $\mathcal{A}$ is nonempty.
(ii) There is a structure M contained in $\mathcal{A}$, accepted by $\mathcal{A}$ so that $M, S_0 \models A\Phi$.
(iii) There exists $H = ao(M)$, where M is contained in $\mathcal{A}$, such that in H, each C_j has an edge to some x_l and no other C_k has an edge to the negation of x_l.
(iv) f is satisfiable.

Claims (i) and (ii) are equivalent by the linear size model theorem. The equivalence of (iii) and (iv) is immediate from the construction of $\mathcal{A}$. The equivalence of (ii) and (iii) follows from a slightly sharper equivalence. Let $H = ao(M)$, where M is contained in $\mathcal{A}$. Then the following are equivalent:

(ii)′ $M, S_0 \models A\Phi$.
(iii)′ In H, each C_j has an edge to some x_l and no other C_k has an edge to the negation of x_l.

Condition (iii)′ implies that for every green light labeling a node in H, its corresponding red light does not occur in H. Hence, along every infinite path some green light appears infinitely often but its corresponding red light never appears, and Φ holds along the path. Condition (ii)′ follows. Now assume (ii)′. Then M is total as is H. It must be that (iii)′ holds of H. Otherwise, there is a C_j with an edge to x_l and a C_k with an edge to $\neg x_l$. Then we have the following subgraph in H.

[7] We will actually describe the diagram of an automaton on trees of arity at most m, where, moreover, the propositions (or "colors") defining acceptance label AND-nodes rather than OR-nodes. It is not difficult to show that it can be converted into an "equivalent, ordinary" automaton. Here "equivalent" means that the original automaton accepts iff the derived automaton accepts. Conversion to a binary tree automaton is effected by inserting "dummy" nodes in the transition diagram to reduce fan-in m to fan-in 2. This causes a linear blowup in size. The acceptance condition colors can be moved to the OR-nodes by having each derived node be of the form (OR-node, AND-node predecessor causing transition). This can cause a quadratic blowup in size.



Here $(G,\ R)$ and $(G',\ R')$ are the pairs corresponding to the literals x_l and $\neg x_l$, respectively. The arcs $x_l \to C_k$ and $\neg x_l \to C_j$ exist by definition of $\mathcal{A}$, considering that $\neg x_l$ is in C_k and x_l is in C_j. The above subgraph generates a path which has for all green lights flashing infinitely often its corresponding red light flashing infinitely often, too. But then there would be a "bad" path in M violating Φ, contrary to our assumption of (ii)$'$. The equivalence of (ii) and (iii) follows. This completes the reduction. □

5. Complexity of complemented pairs tree automata. In this section, we will show that there is also a deterministic algorithm to test nonemptiness of a complemented pairs tree automaton (cf. [33]) which runs in time $(mn)^{O(n)}$, where m is the number of states of the automaton and n is the number of pairs in its acceptance condition. Moreover, we will show that testing nonemptiness of such automata is co-NP-complete.

The key idea is that for a tree automaton $\mathcal{A}$ over a one symbol alphabet we can define its dual tree automaton $\tilde{\mathcal{A}}$ such that $\mathcal{A}$ is nonempty iff $\tilde{\mathcal{A}}$ is empty. The dual is essentially obtained by swapping AND-nodes with OR-nodes and complementing the acceptance condition. Since we view the transition diagram of a nondeterministic tree automaton as a bipartite AND/OR graph, the dual is also a bipartite AND/OR graph and hence can be viewed as a nondeterministic automaton. Moreover, the dual of a pairs automaton is a complemented pairs automaton and vice versa. Muller and Schupp also define a dual automaton in [24], but for a nondeterministic automaton their dual automaton is in general an alternating automaton. For the purpose of checking nonemptiness of automata over one symbol alphabets, the dual defined in this new way suffices.

For an automaton $\mathcal{A}$ and its dual $\tilde{\mathcal{A}}$, we are interested in showing that $\mathcal{A}$ is nonempty iff $\tilde{\mathcal{A}}$ is empty. In other words, we must show that

$$\exists \text{ Run } \rho \text{ of } \mathcal{A} \quad \text{for all paths in } \rho \quad \Phi_{\mathcal{A}} \tag{5.1}$$

$$\equiv \neg\ \exists \text{ Run } \rho \text{ of } \tilde{\mathcal{A}} \quad \text{for all paths in } \rho \quad \Phi_{\tilde{\mathcal{A}}}, \tag{5.2}$$

where $\Phi_{\mathcal{A}}$ is the acceptance condition of $\mathcal{A}$ and $\Phi_{\tilde{\mathcal{A}}} \equiv \neg\Phi_{\mathcal{A}}$ is the acceptance condition of $\tilde{\mathcal{A}}$. We can argue this informally as follows. By expanding (1) we get that

$$(1) \equiv \forall! d_0 \exists c_0 \forall d_1 \exists c_1 \forall d_2 \exists c_2 \ldots\ d_0 c_0 d_1 c_1 d_2 c_2 \ldots \models \Phi_{\mathcal{A}},$$

meaning that for the unique start OR-node d_0 of $\mathcal{A}$ there exists an AND-node successor c_0 such that for all OR-node successors d_1 of c_0 there exists an AND-node successor

c_1, etc., ad infinitum such that $d_0c_0d_1c_1d_2c_2\ldots \models \Phi_{\mathcal{A}}$. Similarly, by expanding (2), we get that

$$(2) \equiv \neg\forall! e_0 \exists! d_0 \forall c_0 \exists d_1 \forall c_1 \exists d_2 \forall c_2 \ldots\ e_0d_0c_0d_1c_1d_2c_2\ldots \models \neg\Phi_{\mathcal{A}},$$

where e_0 is the unique "dummy" start state of $\tilde{\mathcal{A}}$, all of whose successors are d_0. (This is explained in more detail below.) Applying the well-known quantifier negation law to the infinite string of quantifiers for (2), we get after driving the negation inside that

$$(2) \equiv \exists! e_0 \forall! d_0 \exists c_0 \forall d_1 \exists c_1 \forall d_2 \exists c2 \ldots\ e_0d_0c_0d_1c_1d_2c_2\ldots \models \Phi_{\mathcal{A}}.$$

Since the truth of $\Phi_{\mathcal{A}}$ is oblivious to the initial e_0 we should be able to conclude that (1) $\equiv$ (2) as desired. But the quantifier negation law for infinite strings of quantifiers is known to contradict the axiom of choice in general. Therefore to formally prove the above, we show that the set of paths $\Phi_{\mathcal{A}}$ and its complement are "nice" in the sense that they are finite automaton definable (and hence Borel) and conclude the desired equivalence using Martin's theorem on determinacy of infinite Borel games (cf. [22]).[8]

The above notions are formalized in what follows.

Definition 5.1. *Let λ denote the empty sequence. For an infinite sequence $x_0x_1\ldots$, let x^i be the suffix $x_ix_{i+1}\ldots$. In particular, tail(x) stands for x^1. If $x = x_0x_1\ldots$ and $y = y_0y_1\ldots$ are two infinite sequences, then let $x\hat{\ }y$ ("zip") denote the sequence $x_0y_0x_1y_1\ldots$. We let $\lambda^\omega = \lambda^n = \lambda$ and $x\lambda = x$. Then we can define zip of two finite/infinite sequences by appending finite sequences with λ^ω.*

We are given an automaton $\mathcal{A}$ over a one symbol alphabet with acceptance condition $\Phi_{\mathcal{A}}$. Without loss of generality we may stipulate that each node of its transition diagram has exactly two successors.[9] Thus we may assume $\mathcal{A}$ is of the form (D, C, R, d_0, L) with OR-node set D, AND-node set C, start OR-node d_0, labeling L, and transition relation $R = R_{DC} \cup R_{CD0} \cup R_{CD1}$. Since each node has exactly two successors we may view R as a function so that $R(d, i) = c$ indicates that c is the AND-node successor of OR-node d of index $i \in \{0, 1\}$ and $R(c, j) = d$ indicates that d is the OR-node successor of AND-node c in direction $j \in \{0, 1\}$. We also assume that the labeling L assigning "colors" associated with $\Phi_{\mathcal{A}}$ to each node has been extended to AND-nodes so that each AND-node is colored exactly as is its unique OR-node parent.[10]

We shall define the dual automaton $\tilde{\mathcal{A}}$ essentially by swapping OR-nodes and AND-nodes in $\mathcal{A}$. However, we shall have to do a bit more to ensure that the result meets the technical definition of being an automaton as we have defined them to be.

Definition 5.2. *We first define $\hat{\mathcal{A}}$ with diagram of the form $(\hat{D}, \hat{C}, \hat{R}, \hat{d}_0, \hat{L})$, where $\hat{D} = C \cup \{e_0\}$, $\hat{C} = D$, $\hat{R}(e_0, 0) = \hat{R}(e_0, 1) = d_0$ with $\hat{R}(b, i) = R(b, i)$ for all $b \in C \cup D$ and $i \in [0, 1]$, and $\hat{L}$ is the same as L but it includes e_0 in its domain, assigning it the empty set of color propositions. We see that $\hat{\mathcal{A}}$ is the result of swapping OR-nodes and AND-nodes from $\mathcal{A}$ and adding a new dummy start state e_0 both of whose successors are d_0, start state of $\mathcal{A}$. $\hat{\mathcal{A}}$ is almost what we want for the dual except that its AND-nodes, which were OR-nodes of $\mathcal{A}$, are not guaranteed to have unique predecessors. Technically, this violates the definition of an automaton.*

[8]Since $\Phi_{\mathcal{A}}$ is finite automaton definable, a weaker result of Büchi–Landweber [3], showing determinacy of such games, will do.

[9]The argument generalizes in a straightforward way to k successors.

[10]Thus, if x is a path through $\mathcal{A}$, we have $x \models \Phi_{\mathcal{A}}$ iff $x|D \models \Phi_{\mathcal{A}}$ iff $x|C \models \Phi_{\mathcal{A}}$.

Therefore, to get $\tilde{\mathcal{A}}$ from $\hat{\mathcal{A}}$ we must create duplicates of the AND-nodes in $\hat{C}$. In other words, we locally unravel $\hat{\mathcal{A}}$: if $\hat{d} \to \hat{c}$ and $\hat{c} \to \hat{d}'$ appear in $\hat{\mathcal{A}}$, then $\hat{d} \to (\hat{d}, \hat{c})$ and $(\hat{d}, \hat{c}) \to \hat{d}'$ appear in $\tilde{\mathcal{A}}$ with the AND-node $(\hat{d}, \hat{c})$ of $\tilde{\mathcal{A}}$ labeled exactly as is AND-node $\hat{c}$ of $\hat{ca}$. The result is the underlying diagram of $\tilde{\mathcal{A}}$. Formally, we let $\tilde{A}$ have diagram $(\tilde{D}, \tilde{C}, \tilde{R}, \tilde{d_0}, \tilde{L})$. Here $\tilde{D} = \hat{D}$ and $\tilde{d_0} = \hat{d_0}$. We define $\tilde{C} \subseteq \hat{D} \times \hat{C}$ such that if AND-node $\hat{c}$ has OR-node predecessors $\hat{d_1}, \dots, \hat{d_k}$ in $\hat{\mathcal{A}}$, then AND-nodes $(\hat{d_1}, \hat{c}), \dots, (\hat{d_k}, \hat{c})$ are in $\tilde{C}$. If $\hat{R}(\hat{d}, i) = \hat{c}$, then $\tilde{R}(\hat{d}, i) = (\hat{d}, \hat{c})$ for $i \in \{0,1\}$. If $\hat{R}(\hat{c}, j) = \hat{d}$, then $\tilde{R}((\hat{d_l}, \hat{c}), j) = \hat{d}$ for $j \in \{0,1\}$ and where $\hat{d_l}$ is any predecessor of $\hat{c}$ in $\hat{\mathcal{A}}$. Finally, $\tilde{L}(\hat{d}) = \hat{L}(\hat{d})$ and $\tilde{L}((\hat{d_l}, \hat{c})) = \hat{L}(\hat{c})$. This transformation of $\hat{\mathcal{A}}$ into $\tilde{\mathcal{A}}$ can cause at worst a quadratic blowup in size.

DEFINITION 5.3. *Given an infinite string $z \in \{0,1\}^\omega$ and automaton $\mathcal{A}$ with diagram (D, C, R, d_0, L), we can associate with z, by starting at d_0 and following the arc labels spelling out z, a unique infinite path through the diagram of $\mathcal{A}$ and vice versa.*

Formally, we define $path_{\mathcal{A}} : \{0,1\}^\omega \to (DC)^\omega$ such that for $z = x\hat{\ }y$, $path_{\mathcal{A}}(z) = s\hat{\ }t$, where $x = x_0x_1\dots$, $y = y_0y_1\dots$, $s = s_0s_1\dots$, $t = t_0t_1\dots$, $s_0 = d_0$ is the start node in D, $t_n = R(s_n, x_n)$, and $s_{n+1} = R(t_n, y_n)$.

Observation 5.4. $\tilde{\pi} = path_{\tilde{\mathcal{A}}}(z)$ is the same as $\hat{\pi} = path_{\hat{\mathcal{A}}}(z)$, except that each AND-node $\tilde{c}$ along $\tilde{\pi}$ is a duplicate of the corresponding AND-node $\hat{c}$ along $\hat{\pi}$ of the form $(\hat{d}, \hat{c})$, where $\hat{d}$ is the predecessor of $\hat{c}$ along $\hat{\pi}$. Therefore, $\tilde{\pi} \models \Phi_{\mathcal{A}}$ iff $\hat{\pi} \models \Phi_{\mathcal{A}}$.

Observation 5.5. $path_{\tilde{\mathcal{A}}}(x\hat{\ }y) = e_0 \cdot path_{\mathcal{A}}(y\hat{\ }tail(x))$.

This follows because, all successors of e_0 are d_0, and hence x_0 is redundant.

DEFINITION 5.6. *We now define a* two player infinite game $\mathcal{G}$ *associated with* $\mathcal{A}$. *There are two players* I *and* II. I *goes first and picks $x_0 \in \{0,1\}$, then* II *picks some $y_0 \in \{0,1\}$, then* I *picks some $x_1 \in \{0,1\}$, and so on alternatively. The resulting infinite string $z = x_0y_0x_1y_1\dots$ is a* play *of the game. Player* I *wins this particular play z if z is in the* winning set Γ, *which is defined by letting $\Gamma = \{x : x \in \{0,1\}^\omega$ $path_G(x)$ satisfies $\Phi_{\mathcal{A}}\}$; otherwise* II *wins the play.*

A strategy *for* I *is a function f_{I} $\{0,1\}^* \to \{0,1\}$, and a strategy for* II *is a function $f_{\mathrm{II}} : \{0,1\}^+ \to \{0,1\}$. The family of all such strategy function will be denoted Strat* I *and Strat* II, *respectively, with typical elements denoted f_{I} and f_{II}, respectively.*

Any function f $\{0,1\}^* \to \Sigma$ induces a map $\overline{f} : \{0,1\}^\omega \to \Sigma^\omega$. If $z = z_0z_1\dots$ and $x = x_0x_1\dots$, $\overline{f}(x) = z$ such that, for all n, $z_n = f(x_0x_1\dots x_{n-1})$ and $z_0 = f(\lambda)$. Similarly, a function $f : \{0,1\}^+ \to \Sigma$ induces a map $\overline{f} : \{0,1\}^\omega \to \Sigma^\omega$ such that $z_n = f(x_0x_1\dots x_n)$.

We say that Player I *follows strategy f_{I} if it chooses $f_{\mathrm{I}}(y_0y_1\dots y_{n-1})$ when* II *has chosen $y_0y_1\dots y_{n-1}$. Similarly for Player* II. *If* II *builds up y during a play, and* I *follows f_{I}, then the resulting play is $\overline{f_{\mathrm{I}}}(y)\hat{\ }y$. Similarly, if I builds up x, and* II *follows f_{II}, the resulting play is $x\hat{\ }\overline{f_{\mathrm{II}}}(x)$.*

We say that f_{I} is a winning strategy *for* I *if for all $y \in \{0,1\}^\omega$ $\overline{f_{\mathrm{I}}}(y)\hat{\ }y \in \Gamma$. Similarly, f_{II} is a winning strategy for* II *if for all $y \in \{0,1\}^\omega$ $y\hat{\ }\overline{f_{\mathrm{II}}}(y) \notin \Gamma$.*

Remark. When the transition diagram is presented as in this section, the definition of a run ρ is formulated as

$\rho(\lambda) = d_0$

for all $y \in \{0,1\}^*$ $\exists i \in \{0,1\}$ $\exists c \in C$ $c = R(\rho(y), i)$ and for all $j \in \{0,1\}$ $\rho(yj) = R(b, j)$.

The first condition asserts that ρ annotates the root node with the start state. The second condition asserts that each node y of the tree has its successors $y0, y1$ annotated in a manner consistent with the diagram because there is an AND-node

c from OR-node $\rho(y)$ to OR-nodes $\rho(y0), \rho(y1)$ in the diagram. Note also that the condition that "along all paths of a run ρ, $\Phi_{\mathcal{A}}$ holds," is now formulated as "for all $y \in \{0,1\}^\omega$ $\overline{\rho}(y)$ satisfies $\Phi_{\mathcal{A}}$," since y here is spelling out a path through the tree in terms of edge labels.

LEMMA 5.7. *Let $\mathcal{A}$ be an automaton with acceptance condition $\Phi_{\mathcal{A}}$. Then,*

$\exists$ run ρ of $\mathcal{A}$ for all $y \in \{0,1\}^\omega$ $\overline{\rho}(y)$ satisfies $\Phi_{\mathcal{A}}$

iff

$\exists f_I$ for all $y \in \{0,1\}^\omega$ $path_{\mathcal{A}}(\overline{f_I}(y)\hat{\ }y)$ satisfies $\Phi_{\mathcal{A}}$.

This lemma says that an accepting run defines a corresponding winning strategy and vice versa. Intuitively, given a run as shown in Figure 5.1 (a) we can extend it to indicate the intermediate AND-nodes and edges, indexed by 0 or 1, between nodes, as shown in Figure 5.1 (b). These edges indicating that c_n is the x_n-successor of d_n, that d_{n+1} is the y_{n+1}-successor of c_n, and so forth constitute an edge-labeled tree defining the strategy, as shown in Figure 5.1 (c). Conversely, given the strategy we can view it as an edge-labeled tree, and given the start node d_0, infer the corresponding run. This argument is formalized below.

Proof. Given ρ, let $f_{\mathrm{I}}(y) = \min\{i : \exists b\ b = R(\rho(y), i)$ and for all j $\rho(yj) = R(b,j)\}$ so that f_{I} picks, for the sake of definiteness, the AND-node successor of least index. The above definition is well defined by the definition of a run.

We show that $\overline{\rho}(y)$ is exactly s, where $s\hat{\ }t = path_{\mathcal{A}}(\overline{f_I}(y)\hat{\ }x)$. By the definition of $path_{\mathcal{A}}$, $s_{n+1} = R(t_n, y_n)$ and $t_n = R(s_n, x_n)$, where $x = \overline{f_I}(y)$. We show by induction that $\rho(y_0y_1\ldots y_n) = s_{n+1}$.

The base case is trivial because $\rho(\lambda) = s_0$. By induction hypothesis, $\rho(y_0y_1\ldots y_{n-1}) = s_n$. By definition of f_{I}, $t_n = g(\rho(y_0y_1\ldots y_{n-1}), x_n) = b$ and $\rho(y_0y_1\ldots y_n) = g(b, y_n) = g(t_n, y_n) = s_{n+1}$.

For the other direction, given f_I we define ρ:

$\rho(\lambda) = s_0$,

$\rho(yj) = R(R(\rho(y), f_{\mathrm{I}}(y)), j)$.

It follows from this definition of ρ and the definition of $path_{\mathcal{A}}$ that, if $s\hat{\ }t = path_{\mathcal{A}}(\overline{f_I}(y)\hat{\ }y)$, then $s = \overline{\rho}(y)$.

In the definition of $\tilde{\mathcal{A}}$, we required that the proposition labels be the same on the OR-nodes and their AND-node successors. For the dual automaton, it follows that the labels on the OR-nodes are the same as on their predecessor AND-nodes. Thus, $path_{\mathcal{A}}(\overline{f_I}(y)\hat{\ }x)$ satisfies $\Phi_{\mathcal{A}}$ iff $\overline{\rho}(y)$ satisfies $\Phi_{\mathcal{A}}$. □

LEMMA 5.8. *Let $\tilde{\mathcal{A}}$ be the dual automaton which has acceptance condition $\neg\Phi_{\mathcal{A}}$. Then,*

$\exists$ run ρ of $\tilde{\mathcal{A}}$ for all $y \in \{0,1\}^\omega$ $\overline{\rho}(y)$ satisfies $\neg\Phi_{\mathcal{A}}$

iff

$\exists f_{\mathrm{II}}$ for all $x \in \{0,1\}^\omega$ $path_{\tilde{\mathcal{A}}}(x\hat{\ }\overline{f_{\mathrm{II}}}(x))$ satisfies $\neg\Phi_{\mathcal{A}}$.

Proof. We argue as follows:

$\exists f_{\mathrm{II}}$ for all $x \in \{0,1\}^\omega$ $path_{\mathcal{A}}(x\hat{\ }\overline{f_{\mathrm{II}}}(x))$ satisfies $\neg\Phi_{\mathcal{A}}$

iff (since $\Phi_{\mathcal{A}}$ is oblivious to finite prefixes being altered)

$\exists f_{\mathrm{II}}$ for all $x \in \{0,1\}^\omega$ $e_0 \cdot path_{\mathcal{A}}(x\hat{\ }\overline{f_{\mathrm{II}}}(x))$ satisfies $\neg\Phi_{\mathcal{A}}$

iff (taking f_{I} to be the same as f_{II}, except $f_{\mathrm{I}}(\lambda)$ is defined arbitrarily)

$\exists f_{\mathrm{I}}$ for all $x \in \{0,1\}^\omega$ $e_0 \cdot path_{\mathcal{A}}(x\hat{\ }tail(\overline{f_{\mathrm{I}}}(x)))$ satisfies $\neg\Phi_{\mathcal{A}}$

iff (by Observation 5.4)

$\exists f_{\mathrm{I}}$ for all $x \in \{0,1\}^\omega$ $path_{\tilde{\mathcal{A}}}(\overline{f_{\mathrm{I}}}(x)\hat{\ }x)$ satisfies $\neg\Phi_{\mathcal{A}}$

iff (by Observation 5.5)

FIG. 5.1.

$\exists f_{\mathrm{I}}$ for all $x \in \{0,1\}^\omega$ $path_{\tilde{A}}(\overline{f_I}(x)\hat{\ }x)$ satisfies $\neg\Phi_{\mathcal{A}}$
iff (by Lemma 5.7)
$\exists$ run ρ of $\tilde{A}$ for all $x \in \{0,1\}^\omega$ $\overline{\rho}(x)$ satisfies $\neg\Phi_{\mathcal{A}}$.

This completes the proof. ∎

LEMMA 5.9. *Γ is Borel.*

Proof. We show that Γ is accepted by a deterministic string automata $\bar{A}$ with acceptance condition $\Phi_{\mathcal{A}}$. $\bar{A}$ has as its alphabet $\{0,1\}$. Let the states of $\bar{A}$ be from $S \cup T$. The transition function $\overline{\delta}$ is g itself, i.e., $\overline{\delta}(u,i) = R(u,i)$. A routine inspection shows that $\bar{A}$ accepts Γ.

Landweber [20] showed that every set accepted by a deterministic Muller string automaton is in the Borel class $G_{\delta\omega} \cap F_{\omega\delta}$ with the usual product topology on the set of all infinite binary sequences. Since we are interested in $\Phi_{\mathcal{A}}$ being either pairs or complemented pairs acceptance condition, the ω-string automaton with such $\Phi_{\mathcal{A}}$ are well known to be equivalent to deterministic Muller string automaton (see, e.g., [20]). ∎

Now, we are ready to prove the main lemma.

LEMMA 5.10. *$\mathcal{A}$ is nonempty iff $\tilde{\mathcal{A}}$ is empty.*

Proof. By Lemma 5.9, the acceptance condition of $\mathcal{A}$, Γ, is Borel, and hence the game $\mathcal{G}$ associated with Γ is determined by Martin's theorem [22]. Thus, I has a winning strategy iff II does not have a winning strategy. By Lemma 5.7, Player I has a winning strategy iff $\mathcal{A}$ is nonempty. By Lemma 5.8, Player II has a winning strategy iff $\tilde{\mathcal{A}}$ is nonempty. It immediately follows then that $\mathcal{A}$ is nonempty iff $\tilde{\mathcal{A}}$ is empty. □

Given a complemented pairs automaton $\mathcal{A}$, we can construct with at most a quadratic blowup its pairs dual automaton $\tilde{\mathcal{A}}$ such that $\mathcal{A}$ is nonempty iff $\tilde{\mathcal{A}}$. Since by Theorem 4.10 of the previous section testing nonemptiness of pairs automata is NP-complete, we immediately get the following corollary.

COROLLARY 5.11. *Testing nonemptiness of complemented pairs automata is co-NP-complete.*

Since the quadratic reduction is deterministic, we also get the following.

COROLLARY 5.12. *There is a deterministic algorithm to test nonemptiness of complemented pairs automata with m states and n pairs that runs in time $(mn)^{O(n)}$.*

6. Applications to logics of programs.

Using existing reductions and our new algorithms for tree automata, we give essentially optimal algorithms for CTL*, PDL-delta, and the Mu-calculus. The "standard" algorithms for each of these logics are of triple exponential complexity (cf. [13, 33, 35]). The existing reductions to which we appeal reduce satisfiability of these logics to nonemptiness of tree automata. These reductions employ determinization of a nondeterministic Büchi automaton on ω-strings. With preexisting algorithms for testing nonemptiness of (pairs) tree automata of [6] (cf. [41]) and the McNaughton determinization construction [23],[11] we can get a nondeterministic double exponential algorithm for testing (un)satisfiability of PDL-delta and the Mu-calculus. Using the new ω-string automaton determinization construct of Safra [32], we can get a nondeterministic single exponential time algorithm for these two logics. As described below, using our new nonemptiness testing algorithms we get a deterministic single exponential time algorithm. The best previously existing upper bounds for these logics, viz., nondeterministic single exponential time (which amounts to deterministic double exponential time in practice), employed "hybrid automata" (cf. [41]). The Safra construction alone does not help reduce the complexity using the hybrid automata. For CTL*, the existing reductions [13], which use a special structure of the ω-string automata associated with the logic, viz., uniqueness of accepting runs, to determinize with only a single exponential blowup, Safra's construction provides no additional help. The previous nonemptiness algorithms give a nondeterministic double exponential time algorithm. Our new nonemptiness algorithm reduces the upper bound to deterministic double exponential time. In what follows $\exp(n)$ denotes the class of functions bounded above by $2^{q(n)}$ for some polynomial $q(n)$.

THEOREM 6.1. *There is an* $\exp(\exp(|p|))$ *time reduction of a CTL* formula p into a pairs automaton $\mathcal{A}_p$ on infinite trees with* $\exp(\exp(|p|))$ *states and* $\exp(|p|)$ *pairs such that p is satisfiable iff $\mathcal{A}_p$ is nonempty.*

THEOREM 6.2. *The satisfiability problem for CTL* is complete for deterministic double exponential time.*

Proof. Applying the nonemptiness algorithm (Theorem 4.1) to the pairs tree automaton obtained by Theorem 6.1, it follows directly that CTL* can be decided in deterministic double exponential time. CTL* was shown hard for double exponential time in [41]. □

THEOREM 6.3. *Satisfiability of the Mu-calculus is in deterministic exponential time.*

[11] Here we also use our Lemma 5.10.

Proof. For a Mu-calculus formula p a complemented pairs automaton $\mathcal{A}_p$ of size $\exp(|p|)$ and number of pairs polynomial in $|p|$ can be constructed in time $\exp(|p|)$ such that p is satisfiable iff $\mathcal{A}_p$ is nonempty. This reduction follows by the technique described in [35], but by using Safra's construction instead of McNaughton's construction. The upper bound follows by using the nonemptiness algorithm for complemented pairs automata (Corollary 5.12). $\square$

PDL-delta has a linear blowup translation into the Mu-calculus [12, 19] (provided we allow consolidation of common subformulae). Hence, we have the following theorem.

THEOREM 6.4. *Satisfiability of PDL-delta is in deterministic exponential time.*

Remark. A direct algorithm, similar to the one mentioned for the Mu-calculus, can also be given (see [33, 41]).

Because of the known deterministic exponential time lower bound for PDL [14], it follows that the above algorithms for the Mu-calculus and PDL-delta are essentially optimal (i.e., up to polynomial blowup). Moreover, we have the next corollary.

COROLLARY 6.5. *Satisfiability of the Mu-calculus and PDL-delta are complete for deterministic exponential time.*

7. Conclusion.

We have investigated the complexity of testing nonemptiness of finite state automata on infinite trees. For the classical pairs acceptance condition of Rabin [30] we show the problem is NP-complete, while for the complemented pairs condition of Streett [33] we show the problem is co-NP-complete. In both cases, we are still able to give a deterministic algorithm that runs in time polynomial in the number of states but exponential in the number of pairs. These nonemptiness algorithms improve previous results in the literature and permit us to give exponentially improved, essentially tight, upper bounds on the complexity of testing satisfiability for a number of important modal logics of programs including CTL*, PDL-delta, and the propositional Mu-calculus. Moreover, we believe that the technique of pseudomodel checking may be useful in connection with other types of automata (cf. [11]).

Among related work we mention the following. Historically, Rabin [30] gave an exponential time algorithm for pairs tree automaton nonemptiness but did not perform a multiparameter analysis or provide a lower bound. Hossley and Rackoff [18] gave an elegant reduction to the nonemptiness problem for automata on finite trees, but the complexity stated for their algorithm was triple exponential. More recently, subsequent to the appearance of the preliminary version of this work in [10], Pnueli and Rosner [28] independently developed a different nonemptiness algorithm for pairs tree automata providing essentially the same upper bound as ours and intended for program synthesis applications; however, they did not consider lower bounds. Their work was extended to a corresponding upper bound for complemented pairs tree automata in [29]. A control-theoretic view of tree automata is given in [36] and [37], while an authoritative survey of automata on infinite objects is presented in [38].

Appendix A.

Proof of Lemma 4.2. We will establish the dual claim. Note that given a pairs condition $\Phi = \bigvee_\gamma(\overset{\infty}{G}P_\gamma \wedge \overset{\infty}{F}Q_\gamma)$, the corresponding "complemented" pairs condition $\hat{\Phi} = \wedge_\gamma(\overset{\infty}{F}P_\gamma \vee \overset{\infty}{G}Q_\gamma)$ is intended to capture the dual property. Interpreted over fullpaths in total structures, which must be infinite paths, $\hat{\Phi} \equiv \tilde{\Phi}$, the actual dual of Φ, i.e., $\neg\Phi(\neg P_1, \ldots, \neg P_\gamma, \neg Q_1, \ldots, \neg Q_\gamma)$. However, over partial structures, as we are permitting, finite fullpaths are allowed and we do not necessarily have the equivalence of $\hat{\Phi}$ and $\tilde{\Phi}$. Rather, $\Phi \equiv \Phi \wedge \mathrm{inf} \equiv \vee_\gamma(FGP_\gamma \wedge GFQ_\gamma) \wedge \mathrm{inf}$. Thus, $\tilde{\Phi} \equiv \wedge_\gamma(GFP_\gamma \vee$

$FGQ_\gamma) \vee fin \equiv (\wedge_\gamma(GFP_\gamma \vee FGQ_\gamma) \wedge \text{inf}) \vee fin \equiv \hat{\Phi} \vee fin$. We thus have that $A(\Phi \vee FR) \equiv A((\Phi \wedge \text{inf}) \vee FR)$ so that the dual $E(\tilde{\Phi} \wedge GR) \equiv E((\hat{\Phi} \vee fin) \wedge GR)$.

We must show that $E(\tilde{\Phi} \wedge GR) \equiv \nu Y.\tilde{\tau}(Y)$, where

$$\tilde{\tau}(Y) = R \wedge \wedge_\gamma EX_w E[RU_s R \wedge (E(\tilde{\Phi}_{-\gamma} \wedge G(R \wedge Q_\gamma)) \vee (P_\gamma \wedge Y) \vee AX_w false)].$$

In the following, let M be an arbitrary structure, which is understood but not explicitly mentioned.

We first show that $E(\tilde{\Phi} \wedge GR)$ is a fixpoint of $\tilde{\tau}(Y)$, i.e., $E(\tilde{\Phi} \wedge GR) \equiv \tilde{\tau}(E(\tilde{\Phi} \wedge GR))$ is valid. For the forward ($\Rightarrow$) direction, assume $s_0 \models E(\tilde{\Phi} \wedge GR)$. Then there is a fullpath x starting at s_0 satisfying $\tilde{\Phi} \wedge GR$, which is equivalent to $(\hat{\Phi} \vee fin) \wedge GR$. By virtue of x and by definition of $\tilde{\Phi}$, for each γ we also have $s_0 \models R \wedge EX_w E[RU_s R \wedge (AX_w false \vee \ (P_\gamma \wedge E(\tilde{\Phi} \wedge GR)) \vee \ E(\tilde{\Phi}_{-\gamma} \wedge G(R \wedge Q_\gamma)))]$, where the $AX_w false$ disjunct ultimately obtains if the fullpath x is finite, the $(P_\gamma \wedge E(\tilde{\Phi} \wedge GR))$ disjunct ultimately obtains if P_γ occurs along the fullpath x, and the $E(\tilde{\Phi}_{-\gamma} \wedge G(R \wedge Q_\gamma))$ disjunct ultimately obtains otherwise, since if P_γ never occurs, then eventually Q_γ must always hold. Hence, s_0 satisfies all conjuncts of $\tilde{\tau}(E(\tilde{\Phi} \wedge R))$, and $s_0 \models \tilde{\tau}(E(\tilde{\Phi} \wedge GR))$. For the converse ($\Leftarrow$) direction, assume $s_0 \models \tilde{\tau}(E(\tilde{\Phi} \wedge GR))$. Pick an arbitrary γ. We have by definition of $\tilde{\tau}(Y)$ that $s_0 \models R \wedge EX_w E[RU_s R \wedge (AX_w false \vee \ (P_\gamma \wedge E(\tilde{\Phi} \wedge GR)) \vee \ E(\tilde{\Phi}_{-\gamma} \wedge G(R \wedge Q_\gamma)))]$. Whichever disjunct ultimately obtains, it follows that $s_0 \models E(\tilde{\Phi} \wedge GR)$. Thus $E(\tilde{\Phi} \wedge GR)$ is a fixpoint of $\tilde{\tau}(Y)$ as desired.

We now show that $E(\tilde{\Phi} \wedge GR)$ is the greatest fixpoint of $\tilde{\tau}(Y)$. Suppose $Z \equiv \tilde{\tau}(Z)$ is an arbitrary fixpoint. We will show that $Z \Rightarrow E(\tilde{\Phi} \wedge GR)$ is valid.

For any state s such that $s \models Z$, since Z is a fixpoint, we have two cases by analyzing $Z \equiv \tilde{\tau}(Z)$.

(a) For some index γ,

$$s \models R \wedge EX_w E[RU_s R \wedge (E(\Phi_{-\gamma} \wedge G(R \wedge Q_\gamma)) \vee AX_w false)],$$

or

(b) for all indices γ, $s \models R \wedge EX_w E[RU_s R \wedge (P_\gamma \wedge Z)]$.

If (b) holds, then we either have the strengthened

(b)$'$ for all indices γ, $s \models R \wedge EX_s E[RU_s R \wedge (P_\gamma \wedge Z)]$, or

(b)$''$ for some index γ, $s \models R \wedge EX_w false$.

But case (b)$''$ implies case (a). Thus either (a) or (b)$'$ must obtain.

Observation A.1. If state s can reach state t by a finite path y where R holds everywhere along y, then if case (a) applies to t, it applies to s, also.

Now let s_0 be an arbitrary state such that $s_0 \models Z$. If case (a) applies to s_0, then $s_0 \models E((\hat{\Phi} \vee fin) \wedge GR)$ and we are done. Otherwise, case (b)$'$ applies. We will show how to use the recursion $Z \equiv \tilde{\tau}(Z)$ infinitely many times to construct an infinite path satisfying $E(\tilde{\Phi} \wedge GR)$.

Since (b)$'$ applies to s_0, there exists a path from s_0 to some state s_1 of the form $s_0 = t_0, t_1, \ldots, t_k = s_1$ ($k \geq 0$) such that $s_1 \models P_1 \wedge Z$ and for all $i \in [0:k]$, $t_i \models R$.

We now do case analysis on s_1. By Observation A.1, we see that case (a) cannot apply to s_1, for if it did, it would apply to s_0 also. So case (b)$'$ applies to s_1, and there exists a path from s_1 to some state s_2 of the form $s_1 = u_0, u_1, \ldots, u_l$ ($l \geq 0$) such that $s_2 \models P_2 \wedge Z$ and for all $j \in [0:l]$, $u_j \models R$.

Continuing in this fashion, we construct an infinite path x of the form

$$s_0 \ldots s_1 \ldots s_2 \ldots s_i \ldots$$

along which R always holds and which successively visits states where $P_1, P_2, \ldots, P_m$, $P_1, P_2, \ldots, P_m, \ldots$, etc. hold in succession. Technically, we have $x \models GR$, and for each i, $s_i \models P_{i \text{ modd } m}$, where i modd m is defined to be i mod m (the remainder of i on division by m) if i mod $m \neq 0$ and to be m if i mod $m = 0$. ▯

Proof of Lemma 4.3. We have $\bigcup_i \tau^i(false)^{T,con} = A(\Phi \vee FR)^{T,con} = A(\Phi \vee FR)^{T,gen} = \bigcup_i \tau^i(false)^{T,gen}$, where the first and third equalities follow from the Tarski–Knaster theorem together with the disjunctivity of *con* and *gen*, while the second equality follows from the generalized linear size model theorem.

It will thus be sufficient to show that for all i,

$$(*) \quad \tau^i(false)^{T,con} \subseteq \mathsf{Y}^{\mathsf{i}} \subseteq \tau^i(false)^{T,gen}.$$

We do this by induction on i.

The base case $i = 0$ is immediate since $\mathsf{Y}^0 = false^{T,con}$.

For the induction step, we assume that (*) holds for i and argue that it holds for $i + 1$.

To establish the first containment $\tau^{i+1}(false)^{T,con} \subseteq \mathsf{Y}^{\mathsf{i+1}}$, assume that $s \in \tau(\tau^i(false))^{T,con}$. Then $M, s \models \tau(\tau^i(false))$ for some M contained in T. It follows, as justified below, that $M, s \models \tau(Y^i)$, from which we conclude that $s \in \tau(Y^i)^{T,con} = \mathsf{Y}^{\mathsf{i+1}}$.

The key step to be justified is that $\tau^i(false)^M \subseteq (Y^i)^M$. Note that for any temporal formula f and for any M contained in T, $f^M \subseteq f^{T,con} \cap M$. And we have by induction hypothesis that $\tau^i(false)^{T,con} \subseteq (Y^i)^{T,con}$. Thus

$$\tau^i(false)^M \subseteq \tau^i(false)^{T,con} \cap M \subseteq (Y^i)^{T,con} \cap M = (Y^i)^M$$

. To establish the second containment $\mathsf{Y}^{\mathsf{i+1}} \subseteq \tau^{i+1}(false)^{T,gen}$, assume $s \in \mathsf{Y}^{\mathsf{i+1}} = \tau(Y^i)^{T,con}$. There exists M contained in T such that $M, s \models \tau(Y^i)$. We will construct from M a new structure M' that will be generated by T and will satisfy $\tau^{i+1}(false)$ at s.

For each state $y \in M \cap \mathsf{Y}^{\mathsf{i}}$, let M_y be a structure generated by T rooted at $\hat{y}$ (a copy of y) such that $M_y, \hat{y} \models \tau^i(false)$. Such an M_y is guaranteed to exist by the induction hypothesis. Let M' be the structure obtained from M by replacing each y by M_y, i.e., redirecting edges from predecessors of y into $\hat{y}$.

It follows that M' is generated by T by virtue of its construction from structures generated by T. It is also the case that $M', s \models \tau(Y^i)$ since each $\hat{y}$ has the same labeling with Y^i as y. Moreover, each $\hat{y}$ is the root of M_y, so $M', s \models \tau^{i+1}(false)$ and $s \in \tau^{i+1}(false)^{T,gen}$. Hence, $s \in \tau^{i+1}(false)^{T,gen}$, establishing the second containment. ▯

Remark. In the construction above, there may be multiple copies of nodes from T in M'; since we do not have a generalized linear size model theorem for $\tau^j(false)$ for $j \geq 2$, it is not, in general, possible to get a structure contained in T. For this reason $Y^i \neq \tau^i(false)^{T,con}$. However, a more involved argument than that above can be given to show that $Y^i = \tau^i(false)^{T,gen}$.

Proof of Lemma 4.4. We use the fixpoint characterization $\mu V.(R \vee AX_s V)$ for AFR. Let $q(V) = R \vee AX_s V$ and $q'(V) = R \vee EX_s AX_s V$.

Now, $T, s \mathrel{\|\!-} AFR$ iff $\exists$ a structure M contained in T such that $M, s \models AFR$ iff $\exists j > 0 \, \exists$ a structure M contained in T such that $M, s \models q^j(false)$.

We will argue by induction on j that

$\exists$ a structure M contained in T such that $M, s \models q^j(false)$ iff $T, s \models (q')^j(false)$ (*), which will, by taking the disjunction over j, establish the lemma.

The base case $j = 1$ is immediate since R is a proposition. Therefore assume (*) holds for j and show that it holds for $j + 1$.

($\Rightarrow$) Assume $\exists$ a structure M contained in T such that $M, s \models q^{j+1}(false)$. Then $M, s \models R \vee AX_s q^j(false)$. If $M, s \models R$, we are done, since R is propositional. If $M, s \models AX_s q^j(false)$, then all successors t_i of s in M (there is at least one) are such that $M, t_i \models q^j(false)$. Hence, $T, t_i || - q^j(false)$ as M is contained in T, and $T, t_i \models (q')^j(false)$ by induction hypothesis. Also, there exists an AND-node c_s from s to the t_i's in T. So $T, s \models EX_s AX_s (q')^j(false)$ and $T, s \models (q')^{j+1}(false)$ as desired.

($\Leftarrow$) Suppose $T, s \models (q')^{j+1}(false)$. Then $T, s \models R \vee EX_s AX_s (q')^j(false)$. If $T, s \models R$, then because R is propositional, $T, s || - R$, and we are done. If $T, s \models EX_s AX_s (q')^j(false)$, then there is an AND-node successor c_s from s to OR-nodes t_0, t_1 such that each $T, t_i \models (q')^j(false)$. By induction hypothesis, for each t_i, $T, t_i || - q^j(false)$, and $\exists$ a structure M_i contained in T such that $M_i, t_i \models q^j(false)$.

We let M_0', M_1' be copies[12] of M_0, M_1, respectively, and graft them onto s by letting t_0', t_1' (the copies of t_0, t_1, respectively) be the successors of s. Then the resulting M' is a structure generated by T such that $M', s \models q^{j+1}(false)$. Now we can get a structure $\hat{M}$ contained in T such that $\hat{M}, s \models q^{j+1}(false)$, as follows.

Suppose nodes u, u' of M' are copies of the same OR-node of T, i.e., map to the same OR-node under the generation function. There is a smallest $k \leq j$ and a smallest $k' \leq j$ such that $M', u \models q^k(false)$ and $M', u' \models q^{k'}(false)$, respectively. If $k \leq k'$, then let u replace u' by redirecting all arcs going from predecessors of u' into u' so that they go from predecessors of u' into u instead. Thus u' is no longer accessible and may be deleted. Similarly, if $k > k'$, then let u' replace u. Call the resulting structure, which has one of u, u' "chopped out," M''. Note that for every node v common to M' and M'', if $M', v \models q^l(false)$, then $M'', v \models q^l(false)$. Accordingly, we have that the "q-rank" of nodes does not increase in going from M' to M''. Moreover, M'' is still a structure generated by T with one fewer pair of duplicates than M' such that $M'', s \models q^j(false)$. This process can be repeated until all duplicates are eliminated. Call the resulting final structure $\hat{M}$. Then $\hat{M}, s \models q^{j+1}(false)$ and is (a copy of) a structure contained in T. □

Proof of Lemma 4.8. The argument depends on the following.

Merging property. If for all $s \in \mathsf{Z}^k$ there exists M contained in Z^k such that $M, s \models g_\gamma \wedge AX_s Z^k \vee R$, then there exists a single M_0 contained in Z^k such that for all $s \in \mathsf{Z}^k$, $M_0, s \models g_\gamma \wedge AX_s Z^k \vee R$.

Proof of property. Let $s_1, \ldots, s_n$ be an enumeration without repetitions of $\mathsf{Z}^k \setminus R$. We will show that we can repeatedly apply the generalized linear size model theorem to get M contained in Z^k such that $M, s_1, \ldots, s_n \models g_\gamma \wedge AX_s Z^k$.

For s_1 there exists M_1 contained in Z^k such that $M_1, s_1 \models g_\gamma \wedge AX_s Z^k$. A similar M_2 for s_2 exists. Let M_1' be a copy of M_1 that is disjoint from M_1 except that the original node s_1 is retained. Similarly, let M_2' be a copy of M_2 that is also disjoint from M_1'. Then, defining the union of two disjoint structures in the obvious way, the structure $M_{12}' = M_1' \cup M_2'$ is generated by Z^k, and we have $M_{12}', s_1, s_2 \models g_\gamma \wedge AX_s Z^k$.

By the generalized linear size model theorem, we can collapse out duplicates yielding M_{12}'' contained in Z^k such that $M_{12}'', s_1'', s_2'' \models g_\gamma$, where M_{12}'' contains no duplicates and s_1'', s_2'' are (possibly copies of) s_1, s_2, respectively.

[12]We say M' is a copy of M if it is an isomorphic structure, i.e., labeled graph, with a fresh set of nodes disjoint from those of M.

Note that for any node t in M''_{12}, if t had successors in M'_{12}, it also has successors in M''_{12} by the nature of the method of chopping out duplicates. Hence, $M''_{12}, s''_1, s''_2 \models g_\gamma \wedge AX_s Z^k$. Of course, M''_{12} is isomorphic to a structure M_{12} contained in Z^k with s''_1, s''_2 corresponding to s_1, s_2, respectively, and $M_{12}, s_1, s_2 \models g_\gamma \wedge AX_s Z^k$.

We now continue with s_3 and use M_{12}, M_3 to get M_{123} contained in Z^k such that $M_{123}, s_1, s_2, s_3 \models g_\gamma \wedge AX_s Z^k$. Continue this process until $\mathsf{Z}^k \setminus R$ is exhausted, yielding $M_{1,\dots,k}$ contained in Z such that $M_{1,\dots,k}, s_1, \dots, s_k \models g_\gamma \wedge AX_s Z^k$. Now let $M_0 = M_{1,\dots,k} \cup N$, where N is the structure formed by just those single nodes t in Z^k satisfying R such that a copy of t does not appear in $M_{1\dots k}$. Then M_0 is contained in Z^k and for all $s \in \mathsf{Z}^k$ we have $M_0, s \models g_\gamma \wedge AX_s Z^k \vee R$.

This completes the proof of the merging property.

To establish soundness of the calculation, i.e., $\mathsf{Z}^k \subseteq A(g_\gamma U_w R)^{T,con}$, we first note that $\mathsf{Z}^k = (g \wedge AX_s \mathsf{Z}^k \vee R)^{\mathsf{Z}^k}$ implies, by definition of the f^{Z^k} notation, for each $s \in \mathsf{Z}^k$ that $\mathsf{Z}^k, s \Vdash_{con} g \wedge AX_s \mathsf{Z}^k \vee R$. By the merging property, this in turn implies that there exists a single M_0 contained in Z^k such that for every $s \in \mathsf{Z}^k \setminus R$, $M_0, s \models g$. It follows that for each $s_0 \in M_0$, $M_0, s_0 \models A(g_\gamma U_w R)$. To see this, let $x = s_0, s_1, s_2, \dots$ be a fullpath in M_0. For each s_i, $M_0, s_i \models g$ or $M_0, s_i \models R$. So $M_0, x \models (g_\gamma U_w R)$ as desired.

By virtue of M_0, for every $s_0 \in \mathsf{Z}^k \setminus R$, we now have that $\mathsf{Z}^k, s_0 \Vdash_{con} A(g_\gamma U_w R)$. Since M_0 is contained in Z^k and $\mathsf{Z}^k \subseteq T$, we also have that M_0 is contained in T, and for each $s_0 \in \mathsf{Z}^k \setminus R$, we get $T, s_0 \Vdash_{con} A(g_\gamma U_w R)$. Since for all $s_0 \in R^{T,con}$, we have $T, s_0 \Vdash_{con} A(g_\gamma U_w R)$, we get for all $s_0 \in \mathsf{Z}^k$ that $T, s_0 \Vdash_{con} A(g_\gamma U_w R)$. Thus, $\mathsf{Z}^k \subseteq A(g_\gamma U_w R)^{T,con}$.

In order to show completeness, i.e., $A(g_\gamma U_w R)^{T,con} \subseteq \mathsf{Z}^k$, we argue that for any i and for any state s_0

$$(*) \qquad \mathsf{Z}^i, s_0 \Vdash_{con} A(g_\gamma U_w R) \quad \text{implies} \quad \mathsf{Z}^{i+1}, s_0 \Vdash_{con} A(g_\gamma U_w R).$$

Assume that $\mathsf{Z}^i, s_0 \Vdash_{con} A(g_\gamma U_w R)$. Thus for some M contained in Z^i we have $M, s_0 \models A(g_\gamma U_w R)$. Without loss of generality, we may assume that every state t of M is reachable from s_0 and $M, t \models A(g_\gamma U_w R)$.

We claim that M is contained in Z^{i+1}. For all $t \in M$, since $M, t \models A(g_\gamma U_w R)$, it follows that $M, t \models (g \wedge AX_s Z^i) \vee R$, and thus $t \in \mathsf{Z}^{i+1} = \{u \in \mathsf{Z}^i : \mathsf{Z}^i, u \Vdash_{con} (g \wedge AX_s Z^i) \vee R\}$. Hence, $M \subseteq \mathsf{Z}^{i+1}$. Since M is contained in Z^i and $M \subseteq \mathsf{Z}^{i+1} \subseteq \mathsf{Z}^i$, it follows by the definition of containment that M is contained in Z^{i+1}.

Thus, $M, s_0 \models A(g_\gamma U_w R)$ and M is contained in Z^{i+1}, so $\mathsf{Z}^{i+1}, s_0 \Vdash_{con} A(g_\gamma U_w R)$ as desired. (Note that by definition of the $\Vdash_{con}$ notation, $\mathsf{Z}^{i+1}, s_0 \Vdash_{con} A(g_\gamma U_w R)$ implies $s_0 \in \mathsf{Z}^{i+1}$ and the above argument guarantees this.)

Since $\mathsf{Z}^0 = T$, for any $s \in A(g_\gamma U_w R)^{T,con}$, $\mathsf{Z}^0, s \Vdash_{con} A(g_\gamma U_w R)$ and by induction on i using $(*)$, we have that for all i, $\mathsf{Z}^i, s \Vdash_{con} A(g_\gamma U_w R)$. In particular, $\mathsf{Z}^k, s \Vdash_{con} A(g_\gamma U_w R)$. Since s was an arbitrary member of $A(g_\gamma U_w R)^{T,con}$, we conclude $A(g_\gamma U_w R)^{T,con} \subseteq \mathsf{Z}^k$, as desired.

To implement the calculation, we see by using disjunctivity of *con* that $((g_\gamma \wedge AX_s \mathsf{Z}^i) \vee R)^{\mathsf{Z}^i,con} = (g_\gamma \wedge AX_s \mathsf{Z}^i)^{\mathsf{Z}^i,con} \cup R^{\mathsf{Z}^i,con}$. Now

$$(g_\gamma \wedge AX_s \mathsf{Z}^i)^{\mathsf{Z}^i,con} = (g_\gamma \wedge AX_s true)^{\mathsf{Z}^i,con}$$

within the scope of $\mathsf{Z}^i, con = g_\gamma^{\mathsf{Z}^i,con}$, since g_γ already has $AX_s true$ as a conjunct. Now apply Lemma 4.9. $\square$

Proof of Lemma 4.9. The $\subseteq$ direction is immediate.

For the $\supseteq$ direction, pick an arbitrary element s of the right-hand side. Because s is in the first term, it must be that there exists an M contained in T such that $M, s \models A(\Phi_{-\gamma} \vee F(R \vee Q_\gamma))$. Since s is also in the second term, it follows that $M, s \models A(\Phi_{-\gamma} \vee F(R \vee Q_\gamma)) \wedge (P_\gamma \vee Y)$. If s has successors in M, then $M, s \models A(\Phi_{-\gamma} \vee F(R \vee Q_\gamma)) \wedge (P_\gamma \vee Y) \wedge AX_s true$, and we are done. If s has no successors in M, then since we still have $M, s \models A(\Phi_{-\gamma} \vee F(R \vee Q_\gamma))$ it must be that $M, s \models R \vee Q_\gamma$. Attach to s the successors t, u it must have by virtue of membership in the third term and call the resulting structure M'. We have $M', s \models A(\Phi_{-\gamma} \vee F(R \vee Q_\gamma)) \wedge (P_\gamma \vee Y) \wedge AX_s true$, the first conjunct holding because s satisfies $R \vee Q_\gamma$ in M and M', the second conjunct holding because s satisfies $P_\gamma \vee Y$ in M and M', and the third conjunct holding by virtue of t, u. Again, $s \in g_\gamma^{T,con}$ and we are done. ◻

FINDING SEPARATOR CUTS IN PLANAR GRAPHS WITHIN TWICE THE OPTIMAL[*]

NAVEEN GARG[†], HUZUR SARAN[‡], AND VIJAY V. VAZIRANI[§]

Abstract. A factor 2 approximation algorithm for the problem of finding a minimum-cost b-balanced cut in planar graphs is presented, for $b \leq \frac{1}{3}$. We assume that the vertex weights are given in unary; for the case of binary vertex weights, a pseudoapproximation algorithm is presented. This problem is of considerable practical significance, especially in VLSI design.

The natural algorithm for this problem accumulates sparsest cuts iteratively. One of our main ideas is to give a definition of sparsity, called *net-sparsity*, that reflects precisely the cost of the cuts accumulated by this algorithm. However, this definition is too precise: we believe it is **NP**-hard to compute a minimum–net-sparsity cut, even in planar graphs. The rest of our machinery is built to work with this definition and still make it computationally feasible. Toward this end, we use several ideas from the works of Rao [*Proceedings,* 28th *Annual IEEE Symposium on Foundations of Computer Science*, 1987, pp. 225–237; *Proceedings,* 24th *Annual ACM Symposium on Theory of Computing*, 1992, pp. 229–240] and Park and Phillips [*Proceedings,* 25th *Annual ACM Symposium on Theory of Computing*, 1993, pp. 766–775].

1. Introduction.

Given an undirected graph with edge costs and vertex weights, the *balance* of a cut is the ratio of the weight of vertices on the smaller side to the total weight in the graph. For $0 < b \leq \frac{1}{2}$, a cut having a balance of at least b is called a b-balanced cut; a $\frac{1}{3}$-balanced cut is given the special name *separator*. In this paper, we present a factor 2 approximation algorithm for finding a minimum-cost b-balanced cut in planar graphs, for $b \leq \frac{1}{3}$, assuming that vertex weights are given in unary. We also give examples to show that our analysis is tight. For the case of binary vertex weights, we use scaling to give a pseudoapproximation algorithm: for each $\alpha > 2/b$, it finds a $(b - 2/\alpha)$-balanced cut of cost within twice the cost of an optimal b-balanced cut, for $b \leq 1/3$, in time polynomial in n and α. The previous best approximation guarantee known for b-balanced cuts in planar graphs was $O(\log n)$, due to Rao [8, 9]; for general graphs, no approximation algorithms are known.

The problem of breaking a graph into "small"-sized pieces by removal of a "small" set of edges or vertices has attracted much attention since the seminal work of Lipton and Tarjan [5], because this opens up the possibility of a divide-and-conquer strategy for the solution of several problems on the graph. Small balanced cuts have numerous applications; see, for example, [1, 3, 4, 6]. Several of these applications pertain to planar graphs, the most important one being circuit partitioning in VLSI design.

The *sparsity* of a cut is defined to be the ratio of the cost of the cut and the weight on its smaller side, and a cut having minimum sparsity in the graph is called

the *sparsest cut*. Rao [9] gave a $\frac{3}{2}$-approximation algorithm for the problem of finding a sparsest cut in planar graphs, and recently Park and Phillips [7] showed that this problem is polynomial time–solvable. A sparsest cut limits multicommodity flow in the same way that a min-cut limits max-flow. Leighton and Rao [3] derived an approximate max-flow min-cut theorem for uniform multicommodity flow and in the process gave an $O(\log n)$-approximation algorithm for finding a sparsest cut in general graphs. By finding and removing these cuts iteratively, one can show how to find in planar (general) graphs a b-balanced cut that is within an $O(1)$ factor ($O(\log n)$ factor) of the optimal b'-balanced cut for $b < b'$, and $b \leq \frac{1}{3}$ [8, 9, 3]. For instance, using the Park–Phillips algorithm for sparsest cut in planar graphs, this approach gives a $\frac{1}{3}$-balanced cut that is within 7.1 times the cost of the best $\frac{1}{2}$-balanced cut in planar graphs. Notice, however, that these are not true approximation algorithms, since the best $\frac{1}{2}$-balanced cut may have a much higher cost than the best $\frac{1}{3}$-balanced cut.

This iterative algorithm has shortcomings which prevent it from leading to a good true approximation algorithm; these are illustrated via an example in section 3. One of our main ideas is to give a definition of sparsity, called *net-sparsity*, that overcomes these shortcomings. The notion of *net-cost*, on which this definition of net-sparsity is based, reflects *precisely* the cost of the cuts accumulated iteratively. Indeed, it is too precise to be directly useful computationally—we believe that computing the sparsest cut under this definition is **NP**-hard even in planar graphs. The rest of our machinery is built to work with this definition and still make it computationally feasible, and we manage to scrape by narrowly!

Planarity is exploited in several ways: First, a cut in a planar graph corresponds to a set of cycles in the dual. Second, the notion of a *transfer function* turns out to be very useful. Given a planar graph with weights on faces, this notion can be used to define a function on the edges of the graph so that on any cycle it evaluates to the sum of the weights of the faces enclosed by the cycle. Such an idea has been used in the past by Kasteleyn [2] for computing the number of perfect matchings in a planar graph in polynomial time. Kasteleyn defined his function over $GF[2]$. Park and Phillips [7] first defined the function over reals, thereby demonstrating the full power of this notion.

Park and Phillips [7] have shown that the problems of finding a sparsest cut and a minimum b-balanced cut in planar graphs are weakly **NP**-hard; i.e., these problems are **NP**-hard if the vertex weights are given in binary. Indeed, the algorithm they give for finding the sparsest cut in planar graphs is a pseudopolynomial time algorithm. As a consequence of this algorithm, it follows that if $\mathbf{P} \neq \mathbf{NP}$, finding sparsest cuts in planar graphs is not strongly **NP**-hard. On the other hand it is not known if the b-balanced cut problem in planar graphs is strongly **NP**-hard or if there is a pseudopolynomial time algorithm for it. (The present paper gives only a pseudopolynomial approximation algorithm.) Park and Phillips leave open the question of finding a fully polynomial approximation scheme for sparsest cuts in planar graphs, i.e., if the vertex weights are given in binary. We give such an algorithm using a scaling technique.

2. Preliminaries.

Let $G = (V, E)$ be a connected undirected graph with an edge cost function $c : E \to \mathbf{R}^+$ and a vertex weight function $wt : V \to \mathbf{Z}^+$. Any function that we define on the elements of a universe extends to sets of elements in the obvious manner; the value of the function on a set is the sum of its values on the elements in the set. Let W be the sum of weights of all vertices in G. A partition $(S, \overline{S})$ of V defines a *cut* in G; the cut consists of all edges that have one end point in

S and the other in $\overline{S}$. A set of vertices, S, is said to be *connected* when the subgraph induced on it is connected. If either S or $\overline{S}$ is connected then cut $(S, \overline{S})$ will be called a *simple cut*, and when both S and $\overline{S}$ are connected then the cut $(S, \overline{S})$ is called a *bond*.

Given a set of vertices $S \subset V$, we define the cost of this set, $\text{cost}(S)$, as the sum of the costs of all edges in the cut $(S, \overline{S})$. The weight of the set S, $\text{wt}(S)$, is the sum of the weights of the vertices included in S.

A cut $(S, \overline{S})$ is a *separator* if $\frac{W}{3} \le \text{wt}(S), \text{wt}(\overline{S}) \le \frac{2W}{3}$. The cost of a separator is the sum of the costs of the edges in the separator.

LEMMA 2.1. *For any connected graph G there exists a minimum-cost separator, $(S, \overline{S})$, which is a simple cut. Further, if S is the side that is not connected, then each connected component of S has weight strictly less than $\frac{W}{3}$.*

Proof. Let $(S, \overline{S})$ be a minimum-cost separator in G. Consider the connected components obtained on removing the edges of this separator. Clearly, no component has weight strictly larger than $\frac{2W}{3}$. If all components have weight strictly less than $\frac{W}{3}$ then both S and $\overline{S}$ are not connected and we can arrive at a contradiction as follows. We first pick two components that have an edge between them and then pick the remaining, one by one, in an arbitrary order until we accumulate a weight of at least $\frac{W}{3}$. The accumulated weight cannot exceed $\frac{2W}{3}$ since each component has weight at most $\frac{W}{3}$. Thus we obtain a separator of cost strictly less than the cost of the separator $(S, \overline{S})$, a contradiction. Hence, at least one component has weight between $\frac{W}{3}$ and $\frac{2W}{3}$. If there are two such components then these are the only components since by switching the side of a third component we obtain a cheaper separator. If there is only one component of weight between $\frac{W}{3}$ and $\frac{2W}{3}$ then this separator is optimum iff this component forms one side of the cut and the remaining components the other side. Thus $(S, \overline{S})$ is a bond and if some side of the cut is not connected then all components on that side have weight strictly less than $\frac{W}{3}$. $\square$

Hence there always exists a minimum-cost separator that is a simple cut. Let OPT denote the set of vertices on the side of this separator that is not connected.

3. Overview of the algorithm.

Let S be a set of vertices such that $\text{wt}(S) \le \text{wt}(\overline{S})$. The *sparsity* of S is usually defined as the quotient of the cost and the weight of this set, i.e.,

$$\text{sparsity}(S) = \frac{\text{cost}(S)}{\text{wt}(S)}.$$

A natural approach to finding good separators is to repeatedly find a set of minimum sparsity and remove it from the graph, eventually reporting the union of the removed vertices. It is easy to concoct “bad” examples for this approach by ensuring that the picked vertices always come from the smaller side of the optimal separator, thereby ensuring that the minimum sparsity available in the remaining graph keeps increasing. This is illustrated in Figure 3.1; here the first cut picked has a sparsity of $\frac{1}{m}$, whereas the last cut has a sparsity of $\frac{1}{2}$.

This approach has two shortcomings: it removes the vertices picked in each iteration and deals only with the remaining graph in subsequent iterations, and it assumes that edges of the cuts found in each iteration are picked permanently, even though they may not be needed in the final cut. One of our main ideas is to give a definition of “sparsity” under which this algorithm does not suffer from either of these shortcomings.

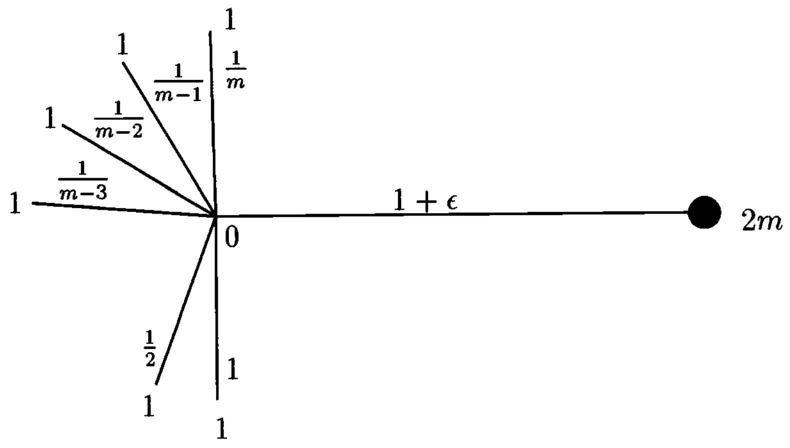

FIG. 3.1. *Graph with vertex weights and edge costs showing how minimum sparsity increases. Here* $m = \frac{n}{3}$.

Let $S, T \subset V$ be two sets of vertices. Define the *net-cost* of S with respect to T as

$$\text{net-cost}_T(S) = \text{cost}(T \cup S) - \text{cost}(T)$$

and the *net-weight* of S with respect to T as

$$\text{net-weight}_T(S) = \text{wt}(T \cup S) - \text{wt}(T).$$

Thus, if we have already picked the set of vertices T, then net-cost$_T(S)$ measures the extra cost incurred and net-weight$_T(S)$ the weight added in picking the set $S \cup T$. Finally, define the *net-sparsity* of S with respect to T as

$$\text{net-sparsity}_T(S) = \frac{\text{net-cost}_T(S)}{\text{net-weight}_T(S)}.$$

For any algorithm that picks a cut by accumulating sets of vertices, the notion of net-cost gives precisely the extra cost incurred in each iteration. But is it so precise that computing the sparsest cut under this definition turns out to be **NP**-hard even in planar graphs? Although we do not have an answer to this question, we believe that it is "yes"! Indeed, the rest of our machinery is built to work with this definition and still make it computationally feasible, and we manage to scrape by narrowly!

Let us first show that it is not sufficient to just keep picking sets of minimum net-sparsity. Consider the following example: Suppose OPT $= S_1 \cup S_2$, where S_1 is a very sparse set of weight $\frac{W}{3} - \epsilon$ and S_2 is a set of high sparsity and weight ϵ for a small ϵ. Having picked S_1, we might pick another set, S_3 of sparsity almost that of S_2, and weight $\frac{W}{3} - \epsilon$; hence, the cost incurred would be arbitrarily high compared to the optimum.

We get around this difficulty by ensuring that in each iteration the set of vertices we pick is such that the total weight accumulated is strictly under $\frac{W}{3}$. More formally, let T_{i-1} be the set of vertices picked by the end of the $(i-1)$th iteration ($T_0 = \phi$). In the ith iteration we pick a set D_i such that

[weight] $\mathrm{wt}(T_{i-1} \cup D_i) < \frac{W}{3}$.
[net-sparsity] $\forall S : \mathrm{wt}(T_{i-1} \cup S) < \frac{W}{3}$, $\text{net-sparsity}_{T_{i-1}}(D_i) \leq \text{net-sparsity}_{T_{i-1}}(S)$.
[minimality] D_i has minimum net-weight among all sets satisfying the above conditions.

We call set D_i a *dot* and denote it by $\bullet$. Thus, at the end of the ith iteration the set of vertices we have picked is given by $T_i = T_{i-1} \cup D_i$. This is how we augment the "partial solution" $(T_1, T_2, \ldots, T_i)$ in each iteration.

How do we ever obtain a "complete solution" (a separator)? In the ith iteration, besides augmenting the partial solution T_{i-1} to the partial solution T_i we also augment it to a complete solution, i.e., we pick a set of vertices B_i such that

[weight] $\frac{W}{3} \leq \mathrm{wt}(T_{i-1} \cup B_i) \leq \frac{2W}{3}$.
[cost] $\forall S : \frac{W}{3} \leq \mathrm{wt}(T_{i-1} \cup S) \leq \frac{2W}{3}$, $\mathrm{cost}(B_i) \leq \mathrm{cost}(S)$.

Since $T_0 = \phi$, finding the set B_1 corresponds to finding the minimum-cost separator. To avoid this circularity in the argument we restrict B_i to a smaller class of sets:

[cost] $\forall S : (S, \overline{S})$ is a bond and $\frac{W}{3} \leq \mathrm{wt}(T_{i-1} \cup S) \leq \frac{2W}{3}$, $\mathrm{cost}(B_i) \leq \mathrm{cost}(S)$.

We call the set B_i a *box* and denote it by $\square$. Notice that a box set need not be a bond and that we count a $\square$ at its cost rather than its net-cost. This is done only to simplify the algorithm and its analysis. The example which shows that the analysis of our algorithm is tight also shows that counting the $\square$ at its net-cost would not have led to any improvement in the approximation guarantee.

Thus, in each iteration we obtain a separator. The solution reported by the algorithm is the one of minimum cost from among all these separators. The algorithm, which we call the *dot-box algorithm*, is the following.

Dot-Box Algorithm.

```
    1. MINSOL ← $\infty$, $i \leftarrow 0$, $T_0 \leftarrow \phi$
    2. while $\mathrm{wt}(T_i) < \frac{W}{3}$ do
          2.1. $i \leftarrow i + 1$
          2.2. Find $\bullet$ and $\square$ sets, $D_i$ and $B_i$, respectively.
               If there is no $\bullet$ set, exit.
          2.3. MINSOL ← min(MINSOL, $\mathrm{cost}(T_{i-1}) + \mathrm{cost}(B_i)$)
          2.4. $T_i \leftarrow T_{i-1} \cup D_i$
end.
```

We make two remarks regarding step (2.2). First, we conjecture that finding the $\bullet$ set is **NP**-hard. Our procedure to find $\bullet$ sets may not always succeed; however, we will prove that if it fails, then the $\square$ set found in the current iteration gives a separator within twice OPT. Second, at some iteration it might be the case that no subset of vertices satisfies the weight criterion for a $\bullet$, since each set takes the total weight accumulated to $W/3$ or more. In this case, the dot-box algorithm halts and outputs the best separator found so far.

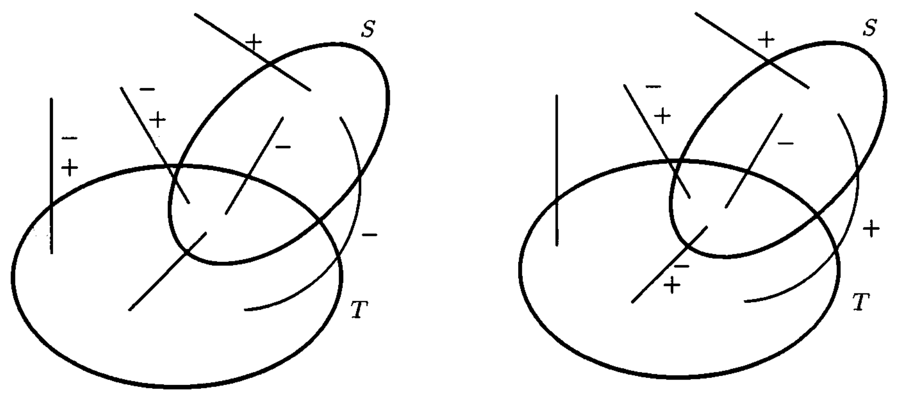

FIG. 4.1. *Computation of* net-cost$_T(S)$ *and* net-cost$_{S\cap T}(S)$. *A* $+/-$ *on an edge signifies that the edge is counted in the positive/negative term in the net-cost computation.*

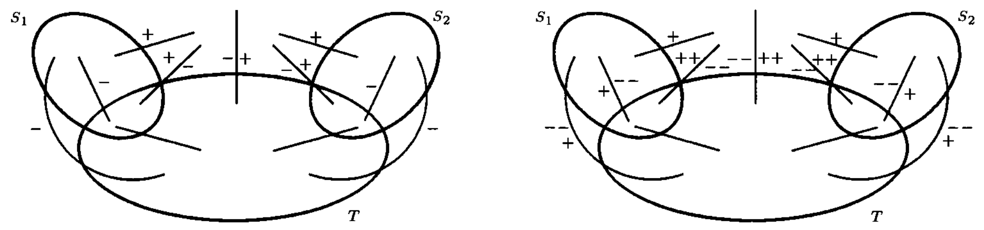

FIG. 4.2. *Computation of* net-cost$_T(S_1 \cup S_2)$ *and* net-cost$_T(S_1)$+net-cost$_T(S_2)$.

4. Analysis of the dot-box algorithm.

We first prove some properties of net-cost and net-weight which will be useful for the analysis. From the definition of net-cost and net-weight we have that net-cost$_T(S)$ = net-cost$_T(S-T)$ and net-weight$_T(S)$ = net-weight$_T(S-T)$ = wt$(S-T)$. The following property also follows from the definitions

PROPERTY 4.1. *Let S_1, S_2 be two sets of vertices not necessarily disjoint. Then*

$$\text{net-cost}_T(S_1 \cup S_2) = \text{net-cost}_T(S_1) + \text{net-cost}_{T\cup S_1}(S_2),$$
$$\text{net-weight}_T(S_1 \cup S_2) = \text{net-weight}_T(S_1) + \text{net-weight}_{T\cup S_1}(S_2).$$

PROPERTY 4.2. net-cost$_T(S) \leq$ net-cost$_{S\cap T}(S)$.

Proof. Figure 4.1 shows the edges between the sets $S\cap T$, $S-T$, $T-S$, and $\overline{S\cup T}$ from which the above property is immediate. The net-cost of S with respect to $S\cap T$ may be higher because it includes the cost of edges from $S-T$ to $T-S$. □

The following property is immediate from Figure 4.2.

PROPERTY 4.3. *Let S_1, S_2 be two disjoint sets of vertices with no edges between them. Then*

$$\text{net-cost}_T(S_1 \cup S_2) = \text{net-cost}_T(S_1) + \text{net-cost}_T(S_2).$$

REMARK 4.1. *For positive real numbers a, b, c, d,*

$$\min\left(\frac{a}{b}, \frac{c}{d}\right) \leq \frac{a+c}{b+d} \leq \max\left(\frac{a}{b}, \frac{c}{d}\right).$$

Further, let $a_i, b_i, 1 \leq i \leq k$, be positive real numbers. Then, $\exists i, 1 \leq i \leq k$, such that

$$\frac{a_i}{b_i} \leq \frac{\sum_{j=1}^{k} a_j}{\sum_{j=1}^{k} b_j}.$$

LEMMA 4.1. *The net-sparsity of the ●'s is increasing, i.e.,*

$$\forall i : i \geq 1, \quad \text{net-sparsity}_{T_{i-1}}(D_i) \leq \text{net-sparsity}_{T_i}(D_{i+1}).$$

Proof. Since the set $D_i \cup D_{i+1}$ satisfies the weight requirement for a ● at the ith iteration,

$$\text{net-sparsity}_{T_{i-1}}(D_i) \leq \text{net-sparsity}_{T_{i-1}}(D_i \cup D_{i+1}).$$

By Property 4.1,

$$\text{net-cost}_{T_{i-1}}(D_i \cup D_{i+1}) = \text{net-cost}_{T_{i-1}}(D_i) + \text{net-cost}_{T_i}(D_{i+1}),$$
$$\text{net-weight}_{T_{i-1}}(D_i \cup D_{i+1}) = \text{net-weight}_{T_{i-1}}(D_i) + \text{net-weight}_{T_i}(D_{i+1}),$$

which, using Remark 4.1, gives us

$$\begin{aligned}\min(\text{net-sparsity}_{T_{i-1}}(D_i), \text{net-sparsity}_{T_i}(D_{i+1})) &\leq \text{net-sparsity}_{T_{i-1}}(D_i \cup D_{i+1}) \\ &\leq \max(\text{net-sparsity}_{T_{i-1}}(D_i), \\ &\qquad \text{net-sparsity}_{T_i}(D_{i+1})).\end{aligned}$$

Now, by the first inequality, it must be the case that

$$\max(\text{net-sparsity}_{T_{i-1}}(D_i), \text{net-sparsity}_{T_i}(D_{i+1})) = \text{net-sparsity}_{T_i}(D_{i+1}).$$

The lemma follows. ▯

Let k be the first iteration at which some connected component of OPT meets the weight requirement of a □.

LEMMA 4.2. $\forall i : 1 \leq i \leq k-1$, $\text{net-sparsity}_{T_{i-1}}(D_i) \leq \text{net-sparsity}_{T_{i-1}}(\text{OPT})$.

Proof. Since OPT $\not\subseteq T_{i-1}$ there are connected components of OPT which are not completely contained in T_{i-1}. By assumption, none of these components satisfies the weight requirement for a □; hence each of these components meets the weight requirement for a ●. Hence the ● picked in this iteration should have net-sparsity at most that of any of these components.

By Property 4.3, the net-cost of OPT is the sum of the net-costs of these components of OPT. The same is true for net-weight; hence the component of OPT with minimum net-sparsity has net-sparsity less than that of OPT. The lemma follows. ▯

The above two lemmas imply that the net-sparsity at which the ●'s are picked is increasing and that for any iteration before the kth, this net-sparsity is less than the net-sparsity of OPT in that iteration.

LEMMA 4.3. $\forall i : 1 \leq i \leq k-1$, $\text{cost}(T_i) < \text{cost}(\text{OPT})$.

Proof. To establish this inequality for i we consider two processes.

1. The first process is our algorithm which picks the set of vertices D_j at the jth step, $1 \leq j \leq i$.
2. The second process picks the vertices $D_j \cap \text{OPT}$ at the jth step, $1 \leq j < i$. At the ith step it picks the remaining vertices of OPT.

Let P_j be the set of vertices picked by the second process in the first j steps. Then $P_j = \mathrm{OPT} \cap T_j, 1 \le j < i$ and $P_i = \mathrm{OPT}$. At the jth step the second process picks an additional weight of net-weight$_{P_{j-1}}(P_j)$ at a cost of net-cost$_{P_{j-1}}(P_j)$. By the fact that the second process picks a subset of what the first process picks at each step we have the following.

CLAIM 4.1. *For* $1 \le j \le i-1$, net-weight$_{T_{j-1}}(D_j) \ge$ net-weight$_{P_{j-1}}(P_j)$.

CLAIM 4.2. *For* $1 \le j \le i$, net-sparsity$_{T_{j-1}}(D_j) \le$ net-sparsity$_{P_{j-1}}(P_j)$.

Proof. Since $P_j \cap T_{j-1} = P_{j-1}$, by Property 4.2 we have

$$\text{net-cost}_{T_{j-1}}(P_j) \le \text{net-cost}_{P_{j-1}}(P_j).$$

Further,

$$\text{net-weight}_{T_{j-1}}(P_j) = \text{net-weight}_{P_{j-1}}(P_j)$$

and hence net-sparsity$_{T_{j-1}}(P_j) \le$ net-sparsity$_{P_{j-1}}(P_j)$.

For $j < i$, the claim follows since P_j satisfies the weight requirement for a $\bullet$ and D_j was picked as the $\bullet$. For $j = i$, $P_j = \mathrm{OPT}$ and the claim follows from Lemma 4.2. $\square$

The above claims imply that in each iteration (1 through i) the first process picks vertices at a lower net-sparsity than the second process. If both these processes were picking the same additional weight in each iteration then this fact alone would have implied that the cost of the vertices picked by the first process is less than the cost of the vertices picked by the second. But this is not the case. What is true, however, is the fact that in iterations 1 through $i-1$ the first process picks a larger additional weight than the second process. In the ith iteration, the second process picks enough additional weight so that it now has accumulated a total weight strictly larger than that picked by the first process (since $\mathrm{wt}(\mathrm{OPT}) \ge \frac{W}{3} > \mathrm{wt}(T_i)$). But the net-sparsity at which the second process picks vertices in the ith iteration is more than the maximum (over iterations 1 through i) net-sparsity at which the first process picks vertices. So it follows that the cost of the vertices picked by the first process is strictly less than the cost of the vertices picked by the second, i.e., $\mathrm{cost}(T_i) < \mathrm{cost}(\mathrm{OPT})$. $\square$

Consider the separator found in the kth iteration, i.e., the cut $(T_{k-1} \cup B_k, \overline{T_{k-1} \cup B_k})$. This solution is formed by picking $\bullet$'s in the first $k-1$ steps and a $\square$ in the kth step.

LEMMA 4.4. $\mathrm{cost}(T_{k-1} \cup B_k) \le 2 \cdot \mathrm{cost}(\mathrm{OPT})$.

Proof. Any connected component of OPT is a bond. In the kth iteration there exists a connected component of OPT, say OPT_j, such that $\frac{W}{3} \le \mathrm{wt}(T_{k-1} \cup \mathrm{OPT}_j) \le \frac{2W}{3}$. Hence the $\square$ at the kth step should have cost at most $\mathrm{cost}(\mathrm{OPT}_j)$, i.e., $\mathrm{cost}(B_k) \le \mathrm{cost}(\mathrm{OPT}_j) \le \mathrm{cost}(\mathrm{OPT})$.

From Lemma 4.3 we know that $\mathrm{cost}(T_{k-1}) < \mathrm{cost}(\mathrm{OPT})$. Hence

$$\mathrm{cost}(T_{k-1} \cup B_k) < \mathrm{cost}(T_{k-1}) + \mathrm{cost}(B_k) < 2 \cdot \mathrm{cost}(\mathrm{OPT}). \qquad \square$$

Since the dot-box algorithm outputs the best separator found, we have the following theorem.

THEOREM 4.5. *The cost of the separator found by the dot-box algorithm is at most twice the cost of* OPT.

Our analysis of the dot-box algorithm is tight; when run on the example in Figure 4.3, it picks a separator of cost almost twice the optimum. In this example,

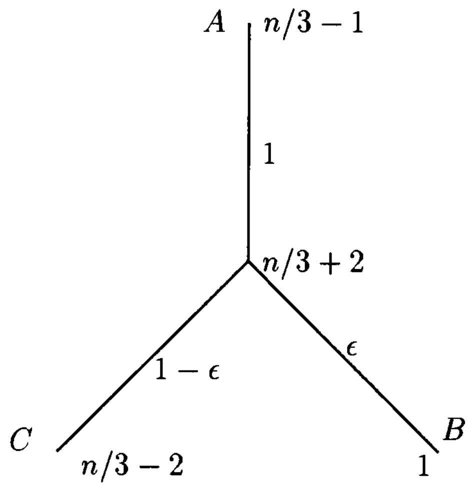

FIG. 4.3. *A tight example for our analysis. Vertex weights and edge costs are given and $\epsilon = 3/n$.*

OPT $= A \cup B$ and so cost(OPT) $= 1 + \epsilon$. For $\epsilon > 3/n$, the $\bullet$ in the first iteration is the set C and the $\Box$ is the set A. This separator, which is also the one returned by the dot-box algorithm, has cost $2 - 2\epsilon$ and hence the approximation ratio is $2(\frac{n-3}{n+3})$.

5. Structural properties of our solution, and a computationally easier definition of net-cost. In this section we prove some structural properties of the solution found by the dot-box algorithm. This allows us to redefine net-cost in such a manner that it becomes computationally easier and yet the analysis from the previous section continues to hold.

LEMMA 5.1. *For $1 \le i \le k-1$, $\overline{T_i}$ is connected.*

Proof. For contradiction assume that $\overline{T_i}$ is not connected. Let A be a connected component of $\overline{T_i}$. There are three cases.

$\text{wt}(T_i \cup A) < \mathbf{W/3}$: The set A satisfies the weight requirement for a $\bullet$ at the $(i+1)$th iteration. Since A has edges only to vertices in T_i, the net-cost of A with respect to T_i is negative. Hence net-sparsity$_{T_i}(A)$ is negative, contradicting Lemma 4.1.

$\mathbf{W/3} \le \text{wt}(T_i \cup A) \le \mathbf{2W/3}$: The cut $(T_i \cup A, \overline{T_i \cup A})$ is a separator of cost, $\text{cost}(T_i \cup A) < \text{cost}(T_i) < \text{cost(OPT)}$, a contradiction.

$\text{wt}(T_i \cup A) > \mathbf{2W/3}$: Since $\text{wt}(T_i) < W/3$, the condition of this case implies that $\text{wt}(A) > W/3$. If $\text{wt}(A) \le 2W/3$ then once again we have a contradiction since now the cut $(A, \overline{A})$ is a separator of cost, $\text{cost}(A) < \text{cost}(T_i) < \text{cost(OPT)}$. Thus it must be the case that $\text{wt}(A) > 2W/3$.

Since the above argument implies that each connected component of $\overline{T_i}$ has weight greater than $2W/3$, $\overline{T_i}$ must have only one connected component. ∎

LEMMA 5.2. *For $1 \le i \le k-1$, the set $T_i - T_{i-1}$ is connected.*

Proof. For contradiction assume that $T_i - T_{i-1}$ is not connected. Let A be a connected component of $T_i - T_{i-1}$ and B be the rest of $T_i - T_{i-1}$. (We also denote by A, B the corresponding sets of vertices.)

If D_i is the $\bullet$ at the ith iteration then $\text{net-cost}_{T_{i-1}}(D_i) = \text{net-cost}_{T_{i-1}}(A \cup B)$.

Since A and B are disjoint set of vertices with no edges between them, by Property 4.3

$$\text{net-cost}_{T_{i-1}}(D_i) = \text{net-cost}_{T_{i-1}}(A) + \text{net-cost}_{T_{i-1}}(B).$$

Further,

$$\text{net-weight}_{T_{i-1}}(D_i) = \text{net-weight}_{T_{i-1}}(A) + \text{net-weight}_{T_{i-1}}(B).$$

Thus it is the case that either A or B has smaller net-sparsity than D_i, which contradicts the assumption that D_i is a $\bullet$, or both A and B have the same net-sparsity as D_i, but this contradicts the minimality requirement on D_i. $\square$

LEMMA 5.3. *For every iteration $i : 1 \leq i \leq k-1$, there exists a $\bullet$, D_i, satisfying the following:*

1. *$(D_i, \overline{D_i})$ is a bond.*
2. *Each connected component of T_{i-1} is contained in D_i or $\overline{D_i}$ and there is no edge between D_i and components of T_{i-1} in $\overline{D_i}$.*

Proof. The set $T_i - T_{i-1}$ together with any subset of T_{i-1} is also a $\bullet$ for the ith iteration. We form a new $\bullet$, D_i, by merging with $T_i - T_{i-1}$ all connected components of T_{i-1} which have an edge to $T_i - T_{i-1}$. Since $T_i - T_{i-1}$ is connected, so is D_i. Further, since the graph is connected, every remaining component of T_{i-1} has an edge to $\overline{T_i}$ so that $\overline{D_i}$ is also connected. Thus $(D_i, \overline{D_i})$ is a bond. It follows from the definition of D_i that there is no edge between D_i and components of T_{i-1} in $\overline{D_i}$. $\square$

Since every $\bullet$ in iterations 1 through $k-1$ satisfies the conditions in Lemma 5.3, we can restrict our search for the $\bullet$ at the ith iteration to sets that satisfy these conditions as additional requirements.

$(D_i, \overline{D_i})$ is a bond.
Each connected component of T_{i-1} is contained in D_i or $\overline{D_i}$ and there is no edge between D_i and components of T_{i-1} in $\overline{D_i}$.

Let $G_i = (V_i, E_i)$ be the graph obtained by shrinking each connected component of T_{i-1} into a single vertex, removing the self-loops formed and replacing each set of parallel edges by one edge of cost equal to the sum of the cost of the edges in the set. For finding a $\bullet$ at the ith iteration we consider only such sets, S, such that no connected component of T_{i-1} is split across $(S, \overline{S})$ and $(S, \overline{S})$ is a bond. Therefore, we need to look only at subsets of V_i that correspond to bonds in G_i.

Let S be a subset of vertices in G_i. The *trapped cost of S with respect to T_{i-1}*, denoted by $\text{trapped-cost}_{T_{i-1}}(S)$, is the sum of the costs of the components of T_{i-1} that are contained in S. We now redefine the *net-cost of S with respect to T_{i-1}* as

$$\text{net-cost}_{T_{i-1}}(S) = \text{cost}(S) - \text{trapped-cost}_{T_{i-1}}(S).$$

Note that for any subset of vertices in G_i, the net-cost under this new definition is at least as large as that under the previous definition. However, and this is crucial, the net-cost of the $\bullet$ set D_i remains unchanged. This is so because by Lemma 5.3 there are no edges between D_i and the components of T_{i-1} not in D_i. Therefore, a $\bullet$ under this new definition of net-cost will also be a $\bullet$ under the previous definition, and so our analysis of the dot-box algorithm continues to hold.

6. Onto planar graphs.

We do not know the complexity of computing $\bullet$ sets; we suspect that it is **NP**-hard even in planar graphs. Yet, we can implement the dot-box algorithm for planar graphs—using properties of cuts in planar graphs, and by showing that if in any iteration, the algorithm does not find the • set, then in fact, the separator found (using the □ set found in this iteration) is within twice the optimal. (This is proven in Theorem 7.1.)

6.1. Associating cycles with sets. We let G^D be the planar dual of G and fix an embedding of G^D.

PROPOSITION 6.1. *There is a one-to-one correspondence between bonds in* G *and simple cycles in* G^D.

Proof. Let $(S, \overline{S})$ be a bond in G. Since S is connected, the faces corresponding to S in G^D are adjacent, so the edges of G^D corresponding to $(S, \overline{S})$ form a simple cycle.

For the converse, let C be a simple cycle in G^D which corresponds to the cut $(S, \overline{S})$ in G. Let u, v be two vertices in G that are on the same side of the cut $(S, \overline{S})$. To prove that $(S, \overline{S})$ is a bond it suffices to show a path between u and v in G that does not use any edge of $(S, \overline{S})$.

Embed G and G^D in $\mathbf{R} \times \mathbf{R}$, and consider the two faces of G^D corresponding to vertices u and v. Pick an arbitrary point in each face, for instance, the points corresponding to u and v. Since C is a simple cycle in G^D (and hence in $\mathbf{R} \times \mathbf{R}$) there is a continuous curve (in $\mathbf{R} \times \mathbf{R}$) that connects the two points without intersecting C. By considering the faces of G^D that this curve visits, and the edges of G^D that the curve intersects, we obtain a path in G that connects vertices u, v without using any edge of $(S, \overline{S})$. □

Since for finding a • and □ we need to consider only sets, S, such that $(S, \overline{S})$ is a bond, we can restrict ourselves to simple cycles in G^D. Furthermore, the two orientations of a simple cycle can be used to distinguish between the two sides of the cut to which this cycle corresponds. The notation we adopt is the following: with a cycle C directed clockwise we associate the set of faces in G^D (and hence vertices in G) *enclosed* by C. (The side that does not include the infinite face is said to be enclosed by C and the side containing the infinite face is said to be *outside* C.)

Let $\vec{G^D}$ be the graph obtained from G^D by replacing each undirected edge (u, v) by two directed edges $(u \to v)$ and $(v \to u)$. By the preceding discussion, there exists a correspondence between sets of vertices, S, in G such that $(S, \overline{S})$ is a bond and directed simple cycles in $\vec{G^D}$.

6.2. Transfer function. We associate a cost function, c, with the edges of $\vec{G^D}$ in the obvious manner; an edge in $\vec{G^D}$ is assigned the same cost as the corresponding dual edge in G. Thus, for a directed cycle, C, $c(C)$, denotes the sum of the costs of the edges along the cycle. We would also like to associate functions, t_i, w_i with the edges of $\vec{G^D}$ so that if S is the set corresponding to a directed simple cycle C, then $t_i(C) = \text{trapped-cost}_{T_{i-1}}(S)$ and $w_i(C) = \text{net-weight}_{T_{i-1}}(S)$. We achieve this by means of a *transfer function*.

The notion of a transfer function was introduced by Park and Phillips [7] and can be viewed as an extension of a function given by Kasteleyn [2]. A function g defined on the edges of $\vec{G^D}$ is *antisymmetric* if $g(u \to v) = -g(v \to u)$. (Notice that the function c defined above is *symmetric*.) Let $f : V \to \mathbf{R}$ be a function on the vertices of G. The transfer function corresponding to f is an antisymmetric function, f_t, on the edges of $\vec{G^D}$ such that the sum of the values that f_t takes on the edges of any clockwise (anticlockwise) simple cycle in $\vec{G^D}$ is equal to the (negative of the) sum of the values that f takes on the vertices corresponding to the faces enclosed by this cycle.

That a transfer function exists for every function defined on the vertices of G and that it can be computed efficiently from the following simple argument. Pick a spanning tree in G^D, and set f_t to zero for the corresponding edges in $\vec{G^D}$. Now, add the remaining edges of G^D in an order so that with each edge added, one face of this graph is completed. Note that before the edge e is added, all other edges of the face that e completes have been assigned a value under f_t. One of the two directed edges corresponding to e is used in the clockwise traversal of this face, and the other in the anticlockwise traversal. Since the value of f for this face is known and since f_t should sum to this value (the negative of this value) in a clockwise (anticlockwise) traversal of this face, the value of f_t for the two directed edges corresponding to e can be determined. Note that the function f_t obtained in this manner is antisymmetric, and this together with the fact that the edges of any simple cycle in G^D can be written as a $GF[2]$ sum of the edges belonging to the faces contained in the cycle implies that f_t has the desired property.

7. Finding • sets.

Recall that a • at the ith iteration is a bond in the graph $G_i = (V_i, E_i)$; hence we can restrict our search for a • at the ith iteration to directed simple cycles in $\vec{G_i^D}$.

7.1. Obtaining net-weight and net-cost from transfer functions.

Let $\tilde{w}_i : V_i \to \mathbf{Z}^+$, $\tilde{t}_i : V_i \to \mathbf{R}^+$ be two functions defined on the vertices of G_i as follows. The vertices in V_i obtained by shrinking connected components of T_{i-1} have $\tilde{w}_i = 0$ and $\tilde{t}_i$ equal to the cost of the corresponding component of T_{i-1}. The remaining vertices have $\tilde{w}_i = wt$ and $\tilde{t}_i = 0$. Let w_i, t_i denote the transfer functions corresponding to functions $\tilde{w}_i, \tilde{t}_i$. We now relate the values of the functions c, w_i, t_i on a directed simple cycle to the net-cost, net-weight, and net-sparsity of the set corresponding to the cycle.

Let C be a directed simple cycle in $\vec{G_i^D}$ and $S \subset V$ the set corresponding to it. If C is clockwise then the net-weight and trapped cost of S are given by the values of the transfer functions on C, i.e.,

$$\text{net-weight}_{T_{i-1}}(S) = w_i(C),$$
$$\text{trapped-cost}_{T_{i-1}}(S) = t_i(C).$$

If C is anticlockwise then the values of the transfer functions w_i, t_i on C equal the negative of the net-weight and the trapped cost of the set enclosed by C (which is $\overline{S}$ in our notation). Hence

$$\text{net-weight}_{T_{i-1}}(S) = W - \text{wt}(T_{i-1}) - \text{net-weight}_{T_{i-1}}(\overline{S}) = W - \text{wt}(T_{i-1}) + w_i(C),$$

$$\text{trapped-cost}_{T_{i-1}}(S) = \text{cost}(T_{i-1}) - \text{trapped-cost}_{T_{i-1}}(\overline{S}) = \text{cost}(T_{i-1}) + t_i(C).$$

Recalling our new definition of net-cost,

$$\text{net-cost}_{T_{i-1}}(S) = \text{cost}(S) - \text{trapped-cost}_{T_{i-1}}(S).$$

We conclude that if C is clockwise

$$\text{net-sparsity}_{T_{i-1}}(S) = \frac{c(C) - t_i(C)}{w_i(C)},$$

and for anticlockwise C,

$$\text{net-sparsity}_{T_{i-1}}(S) = \frac{c(C) - (t_i(C) + \text{cost}(T_{i-1}))}{w_i(C) + W - \text{wt}(T_{i-1})}.$$

Hence, for a simple directed cycle C, once we know the values of the transfer functions w_i, t_i it is easy to determine the net-weight and net-sparsity of the corresponding set S. Note that the orientation of C can be determined by the sign of $w_i(C)$ since $w_i(C) > 0$ ($w_i(C) < 0$) implies that C is clockwise (anticlockwise).

7.2. The approach to finding a •. For a fixed value of $w_i(C)$, net-sparsity$_{T_{i-1}}(S)$ is minimized when $c(C) - t_i(C)$ is minimum. This suggests the following approach for finding a •: For each w in the range $(0 \le w \le \frac{W}{3} - \text{wt}(T_{i-1})) \cup (-W + \text{wt}(T_{i-1}) \le w \le \frac{-2W}{3})$, compute **min-cycle($w$)**, a directed simple cycle with minimum $c(C) - t_i(C)$ among all directed cycles C with $w_i(C) = w$. Find the net-sparsity of the set corresponding to each of these cycles. The set with the minimum net-sparsity is the • for this iteration.

However, we can implement only a weaker version of procedure **min-cycle**. Following [7], we construct a graph H_i whose vertices are 2-tuples of the kind (v, j) where v is a vertex in $\vec{G_i^D}$ and j is an integer between $-nW$ and nW. For an edge $e = u \to v$ in $\vec{G_i^D}$ we have, for all possible choices of j, edge $(u, j) \to (v, j + w_i(e))$ of length $c(e) - t_i(e)$. The shortest path between $(v, 0)$ and (v, w) in H_i gives the shortest cycle among all directed cycles in $\vec{G_i^D}$ which contain v and for which $w_i(C) = w$. By doing this computation for all choices of v, we can find the shortest cycle with $w_i(C) = w$.

Two questions arise.

1. Is H_i free of negative cycles? This is essential for computing shortest paths efficiently.
2. Is the cycle obtained in $\vec{G_i^D}$ simple?

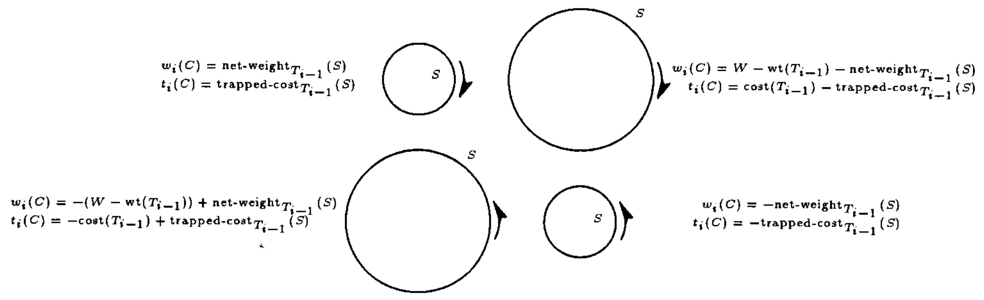
The answer to both questions is "no." Interestingly enough, things still work out. We will tackle first the second question (in Theorem 7.1) and then the first (in Lemma 7.2).

7.3. Overcoming nonsimple cycles. Before we discuss how to get over this problem, we need to have a better understanding of the structure of a nonsimple cycle, C. If C is not a simple cycle in $\vec{G_i^D}$, decompose it arbitrarily into a collection of edge-disjoint directed simple cycles, $\mathcal{C}$. Let $(S_j, \overline{S_j})$ be the cut (in G_i) corresponding to a cycle $C_j \in \mathcal{C}$ and S_j be the side of the cut that has smaller net-weight. Further, let $\mathcal{S}$ be the collection of sets S_j, one for each $C_j \in \mathcal{C}$.

The value of the transfer functions w_i, t_i over C is the sum of their values over the cycles C_j in the collection $\mathcal{C}$. Also,

$$c(C) = \sum_{S_j \in \mathcal{S}} \text{cost}(S_j).$$

For each cycle $C_j \in \mathcal{C}$ we need to relate the net-weight, trapped cost of S_j to the value of the transfer functions w_i, t_i on C_j. C_j might be either clockwise or anticlockwise. Further, S_j might be either inside C_j or outside C_j. This gives us a total of four different cases. The relationship between net-weight$_{T_{i-1}}(S_j)$ and $w_i(C_j)$, and trapped-cost$_{T_{i-1}}(S_j)$ and $t_i(C_j)$ is given in Figure 7.1 and can be captured succinctly



$w_i(C) = \text{net-weight}_{T_{i-1}}(S)$
$t_i(C) = \text{trapped-cost}_{T_{i-1}}(S)$
S
S
$w_i(C) = W - \text{wt}(T_{i-1}) - \text{net-weight}_{T_{i-1}}(S)$
$t_i(C) = \text{cost}(T_{i-1}) - \text{trapped-cost}_{T_{i-1}}(S)$
S
$w_i(C) = -(W - \text{wt}(T_{i-1})) + \text{net-weight}_{T_{i-1}}(S)$
$t_i(C) = -\text{cost}(T_{i-1}) + \text{trapped-cost}_{T_{i-1}}(S)$
S
$w_i(C) = -\text{net-weight}_{T_{i-1}}(S)$
$t_i(C) = -\text{trapped-cost}_{T_{i-1}}(S)$

FIG. 7.1. *Relationship between* net-weight$_{T_{i-1}}(S)$ *and* $w_i(C)$ *for the four cases.*

as

$$w_i(C_j) = x_j(W - \text{wt}(T_{i-1})) + y_j \cdot \text{net-weight}_{T_{i-1}}(S_j),$$
$$t_i(C_j) = x_j \cdot \text{cost}(T_{i-1}) + y_j \cdot \text{trapped-cost}_{T_{i-1}}(S_j),$$

where $x_j \in \{+1, 0, -1\}$ and $y_j \in \{+1, -1\}$.

Hence we get a *decomposition rule* relating the value of the functions w_i, t_i on a nonsimple cycle C to the net-weight and trapped cost of the sets induced by this cycle:

$$w_i(C) = x(W - \text{wt}(T_{i-1})) + \sum_{S_j \in \mathcal{S}} y_j \cdot \text{net-weight}_{T_{i-1}}(S_j),$$
$$t_i(C) = x \cdot \text{cost}(T_{i-1}) + \sum_{S_j \in \mathcal{S}} y_j \cdot \text{trapped-cost}_{T_{i-1}}(S_j),$$

where $x = \sum_j x_j$ is an integer.

7.4. A key theorem. Let D_i be a $\bullet$ at the ith iteration ($i \le k-1$) and C^* be the directed simple cycle in $\vec{G}_i^D$ corresponding to it. Further, let C be the directed cycle reported by **min-cycle**$(w_i(C^*))$.

THEOREM 7.1. *If C is not simple then the separator found in this iteration has cost at most* $2 \cdot \text{cost(OPT)}$*, i.e.,*

$$\text{cost}(T_{i-1} \cup B_i) \le 2 \cdot \text{cost(OPT)}.$$

Proof. Since C is the directed cycle for which $c(C) - t_i(C)$ is minimum among all cycles with $w_i(C) = w_i(C^*)$ we can claim the following.

If C^* is clockwise, i.e., $w_i(C^*) > 0$, then

$$w_i(C) = \text{net-weight}_{T_{i-1}}(D_i),$$
$$c(C) - t_i(C) \le \text{net-cost}_{T_{i-1}}(D_i),$$

and if C^* is anticlockwise, i.e., $w_i(C^*) < 0$, then

$$W - \text{wt}(T_{i-1}) + w_i(C) = \text{net-weight}_{T_{i-1}}(D_i),$$
$$c(C) - t_i(C) - \text{cost}(T_{i-1}) \le \text{net-cost}_{T_{i-1}}(D_i).$$

Substituting for $w_i(C)$ and $t_i(C)$ by the decomposition rule we get

$$z(W - \mathrm{wt}(T_{i-1})) + \sum_{S_j \in \mathcal{S}} y_j \cdot \text{net-weight}_{T_{i-1}}(S_j) = \text{net-weight}_{T_{i-1}}(D_i), \tag{7.1}$$

$$-z \cdot \mathrm{cost}(T_{i-1}) + \sum_{S_j \in \mathcal{S}} (\mathrm{cost}(S_j) - y_j \cdot \text{trapped-cost}_{T_{i-1}}(S_j)) \leq \text{net-cost}_{T_{i-1}}(D_i), \tag{7.2}$$

where z is x if C^* is clockwise and $x + 1$ if C^* is anticlockwise.

We now prove that there exists $S_j \in \mathcal{S}$ which meets the weight requirement for a $\Box$ and has cost no more than the cost of T_i, i.e.,

1. $\frac{W}{3} \leq \mathrm{wt}(T_{i-1} \cup S_j) \leq \frac{2W}{3}$,
2. $\mathrm{cost}(S_j) \leq \mathrm{cost}(T_{i-1}) + \text{net-cost}_{T_{i-1}}(D_i)$.

Assume for contradiction that no such S_j exists. The following observations about the cost/net-cost of a set $S_j \in \mathcal{S}$ are immediate.

OBSERVATION 7.1. *If* $\text{net-weight}_{T_{i-1}}(S_j) \geq W/3 - \mathrm{wt}(T_{i-1})$ *then*

$$\mathrm{cost}(S_j) > \mathrm{cost}(T_{i-1}) + \text{net-cost}_{T_{i-1}}(D_i),$$

which implies

$$\text{net-cost}_{T_{i-1}}(S_j) > \text{net-cost}_{T_{i-1}}(D_i).$$

OBSERVATION 7.2. *If* $\text{net-weight}_{T_{i-1}}(S_j) < W/3 - \mathrm{wt}(T_{i-1})$ *then*

$$\text{net-sparsity}_{T_{i-1}}(S_j) \geq \text{net-sparsity}_{T_{i-1}}(D_i)$$

and hence

$$\text{net-cost}_{T_{i-1}}(S_j) \geq \text{net-sparsity}_{T_{i-1}}(D_i) \cdot \text{net-weight}_{T_{i-1}}(S_j).$$

The next observation follows from the above two observations.

OBSERVATION 7.3. *All sets* $S_j \in \mathcal{S}$ *have nonnegative net-cost, i.e.,* $\text{net-cost}_{T_{i-1}}(S_j) \geq 0$.

The idea behind obtaining a contradiction is as follows. For every integral choice of z we use (7.1) to provide a lower bound on the total net-weight of the sets $S_j \in \mathcal{S}$ and (7.2) to provide an upper bound on the total net-cost of the sets $S_j \in \mathcal{S}$. We then use the above observations on the cost/net-cost of sets $S_j \in S$ to argue that there is no way of having sets with so large a total net-weight at so little a total net-cost.

We shall consider three cases depending upon whether z is positive, negative, or zero.

$z = 0$. Equation (7.2) implies

$$\begin{aligned}\text{net-cost}_{T_{i-1}}(D_i) &\geq \sum_{S_j \in \mathcal{S}} (\mathrm{cost}(S_j) - y_j \cdot \text{trapped-cost}_{T_{i-1}}(S_j)) \\ &\geq \sum_{S_j \in \mathcal{S}} \text{net-cost}_{T_{i-1}}(S_j),\end{aligned}$$

and from (7.1) we have

$$\begin{aligned}\sum_{S_j \in \mathcal{S}} \text{net-weight}_{T_{i-1}}(S_j) &\geq \sum_{S_j \in \mathcal{S}} y_j \cdot \text{net-weight}_{T_{i-1}}(S_j) \\ &= \text{net-weight}_{T_{i-1}}(D_i).\end{aligned}$$

Since the net-cost of each set is nonnegative (Observation 7.3) each set in $\mathcal{S}$ has net-cost no more than net-cost$_{T_{i-1}}(D_i)$. This in turn implies that every set in $\mathcal{S}$ has net-weight strictly less than $W/3 - \text{wt}(T_{i-1})$ (Observation 7.1). Thus every set in $\mathcal{S}$ meets the weight requirement for a $\bullet$. Since the net-cost of every set in $\mathcal{S}$ is nonnegative, Remark 4.1 applied to the above two inequalities implies that either there exists $S_j \in \mathcal{S}$ of lower net-sparsity than D_i or every set in $\mathcal{S}$ has the same net-sparsity as D_i and the sum of the net-weight of the sets in $\mathcal{S}$ is equal to the net-weight of D_i. The first setting leads to a contradiction since every set in $\mathcal{S}$ satisfies the weight requirement for a $\bullet$ and D_i is the $\bullet$ at this iteration. The second setting in turn contradicts the minimality requirement on D_i.

$z > 0$. Let $\mathcal{S}^-$ denote the collection of sets $S_j \in \mathcal{S}$ with $y_j = -1$. Equation (7.2) now yields

$$\begin{aligned}\text{net-cost}_{T_{i-1}}(D_i) + z \cdot \text{cost}(T_{i-1}) &\geq \sum_{S_j \in \mathcal{S}} (\text{cost}(S_j) - y_j \cdot \text{trapped-cost}_{T_{i-1}}(S_j)) \\ &\geq \sum_{S_j \in \mathcal{S}^-} (\text{cost}(S_j) + \text{trapped-cost}_{T_{i-1}}(S_j)) \\ &\geq \sum_{S_j \in \mathcal{S}^-} \text{cost}(S_j),\end{aligned}$$

where the second inequality follows from the fact that all sets in $\mathcal{S} - \mathcal{S}^-$ have nonnegative net-cost. We shall develop a contradiction by showing that the costs of the sets in $\mathcal{S}^-$ is more than the left-hand side of the above inequality. A lower bound on the total net-weight of the sets in $\mathcal{S}^-$ can be obtained from (7.1) as follows:

$$\begin{aligned}z(W - \text{wt}(T_{i-1})) - \text{net-weight}_{T_{i-1}}(D_i) &= -\sum_{S_j \in \mathcal{S}} y_j \cdot \text{net-weight}_{T_{i-1}}(S_j) \\ &\leq \sum_{S_j \in \mathcal{S}^-} \text{net-weight}_{T_{i-1}}(S_j).\end{aligned}$$

What is the cheapest way of picking sets so that their net-weight is at least $z(W - \text{wt}(T_{i-1})) - \text{net-weight}_{T_{i-1}}(D_i)$? By Observation 7.2 a set S_j such that net-weight$_{T_{i-1}}(S_j) < W/3 - \text{wt}(T_{i-1})$ can be picked only at a net-sparsity of at least net-sparsity$_{T_{i-1}}(D_i)$. On the other hand Observation 7.1 says that we could be picking sets with large net-weight for cost little more than $\text{cost}(T_{i-1}) + \text{net-cost}_{T_{i-1}}(D_i)$. Since any set in $\mathcal{S}$ has net-weight at most $\frac{W - \text{wt}(T_{i-1})}{2}$ the unit cost of picking these large sets could be as small as

$$\begin{aligned}\frac{\text{cost}(T_{i-1}) + \text{net-cost}_{T_{i-1}}(D_i)}{\frac{W - \text{wt}(T_{i-1})}{2}} &< \frac{\text{cost}(T_{i-1}) + \text{net-cost}_{T_{i-1}}(D_i)}{\text{wt}(T_{i-1}) + \text{net-weight}_{T_{i-1}}(D_i)} \\ &\leq \max\left\{\frac{\text{cost}(T_{i-1})}{\text{wt}(T_{i-1})}, \frac{\text{net-cost}_{T_{i-1}}(D_i)}{\text{net-weight}_{T_{i-1}}(D_i)}\right\} \\ &\leq \text{net-sparsity}_{T_{i-1}}(D_i),\end{aligned}$$

where the last inequality follows from the fact that $\text{sparsity}(T_{i-1}) \leq$ net-sparsity$_{T_{i-1}}(D_i)$ which in turn is a consequence of Lemma 4.1.

Thus the cheapest possible way of picking sets is to pick sets of net-weight $\frac{W-\mathrm{wt}(T_{i-1})}{2}$, incurring a cost of little more than $\mathrm{cost}(T_{i-1})+\text{net-cost}_{T_{i-1}}(D_i)$ for each set picked. Since we need to pick a net-weight of at least $z(W-\mathrm{wt}(T_{i-1}))-\text{net-weight}_{T_{i-1}}(D_i)$, we would have to pick at least $2z-1$ such sets and so the cost incurred is at least

$$\begin{aligned}\sum_{S_j\in\mathcal{S}^-}\mathrm{cost}(S_j) &> (2z-1)(\mathrm{cost}(T_{i-1})+\text{net-cost}_{T_{i-1}}(D_i))\\ &\geq z\cdot\mathrm{cost}(T_{i-1})+\text{net-cost}_{T_{i-1}}(D_i),\end{aligned}$$

where the last inequality follows from the fact that $z\geq 1$ (hence $2z-1\geq z$ and $2z-1\geq 1$). This, however, contradicts the upper bound on the sum of the costs of the sets in $\mathcal{S}^-$, which we derived at the beginning of this case.

$z<0$. Let $\mathcal{S}^+$ denote the collection of sets $S_j\in\mathcal{S}$ with $y_j=1$. Equation (7.2) now yields

$$\begin{aligned}\text{net-cost}_{T_{i-1}}(D_i) &\geq \sum_{S_j\in\mathcal{S}}(\mathrm{cost}(S_j)-y_j\cdot\text{trapped-cost}_{T_{i-1}}(S_j))\\ &\geq \sum_{S_j\in\mathcal{S}^+}\text{net-cost}_{T_{i-1}}(S_j).\end{aligned}$$

The total net-weight of the sets in $\mathcal{S}^+$ can be bounded using (7.1) as follows:

$$\begin{aligned}\sum_{S_j\in\mathcal{S}^+}\text{net-weight}_{T_{i-1}}(S_j) &\geq \sum_{S_j\in\mathcal{S}} y_j\cdot\text{net-weight}_{T_{i-1}}(S_j)\\ &= \text{net-weight}_{T_{i-1}}(D_i)-z(W-\mathrm{wt}(T_{i-1}))\\ &\geq -z(W-\mathrm{wt}(T_{i-1})),\end{aligned}$$

where the last inequality follows from the fact that the net-weight of D_i is nonnegative.

What is the cheapest way of picking sets so that their net-weight is at least $-z(W-\mathrm{wt}(T_{i-1}))$? Once again by Observation 7.2 a set S_j of net-weight less than $\frac{W}{3}-\mathrm{wt}(T_{i-1})$ can be picked only at a net-sparsity of at least $\text{net-sparsity}_{T_{i-1}}(D_i)$. On the other hand Observation 7.1 says that we could be picking a set of net-weight as large as $(W-\mathrm{wt}(T_{i-1}))/2$ for a net-cost that is only strictly larger than $\text{net-cost}_{T_{i-1}}(D_i)$. Since

$$\begin{aligned}\frac{\text{net-cost}_{T_{i-1}}(D_i)}{(W-\mathrm{wt}(T_{i-1}))/2} &< \frac{\text{net-cost}_{T_{i-1}}(D_i)}{\text{net-weight}_{T_{i-1}}(D_i)}\\ &= \text{net-sparsity}_{T_{i-1}}(D_i),\end{aligned}$$

the cheapest possible way of picking sets is to pick sets of net-weight $\frac{W-\mathrm{wt}(T_{i-1})}{2}$ and incur a net-cost strictly larger than $\text{net-cost}_{T_{i-1}}(D_i)$ for each set picked. Since we need to pick a net-weight of at least $-z(W-\mathrm{wt}(T_{i-1}))$, we should pick at least $-2z$ such sets. Since $z\leq -1$, the total net-cost of these sets is strictly larger than $\text{net-cost}_{T_{i-1}}(D_i)$ contradicting the upper bound derived at the beginning of this case.

We have thus established that there exists a set $S_j\in\mathcal{S}$ which meets the weight requirement for a $\square$ and has cost no more than $\mathrm{cost}(T_i)$. Further, S_j corresponds to a directed simple cycle in $\vec{G_i^D}$. Our procedure for finding a □ returns a set of cost less than the cost of any set that meets the weight requirement for a □ and corresponds to a directed simple cycle in $\vec{G^D}$. Hence

$$\text{cost}(B_i) \leq \text{cost}(S_j) \leq \text{cost}(T_i).$$

Therefore,

$$\text{cost}(T_{i-1} \cup B_i) \leq \text{cost}(T_{i-1}) + \text{cost}(B_i) \leq \text{cost}(T_{i-1}) + \text{cost}(T_i) \leq 2 \cdot \text{cost(OPT)},$$

where the last inequality follows from Lemma 4.3 and the fact that $i \leq k-1$. ∎

For each w in the range $[0..\frac{W}{3} - \text{wt}(T_{i-1})] \cup [-W + \text{wt}(T_{i-1})..\frac{-2W}{3}]$, it suffices to find in G_i a directed cycle (not necessarily simple) with minimum $c(C) - t_i(C)$ among all directed cycles C with $w_i(C) = w$. If for some w the shortest cycle is not simple we discard the cycle and do not consider that w for the purpose of computing the •. If in the process we discard the cycle with $w_i(C) = w_i(C^*)$ then by the above theorem the separator found in this iteration is within twice the optimum. Otherwise, we obtain a simple cycle C with $w_i(C) = w_i(C^*)$ and the set corresponding to this cycle is a •.

Finally, we have to deal with the case that there are negative cycles in H_i. A negative cycle in H_i corresponds to a cycle C in $\vec{G_i^D}$ such that $w_i(C) = 0$ and $c(C) - t_i(C) < 0$.

LEMMA 7.2. *If C is a cycle in $\vec{G_i^D}$ such that $w_i(C) = 0$ and $c(C) - t_i(C) < 0$ then the separator found in this iteration has cost at most $2 \cdot \text{cost(OPT)}$.*

Proof. The proof of this lemma is along the lines of Theorem 7.1. We decompose C into a collection $\mathcal{C}$ of directed simple cycles. For $C_j \in \mathcal{C}$ let S_j be the side of the cycle with smaller net-weight and let $\mathcal{S}$ be the collection of sets S_j, one for each $C_j \in \mathcal{C}$. Using the decomposition rule, we have

$$z(W - \text{wt}(T_{i-1})) + \sum_{S_j \in \mathcal{S}} y_j \cdot \text{net-weight}_{T_{i-1}}(S_j) = 0, \tag{7.3}$$

$$-z \cdot \text{cost}(T_{i-1}) + \sum_{S_j \in \mathcal{S}} (\text{cost}(S_j) - y_j \cdot \text{trapped-cost}_{T_{i-1}}(S_j)) < 0. \tag{7.4}$$

For contradiction we assume that every $S_j \in \mathcal{S}$ which satisfies the weight requirement for a □ has cost more than $\text{cost}(T_i)$. By Observation 7.3 every set $S_j \in \mathcal{S}$ has nonnegative net-cost. Hence (7.4) yields

$$\begin{aligned} z \cdot \text{cost}(T_{i-1}) &> \sum_{S_j \in \mathcal{S}} (\text{cost}(S_j) - y_j \cdot \text{trapped-cost}_{T_{i-1}}(S_j)) \\ &\geq \sum_{S_j \in \mathcal{S}^-} (\text{cost}(S_j) + \text{trapped-cost}_{T_{i-1}}(S_j)) \\ &\geq \sum_{S_j \in \mathcal{S}^-} \text{cost}(S_j), \end{aligned}$$

which implies that $z > 0$.

A lower bound on the total net-weight of sets in $\mathcal{S}^-$ can be obtained using (7.3):

$$\begin{aligned} z(W - \text{wt}(T_{i-1})) &= -\sum_{S_j \in \mathcal{S}} y_j \cdot \text{net-weight}_{T_{i-1}}(S_j) \\ &\leq \sum_{S_j \in \mathcal{S}^-} \text{net-weight}_{T_{i-1}}(S_j). \end{aligned}$$

Beyond this point the argument is almost identical to that for the case when $z > 0$ in the proof of Theorem 7.1. This contradicts our assumption that every set $S_j \in \mathcal{S}$ which meets the weight requirement of a $\square$ has cost more than $\text{cost}(T_i)$. As in the proof of Theorem 7.1, the $\square$ picked in this iteration has cost at most $\text{cost}(T_i)$ and hence the cost of the separator output is at most $2 \cdot \text{cost}(\text{OPT})$. $\square$

By Lemma 7.2, we need to compute shortest paths in graph H_i only if it has no negative cycles.

8. Finding $\square$ sets. We will use Rao's algorithm [8, 9] to find a $\square$ set. Let $w : V \to Z^+$ be a weight function on the vertices of G such that $w(v) = 0$ if $v \in T_{i-1}$ and $wt(v)$ otherwise. If B_i is a $\square$ in the ith iteration, then $(B_i, \overline{B_i})$ is a b-balanced bond in G when the weights on the vertices are given by w and $b = \frac{W/3 - \text{wt}(T_{i-1})}{W - \text{wt}(T_{i-1})}$. Thus, to find the $\square$ we need to find the minimum-cost simple cycle in G^D which corresponds to a b-balanced bond in G.

Rao [8, 9] gives an algorithm for finding a minimum-cost b-balanced *connected circuit* in G^D. A connected circuit in G^D is a set of cycles in G^D connected by an acyclic set of paths. Intuitively, a connected circuit can be viewed as a simple cycle with "pinched" portions corresponding to the paths. The cost of a connected circuit is defined to be the cost of the closed walk that goes through each pinched portion twice and each cycle once. A connected circuit in G^D defines a simple cut in G; the vertices corresponding to faces included in the cycles of the connected circuit form one side of the cut. A connected circuit is b-balanced if the cut corresponding to it is b-balanced. Note that the cost of the cut defined by a connected circuit is just the sum of the costs of the cycles in it. Hence, the definition of cost of a connected circuit is an upper bound on the cost of the underlying cut; the two are equal if the connected circuit is a simple cycle.

Notice that for a $\square$ we do not really need to find a minimum-cost b-balanced bond in G; any cut that is b-balanced and has cost no more than the minimum-cost b-balanced bond will serve our purpose. Hence we can use Rao's algorithm to find a $\square$. The total time taken by Rao's algorithm to obtain an optimal b-balanced connected circuit cut is $O(n^2 W)$.

9. Running time. Clearly, the algorithm terminates in at most n iterations. The running time of each iteration is dominated by the time to find a $\bullet$. In each iteration, computing a $\bullet$ involves $O(n)$ single source shortest path computations in a graph with $O(n^2 W)$ vertices and $O(n^2 W)$ edges; the edge-lengths may be negative. This can be done in $O(n^4 W^2)$ time by preprocessing the network so that all edge-lengths are negative and then applying Dijkstra's algorithm n times. Hence, the total running time of the dot-box algorithm is $O(n^5 W^2)$. This is polynomial if W is polynomially bounded.

THEOREM 9.1. *The dot-box algorithm finds an edge-separator in a planar graph of cost within twice the optimum and runs in time $O(n^5 W^2)$, where W is the sum of weights of the vertices.*

10. Dealing with binary weights. The size of the graph in which we compute shortest paths (and hence the running time of the dot-box algorithm) depends on the sum of the vertex weights. Using scaling we can make our algorithm strongly polynomial; however, the resulting algorithm is a pseudoapproximation algorithm in the sense that it compares the cut obtained with an optimal cut having a better balance. Finally, we use our scaling ideas to extend the algorithm of Park and Phillips into a fully polynomial approximation scheme for finding sparsest cuts in planar graphs with vertex weights given in binary, thereby settling their open problem.

10.1. *b*-balanced cut. Let us scale the vertex weights so that the sum of the weights is no more than αn $(\alpha > 1)$. This can be done by defining a new weight function $\hat{wt} : V \rightarrow \mathbf{Z}^+$ as

$$\hat{wt}(v) = \left\lfloor \frac{\mathrm{wt}(v)}{W} \cdot \alpha n \right\rfloor .$$

The process of obtaining the new weights can be viewed as a two-step process: first we scale the weights by a constant factor $\frac{\alpha n}{W}$ and then we truncate. The first step does not affect the balance of any cut since all vertex weights are scaled by the same factor. However, the second step could affect the balance of a cut. Thus a cut $(S, \overline{S})$ with balance b under the weight function wt might have a worse balance under $\hat{wt}$ since all vertices on the side with smaller weight might have their weights truncated. However, the total loss in weight due to truncations is at most n (1 for each vertex). The balance would be worst when the total weight stays at αn (not drop by the truncations) and then the loss of weight of the smaller side is a $1/\alpha$ fraction of the total weight. Thus the balance of the cut $(S, \overline{S})$ under $\hat{wt}$ might be $b - 1/\alpha$ but no worse.

Similarly, a cut $(S, \overline{S})$ with balance $\hat{b}$ under $\hat{wt}$ might have a worse balance under wt. It is easy to show by a similar argument that under wt, $(S, \overline{S})$ has a balance no worse than $\hat{b} - 1/\alpha$.

Let OPT denote the cost of the optimum b-balanced cut under the weight assignment wt. Since this cut might be $(b - 1/\alpha)$-balanced under $\hat{wt}$, we use the dot-box algorithm to find a $(b - 1/\alpha)$-balanced cut of cost within 2OPT. The cut returned by our algorithm, while being $(b - 1/\alpha)$-balanced under $\hat{wt}$, might only be $(b - 2/\alpha)$-balanced under wt. Thus we obtain a $(b - 2/\alpha)$-balanced cut of cost within twice the optimum b-balanced cut.

THEOREM 10.1. *For $\alpha > 2/b$, the dot-box algorithm, with weight scaling, finds a $(b - 2/\alpha)$-balanced cut in a planar graph of cost within twice the cost of an optimum b-balanced cut for $b \leq \frac{1}{3}$ in $O(\alpha^2 n^7)$ time.*

10.2. Sparsest cut. Assume that vertex weights in planar graph G are given in binary. Let 2^p be the least power of 2 that bounds the weight of each vertex and W be the sum of weights of all vertices. We will construct $p + 1$ copies of G, $G_i, 0 \leq i \leq p$, each having the same edge costs as G. In G_i, vertex weights are assigned as follows: Let α be a positive integer; α determines the approximation guarantee as described below. Vertices having weights in the range $[2^i, 2^{i+2\log n+\alpha+2}]$ are assigned their original weight; those having weight $< 2^i$ are assigned weight 0, i.e., they can be deleted from the graph; and those having weight $> 2^{i+2\log n+\alpha+2}$ are assigned weight $2^{i+2\log n+\alpha+2}$. The sparsest cut is computed in each of these graphs using the algorithm of Park and Phillips. For the purpose of this computation, the weights of all vertices in G_i are divided by 2^i; notice that this leaves the weights integral, and the total weight of vertices is at most $O(2^\alpha n^3)$. The running time of [7] is $O(n^2 w \log nw)$, where w is the total weight of vertices in the graph. Thus, this computation takes time $O(\alpha 2^\alpha n^5 \log W \log n)$, which is polynomial in the size of the input, for fixed α. The sparsity of the $p + 1$ cuts so obtained is computed in the original graph, and the sparsest one is chosen.

Let $(S, \overline{S})$ be an optimal sparsest cut in G, and let S be its lighter side. Let the weight of S be t, and let q be the weight of the heaviest vertex in S. Pick the smallest integer i such that $2^{i+\log n+\alpha+1} \geq q$.

LEMMA 10.2. *The cut found in G_i has cost at most that of $(S, \overline{S})$, and weight at least $(1-\frac{1}{2^\alpha})t$. Therefore, this cut has sparsity within a factor of $\frac{1}{1-\frac{1}{2^\alpha}}$ of the sparsity of $(S, \overline{S})$.*

Proof. The algorithm of Park and Phillips searches for the cheapest cut of each weight, for all choices of weight between 0 and half the weight of the given graph. It then outputs the sparsest of these cuts.

First notice that for the choice of i given above, the weight of S in G_i, say t', satisfies $(1-\frac{1}{2^\alpha})t \leq t' \leq t$. Indeed, any set of vertices whose weights are at most $2^{i+2\log n+\alpha+2}$ in G satisfies that its weight drops by a factor of at most $(1-\frac{1}{2^\alpha})$ in G_i. On the other hand, any set of vertices containing a vertex having weight $> 2^{i+2\log n+\alpha+2}$ in G has weight exceeding t in G_i. Therefore, the cut found in G_i for the target weight of t' satisfies the conditions of the lemma. $\square$

For a given choice of $\delta > 0$, pick the smallest positive integer α so that $1+\delta \geq \frac{1}{(1-\frac{1}{2^\alpha})}$. Then we get the following.

THEOREM 10.3. *The above algorithm gives a fully polynomial time approximation scheme for the minimum-sparsity cut problem in planar graphs. For each $\delta > 0$, this algorithm finds a cut of sparsity within a factor of $(1+\delta)$ of the optimal in $O(\frac{1}{\delta}\log(\frac{1}{\delta})n^5 \log W \log n)$ time.*

11. Open problems.

Several open problems remain.

1. Is the problem of finding the cheapest b-balanced cut in planar graphs strongly **NP**-hard, or is there a pseudo–polynomial time algorithm for it?
2. What is the complexity of finding a minimum net-sparsity cut in planar graphs, assuming that the vertex weights are given in unary?
3. What is the complexity of finding $\bullet$ sets in planar graphs, assuming that the vertex weights are given in unary?
4. Can the algorithm given in this paper be extended to other submodular functions?
5. Can it be extended to other classes of graphs? In particular, can the notion of transfer function be extended to other classes of graphs?

BALANCED ALLOCATIONS[*]

YOSSI AZAR[†], ANDREI Z. BRODER[‡], ANNA R. KARLIN[§], AND ELI UPFAL[¶]

Abstract. Suppose that we sequentially place n balls into n boxes by putting each ball into a randomly chosen box. It is well known that when we are done, the fullest box has with high probability $(1+o(1))\ln n/\ln\ln n$ balls in it. Suppose instead that for each ball we choose two boxes at random and place the ball into the one which is less full at the time of placement. We show that with high probability, the fullest box contains only $\ln\ln n/\ln 2+O(1)$ balls—exponentially less than before. Furthermore, we show that a similar gap exists in the infinite process, where at each step one ball, chosen uniformly at random, is deleted, and one ball is added in the manner above. We discuss consequences of this and related theorems for dynamic resource allocation, hashing, and on-line load balancing.

Key words. urn models, occupancy problems, on-line algorithms, resource allocation, hashing, load balancing

1. Introduction.

Suppose that we sequentially place n balls into n boxes by putting each ball into a randomly chosen box. Properties of this random allocation process have been extensively studied in the probability and statistics literature. (See, e.g., [20, 17].) One of the classical results in this area is that, asymptotically, when the process has terminated, with high probability (that is, with probability $1-o(1)$) the fullest box contains $(1+o(1))\ln n/\ln\ln n$ balls. (G. Gonnet [16] has proven a more accurate result, $\Gamma^{-1}(n)-3/2+o(1)$.)

Consider a variant of the process above whereby each ball comes with d possible destinations, chosen independently and uniformly at random. (Hence the d destinations are not necessarily distinct.) The ball is placed in the least full box among the d possible locations. Surprisingly, even for $d=2$, when the process terminates the fullest box has only $\ln\ln n/\ln 2+O(1)$ balls in it. Thus, this apparently minor change in the random allocation process results in an exponential decrease in the maximum occupancy per location. The analysis of this process is summarized as follows

THEOREM 1.1. *Suppose that m balls are sequentially placed into n boxes. Each ball is placed in the least full box, at the time of the placement, among d boxes, $d\geq 2$, chosen independently and uniformly at random. Then after all the balls are placed,*

- *with high probability, as $n\to\infty$ and $m\geq n$, the number of balls in the fullest box is $(1+o(1))\ln\ln n/\ln d+\Theta(m/n)$;*

- *in particular, with high probability, as $n \to \infty$ and $m = n$, the number of balls in the fullest box is* $\ln \ln n / \ln d + \Theta(1)$;
- *any other on-line strategy that places each ball into one of d randomly chosen boxes results in stochastically more balls*[1] *in the fullest box.*

It is also interesting to study the infinite version of the random allocation process. There, at each step a ball is chosen uniformly at random and removed from the system, and a new ball appears. The new ball comes with d possible destinations, chosen independently at random, and it is placed into the least full box among these d possible destinations.

The analysis of the case $d = 1$ in this infinite stochastic process is simple since the location of any ball does not depend on the locations of other balls in the system. Thus, for $d = 1$, in the stationary distribution, with high probability the fullest box has $\Theta(\log n / \log \log n)$ balls. The analysis of the case $d \geq 2$ is significantly harder, since the locations of the current n balls might depend on the locations of balls that are no longer in the system. We prove that when $d \geq 2$, in the stationary distribution, the fullest box has $\ln \ln n / \ln d + O(1)$ balls, with high probability. Thus, the same exponential gap holds in the infinite process. Theorem 1.2 is proven in section 4.

THEOREM 1.2. *Consider the infinite process with $d \geq 2$, starting at time 0 in an arbitrary state. There is a constant c such that for any fixed $T > cn^2 \log \log n$, the fullest box at time T contains, with high probability, less than $\ln \ln n / \ln d + O(1)$ balls. Thus, in the stationary distribution, with high probability, no box contains more than $\ln \ln n / \ln d + O(1)$ balls.*

Karp, Luby, and Meyer auf der Heide [18] were the first to notice a dramatic improvement when switching from one hash function to two in the context of PRAM simulations. In fact, it is possible to use a result from [18] to derive a weaker form of our static upper bound. (For details see [7].)

A preliminary version of this paper has appeared in [7]. Subsequently, Adler et al. [1] analyzed parallel implementation of the balanced allocation mechanism and obtained interesting communication vs. load tradeoffs.

A related question was considered by Broder et al. [10]. In their model the set of choices is such that there is a placement that results in maximum load equal to one. The question they analyze is, what is the expected maximum load under a random order of insertion under the greedy strategy?

More recent results, based on the balanced allocation paradigm, have appeared in [23, 24, 25, 12].

1.1. Applications.

Our results have a number of interesting applications to computing problems. We elaborate here on three of them.

1.1.1. Dynamic resource allocation.

Consider a scenario in which a user or a process has to choose between a number of identical resources on-line (choosing a server to use among the servers in a network, choosing a disk to store a directory, etc.). To find the least loaded resource, users may check the load on all resources before placing their requests. This process is expensive, since it requires sending an interrupt to each of the resources. A second approach is to send the task to a random resource. This approach has minimum overhead, but if all users follow it, the difference in load between different servers will vary by up to a logarithmic factor. Our analysis suggests

[1]By this we mean that for any other strategy and any k the probability that the number of balls in the fullest box is greater than k is at least the probability that the number of balls in the fullest box is greater than k under the greedy strategy. See Corollary 3.6.

a more efficient solution. If each user samples the load of two resources and sends his request to the least loaded, the total overhead is small, and the load on the n resources varies by only a $O(\log\log n)$ factor.

1.1.2. Hashing. The efficiency of a hashing technique is measured by two parameters: the expected and the maximum access time. Our approach suggests a simple hashing technique, similar to hashing with chaining. We call it 2-*way chaining.* It has $O(1)$ expected and $O(\log\log n)$ maximum access time. We use two random hash functions. The two hash functions define two possible entries in the table for each key. The key is inserted to the least full location, at the time of the insertion. Keys in each entry of the table are stored in a linked list. Assume that n keys are sequentially inserted by this process into a table of size n. As shown in section 5, the expected insertion and look-up time is $O(1)$, and our analysis summarized above immediately implies that with high probability the maximum access time is $\ln\ln n/\ln 2+O(1)$, vs. the $\Theta(\log n/\log\log n)$ time when only one random hash function is used.

An advantage of our scheme over some other known techniques for reducing worst-case behavior of hashing (e.g., [14, 13, 11]) is, that it uses only two hash functions, it is easy to parallelize, and it does not involve rehashing of data. Other commonly used schemes partition the available memory into multiple tables, and use a different hash function in each table. For example, the Fredman, Komlos, Szemeredi scheme for perfect hashing [14] uses up to n different hash functions to get $O(1)$ worst-case access time (not on-line however), and the algorithm of Broder and Karlin [11] uses $O(\log\log n)$ hash functions to achieve $O(\log\log n)$ maximum access time on-line but using rehashings.

Karp, Luby, and Meyer auf der Heide [18] studied the use of two hash functions in the context of PRAM simulations. Other PRAM simulations using multiple hash functions were developed and analyzed in [21].

1.1.3. Competitive on-line load balancing. Consider the following on-line load balancing problem: We are given a set of n servers and a sequence of arrivals and departures of tasks. Each task comes with a list of servers on which it can be executed. The load balancing algorithm has to assign each task to a server on-line, with no information on future arrivals and departures of tasks. The goal of the algorithm is to minimize the maximum load on any server. The quality of an on-line algorithm is measured by the *competitive ratio*: the ratio between the maximum load it achieves and the maximum load achieved by the optimal off-line algorithm that knows the whole sequence in advance. This load balancing problem models, for example, communication in heterogeneous networks containing workstations, I/O devices, etc. Servers correspond to communication channels and tasks correspond to requests for communication links between devices. A network controller must coordinate the channels so that no channel is too heavily loaded.

On-line load balancing has been studied extensively against worst-case adversaries [9, 6, 5, 3, 8, 4]. For permanent tasks (tasks that arrive but never depart), Azar, Naor and Rom [9] showed that the competitive ratio of the greedy algorithm is $\log n$ and that no algorithm can do better. For temporary tasks (tasks that depart at unpredictable times), the works of Azar, Broder, and Karlin [6] and Azar et al. [8] show that there is an algorithm with competitive ratio $\Theta(\sqrt{n})$ and that no algorithm can do better.

It is interesting to compare these high competitive ratios, obtained from inputs generated by an adversary, to the competitive ratio against randomly generated inputs. Our results show that under reasonable probabilistic assumptions the competitive ratios for both permanent and temporary tasks are significantly better. In the case of permanent tasks, if the set of servers on which a task can be executed is a small set (that is, constant size ≥ 2) chosen at random, the competitive ratio decreases from $\Theta(\log n)$ to $\Theta(\log\log n)$. In the case of temporary tasks, if we further assume that at each time step a randomly chosen existent task is replaced by a new task, then at any fixed time the ratio between the maximum on-line load and the maximum off-line load is $\Theta(\log\log n)$ with high probability. Further details are presented in section 6.

2. Definitions and notation.

We consider two stochastic processes: the *finite process* and the *infinite process.*

The finite process. There are n boxes, initially empty, and m balls. Each ball is allowed to go into $d \geq 1$ boxes chosen independently and uniformly at random. The balls arrive one by one, and a *placement algorithm* must decide on-line (that is, without knowing what choices are available to future balls) in which box to put each ball as it comes. Decisions are irrevocable. We will subsequently refer to this setup as a (m, n, d)-problem.

The infinite process. There are n boxes, initially containing n balls in an arbitrary state. (For example, all the balls could be in one box.) At each step, one random ball is removed, and one new ball is added; the new ball is allowed to go into $d \geq 1$ boxes chosen independently and uniformly at random. Once again, a placement algorithm must decide on-line (that is, without knowing what choices are available to future balls and without knowing which ball will be removed at any future time) in which box to put each arriving ball. Decisions are irrevocable.

We use the following notations for the random variables associated with a placement algorithm A. Note that the state at time t refers to the state immediately after the placement of the tth ball.

$\lambda_j^A(t)$	called the *load* of box j, is the number of balls in box j at time t, resulting from algorithm A.
$\nu_k^A(t)$	is the number of boxes that have load k at time t.
$\nu_{\geq k}^A(t)$	is the number of boxes that have load $\geq k$ at time t, that is, $\nu_{\geq k}^A(t) = \sum_{i\geq k} \nu_i^A(t)$.
h_t^A	called the *height* of ball t (= the ball that arrives at time t), is the number of balls at time t in the box where ball t is placed. In other words, the first ball to be placed in a particular box has height 1, the second ball has height 2, etc.
$\mu_k^A(t)$	is the number of balls that have height k at time t.
$\mu_{\geq k}^A(t)$	is the number of balls that have height $\geq k$ at time t, that is, $\mu_{\geq k}^A(t) = \sum_{i\geq k} \mu_i^A(t)$.

We omit the superscript A when it is clear which algorithm we are considering. Constants were chosen for convenience, and we made no attempts to optimize them.

Algorithm GREEDY assigns ball j to the box that has the lowest load among the d random choices that j has. We use the superscript G for GREEDY.

The basic intuition behind the proofs that follow is simple: Let $p_i = \mu_{\geq i}/n$. Since the available choices for each ball are independent and $\nu_{\geq i} \leq \mu_{\geq i}$, we roughly have ("on average" and disregarding conditioning) $p_{i+1} \leq p_i^d$, which implies a doubly exponential decrease in p_i, once $\mu_{\geq i} < n/2$. Of course the truth is that $\mu_{\geq i+1}$ is strongly dependent on $\mu_{\geq i}$ and a rather complex machinery is required to construct a correct proof.

3. The finite process. We use the notation $B(n,p)$ to denote a binomially distributed random variable with parameters n and p, and start with the following standard lemma, whose proof is omitted.

LEMMA 3.1. *Let $X_1, X_2, \ldots, X_n$ be a sequence of random variables with values in an arbitrary domain, and let $Y_1, Y_2, \ldots, Y_n$ be a sequence of binary random variables, with the property that $Y_i = Y_i(X_1, \ldots, X_i)$. If*

$$\mathbf{Pr}(Y_i = 1 \mid X_1, \ldots, X_{i-1}) \le p,$$

then

$$\mathbf{Pr}\left(\sum Y_i \ge k\right) \le \mathbf{Pr}(B(n,p) \ge k),$$

and similarly if

$$\mathbf{Pr}(Y_i = 1 \mid X_1, \ldots, X_{i-1}) \ge p,$$

then

$$\mathbf{Pr}\left(\sum Y_i \le k\right) \le \mathbf{Pr}(B(n,p) \le k). \qquad \square$$

We now turn to the analysis of the finite process. In what follows, we omit the argument t when $t = m$, that is, when the process terminates. In the interest of a clearer exposition, we start with the case $m = n$, although the general case (Theorem 3.7) subsumes it.

THEOREM 3.2. *The maximum load achieved by the* GREEDY *algorithm on a random (n, n, d)-problem is less than $\ln \ln n / \ln d + O(1)$ with high probability.*

Proof. Since the d choices for a ball are independent, we have

$$\mathbf{Pr}(h_t \ge i+1 \mid \nu_{\ge i}(t-1)) = \frac{\left(\nu_{\ge i}(t-1)\right)^d}{n^d}.$$

Let $\mathcal{E}_i$ be the event that $\nu_{\ge i}(n) \le \beta_i$ where β_i will be exposed later. (Clearly, $\mathcal{E}_i$ implies that $\nu_{\ge i}(t) \le \beta_i$ for $t = 1, \ldots, n$.) Now fix $i \ge 1$ and consider a series of binary random variables Y_t for $t = 2, \ldots, n$, where

$$Y_t = 1 \text{ iff } h_t \ge i+1 \text{ and } \nu_{\ge i}(t-1) \le \beta_i.$$

(Y_t is 1 if the height of the ball t is $\ge i+1$ despite the fact that the number of boxes that have load $\ge i$ is less than β_i.)

Let ω_j represent the choices available to the jth ball. Clearly,

$$\mathbf{Pr}(Y_t = 1 \mid \omega_1, \ldots, \omega_{t-1}) \le \frac{\beta_i^d}{n^d} \overset{def}{=} p_i.$$

Thus we can apply Lemma 3.1 to conclude that

$$\mathbf{Pr}\left(\sum Y_t \ge k\right) \le \mathbf{Pr}(B(n, p_i) \ge k). \tag{3.1}$$

Observe that conditioned on $\mathcal{E}_i$, we have $\mu_{\ge i+1} = \sum Y_t$. Therefore

$$\mathbf{Pr}(\mu_{\ge i+1} \ge k \mid \mathcal{E}_i) = \mathbf{Pr}\left(\sum Y_t \ge k \mid \mathcal{E}_i\right) \le \frac{\mathbf{Pr}\left(\sum Y_t \ge k\right)}{\mathbf{Pr}(\mathcal{E}_i)}. \tag{3.2}$$

Combining (3.1) and (3.2) we obtain that

$$\mathbf{Pr}(\nu_{\geq i+1} \geq k \mid \mathcal{E}_i) \leq \mathbf{Pr}(\mu_{\geq i+1} \geq k \mid \mathcal{E}_i) \leq \frac{\mathbf{Pr}(B(n,p_i) \geq k)}{\mathbf{Pr}(\mathcal{E}_i)}. \tag{3.3}$$

We can bound large deviations in the binomial distribution with the formula (see, for instance, [2, Appendix A])

$$\mathbf{Pr}(B(n,p_i) \geq ep_i n) \leq e^{-p_i n}, \tag{3.4}$$

which inspires us to set

$$\beta_i = \begin{cases} n, & i = 1,2,\ldots,5; \\ \dfrac{n}{2e}, & i = 6; \\ \dfrac{e\beta_{i-1}^d}{n^{d-1}}, & i > 6. \end{cases}$$

With these choices $\mathcal{E}_{\geq 6} = \{\nu_6 \leq n/(2e)\}$ holds with certainty, and from (3.3) and (3.4), for $i \geq 6$

$$\mathbf{Pr}(\neg\mathcal{E}_{i+1} \mid \mathcal{E}_i) \leq \frac{1}{n^2 \mathbf{Pr}(\mathcal{E}_i)},$$

provided that $p_i n \geq 2\ln n$. Since

$$\mathbf{Pr}(\neg\mathcal{E}_{i+1}) \leq \mathbf{Pr}(\neg\mathcal{E}_{i+1} \mid \mathcal{E}_i)\mathbf{Pr}(\mathcal{E}_i) + \mathbf{Pr}(\neg\mathcal{E}_i),$$

it follows that for $p_i n \geq 2\ln n$

$$\mathbf{Pr}(\neg\mathcal{E}_{i+1}) \leq \frac{1}{n^2} + \mathbf{Pr}(\neg\mathcal{E}_i). \tag{3.5}$$

To finish the proof let i^* be the smallest i such that $\beta_{i^*}^d/n^d \leq 2\ln n/n$. Notice that $i^* \leq \ln\ln n/\ln d + O(1)$ since

$$\beta_{i+6} = \frac{ne^{(d^i-1)/(d-1)}}{(2e)^{d^i}} \leq \frac{n}{2^{d^i}}.$$

As before,

$$\mathbf{Pr}(\nu_{\geq i^*+1} \geq 6\ln n \mid \mathcal{E}_{i^*}) \leq \frac{\mathbf{Pr}(B(n, 2\ln n/n) \geq 6\ln n)}{\mathbf{Pr}(\mathcal{E}_{i^*})} \leq \frac{1}{n^2\mathbf{Pr}(\mathcal{E}_{i^*})},$$

and thus

$$\mathbf{Pr}(\nu_{\geq i^*+1} \geq 6\ln n) \leq \frac{1}{n^2} + \mathbf{Pr}(\neg\mathcal{E}_{i^*}). \tag{3.6}$$

Finally,

$$\begin{aligned} \mathbf{Pr}(\mu_{\geq i^*+2} \geq 1 \mid \ \nu_{\geq i^*+1} \leq 6\ln n) &\leq \frac{\mathbf{Pr}(B(n, (6\ln n/n)^d) \geq 1)}{\mathbf{Pr}(\nu_{\geq i^*+1} \leq 6\ln n)} \\ &\leq \frac{n(6\ln n/n)^d}{\mathbf{Pr}(\nu_{\geq i^*+1} \leq 6\ln n)} \end{aligned}$$

by the Markov inequality, and thus

$$\mathbf{Pr}(\mu_{\geq i^*+2} \geq 1) \leq \frac{(6\ln n)^d}{n^{d-1}} + \mathbf{Pr}(\nu_{\geq i^*+1} \geq 6\ln n). \tag{3.7}$$

Combining (3.7), (3.6), and (3.5), we obtain that

$$\mathbf{Pr}(\nu_{\geq i^*+2} \geq 1) \leq \frac{(6\ln n)^d}{n^{d-1}} + \frac{i^*+1}{n^2} = o(1),$$

which implies that with high probability the maximum load achieved by GREEDY is less than $i^*+2 = \ln\ln n/\ln d + O(1)$. □

We now prove a matching lower bound.

THEOREM 3.3. *The maximum load achieved by the* GREEDY *algorithm on a random* (n,n,d)*-problem is at least* $\ln\ln n/\ln d - O(1)$ *with high probability.*

Proof. Let $\mathcal{F}_i$ be the event that $\nu_{\geq i}(n(1-1/2^i)) \geq \gamma_i$ where γ_i will be exposed later. For the time being, it suffices to say that $\gamma_{i+1} < \gamma_i/2$. We want to compute $\mathbf{Pr}(\neg\mathcal{F}_{i+1} \mid \mathcal{F}_i)$. To this aim, for t in the range $R = \{n(1-1/2^i)+1, \ldots, n(1-1/2^{i+1})\}$, let Z_t be defined by

$$Z_t = 1 \text{ iff } h_t = i+1 \text{ or } \nu_{\geq i+1}(t-1) \geq \gamma_{i+1},$$

and observe that while $\nu_{\geq i+1}(t-1) < \gamma_{i+1}$, if $Z_t = 1$, then the box where the tth ball is placed had load exactly i at time $t-1$. This means that all the d choices that ball t had pointed to boxes with load $\geq i$ and at least one choice pointed to a box with load exactly i.

Now let ω_j represent the choices available to the jth ball. Using

$$\begin{aligned}\mathbf{Pr}(A \vee B \mid C) &= \mathbf{Pr}(A \wedge \bar{B} \mid C) + \mathbf{Pr}(B \mid C)\\ &= \mathbf{Pr}(A \mid \bar{B} \wedge C)\mathbf{Pr}(\bar{B} \mid C) + \mathbf{Pr}(B \mid C) \geq \mathbf{Pr}(A \mid \bar{B} \wedge C),\end{aligned}$$

and in view of the observation above, we derive that

$$\mathbf{Pr}(Z_t = 1 \mid \omega_1, \ldots, \omega_{t-1}, \mathcal{F}_i) \geq \left(\frac{\gamma_i}{n}\right)^d - \left(\frac{\gamma_{i+1}}{n}\right)^d \geq \frac{1}{2}\left(\frac{\gamma_i}{n}\right)^d \overset{def}{=} p_i. \tag{3.8}$$

Applying Lemma 3.1 we get

$$\mathbf{Pr}\left(\sum_{t\in R} Z_t \leq k \;\middle|\; \mathcal{F}_i\right) \leq \mathbf{Pr}(B(n/2^{i+1}, p_i) \leq k).$$

We now choose

$$\begin{aligned}\gamma_0 &= n;\\ \gamma_{i+1} &= \frac{\gamma_i^d}{2^{i+3}n^{d-1}} = \frac{n}{2^{i+3}}\left(\frac{\gamma_i}{n}\right)^d = \frac{1}{2}\frac{n}{2^{i+1}}p_i.\end{aligned}$$

Since $\mathbf{Pr}(B(N,p) < Np/2) < e^{-Np/8}$ (see, for instance, [2, Appendix A]), it follows that

$$\mathbf{Pr}(B(n/2^{i+1}, p_i) \leq \gamma_{i+1}) = o(1/n^2), \tag{3.9}$$

provided that $p_i n/2^{i+1} \geq 17\ln n$. Let i^* be the largest integer for which this holds. Clearly $i^* = \ln\ln n/\ln d - O(1)$.

Now observe that by the definition of $\mathcal{F}$ and Z_t, the event $\{\sum_{t\in R} Z_t \geq \gamma_{i+1}\}$ implies $\mathcal{F}_{i+1}$. Thus in view of (3.8) and (3.9)

$$\mathbf{Pr}(\neg\mathcal{F}_{i+1} \mid \mathcal{F}_i) \leq \mathbf{Pr}\left(\sum_{t\in R} Z_t \leq \gamma_{i+1} \,\middle|\, \mathcal{F}_i\right) = o(1/n^2),$$

and therefore

$$\begin{aligned}\mathbf{Pr}(\mathcal{F}_{i^*}) &\geq \mathbf{Pr}(\mathcal{F}_{i^*} \mid \mathcal{F}_{i^*-1}) \times \mathbf{Pr}(\mathcal{F}_{i^*-1} \mid \mathcal{F}_{i^*-2}) \times \cdots \times \mathbf{Pr}(\mathcal{F}_1 \mid \mathcal{F}_0) \times \mathbf{Pr}(\mathcal{F}_0)\\ &\geq (1-1/n^2)^{i^*} = 1 - o(1/n),\end{aligned}$$

which completes the proof. ∎

We now turn to showing that the GREEDY algorithm is stochastically optimal under our model, that is, we assume that each ball has d destinations chosen uniformly at random and that all balls have equal weight. (The optimality is not preserved if either condition is violated.) It suffices to consider only deterministic algorithms since randomized algorithms can be considered as a distribution over deterministic algorithms.

We say that a vector $\bar{v} = (v_1, v_2, \ldots, v_n)$ *majorizes* a vector $\bar{u}$, written $\bar{v} \succeq \bar{u}$, if for $1 \leq i \leq n$, we have $\sum_{1\leq j\leq i} v_{\pi(j)} \geq \sum_{1\leq j\leq i} u_{\sigma(j)}$, where π and σ are permutations of $1, \ldots, n$ such that $v_{\pi(1)} \geq v_{\pi(2)} \geq \cdots \geq v_{\pi(n)}$ and $u_{\sigma(1)} \geq u_{\sigma(2)} \geq \cdots \geq u_{\sigma(n)}$.

LEMMA 3.4. *Let $\bar{v}$ and $\bar{u}$ be two positive integer vectors such that $v_1 \geq v_2 \geq \cdots \geq v_n$ and $u_1 \geq u_2 \geq \cdots \geq u_n$. If $\bar{v} \succeq \bar{u}$ then also $\bar{v} + \bar{e}_i \succeq \bar{u} + \bar{e}_i$, where $\bar{e}_i$ is the ith unit vector, that is $\bar{e}_{i,j} = \delta_{i,j}$.*

Proof. Let $S_j(\bar{x})$ be the sum of the j largest components of the vector $\bar{x}$. Notice first that for all j

$$S_j(\bar{x}) \leq S_j(\bar{x} + \bar{e}_i) \leq S_j(\bar{x}) + 1. \tag{3.10}$$

By hypothesis, for all j, we have $S_j(\bar{v}) \geq S_j(\bar{u})$. To prove the lemma we show that for all j, we also have $S_j(\bar{v} + \bar{e}_i) \geq S_j(\bar{u} + \bar{e}_i)$. Fix j. By (3.10) if $S_j(\bar{v}) > S_j(\bar{u})$, then $S_j(\bar{v} + \bar{e}_i) \geq S_j(\bar{u} + \bar{e}_i)$. Now assume $S_j(\bar{v}) = S_j(\bar{u})$. There are three cases to consider:

Case 1. $i \leq j$. Then

$$S_j(\bar{v} + \bar{e}_i) = S_j(\bar{v}) + 1 = S_j(\bar{u}) + 1 = S_j(\bar{u} + \bar{e}_i).$$

Case 2. $i > j$ and $u_j > u_i$. Since $u_j \geq u_i + 1$, it follows that $S_j(\bar{u}) = S_j(\bar{u} + \bar{e}_i)$ and therefore

$$S_j(\bar{v} + \bar{e}_i) \geq S_j(\bar{v}) = S_j(\bar{u}) = S_j(\bar{u} + \bar{e}_i).$$

Case 3. $i > j$ and $u_j = u_{j+1} = \cdots = u_i$. Observe first that since $S_{j-1}(\bar{v}) \geq S_{j-1}(\bar{u})$, $S_j(\bar{v}) = S_j(\bar{u})$, and $S_{j+1}(\bar{v}) \geq S_{j+1}(\bar{u})$, we have

$$v_j \leq u_j \qquad \text{and} \qquad v_{j+1} \geq u_{j+1}.$$

Hence

$$v_j \geq v_{j+1} \geq u_{j+1} = u_j \geq v_j.$$

We conclude that $v_j = u_j = v_{j+1} = u_{j+1}$, and thus $S_{j+1}(\bar{v}) = S_{j+1}(\bar{u})$. Repeating the argument, we obtain that

$$v_j = u_j = v_{j+1} = u_{j+1} = \cdots = v_i = u_i,$$

and therefore

$$S_j(\bar{v} + \bar{e}_i) = S_j(\bar{v}) + 1 = S_j(\bar{u}) + 1 = S_j(\bar{u} + \bar{e}_i). \qquad \Box$$

Let Ω be the set of all possible n^d choices for each ball and Ω^t be the set of sequences of choices for the first t balls.

THEOREM 3.5. *For any on-line deterministic algorithm A, and $t \geq 0$, there is* 1-1 *correspondence $f : \Omega^t \to \Omega^t$ such that for any $\omega_t \in \Omega^t$ the vector of box loads associated with* GREEDY *acting on ω_t, written*

$$\bar{\lambda}^G(\omega_t) = (\lambda_1^G(\omega_t), \lambda_2^G(\omega_t), \ldots, \lambda_n^G(\omega_t)),$$

is majorized by the vector of box loads associated with A acting on $f(\omega_t)$, that is

$$\bar{\lambda}^G(\omega_t) \preceq \bar{\lambda}^A(f(\omega_t)).$$

Proof. To simplify notation we assume $d = 2$. The proof for larger d is analogous. The proof proceeds by induction on t, the length of the sequence. The base case $(t = 0)$ is obvious. Assume the theorem valid for t and let f_t be the mapping on Ω^t. Fix a sequence $\omega_t \in \Omega^t$. It suffices to show that we can refine f_t to obtain a 1-1 correspondence for all possible 1-step extensions of ω_t. Without loss of generality, renumber the boxes such that

$$\lambda_1^G(\omega_t) \geq \lambda_2^G(\omega_t) \geq \cdots \geq \lambda_n^G(\omega_t),$$

and let π be a permutation of $1, \ldots, n$ such that

$$\lambda_{\pi(1)}^A(f_t(\omega_t)) \geq \lambda_{\pi(2)}^A(f_t(\omega_t)) \geq \cdots \geq \lambda_{\pi(n)}^A(f_t(\omega_t)).$$

Let (i, j) be two choices for the $t + 1$ ball. For every i, j we define

$$f_{t+1}(\omega_t \diamond (i, j)) = f_t(\omega_t) \diamond (\pi(i), \pi(j)),$$

where "$\diamond$" represents extension of sequences.

Clearly f_{t+1} is 1-1. We need to show that

$$\bar{\lambda}^G(\omega_t \diamond (i, j)) \preceq \bar{\lambda}^A\bigl(f_t(\omega_t) \diamond (\pi(i), \pi(j))\bigr).$$

Notice that when the sequence ω_t is extended by the step (i, j) for any algorithm, exactly one component of the vector $\bar{\lambda}(\omega_t)$ changes, namely either $\lambda_i(\omega_t)$ or $\lambda_j(\omega_t)$ increases by one. Assume that $i \geq j$; then

$$\bar{\lambda}^G(\omega_t \diamond (i, j)) = \bar{\lambda}^G(\omega_t) + \bar{e}_i \preceq \bar{\lambda}^A(f_t(\omega_t)) + \bar{e}_{\pi(i)} \preceq \bar{\lambda}^A\bigl(f_t(\omega_t) \diamond (\pi(i), \pi(j))\bigr),$$

where the first inequality follows from Lemma 3.4 and the second is due to the fact that

$$\bar{\lambda}^A(f_t(\omega_t)) + \bar{e}_{\pi(i)} \preceq \bar{\lambda}^A(f_t(\omega_t)) + \bar{e}_{\pi(j)}. \qquad \Box$$

COROLLARY 3.6. *For any fixed k and any t*

$$\mathbf{Pr}(\max_i \lambda_i^A(t) > k) \geq \mathbf{Pr}(\max_i \lambda_i^G(t) > k).$$

We are now ready to discuss the general case of the finite process.

THEOREM 3.7. *The maximum load achieved by the* GREEDY *algorithm on a random (m,n,d)-problem, with $d \geq 2$ and $m \geq n$, is, with high probability, less than $(1+o(1))\ln\ln n/\ln d + O(m/n)$.*

Proof. We start by replaying the proof of Theorem 3.2, taking into account the fact that there are now m balls. So let $\mathcal{E}_i$ be the event that $\nu_{\geq i}(m) \leq \beta_i$, and define $p_i = \beta_i^d/n^d$. Following the proof of Theorem 3.2 we derive that

$$\mathbf{Pr}(\nu_{\geq i+1} \geq k \mid \mathcal{E}_i) \leq \frac{\mathbf{Pr}(B(m,p_i) \geq k)}{\mathbf{Pr}(\mathcal{E}_i)}.$$

Suppose that for some value x we set $\beta_x = n^2/(2em)$ and show that $\mathcal{E}_x$ holds with high probability, that is,

$$\mathbf{Pr}\left(\nu_x \geq \frac{n^2}{2em}\right) = o(1). \tag{3.11}$$

Then

$$\beta_{i+x} = \frac{n}{2^{d^i}}\left(\frac{me}{n}\right)^{(d^i-1)/(d-1)-d^i} \leq \frac{n}{2^{d^i}},$$

and continuing as before, we obtain that

$$\mathbf{Pr}(\mu \geq x + \ln\ln n/\ln d + 2) = o(1).$$

It remains to be shown that x can be taken to be $O(m/n) + o(\ln\ln n/\ln d)$. First assume that $m/n \geq w(n)$ where $w(n)$ is an increasing function of n, but $w(n) = o(\ln\ln n/\ln d)$. Then we claim that we can take $x = \lceil em/n \rceil$.

Consider a placement algorithm, denoted R, that always puts a ball in the box corresponding to the first choice offered. This is entirely equivalent with the case $d = 1$, the classical occupancy problem. The load within a box under this process is a binomial random variable $B(m, 1/n)$, and therefore (via (3.4)), the probability that the load within a box exceeds em/n is bounded by $e^{-m/n}$. Now consider the height of the tth ball, denoted h_t^R. The probability that the box into which the tth ball is placed has load greater than em/n is less than $e^{-m/n}$, and therefore the expected number of balls of height $\geq em/n$ satisfies

$$\mathbf{E}(\mu^R_{\geq em/n}) \leq me^{-m/n}.$$

Hence by Markov's inequality

$$\mathbf{Pr}\left(\mu^R_{\geq em/n} \geq \frac{n^2}{2em}\right) \leq \frac{2em^2}{n^2}e^{-m/n} = o(1),$$

since $m/n \to \infty$.

We claim that Theorem 3.5 implies

$$\mathbf{Pr}\left(\mu^G_{\geq k} \geq r\right) \leq \mathbf{Pr}\left(\mu^R_{\geq k} \geq r\right). \tag{3.12}$$

Indeed, suppose that there is an outcome ω_t for which GREEDY has exactly i boxes with load greater than or equal to k. As in the proof of Theorem 3.5, renumber the boxes such that

$$\lambda_1^G(\omega_t) \geq \lambda_2^G(\omega_t) \geq \cdots \geq \lambda_n^G(\omega_t).$$

Let $f_t(\omega_t)$ be the corresponding outcome for algorithm R and let π be a permutation of $1, \ldots, n$ such that

$$\lambda_{\pi(1)}^R(f_t(\omega_t)) \geq \lambda_{\pi(2)}^R(f_t(\omega_t)) \geq \cdots \geq \lambda_{\pi(n)}^R(f_t(\omega_t)).$$

Then

$$\mu_{\geq k}^G(\omega_t) = \sum_{1 \leq j \leq i} (\lambda_j^G(\omega_t) - (k-1))$$

and

$$\mu_{\geq k}^R(f_t(\omega_t)) \geq \sum_{1 \leq j \leq i} (\lambda_{\pi(j)}^R(f_t(\omega_t)) - (k-1)).$$

But Theorem 3.5 implies that

$$\sum_{1 \leq j \leq i} \lambda_j^R(f(\omega_t)) \geq \sum_{1 \leq j \leq i} \lambda_j^G(\omega_t),$$

and by considering all outcomes we obtain (3.12). Therefore,

$$\mathbf{Pr}\left(\mu_{\geq em/n}^G \geq \frac{n^2}{2em}\right) \leq \mathbf{Pr}\left(\mu_{\geq em/n}^R \geq \frac{n^2}{2em}\right),$$

and since

$$\mathbf{Pr}\left(\nu_{\geq em/n}^G \geq \frac{n^2}{2em}\right) \leq \mathbf{Pr}\left(\mu_{\geq em/n}^G \geq \frac{n^2}{2em}\right),$$

we have that for $x = \lceil em/n \rceil$ (3.11) is satisfied.

To remove the assumption $m/n \geq w(n)$, we can simply imagine that the number of balls is increased to $\max(m, nw(n))$. Then the corresponding value of x becomes $O(\max(m, nw(n))/n) = O(m/n) + o(\ln \ln n / \ln d)$. ◻

4. The infinite process. In this section we consider the infinite process. Analogously to Theorem 3.5 it is possible to show that the GREEDY algorithm minimizes the expected maximum load on any box. We analyze its performance below. The main theorem of this section is the following.

THEOREM 4.1. *Assume that the infinite process starts in an arbitrary state. Under* GREEDY*, with $d \geq 2$, there is a constant c such that for any fixed $T \geq cn^2 \log \log n$,*

$$\mathbf{Pr}(\exists j, \lambda_j(T) \geq \ln \ln n / \ln d + O(1)) = o(1).$$

Thus in the stationary distribution the maximum load is $\ln \ln n / \ln d + O(1)$ with high probability.

Proof. For simplicity of presentation we state and prove the results only for $d = 2$. The proof assumes that at time $T - cn^2 \log \log n$ the process is in an arbitrary state and therefore we can let $T = cn^2 \log \log n$ with no loss of generality.

By the definition of the process, the number of balls of height at least i cannot change by more than 1 in a time step, that is $|\mu_{\geq i}(t+1) - \mu_{\geq i}(t)| \leq 1$. The random variable $\mu_{\geq i}(t)$ can be viewed as a random walk on the integers l, $0 \leq l \leq n$. The proof is based on bounding the maximum values taken by the variables $\mu_{\geq i}(t)$ by studying the underlying process.

We define an integer i^* and a decreasing sequence α_i, for $200 \leq i \leq i^* + 1$ as follows:

$$\begin{aligned}
\alpha_{200} &= \frac{n}{200}, \\
\alpha_i &= \frac{100\alpha_{i-1}^2}{n} && \text{for } i > 200 \text{ and } \alpha_{i-1} \geq \sqrt{n \log_2 n}, \\
\alpha_{i^*} &= 100 \log_2 n, && i^* = \text{the smallest } i \text{ for which} \\
& && \quad \alpha_{i-1} < \sqrt{n \log_2 n}, \\
\alpha_{i^*+1} &= 100.
\end{aligned}$$

Clearly $i^* \leq \ln \ln n / \ln 2 + O(1)$. For future reference, observe also that for $200 < i \leq i^* + 1$

$$\alpha_i \geq \frac{100\alpha_{i-1}^2}{n}. \tag{4.1}$$

We also define an increasing sequence of times: $t_{200} = 0$ and $t_i = t_{i-1} + n^2$ for $i > 200$. Thus $t_{i^*+1} = O(n^2 \log \log n) = O(T)$.

Let $\{\mu_{\geq i}[t^-, t^+] \leq \alpha\}$ denote the event that $\mu_{\geq i}(t) \leq \alpha$ for all t, such that $t^- < t \leq t^+$, and similarly, let $\{\mu_{\geq i}[t^-, t^+] > \alpha\}$ denote the event that $\mu_{\geq i}(t) > \alpha$ for all t, such that $t^- < t \leq t^+$. We define the events C_i as follows:

$$\begin{aligned}
C_{200} &= \{\nu_{\geq 200}[t_{200}, T] \leq 2\alpha_{200}\} \equiv \{\nu_{\geq 200}[0, T] \leq n/100\}; \\
C_i &= \{\mu_{\geq i}[t_i, T] \leq 2\alpha_i\} \qquad \text{for } i > 200.
\end{aligned}$$

Note that C_{200} always holds, and for $i > 200$, the event $C - i$ implies that $\nu_{\geq i}[t_i, T] \leq 2\alpha_i$.

We shall prove inductively that for all $i = 200, \ldots, i^* + 1$

$$\mathbf{Pr}(\neg C_i) \leq \frac{2i}{n^2}. \tag{4.2}$$

This implies that the event $\{\mu_{\geq i^*+1}[t_{i^*+1}, T] \leq 200\}$ occurs with probability $1 - o(1)$, and therefore with high probability, for every j, $\lambda_j(T) \leq i^* + 201 = \ln \ln n / \ln 2 + O(1)$, which completes the proof of the main part of the theorem.

Finally, we show that in the stationary distribution

$$\mathbf{Pr}(\forall j, \lambda_j \leq \log \log n + O(1)) = 1 - o(1).$$

Indeed, let S be the set of states such that for all $j, \lambda_j(t) \leq \log \log n + O(1)$. Let $s(t)$ be the state of the chain at time t. Then the previous observation implies that

$$\mathbf{Pr}(s(t+T) \notin S \mid s(t)) = o(1).$$

Let π be the stationary distribution; then

$$\sum_{i \notin S} \pi_i = \sum_j \mathbf{Pr}(s(t+T) \notin S \mid s(t) = j) \cdot \pi_j = \sum_j \pi_j o(1) = o(1),$$

which completes the proof of the theorem assuming (4.2). To prove it, we show that conditioned on C_{i-1}:

a. With high probability $\mu_{\geq i}(t)$ becomes less than α_i before time t_i. (This is shown in Lemma 4.2.)
b. If $\mu_{\geq i}(t)$ becomes less than α_i at any time before T, from then until T, with high probability, it does not become larger than $2\alpha_i$. (This is shown in Lemma 4.3.)

The two facts above imply that if C_{i-1} holds, then with high probability $\mu_{\geq i}[t_i, T] \leq 2\alpha_i$, that is, C_i holds as well.

Base case. The base case is straightforward since $\mathbf{Pr}(\neg C_{200}) = \mathbf{Pr}(\neg\{\nu_{\geq 200}[0,T] \leq n/100\}) = 0$.

Induction. Suppose that

$$\mathbf{Pr}(\neg C_{i-1}) \leq \frac{2(i-1)}{n^2}, \tag{4.3}$$

where $200 < i \leq i^* + 1$.

Let $s(t)$ be the state at time t. It is easy to verify the following bounds on the underlying transition probabilities. For any t,

$$\mathbf{Pr}(\mu_{\geq i}(t+1) > \mu_{\geq i}(t) \mid s(t)) \leq \left(\frac{\nu_{\geq(i-1)}(t)}{n}\right)^2 \leq \left(\frac{\mu_{\geq(i-1)}(t)}{n}\right)^2 \tag{4.4}$$

and

$$\mathbf{Pr}(\mu_{\geq i}(t+1) < \mu_{\geq i}(t) \mid s(t)) \geq \frac{\mu_{\geq i}(t)}{n}\left(1 - \left(\frac{\nu_{\geq(i-1)}(t)}{n}\right)^2\right) \geq \frac{\mu_{\geq i}(t)}{2n}. \tag{4.5}$$

From (4.4) and (4.5) we obtain that the transition probabilities satisfy

$$\mathbf{Pr}(\mu_{\geq i}(t+1) > \mu_{\geq i}(t) \mid \mu_{\geq i-1}(t) \leq 2\alpha_{i-1}) \leq \left(\frac{2\alpha_{i-1}}{n}\right)^2 \overset{def}{=} q_i^+$$

and

$$\mathbf{Pr}(\mu_{\geq i}(t+1) < \mu_{\geq i}(t) \mid \mu_{\geq i}(t) \geq \alpha_i) \geq \frac{\alpha_i}{2n} \overset{def}{=} q_i^-.$$

Thus in view of (4.1)

$$q_i^+ \leq \frac{\alpha_i}{25n}.$$

We define two new binary random variables for $0 < t \leq T$ as follows:

$$X_t = 1 \text{ iff } \mu_{\geq i}(t) > \mu_{\geq i}(t-1) \text{ and } \mu_{\geq i-1}(t-1) \leq 2\alpha_{i-1},$$

and

$$Y_t = 1 \text{ iff } \mu_{\geq i}(t) < \mu_{\geq i}(t-1) \text{ or } \mu_{\geq i}(t-1) \leq \alpha_i.$$

Clearly

$$\mathbf{Pr}(X_t = 1) \leq q_i^+ \qquad \text{and} \qquad \mathbf{Pr}(Y_t = 1) \geq q_i^-. \tag{4.6}$$

We also define F_i to be the event

$$F_i \overset{def}{=} \{\exists t^* \in [t_{i-1}, t_i] \text{ s.t. } \mu_{\geq i}(t^*) \leq \alpha_i\};$$

thus $\neg F_i$ is the event

$$\neg F_i = \{\mu_{\geq i}[t_{i-1}, t_i] > \alpha_i\}.$$

Two lemmas are necessary in order to conclude that $\mathbf{Pr}(\neg C_i) \leq 2i/n^2$.

LEMMA 4.2. *Under the inductive hypothesis*

$$\mathbf{Pr}(\neg F_i \mid C_{i-1}) \leq \frac{1}{n^2}.$$

Proof. Notice that conditioned on C_{i-1}, the sum $\sum_{t\in[t_{i-1},t_i]} X_t$ is the number of times $\mu_{\geq i}(t)$ increased in the interval $[t_{i-1}, t_i]$; similarly, if within this interval $\mu_{\geq i}$ did not become less than α_i, then $\sum_{t\in[t_{i-1},t_i]} Y_t$ equals the number of times $\mu_{\geq i}(t)$ decreased in this interval. We conclude that

$$\begin{aligned}\mathbf{Pr}(\neg F_i \mid C_{i-1}) &\leq \mathbf{Pr}\left(\sum_{t\in[t_{i-1},t_i]} Y_t - \sum_{t\in[t_{i-1},t_i]} X_t \leq n \;\middle|\; C_{i-1}\right) \\ &\leq \frac{1}{\mathbf{Pr}(C_{i-1})}\mathbf{Pr}\left(\sum_{t\in[t_{i-1},t_i]} Y_t - \sum_{t\in[t_{i-1},t_i]} X_t \leq n\right).\end{aligned}$$

In view of (4.6) and Lemma 3.1, Chernoff-type bounds imply that for every $i \leq i^* + 1$

$$\mathbf{Pr}\left(\sum_{t\in[t_{i-1},t_i]} X_t > 2n^2 q_i^+ \right) \leq \mathbf{Pr}\left(B(n^2, q_i^+) \geq 2n^2 q_i^+\right) \leq e^{-\Omega(n^2 q_i^+)} = o(1/n^c)$$

and

$$\mathbf{Pr}\left(\sum_{t\in[t_{i-1},t_i]} Y_t < \tfrac{1}{2} n^2 q_i^- \right) \leq \mathbf{Pr}\left(B(n^2, q_i^-) \leq \tfrac{1}{2} n^2 q_i^-\right) \leq e^{-\Omega(n^2 q_i^-)} = o(1/n^c)$$

for any constant c. On the other hand, in view of (4.1),

$$\frac{1}{2} n^2 q_i^- - 2n^2 q_i^+ \geq \frac{1}{4} n\alpha_i - \frac{2}{25} n\alpha_i \geq \frac{n\alpha_i}{10} \geq n,$$

and therefore we conclude that

$$\mathbf{Pr}(\neg F_i \mid C_{i-1}) \leq \frac{1}{n^c \mathbf{Pr}(C_{i-1})}$$

for any constant c. Taking $c = 3$ and using the inductive hypothesis on C_{i-1} (4.3) completes the proof. ∎

LEMMA 4.3. *Under the inductive hypothesis*

$$\mathbf{Pr}(\neg C_i \mid C_{i-1}, F_i) \leq \frac{1}{n^2}.$$

Proof. Since $\mathbf{Pr}(A \mid B \wedge C) \le \mathbf{Pr}(A \wedge B|C)$ we get that

$$\begin{aligned}
&\mathbf{Pr}(\neg C_i \mid C_{i-1}, F_i)\\
&\qquad \le \mathbf{Pr}(\neg C_i \wedge F_i \mid C_{i-1})\\
&\qquad \le \mathbf{Pr}(\exists t_1, t_2 \in [t_{i-1}, T]\\
&\qquad\qquad\qquad \text{s.t. } \mu_{\ge i}(t_1) = \alpha_i, \mu_{\ge i}(t_2) = 2\alpha_i, \mu_{\ge i}[t_1, t_2] \ge \alpha_i \mid C_{i-1})\\
&\qquad \le \sum_{t_{i-1} \le t_1 < t_2 \le T} \mathbf{Pr}(\mu_{\ge i}(t_1) = \alpha_i, \mu_{\ge i}(t_2) = 2\alpha_i, \mu_{\ge i}[t_1, t_2] \ge \alpha_i \mid C_{i-1})\\
&\qquad \le \sum_{t_{i-1} \le t_1 < t_2 \le T} \mathbf{Pr}\left(\sum_{t \in [t_1, t_2]} X_t - \sum_{t \in [t_1, t_2]} Y_t \ge \alpha_i \mid C_{i-1} \right)\\
&\qquad \le \frac{1}{\mathbf{Pr}(C_{i-1})} \sum_{t_{i-1} \le t_1 < t_2 \le T} \mathbf{Pr}(\sum_{t \in [t_1, t_2]} X_t - \sum_{t \in [t_1, t_2]} Y_t \ge \alpha_i).
\end{aligned}$$

Fix t_1 and t_2 and let $\Delta = t_2 - t_1$. We now consider four cases.

A. $\Delta \le n$ and $i \le i^*$:

$$\mathbf{Pr}\Big(\sum_{t \in [t_1, t_2]} X_t \ge \alpha_i \Big) \le \binom{\Delta}{\alpha_i} (q^+)^{\alpha_i} \le \left(\frac{e\Delta}{\alpha_i} \cdot \frac{\alpha_i}{25n} \right)^{\alpha_i} \le n^{-100}.$$

B. $\Delta \le n \log n$ and $i = i^* + 1$:

$$\begin{aligned}
\mathbf{Pr}\Big(\sum_{t \in [t_1, t_2]} X_t \ge \alpha_{i^*+1} \Big) &\le \binom{\Delta}{\alpha_{i^*+1}} (q^+)^{\alpha_{i^*+1}} \le \left(\frac{e\Delta}{\alpha_{i^*+1}} \cdot \frac{4\alpha_{i^*}^2}{n^2} \right)^{\alpha_{i^*+1}}\\
&\le \left(\frac{en \log n}{100} \cdot \frac{4 \cdot 100^2 \log^2 n}{n^2} \right)^{100} \le n^{-100}.
\end{aligned}$$

C. $\Delta \ge n$ and $i \le i^*$: Again using large deviation bounds and the fact that $\alpha_i \Delta \ge 100 \log n$ we obtain that

$$\mathbf{Pr}\left(\sum_{t \in [t_1, t_2]} Y_t \le \frac{1}{2} q^- \Delta \right) \le e^{-q^- \Delta/8} = e^{-\alpha_i \Delta/(16n)} \le n^{-6.1}$$

and that

$$\mathbf{Pr}\left(\sum_{t \in [t_1, t_2]} X_t \ge \frac{1}{2} q^- \Delta \right) \le \left(\frac{2eq^+ \Delta}{q^- \Delta} \right)^{q^- \Delta/2} \le \left(\frac{4e}{25} \right)^{\alpha_i \Delta/(4n)} \le n^{-25}.$$

D. $\Delta \ge n \log n$ and $i = i^* + 1$: We use the same proof as case **C** using the fact that $\alpha_{i^*+1} \Delta \ge 100 \log n$.

Thus in all four cases,

$$\mathbf{Pr}\left(\sum_{t \in [t_1, t_2]} X_t - \sum_{t \in [t_1, t_2]} Y_t \ge \alpha_i \right) \le \frac{1}{n^{6.1}},$$

therefore, under the induction hypothesis,

$$\frac{1}{\mathbf{Pr}(C_{i-1})} \sum_{t_{i-1} \le t_1 < t_2 \le T} \mathbf{Pr}\Big(\sum_{t \in [t_1, t_2]} X_t - \sum_{t \in [t_1, t_2]} Y_t \ge \alpha_i \Big) \le \frac{2T^2}{n^{6.1}} \le \frac{1}{n^2}. \qquad \square$$

Returning to the proof of (4.2), by using the induction hypothesis, Lemmas 4.2 and 4.3, and the law of total probability, we can complete the induction as follows:

$$\begin{aligned}
\mathbf{Pr}(\neg C_i) &= \mathbf{Pr}(\neg C_i \mid C_{i-1}) \cdot \mathbf{Pr}(C_{i-1}) \\
&\quad + \mathbf{Pr}(\neg C_i \mid \neg C_{i-1}) \cdot \mathbf{Pr}(\neg C_{i-1}) && \text{Now apply IH} \\
&\le \mathbf{Pr}(\neg C_i \mid C_{i-1}) + 2(i-1)/n^2 \\
&= \mathbf{Pr}(\neg C_i \mid C_{i-1}, F_i) \cdot \mathbf{Pr}(F_i \mid C_{i-1}) && \text{Now apply Lemma 4.3} \\
&\quad + \mathbf{Pr}(\neg C_i \mid C_{i-1}, \neg F_i) \cdot \mathbf{Pr}(\neg F_i \mid C_{i-1}) && \text{Now apply Lemma 4.2} \\
&\quad + 2(i-1)/n^2 \\
&\le 1/n^2 + 1/n^2 + 2(i-1)/n^2 = 2i/n^2. \qquad \square
\end{aligned}$$

5. Hashing. We define a simple hashing algorithm, called 2-*way chaining*, by analogy with the popular direct chaining method. We use two random hash functions. For each key, the two hash functions define two indices in a table. Each table location contains a pointer to a linked list. When a new key arrives, we compare the current length of the two lists associated to the key, and the key is inserted at the end of the shortest list. (The direct chaining method corresponds to having only one associated random index.)

For searching, the two hash values are computed, and two linked lists are searched in alternate order. (That is, after checking the ith element of the first list, we check the ith element of the second list, then element $i+1$ of the first list, and so on.) When the shorter list is exhausted, we continue searching the longer list until it is exhausted as well. (In fact, if no deletions are allowed, we can stop after checking only one more element in the longer list. For the analysis below, this is immaterial.)

Assume that n keys are sequentially inserted by this process to a table of size n. Theorem 1.1 analysis implies that with high probability the maximum access time, which is bounded by twice the length of the longest list, is $2 \ln n \ln n / \ln 2 + O(1)$, versus the $\Theta(\log n / \log\log n)$ time when one random hash function is used. More generally, if m keys are stored in the table with d hash functions, then the maximum access time under this scheme is $2(1 + o(1)) \ln\ln n / \ln d + \Theta(m/n)$.

Next we show that the average access time of 2-way chaining is no more than twice the average access time of the standard direct chaining method. As customary, we discuss the average access time separately for successful searches and unsuccessful searches. The latter, denoted C'_G, is bounded by twice the expected cost of checking a list chosen uniformly at random. Therefore

$$C'_G(m,n) \le 2 + \frac{2m}{n}.$$

For successful searches, the cost C_G, is given by

$$C_G(m,n) \le \frac{2}{m} \sum_{1 \le i \le m} h_i = \frac{2}{m} \sum_{1 \le j \le n} \binom{\lambda_j + 1}{2},$$

where all the notations are as in section 2. Since we know that ν_k eventually decreases doubly exponentially, we can bound C_G via the inequality

$$C_G(m,n) \le \frac{2}{m} \sum_{k>0} k\nu_{\ge k}.$$

However, we can achieve better bounds, using the majorization Theorem 3.5. We start from the following.

LEMMA 5.1. *Let $\bar{v} = (v_1, v_2, \ldots, v_n)$ and $\bar{u} = (u_1, v_2, \ldots, u_n)$ be two positive integer vectors. If $\bar{v} \succeq \bar{u}$, then*

$$\sum_{1\le i\le n} v_i^2 \ge \sum_{1\le i\le n} u_i^2.$$

This lemma is a special case of a well-known theorem from majorization (see, e.g., [22]), but for completeness we present a proof.

Proof. Let $\bar{x}$ be a n-vector and let $(\bar{x}, \bar{u})$ denote the inner product of $\bar{x}$ and $\bar{u}$. Consider the linear program

$$\text{Maximize } (\bar{x}, \bar{u}) \text{ subject to } \bar{x} \preceq \bar{v} \text{ and } \bar{x} \ge 0.$$

It is easy to check that $\bar{x} = \bar{u}$ is a feasible point and that the optimal solution is $\bar{x} = \bar{v}$. Hence $(\bar{u}, \bar{u}) \le (\bar{v}, \bar{u})$. Now consider the same program with the objective function $(\bar{x}, \bar{v})$. Then again $\bar{x} = \bar{u}$ is a feasible point and the optimal solution is $\bar{x} = \bar{v}$. Hence $(\bar{u}, \bar{u}) \le (\bar{u}, \bar{v}) \le (\bar{v}, \bar{v})$. ◻

Consider now the standard direct chaining method. In our terminology it corresponds to the random placement algorithm R and it therefore majorizes G. It is well known that the cost for successful search for direct chaining is [19, Ex. 6.4.34]

$$C_R(m,n) = \frac{1}{m} \sum_{1\le j\le n} \binom{\lambda_j^R + 1}{2} = 1 + \frac{m-1}{2n}.$$

Applying the lemma above we obtain that the cost of successful search in 2-way chaining satisfies

$$C_G(m,n) \le 2 + \frac{m-1}{n}.$$

6. Competitive on-line load balancing.

6.1. Preliminaries.

6.1. Preliminaries. The on-line load balancing problem is defined as follows. Let M be a set of servers (or machines) that is supposed to run a set of tasks that arrive and depart in time. Each task j has associated with it a weight, or load, $w(j) \ge 0$, an arrival time $\tau(j)$, and a set $M(j) \subset M$ of servers capable of running it. We distinguish among two variants of this problem: the case of *permanent tasks*, tasks that arrive but never depart, and the case of *temporary tasks*, tasks that depart the system at a time unknown in advance.

As soon as each task arrives, it must be assigned to exactly one of the servers capable of running it, and once assigned, it can not be transferred to a different server. The assigned server starts to run the task immediately, and continues to run it until the task departs.

When task j arrives, an *assignment algorithm* must select a server $i \in M(j)$, and assign task j to it.

The *load* on server i at time t, denoted $L_i^A(t)$, is the sum of the weights of all the tasks running on server i at time t under assignment algorithm A.

Let σ be a sequence of task arrivals and departures, and let $|\sigma|$ be the time of the last arrival. Then the cost, $C_A(\sigma)$, of an assignment algorithm A on the sequence σ is defined as

$$C_A(\sigma) = \max_{0 \leq t \leq |\sigma|; i \in M} L_i^A(t).$$

An *on-line assignment algorithm* must assign an arriving task j at time $\tau(j)$ to a server in $M(j)$ knowing only $w(j)$, $M(j)$, and the past and current state of the servers—the decision is made without any knowledge about future arrivals or departures. The *optimal off-line assignment algorithm*, denoted OPT, assigns arriving tasks knowing the entire sequence of task arrivals and departures and does so in a way that minimizes cost.

The worst-case behavior of an on-line algorithm A is characterized by the *competitive ratio,* defined as the supremum over all sequences σ of the ratio $C_A(\sigma)/C_{\text{OPT}}(\sigma)$.

To characterize the average behavior of A, let $C_A(\mathcal{P})$ (resp., $C_{\text{OPT}}(\mathcal{P})$) be the expected cost of algorithm A (resp., OPT) on sequences σ generated by the distribution $\mathcal{P}$. The competitive ratio of an on-line algorithm, *A against distribution $\mathcal{P}$*, is defined as the ratio $C_A(\mathcal{P})/C_{\text{OPT}}(\mathcal{P})$.

Finally, the GREEDY algorithm is formally defined as follows.

ALGORITHM GREEDY. Upon arrival of a task j, assign it to the server in $M(j)$ with the current minimum load (ties are broken arbitrarily).

6.1.1. Permanent tasks. For permanent tasks, Azar, Naor, and Rom [9] have shown that the competitive ratio of the GREEDY algorithm is $\Theta(\log n)$ and that no algorithm can do better.

To bring this problem into our framework, we present our results for the case where for each task j the set of servers that can run it, $M(j)$, consists of $d \geq 2$ servers chosen uniformly at random (with replacement), the number of requests $|\sigma|$ equals n, and all weights are equal. Let $\mathcal{P}_d$ be the associated probability distribution on request sequences.

LEMMA 6.1. *With probability* $1 - O(1/n)$, $C_{\text{OPT}}(\mathcal{P}_d) = O(1)$.

Proof. We show that with high probability there is an assignment with cost 10 for the case $d = 2$. A fortiori the result is true for $d > 2$.

The problem can be reduced to showing that in a random n-by-n bipartite graph (U, V, E) where each node in U has two random edges to V, there is an assignment of value 10. Arbitrarily break U into 10 pieces of size $n/10$ each. We show that each of these pieces contains a perfect matching. By Hall's theorem, the probability that there is no such assignment is bounded by the probability that there is a set of size k in one of the pieces of U whose neighborhood has size less than k. Ipso facto, this probability is at most

$$10 \sum_{k \leq n/10} \binom{n}{k-1} \binom{n/10}{k} \left(\left(\frac{k-1}{n} \right)^2 \right)^k .$$

Using standard approximations to the binomial coefficients, this is at most

$$10 \sum_{k \le n/10} \left(\frac{en}{k-1}\right)^{k-1} \left(\frac{en}{10k}\right)^k \left(\left(\frac{k-1}{n}\right)^2\right)^k .$$

Finally, rewriting and simplifying yield

$$\frac{10}{n} \sum_{k \le n/10} \frac{k-1}{e} \left(\frac{e^2 n^2 (k-1)^2}{10k(k-1)n^2}\right)^k = \frac{10}{n} \sum_{k \le n/10} \frac{k-1}{e} \left(\frac{e^2}{10}\right)^k = O\left(\frac{1}{n}\right). \qquad \square$$

(A more delicate analysis [15] shows that the maximum load achieved by the off-line case is 2 with high probability, for $d \ge 2$ and $m \le 1.6n$.)

LEMMA 6.2. *With high probability,* $C_{\text{GREEDY}}(\mathcal{P}_d) = O(\log\log n/\log d)$

Proof. The proof follows immediately from Theorem 3.2. $\square$

Thus, we obtain the following theorem.

THEOREM 6.3. *The competitive ratio of the* GREEDY *algorithm against the distribution* $\mathcal{P}_d$ *is* $O(\log\log n/\log d)$*, and no algorithm can do better.*

Proof. The proof follows from Lemmas 6.1 and 6.2 and Corollary 3.6. $\square$

6.1.2. Temporary tasks. For temporary tasks, the results of Azar, Broder, and Karlin [6] and Azar et al. [8] showed that there is an algorithm with competitive ratio $\Theta(\sqrt{n})$ and that no algorithm can do better.

It is difficult to construct a natural distribution of task arrivals and departures. As an approximation, we consider the following stochastic process $\mathcal{S}$: First, n tasks arrive; for each task, the set of servers that can run it consists of $d \ge 2$ servers chosen uniformly at random (with replacement). Then the following repeats forever: a random task among those present departs and a random task arrives, which again may be served by any one of d random servers. Clearly, in such an infinite sequence, eventually there will be n tasks which can only be served by one server, and so for trivial reasons the competitive ratio for long enough sequences is 1. However, we can state a competitiveness result in the following way:

THEOREM 6.4. *Let* $L_A[t]$ *be the maximum load on any server at time* t*, for tasks arriving according to the stochastic process* $\mathcal{S}$*, and assigned using algorithm* A*, that is,* $L_A[t] = \max_{i \in M} L_i^A(t)$*. Then for any fixed* $t > 0$*, with high probability,*

$$\frac{L_{\text{GREEDY}}[t]}{L_{\text{OPT}}[t]} = O(\log\log n).$$

Proof. The proof follows from Lemma 6.1 and Theorem 4.1. $\square$

7. Experimental results. The bound proven in Theorem 3.2 for the $O(1)$ term in the formula for the upper bound on the maximum load is rather weak (≈ 8), so it might be the case that for practical values of n, the constant term dominates the $\ln\ln n/\ln d$ term. However, experiments seem to indicate that this is not the case, and in fact even for small values of n, the maximum load achieved with $d = 2$ is substantially smaller than the maximum load achieved with $d = 1$. For the values we considered, $256 \le n \le 16777216$, increasing d beyond 2 has only limited further effect. For each value of n and d we ran 100 experiments. The results are summarized in Table 7.1.

Table 7.1
Experimental maximum load ($m = n$).

n	$d = 1$	$d = 2$	$d = 3$	$d = 4$

THE ALGORITHMIC ASPECTS OF UNCROWDED HYPERGRAPHS[*]

CLAUDIA BERTRAM-KRETZBERG[†] AND HANNO LEFMANN[†]

Abstract. We consider the problem of finding deterministically a large independent set of guaranteed size in a hypergraph on n vertices and with m edges. With respect to the Turán bound, the quality of our solutions is better for hypergraphs with not too many small cycles by a logarithmic factor in the input size. The algorithms are fast; they often have a running time of $O(m) + o(n^3)$. Indeed, the denser the hypergraphs are the closer the running times are to the linear times. For the first time, this gives for some combinatorial problems algorithmic solutions with state-of-the-art quality, solutions of which only the existence was known to date. In some cases, the corresponding upper bounds match the lower bounds up to constant factors. The involved concepts are uncrowded hypergraphs.

1. Introduction.

A fundamental problem in computer science and mathematics is to find a large independent set in an arbitrary graph [6], [16], [22]. Recall that for a graph $G = (V, E)$ with vertex set V and edge set $E \subseteq [V]^2$, a subset $I \subseteq V$ of the vertex set is called *independent* if the subgraph induced on I contains no edges $e \in E$, i.e., $E \cap [I]^2 = \emptyset$. The maximum cardinality of an independent set I is called the *independence number* $\alpha(G)$ of G. It is well known that finding an independent set of size $\alpha(G)$ in a graph G is an NP-hard problem, even for graphs with bounded maximum degree.

This suggests that we should look for approximation algorithms with guaranteed performance ratio, which is the quotient of the sizes of the optimal and the found solution in the worst case. The results of Arora et al. [10] on interactive proof systems show that with respect to polynomial time algorithms there is no constant performance ratio for the independent set problem for graphs on n vertices, indeed no ratio of $n^{1/4}$ unless $P = NP$; cf. the work of Bellare, Goldreich, and Sudan [13]. Recently, Håstad [28] showed that there is no performance ratio of $n^{1/2-\epsilon}$ unless $NP = P$ and no such ratio of $n^{1-\epsilon}$ unless $NP = coR$. With respect to polynomial time algorithms for triangle-free graphs with maximum degree Δ, a performance ratio of $O(\Delta/\ln\Delta)$ was given in [25] and [29] (see [45], [46]), and moreover, if they contain no complete subgraph K_l, $l \geq 4$, then a performance ratio of $O(\Delta/\ln\ln\Delta)$ is known; cf. [25], [26], [1]. Recently it was shown by Brandt [17] that the independence number of triangle-free graphs with minimum degree $\delta > n/3$ can be computed as fast as matrix multiplication in time $O(n^{2.376})$, while within the class of graphs with minimum degree $\delta > (1-\epsilon)n/4$, where $\epsilon > 0$, the problem is NP-hard.

For hypergraphs, the corresponding problem has been studied less; some papers are concerned with finding in parallel a maximal independent set; cf. [30] and [39].

[†]Lehrstuhl Informatik II, Universität Dortmund, Dortmund, D-44221, Germany (bertram@Ls2.informatik.uni-dortmund.de, lefmann@Ls2.informatik.uni-dortmund.de).

However, the size of a maximal independent set might be far off the size of a maximum independent set. Here we consider the problem of finding a large independent set in a hypergraph. Hypergraphs are important because many problems can be formulated in terms of them. A *hypergraph* $\mathcal{G} = (V, \mathcal{E})$ is given by a set V of vertices and a set $\mathcal{E}$ of edges (hyperedges), where each edge $E \in \mathcal{E}$ is a nonempty subset of V. A hypergraph $\mathcal{G} = (V, \mathcal{E})$ is called $(k+1)$-*uniform* if $\mathcal{E} \subseteq [V]^{k+1}$, i.e., each edge $E \in \mathcal{E}$ contains exactly $(k+1)$ vertices. If the hypergraph $\mathcal{G} = (V, \mathcal{E})$ is $(k+1)$-uniform, then

$$t(\mathcal{G}) = t = \left(\frac{(k+1) \cdot |\mathcal{E}|}{|V|}\right)^{1/k}$$

is the kth root of the *average degree* of $\mathcal{G}$. Similarly to the graph case, the *independence number* $\alpha(\mathcal{G})$ of a hypergraph $\mathcal{G} = (V, \mathcal{E})$ is defined as the maximum size of a subset $I \subseteq V$ which contains no edges $E \in \mathcal{E}$, i.e., there is no edge $E \in \mathcal{E}$ with $E \subseteq I$.

We give a general approximation strategy which has a performance ratio of $O(t/(\ln t)^{1/k})$ for $(k+1)$-uniform hypergraphs with average degree t^k and not too many small cycles. For random hypergraphs, no algorithm has a better performance ratio. The idea for doing this originates in a powerful result of Ajtai et al. [2] on *uncrowded hypergraphs.* These have the property that they contain no small cycles. We remark that derandomizing a probabilistic argument of Spencer [48] yields a performance ratio of $O(t)$ for arbitrary hypergraphs. We apply our approximation strategy to some combinatorial and graph problems for which only the existence of solutions of a certain quality was known to date. Our algorithms match these qualities and yield for these problems algorithmic solutions of state-of-the-art quality.

2. Uncrowded hypergraphs.

Turán's theorem for hypergraphs $\mathcal{G}$ gives a lower bound for the independence number $\alpha(\mathcal{G})$; cf. Spencer [48].

THEOREM 2.1 (see [48]). *Let $\mathcal{G} = (V, \mathcal{E})$ be a $(k+1)$-uniform hypergraph, $k \geq 1$, with average degree $t^k \geq 1$ and $|V| = n$. Then,*

$$\alpha(\mathcal{G}) \geq c_k \cdot \frac{n}{t}. \tag{2.1}$$

Moreover, an independent set of size at least $c_k \cdot n/t$ can be found in time $O(|\mathcal{E}|)$.

We remark that for $(k+1)$-uniform hypergraphs on n vertices with average degree $t^k < 1$, one can simply use a Greedy strategy to obtain in time $O(n)$ an independent set of size at least $c'_k \cdot n$; more simply, in an arbitrary way we add a few edges to the hypergraph to achieve in the resulting hypergraph that $1 \leq t^k < (k+1)$, and then we apply Theorem 2.1.

For completeness we give the algorithmic proof of (2.1).

Proof. Let $V = \{v_1, v_2, \ldots, v_n\}$ be the set of vertices of $\mathcal{G}$. The existence of an independent set of size as guaranteed in (2.1) can be shown by picking vertices of V independently of each other at random with probability $p = 1/t$. The set of picked vertices will yield the independent set. For the algorithm we imitate this approach by using the method of conditional probabilities; cf. [9], [42]. To give a deterministic algorithm, we start by generalizing the probabilistic experiment. For $i = 1, 2, \ldots, n$ vertex v_i will be assigned a weight (probability) $p_i \in [0, 1]$. Define a potential $V(p_1, p_2, \ldots, p_n)$ by

$$V(p_1, p_2, \ldots, p_n) = \sum_{i=1}^{n} p_i - \sum_{E \in \mathcal{E}} \prod_{v_i \in E} p_i.$$

Note that in the corresponding random experiment, $\sum_{i=1}^{n} p_i$ is the expected number of picked vertices and $\sum_{E\in\mathcal{E}} \prod_{v_i\in E} p_i$ is the expected number of edges in the induced random hypergraph.

Now, for $i = 1, 2, \ldots, n$ in each step i we choose either $p_i = 0$ or $p_i = 1$ in order to maximize the value of the potential $V(p_1, p_2, \ldots, p_n)$. As $V(p_1, p_2, \ldots, p_n)$ is linear in each p_i, i.e., for $i = 1$

$$V(p_1, p_2, \ldots, p_n) = p_1 \cdot V(1, p_2, \ldots, p_n) + (1 - p_1) \cdot V(0, p_2, \ldots, p_n),$$

either $V(1, p_2, \ldots, p_n) \geq V(p_1, p_2, \ldots, p_n)$ or $V(0, p_2, \ldots, p_n) \geq V(p_1, p_2, \ldots, p_n)$. We take vertex v_1 for the independent set if $V(1, p_2, \ldots, p_n) > V(p_1, p_2, \ldots, p_n)$; otherwise we discard it. Doing this one after the other for $i = 1, 2, \ldots, n$, finally, each vertex v_i is assigned a weight $p_i \in \{0, 1\}$, $i = 1, 2, \ldots, n$.

Choosing in the beginning $p_1 = p_2 = \cdots = p_n = p$, we have

$$V(p, \ldots, p) = p \cdot n - p^{k+1} \cdot \frac{n \cdot t^k}{k+1},$$

which is maximal (taking the derivative) for $p = 1/t$, i.e., with this choice of p we have

$$V(p, \ldots, p) = \frac{k}{k+1} \cdot \frac{n}{t}. \tag{2.2}$$

By our strategy we finally obtain $V(p_1, p_2, \ldots, p_n) \geq V(p, \ldots, p)$. Let $V' = \{v_i \in V \mid p_i = 1\}$. By (2.2), and using that $p_i \geq 0$ for $i = 1, 2, \ldots, n$, we infer

$$|V'| = \sum_{i=1}^{n} p_i = V(p_1, \ldots, p_n) + \sum_{E\in\mathcal{E}} \prod_{v_i\in E} p_i \geq V(p, \ldots, p) + \sum_{E\in\mathcal{E}} \prod_{v_i\in E} p_i \geq \frac{k}{k+1} \cdot \frac{n}{t}.$$

We claim that V' is an independent set in $\mathcal{G}$. Suppose for contradiction that this is not the case, and let $E = \{v_{i_1}, v_{i_2}, \ldots, v_{i_{k+1}}\} \in \mathcal{E} \cap [V']^{k+1}$, where $i_1 < i_2 < \cdots < i_{k+1} = s$. Consider step s. Because we had chosen $p_s = 1$ in this step, we have

$$V(p_1, \ldots, p_{s-1}, 1, p_{s+1}, \ldots, p_n) > V(p_1, \ldots, p_n)\ . \tag{2.3}$$

However, as edge E came in in step s, we infer

$$V(p_1, \ldots, p_{s-1}, 1, p_{s+1}, \ldots, p_n) - V(p_1, \ldots, p_n) \leq (1 - p_s) - (1 - p_s) = 0,$$

which contradicts (2.3). Thus V' is an independent set in $\mathcal{G}$ of size at least $\frac{k}{k+1} \cdot \frac{n}{t}$, i.e., $\alpha(\mathcal{G}) \geq \frac{k}{k+1} \cdot \frac{n}{t}$.

During the algorithm each vertex and each edge is considered only a constant number of times; hence, with $t^k \geq 1$ the running time is $O(|\mathcal{E}|)$. □

For fixed integers $k \geq 1$, there are examples of $(k+1)$-uniform hypergraphs whose independence numbers match the lower bound (2.1) up to constant factors. Simply take n/x vertex disjoint copies of complete $(k+1)$-uniform hypergraphs on x vertices each where $t^k = \binom{x-1}{k}$. However, quite often the hypergraphs under consideration are in some sense *sparse*, and for these the general lower bound (2.1) can be improved, as can be seen in the following.

A *cycle* of length i in a $(k+1)$-uniform hypergraph $\mathcal{G} = (V, \mathcal{E})$ is a set of i pairwise distinct edges from $\mathcal{E}$ whose union contains at most $i \cdot k$ vertices. An *i-cycle* is a cycle of length i which does not contain any cycles of length $2, 3, \dots, i-1$. To specify the notion of "sparse" mentioned above, we define a hypergraph $\mathcal{G}$ to be *uncrowded* if it does not contain any 2-, 3-, or 4-cycles. For a vertex $v \in V$ let $d(v)$ denote its *degree*, i.e., the number of edges $E \in \mathcal{E}$ which contain v. Let $\Delta(\mathcal{G}) = \max_{v\in V} \{d(v)\}$ be the *maximum degree* of $\mathcal{G}$. For a subset $V' \subseteq V$ let $\mathcal{G}' = (V', \mathcal{E}')$ with $\mathcal{E}' = \mathcal{E} \cap [V']^{k+1}$ be on the V' *induced subhypergraph* of $\mathcal{G}$.

For uncrowded hypergraphs, the lower bound (2.1) was improved by the following powerful result of Ajtai et al. [2].

THEOREM 2.2 (see [2]). *Let $k \geq 2$ be a fixed integer. Let $\mathcal{G}$ be a $(k+1)$-uniform hypergraph on n vertices. Assume that*

(i) *$\mathcal{G}$ is uncrowded, i.e., contains no 2-, 3-, or 4-cycles,*

(ii) *the maximum degree $\Delta(\mathcal{G})$ satisfies $\Delta(\mathcal{G}) \leq t^k$ where $t \geq t_0(k)$, and*

(iii) *$n \geq n_0(k, t)$.*

Then the independence number $\alpha(\mathcal{G})$ satisfies

$$\alpha(\mathcal{G}) \geq \frac{0.98}{e} \cdot 10^{-5/k} \cdot \frac{n}{t} \cdot (\ln t)^{1/k}. \tag{2.4}$$

Various applications of Theorem 2.2 have been found, including the disproof of Heilbronn's conjecture [32], results on Sidon sets [4], Steiner systems [44], [18], complexity theory [41], Ramsey numbers [3], geometric selection problems [37], Turán numbers for random graphs [31], and graph coloring problems [8], [36].

Indeed, for a certain range of the involved parameters k, n, t, inequality (2.4) is best possible up to constant factors, as a random hypergraph argument shows. Namely, for a fixed integer $k \geq 2$ consider a random $(k+1)$-uniform hypergraph on n vertices, where the edges are chosen independently at random with probability $p = (t/n)^k$, where $n \gg t \gg k$. Let $l = C \cdot n/t \cdot (\ln t)^{1/k}$, where $C > 0$ is a large enough constant. For a fixed l-element subset $I \subseteq V$ of the vertex set, the probability that I is an independent set is equal to

$$(1-p)^{\binom{l}{k+1}} \leq \exp\left\{-p \cdot \binom{l}{k+1}\right\} \leq \exp\left\{-\frac{p \cdot l^{k+1} \cdot (1-o(1))}{(k+1)!}\right\},$$

where we used the inequality $1 - x \leq \exp\{-x\} := e^{-x}$. Using the inequality $\binom{n}{l} \leq (e \cdot n/l)^l$, the expected number of independent sets of size l is at most

$$\begin{aligned}
&\binom{n}{l} \cdot \exp\left\{-\frac{p \cdot l^{k+1} \cdot (1-o(1))}{(k+1)!}\right\} \\
&\leq \left(\frac{e \cdot n}{l} \cdot \exp\left\{-\frac{p \cdot l^k \cdot (1-o(1))}{(k+1)!}\right\}\right)^l \\
&\leq \left(\frac{e}{C} \cdot \frac{t}{(\ln t)^{1/k}} \cdot \exp\left\{-\frac{C^k \cdot (1-o(1)) \cdot \ln t}{(k+1)!}\right\}\right)^l \\
&\leq \left(\frac{e}{C} \cdot \exp\left\{\ln t - \frac{\ln \ln t}{k} - \frac{C^k \cdot (1-o(1)) \cdot \ln t}{(k+1)!}\right\}\right)^l \\
&< \frac{1}{5}
\end{aligned}$$

for $C^k \geq 2 \cdot (k+1)!$ and t large enough. However, the expected number of cycles of length $i \leq 4$ in the random hypergraph is at most

$$n^{ik} \cdot p^i = t^{ik} \leq t^{4k}.$$

By Markov's inequality there exists a hypergraph $\mathcal{G}$ on n vertices with at most

$$5 \cdot p \cdot \binom{n}{k+1} \le 5 \cdot n \cdot \frac{t^k}{(k+1)!}$$

edges which contains no independent set of size $5 \cdot C \cdot n/t \cdot (\ln t)^{1/k}$ and with at most $15 \cdot t^{4k}$ cycles of length at most 4. Note that for each induced subhypergraph $\mathcal{G}'$ of $\mathcal{G}$ we have $\alpha(\mathcal{G}') \le \alpha(\mathcal{G})$. Now, omitting one vertex from each cycle of length at most 4 gives a $(k+1)$-uniform uncrowded hypergraph on $n - 15 \cdot t^{4k} = (1 - o(1)) \cdot n$ vertices with average degree at most $5/k! \cdot t^k$ and with independence number at most $5 \cdot C \cdot n/t \cdot (\ln t)^{1/k}$, provided $t^{4k} = o(n)$. Hence, for many hypergraphs, inequality (2.4) is best possible up to constant factors.

Notice that in (2.4) we gain a logarithmic factor if we compare it to Turán's lower bound (2.1). This additional logarithmic factor is of interest because in some applications one can use Theorem 2.2 to prove lower bounds which, with respect to the corresponding applications, asymptotically match the upper bounds.

We remark that recently Łuczak and Szymańska [39] gave a randomized parallel algorithm with polylogarithmic running time to find a maximal (not necessarily maximum) independent set in hypergraphs without 2-cycles.

Fundia [21] gave a polynomial time algorithm for uncrowded hypergraphs, which finds an independent set of size asymptotically at least as guaranteed by inequality (2.4).

THEOREM 2.3 (see [21]). *Let $k \ge 2$ be a fixed integer. Let $\mathcal{G}$ be an uncrowded $(k+1)$-uniform hypergraph on n vertices with average degree t^k, where $k^4 \cdot t^{4k} < n$ and $k < t$. Then, one can find in time $O\left(n^3 \cdot t^{6k} \cdot \ln t\right)$ an independent set of size at least $\Omega(n/t \cdot (\ln t)^{1/k})$.*

Notice that in uncrowded $(k+1)$-uniform hypergraphs $\mathcal{G} = (V, \mathcal{E})$ with $|V| = n$, two distinct edges have at most one vertex in common; hence $|\mathcal{E}| \le \binom{n}{2}/\binom{k+1}{2}$ and $t = O(n^{1/k})$.

We remark that in Theorem 2.3 the condition $k^4 \cdot t^{4k} < n$ is not that important (cf. [8]) if we ignore for the moment the algorithmic aspects. Namely, if $k^4 \cdot t^{4k} \ge n$, then we set

$$N = \left\lceil \frac{k^4 \cdot t^{4k} + 1}{n} \right\rceil$$

and we form a new hypergraph $\mathcal{H} = (V', \mathcal{E}')$ by taking N vertex disjoint copies of $\mathcal{G}$. Clearly, $|V'| = N \cdot n$ and $|\mathcal{E}'| = N \cdot |\mathcal{E}|$; thus $\mathcal{G}$ and $\mathcal{H}$ have the same average degree. However, $\mathcal{H}$ fulfills the assumptions of Theorem 2.3, and we obtain in time $O((N \cdot n)^3 \cdot t^{6k} \cdot \ln t)$ an independent set of size $\Omega(N \cdot n/t \cdot (\ln t)^{1/k})$. Then, restricting the independent set to one copy of $\mathcal{G}$ yields the desired result, i.e., an independent set of size $\Omega(n/t \cdot (\ln t)^{1/k})$. We have in uncrowded hypergraphs $t = O(n^{1/k})$; hence, we infer for the running time $O((N \cdot n)^3 \cdot t^{6k} \cdot \ln t) = O(t^{18k} \cdot \ln t) = O(n^{18} \cdot \ln n)$, i.e., polynomial running time for fixed k.

Contrary to our considerations of blowing up the hypergraph, i.e., taking copies, we will work on small subhypergraphs of $\mathcal{G}$ to keep the running times of the corresponding algorithms small; cf. Kortsarz and Peleg [33]. Throughout this paper, k will always be a fixed integer with $k \ge 2$ and t^k, the average degree, will always be an increasing function of n, the number of vertices of the hypergraph, i.e., $t = t(n) \to \infty$ with $n \to \infty$.

Theorem 2.3 does not seem to be applicable to many hypergraphs. In general, the hypergraphs under consideration are not uncrowded and have quite a lot of 2-, 3-, or 4-cycles. However, as we will see, in several cases the trick is to choose at random an appropriate small subhypergraph, which turns out to be "nearly" uncrowded, i.e., has only a few small cycles. After deleting these cycles one can apply Theorem 2.3. Indeed, seemingly against the intuition, one chooses vertices with a probability $p = t^{-1+\epsilon}$ for some $\epsilon > 0$, which is a little bigger than that which one would usually take, i.e., $p = t^{-1}$. But this gives the improvement by a logarithmic factor.

In the following we state our main results. First, we improve Theorem 2.3 as follows.

THEOREM 2.4. *Let $k \geq 2$ be a fixed integer. Let $\mathcal{G}$ be an uncrowded $(k+1)$-uniform hypergraph on n vertices with average degree t^k and $t \to \infty$ with $n \to \infty$. Then, for each fixed $\delta > 0$, one can find in time*

$$O\left(n \cdot t^k + \frac{n^3}{t^{3-\delta}}\right) \tag{2.5}$$

an independent set in $\mathcal{G}$ of size at least $\Omega(n/t \cdot (\ln t)^{1/k})$.

The parameter $\delta > 0$ can be chosen to be small. Thus, the more edges the hypergraph has, the closer the running time is to the linear one, $O(n \cdot t^k)$. However, as $t = O(n^{1/k})$ for $k \geq 3$ and $\delta > 0$, the time bound is always $O(|\mathcal{E}| + n^{3-3/k+\delta}) = O(n^{3-3/k+\delta})$.

The proof of Theorem 2.4 shows that with the factor t^δ, $0 < \delta < 1$, in the running time there comes a factor $(\delta/(6k+4))^{1/k}$ in the quality of the solution. Hence, for $k \geq 3$, dropping the running time from $O(n^3/t^{3-\delta})$ to $O(n^3/t^{3-\delta/2})$, i.e., by the factor $t^{\delta/2}$, means that we lose in the guaranteed quality the factor $2^{1/k}$.

COROLLARY 2.5. *Let $k \geq 2$ be a fixed integer. Let $\mathcal{G}$ be an uncrowded $(k+1)$-uniform hypergraph on n vertices with average degree at most t^k and $t \to \infty$ with $n \to \infty$. Then, for each fixed $\delta > 0$, one can find in time*

$$O\left(n \cdot t^k + \frac{n^3}{t^{3-\delta}}\right) \tag{2.6}$$

an independent set in $\mathcal{G}$ of size at least $\Omega(n/t \cdot (\ln t)^{1/k})$.

Proof. If the average degree $t(\mathcal{G})^k$ of $\mathcal{G}$ satisfies $t(\mathcal{G})^k \leq t^k/\ln t$, then by Theorem 2.1 we find in time $O(n \cdot t(\mathcal{G})^k) = O(n \cdot t^k)$ an independent set of size

$$\Omega\left(\frac{n}{t(\mathcal{G})}\right) = \Omega\left(\frac{n}{t} \cdot (\ln t)^{1/k}\right).$$

Otherwise, if $t^k \geq t(\mathcal{G})^k > t^k/\ln t$, then we apply Theorem 2.4 with $\delta' = \delta/2$ and we obtain in time

$$O\left(n \cdot t(\mathcal{G})^k + \frac{n^3}{t(\mathcal{G})^{3-\delta'}}\right) = O\left(n \cdot t^k + \frac{n^3}{t^{3-\delta'}} \cdot (\ln t)^{(3-\delta')/k}\right) = O\left(n \cdot t^k + \frac{n^3}{t^{3-\delta}}\right)$$

an independent set of size at least $\Omega(n/t(\mathcal{G}) \cdot (\ln t(\mathcal{G}))^{1/k}) = \Omega(n/t \cdot (\ln t)^{1/k})$. Here we used that the function $f(t) = (\ln t)^{1/k}/t$ is decreasing for $t \geq 2$. $\square$

It turns out that the 2-cycles are important. For a hypergraph $\mathcal{G} = (V, \mathcal{E})$, a 2-cycle $\{E_1, E_2\}$ with $E_1, E_2 \in \mathcal{E}$ is called *$(2, j)$-cycle* if $|E_1 \cap E_2| = j$. Let $s_{2,j}(\mathcal{G})$ denote the number of $(2, j)$-cycles in $\mathcal{G}$.

The next theorem yields an algorithmic version of the existence result which was proved by Duke, Lefmann, and Rödl [18]. Corollary 2.8 gives an algorithmic solution of a conjecture of Spencer [49].

THEOREM 2.6. *Let $k \geq 2$ be a fixed integer. Let $\mathcal{G} = (V, \mathcal{E})$ be a $(k+1)$-uniform hypergraph on n vertices with average degree t^k, where $t \to \infty$ with $n \to \infty$. If the $(2, j)$-cycles satisfy*

$$s_{2,j}(\mathcal{G}) \leq c \cdot n \cdot t^{2k+1-j-\gamma}$$

for $j = 2, 3, \ldots, k$ and some constants $c, \gamma > 0$, then one can find for every fixed $\delta > 0$ in time $O(n \cdot t^k + \sum_{j=2}^{k} s_{2,j}(\mathcal{G}) + n^3/t^{3-\delta})$ an independent set of size at least

$$C(k, \gamma, \delta, c) \cdot \frac{n}{t} \cdot (\ln t)^{1/k} .$$

COROLLARY 2.7. *Let $k \geq 2$ be a fixed integer. Let $\mathcal{G} = (V, \mathcal{E})$ be a $(k+1)$-uniform hypergraph on n vertices with average degree at most t^k, where $t \to \infty$ with $n \to \infty$. If the $(2, j)$-cycles satisfy*

$$s_{2,j}(\mathcal{G}) \leq c \cdot n \cdot t^{2k+1-j-\gamma}$$

for $j = 2, 3, \ldots, k$ and some constants $c, \gamma > 0$, then one can find for every fixed $\delta > 0$ in time $O(n \cdot t^k + \sum_{j=2}^{k} s_{2,j}(\mathcal{G}) + n^3/t^{3-\delta})$ an independent set of size at least $\Omega(n/t \cdot (\ln t)^{1/k})$.

Proof. If the average degree $t(\mathcal{G})^k$ of $\mathcal{G}$ satisfies $t^k \geq t(\mathcal{G})^k \geq t^k / \ln t$, then the $(2, j)$-cycles satisfy

$$s_{2,j}(\mathcal{G}) \leq c \cdot n \cdot t^{2k+1-j-\gamma} \leq c \cdot n \cdot t(\mathcal{G})^{2k+1-j-\gamma/2}$$

for t large. Thus, the assumptions of Theorem 2.6 are fulfilled, and we obtain for every fixed $\delta > 0$ in time $O(n \cdot t^k + \sum_{j=2}^{k} s_{2,j}(\mathcal{G}) + n^3/t^{3-\delta})$ an independent set of size at least $\Omega(n/t \cdot (\ln t)^{1/k})$. Otherwise, if $t(\mathcal{G})^k < t^k / \ln t$, we apply Theorem 2.1 and obtain in time $O(n \cdot t^k)$ an independent set of size at least $\Omega(n/t \cdot (\ln t)^{1/k})$. $\square$

As an immediate consequence of Corollary 2.7 we have the following.

COROLLARY 2.8. *Let $k \geq 2$ be a fixed integer. Let $\mathcal{G} = (V, \mathcal{E})$ be a $(k+1)$-uniform hypergraph on n vertices with average degree at most t^k, where $t \to \infty$ with $n \to \infty$. If $\mathcal{G}$ does not contain any 2-cycles, then one can find for every fixed $\delta > 0$ in time $O(n \cdot t^k + n^3/t^{3-\delta})$, an independent set of size at least $\Omega(n/t \cdot (\ln t)^{1/k})$.*

3. Choosing small subhypergraphs.

For proving our results, we use the idea of choosing small subhypergraphs on which we control certain parameters such as the number of vertices, edges, or cycles. The control on the small subhypergraphs reflects a probabilistic approach.

LEMMA 3.1. *Let $k \geq 2$ be a fixed integer. Let $\mathcal{G} = (V, \mathcal{E})$ be a $(k+1)$-uniform hypergraph with $s_{2,j}(\mathcal{G})$ many $(2, j)$-cycles, $j = 2, 3, \ldots, k$. For every p with $0 \leq p \leq 1$, one can find in time $O(|V| + |\mathcal{E}| + \sum_{j=2}^{k} s_{2,j}(\mathcal{G}))$ an induced subhypergraph $\mathcal{H} = (V', \mathcal{E}')$ such that for $j = 2, 3, \ldots, k$ it holds*

$$|V'| \geq p/3 \cdot |V| \quad \textit{and} \quad |\mathcal{E}'| \leq 3 \cdot p^{k+1} \cdot |\mathcal{E}| \quad \textit{and} \quad s_{2,j}(\mathcal{H}) \leq 3 \cdot (k-1) \cdot p^{2k+2-j} \cdot s_{2,j}(\mathcal{G}).$$

Proof. By inspecting each two-element subset which is contained in an edge $E \in \mathcal{E}$, we obtain for each two-element set $\{x, y\}$ all edges $E \in \mathcal{E}$ with $\{x, y\} \subset E$. This can be done in time $O(|\mathcal{E}|)$. Then, the sets C_j, which contain the vertex sets of all $(2,j)$-cycles in $\mathcal{G}$, $j = 2, 3, \ldots, k$, can be constructed in time $O(|V| + |\mathcal{E}| + \sum_{j=2}^{k} s_{2,j}(\mathcal{G}))$.

Let $V = \{v_1, v_2, \ldots, v_n\}$. Every vertex v_i will be assigned a weight $p_i \in [0,1]$, $i = 1, 2, \ldots, n$. Define a potential $V(p_1, p_2, \ldots, p_n)$ by

$$V(p_1, p_2, \ldots, p_n) = 3^{pn/3} \cdot \prod_{i=1}^{n} \left(1 - \frac{2}{3} \cdot p_i\right) + \frac{\sum_{E \in \mathcal{E}} \prod_{v_i \in E} p_i}{3 \cdot p^{k+1} \cdot |\mathcal{E}|} + \sum_{j=2}^{k} \frac{\sum_{C \in C_j} \prod_{v_i \in C} p_i}{3 \cdot (k-1) \cdot p^{2k+2-j} \cdot |C_j|} \,.$$

If $pn < 6$, any two vertices will do since they do not yield an edge. Hence, we assume that $pn \geq 6$. With $p_1 = \cdots = p_n = p$ in the beginning, and using $1 - x \leq e^{-x}$, we infer

$$V(p, \ldots, p) = 3^{pn/3} \cdot \left(1 - \frac{2}{3} \cdot p\right)^n + \frac{p^{k+1} \cdot |\mathcal{E}|}{3 \cdot p^{k+1} \cdot |\mathcal{E}|} + \sum_{j=2}^{k} \frac{p^{2k+2-j} \cdot s_j(\mathcal{G})}{3 \cdot (k-1) \cdot p^{2k+2-j} \cdot s_{2,j}(\mathcal{G})}$$
$$\leq \left(\frac{3}{e^2}\right)^{pn/3} + \frac{2}{3} < 1 \,.$$

The potential $V(p_1, p_2, \ldots, p_n)$ is linear in each p_i. As in the algorithmic argument for proving Theorem 2.1 step by step, we decide which choice of p_i, either $p_i = 0$ or $p_i = 1$, minimizes the current value of $V(p_1, p_2, \ldots, p_n)$. We put vertex v_1 in V' iff $V(1, p_2, \ldots, p_n) \leq V(0, p_2, \ldots, p_n)$. Doing this for all vertices $v_1, v_2, \ldots, v_n$ yields the desired set $V' = \{v_i \in V \mid p_i = 1\}$. We always choose the value of $p_i \in \{0,1\}$ to minimize the value of the potential, i.e., finally, we have $V(p_1, p_2, \ldots, p_n) < 1$, too. All summands in $V(p_1, p_2, \ldots, p_n)$ are nonnegative. If the chosen subhypergraph $\mathcal{H} = (V', \mathcal{E}')$ with $\mathcal{E}' = \mathcal{E} \cap [V']^{k+1}$ violated one of the desired properties, then the corresponding summand would be bigger than 1, which is not possible by our strategy.

The computation of $V(p, p, \ldots, p)$ in the beginning can be done in time $O(|V| + |\mathcal{E}| + \sum_{j=2}^{k} s_{2,j}(\mathcal{G}))$, and updating all the potentials $V(p_1, \ldots, p_n)$ during the algorithm can be done in the same time. □

For a hypergraph $\mathcal{G}$, let $\mu_i(\mathcal{G})$, $i = 3, 4$, denote the number of i-cycles in $\mathcal{G}$.

LEMMA 3.2. *Let $k \geq 2$ be a fixed integer. Let $\mathcal{G} = (V, \mathcal{E})$ be a $(k+1)$-uniform hypergraph on $|V| = n$ vertices with average degree t^k. If $\mathcal{G}$ does not contain any 2-cycles, then one can find in time $O(n + n \cdot t^k)$ an induced subhypergraph $\mathcal{G}' = (V', \mathcal{E}')$ with $|V'| \geq |V|/2$ and*

$$\mu_i(\mathcal{G}) \leq c_i(k) \cdot n \cdot t^{(i-1)k} \tag{3.1}$$

for $i = 3, 4$. The sets C_i of i-cycles, $i = 3, 4$, can be computed in time $O(n + n \cdot t^{(i-1)k}) = O(n + n \cdot t^{3k})$.

Proof. For each edge $E \in \mathcal{E}$ we mark in time $O(|\mathcal{E}|)$ all two-element subsets which are contained in E by "E." Then, in time $O(1)$ we can decide whether a two-element set is contained in some edge $E \in \mathcal{E}$.

First we discard all vertices $v \in V$ with degree $d(v) > 2(k+1) \cdot t^k =: \Delta$ and all edges incident with such vertices v. This can be done in time $O(n + n \cdot t^k)$. The resulting induced hypergraph $\mathcal{G}' = (V', \mathcal{E}')$ of $\mathcal{G}$ has $|V'| \geq n/2$ vertices. As $\mathcal{G}$ contains no 2-cycles for each two distinct vertices $x, y \in V'$, there exists at most one edge which contains both x and y. The maximum degree of $\mathcal{G}'$ is at most Δ; hence

$$\mu_3(\mathcal{G}') \leq \frac{1}{3} \cdot n \cdot \binom{\Delta}{2} \cdot k^2 \leq c_3(k) \cdot n \cdot t^{2k},$$
$$\mu_4(\mathcal{G}') \leq \frac{1}{4} \cdot n \cdot \binom{\Delta}{2} \cdot k \cdot \Delta \cdot k^2 \leq c_4(k) \cdot n \cdot t^{3k}.$$

To determine the set C_3 of all 3-cycles in $\mathcal{G}'$, we consider each vertex $v \in V_0$ and all pairs $\{E_1, E_2\} \in [\mathcal{E}']^2$ of edges with $v \in E_1$ and $v \in E_2$. This can be done in time $O(n \cdot \Delta^2)$. Then, for each two vertices $x \in E_1 \setminus \{v\}$ and $y \in E_2 \setminus \{v\}$, we test in time $O(1)$ whether there exists an edge $E \in \mathcal{E}'$ with $x, y \in E$. Thus, determining the set C_3 of 3-cycles in $\mathcal{G}'$ can be done in time $O(n + n \cdot t^{2k})$. Similarly, one can determine the set C_4 of 4-cycles in $\mathcal{G}'$ in time $O(n + n \cdot t^{3k})$. ∎

LEMMA 3.3. *Let $k \geq 2$ be a fixed integer. Let $\mathcal{G} = (V, \mathcal{E})$ be a $(k+1)$-uniform hypergraph on $|V| = n$ vertices with average degree t^k, where $\mathcal{G}$ contains no 2-cycles. For every p with $0 \leq p \leq 1$, one can find in time $O(n + n \cdot t^{3k})$ an induced subhypergraph $\mathcal{H} = (V', \mathcal{E}')$ of $\mathcal{G}$ such that*

$$\begin{aligned} &|V'| \geq p/6 \cdot |V|, \\ &|\mathcal{E}'| \leq 3 \cdot p^{k+1} \cdot |\mathcal{E}|, \\ &\mu_i(\mathcal{H}) \leq 6 \cdot p^{ik} \cdot c_i(k) \cdot n \cdot t^{(i-1)k} \quad \textit{for } i = 3, 4. \end{aligned} \tag{3.2}$$

Proof. By Lemma 3.2, we find in $\mathcal{G}$ in time $O(n + n \cdot t^k)$ an induced subhypergraph $\mathcal{G}' = (V', \mathcal{E}')$ with $V' = \{v_1, v_2, \ldots, v_l\}$ and $|V'| \geq |V|/2$, which contains at most $c_i(k) \cdot n \cdot t^{(i-1)k}$ i-cycles. The sets C'_i of i-cycles in $\mathcal{G}'$, $i = 3, 4$, can be computed in time $O(n + n \cdot t^{3k})$. Then we apply to $\mathcal{G}'$ the same derandomization technique as in the proof of Lemma 3.1 using the potential

$$V(p_1, p_2, \ldots, p_l) = 3^{pn/6} \prod_{v_i \in V'} \left(1 - \frac{2}{3} \cdot p_i\right) + \frac{\sum_{E \in \mathcal{E}'} \prod_{v_i \in E} p_i}{3 \cdot p^{k+1} \cdot |\mathcal{E}|}$$
$$+ \sum_{j=3}^{4} \frac{\sum_{C \in C'_j} \prod_{v_i \in C} p_i}{6 \cdot p^{jk} \cdot c_j(k) \cdot n \cdot t^{(j-1)k}},$$

and we obtain in time $O(n + n \cdot t^{3k})$ an induced subhypergraph fulfilling all three properties (3.2). ∎

Similarly, one can show the following.

LEMMA 3.4. *Let $\mathcal{G} = (V, \mathcal{E})$ be a $(k+1)$-uniform hypergraph with $|V| = n$. For every p with $0 \leq p \leq 1$, one can find in time $O(n + |\mathcal{E}|)$ an induced subhypergraph $\mathcal{H} = (V', \mathcal{E}')$ of $\mathcal{G}$ such that*

$$|V'| \geq p/2 \cdot |V| \quad \textit{and} \quad |\mathcal{E}'| \leq 2 \cdot p^{k+1} \cdot |\mathcal{E}| \,.$$

Proof. We apply the same derandomization technique as in the proof of Lemma 3.1 by using the potential

$$V(p_1, p_2, \ldots, p_n) = 2^{pn/2} \cdot \prod_{i=1}^{n} \left(1 - \frac{p_i}{2}\right) + \frac{\sum_{E \in \mathcal{E}} \prod_{v_i \in E} p_i}{2 \cdot p^{k+1} \cdot |\mathcal{E}|}. \qquad ∎$$

4. Avoiding 2-cycles.

Here we will give the proof of Theorem 2.4.

Proof. Let $\mathcal{G}$ be an uncrowded $(k+1)$-uniform hypergraph on n vertices with average degree t^k; thus $t = O(n^{1/k})$. The idea is to choose a small induced subhypergraph $\mathcal{G}_0$ of $\mathcal{G}$ to which we apply Theorem 2.3.

First, we apply Lemma 3.4 to $\mathcal{G}$ with $p = t^{-1+\epsilon}$, where $\epsilon = \min\{\frac{\delta}{6k+4}, \frac{k-1}{4k}\}$, and we obtain in time $O(n \cdot t^k)$ an induced subhypergraph $\mathcal{G}_0 = (V_0, \mathcal{E}_0)$ of $\mathcal{G}$ with

$$|V_0| \geq p/2 \cdot |V| \quad \text{and} \quad |\mathcal{E}_0| \leq 2 \cdot p^{k+1} \cdot |\mathcal{E}| \, .$$

Notice that if we had chosen the probability to be $p = 1/t$, then the resulting subhypergraph would only have n/t vertices, but our aim is to find an independent set of size at least $\Omega(n/t \cdot (\ln t)^{1/k})$.

The hypergraph $\mathcal{G}_0$ has average degree

$$t(\mathcal{G}_0)^k \leq t_0^k := 4 \cdot (p \cdot t)^k \, .$$

If $t(\mathcal{G}_0) \leq p \cdot t/(\ln(p \cdot t))^{1/k}$, then we apply Theorem 2.1 and we obtain in time $O(p \cdot n + p^{k+1} \cdot |\mathcal{E}|)$ an independent set of size

$$\Omega\left(\frac{p \cdot n}{t(\mathcal{G}_0)}\right) = \Omega\left(\frac{p \cdot n}{p \cdot t} \cdot (\ln(p \cdot t))^{1/k}\right) = \Omega\left(\frac{n}{t} \cdot (\ln t)^{1/k}\right).$$

Otherwise, let $t(\mathcal{G}_0) > p \cdot t/(\ln(p \cdot t))^{1/k}$. We have $t^\epsilon/(\epsilon \cdot \ln t)^{1/k} > k$, as k, ϵ are constants and $t \to \infty$ with $n \to \infty$. With $t = O(n^{1/k})$ and $\epsilon \leq (k-1)/(4k)$, we infer

$$p/2 \cdot n = n/2 \cdot t^{-1+\epsilon} > k^4 \cdot 4^4 \cdot t^{4k\epsilon} = k^4 \cdot t_0^{4k};$$

hence the assumptions of Theorem 2.3 are fulfilled and we apply it to the hypergraph $\mathcal{G}_0$. By omitting some more vertices we can assume without loss of generality (w.l.o.g.) that $|V_0| = p/2 \cdot n$. As $\epsilon \leq \delta/(6k+4)$, we obtain in time

$$O\left((p \cdot n)^3 \cdot (p \cdot t)^{6k} \cdot \ln t\right) = O\left(\frac{n^3}{t^{3-3\epsilon-6k\epsilon}} \cdot \ln t\right) = O\left(\frac{n^3}{t^{3-\delta}}\right)$$

an independent set of size at least

$$\Omega\left(\frac{p \cdot n}{t_0} \cdot (\ln t_0)^{1/k}\right) = \Omega\left(\frac{p \cdot n}{p \cdot t} \cdot (\ln(p \cdot t))^{1/k}\right) = \Omega\left(\frac{n}{t} \cdot (\ln t^\epsilon)^{1/k}\right) = \Omega\left(\frac{n}{t} \cdot (\ln t)^{1/k}\right)$$

as $\epsilon > 0$ is a constant. Here, we used that the function $f(t) = (\ln t)^{1/k}/t$ is decreasing for $t \geq 2$. The algorithm has the desired running time $O(n \cdot t^k + n^3/t^{3-\delta})$. $\square$

Indeed, provided an algorithm does not require any assumptions on the mutual growth of k, t, n, we have the following *Meta-Algorithm*.

Let $k \geq 2$ be a fixed integer. Let $\mathcal{G}$ be an uncrowded $(k+1)$-uniform hypergraph on n vertices with average degree t^k and $t \to \infty$ with $n \to \infty$. Let $\delta > 0$ be any fixed real number.

If one can find in time $f(n,t)$ an independent set in $\mathcal{G}$ of size $\Omega(n/t \cdot (\ln t)^{1/k})$, then one can find in time $O(f(n/t^{1-\delta}, t^\delta) + n \cdot t^k)$ an independent set in $\mathcal{G}$ of size at least $\Omega(n/t \cdot (\ln t)^{1/k})$.

Now we come to the proof of Theorem 2.6.

Proof. Let the $(2,j)$-cycles of $\mathcal{G}$ satisfy $s_{2,j}(\mathcal{G}) \leq c \cdot n \cdot t^{2k+1-j-\gamma}$ for $j = 2, 3, \ldots, k$ and constants $c, \gamma > 0$. Set

$$p = t^{-1+\epsilon}, \tag{4.1}$$

where

$$\epsilon = \min \left\{ \frac{\gamma}{2k}, \frac{1}{3k+2} \right\}.$$

By Lemma 3.1, we obtain in time

$$O\left(|V| + |\mathcal{E}| + \sum_{j=2}^{k} s_{2,j}(\mathcal{G}) \right) \tag{4.2}$$

an induced subhypergraph $\mathcal{G}_0 = (V_0, \mathcal{E}_0)$ of $\mathcal{G}$ such that, possibly after omitting some more vertices, we have

$$\begin{aligned} |V_0| &= p/3 \cdot |V| \text{ , and} \\ |\mathcal{E}_0| &\leq 3 \cdot p^{k+1} \cdot |\mathcal{E}| \text{ , and} \\ s_{2,j}(\mathcal{G}_0) &\leq 3 \cdot (k-1) \cdot p^{2k+2-j} \cdot s_{2,j}(\mathcal{G}) \qquad \text{for } j = 2, 3, \ldots, k. \end{aligned}$$

With (4.1) for $t^\epsilon \geq 2$, i.e., $t \geq t_0(\epsilon)$, we have for $j = 2, 3, \ldots, k$ that

$$p^{2k+2-j} \cdot n \cdot t^{2k+1-j-\gamma} \geq 2 \cdot p^{2k+2-j-1} \cdot n \cdot t^{2k+1-j-1-\gamma}.$$

Hence, since $\epsilon \leq \gamma/2k$ and $t \geq t_0(k, \gamma)$, i.e., $t^\gamma \geq (36 \cdot c \cdot (k-1))^{2k}$, we have

$$\begin{aligned} \sum_{j=2}^{k} s_{2,j}(\mathcal{G}_0) &\leq \sum_{j=2}^{k} 3 \cdot (k-1) \cdot p^{2k+2-j} \cdot s_{2,j}(\mathcal{G}) \\ &\leq 6 \cdot (k-1) \cdot c \cdot p^{2k} \cdot n \cdot t^{2k-1-\gamma} \\ &\leq 6 \cdot (k-1) \cdot c \cdot n \cdot t^{-1-\gamma+2k\epsilon} \\ &\leq 36 \cdot (k-1) \cdot c \cdot t^{-\frac{\gamma}{2k}} \cdot (p \cdot n/6) \\ &\leq p \cdot n/6; \end{aligned}$$

thus,

$$|V_0| \geq 2 \cdot \sum_{j=2}^{k} s_{2,j}(\mathcal{G}_0) \ . \tag{4.3}$$

The sets of $(2,j)$-cycles in $\mathcal{G}_0$ can be constructed in time $O(p \cdot n + |\mathcal{E}_0| + \sum_{j=2}^{k} s_{2,j}(\mathcal{G}_0))$. By losing at most half of the vertices, cf. (4.3), we delete in $\mathcal{G}_0$ in time

$$\begin{aligned} O\left(p \cdot n + p^{k+1} \cdot |\mathcal{E}| + \sum_{j=2}^{k} s_{2,j}(\mathcal{G}) \cdot p^{2k+2-j} \right) &= O\left(\frac{n}{t^{1-\epsilon}} + \frac{n}{t^{1-(k+1)\epsilon}} + \frac{n}{t^{1+\gamma-2k\epsilon}} \right) \\ &= o(n) \end{aligned}$$

for $\epsilon \leq 1/(k+2)$ and $\epsilon \leq \gamma/(2k)$ one vertex from each 2-cycle. By deleting possibly more vertices, we obtain an induced subhypergraph $\mathcal{G}_1 = (V_1, \mathcal{E}_1)$ of $\mathcal{G}_0$ with

$$|V_1| = p \cdot n/6 \quad \text{and} \quad |\mathcal{E}_1| \leq 3 \cdot p^{k+1} \cdot |\mathcal{E}|$$

such that $\mathcal{G}_1$ no longer contains any 2-cycles and we have

$$t(\mathcal{G}_1)^k \leq \frac{(k+1) \cdot |\mathcal{E}_1|}{p \cdot n/6} = 18 \cdot (p \cdot t)^k \ . \tag{4.4}$$

Next we apply Lemma 3.3 to the hypergraph $\mathcal{G}_1$ with

$$p_1 = \left(\frac{1}{p \cdot t}\right)^{1-\epsilon_1} = t^{-\epsilon(1-\epsilon_1)},$$

where $\epsilon_1 = (k-1)/(4k)$, and we obtain a subhypergraph $\mathcal{G}_2 = (V_2, \mathcal{E}_2)$ of $\mathcal{G}_1$, which, after possibly deleting more vertices, satisfies

$$\begin{aligned} &|V_2| = p_1 p \cdot n/36, \\ &|\mathcal{E}_2| \leq 3 \cdot p_1^{k+1} \cdot |\mathcal{E}_1| \leq 9 \cdot (p_1 p)^{k+1} \cdot |\mathcal{E}| \end{aligned}$$

and, by (3.2), (4.4), for $i = 3, 4$ also fulfills

$$\mu_i(\mathcal{G}_2) \leq 6 \cdot p_1^{ik} \cdot c_i(k) \cdot \frac{p \cdot n}{6} \cdot t(\mathcal{G}_1)^{(i-1)k} \leq c_i(k) \cdot p_1^{ik} \cdot p \cdot n \cdot (18 \cdot p^k \cdot t^k)^{i-1}.$$

This can be done in time $O(p \cdot n + p \cdot n \cdot (p \cdot t)^{3k}) = O(n \cdot t^{-1+\epsilon(3k+1)}) = o(n)$. We claim that

$$|V_2| \geq 4 \cdot (\mu_3(\mathcal{G}_2) + \mu_4(\mathcal{G}_2)). \tag{4.5}$$

Namely, by our choice of p and p_1, i.e., $p = t^{-1+\epsilon}$ and $p_1 = t^{-\epsilon(1-\epsilon_1)}$, we have

$$\begin{aligned} &\frac{p_1 p \cdot n}{36} \geq 8 \cdot c_i(k) \cdot p_1^{ik} \cdot pn \cdot (18 \cdot p^k \cdot t^k)^{i-1} \\ \Longleftrightarrow\ &1 \geq 288 \cdot c_i(k) \cdot p_1^{ik-1} \cdot (18 \cdot p^k \cdot t^k)^{i-1} \\ \Longleftrightarrow\ &1 \geq 288 \cdot 18^{i-1} \cdot c_i(k) \cdot t^{-\epsilon(k-1)+\epsilon\epsilon_1(ik-1)}. \end{aligned}$$

Thus, for $\epsilon_1 < (k-1)/(4k-1)$ and t large enough, (4.5) holds and $\mathcal{G}_2$ contains at least four times as many vertices as 3- and 4-cycles. Moreover, the average degree of $\mathcal{G}_2$ satisfies $t(\mathcal{G}_2)^k = O((p_1 p \cdot t)^k)$. We omit in $\mathcal{G}_2$ all vertices of degree bigger than $2 \cdot (k+1) \cdot t(\mathcal{G}_2)^k$; hence losing at most $p_1 p \cdot n/72$ vertices, and then we determine in the resulting induced subhypergraph $\mathcal{G}_2'$ of $\mathcal{G}_2$ the sets of 3- and 4-cycles in time

$$O(p_1 p \cdot n + p_1 p \cdot n \cdot t(\mathcal{G}_2)^{3k}) = O(p_1 p \cdot n \cdot (p_1 p \cdot t)^{3k}) = O(n \cdot t^{-1+\epsilon\epsilon_1(3k+1)}) = o(n)$$

for $\epsilon\epsilon_1 < 1/(3k+1)$. By deleting in time $o(n)$ one vertex from each 3- or 4-cycle from $\mathcal{G}_2'$, we obtain a subhypergraph $\mathcal{G}_3 = (V_3, \mathcal{E}_3)$ of $\mathcal{G}_2$, which does not contain any 2-, 3-, or 4-cycles, i.e., $\mathcal{G}_3$ is uncrowded and satisfies w.l.o.g.

$$|V_3| = |V_2|/2 = p_1 p \cdot n/144 \quad \text{and} \quad |\mathcal{E}_3| \leq 9 \cdot (p_1 p)^{k+1} \cdot |\mathcal{E}|;$$

thus,

$$t(\mathcal{G}_3)^k \leq \frac{(k+1) \cdot 9 \cdot (p_1 p)^{k+1} \cdot |\mathcal{E}|}{p_1 p \cdot n/144} = 1296 \cdot (p_1 p)^k \cdot t^k.$$

To the hypergraph $\mathcal{G}_3$ we apply Corollary 2.5, and for fixed $\delta > 0$ we obtain in time

$$O\left(n \cdot t(\mathcal{G}_3)^k + \frac{(p_1 p \cdot n)^3}{(p_1 p \cdot t)^{3-\delta}}\right) = O\left(\frac{n^3}{t^{3-\delta}}\right)$$

an independent set in $\mathcal{G}_3$, and hence in $\mathcal{G}$, of size at least

$$\Omega\left(\frac{p_1 p \cdot n}{p_1 p \cdot t} \cdot (\ln(p_1 p \cdot t))^{1/k}\right) = \Omega\left(\frac{n}{t} \cdot (\ln t)^{1/k}\right)$$

as desired. The overall running time is given by (4.2). $\Box$

5. Applications. In this section, we give applications of our results to some combinatorial problems. Our arguments are guided by the probabilistic existence proofs. However, for computational reasons additional ideas are required.

DEFINITION 5.1. *Let X be a set. A triple system $\mathcal{F} \subseteq [X]^3$ is called a* partial Steiner triple system *if for any two vertices $x_1, x_2 \in X$ there is at most one set $F \in \mathcal{F}$ with $\{x_1, x_2\} \subset F$.*

Hence, every partial Steiner triple system $\mathcal{F}$ is nothing else than a 3-uniform hypergraph which contains no 2-cycles, i.e., $|\mathcal{F}| \leq 1/3 \cdot \binom{n}{2}$.

The next result is essentially a reformulation of Corollary 2.8.

COROLLARY 5.2. *Let X be an n-element set, and let $\mathcal{F} \subset [X]^3$ be a partial Steiner triple system.*

Then, one can find in time $O(n^2)$ an independent set $I \subseteq X$ with

$$|I| \geq c \cdot \sqrt{n \cdot \ln n}. \tag{5.1}$$

We remark that the existence of an independence set of size as in (5.1) was shown first by Phelps and Rödl [40].

Proof. Since $t^2 = O(n)$, by Corollary 2.8 we find such an independent set of size at least $\Omega(\sqrt{n \cdot \ln n})$ in time $O(n^2)$. $\Box$

Next we consider a generalization of partial Steiner triple systems.

DEFINITION 5.3. *Let h, k be positive integers with $h \leq k$. Let X be an n-element set. A family $\mathcal{F} \subseteq [X]^{k+1}$ of $(k+1)$-element subsets is called* $(n, k+1, h)$-Steiner system *if for any two distinct sets $F_1, F_2 \in \mathcal{F}$, it holds that $|F_1 \cap F_2| < h$.*

In an $(n, k+1, h)$-Steiner system $\mathcal{F}$ on X, each h-element subset of X is contained in at most one set $F \in \mathcal{F}$; hence, $|\mathcal{F}| \leq \binom{n}{h}/\binom{k+1}{h}$. Note that an $(n, 3, 2)$-Steiner system is a partial Steiner triple system. In every $(n, k+1, 1)$-Steiner system, $\mathcal{F}$ distinct sets $F, F' \in \mathcal{F}$ are disjoint; hence, $|\mathcal{F}| = O(n)$ and $\alpha(\mathcal{F}) \geq \frac{k}{k+1} \cdot n$, and such an independent set can be found easily in time $O(n)$. For values $h \geq 2$, we have the following result.

THEOREM 5.4. *Let X be an n-element set, and let $\mathcal{F} \subset [X]^{k+1}$ be an $(n, k+1, h)$-Steiner system where $h \geq 2$. Then, for every $\delta > 0$, one can find in time $O(n^h + n^{3-3\cdot(h-1)/k+\delta} + n^{2h-3-(h-1)/k+\delta})$ an independent set $I \subseteq X$ with*

$$|I| \geq c \cdot n^{\frac{k-h+1}{k}} \cdot (\ln n)^{\frac{1}{k}}\ . \tag{5.2}$$

The existence of an independent set of size at least as given in (5.2) was proved by Rödl and Siňajová [44]. By using the local lemma of Lovász (cf. [5]), they also showed that there exists an $(n, k+1, h)$-Steiner system $\mathcal{F}$ with independence number bounded from above by $C \cdot n^{(k-h+1)/k} \cdot (\ln n)^{1/k}$ for some constant $C > 0$. Hence in general, for $|\mathcal{F}| = \Theta(n^h)$ one cannot expect, up to constant factors, any better bound than (5.2).

Concerning the running times in Theorem 5.4, we have $O(n^2)$ for $h = k = 2$ and $O(n^{3-3/k+\delta})$ for $h = 2$ and $k \geq 3$. For $h \geq 3$ we have the time bound $O(n^{2h-3-(h-1)/k+\delta})$.

Proof. Let $\mathcal{F}$ be an $(n, k+1, h)$-Steiner system on X. The corresponding hypergraph $(X, \mathcal{F})$ is $(k+1)$-uniform with $|\mathcal{F}| \leq \binom{n}{h}/\binom{k+1}{h}$ edges and has average degree

$$t(\mathcal{F})^k \leq t^k = \frac{(k+1) \cdot \binom{n}{h}}{\binom{k+1}{h} \cdot n} \leq c_1 \cdot n^{h-1}.$$

First, we consider the $(2, j)$-cycles in $\mathcal{G} = (X, \mathcal{F})$. For each set $F \in \mathcal{F}$, we take a j-element subset $S \subset F$ and try to extend it to a set $F' \in \mathcal{F}$. This can be done in at most $O(n^{h-j})$ ways. Thus,

$$s_{2,j}(\mathcal{G}) \leq c_j \cdot |\mathcal{F}| \cdot n^{h-j} \leq c_{2,j} \cdot n^{2h-j}$$

for $j = 2, 3, \ldots, h-1$. Moreover, constructing the set of $(2, j)$-cycles can be done in time

$$O\left(|\mathcal{F}| \cdot \binom{|V|}{h-j}\right).$$

Also for every subset $X' \subseteq X$, the induced subsystem $\mathcal{G}' = (X', \mathcal{F}')$ with $\mathcal{F}' = \mathcal{F} \cap [X']^{k+1}$ satisfies

$$s_{2,j}(\mathcal{G}') \leq c'_{2,j} \cdot |\mathcal{F}'| \cdot \binom{|X'|}{h-j}$$

for $j = 2, 3, \ldots, h-1$, and the set of $(2, j)$-cycles in $\mathcal{G}'$ can be determined in time $O(|\mathcal{F}'| \cdot |X'|^{h-j})$.

Given $\delta > 0$, by Lemma 3.4 for $p = n^{-1/k+\epsilon}$ with $0 < \epsilon \leq \min\{1/k, \delta/(k+h-1)\}$, we select in time $O(n^h)$ an induced subsystem $(X_0, \mathcal{F}_0)$ of $(X, \mathcal{F})$ which satisfies, after possibly omitting more vertices,

$$|X_0| = p/2 \cdot |X| \text{ and } |\mathcal{F}_0| \leq 2 \cdot p^{k+1} \cdot |\mathcal{F}|.$$

Then

$$t(\mathcal{F}_0)^k \leq t_0^k = 4 \cdot (p \cdot t)^k .$$

For sequences a_n, b_n, $n = 1, 2, \ldots$, let $a_n \ll b_n$ if $a_n/b_n \to 0$ with $n \to \infty$. To apply Corollary 2.7, we want to have for some constant $\gamma > 0$ that

$$p^{k+1} \cdot |\mathcal{F}| \cdot \binom{p \cdot n}{h-j} \ll p \cdot n \cdot (t_0)^{2k+1-j-\gamma}$$
$$\iff p^{-(k-h+1)+\gamma} \cdot n^{-(j-1)\cdot\frac{k-h+1}{k}+\gamma\cdot\frac{h-1}{k}} \ll 1$$
$$\iff n^{-(j-2)\cdot\frac{k-h+1}{k}-\epsilon\cdot(k-h+1)+\gamma\cdot\frac{h-2+\epsilon k}{k}} \ll 1,$$

and the last inequality holds since $j \geq 2$ for $\gamma < (\epsilon \cdot (k-h+1))/((h-2)/k+\epsilon)$. By Corollary 2.7 we obtain an independent set in $\mathcal{F}_0$; hence in $\mathcal{F}$, of size at least

$$\Omega\left(\frac{p \cdot n}{t_0} \cdot (\ln t_0)^{\frac{1}{k}}\right) = \Omega\left(\frac{p \cdot n}{p \cdot t} \cdot (\ln(p \cdot t))^{\frac{1}{k}}\right) = \Omega\left(n^{\frac{k-h+1}{k}} \cdot (\ln n)^{\frac{1}{k}}\right).$$

The time for doing this is for any $\delta, \delta^* > 0$ and $\delta^* \cdot \frac{h-1}{k} < \delta$,

$$\begin{aligned}
&O\left(p \cdot n + p^{k+1} \cdot n^h + \sum_{j=2}^{h-1} p^{k+1} \cdot n^h \cdot (p \cdot n)^{h-j} + \frac{(p \cdot n)^3}{(t_0)^{3-\delta^*}}\right) \\
&= O\left(p^{k+1} \cdot n^h \cdot (p \cdot n)^{h-2} + n^{3-(3-\delta^*)\cdot\frac{h-1}{k}}\right) \\
&= O\left(n^{2h-3-\frac{h-1}{k}+\epsilon(k+h-1)} + n^{3-3(h-1)/k+\delta}\right) \\
&= O\left(n^{2h-3-\frac{h-1}{k}+\delta} + n^{3-3(h-1)/k+\delta}\right).
\end{aligned}$$

Thus, the total running time is $O(n^h + n^{3-3(h-1)/k+\delta} + n^{2h-3-(h-1)/k+\delta})$ for each given $\delta > 0$. $\square$

The following problem was considered for the first time by Erdös and Guy [20]: Determine the maximum cardinality of a subset X of the $n \times n$-grid such that all mutual Euclidean distances between distinct points of X are distinct. By a Greedy-type argument it was shown in [20] that for every $\epsilon > 0$, such a set X with $|X| \geq c_1 \cdot n^{2/3-\epsilon}$ exists. By a probabilistic argument, this lower bound was improved by Thiele [50] to $|X| \geq c_2 \cdot n^{2/3}/(\ln n)^{1/3}$. Subsequently, in [37] the existence of such a set X with $|X| \geq c_3 \cdot n^{2/3}$ was shown. The problem of how to achieve this nonconstructive lower bound remained open. Here we will give such an algorithm. Such problems are related to problems arising from measuring distances using sonar signals, cf. [19], [23], and [24].

THEOREM 5.5. *One can determine in time $O(n^6 \cdot \ln n)$ a subset X of the $n \times n$-grid such that the distances between distinct points of X are mutually distinct and*

$$|X| \geq c \cdot n^{2/3}. \tag{5.3}$$

We remark that by results from number theory, currently one can show only the upper bound $|X| \leq c \cdot n/(\ln n)^{1/4}$, cf. [20].

Proof. Let $G_n = \{1, 2, \ldots, n\} \times \{1, 2, \ldots, n\}$ denote the vertex set of the $n \times n$-grid. We form a (nonuniform) hypergraph $\mathcal{G} = (V, \mathcal{E}_3 \cup \mathcal{E}_4)$ on $V = G_n$ with $\mathcal{E}_3 \subseteq [V]^3$ and $\mathcal{E}_4 \subseteq [V]^4$ as follows. Let $d(x, y)$ denote the Euclidean distance between x and y, i.e., $d(x, y) = \sqrt{(x_1 - x_2)^2 + (y_1 - y_2)^2}$ for $x = (x_1, x_2)$ and $y = (y_1, y_2)$. For pairwise distinct vertices $x, y, z \in V$ we form a *three-element edge* $E = \{x, y, z\} \in \mathcal{E}_3$ iff $d(x, y) = d(x, z)$. Moreover, for pairwise distinct vertices $x^1, x^2, x^3, x^4 \in V$ we form a *four-element edge* $E = \{x^1, x^2, x^3, x^4\} \in \mathcal{E}_4$ iff $d(x^1, x^2) = d(x^3, x^4)$.

Our strategy will be to find a large independent set $I \subseteq V$ in the hypergraph $\mathcal{G}$. Clearly, an independent set $I \subseteq V$ is (in the grid) a set with mutual distinct distances. We will find this independent set $I \subseteq V$ again by picking vertices at random and using derandomization. The usual process of choosing a subhypergraph and controlling the number of $(2, 2)$-cycles right from the beginning would result in a running time of $O\left(n^{8+\frac{c}{\ln \ln n}}\right)$. Therefore, some additional ideas are involved here to get the time bound $O(n^6 \cdot \ln n)$. To achieve this, we will control the $(2, 2)$-cycles at a later stage. We remark that $|\mathcal{E}_3 \cup \mathcal{E}_4| = O(n^6 \cdot \ln n)$, as will be seen later. Thus, our algorithm will be linear in the size of $\mathcal{G}$.

In a preprocessing, we compute and store the sets S_d of all solutions of the diophantine equation $x^2 + y^2 = d$ for $d = 1, 2, \ldots, 2(n-1)^2$ with integers x and y. For a fixed value of d this can be done in time $O(\sqrt{d})$ by simply inserting

$x = -\lfloor\sqrt{d}\rfloor, -\lfloor\sqrt{d}\rfloor + 1, \ldots, \lfloor\sqrt{d}\rfloor$ in $x^2 + y^2 = d$ and solving this for y. This preprocessing can be done in time

$$O\left(\sum_{d=1}^{2(n-1)^2} \sqrt{d}\right) = O\left(n^3\right).$$

For positive integers d, let $r_2(d)$ denote the number of solutions of the equation $x^2 + y^2 = d$ within the integers. By a result of Wigert (cf. [27]), we have

$$\max\{r_2(d) \mid d = 1, 2, \ldots, n\} \leq n^{\frac{c'}{\ln \ln n}} \tag{5.4}$$

for some constant $c' > 0$; hence,

$$|S_d| = r_2(d) \leq n^{\frac{c'}{\ln \ln n}}$$

for $d = 1, 2, \ldots, 2(n-1)^2$. We will use the following identity by Ramanujan [43]:

$$\sum_{d=1}^{m} (r_2(d))^2 = \Theta(m \cdot \ln m). \tag{5.5}$$

Given the $n \times n$ grid, we first construct the sets $\mathcal{E}_3$ and $\mathcal{E}_4$ of edges. For $d = 1, 2, \ldots, 2(n-1)^2$ and for each vertex $x_0 \in V$, there are at most $|S_d|$ vertices $x^1, x^2, \ldots, x^l \in V$ with $d(x_0, x^j)^2 = d$, $j = 1, 2, \ldots, l$, and all these vertices can easily be determined in time $O(r_2(d))$. Then, $\{x_0, x^i, x^j\}$, $1 \leq i < j \leq l$ yields a 3-element edge in $\mathcal{E}_3$. Hence, using (5.5) the set $\mathcal{E}_3$ of 3-element edges can be constructed in time

$$O\left(n^2 \cdot \sum_{d=1}^{2(n-1)^2} \binom{r_2(d)}{2}\right) = O\left(n^2 \cdot \sum_{d=1}^{2(n-1)^2} (r_2(d))^2\right) = O\left(n^4 \cdot \ln n\right),$$

and we also infer that

$$|\mathcal{E}_3| \leq c_3 \cdot n^4 \cdot \ln n. \tag{5.6}$$

In a similar fashion we construct the set $\mathcal{E}_4$ of 4-element edges. Namely, we pick two distinct vertices $x, y \in V$ and consider the sets $A = \{z \in V \mid d(x,z)^2 = d\}$ and $B = \{w \in V \mid d(y,w)^2 = d\}$ for $d = 1, 2, \ldots, 2(n-1)^2$. Then, $\{x, y, z, w\}$ with $z \in A$, $w \in B$, and $z \neq w$ yields a 4-element edge $E \in \mathcal{E}_4$. Using (5.5), this can be done in time

$$O\left(n^2 \cdot n^2 \cdot \sum_{d=1}^{2(n-1)^2} (r_2(d))^2\right) = O\left(n^6 \cdot \ln n\right),$$

and also

$$|\mathcal{E}_4| \leq c_4 \cdot n^6 \cdot \ln n. \tag{5.7}$$

We want to find again a small, but large enough, uncrowded induced subhypergraph in $\mathcal{G}$. The running time will depend essentially on the number of $(2,j)$-cycles, which we have to handle and which are determined by pairs of distinct edges from $\mathcal{E}_4$. Consider only the 4-element edges in $\mathcal{G}$, i.e., $\mathcal{G}|\mathcal{E}_4 = (V, \mathcal{E}_4)$. We show how to construct the sets $C_{2,2}$ and $C_{2,3}$ of $(2,2)$- and $(2,3)$-cycles in $\mathcal{G}|\mathcal{E}_4$, $j = 2, 3$. Fix an integer d with $1 \le d \le 2(n-1)^2$. For an edge $E = \{x^1, x^2, x^3, x^4\} \in \mathcal{E}_4$ with $d(x^1, x^2) = d(x^3, x^4)$ and distinct vertices $x^i, x^j \in E$ and $y, z \in V \setminus E$ with $d(x^i, x^j) = d(y, z)$ or with $d(x^i, y) = d(x^j, z)$, a pair $\{\{x^1, x^2, x^3, x^4\}, \{x^i, x^j, y, z\}\}$ yields a $(2,2)$-cycle. Hence, using (5.4) and (5.7) the time to construct the set $C_{2,2}$ of $(2,2)$-cycles is given by

$$\begin{aligned} (5.8) \qquad & O\left(|\mathcal{E}_4| \cdot n^2 \cdot \max\{r_2(d) \mid 1 \le d \le 2(n-1)^2\}\right) \\ & = O\left(n^{8+\frac{c_1}{\ln \ln n}} \cdot \ln n\right) = O\left(n^{8+\frac{c}{\ln \ln n}}\right) \end{aligned}$$

for some constant $c > 0$. Thus, for some constant $c_{2,2} > 0$ we have

$$s_{2,2}(\mathcal{G}|\mathcal{E}_4) \le c_{2,2} \cdot n^{8+\frac{c}{\ln \ln n}}.$$

To construct the set $C_{2,3}$ of $(2,3)$-cycles in $\mathcal{G}|\mathcal{E}_4$, we pick an edge $E \in \mathcal{E}_4$ and a 3-element subset $S \subset E$, which determines a constant number of distances. Then S can be extended in at most $O(\max\{r_2(d) \mid 1 \le d \le 2(n-1)^2\})$ ways to an edge $E' \in \mathcal{E}_4$ with $S \subset E'$. Thus, we can construct the set $C_{2,3}$ in $\mathcal{G}|\mathcal{E}_4$ in time

$$(5.9) \qquad O(|\mathcal{E}_4| \cdot \max\{r_2(d) \mid 1 \le d \le 2(n-1)^2\}),$$

and also for some constant $c_{2,3} > 0$, we have

$$s_{2,3}(\mathcal{G}|\mathcal{E}_4) \le c'_{2,3} \cdot n^6 \cdot \ln n \cdot n^{\frac{c_1}{\ln \ln}} \le c_{2,3} \cdot n^{6+\frac{c}{\ln \ln n}}.$$

However, we do not construct the sets $C_{2,j}$ of $(2,j)$-cycles right from the beginning. We first determine a small, but big enough, induced subhypergraph, where we only control the number of vertices and edges, and in this we will construct the sets of $(2,j)$-cycles, $j = 2, 3$.

From the considerations leading to (5.8) we infer that every induced subhypergraph $\mathcal{G}' = (V', \mathcal{E}')$ of the hypergraph $\mathcal{G}|\mathcal{E}_4 = (V, \mathcal{E}_4)$, consisting only of the 4-element edges, satisfies

$$\begin{aligned} (5.10) \qquad s_{2,2}(\mathcal{G}') & = O\left(|\mathcal{E}^{'}| \cdot |V^{'}| \cdot \max\{r_2(d) \mid 1 \le d \le 2(n-1)^2\}\right) \\ & = O\left(|\mathcal{E}^{'}| \cdot |V^{'}| \cdot n^{\frac{c}{\ln \ln n}}\right). \end{aligned}$$

Similarly, with the consideration before (5.9) we infer that

$$(5.11) \qquad s_{2,3}(\mathcal{G}') = O\left(|\mathcal{E}'| \cdot n^{\frac{c}{\ln \ln n}}\right).$$

Also, the set of $(2,2)$-cycles in $\mathcal{G}'$ can be determined in time $O(|\mathcal{E}^{'}| \cdot |V^{'}| \cdot n^{\frac{c}{\ln \ln n}})$, and the set of $(2,3)$-cycles can be constructed in time $O(|\mathcal{E}'| \cdot n^{\frac{c}{\ln \ln n}})$.

Lemma 5.6. *Let p be a real number, $0 \le p \le 1$. Then, one can construct in time $O(|V| + |\mathcal{E}_3| + |\mathcal{E}_4|)$ a subhypergraph $\mathcal{G}_0 = (V_0, \mathcal{E}_3^0 \cup \mathcal{E}_4^0)$ of $\mathcal{G} = (V, \mathcal{E}_3 \cup \mathcal{E}_4)$ with $\mathcal{E}_i^0 \subseteq \mathcal{E}_i$, $i = 3, 4$, such that $|V_0| = p/3 \cdot |V|$ and $|\mathcal{E}_3^0| \le 3 \cdot p^3 \cdot |\mathcal{E}_3|$ and $|\mathcal{E}_4^0| \le 3 \cdot p^4 \cdot |\mathcal{E}_4|$.*

Proof. The proof follows earlier arguments; cf. Lemma 3.4. For $V = \{v_1, v_2, \ldots, v_m\}$, we use the potential

$$V(p_1, p_2, \ldots, p_m) = 3^{pm/3} \cdot \prod_{i=1}^{m} \left(1 - \frac{2}{3} \cdot p_i\right) + \frac{\sum_{E \in \mathcal{E}_3} \prod_{v_i \in E} p_i}{3 \cdot p^3 \cdot |\mathcal{E}_3|} + \frac{\sum_{E \in \mathcal{E}_4} \prod_{v_i \in E} p_i}{3 \cdot p^4 \cdot |\mathcal{E}_4|}.$$

We obtain in time $O(|V| + |\mathcal{E}_3| + |\mathcal{E}_4|)$ a subhypergraph $\mathcal{G}_0 = (V_0, \mathcal{E}_3^0 \cup \mathcal{E}_4^0)$ of $\mathcal{G} = (V, \mathcal{E}_3 \cup \mathcal{E}_4)$ with $|V_0| \geq p/3 \cdot |V|$ and $|\mathcal{E}_3^0| \leq 3 \cdot p^3 \cdot |\mathcal{E}_3|$ and $|\mathcal{E}_4^0| \leq 3 \cdot p^4 \cdot |\mathcal{E}_4|$. By possibly omitting more vertices we get $|V_0| = p/3 \cdot |V|$. □

In time $O(|V| + |\mathcal{E}_3| + |\mathcal{E}_4|) = O(n^6 \cdot \ln n)$ we apply Lemma 5.6 to the hypergraph $\mathcal{G}$ with

$$p = n^{-2/3+\epsilon}, \tag{5.12}$$

where $0 < \epsilon < 2/3$, and we obtain a subhypergraph $\mathcal{G}_0 = (V_0, \mathcal{E}_3^0 \cup \mathcal{E}_4^0)$ of $\mathcal{G}$ with

$$|V_0| = p \cdot n^2/3, \quad |\mathcal{E}_3^0| \leq 3 \cdot p^3 \cdot |\mathcal{E}_3|, \quad |\mathcal{E}_4^0| \leq 3 \cdot p^4 \cdot |\mathcal{E}_4|. \tag{5.13}$$

We did not control the number $s_{2,j}(\mathcal{G}_0|\mathcal{E}_4^0)$ of $(2,j)$-cycles, $j = 2, 3$, in $\mathcal{G}_0|\mathcal{E}_4^0$. However, by (5.11) we know for $\epsilon < 4/15$ that

$$\begin{aligned} s_{2,2}(\mathcal{G}_0|\mathcal{E}_4^0) &\leq c'_{2,2} \cdot |\mathcal{E}_4^0| \cdot |V_0| \cdot n^{\frac{c}{\ln \ln n}} \\ &\leq c^*_{2,2} \cdot p^4 \cdot n^6 \cdot \ln n \cdot p \cdot n^2 \cdot n^{\frac{c}{\ln \ln n}} \\ &= c^*_{2,2} \cdot p^5 \cdot n^{8+\frac{c}{\ln \ln n}} \cdot \ln n \\ &\leq c^*_{2,2} \cdot n^{14/3+5\epsilon+\frac{c}{\ln \ln n}} \cdot \ln n \\ &= o(n^6 \cdot \ln n). \end{aligned} \tag{5.14}$$

Moreover, for $\epsilon < 2/3$ we infer from (5.11) that

$$\begin{aligned} s_{2,3}(\mathcal{G}_0, \mathcal{E}_4^0) &\leq c'_{2,3} \cdot |\mathcal{E}_4^0| \cdot n^{\frac{c}{\ln \ln n}} \\ &\leq c^*_{2,3} \cdot p^4 \cdot n^{6+\frac{c}{\ln \ln n}} \cdot \ln n \\ &\leq c^*_{2,3} \cdot n^{10/3+4\epsilon+\frac{c}{\ln \ln n}} \cdot \ln n \\ &= o(n^6 \cdot \ln n). \end{aligned} \tag{5.15}$$

The value p is chosen in (5.12) such that the assumptions of Corollary 2.7 are fulfilled for the hypergraph $\mathcal{G}_0|\mathcal{E}_4^0$, i.e., we choose for p that minimal value for which the following two conditions hold for some constants $c, \gamma > 0$:

$$\begin{aligned} s_{2,2}(\mathcal{G}_0|\mathcal{E}_4^0) &\leq c \cdot p \cdot n^2 \cdot t(\mathcal{G}_0|\mathcal{E}_4^0)^{5-\gamma}, \\ s_{2,3}(\mathcal{G}_0|\mathcal{E}_4^0) &\leq c \cdot p \cdot n^2 \cdot t(\mathcal{G}_0|\mathcal{E}_4^0)^{4-\gamma}. \end{aligned}$$

We proceed similarly to the proof of Theorem 2.6. Namely, we use the following lemma, whose proof is along the lines of former statements.

LEMMA 5.7. *For every p_1 with $0 \leq p_1 \leq 1$, one can construct in time*

$$O\left(|V_0| + |\mathcal{E}_3^0| + |\mathcal{E}_4^0| + s_{2,3}(\mathcal{G}|\mathcal{E}_4^0) + s_{2,2}(\mathcal{G}_0|\mathcal{E}_4^0)\right)$$

a subhypergraph $\mathcal{G}_1 = (V_1, \mathcal{E}_3^1 \cup \mathcal{E}_4^1)$ of $\mathcal{G}_0 = (V_0, \mathcal{E}_3^0 \cup \mathcal{E}_4^0)$ with $\mathcal{E}_i^1 \subseteq \mathcal{E}_i^0$, $i = 3, 4$, such that

$$|V_1| = p_1/5 \cdot |V_0|\,, \quad |\mathcal{E}_3^1| \leq 5 \cdot p_1^3 \cdot |\mathcal{E}_3^0|\,, \quad |\mathcal{E}_4^1| \leq 5 \cdot p_1^4 \cdot |\mathcal{E}_4^0|\,, \quad s_{2,3}(\mathcal{G}_1|\mathcal{E}_4^1) \leq 5 \cdot p_1^5 \cdot s_{2,3}\left(\mathcal{G}_0|\mathcal{E}_4^0\right),$$

and $s_{2,2}(\mathcal{G}_1|\mathcal{E}_4^1) \leq 5 \cdot p_1^6 \cdot s_{2,2}(\mathcal{G}_0|\mathcal{E}_4^1)$.

Before applying Lemma 5.7, we estimate the corresponding running time, namely, using (5.6), (5.7), (5.12), (5.13), (5.14), and (5.15) we obtain

$$O\left(|V_0| + |\mathcal{E}_3^0| + |\mathcal{E}_4^0| + s_{2,3}(\mathcal{G}|\mathcal{E}_4^0) + s_{2,2}(\mathcal{G}_0|\mathcal{E}_4^0)\right) = o(n^6 \cdot \ln n).$$

Let

$$p_1 = \left(\frac{(\ln n)^{1/3}}{p \cdot t}\right)^{1-\epsilon_1} = \left(\frac{1}{n^{2/3+\epsilon}}\right)^{1-\epsilon_1},$$

where

$$\epsilon_1 = \frac{\epsilon}{5\epsilon + 11/3} . \tag{5.16}$$

By Lemma 5.7 we obtain in time $o(n^6 \cdot \ln n)$ a subhypergraph $\mathcal{G}_1 = (V_1, \mathcal{E}_3^1 \cup \mathcal{E}_4^1)$ of $\mathcal{G}_0$ with $\mathcal{E}_i^1 \subseteq \mathcal{E}_i^0$, $i = 3, 4$, where

$$|V_1| = \frac{p_1}{5} \cdot |V_0| = \frac{p_1 p}{15} \cdot n^2 = \frac{1}{15} \cdot n^{2/3+2\epsilon_1/3+\epsilon\epsilon_1}$$

and

$$|\mathcal{E}_3^1| \leq 5 \cdot p_1^3 \cdot |\mathcal{E}_3^0| \leq 15 \cdot p_1^3 \cdot p^3 \cdot |\mathcal{E}_3| \leq 15 \cdot c_3 \cdot n^{2\epsilon_1+3\epsilon\epsilon_1} \cdot \ln n = o(|V_1|) .$$

For the number of $(2,3)$-cycles, we have using (5.15) that

$$\begin{aligned} s_{2,3}\left(\mathcal{G}_1|\mathcal{E}_4^1\right) &\leq 5 \cdot p_1^5 \cdot s_{2,3}\left(\mathcal{G}_0|\mathcal{E}_4^0\right) \\ &\leq 15 \cdot c_{2,3} \cdot p_1^5 \cdot n^{10/3+4\epsilon+\frac{c}{\ln\ln n}} \cdot \ln n \\ &\leq 15 \cdot c_{2,3} \cdot n^{-\epsilon+10\epsilon_1/3+5\epsilon\epsilon_1+\frac{c}{\ln\ln n}} \cdot \ln n \\ &= o(|V_1|). \end{aligned}$$

Finally, using (5.14) we obtain for the number of $(2,2)$-cycles that

$$\begin{aligned} s_{2,2}\left(\mathcal{G}_1|\mathcal{E}_4^1\right) &\leq 5 \cdot p_1^6 \cdot s_{2,2}(\mathcal{G}_0|\mathcal{E}_4^0) \\ &\leq 5 \cdot c_{2,2}^* \cdot p_1^6 \cdot n^{14/3+5\epsilon+\frac{c}{\ln\ln n}} \cdot \ln n \\ &\leq 5 \cdot c_{2,2}^* \cdot n^{2/3-\epsilon+4\epsilon_1+6\epsilon\epsilon_1+\frac{c}{\ln\ln n}} \cdot \ln n \\ &= o(|V_1|). \end{aligned}$$

Summarizing, we have $|\mathcal{E}_3^1| + s_{2,3}(\mathcal{G}_1|\mathcal{E}_4^1) + s_{2,2}(\mathcal{G}_1|\mathcal{E}_4^1) = o(|V_1|)$. We delete from $\mathcal{G}_1$ one vertex from each 3-element edge $E \in \mathcal{E}_3^1$ and from each $(2,2)$- or $(2,3)$-cycle in $\mathcal{G}_1|\mathcal{E}_4^0$, and, possibly deleting more vertices, we obtain a 4-uniform induced subhypergraph $\mathcal{G}_2 = (V_2, \mathcal{E}_4^2)$ of $\mathcal{G}_1$ with

$$|V_2| = \frac{|V_1|}{2} = \frac{p_1 p}{30} \cdot n^2$$

and

$$|\mathcal{E}_4^2| \leq 15 \cdot c_4 \cdot (p_1 p)^4 \cdot n^6 \cdot \ln n,$$

and $\mathcal{G}_2$ no longer contains any 2-cycles. By Corollary 2.8 we obtain an independent set in $\mathcal{G}_2$, and hence in $\mathcal{G}$, of size

$$\begin{aligned} \Omega\left(\frac{p_1 p \cdot n^2}{p_1 p \cdot t} \cdot (\ln(p_1 p \cdot t))^{1/3}\right) &= \Omega\left(\frac{n^2}{t} \cdot \left(\ln\left(n^{2\epsilon_1/3+\epsilon\epsilon_1} \cdot \ln n\right)\right)^{1/3}\right) \\ &= \Omega\left(\frac{n^2}{n^{4/3} \cdot (\ln n)^{1/3}} \cdot (\ln n)^{1/3}\right) \\ &= \Omega\left(n^{2/3}\right) \end{aligned}$$

as $\epsilon, \epsilon_1 > 0$ are fixed.

The time for doing this is for any given δ with $0 < \delta < 1$

$$\begin{aligned} O\left(p_1 p \cdot n^2 \cdot (p_1 p \cdot t)^3 + \frac{(p_1 p \cdot n^2)^3}{(p_1 p \cdot t)^{3-\delta}}\right) &= O\left((p_1 p)^4 \cdot n^2 \cdot t^3 + \frac{n^6}{t^{3-\delta}}\right) \\ &= O\left((p_1 p)^4 \cdot n^6 \cdot \ln n + n^{2+4\delta/3}\right) \\ &= O\left(n^{2/3+8\epsilon_1/3+4\epsilon\epsilon_1} \cdot \ln n + n^{2+4\delta/3}\right) \\ &= o\left(n^6 \cdot \ln n\right). \end{aligned}$$

Hence, we have an overall running time of $O(n^6 \cdot \log n)$. □

The next result gives a k-dimensional version of Theorem 5.5.

THEOREM 5.8. *Let $k \geq 3$ be a fixed integer. For every fixed $\delta > 0$, one can find in time $O(n^{6k-22/3+\delta})$ a subset X of the k-dimensional $n \times \cdots \times n$ grid such that the distances between distinct points of X are mutually distinct and for some constant $c = c(k, \delta) > 0$ it is*

$$|X| \geq c \cdot n^{2/3} \cdot (\ln n)^{1/3}. \tag{5.17}$$

The existence of such a set X which satisfies (5.17) was shown in [37]. We remark that here only the upper bound $|X| \leq c \cdot \sqrt{k} \cdot n$ is known, as shown by Erdös and Guy [20].

Proof. Let $V = \{1, 2, \ldots, n\}^k$ be the set of vertices of the k-dimensional grid. As in the proof of Theorem 5.5, we form a nonuniform hypergraph $\mathcal{G} = (V, \mathcal{E}_3 \cup \mathcal{E}_4)$ with $\mathcal{E}_3 \subseteq [V]^3$ and $\mathcal{E}_4 \subseteq [V]^4$ as follows. For vertices $x = (x_1, x_2, \ldots, x_k) \in V$ and $y = (y_1, y_2, \ldots, y_k) \in V$ let $d(x, y) = \sqrt{\sum_{i=1}^k (x_i - y_i)^2}$ denote the Euclidean distance between x and y. For pairwise distinct vertices $x, y, z \in V$ let $\{x, y, z\} \in \mathcal{E}_3$ iff $d(x, y) = d(x, z)$. Also, for pairwise distinct vertices $x^1, x^2, x^3, x^4 \in V$ let $\{x^1, x^2, x^3, x^4\} \in \mathcal{E}_4$ iff $d(x^1, x^2) = d(x^3, x^4)$. Again our strategy will be to find a large independent set in $\mathcal{G}$. In a preprocessing we compute and store the sets S_d^k of all solutions of the diophantine equation $x_1^2 + x_2^2 + \cdots + x_k^2 = d$ for $d = 1, 2, \ldots, k(n-1)^2$. By inserting integers $x_1, x_2, \ldots, x_{k-1}$ with $|x_i| \leq \sqrt{d}$ and solving for x_k, this can be done in time

$$O\left(\sum_{d=1}^{k(n-1)^2} (2 \cdot \sqrt{d})^{k-1}\right) = O\left(\int_1^{k \cdot n^2} x^{\frac{k-1}{2}} dx\right) = O\left(n^{k+1}\right).$$

For positive integers d, let $r_k(d)$ denote the number of solutions of $x_1^2 + x_2^2 + \cdots + x_k^2 = d$ within the integers. Rewriting this as $x_1^2 + x_2^2 = d - \sum_{i=3}^k x_i^2$, we infer with (5.4) that

$$r_k(n) \leq (2 \cdot \sqrt{n})^{k-2} \cdot \max_{1 \leq d \leq \sqrt{n}} r_2(d) = O\left(n^{\frac{k}{2} - 1 + \frac{c'}{\ln \ln n}}\right).$$

Hence, for fixed integers $k \geq 3$, we have

$$\max\{r_k(d) \mid d = 1, 2, \ldots, k(n-1)^2\} \leq n^{k-2+\frac{c}{\ln \ln n}} \tag{5.18}$$

for some constant $c > 0$, and therefore,

$$|S_d^k| = r_k(d) \leq n^{k-2+\frac{c}{\ln \ln n}}.$$

For fixed $k \geq 3$, we have by results from [37] that

$$\sum_{d=1}^{n} (r_k(d))^2 = \Theta\left(n^{k-1}\right). \tag{5.19}$$

First we construct the sets $\mathcal{E}_3$ and $\mathcal{E}_4$. For $d = 1, 2, \ldots, k(n-1)^2$ and for each vertex $x_0 \in V$, there are at most $|S_d^k|$ vertices $x^1, x^2, \ldots, x^l \in V$ with $d(x_0, x^j)^2 = d$, $j = 1, 2, \ldots, l$, and all these vertices can easily be determined by a coordinate transformation in time $O(r_k(d))$. Then, $\{x_0, x^i, x^j\}$, $1 \leq i < j \leq l$ yields a 3-element edge $E \in \mathcal{E}_3$. Using (5.19), the set $\mathcal{E}_3$ of 3-element edges can be constructed in time

$$O\left(n^k \cdot \sum_{d=1}^{k(n-1)^2} \binom{r_k(d)}{2}\right) = O\left(n^k \cdot (k \cdot n^2)^{k-1}\right) = O\left(n^{3k-2}\right)$$

and also

$$|\mathcal{E}_3| \leq c_3 \cdot n^{3k-2}.$$

In a similar fashion, we construct the set $\mathcal{E}_4$ of 4-element edges. We pick two distinct vertices $x, y \in V$ and consider the sets $A_d = \{z \in V \mid d(x,z)^2 = d\}$ and $B_d = \{w \in V \mid d(y,w)^2 = d\}$ for $d = 1, 2, \ldots, k(n-1)^2$. Then, $\{x, y, z, w\}$ with $z \in A$ and $w \in B$ yields a 4-element edge $E \in \mathcal{E}_4$ if x, y, z, w are pairwise distinct. Using (5.19), this can be done in time

$$O\left(n^k \cdot n^k \cdot \sum_{d=1}^{k(n-1)^2} (r_k(d))^2\right) = O\left(n^{4k-2}\right)$$

and also

$$|\mathcal{E}_4| \leq c_4 \cdot n^{4k-2}. \tag{5.20}$$

As in the proof of Theorem 5.5, and using (5.18), the set $C_{2,3}$ of $(2,3)$-cycles in the 4-uniform subhypergraph $\mathcal{G}|\mathcal{E}_4 = (V, \mathcal{E}_4)$ can be constructed in time

$$O(|\mathcal{E}_4| \cdot \max\{r_k(d) \mid 1 \leq d \leq k(n-1)^2\}) = O\left(n^{5k-4+\frac{c}{\ln \ln n}}\right),$$

and, for some constant $c_{2,3} > 0$, we have

$$s_{2,3}(\mathcal{G}|\mathcal{E}_4) \leq c_{2,3} \cdot n^{5k-4+\frac{c}{\ln \ln n}}.$$

This shows that for each induced subhypergraph $\mathcal{G}' = (V', \mathcal{E}_4')$ of $\mathcal{G}|\mathcal{E}_4 = (V, \mathcal{E}_4)$, the set of $(2,3)$-cycles can be constructed in time

$$O\left(|\mathcal{E}_4'| \cdot n^{k-2+\frac{c}{\ln \ln n}}\right)$$

and

$$s_{2,3}(\mathcal{G}') = O\left(|\mathcal{E}_4'| \cdot n^{k-2+\frac{c}{\ln \ln n}}\right). \tag{5.21}$$

Again, as in the proof of Theorem 5.5, using (5.18) and (5.20) the construction of the set $C_{2,2}$ of $(2,2)$-cycles in $\mathcal{G}|\mathcal{E}_4$ can be done in time

$$O\left(|\mathcal{E}_4| \cdot |V| \cdot n^{k-2+\frac{c}{\log \log n}}\right) = O\left(n^{6k-4+\frac{c}{\ln \ln n}}\right),$$

and, for some constant $c_{2,2} > 0$, we have

$$s_{2,2}(\mathcal{G}|\mathcal{E}_4) \leq c_{2,2} \cdot n^{6k-4+\frac{c}{\ln\ln n}}.$$

Moreover, for every subhypergraph $\mathcal{G}' = (V', \mathcal{E}_4^{'})$ of $\mathcal{G}|\mathcal{E}_4 = (V, \mathcal{E}_4)$, we have

$$s_{2,2}(\mathcal{G}') = O\left(|\mathcal{E}_4'| \cdot |V'| \cdot n^{k-2+\frac{c}{\ln\ln n}}\right). \tag{5.22}$$

By Lemma 5.6 with $p = n^{-2/3+\epsilon}$, where $0 < \epsilon < 2/3$, we obtain in time $O(|V| + |\mathcal{E}_3| + |\mathcal{E}_4|) = O(n^{4k-2})$ a subhypergraph $\mathcal{G}_0 = (V_0, \mathcal{E}_3^0 \cup \mathcal{E}_4^0)$ of $\mathcal{G}$ with $\mathcal{E}_3^0 \subseteq \mathcal{E}_3$ and $\mathcal{E}_4^0 \subseteq \mathcal{E}_4$ such that

$$|V_0| = p/3 \cdot |V|, \qquad |\mathcal{E}_3^0| \leq 3 \cdot p^3 \cdot |\mathcal{E}_3|, \qquad |\mathcal{E}_4^0| \leq 3 \cdot p^4 \cdot |\mathcal{E}_4|.$$

The value of p is chosen such that the assumptions of Corollary 2.7 are fulfilled for some constants $c, \gamma > 0$:

$$\begin{aligned} s_{2,2}(\mathcal{G}_0|\mathcal{E}_4^0) &\leq c \cdot p \cdot n^k \cdot (p \cdot t)^{5-\gamma}, \\ s_{2,3}(\mathcal{G}_0|\mathcal{E}_4^0) &\leq c \cdot p \cdot n^k \cdot (p \cdot t)^{4-\gamma}, \end{aligned}$$

where

$$\begin{aligned} s_{2,2}(\mathcal{G}_0|\mathcal{E}_4^0) &= O(p^4 \cdot |\mathcal{E}_4| \cdot p \cdot n^k \cdot n^{k-2+\frac{c}{\log\log n}}) \\ &= O(n^{6k-22/3+5\epsilon+\frac{c}{\log\log n}}) \end{aligned}$$

and

$$\begin{aligned} s_{2,3}(\mathcal{G}_0|\mathcal{E}_4^0) &= O(p^4 \cdot |\mathcal{E}_4| \cdot n^{k-2+\frac{c}{\log\log n}}) \\ &= O(n^{5k-20/3+4\epsilon+\frac{c}{\log\log n}}). \end{aligned}$$

Let t^3 be the average degree of $\mathcal{G}|\mathcal{E}_4$. By (5.20) we have

$$t^3 \leq \frac{4 \cdot c_4 \cdot n^{4k-2}}{n^k} \leq 4 \cdot c_4 \cdot n^{3k-2}. \tag{5.23}$$

By Lemma 5.7 with $p_1 = (p \cdot t)^{-1+\epsilon_1}$, where $\epsilon_1 = \epsilon/(5k + 5\epsilon)$, we obtain a subhypergraph $\mathcal{G}_1 = (V_1, \mathcal{E}_3^1 \cup \mathcal{E}_4^1)$ of $\mathcal{G}_0$ with $\mathcal{E}_i^1 \subseteq \mathcal{E}_i^0$ for $i = 3, 4$ such that $|V_1| = p_1/5 \cdot |V_0|$, $|\mathcal{E}_3^1| \leq 5 \cdot p_1^3 \cdot |\mathcal{E}_3^0|$, $|\mathcal{E}_4^1| \leq 5 \cdot p_1^4 \cdot |\mathcal{E}_4^0|$, $s_{2,3}(\mathcal{G}_1|\mathcal{E}_4^1) \leq 5 \cdot p_1^5 \cdot s_{2,3}(\mathcal{G}_1|\mathcal{E}_4^1)$, and $s_{2,2}(\mathcal{G}_1|\mathcal{E}_4^1) \leq 5 \cdot p_1^6 \cdot s_{2,2}(\mathcal{G}_1|\mathcal{E}_4^1)$. This can be done in time

$$\begin{aligned} &O(|V_0| + |\mathcal{E}_3^0| + |\mathcal{E}_4^0| + s_{2,3}(\mathcal{G}_0|\mathcal{E}_4^0) + s_{2,2}(\mathcal{G}_0|\mathcal{E}_4^0)) \\ &= O\left(p \cdot n^k + p^3 \cdot |\mathcal{E}_3| + p^4 \cdot |\mathcal{E}_4|\right. \\ &\quad \left. + p^4 \cdot |\mathcal{E}_4| \cdot n^{k-2+\frac{c}{\ln\ln n}} + p^4 \cdot |\mathcal{E}_4| \cdot p \cdot n^k \cdot n^{k-2+\frac{c}{\ln\ln n}}\right) \\ &= O\left(n^{k-2/3+\epsilon} + n^{3k-4+3\epsilon} + n^{6k-22/3+5\epsilon+\frac{c}{\ln\ln n}}\right) \\ &= O\left(n^{6k-22/3+5\epsilon+\frac{c}{\ln\ln n}}\right). \end{aligned} \tag{5.24}$$

Since $p_1 p = c \cdot n^{-k+2/3+\epsilon_1(k-4/3+\epsilon)}$, we have by choice of ϵ_1 that

$$|\mathcal{E}_3^1| \leq 15 \cdot (p_1 p)^3 \cdot |\mathcal{E}_3| = O(n^{3\epsilon_1(k-4/3+\epsilon)}) = o(|V_1|).$$

Also, by choice of ϵ_1 we have

$$s_{2,2}(\mathcal{G}_1|\mathcal{E}_4^1) = O(p_1^6 \cdot s_{2,2}(\mathcal{G}_0|\mathcal{E}_4^0) = O(n^{2/3-\epsilon+6\epsilon_1(k-4/3+\epsilon)+\frac{c}{\ln\ln n}}) = o(|V_1|),$$
$$s_{2,3}(\mathcal{G}_1|\mathcal{E}_4^1) = O(p_1^5 \cdot s_{2,3}(\mathcal{G}_0|\mathcal{E}_4^0) = O(n^{-\epsilon+5\epsilon_1(k-4/3+\epsilon)+\frac{c}{\ln\ln n}}) = o(|V_1|).$$

In the resulting subhypergraph $\mathcal{G}_1 = (V_1, \mathcal{E}_3^1 \cup \mathcal{E}_4^1)$, we delete in time $O(|V_1|)$ one vertex from each 3-element edge and from all $(2,2)$- and $(2,3)$-cycles in $\mathcal{G}_1|\mathcal{E}_4^1$. In losing $o(|V_1|)$ vertices, we obtain a subhypergraph $\mathcal{G}_2 = (V_2, \mathcal{E}_4^2)$, which no longer contains any 2-cycles and, possibly after deleting more vertices, satisfies

$$|V_2| = |V_1|/2 = 1/30 \cdot p_1 p \cdot n^k$$

and

$$|\mathcal{E}_4^2| \leq 15 \cdot c_4 \cdot (p_1 p)^4 \cdot n^{4k-2}.$$

We apply Corollary 2.8 to $\mathcal{G}_2$, and we obtain an independent set in $\mathcal{G}_2$; hence in $\mathcal{G}$ of size at least

$$\Omega\left(\frac{p_1 p \cdot n^k}{p_1 p \cdot t} \cdot (\ln(p_1 p \cdot t))^{1/3}\right) = \Omega\left(\frac{n^k}{n^{k-2/3}} \cdot (\ln n)^{1/3}\right) = \Omega\left(n^{2/3} \cdot (\ln n)^{1/3}\right).$$

The time for doing this is for $0 < \delta_1 < 1$ and $\delta_2 = (k - 2/3) \cdot \delta_1$ given by

$$O\left(p_1 p \cdot n^k \cdot (p_1 p \cdot t)^3 + \frac{(p_1 p \cdot n^k)^3}{(p_1 p \cdot t)^{3-\delta_1}}\right) = O\left((p_1 p)^4 \cdot n^k \cdot t^3 + n^{2+\delta_2}\right)$$
$$= o\left(n^{6k-22/3+5\epsilon+\frac{c}{\ln\ln n}}\right).$$

By (5.24), for $\epsilon < \delta/5$ the overall running time is

$$O\left(n^{6k-22/3+5\epsilon+\frac{c}{\ln\ln n}}\right) = O\left(n^{6k-22/3+\delta}\right). \qquad \square$$

The next problem that we consider concerns colorings of the edges of a complete graph. The colorings are such that each color class is a *matching*; that is, edges of the same color have no vertex in common.

THEOREM 5.9. *Let the edges of the complete graph K_n be colored such that every color class is a matching. Then, one can determine in time $O(n^3)$ a complete subgraph K_l of K_n such that the edges of K_l are totally multicolored (injectively colored) and*

$$l \geq c \cdot (n \cdot \ln n)^{1/3}. \tag{5.25}$$

The existence of such a totally multicolored subgraph satisfying (5.25) was shown in [8]. Moreover, Babai [11] showed the existence of colorings of the complete graph K_n, where every color class is a matching, such that every totally multicolored complete subgraph K_l satisfies $l \leq C \cdot (n \cdot \ln n)^{1/3}$, where $C \approx 7.3$. The value of the constant C was improved in [36] to $C = 2.21$. Hence, up to a constant factor we cannot do better in Theorem 5.9 with respect to the size of l.

Proof. Let $\Delta: E(K_n) \longrightarrow N$ be a coloring of the edges of the complete graph K_n with n-element vertex set V, where every color class is a matching.

We form a 4-uniform hypergraph $\mathcal{G} = (V, \mathcal{E})$ on the same vertex set as K_n by collecting pairs of edges of the same color. For distinct edges $e_1 = \{v_1, w_1\} \in E(K_n)$

and $e_2 = \{v_2, w_2\} \in E(K_n)$, we have $E = e_1 \cup e_2 \in \mathcal{E} \in [V]^4$ iff $\Delta(e_1) = \Delta(e_2)$, i.e., $\Delta(e_1) = \Delta(e_2)$ implies $e_1 \cap e_2 = \emptyset$, as every color class is a matching. With $|\Delta^{-1}(i)| \leq n/2$ for $i \in N$ we infer that

$$|\mathcal{E}| = \sum_{i \in N} \binom{|\Delta^{-1}(i)|}{2} \leq \frac{\binom{n}{2}}{\frac{n}{2}} \cdot \binom{\frac{n}{2}}{2} < \frac{1}{8} \cdot n^3. \tag{5.26}$$

By first sorting the edges in $E(K_n)$ according to their color, the hypergraph $\mathcal{G}$ can be constructed in time $O(n^3)$. The average degree $t(\mathcal{G})^3$ of $\mathcal{G}$ satisfies

$$t(\mathcal{G})^3 = \frac{4 \cdot |\mathcal{E}|}{|V|} \leq \frac{n^2}{2} = t^3.$$

First, we construct the $(2,3)$-cycles in $\mathcal{G}$. For each edge $E \in \mathcal{E}$ and each 3-element subset $S \subset E$, the set S can be extended in at most a constant number of ways to an edge $E' \in \mathcal{E}$, i.e., $S \subset E'$, as every color class is a matching. Thus the set of $(2,3)$-cycles can be constructed in time $O(|\mathcal{E}|) = O(n^3)$, and for some constant $c_{2,3} > 0$ we have

$$s_{2,3}(\mathcal{G}) \leq c_{2,3} \cdot n^3. \tag{5.27}$$

We do not construct the set of $(2,2)$-cycles right now. To do this, observe that for each edge $E \in \mathcal{E}$ and each 2-element subset $e \in [E]^2$ there are less than n edges $e' \in E(K_n)$ with $\Delta(e) = \Delta(e')$. Also for distinct vertices $v, w \in E$ and $z \in V \setminus E$, there is at most one edge $e' \in E(K_n)$ with $w \in e'$ and $\Delta(\{v, z\}) = \Delta(e')$. Thus the set of $(2,2)$-cycles can be constructed in time $O(|\mathcal{E}| \cdot n) = O(n^4)$. Similarly, for each subhypergraph $\mathcal{G}' = (V', \mathcal{E}')$ of $\mathcal{G}$, its set of $(2,2)$-cycles can be constructed in time $O(|\mathcal{E}'| \cdot |V'|)$, and also

$$s_{2,2}(\mathcal{G}') \leq c'_{2,2} \cdot |\mathcal{E}'| \cdot |V'|. \tag{5.28}$$

By Lemma 5.6, for $p = n^{-1/3+\epsilon}$ with $0 < \epsilon < 1/3$, using (5.26) and (5.27) we find in time $O(|V| + |\mathcal{E}| + s_{2,3}(\mathcal{G})) = O(n^3)$ a subhypergraph $\mathcal{G}_0 = (V_0, \mathcal{E}_0)$ of $\mathcal{G} = (V, \mathcal{E})$ with

$$|V_0| = p/3 \cdot |V|\ , \quad |\mathcal{E}_0| \leq 3 \cdot p^4 \cdot |\mathcal{E}|\ , \quad \text{and} \quad s_{2,3}(\mathcal{G}_0) \leq 3 \cdot p^5 \cdot s_{2,3}(\mathcal{G}). \tag{5.29}$$

Then, $t(\mathcal{G}_0)^3 \leq 9 \cdot (p \cdot t)^3$. We claim that for $\gamma = \epsilon/(1+\epsilon)$ the following holds:

$$s_{2,2}(\mathcal{G}_0) \ll p \cdot n \cdot (p \cdot t)^{5-\gamma}.$$

To see this, observe, using (5.28), that

$$\begin{aligned} & p^4 \cdot |\mathcal{E}| \cdot p \cdot n \ll p \cdot n \cdot (p \cdot t)^{5-\gamma} \\ \iff & p^{-1+\gamma} \cdot n^{-1/3+2\gamma/3} \ll 1 \\ \iff & n^{-\epsilon+\gamma(\epsilon+1/3)} \ll 1, \end{aligned}$$

and the last inequality holds. Moreover, by (5.27) and (5.29), we have

$$s_{2,3}(\mathcal{G}_0) \leq 3 \cdot p^5 \cdot s_{2,3}(\mathcal{G}) \leq c'_{2,3} \cdot p^5 \cdot n^3 \ll p \cdot n \cdot (p \cdot t)^{4-\gamma}.$$

The assumptions of Corollary 2.7 are fulfilled, and we obtain an independent set of size at least

$$\Omega\left(\frac{p \cdot n}{p \cdot t} \cdot (\ln(p \cdot t))^{1/3}\right) = \Omega\left((n \cdot \ln n)^{1/3}\right).$$

The time for doing this is by (5.28) and (5.29) for $0 < \delta < 1$ and $\epsilon < 2/15$ given by

$$\begin{aligned} & O\left(p \cdot n + p^4 \cdot n^3 + s_{2,2}(\mathcal{G}_0) + s_{2,3}(\mathcal{G}_0) + \frac{(p \cdot n)^3}{(p \cdot t)^{3-\delta}}\right) \\ &= O\left(p \cdot n + p^4 \cdot n^3 + p^5 \cdot |\mathcal{E}| \cdot n + p^5 \cdot n^3 + \frac{n^3}{t^{3-\delta}}\right) \\ &= O\left(n^{7/3+5\epsilon} + \frac{n^3}{n^{2-2\delta/3}}\right) \\ &= O\left(n^{7/3+5\epsilon} + n^{1+2\delta/3}\right) \\ &= o(n^3). \end{aligned}$$

The overall running time is $O(n^3)$. □

Closely related to the problem just considered is that of finding large Sidon sets in Abelian groups [11].

DEFINITION 5.10. *Let $(G, +)$ be an Abelian group. A subset $S \subset G$ is called a* Sidon set *if all pairwise sums $s_1 + s_2$ with $s_1, s_2 \in S$ and $s_1 \neq s_2$ are distinct.*

In the following we will assume that each addition $g + h$ of elements $g, h \in G$ can be done in constant time.

COROLLARY 5.11. *Let $(G, +)$ be an Abelian group. Let $W \subseteq G$ be an n-element subset of G. Then one can compute in time $O(n^3)$ a Sidon set $S \subseteq W$ with*

$$|S| \geq c \cdot (n \cdot \ln n)^{1/3}. \tag{5.30}$$

Note that if $W = G$, where $|W| = n$, each Sidon set S satisfies $\binom{|S|}{2} \leq n$, i.e., $|S| \leq 1 + \sqrt{2 \cdot n}$. The existence of a Sidon set with size as in (5.30) follows from results in [8].

We remark that within the set of integers, finding a Sidon set $S \subseteq \{1, 2, \ldots, n\}$ with $|S| \geq c \cdot \sqrt{n}$ can easily be done in time $O(n)$ using Singer sets; cf. [47].

Proof. Given the set $W \subseteq G$ with $|W| = n$, we form a complete graph K_n with vertex set W. Then we color the edges $\{v, w\}$ of K_n by color $v + w$. This can be done in time $O(n^2)$. As $(G, +)$ is Abelian, every color class is a matching. Then, we apply Theorem 5.9 to our colored K_n, and we obtain in time $O(n^3)$ a totally multicolored complete subgraph K_l with $l \geq c \cdot (n \cdot \ln n)^{1/3}$. As K_l is totally multicolored, the vertices of K_l yield in W a Sidon set. □

The next problem—Sidon sets within the set $\{1^2, 2^2, \ldots, n^2\}$ of squares of integers—was considered for the first time by Alon and Erdös [7], where for any $\epsilon > 0$ the lower bound $|S| \geq c \cdot n^{2/3-\epsilon}$ was proved by a Turán strategy.

THEOREM 5.12. *For every fixed $\delta > 0$, one can find in time $O(n^{2+\delta})$ a Sidon set $S \subset \{1^2, 2^2, \ldots, n^2\}$ with*

$$|S| \geq c_\delta \cdot n^{2/3}. \tag{5.31}$$

The existence of an independent set of size at least as in (5.31) was proved in [37]. By a result of Landau [34], one has the upper bound $|S| \leq c \cdot n/(\ln n)^{1/4}$ for every Sidon set $S \subseteq \{1^2, 2^2, \ldots, n^2\}$.

Proof. We consider a 4-uniform hypergraph $\mathcal{G} = (V, \mathcal{E})$ with vertex set $V = \{1^2, 2^2, \ldots, n^2\}$ and edge set $\mathcal{E} \subseteq [V]^4$. Let $\{i_1^2, i_2^2, i_3^2, i_4^2\} \in \mathcal{E}$ iff $i_1^2 + i_2^2 = i_3^2 + i_4^2$. To construct $\mathcal{G}$, we consider all pairs (i^2, j^2), $1 \leq i < j \leq n$, and sort them according to the value of their sums $i^2 + j^2$ in time $O(n^2 \cdot \ln n)$. Then, we collect pairwise the pairs with the same value of the sum. Recall, that $r_2(d)$ denotes the number of representations of d as a sum of two squares, i.e., $x^2 + y^2 = d$ for integers x, y. By (5.4), we have

$$r_2(n) \leq n^{\frac{c'}{\ln \ln n}}.$$

Using (5.5), we infer that

$$|\mathcal{E}| \leq \sum_{d=1}^{2n^2} \binom{r_2(d)}{2} \leq c_4 \cdot n^2 \cdot \ln n, \tag{5.32}$$

and $\mathcal{E}$ can be constructed in time $O(n^2 \cdot \ln n)$.

Now we consider the 2-cycles in the hypergraph $\mathcal{G}$. To count the number $s_{2,2}(\mathcal{G}')$ of $(2,2)$-cycles in any subhypergraph $\mathcal{G}' = (V', \mathcal{E}')$, consider a fixed edge $\{i_1^2, i_2^2, i_3^2, i_4^2\} \in \mathcal{E}'$. The number of edges $\{i_1^2, i_2^2, x^2, y^2\} \in \mathcal{E}'$ with $i_1^2 + i_2^2 = x^2 + y^2$ is at most $r_2(i_1^2 + i_2^2) \leq n^{\frac{c_1}{\ln \ln n}}$. Moreover, the number of edges $\{i_1^2, i_2^2, x^2, y^2\} \in \mathcal{E}'$ with $i_1^2 + x^2 = i_2^2 + y^2$ is given by a constant times the number of divisors of $i_1^2 - i_2^2$ and hence is at most $n^{\frac{c_2}{\ln \ln n}}$; cf. [27], [37]. Thus, we have for constants $c_3, c_{2,2} > 0$ that

$$s_{2,2}(\mathcal{G}') \leq c_{2,2} \cdot |\mathcal{E}'| \cdot n^{\frac{c_3}{\ln \ln n}} ,$$

and the set of $(2,2)$-cycles in $\mathcal{G}'$ can be constructed in time $O(|\mathcal{E}'| \cdot n^{\frac{c_3}{\ln \ln n}})$.

As every 3-element subset $S \subset V$ can be extended only in a constant number of ways to an edge $E \in \mathcal{E}$, i.e., $S \subset E$, every subhypergraph $\mathcal{G}' = (V', \mathcal{E}')$ of $\mathcal{G}$ satisfies for some constant $c_{2,3} > 0$ that

$$s_{2,3}(\mathcal{G}') \leq c_{2,3} \cdot |\mathcal{E}'|,$$

and the set of $(2,3)$-cycles in $\mathcal{G}'$ can be constructed in time $O\left(|\mathcal{E}'|\right)$.

Now, for the average degree $t(\mathcal{G})^3$ of $\mathcal{G}$ we have by (5.32) that

$$t(\mathcal{G})^3 \leq t^3 = \frac{4 \cdot c_4 \cdot n^2 \cdot \ln n}{n} = c_5 \cdot n \cdot \ln n.$$

Then, for $0 < \gamma < 1/3$, some constant $c > 0$, and n large we have

$$\begin{aligned} s_{2,2}(\mathcal{G}) &\leq c_{2,2} \cdot n^2 \cdot \ln n \cdot n^{\frac{c_3}{\ln \ln n}} \ll n^{8/3 - \gamma/3} \leq c \cdot n \cdot t^{5-\gamma}, \\ s_{2,3}(\mathcal{G}) &\leq c_{2,3} \cdot n^2 \cdot \ln n \ll n^{7/3 - \gamma/3} \leq c \cdot n \cdot t^{4-\gamma}; \end{aligned}$$

hence, the assumptions of Corollary 2.7 are fulfilled, and we obtain for any fixed $\delta' > 0$ with $\delta' < 3\delta$ in time

$$O\left(n^2 \cdot \ln n \cdot n^{\frac{c_3}{\ln \ln n}} + \frac{n^3}{t^{3-\delta'}}\right) = O\left(n^{2+\delta'/3} \cdot (\ln n)^{\delta'/3}\right) = O\left(n^{2+\delta}\right)$$

an independent set of size at least

$$\Omega\left(\frac{n}{(n \cdot (\ln n))^{1/3}} \cdot (\ln n)^{1/3}\right) = \Omega\left(n^{2/3}\right). \qquad \square$$

Sidon sets in arbitrary groups were considered by Babai and Sós [12]. They distinguish two types, as shown in the following.

Definition 5.13. *Let $(G, \cdot)$ be a group, and let S be a subset of G. The set S is a Sidon set of the* first kind *if for all $x, y, z, w \in S$, where at least three are distinct, it is*

$$x \cdot y \neq z \cdot w.$$

The set S is a Sidon set of the second kind *if*

$$x \cdot y^{-1} \neq z \cdot w^{-1}.$$

Theorem 5.14. *Let $(G, \cdot)$ be an arbitrary group. Then for every subset $W \subseteq G$ with $|W| = n$, one can determine in time $O(n^3)$ a subset $S \subseteq W$, which is a Sidon set of both kinds, first and second, and satisfies*

$$|S| \geq c \cdot (n \cdot \ln n)^{1/3}. \tag{5.33}$$

The existence of a Sidon set with $|S| \geq c \cdot n^{1/3}$ was first shown by Babai and Sós [12]. In [36] the existence of a Sidon set S satisfying (5.33) was shown.

Proof. We sketch the arguments for Sidon sets of the second kind. The arguments for Sidon sets of the first kind are similar (also for Sidon sets of both kinds). By results from [12], a subset $S \subseteq G$ is a Sidon set of the second kind if for pairwise distinct elements $x, y, z \in S$ it is

$$x \cdot y^{-1} \neq y \cdot z^{-1} \tag{i}$$

and for all pairwise distinct elements $x, y, z, w \in S$ it is

$$x \cdot y^{-1} \neq z \cdot w^{-1}. \tag{ii}$$

Given a subset $W \subseteq G$, we form a hypergraph $\mathcal{G} = (W, \mathcal{E}_3 \cup \mathcal{E}_4)$ by collecting triples and quadruples of W, which violate conditions (i) or (ii). For pairwise distinct elements $x, y, z \in W$ let $\{x, y, z\} \in \mathcal{E}_3$ iff $x \cdot y^{-1} = y \cdot z^{-1}$. Moreover, for pairwise distinct elements $x, y, z, w \in W$, let $\{x, y, z, w\} \in \mathcal{E}_4$ iff $x \cdot y^{-1} = z \cdot w^{-1}$. Constructing the sets $\mathcal{E}_3, \mathcal{E}_4$ can be done in time $O(n^3)$. Again, we want to find a large independent set in $\mathcal{G}$.

Let $\mathcal{G}|\mathcal{E}_4 = (W, \mathcal{E}_4)$. It is easy to see (cf. [36]) that

$$|\mathcal{E}_3| \leq c_3 \cdot n^2, \quad |\mathcal{E}_4| \leq c_4 \cdot n^3, \quad s_{2,3}(\mathcal{G}|\mathcal{E}_4) \leq c_{2,3} \cdot n^3, \quad \text{and} \quad s_{2,2}(\mathcal{G}|\mathcal{E}_4) \leq c_{2,2} \cdot n^4$$

and the sets of $(2,3)$-cycles can be constructed in time $O(s_{2,3}(\mathcal{G}|\mathcal{E}_4))$. Moreover, for every subhypergraph $\mathcal{G}' = (W', \mathcal{E}_4')$ of $\mathcal{G}|\mathcal{E}_4$, we have

$$s_{2,2}(\mathcal{G}') \leq c'_{2,2} \cdot |\mathcal{E}'| \cdot |W'|.$$

The situation is similar to that in the proof of Theorem 5.9. We first choose with $p = n^{-1/3+\epsilon}$, where $0 < \epsilon < 1/3$, in time $O(n^3)$ a small subhypergraph $\mathcal{G}_0$ of $\mathcal{G}$, where we control the number of vertices, edges, and $(2,3)$-cycles in $\mathcal{G}|\mathcal{E}_4$. In the resulting hypergraph $\mathcal{G}_0$, the number of $(2,2)$-cycles is only $O(p^4 \cdot |\mathcal{E}_4| \cdot p \cdot n) = o(n^3)$ for $\epsilon < 2/15$. Then, on this small subhypergraph we again choose in time $o(n^3)$ with $p = n^{-1/3+\epsilon_1}$ a small subhypergraph $\mathcal{G}_1$, where we control the number of vertices, edges, and, among the 4-element edges, the $(2,3)$-cycles and now also the $(2,2)$-cycles. In the resulting hypergraph $\mathcal{G}_1$, we delete in time $o(n)$ one vertex from each 3-element edge, each $(2,2)$-cycle, and each $(2,3)$-cycle, and we obtain a 4-uniform hypergraph without any

2-cycles, to which we apply Corollary 2.8 in time $o(n^3)$, and we get a desired Sidon set. $\square$

DEFINITION 5.15. *Let $(G, \cdot)$ be a group. Let $C \subset G$ be a subset of G with $1 \notin C$, where C is invariant under taking inverses, i.e., with $C = C^{-1} = \{c^{-1} \mid c \in C\}$. The* Cayley graph *$\Gamma(G, C)$ has vertex set G and edge set $\{\{g, h\} \mid g \cdot h^{-1} \in C$ and $g, h \in G\}$.*

COROLLARY 5.16. *Let $(G, \cdot)$ be a group. There exists a constant $c > 0$ such that the following holds. Let H be a graph on n vertices. Then, for every subset $W \subseteq G$ with $|W| \geq c \cdot n^3/\ln n$, one can construct in time $O(n^9/(\ln n)^3)$ some Cayley subgraph of G and find in it an induced subgraph, which is isomorphic to H.*

The existence of such a subset W with $|W| \geq c \cdot n^3$ was shown first by Babai and Sós [12]. This was improved to $|W| \geq c \cdot n^3/\log n$ in [36].

Proof. The arguments follow [12]. Let $H = (V, E)$ be a graph on n vertices, and let $W \subseteq G$ be a subset of G with $|W| \geq c \cdot n^3/\ln n$, where $c > 0$ is a large enough constant. By Theorem 5.14 we obtain in time

$$O\left(\left(\frac{n^3}{\ln n}\right)^3\right) = O\left(\frac{n^9}{(\ln n)^3}\right)$$

a subset $S \subseteq W$ with $|S| = n$, where S is a Sidon set of the second kind. Now, we identify S with the vertex set V of H. Set $C = \{s \cdot t^{-1} \mid \{s, t\} \in E\}$. Then $1 \notin C$ and $C = C^{-1}$. Moreover, the Cayley graph $\Gamma(S, C)$ is an induced copy of the graph H. $\square$

In connection with the study of random Turán numbers the existence of graphs with many edges and without cycles of small lengths was shown by Kohayakawa, Kreuter, and Steger [31]. We mention without detailed proof that along the lines discussed in this paper the following can be shown.

PROPOSITION 5.17. *Let $k \geq 2$ be a fixed integer. Then, one can compute in time $O(n^{4k-3})$ a graph G on n vertices, which does not contain any cycle $C_3, C_4, \ldots, C_{2k}$, and the number of edges in G is at least*

$$\Omega\left(n^{1+\frac{1}{2k-1}} \cdot (\ln n)^{\frac{1}{2k-1}}\right).$$

Although there are better constructions known, for example, Ramanujan graphs arising from the work of Lubotzky, Phillips, and Sarnak [38], i.e., graphs with at least $\Omega(n^{1+\frac{2}{3k+3}})$ edges which do not contain any cycle $C_3, C_4, \ldots, C_{2k}$, the method used in [31] is interesting to gain a logarithmic factor. Namely, seemingly against the intuition they delete edges in a complete graph K_n with probability $p = n^{-1+\frac{1}{2k-1}+\epsilon}$, where $\epsilon > 0$, which is above the usual choice $p_0 = \Theta(n^{-1+\frac{1}{2k-1}})$. Then they form a hypergraph with vertices being the edges of the resulting random graph G_n and (hyper-)edges consisting of the cycles $C_3, C_4, \ldots, C_{2k}$ in G_n. The resulting hypergraph contains an independent set of size $\Omega(n^{1+\frac{1}{2k-1}} \cdot (\ln n)^{\frac{1}{2k-1}})$, i.e., the corresponding edges in the graph form no cycles $C_3, C_4, \ldots, C_{2k}$.

For algorithmic reasons, we do not use the probabilistic argument from [31]. We consider the complete graph K_n on n vertices. We form a hypergraph $\mathcal{G}$ with vertices being the edges of K_n. The (hyper-)edges in $\mathcal{G}$ are determined by the edges of cycles of length at most $2k$ in K_n. Thus, the hypergraph $\mathcal{G}$ has $\binom{n}{2}$ vertices and $\Theta(n^i)$ edges of cardinality i, where $i = 3, 4, \ldots, 2k$. Then we determine all 2-cycles among the $2k$-element edges of $\mathcal{G}$. The number of $(2, j)$-cycles, $j = 2, 3, \ldots, 2k-1$, among the $2k$-element edges of $\mathcal{G}$ is $\Theta(n^{4k-j-1})$. Hence, the assumptions of Corollary 2.7 are fulfilled. We get rid of those (hyper-)edges with cardinality less than $2k$ by choosing vertices of $\mathcal{G}$ with probability $p = n^{-\frac{2k-2}{2k-1}+\epsilon}$ for some $\epsilon > 0$, i.e., using the derandomized argument, and we obtain a $2k$-uniform subhypergraph to which we apply Corollary 2.7. The running time of this algorithm is given by the number of $(2, 2)$-cycles, i.e., is at most $O(n^{4k-3})$.

We remark that Proposition 5.17 was recently generalized in [15]; see also [35]. Moreover, an algorithm for Heilbronn's problem (cf. [32]) was given in [14].

ACHILLES, TURTLE, AND UNDECIDABLE BOUNDEDNESS PROBLEMS FOR SMALL DATALOG PROGRAMS[*]

JERZY MARCINKOWSKI[†]

Abstract. DATALOG is the language of logic programs without function symbols. It is considered to be the paradigmatic database query language. If it is possible to eliminate recursion from a DATALOG program then it is *bounded.* Since bounded programs can be executed in parallel constant time, the possibility of automatized boundedness detecting is believed to be an important issue and has been studied in many papers. Boundedness was proved to be undecidable for different kinds of semantical assumptions and syntactical restrictions. Many different proof techniques were used.

In this paper we propose a uniform proof method based on the discovery of, as we call it, the Achilles–Turtle machine, and make strong improvements on most of the known undecidability results. In particular we solve the famous open problem of Kanellakis showing that uniform boundedness is undecidable for single rule programs (called also *sirups*).

This paper is the full version of [J. Marcinkowski, *Proc.* 13*th STACS*, Lecture Notes in Computer Science 1046, pp. 427–438], and [J. Marcinkowski, 11*th IEEE Symposium on Logic in Computer Science*, pp. 13–24].

Key words. DATALOG, query optimization, decidability

AMS subject classification. 68P15

PII. S0097539797322140

1. Introduction.

1.1. Introduction. Consider the query relation R, which answers for a given directed graph and for two given nodes A and B of the graph, whether it is possible to reach B from A in an odd number of steps. It turns out that R is not expressible in first order logic. That is due to lack of recursion in the first order logic. This observation led to the study of DATALOG (DATAbase LOGic) programs which combine existential positive first order logic with recursion. For example, the relation R can be defined by an "odd-distance" DATALOG program:

(i) $R(X,Y){:-}\, E(X,Y)$,

(ii) $R(X,Y){:-}\, R(X,Z), R(Z,W), E(W,Y)$,

where E is the edge relation of the graph. E is the so-called extensional predicate (EDB): we treat it as an input and are not able to prove new facts about it. R is the output, or intensional predicate (IDB). The program proves facts about it. The first rule is an initialization rule: it has only the extensional predicate in the body. But the second rule contains the intensional predicate within its premises; it can be used recursively and deep proofs can be constructed. It is clear that if in some graph there is a path from an element A to B of an odd length n, then to prove $R(A,B)$ for such elements, a proof of a depth about $\log n$ may be needed. Thus in huge databases arbitrarily deep proofs are necessary to evaluate the program.

On the other hand, consider a program which computes the "has 3-tail" query:

(iii) $1TAIL(Z){:-}\, E(Z,X)$,

(iv) $2TAIL(Z){:-}\, 1TAIL(Y), E(Z,Y)$,

[†]Institute of Computer Science, Wrocław University, ul Przesmyckiego 20, 51151 Wrocław, Poland (jma@tcs.uni.wroc.pl).

(v) $3TAIL(Z)$:– $2TAIL(Y), E(Z,Y)$.

If $3TAIL(A)$ is provable for some A, then there exists a proof of the fact which is not deeper than 3, regardless of the number of elements in the database. $1TAIL$, $2TAIL$, and $3TAIL$ are IDB and the second and third rules are recursive. But in fact, the recursion can be eliminated completely from the last program. It is possible to write an equivalent one where only proofs of depth 1 will be necessary:

$3TAIL(X)$:– $E(T,W), E(W,Z), E(Z,X)$.

The recursion can be eliminated from a given program, and the program is equivalent to a first order query if and only if there is an a priori upper bound on the depth of the proofs needed to evaluate queries. Every fact that can be derived by the program can be derived in constant time (in parallel, with polynomially many processors) independent of the size of the database (this equivalence was proved in [3]; the "if" direction is nontrivial). Such programs are called *bounded*.

1.2. Previous works and our contribution. The problem of distinction, meaning whether a given DATALOG program is bounded or not, is important for DATALOG queries optimization, but is, in general, undecidable. Sufficient conditions for boundedness were given in [17], [10], [18], and [19]. The decidability-undecidability border, for cases of different syntactical restrictions and semantical assumptions, has been studied in [20], [5], [2], [6], [8], [9], [24], [23].

The syntactical restrictions considered were the number of rules or the number of recursive rules in the program, maximal arity of the IDB symbols, and the linearity of rules.

The semantical assumptions concern the status of the IDB relations before the execution of the program. If they are empty, then we deal with weak (program) boundedness. While arbitrary relations must be considered as possible IDB inputs, strong (uniform) boundedness is studied.

Undecidability of uniform boundedness implies undecidability of program boundedness for fixed syntactical restrictions (with possibly some additional initialization rules; see section 1.7 for a discussion). The survey of previously known results ((i)-(v) below) illustrates the difference in the level of difficulty of undecidability proofs for uniform and program boundedness.

Decidability has been proved for monadic programs program boundedness (so also for the uniform) [6], [5] and for typed single rule programs [20]. It is also known that the program (and uniform) boundedness is decidable for programs with a single linear recursive rule if the IDB is binary [24]. Moreover, program boundedness is decidable for binary programs if each IDB is defined by only one recursive rule [23].

Undecidability has been proved for

(i) program boundedness of linear binary programs [9],

(ii) program boundedness of programs with one recursive rule and two initializations [2],

(iii) program boundedness of programs consisting of two linear recursive rules and one initialization [9],

(iv) uniform boundedness of ternary programs [9],

(v) uniform boundedness of arity 5 linear programs [8].

Decidability of the uniform boundedness for programs consisting of only one rule was stated as an open problem in [11], where NP-hardness of the problem was proved, and then in [2] and [12]. No undecidability results for uniform boundedness of programs with a small number of rules have been proved since then.

In this paper we give strong improvements of the results (ii)–(v) showing that

(vi) uniform boundedness is undecidable for ternary linear programs (section 3.1) (which improves the results (iv) and (v)).

(vii) uniform boundedness is undecidable for single recursive rule ternary programs (section 3.3) (which improves (iv)).

The additional improvement is that our program is syntactically simpler: the recursive rule is quasi-linear, which means that, generally speaking, it has the form $I(tuple1)$:– $J(tuple2), I(tuple3)$, where I and J are intensional predicates. Since it is the only recursive rule, the proof from the program is a tree with only one (possibly) long branch.

Notice that in (vi) and (vii) we still allow a number of initializations so the results hold also for program boundedness.

(viii) Uniform and program boundedness are undecidable for programs consisting of one linear recursive rule and one initialization (section 4.3).

Since program boundedness is clearly decidable for programs consisting of one rule, the result (viii) closes the number/linearity of rules classification for program boundedness. It is a strong improvement of (ii) and (iii).

Finally, in section 4.5 we solve the problem of Kanellakis showing that

(ix) uniform boundedness of single rule programs is undecidable.

1.3. The method. While different techniques were used in the proofs of the results (i)–(v) (reduction to the halting and mortality problems of a Turing machine, reduction from the halting problem of a two counters machine, syntactical reduction of an arbitrary DATALOG program to a single recursive rule program), we develop for all our results a universal method, based on an encoding of Conway functions. We have learned about Conway functions from the paper of Philippe Devienne, Patrick Lebègue and Jean-Christophe Routier [7], who used them to prove undecidability of the so-called cycle unification. We feel that our paper would not have been written without their previous work. Our encoding is nevertheless quite different from the one in [7]: the first difference is that a language with functions was used there.

We construct, as we call it, the Achilles-Turtle machine, a variant of the Turing machine. Next, we use a version of the Conway theorem to prove that what we constructed is really a universal machine. Then we encode the Achilles-Turtle machine with DATALOG programs. Due to the particular simplicity of Achilles-Turtle machine (one is really tempted to claim that it is the simplest known universal machine), it is possible to encode it with syntactically very small DATALOG programs. We believe that this is not the last time that the Achilles-Turtle machine is used in undecidability proofs.

We combine the Conway functions method with the technique of using a binary EDB relation as an order: if there is a chain long enough in the relation, then we can think that it represents a tape of the machine. If there is no such chain then proofs are not too long. This method goes back to [9] and [8].

1.4. Open problems. While the classification is finished for program boundedness, the following syntactical restrictions still give interesting open problems concerning decidability of uniform boundedness:

(i) binary programs,

(ii) linear binary programs,

(iii) programs consisting of a single linear rule.

We do not know any example of syntactical restrictions for which uniform boundedness would be decidable and program boundedness not. It seems that the most likely candidate for the example is the class of linear binary programs. Program boundedness is known to be undecidable for the class.

1.5. Preliminaries. A *DATALOG program* is a finite set of Horn clauses (called *rules*) in the language of first order logic without equality and without functions. The predicates, used in the program, but only in the bodies of the rules, are called *extensional predicates* or EDB. A predicate which occurs in a head of some rule is called *intensional* or IDB. A rule is called *recursive* if an IDB occurs in its body. A rule which is not recursive is an *initialization rule*. A recursive rule is *linear* if it has only one occurrence of an IDB in the body. A program is linear if each of its recursive clauses is linear. *Arity* of a DATALOG program is the highest arity of the IDB predicates used.

So, for example, in the two programs of section 1.1 the predicate E is extensional, and all the other predicates are intensional. The rules (i) and (iii) are initializations. Rules (ii), (iv), and (v) are recursive. Rules (iv) and (v) are linear and so the "has 3-tail" program is linear. It is also monadic, while the "odd-distance" program is binary.

A database is a finite set of ground atomic formulas. A *derivation* (or a *proof*) of a ground atomic formula $\mathcal{A}$, from the program $\mathcal{P}$ and the database $\mathcal{D}$, is a finite tree such that (i) each of its nodes is labeled with a ground atomic formula; (ii) each leaf is labeled with an atom from $\mathcal{D}$; (iii) for each nonleaf node there exists a rule R in the program $\mathcal{P}$ and a substitution σ, such that σ of the head of R is the label of the node and the substitutions of the body of R are the labels of its children; (iv) $\mathcal{A}$ is the label of the root of the tree. The *depth* of the proof is the depth of the derivation tree.

Instead of writing *proof from the program* $\mathcal{P}$ *in the database* $\mathcal{D}$ we use the expression $\mathcal{P} - \mathcal{D}$*-proof*, or simply *proof* if the context is clear.

Notice that if $\mathcal{P}$ is a linear program, then a $\mathcal{P}$-proof is a sequence of ground atomic formulas. In such a case we use the word *length* for the depth of the proof.

In general, a program $\mathcal{P}$ is bounded if for every database $\mathcal{D}$, if an atom can be proved from $\mathcal{P}$ and $\mathcal{D}$, then it has a proof not deeper than a fixed constant c.

Different conventions concerning the input and output of a DATALOG program correspond to different definitions of boundedness: *predicate*, *program*, and *uniform* boundedness are studied. A program is *predicate bounded*, with respect to a fixed predicate PRE, if there is a constant c such that for every database $\mathcal{D}$, such that there are no facts about IDBs in $\mathcal{D}$; for every ground atom $\mathcal{A} = PRE(tuple)$, if the atom has a proof from $\mathcal{P}$ and $\mathcal{D}$, then it has a proof not deeper than c. This definition reflects the situation when the EDBs are the input and only one predicate is the output of the program. A program $\mathcal{P}$ is *program bounded* if it is predicate bounded for all IDBs.

A program is *uniformly bounded* if there is a constant c such that for every database $\mathcal{D}$ (here we do not suppose that the IDB predicates do not occur in $\mathcal{D}$), and for every ground atom $\mathcal{A}$, if the atom has a proof from $\mathcal{P}$ and $\mathcal{D}$, then it has a proof not deeper then c. Here all the predicates are viewed as the input and as the output of a program.

1.6. Example: Program boundedness vs. uniform boundedness. To make the difference between program boundedness and uniform boundedness clear to the reader, we give an example of a program which is bounded but not uniformly bounded.

The signature of the program consists of one extensional predicate E and one intensional predicate I. Both predicates are binary.

The rules are
(i) $I(X,X) : -E(X,Y), E(Y,Z)$,
(ii) $I(W,R) : -I(Z,Z), E(X,Y), E(Y,Z)$,
(iii) $I(X,Y) : -I(Y,X)$,
(iv) $I(X,Y) : -I(Z,Y), E(X,Z)$,
(v) $I(X,Y) : -I(Z,Y), E(Z,X)$.

It is convenient to think that E is a graph, and I is a kind of a pebble game: by the initialization rule (i) we can start the game by placing both the pebbles in any node which has a tail of length at least 2. By rule (iii) we do not need to distinguish between the pebbles. By rules (iv) and (v) we can always move one of the pebbles to a neighboring node, and finally, if the two pebbles meet in the node that is the end of a tail of length at least two, then by rule (ii) we can move the pebbles to any two nodes.

We prove that the program is program bounded but not uniformly bounded.

LEMMA 1.1. *For a database $\mathcal{D}$ such that the input predicate I is empty, either there are no proofs in $\mathcal{D}$ or for each pair D, E of elements of $\mathcal{D}$, the fact $I(D,E)$ can be proved in no more than 7 derivation steps.*

Proof. We consider two cases.

Case 1. There are elements A, B, C in $\mathcal{D}$ such that $E(A,B)$ and $E(B,C)$ hold. Then, in the first step, we use rule (i) to prove $I(A,A)$. Then, using rule (v) twice we get $I(C,A)$. Then we use rule (iii) to get $I(A,C)$ and rule (v) twice to get $I(C,C)$. Finally, rule (ii) can be used to derive $I(D,E)$.

Case 2. There are no such elements A, B, C in the database $\mathcal{D}$. Then, since I is given as empty, no proofs at all are possible. □

The structure of the proof of the Lemma 1.1 above, as well as the structure of the program itself, is a good illustration of one of the ideas of the proofs in sections 3 and 4. The program contains some initialization rules which allows us to start a kind of game, or computation, if only there exists a substructure of required form in the database. Then, if there is enough facts in the database, we can proceed with the computation and, when it terminates, use an analogue of rule (ii) to "flood" the database. Otherwise, if there are not enough facts, then only short proofs are possible (or no proofs at all, as in the example).

LEMMA 1.2. *For each constant c there exist a database $\mathcal{D}$ with nonempty input predicate I, and elements A, B of $\mathcal{D}$ such that $I(A,B)$ is $\mathcal{P}$-provable, but the shortest proof of the fact requires more than c steps.*

Proof. The database contains the elements $C_1, C_2, \dots C_{2c}$ and the following facts: $E(C_{2k-1}, C_{2k})$ for all $1 \le k \le c$, $E(C_{2k+1}, C_{2k})$ for all $1 \le k \le c-1$, and $I(C_1, C_1)$. We will show that the fact $I(C_{2c}, C_1)$ is provable, and the shortest proof has exactly $2c-1$ steps. First we show that such a proof exists: in the kth step use the already proved fact $I(C_k, C_1)$ to derive $I(C_{k+1}, C_1)$. The rule used in the kth derivation step is (v) if k is odd and (iv) if k is even.

To see that shorter proofs are not possible, notice that only the bodies of the rules (iii)–(v) can be satisfied in $\mathcal{D}$, and so only those rules can be used.

Define the distance between nodes of $\mathcal{D}$ as follows: the distance between A and A is 0, and the distance between A and B is less than or equal to k if and only if there exists a node C such that either $E(B,C)$ or $E(C,B)$ and the distance between A and B is at most $k-1$. The distance between a pair of nodes A, B in $\mathcal{D}$ and a pair of nodes C, D in $\mathcal{D}$ is defined as a sum of distances from A to C and from B to D. Now, notice that if a fact of the form $I(A,B)$ is derived in k steps from the fact $I(C,D)$, and if only rules (iii)–(v) are used in the proof, then the distance between A, B and C, D is not greater than k. Finally, observe that the distance in $\mathcal{D}$ between C_{2c}, C_1 and C_1, C_1 is $2c - 1$. $\square$

1.7. Program boundedness vs. uniform boundedness. Discussion. The notions of uniform and program boundedness formalize, on the technical level, the informal notion of boundedness. Uniform boundedness is what we need when the program under consideration is a subprogram of a bigger one. Then it can happen that the predicates that are supposed to be the output of the program are also a part of the input. Program boundedness, on the other hand, corresponds to the view of an entire DATALOG program as a definition of possibly many output predicates. This is similar to the distinction between program and uniform equivalence of DATALOG programs (see [21]), where again the first notion applies to entire programs, while the second one to subprograms equivalence. It is known that program equivalence is undecidable, while uniform equivalence is decidable [5], [21], [22]. We can observe that also for the case of boundedness, the uniform version, for given syntactical restrictions, is a priori "more decidable." Suppose that program boundedness is decidable for some syntactical restrictions and that the restrictions allow an arbitrary number of initializations. Then uniform boundedness is also decidable for the restrictions. To see that, consider a program $\mathcal{P}$ over a signature with IDB symbols I_i, where $1 \le i \le k$. Let $\mathcal{Q}$ be the program $\mathcal{P}$ with its signature enriched with new EDB symbols E_i, where $1 \le i \le k$ and for each i the arity of E_i is equal to the arity of I_i, and with k new rules: $I_i(X_1, X_2, \ldots, X_{a_i}) : -E_i(X_1, X_2, \ldots, X_{a_i})$.

It is easy to see that $\mathcal{Q}$ is program bounded if and only if $\mathcal{P}$ is uniformly bounded. So we reduced the decision problem of the uniform boundedness of $\mathcal{P}$ to the problem of program boundedness of the program $\mathcal{Q}$.

The survey of results gives evidence that it is more difficult to prove undecidability of uniform boundedness than undecidability of program boundedness; the argument above shows that there are reasons for that. But on the other hand we do not know any example of syntactical restrictions for which uniform boundedness would be decidable and program boundedness not. The most likely candidate for the example is the class of linear binary programs. Program boundedness is undecidable for the class and decidability of uniform boundedness is open.

2. Achilles-Turtle machine.

2.1. The tool: Conway functions.

Definition 2.1. *A Conway function is a function g with natural arguments defined by a system of equations:*

$$g(n) = \begin{cases} a_0 n/q_0 & (n \equiv 0 \pmod{p}), \\ \cdots & \cdots \\ a_i n/q_i & (n \equiv i \pmod{p}), \\ \cdots & \cdots \\ a_{p-1} n/q_{p-1} & (n \equiv p-1 \pmod{p}), \end{cases}$$

where a_i,q_i are natural numbers, $q_i | i$ (which means that i/q_i is a natural number), and $q_i | p$ for each i and $(a_i/q_i) \le p$ for each i.

For a Conway function g and a given natural number N let $C(g, N)$ be a statement asserting that there exists a natural number i such that $g^i(N) = 1$.

See section 2.3 to find a nice example giving an idea of what a Conway function is. Proof of the following theorem can be found in [4], [14], or [7].

THEOREM 2.2 (Conway). *The following problem is undecidable given a Conway function g and a natural number N, does $C(g, N)$ hold?*

Our main tool is the following refined version of Theorem 2.2.

THEOREM 2.3.

1. *There exists a computable sequence $\{g_n\}$ of Conway functions such that*

(i) *$\{n : C(g_n, 2)\}$ is not recursive (is r.e. complete);*

(ii) *for each g_n, if a_i and q_i are coefficients from the definition of the function g_n, then $(a_i/q_i) \leq 2$;*

(iii) *for each g_n, if there are such i, k that $k \equiv 1 \pmod p$ and $g_n^i(2) = k$, then $k = 1$.*

2. *There exists a universal Conway function g, such that*

(i) *the set $\{N : C(g, 2^N)\}$ is not recursive (is r.e. complete);*

(ii) *if a_i and q_i are coefficients from the definition of the function g, then $(a_i/q_i) \leq 2$;*

(iii) *for each N, if there are such i, k that $k \equiv 1 \pmod p$ and $g^i(2^N) = k$ then $k = 1$.*

Proof. 1. It is known that the problem: *given a finite automaton with* 2 *counters, does the computation starting from fixed beginning state, and from empty counters reach some fixed final state* is undecidable, even if we require that the final state can be reached only if the both counters are empty (read the remark in the end of this section to see what precisely we mean by *a finite automaton with* 2 *counters*).

For a given automaton $\mathcal{A}$ of this kind we will construct a Conway function $g_{\mathcal{A}}$ which satisfies conditions (ii) and (iii) of the theorem and such that $C(g_{\mathcal{A}}, 2)$ holds if and only if the computation of $\mathcal{A}$ reaches the final state. First we need to modify $\mathcal{A}$ a little bit: we construct an automaton $\mathcal{B}$ which terminates if and only if $\mathcal{A}$ terminates and which satisfies the following conditions:

(iv) the second counter of $\mathcal{B}$ can be increased only if the first counter is decreased in the same computation step,

(v) the states of $\mathcal{B}$ are numbered. If any of the counters is increased in the computation step when the state s_i is being changed into s_j then $j < i$.

The details of the construction of $\mathcal{B}$ are left as an easy exercise. The hint is that all what must be done is adding a couple of new states. For example if there is an instruction of $\mathcal{A}$ which increases the second counter and keeps the first unchanged, it must be substituted by two instructions: first of them only increases the first counter and changes the state into a new one, the second increases the second counter and decreases the first.

Now, suppose that the states of the automaton $\mathcal{B}$ are $s_1, s_2, \ldots s_k$, where s_b is the beginning state. Let $p_1, p_2, \ldots p_k$ be an increasing sequence of primes such that $p_1 > 4$ and $2p_1 > p_k$ (such a sequence can be found for each k, since the density of primes around n is $c/\log n$). We encode the configuration of $\mathcal{B}$: *state is s_i, the first counter contains the number n and the second counter contains m,* as the natural number $2^n 3^m p_i$. It is easy to notice that, if x and y are codes of two subsequent configurations of $\mathcal{B}$ then y/x depends only of the remainder $x \pmod p$ where $p = 6p_1p_2 \ldots p_k$ and that $y/x \leq 2$. So we can define the required Conway function. To define the first step properly we put $a_2 = p_b$ and $q_2 = 2$, so $g(2) = p_b$ which is the code of the beginning configuration. We put also $a_{p_f} = 1$ and $q_{p_f} = p_f$ to reach 1 in the iteration of the function next to the one when the code of the final configuration is reached.

2. We use the well known fact that there exists a particular finite automaton with two counters for which the problem *does the computation starting from a fixed begin-*

ning state s_b, given first counter, and empty second counter, reaches the configuration of some fixed final state s_f, and empty counters is undecidable. Then the proof is similar as of (i). To start the computation properly we put $a_i = p_b$ and $q_i = 1$ for all such even i that $p_j|i$ does not hold for any $j = 1, 2 \dots k$. So for each N it holds that $g(2^N) = p_b 2^N$. The last is the code of the beginning configuration. □

Remark (automata with counters). Our notion of a finite automaton with two counters is similar to the one in Kozen's book [13], with the difference that we assume that the automaton has no input tape. Since two counter automata (with read-only input tape) are as powerful as Turing machines, the problem whether a given automaton of this kind will terminate for given input is undecidable. But, for each input, separately, we can hide the input in the finite control of the automaton (in fact the input tape **is** a finite object for each input). So also the problem whether a given automaton without input tape will terminate when started from a fixed beginning state and from empty counters is undecidable. Now we show, as it is needed in the proof of the second claim of Theorem 2.3, that there exists a particular finite automaton with two counters for which the problem *does the computation starting from a fixed beginning state s_b, given first counter, and empty second counter, reach the configuration of some fixed final state s_f and empty counters* is undecidable. First observe that there exists an automaton as required but with three counters: it is a universal Turing machine with the contents of the part of the tape left of the head remembered on one counter, right on the head on the second counter, and with an auxiliary third counter needed for operating the first two. Then use the standard techniques to encode the three counters as two. See [13] for details.

Convention 2.4. *Now we consider only Conway functions g_n (for $n = 1, 2 \dots$), whose existence was proved in Theorem* 2.3(1). *In particular we assume that the claims* (ii) *and* (iii) *from Theorem* 2.3(1) *hold.*

2.2. Achilles-Turtle machine. For a given Conway function g and given input N we will construct an Achilles-Turtle machine, which will compute the subsequent iterations of $g(N)$.

It is a variant of a multihead Turing Machine, with read-only tape. Each cell of the tape is colored with one of the colors K_0, K_1,$\dots K_{p-1}$, (where p is as in the definition of the function g). If the cell X is colored with the color K_i (we denote the fact as $K_i(X)$) and the cell $S(X)$ (S is a successor function on the tape) is coloured with K_j then $j - i \equiv 1 \pmod{p}$. The color K_0 will be called *white* and K_1 will be called *red.*

There are three heads. The first is called Achilles, the second is called the Turtle, and the third is called Guide. The transition rules will be designed in such a way, that the heads will never go left. Achilles and Guide will move right in each step of the computation. Achilles will try to catch the Turtle.

The configuration of the machine is described by the positions of the heads. In the beginning of the computation, Achilles is in some arbitrary white cell X on the tape. The Turtle and Guide are both in the cell $S^N(X)$. So the beginning configuration is $CON(X, S^N(X), S^N(X))$, where again S is the successor function on the tape. The idea is that the computation can reach a configuration of a form $CON(Y, S^k(Y), S^k(Y))$ or Achilles can be exactly k cells behind the Turtle, if $g^i(N) = k$ for some i.

In each computation step the heads of the machine move according to one of the following transition rules ($i = 0, 1, \dots, p-1$):
(R_i) $CON(S^p(A), T, S^{p(a_i/q_i)}(G)) \Leftarrow CON(A, T, G), K_i(T),$

(J_i) $CON(S^p(A), S^{d_i}(G), S^{d_i}(G)) \Leftarrow CON(A, S^i(A), G)$.
where $d_i = i(a_i/q_i) + p - i$. Notice that, since $a_i/q_i < 2$ and $i < p$ also $0 < d_i < 2p$.

Rules (R_i) are *run rules* and rules (J_i) are *jump rules.* Configurations of the form $CON(A, T, T)$ are called *special*.

See section 2.3 for a nice example of the Achilles-Turtle machine. The following easy lemma gives an intuition of how the computation of the machine proceeds.

LEMMA 2.5. (i) *If, in some configuration of the machine, the Turtle is in the cell X and the Guide is in Y, then $Y = S^k(X)$ for some $k \geq 0$.*

(ii) *If, in some configuration of the machine, the Turtle is in the cell X and Achilles is in some $S^k(X)$, where $0 < k$, then none of the jump rules will be used later in the computation.*

(iii) *Suppose that in some configuration of the machine, Achilles is in some cell X, Turtle is in some $S^t(X)$, and the Guide is in $S^r(X)$. If one of the jump rules can be used later, then $0 \leq t \leq r$.*

(iv) *A special configuration can only be a result of a transition done according to one of the jump rules.*

(v) *Achilles is always in a white cell.*

(vi) *If in some configuration of the machine the Guide is in the cell X, then in the next configuration he will be in $S^r(X)$ for some $0 < r \leq 2p$*

Proof. (i) The claim is true for the beginning configuration and for every configuration being a result of a use of a jump rule. The run rules move the Guide right and keep the Turtle in his cell.

(ii) If Achilles is right of the Turtle, then the jump rule cannot be used. But the run rules move Achilles only right.

(iii) This rule follows from (i) and (ii).

(iv) By (i) the Guide can never be left of the Turtle. The run rules move him right, so after the execution of a run rule he is right of the Turtle.

(v) He starts in a white cell and moves p cells right in each step.

(vi) Since $0 < p(a_i/q_i) < 2p$ and $0 < d_i < 2p$ hold for every i (see Convention 2.4). ◻

Now we will formulate and prove some lemmas about the equivalence between the behavior of the Conway function and the result of the computation of the Achilles-Turtle machine. Our goal is as follows.

LEMMA 2.6. *The following conditions are equivalent:*

(i) *$C(g, N)$ holds.*

(ii) *The Achilles-Turtle machine can reach a configuration of form $CON(A, T, T)$, where $K_1(T)$.*

(iii) *The Achilles-Turtle machine can reach a configuration of form $CON(A, S(A), S(A))$.*

(iv) *The Achilles-Turtle machine can reach a configuration of form $CON(A, T, G)$, where $K_1(T)$.*

LEMMA 2.7. *Suppose in some special configuration of the machine, Achilles is in some cell A, and Turtle and Guide are in some $T = S^{kp+i}(A)$, where $0 < i < p$ (so $K_i(T)$). Then*

(i) *after k steps the configuration will be $CON(S^{-i}(T), T, S^{kp(a_i/q_i)}(T))$,*

(ii) *there are exactly two configurations that can be reached after $k+1$ steps: $CON(S^{p-i}(T), T, S^{(k+1)p(a_i/q_i)}(T))$ and $CON(S^{p-i}(T), S^{d_i+kp(a_i/q_i)}(T), S^{d_i+kp(a_i/q_i)}(T))$.*

Proof. (i) Each of the k steps will be done according to the rule R_i. So after k steps Achilles will be in the cell $S^{kp}(A) = S^{-i}(T)$, Guide will be in $S^{kp(a_i/q_i)}(T)$, and the Turtle in T.

(ii) By (i), $CON(S^{-i}(T), T, S^{kp(a_i/q_i)}(T))$ is reached after k steps. Then rule R_i may be used once again, which leads to $CON(S^{p-i}(T), T, S^{(k+1)p(a_i/q_i)}(T))$. Also the rule J_i may be used, which leads to $CON(S^{p-i}(T), S^{d_i+kp(a_i/q_i)}(T), S^{d_i+kp(a_i/q_i)}(T))$. ∎

Lemma 2.8. *Suppose in some special configuration of the machine Achilles is in the cell A, and Turtle and Guide are in some $T = S^m(A)$, where $m = kp + i$, $0 \le i < p$. Then the following two conditions are equivalent:*

(i) *it is possible to reach a special configuration $CON(X, S^l(X), S^l(X))$ as the next special configuration,*

(ii) $l = g(m)$.

Proof. By Lemma 2.7(ii) the configuration after $k+1$ steps will be either $CON(S^{p-i}(T), T, S^{(k+1)p(a_i/q_i)}(T))$ or $CON(S^{p-i}(T), S^{d_i+kp(a_i/q_i)}(T), S^{d_i+kp(a_i/q_i)}(T))$.

In the first case Achilles will be already right of the Turtle and, by Lemma 2.5 (ii), (iv), a special configuration will no longer be reached.

To prove the equivalence we show that the configuration reached in the second case is just of the form $CON(X, S^{g(m)}(X), S^{g(m)}(X))$.

In fact,

$$\begin{aligned}
&CON(S^{p-i}(T), S^{d_i+kp(a_i/q_i)}(T), S^{d_i+kp(a_i/q_i)}(T))\\
&= CON(S^{p-i}(T), S^{d_i+kp(a_i/q_i)-p+i}S^{p-i}(T), S^{d_i+kp(a_i/q_i)-p+i}S^{p-i}(T))\\
&= CON(X, S^{d_i+kp(a_i/q_i)-p+i}(X), S^{d_i+kp(a_i/q_i)-p+i}(X))\\
&= CON(X, S^{i(a_i/q_i)+p-i+kp(a_i/q_i)-p+i}(X), S^{i(a_i/q_i)+p-i+kp(a_i/q_i)-i+p}(X))\\
&= CON(X, S^{(i+kp)(a_i/q_i)}(X), S^{(i+kp)(a_i/q_i)}(X))\\
&= CON(X, S^{g(m)}(X), S^{g(m)}(X)). \qquad ∎
\end{aligned}$$

Lemma 2.9. *The following two conditions are equivalent:*

(i) *The Achilles-Turtle machine can reach a configuration of the form $CON(X, S^l(X), S^l(X))$.*

(ii) *There exists a natural number j such that $g^j(N) = l$.*

Proof. The (i)⇒(ii) implication is proved by induction on the number of special configurations reached during the computation.

The (ii)⇒(i) implication is proved by induction on j.

In both cases Lemma 2.8 is used for the induction step. ∎

Proof of Lemma 2.6. (i), (ii), and (iii) are equivalent by Lemma 2.9 and Convention 2.4 (claim (iii) of Theorem 2.3(i)). Clearly, (ii) implies (iv). Also (iv) implies (ii): if a configuration $CON(A, T, G)$ is reached after some number of steps, and $K_1(T)$ holds, then consider the configuration after the last step of the computation which was done according to a jump rule (the last step when the Turtle was moved). This configuration is $CON(A', T, T)$ for some A'. ∎

2.3. Achilles-Turtle machine. An example. In order to give the reader an idea of how the machine works we are going to provide a nice example of a Conway function (or rather Conway-like function) and of the Achilles-Turtle machine built for this function. The function g that we start from will be the well-known Collatz function. Take a natural number: if it is even then divide it by two, if it is odd then multiply it by three and add one. The problem if the iterations of the procedure give finally the result 1, regardless of the natural number that we start from, is open. More formally, in the spirit of Definition 2.1 we can define function g as

$$g(n) = \begin{cases} n/2 & (n \equiv 0 \pmod 2), \\ 3n+1 & (n \equiv 1 \pmod 2), \end{cases}$$

and the open problem is then whether

$$\{N : C(g,N)\} = \mathcal{N}.$$

We do not only multiply the number, but also add 1, so this is not really a Conway function in the sense of Definition 2.1, but we find this example to be interesting nonetheless. We can and will construct our Achilles-Turtle machine for the following function.

The rules of the Example Achilles-Turtle machine
initial configuration: $CON(X, S^N(X), S^N(X)) : -WHITE(X).$

transition rules:

run rules:

$CON(S^2(A), T, S^6(G)) : -CON(A, T, G), RED(T).$

$CON(S^2(A), T, S(G)) : -CON(A, T, G), WHITE(T).$

jump rules:

$CON(S^2(A), S^5(G), S^5(G)) : -CON(A, S(A), G), RED(S(A)).$

$CON(S^2(A), S^2(G), S^2(G)) : -CON(A, A, G), WHITE(A).$

final configuration: $CON(X, S(X), S(X)).$

The coefficients in run rules and in the *white* jump rule are here calculated according to the definitions of (R_i) and (J_i) from the beginning of section 2.2. The left-hand side of the *red* jump rule is not $CON(S^2(A), S^4(G), S^4(G))$, as would follow from the definition: this is the place where we add 1 to form the $3n+1$.

Now suppose, for concreteness of the example, that N is 5. Then the subsequent iterations of g are 5, 16, 8, 4, 2, 1. The beginning configuration of the machine will be then $CON(A, S^5(A), S^5(A))$ for some white cell A and the computation sequence of the machine is as follows:
$CON(S^2(X), S^5(X), S^{11}(X))$ (RR⋆),
$CON(S^4(X), S^5(X), S^{17}(X))$ (RR⋆),
$CON(S^6(X), S^{22}(X), S^{22}(X))$ (RJ⋆),
$CON(S^8(X), S^{22}(X), S^{23}(X))$ (WR⋆),
$CON(S^{10}(X), S^{22}(X), S^{24}(X))$ (WR),
$CON(S^{12}(X), S^{22}(X), S^{25}(X))$ (WR),
$CON(S^{14}(X), S^{22}(X), S^{26}(X))$ (WR),
$CON(S^{16}(X), S^{22}(X), S^{27}(X))$ (WR),
$CON(S^{18}(X), S^{22}(X), S^{28}(X))$ (WR),
$CON(S^{20}(X), S^{22}(X), S^{29}(X))$ (WR),
$CON(S^{24}(X), S^{32}(X), S^{32}(X))$ (WJ),
$CON(S^{26}(X), S^{32}(X), S^{33}(X))$ (WR),
$CON(S^{28}(X), S^{32}(X), S^{34}(X))$ (WR),
$CON(S^{30}(X), S^{32}(X), S^{35}(X))$ (WR),
$CON(S^{32}(X), S^{32}(X), S^{36}(X))$ (WR),
$CON(S^{34}(X), S^{38}(X), S^{38}(X))$ (WJ),
$CON(S^{36}(X), S^{38}(X), S^{39}(X))$ (WR),
$CON(S^{38}(X), S^{38}(X), S^{40}(X))$ (WR),
$CON(S^{40}(X), S^{42}(X), S^{42}(X))$ (WJ),
$CON(S^{42}(X), S^{42}(X), S^{43}(X))$ (WR),

$CON(S^{22}(X), S^{22}(X), S^{30}(X))$ (WR),

where RR means that red run rule was used to obtain the configuration, WR is white run rule, RJ red jump rule, and WJ is white jump rule. The configurations marked with $\star$ are depicted below (see Figure 2.1).

3. Ternary programs.

3.1. The ternary linear program $\mathcal{P}$.

Theorem 3.1. *For each Conway function g_n from Theorem* 2.3(i) *there exists, and can be efficiently constructed, an arity* 3 *linear DATALOG program $\mathcal{P}$ with one IDB predicate which is uniformly bounded if and only if $C(g_n, 2)$ holds.*

The signature of the program contains one binary EDB symbol S, which is going to serve as a kind of order for us, p monadic EDB symbols which will play as the colors and a ternary IDB symbol CON. The program $\mathcal{P}$ consists of the following.

Transition rules (for each i, $0 \le i \le p-1$)**:**

$CON(S^p(A), T, S^{p(a_i/q_i)}(G),){:\!-}\ CON(A, T, G), K_i(T), K_0(A), \ldots, K_{p-1}(S^{p-1}(A)).$

$CON(S^p(A), S^{d_i}(G), S^{d_i}(G)){:\!-}\ CON(A, S^i(A), G), K_0(A), \ldots, K_{p-1}(S^{p-1}(A)).$

Flooding rule: $CON(X, Y, Z){:\!-}CON(S, T, R), K_1(T).$

Initialization: $CON(A, S^2(A), S^2(A)){:\!-}K_0(A), K_1(S(A)), K_2(S^2(A)).$

K_m is understood as K_i if $m \equiv i \pmod p$. Since S is no longer a true successor we must explain the meaning of the S^l symbols in the rules.

Notational Convention: (for example) a rule

$CON(S^2(X), S^4(Y), S(X)){:\!-}CON(X, S(X), Y)$

should be understood as

$CON(X2, Y4, X1)$
 ${:\!-}CON(X, X1, Y),$
 $S(Y, Y1), S(Y1, Y2), S(Y2, Y3), S(Y3, Y4), S(X, X1), S(X1, X2).$

Let us explain the meaning of the rules: The transition rules are the same as in the Achilles-Turtle machine, with the exception that they check if the cells (nodes) that Achilles runs over are painted properly. The flooding rule proves everything in one step if Turtle is in a red node. The initialization allows us to start the computation in each (white) node, if there is a properly colored piece of tape near the node.

Lemma 3.2. *If $C(g_n, 2)$ does not hold, then for each c there exists a database $\mathcal{D}$ and a tuple A, T, G of elements of $\mathcal{D}$ such that $CON(A, T, G)$ can be proved in $\mathcal{D}$ with P and the proof of $CON(A, T, G)$ requires more than c steps.*

Proof. $\mathcal{D}$ is just a long enough S-chain (see Definition 3.4 below) with empty IDB relation. First we prove that the flooding rule can not be used in such a database, provided that $C(g_n, 2)$ does not hold. Suppose it can be used. That means that $CON(A, T, G)$ can be proved for some red T. If we follow the proof of $CON(A, T, G)$ in $\mathcal{D}$ we will notice that it gives a legal computation of the Achilles-Turtle machine and that the first fact in the proof is the beginning configuration of the machine. That is a contradiction by Lemma 2.6. Now, take the first element Z of the order. By initialization we have $CON(Z, S^2(Z), S^2(Z))$. Using 2c times the run rule 2 we get the shortest proof of the fact $CON(S^{2pc}(Z), S^2(Z), S^{2+2cp(a_2/q_2)}(Z))$. ∎

Now we are going to prove the following lemma.

Lemma 3.3. *If $C(g_n, 2)$ holds, then there exists c such that, in any database $\mathcal{D}$, for every tuple A, B, C of elements of $\mathcal{D}$ if $CON(A, B, C)$ can be proved in $\mathcal{D}$ with* *the program P, then there exists a proof of $CON(A, B, C)$ shorter than c steps.*

Proof. Suppose $C(g_n, 2)$ holds. That means that if we start the computation of the Achilles-Turtle machine in a configuration $CON(X, S^2(X), S^2(X))$, then it is possible to reach a final configuration $CON(A, S(A), S(A))$.

Notice, that during the computation, none of the heads will move left of X or right of $S(A)$. Let K be the distance between X and $S(A)$ and let K' be the number of steps of the computation necessary to reach the final configuration. Clearly $pK' + 1 = K$. We are going to prove that $c = K' + 2$ is the proper constant.

We will need some definitions.

Definition 3.4. *An S-chain of elements of a database $\mathcal{D}$ is a set $X_0, X_1, \dots, X_k$ such that $S(X_m, X_{m+1})$ and $K_m(X_m)$ for $m = 0, 1, \dots, k$. A decreasing S-chain of elements of the database $\mathcal{D}$ is a set $X_0, X_1, X_2, \dots, X_k$ such that $S(X_{m+1}, X_m)$ and $K_m(X_m)$ for $m = 0, 1, \dots, k$ (where K_m should be understood as K_i if $m \equiv i \pmod p$). In both cases we say that the chain begins in X_0.*

Definition 3.5. *Let k be a natural number. We say that a node W of a database $\mathcal{D}$ is not k-founded if there exists a decreasing S-chain which begins in W and consists of more than k elements. W is k-founded if such a chain does not exist.*

Definition 3.6. *Let k be a natural number. We say that a database $\mathcal{D}$ is not k-founded if there exists an S-chain consisting of more than k elements.*

Obviously, $\mathcal{D}$ is k-founded if such a chain does not exist.

Now we consider 2 cases.

Lemma 3.7. *If $\mathcal{D}$ is not K-founded, then for each tuple A, B, C of elements of $\mathcal{D}$ the fact $CON(A, B, C)$ can be proved and the proof requires no more than $K' + 2$ steps.*

Proof. Take X such that there exists an S-chain of length K beginning in X. Thanks to the initialization rule $CON(X, S^2(X), S^2(X))$ is provable in $\mathcal{D}$ and has a proof of length 1. Now we can pretend that the chain from X to $S^K(X)$ is a tape and start a computation of the Achilles-Turtle machine. Since the transition rules of the machine are rules of program $\mathcal{P}$, each step of the computation can be encoded by one step of proof. So there exists an element T of the chain such that $S(T)$ is red, and $CON(T, S(T), S(T))$ can be proved after K'+1 steps. One more step (using flooding) is needed to prove CON of every tuple after that. □

Lemma 3.8. *Let $\mathcal{D}$ be a K-founded database.*

(i) *Suppose $\{CON(A_i, T_i, B_i)\}_{i=0}^m$ is a $\mathcal{P}$-proof in $\mathcal{D}$. If the flooding rule is not used in the proof then $m \leq K'$.*

(ii) *Let $\{CON(A_i, T_i, B_i)\}_{i=0}^m$ be a $\mathcal{P}$-proof in $\mathcal{D}$, and suppose it is the shortest possible proof of $CON(A_m, B_m, C_m)$. Then the flooding rule is used at most once, for the last step of the proof.*

(iii) *If $CON(A, B, C)$ can be $\mathcal{P}$-proved in $\mathcal{D}$ for some tuple A, B, C, the proof requires no more than $K' + 1$ steps.*

Proof. (i) The set A_i, $(i = 1 \dots m)$ is a subsequence of an S-chain of length pm.

(ii) Suppose that the step from $CON(A_i, T_i, B_i)$ to $CON(A_{i+1}, T_{i+1}, B_{i+1})$ for some $i \neq m - 1$ is done according to the flooding rule. Then

$CON(A_0, T_0, B_0), CON(A_1, T_1, B_1), \dots CON(A_i, T_i, B_i), CON(A_m, T_m, B_m)$

is a shorter proof of $CON(A_m, T_m, B_m)$.

(iii) It follows from (i) and (ii). □

This ends the proof of Lemma 3.3 and of Theorem 3.1. □

Theorem 3.9. *Uniform boundedness of ternary linear DATALOG programs is undecidable.*

Proof. This follows from Theorems 2.2 and 3.1. ◻

3.2. The arity 5 single recursive rule program $\mathcal{R}$.

THEOREM 3.10. *For each Conway function g_n from Theorem 2.3(i) there exists, and can be efficiently constructed, an arity 5 DATALOG program $\mathcal{R}$ consisting of one quasi-linear recursive rule and of some initializations, which is uniformly bounded if and only if $C(g_n, 2)$ holds.*

As in the previous subsection the signature of the program contains one binary EDB symbol S, which is going to serve as a kind of order for us, p monadic EDB symbols which will play as the colours and a ternary IDB symbol CON. There is also additional IDB symbol $STEER$ of arity 5. The program $\mathcal{R}$ consists of the following.

The recursive rule:
$CON(S^p(A), T', G')$:–
$CON(A, T, G)$,
$STEER(A, T, G, T', G')$,
$K_0(A), K_1(S(A)), \dots K_{p-1}(S^{p-1}(A)), K_0(S^p(A))$.

Initialization "transition" rules (for each i, $0 \le i \le p-1$)**:**

$STEER(A, T, G, T, S^{p(a_i/q_i)}(G))$:–$K_i(T)$.

$STEER(A, S^i(A), G, S^{d_i}(G), S^{d_i}(G))$:–$K_i(S^i(A))$.

The initialization "flooding" rule: $STEER(X, T, Y, R, S)$:–$K_1(T)$.
The initialization: $CON(A, S^2(A), S^2(A))$:–$K_0(A), K_1(S(A)), K_2(S^2(A))$.

Let us explain what is going on here: The triples (Achilles, Turtle, Guide) are nodes of a graph defined on $\mathcal{D}^3$ by means of order and coloring. Each proof, either from program $\mathcal{P}$ or from $\mathcal{R}$, is a path in the graph. The graph is not given by the EDB relations but can be defined from them by a DATALOG program without recursion. If we want to define the vertices beginning in a node A, T, G "online," when the computation reaches the node (as in $\mathcal{P}$), then we must use more than only one rule, but the rules are linear: they read nothing more than the information about the EDB situation around. If we define the graph in advance (by initializations), then one recursive rule is enough: we have a "graph accessibility" program in this case. But the rule is only "quasi-linear": it makes use of the additional IDB (but not recursive) predicate $STEER$. If I were the reader I would ask a question here: why is the $STEER$ predicate not of arity 6? Why do not we want to hide the rule for Achilles in the initializations and have a simpler recursive clause? In fact, some additional problems arise here, since we do not have a flooding rule for Achilles. We were forced to design the recursive rule in this way because of the uniformity reasons. It is crucial that Achilles goes down the chains. Thanks to that we can say: no long chains, no long proofs (Lemmas 3.8 and 3.12, case 1). We could write the initializations of the hypothetical 6-ary $STEER$ in such a way that Achilles would move only down the chains while running according to the $STEER$ facts proved by the initializations. But we would have no control of what is given as the $STEER$ at the beginning.

LEMMA 3.11. *If $C(g_n, 2)$ does not hold, then for each c there exists a database $\mathcal{D}$ and a tuple A, B, C of elements of $\mathcal{D}$ such that $CON(A, B, C)$ can be proved in $\mathcal{D}$ with a program $\mathcal{R}$, and the proof of $C(A, B, C)$ requires more than c steps.*

Proof. The proof is the same as that for Lemma 3.2. ◻

LEMMA 3.12. *If $C(g_n, 2)$ holds, then there exists a c such that, in every database $\mathcal{D}$, for every tuple A, B, C of elements of $\mathcal{D}$, if $CON(A, B, C)$ can be proved in $\mathcal{D}$ with $\mathcal{R}$, then there exists a proof of $CON(A, B, C)$ shorter than of c steps.*

DEFINITION 3.13. *If A, B, C is a tuple of elements of the database $\mathcal{D}$, then we say that $CON(A, B, C)$ is a fact about A.*

Proof of Lemma 3.12. Suppose $C(g_n, 2)$ holds. Then there is a computation of the Achilles-Turtle machine starting in some configuration $CON(X, S^2(X), S^2(X))$ and reaching $CON(Y, S(Y), S(Y))$. The computation requires space kp (that is the distance from X to Y is kp) for some natural k. We will consider two cases.

Case 1. A is $(k+1)p$-founded. Then every proof of a fact about A is no longer than $k+1$. That is because of the Achilles' part in the recursive rule. This is analogous to Lemma 3.8(i).

Case 2. C is not $(k+1)p$-founded.

So take V such that $A = S^{(k+1)p}(V)$ and there is a chain of length $(k+1)p$ from V to A. Because of the initialization rule $CON(V, S^2(V), S^2(V))$ is provable in $\mathcal{D}$ and has a proof of length 1. Now we can pretend that the chain from V to $S^{kp+1}(V)$ is a tape and let Achilles and Turtle play their game there. Among other rules possibly given by the predicate $STEER$ they have also the "standard" Achilles-Turtle machine rules. So, after k moves the configuration $CON(S^{kp}(V), S^{kp+1}(V), S^{kp+1}(V))$ will be reached and we will be allowed to use the flooding. Every fact of the form $CON(A, B, C)$ will be proved in one step. So no new facts about A can be proved later. Of course nothing new about the IDB predicate $STEER$ can be proved after the first step.

This ends the proof of Lemma 3.12 and of Theorem 3.10. □

3.3. The ternary single recursive rule program $\mathcal{Q}$.

THEOREM 3.14. *For each Conway function g_n from Theorem* 2.3(i) *there exists, and can be efficiently constructed, an arity* 3 *DATALOG program $\mathcal{Q}$ consisting of one quasi-linear recursive rule and of some initializations, which is uniformly bounded if and only if $C(g_n, 2)$ holds.*

Similarly, as in the previous subsection the signature of the program contains one binary EDB symbol S, which is going to serve as a kind of order for us, p monadic EDB symbols which will play as colors, and a ternary IDB symbol CON. The graph which was defined by a arity 5 relation in the previous section will be defined here as an intersection of four graphs defined by ternary constraints. So, we will have four additional ternary IDB symbols $E_{G,T,T'}$, $E_{A,T,T'}$, $E_{T,G,G'}$, and $E_{T,T',G'}$ in the language of the program. The rules of the program Q are as follows.

The recursive rule:

$CON(S^p(A), T', G')$:–
$CON(A, T, G)$,
$E_{G,T,T'}(G, T, T'), E_{A,T,T'}(A, T, T'), E_{T,G,G'}(T, G, G'), E_{T,T',G'}(T, T', G')$,
$K_0(A), K_1(S(A)), \dots K_{p-1}(S^{p-1}(A)), K_0(S^p(A)), K_1(S^{p+1}(A))$.

The initialization "constraints" rules:

$E_{G,T,T'}(G, T, T)$.

For each i $(0 \le i \le p-1)$ there is a rule : $E_{G,T,T'}(G, T, S^{d_i}(G))$:–$K_i(T)$.

$E_{G,T,T'}(G, T, T')$:–$K_1(T)$.

$$E_{A,T,T'}(A,T,T).$$

For each i $(0 \leq i \leq p-1)$ there is a rule : $E_{A,T,T'}(A,S^i(A),T').$

$$E_{A,T,T'}(A,T,T'):–K_1(T).$$

For each i $(0 \leq i \leq p-1)$ there is a rule : $E_{T',G,G'}(S^{d_i}(G),G,S^{d_i}(G)).$

For each i $(0 \leq i \leq p-1)$ there is a rule : $E_{T',G,G'}(T',G,S^{p(a_i/q_i)}(G)):–K_i(T).$

$$E_{T',G,G'}(T',G,G'):–K_1(T).$$

$$E_{T,T',G'}(T,T,G').$$

$$E_{T,T',G'}(T,T',T').$$

$$E_{T,T',G'}(T,T',G'):–K_1(T).$$

The initialization:

$CON(A,S^2(A),S^2(A)):–\ K_0(A),K_1(S(A))K_2(S^2(A)).$

To prove the correctness of the construction we shall argue that the ternary relations really define the same graph as the relation $STEER$ of the last section. It is easy to notice that if $STEER(A,T,G,T',G')$ can be proved by one of the initializations of $\mathcal{R}$, then $E_{G,T,T'}(G,T,T')$, $E_{A,T,T'}(A,T,T')$, $E_{T',G,G'}(T',G,G')$, and $E_{T,T',G'}(T,T',G)$ can also be proved. For the opposite inclusion, suppose that T is not red. We first consider the relation $E_{G,T,T'}$. Since the Guide "does not see" how far from each other Achilles and Guide are, the constraint allows the Turtle to stay in the same place or to jump according to the proper jump rule. It is the relation $E_{A,T,T'}$ that decides if the Turtle will be allowed to jump. If Achilles is far away, then the Turtle can only wait. If Achilles is about to catch the Turtle, then the Turtle is allowed to jump (see [1]) anywhere. But, because of the relation $E_{G,T,T'}$, this "anywhere" can be only $S^{d_i}(G)$ for the proper i. In this way, already the first two relations force the Turtle to behave as he should.

The relation $E_{T',G,G'}$ forces the Guide to move ahead. It allows the Guide to execute his jump rule but only if the Turtle jumps together with him (this prevents the danger that the Guide jumps while the Turtle runs). Whatever the Turtle is doing, the Guide is allowed to use his proper run rule. There is a danger here that Turtle will jump, and the Guide will only run, which is not allowed by the Achilles–Turtle machine rules. That is prevented by the relation $E_{T,T',G'}$: if Turtle remains in the same place then the Guide is allowed to go anywhere. But if he moves, then the Guide must join him.

If T is red, then the constraints allow the Guide and Turtle to go anywhere.

THEOREM 3.15. *Uniform boundedness of single recursive rule ternary DATALOG programs is undecidable.*

Proof. It follows from Theorems 2.3(1) and 3.14. □

Remark. We could use Theorem 2.3(2) instead of 2.3(1) and get more "universal" DATALOG programs. For example Theorem 3.1 would then have the following form.

There exists an arity 3 *linear DATALOG program* $\mathcal{P}$ *with one IDB predicate and a computable sequence* $\{p(N)\}$ *of initialization rules, such that the program* $\mathcal{P} \cup p(N)$ *is uniformly bounded if and only if* $C(g, n)$ *holds, where* g *is the universal Conway function from Theorem* 2.3(2).

In fact this is the form from [15]. It can not however be done in section 4, so we decided not to present the results in the most general versions but to preserve the notational uniformity instead.

4. Single rule programs.

4.1. Constants: Notational proviso. In sections 4.2–4.5 we are going to encode the computation of Achilles-Turtle machine into a very small number of rules (one or two). We can no longer afford having a separate predicate for each color. Instead, we are going to have one binary predicate COL, and understand COL(C,A) as "the color of A is C." So, instead of predicates we need to have constants to name colors.

There are no constants in DATALOG. But in fact, if we want to use some (say, k) constants we can simply increase the arity of all the IDB symbols with k and write a sequence $C_1, C_2, \ldots, C_k$ of variables as the k last arguments in each occurrence of each IDB predicate in the program. This is one of the reasons why the programs in the following sections are of high arity.

Example. The program

$$P(X,Y) \text{:-}\ P(X,Z), P(Z,Y), P(a,X), P(b,Z),$$

with constants a, b can be written as

$$P'(X,Y,A,B) \text{:-}\ P'(X,Z,A,B), P'(Z,Y,A,B), P'(A,X,A,B), P'(B,Z,A,B),$$

where $P'(X,Y,A,B)$ means "$P(X,Y)$ if the constants are understood as A, B."

Thanks to that we can suppose that there are constants in the language. We will use the constants *jump*, *run*, *joker* and constants for colours $colour_i$, for $i = 1 \ldots p{-}1$. The constant $colour_0$ will be also called *white*, $colour_1$ will be *red*, and $colour_2$ will be called *pink*.

4.2. The Achilles-Turtle game. In this section we will modify the description of the Achilles-Turtle machine and define its equivalent version with only one transition rule. To make our notation compatible with the database notation we are going to forget about the tape, and use a kind of infinite graph instead. To distinguish between the two, the version of the machine will be called the Achilles-Turtle game.

The transition rules of the Achilles-Turtle machine are indexed with three parameters: the first is either *jump* or *run*, the remaining two are the colors of the Turtle's cell and the Guide's cell before the transition. The idea of what follows is to treat the parameters as arguments occurring in the goals of the body of the single rule. While solving the first four goals of the body we will substitute proper parameters for the variables COND, TCOLOR, and GCOLOR. Then the parameters will be used to compute the positions of Achilles, Turtle, and Guide after the execution of the rule.

The following definition introduces the predicates that will be used in the construction of the single rule. We do not expect that the reader will understand the definition until he reads the proof of Lemma 4.2.

DEFINITION 4.1. *For a given Conway function g, as in Theorem 2.3(1) the Achilles–Turtle graph is the relational structure $\mathcal{G}$ with exactly the nodes and the relations listed below:*

(i) *the nodes of $\mathcal{G}$ are: $colour_0, colour_1, \ldots colour_{p-1}$, jump, run, joker and an infinite sequence of nodes $c_0, c_1, c_2, \ldots$;*

(ii) *$S(c_i, c_{i+1})$ holds for each node c_i;*

(iii) *for each i if $i \equiv j \pmod p$ (where $j \leq p-1$) then $COL(colour_j, c_i)$ holds. $COL(red, joker)$ holds;*

(iv) *$COND_1(run, c_i, joker)$ holds for each i;*
$COND_1(jump, c_i, c_{i+j})$ holds for each $i \equiv 0 \pmod p$ and for each $0 \leq j \leq p-1$;

(v) *$COND_2(run, joker, c_i)$ holds for each i;*
$COND_2(jump, c_i, c_i)$ holds for each i,
$COND_2(run, joker, joker)$ holds;

(vi) *$GRULE_1(run, colour_j, colour_k, c_i, c_{i+a_j/q_j})$ holds if $i \equiv k \pmod p$ and $p(a_j/q_j) < p-k$,*
$GRULE_1(run, colour_j, colour_k, c_i, c_{i+p-k})$ holds if $i \equiv k \pmod p$ and $p(a_j/q_j) \geq p-k$,
$GRULE_1(jump, colour_j, colour_k, c_i, c_{i+d_j})$ holds if $i \equiv k \pmod p$ and $d_j < p-k$,
$GRULE_1(jump, colour_j, colour_k, c_i, c_{i+p-k})$ holds if $i \equiv k \pmod p$ and $d_j \geq p-k$,
$GRULE_1(run, red, colour_k, c_i, joker)$ holds for all $i \equiv k \pmod p$,
$GRULE_1(jump, red, colour_k, c_i, joker)$ holds for all $i \equiv k \pmod p$,

(vii) *$GRULE_2(run, colour_j, colour_k, c_i, c_i)$ holds if $p(a_j/q_j) < p-k$,*
$GRULE_2(run, colour_j, colour_k, c_i, c_{i+p(a_j/q_j)-p+k})$
holds if $i \equiv 0 \pmod p$, $p(a_j/q_j \geq p-k$ but $p(a_j/q_j) < 2p-k$,
$GRULE_2(run, colour_j, colour_k, c_i, c_{i+p})$ holds if $i \equiv 0 \pmod p$, $p(a_j/q_j) \geq 2p-k$,
$GRULE_2(jump, colour_j, colour_k, c_i, c_i)$ holds if $k + d_j < p$,
$GRULE_2(jump, colour_j, colour_k, c_i, c_{i+d_j-p+k})$ holds if $i \equiv 0 \pmod p$, $d_j \geq p-k$ but $d_j < 2p-k$,
$GRULE_2(jump, colour_j, colour_k, c_i, c_{i+p})$ holds if $i \equiv 0 \pmod p$, $d_j \geq 2p-k$,
$GRULE_2(run, red, colour_k, joker, joker)$ holds for all k,
$GRULE_2(jump, red, colour_k, joker, joker)$ holds for all k,

(viii) *$GRULE_3(run, colour_j, colour_k, c_i, c_i)$ holds if $p(a_j/q_j) < 2p-k$,*
$GRULE_3(run, colour_j, colour_k, c_i, c_{i+p(a_j/q_j)-2p+k})$
holds if $i \equiv 0 \pmod p$, $p(a_j/q_j) \geq 2p-k$,
$GRULE_3(jump, colour_j, colour_k, c_i, c_i)$ holds if $d_j < 2p-k$,
$GRULE_3(jump, colour_j, colour_k, c_i, c_{i+d_j-2p+k})$
holds if $i \equiv 0 \pmod p$, $d_j \geq 2p-k$,
$GRULE_3(run, red, colour_k, joker, c_i)$ holds for all i,
$GRULE_3(jump, red, colour_k, joker, c_i)$ holds for all i,

(ix) *$TRULE(run, colour, c_i, c_i)$ holds for each i and for each colour,*
$TRULE(run, red, c_i, joker)$ holds for each i,
$TRULE(jump, colour, c_i, joker)$ holds for each i and for each colour,
$TRULE(run, red, joker, joker)$ holds,

(x) *$GTRULE(jump, c_i, c_i)$ holds for each i,*
$GTRULE(run, c_i, joker)$ holds for each i,
$GTRULE(run, joker, joker)$ holds.

The set of the nodes c_i, $i = 0, 1, \ldots$ of the graph can be in a natural way understood as a tape of Achilles-Turtle machine. Notice that all the facts from the definition are "local" in the sense that if some elements c_i and c_j are directly connected by a fact then $|j-i| \leq p$ and there is no white node between c_i and c_j .

Now we are going to use the relations of the Achilles-Turtle graph to encode all the rules of the machine in only one transition rule:
$CONF(A_p, T', G')$:–
$BODY$,
$S(A, A_1), S(A_1, A_2), \ldots S(A_{p-1}, A_p)$,
$CONF(A, T, G)$.

where $BODY$ is the conjunction of the following facts:

$COND_1(COND, A, X_0)$,
$COND_2(COND, X_0, T)$,
$COL(TCOLOR, T)$,
$COL(GCOLOR, G)$
$GRULE_1(COND, TCOLOR, GCOLOR, G, X_1)$,
$GRULE_2(COND, TCOLOR, GCOLOR, X_1, X_2)$,
$GRULE_3(COND, TCOLOR, GCOLOR, X_2, G')$,
$TRULE(COND, TCOLOR, T, X_3)$,
$TRULE(COND, TCOLOR, T', X_3)$,
$GTRULE(COND, G', X_4)$,
$GTRULE(COND, T', X_4)$.

LEMMA 4.2. *Suppose T is not red. Then $CON(A', T', G')$ can be computed from $CON(A, T, G)$ in a single computation step of the Achilles-Turtle machine if and only if $CONF(A', T', G')$ can be reached from $CONF(A, T, G)$ in a single step of the Achilles-Turtle graph game.*

Proof. It is clear that the move of Achilles is performed in the same way by the machine and the game (he simply moves p cells ahead). We should check that this is also the case with the Turtle and the Guide.

The "only if" direction is easier: if the transition of the machine has been done according to the *run* rule then substitute *run* for the variable $COND$. Otherwise substitute *jump*. For the variable $TCOLOR$ substitute the colour of the Turtle's cell. For the variable $GCOLOR$ substitute the colour of the Guide's cell. Now, if there is no white node between G and G', substitute $X_1 = X_2 = G'$. If there is exactly one such white node, then substitute the node for X_1 and $X_2 = G'$. If there are two such nodes, then substitute the first of them for X_1 and the second for X_2 (notice that by condition (ii) from Theorem 2.3(1) there are at most two white nodes between G and G'). The "GRULE" goals in the lines (v)–(vii) of the BODY are satisfied in this way. If $COND$ is *run*, then substitute T for X_3 (notice that in this case $T = T'$). If $COND$ is *jump*, then substitute *joker* for X_3. The two "TRULE" goals of the BODY are satisfied in this way. To satisfy the last two goals substitute *joker* for X_4 if the $COND$ is *run*, and if the $COND$ is *jump*, then substitute G' for X_4.

For the "if" direction first notice that if the conjunction of
$COND_1(jump, A, X_0)$,
$COND_2(jump, X_0, T)$,
can be satisfied, then really the distance between Achilles and the Turtle, before the transition, is smaller than p; jump is allowed according to the Achilles-Turtle machine

rules. The rules for the Guide (defined by claims (vi), (vii), and (viii) of Definition 4.1) ensure that if only COND, TCOLOR, and GCOLOR are chosen in a fair way, then the Guide of the game moves in the same way as the one from the machine. As for the Turtle, if the COND is *run*, then he should not move, and in fact the conjunction
$TRULE(run, TCOLOR, T, X_3)$,
$TRULE(run, TCOLOR, T', X_3)$
can be satisfied only if $T = T'$.

If the COND is *jump* then the Turtle should go to the same node where Guide does. The conjunction
$TRULE(jump, TCOLOR, T, X_3)$,
$TRULE(jump, TCOLOR, T', X_3)$
can be satisfied for every choice of T, T' then, if *joker* is substituted for X_3, but the conjunction
$GTRULE(jump, G', X_4)$,
$GTRULE(jump, T', X_4)$
is satisfied only if $X_4 = G' = T'$. □

The following lemma is much easier to prove than Lemma 4.2 and is left as an exercise for the reader.

LEMMA 4.3. *If c_t is red, then each configuration of the form $CONF(c_{i+p}, c_{t'}, c_{g'})$ can be reached from $CONF(c_i, c_t, c_g)$ in a single step of the graph game.*

Hint: Put $COND$ equal to *run* and $TCOLOR$ equal to *red*.

4.3. Single linear rule program with initialization. In this section we will use the Achilles-Turtle game to construct a DATALOG program with one linear recursive rule and one initialization, which is uniformly bounded if and only if $C(g, 2)$ holds.

The EDBs of the program will be the same as used in Definition 4.1.

It will be one ternary IDB CONFIG. The variables A, T, G in a fact of the form $CONFIG(A, T, G)$ should be, as usual, understood as Achilles, Turtle, and Guide.

Consider a database $\mathcal{D}$. We suppose that $colour_0, colour_1, \ldots, colour_{p-1}$, *jump*, *run* and *joker* occur in $\mathcal{D}$. A Motorway will be a sequence of elements of the database which can be used for playing the Achilles-Turtle game.

DEFINITION 4.4. *Suppose $X_0, X_1, \ldots, X_n$ are elements of $\mathcal{D}$. We say that the sequence $X_0, X_1, \ldots X_n$ is a Motorway if $\mathcal{G} \cap \{jump, run, joker, colour_0, colour_1, \ldots,$ $colour_{p-1}, c_0, c_1, \ldots, c_n\}$ is a subgraph of $\mathcal{D} \cap \{jump, run, joker, colour_0, colour_1, \ldots,$ $colour_{p-1}, X_0, X_1, \ldots, X_n\}$,*
where ordered sets of elements are considered. $\mathcal{G}$ is the database from Definition 4.1.

So, for example, we require that $S(X_3, X_4)$ and $COL(pink, X_3)$ hold in $\mathcal{D}$, if $X_0, X_1, \ldots X_n$ is a Motorway.

Now we are ready to write the following.

Linear recursive rule of program $\mathcal{T}$:
$CONFIG(A_p, T', G')$:–
$CONFIG(A, T, G)$,
Motorway$(A, A_1 \ldots A_p)$,
$BODY$,
$TRULE(run, red, T', joker)$,
$GRULE_3(run, red, colour_0, joker, G')$,
$GRULE_3(run, red, colour_1, joker, G')$,
...

$GRULE_3(run, red, colour_{p-1}, joker, G')$,
$GTRULE(run, G', joker)$,
$GTRULE(run, T', joker)$,

where Motorway$(A_, A_1, \ldots, A_p)$ is the conjunction of facts needed for the sequence $(A_, A_1, \ldots, A_p)$ to be a Motorway. Notice that the last $p+3$ lines the rule are exactly the literals of $BODY$ in which T' or G' occurs, with run substituted for $COND$ and red substituted for $TCOLOR$.

Initialization of program $\mathcal{T}$:

$CONFIG(A_0, A_2, A_2)$:–
$COL(white, A_0), S_(A_0, A_1), S(A_1, A_2)$.

Thanks to the last $p+3$ lines of the recursive rule, we can be sure that if the fact $CONFIG(A_p, T', G')$ can be proved in one step from $CONFIG(A, T, G)$, then it can also be proved in one step from each fact of the form $CONFIG(A, T'', G'')$ where T'' is red (see the proof of Lemma 4.8, case 1).

Our next goal is to show that if a long proof using the recursive rule is possible in some database $\mathcal{D}$, then there is a long Motorway in $\mathcal{D}$.

Lemma 4.5. *Consider a sequence: $A_0, A_1, A_2, \ldots, A_{xp}$ of elements of a database. If, for each $0 \leq k \leq x-1$ the subsequence $A_{kp}, A_{kp+1}, \ldots, A_{(k+1)p}$ is a Motorway, then also the whole sequence is a Motorway.*

Proof. Conditions (i)–(x) of Definition 4.1 are "local": if some elements c_i and c_j occur in a condition, then $|j-i| \leq p$ and there is no white node between c_i and c_j . □

Lemma 4.6. *Suppose that*
$CONFIG(A^0, T^0, G^0)$,
$CONFIG(A^1, T^1, G^1)$,
$CONFIG(A^2, T^2, G^2)$,
...

$CONFIG(A^l, T^l, G^l)$
is a sequence of facts, such that if $0 \leq i \leq l-1$, then
$CONFIG(A^{i+1}, T^{i+1}, G^{i+1})$
can be derived from $CONFIG(A^i, T^i, G^i)$ by a single use of the recursive rule. Then there exists a sequence
$A^0, A^0_1, \ldots A^0_{p-1}$,
$A^1, A^1_1, \ldots A^1_{p-1}$,
$A^2, A^2_1, \ldots A^2_{p-1}$,
...
$A^{l-1}, A^{l-1}_1, \ldots A^{l-1}_{p-1}, A^l$

of elements of the database which is a Motorway.

Proof. That follows from Lemma 4.5 and from the construction of the recursive rule. □

Definition 4.7. *If A, T, G is a tuple of nodes of the database $\mathcal{D}$, then we say that $CONFIG(A, T, G)$ is a fact about A.*

Now we are ready to prove that if $C(g, 2)$ holds then the program $\mathcal{T}$ is uniformly bounded.

LEMMA 4.8. *If $C(g,2)$ holds then there exists a constant C such that in every database $\mathcal{D}$ if the program $\mathcal{T}$ proves some fact, then the fact can be proved in no more than C derivation steps.*

Proof. If $C(g,2)$ holds then the Achilles-Turtle game can reach the configuration $CONF(X, S(X), S(X))$ for some white X. $S(X)$ is red then. Suppose the K moves are needed to reach this configuration. $X = S^{pK}(Y)$ for some Y then, and the nodes of the machine graph left of Y or right of $S(X)$ are not visited during the computation. We are going to prove that $K{+}2$ is a good candidate to be C.

Consider an element A of $\mathcal{D}$. There are two possibilities.

Case 1. There is a Motorway of length $(K+1)p$ in the database, such that A is its last node.

Suppose

$$A_{-(K+1)p}, A_{-(K+1)p+1}, \dots, A$$

is the Motorway. By the initialization rule

$$CONFIG(A_{-(K+1)p}, A_{-(K+1)p+2}, A_{-(K+1)p+2})$$

can be proved in one derivation step. During the next K derivation steps one can simulate K steps of Achilles-Turtle game, and so after $K{+}1$ steps we derive

$$CONFIG(A_{-p}, A_{-p+1}, A_{-p+1}).$$

Since A_{-p+1} is red one can argue as in the proof of Lemma 4.3, to see that in the next derivation step we can prove

$CONFIG(A, T', G')$

for each T' and each G' such that

$TRULE(run, red, T', joker)$,
$GRULE_3(run, red, colour_0, joker, G')$,
$GRULE_3(run, red, colour_1, joker, G)$,
...
$GRULE_3(run, red, colour_{p-1}, joker, G')$,
$GTRULE(run, G', joker)$,
$GTRULE(run, T', joker)$.

Because of the last $p+3$ lines of the recursive rule, no other facts can be proved about A.

Case 2. There is no such Motorway. Then, by Lemma 4.6, every proof has less than K+3 steps. □

We still need to show that if $C(g,2)$ does not hold, then the program is unbounded.

LEMMA 4.9. *If $C(g,2)$ does not hold, then for each constant C there exists a database $\mathcal{D}$, with empty input IDB relation, and a fact*

$$CONFIG(A, T, G)$$

which can be proved in the database but the proof requires more than C steps.

Proof. It's enough to show that arbitrarily long proofs are needed in the Achilles-Turtle game graph (we suppose that there are no IDB input facts). So start with

$$CONFIG(c_0, c_2, c_2)$$

(which can be done by initialization) and use $2C$ times the run rule for Turtle in a pink-colored cell. Notice that the position of the Turtle will remain unchanged during the computation and the final configuration will be

$$CONFIG(c_{2C}, c_2, c_{2+2C(a_2/q_2)}).$$

The shortest proof of the fact requires $2C+1$ steps (including initialization). □

To summarize, we have the following.

THEOREM 4.10. *Uniform boundedness and program boundedness are undecidable for programs consisting of one linear rule and one initialization.*

Proof. The problem *for given Conway function g, does $C(g, 2)$ hold?* is undecidable, even for functions satisfying conditions (ii) and (iii) of Theorem 2.3(1). For each such function we can construct a DATALOG program, with one linear rule and one initialization which is not program bounded if $C(g, 2)$ does not hold (Lemma 4.9) and which is uniformly bounded if $C(g, 2)$ holds (Lemma 4.8). □

4.4. Single rule program: How one cannot construct it. Now we would like to modify the construction of the previous section and get a single rule program. The only problem is how to initialize the predicate $CONFIG$. The simplest solution would be not to initialize it at all, but just check, in the same way as we use the "Motorway" goal in the body of the rule, that the needed EDB facts hold. So the rule should look like this:

$CONFIG(A_p, T', G')$:–
  $CONFIG(A, T, G)$,
  Motorway$(A, A_1 \dots A_p, A_p)$,
  $CONFIG(A, A_2, A_2)$,
  $BODY$,
  $TRULE(run, red, T', joker)$,
  $GRULE_3(run, red, colour_0, joker, G')$,
  $GRULE_3(run, red, colour_1, joker, G')$,
  ...
  $GRULE_3(run, red, colour_{p-1}, joker, G')$,
  $GTRULE(run, G', joker)$,
  $GTRULE(run, T', joker)$.

In this way, one could think, we secure that it is possible to start the computation of the Achilles-Turtle machine in each place, where any derivation step is made. But it is not enough to go in the footsteps of the proof of Lemma 4.8. We there require that the initial configuration is not only provable—which is really secured by the would-be rule above—but that it is provable in a bounded number of steps (in fact, just one step, in the previous section). We are to think of a new trick to ensure that.

4.5. Single rule program: How to construct it. The single recursive rule $\mathcal{S}$ is

$CONFIG(run, Z, A_p, T', G')$:–

$CONFIG(W, run, A, T, G)$, *main premise*

$CONFIG(jump, run, A, A_2, A_2)$, *initialization premise*

$CONFIG(jump, jump, joker, joker, joker)$, *jump=run premise*

Motorway$(A, A_1, \dots A_p)$,
Motorway$(joker, joker, \dots joker, A_p)$,

$BODY$,
$TRULE(run, red, T', joker)$,
$GRULE_3(run, red, colour_0, joker, G')$,
$GRULE_3(run, red, colour_1, joker, G')$,
$\dots$
$GRULE_3(run, red, colour_{p-1}, joker, G')$,
$GTRULE(run, G', joker)$,
$GTRULE(run, T', joker)$,

where the constant *joker* occurs p times in the "predicate" Motorway. We have added two additional arguments to the recursive predicate here. The rule asserts that if something can be derived then its first argument is *run*. Thus, if only the constants *run* and *jump* are not interpreted in the same way in the database, then the fact

$CONFIG(jump, run, A, A_2, A_2)$

cannot be proved by the program; if it is provable, then it is provable in 0 steps (is given as a part of the input).
Also the fact

$CONFIG(jump, jump, joker, joker, joker)$

does not require a deep proof: if any proof at all is possible, then the fact is given in the input.

The "jump=run premise" is normally useless as the main or the initialization premise of a derivation step: it has "jump" as the second argument. But if *run* and *jump* are equal in the database, then we use it to show that if anything can be proved about A, then everything can be proved about it in one step. That is why Motorway$(joker, joker, \dots, joker, A_p)$ must hold and why *joker* is *red*.

We use the methods of section 4.3 to prove that the constructed single rule program is uniformly bounded if and only if $C(g, 2)$ holds.

LEMMA 4.11. *If $C(g, 2)$ holds, then there exists a constant C such that in every database $\mathcal{D}$ if some fact can be proved with the rule $\mathcal{S}$, then it has a proof no deeper than C.*

Proof. Let K be like in the proof of Lemma 4.8. We need to consider two cases.

Case 1. *jump* and *run* are different elements of the database.

Suppose that for some A there is a fact about it which has a proof of length at least $K{+}2$. Then, we follow the proof of Lemma 4.8: we use the fact that the needed initialization has been given in the input, so it has a short (0-step) proof, and show that everything can be proved about A in no more than $K+2$ derivation steps.

Case 2. *jump* and *run* are interpreted as the same element of the database.

Suppose that anything can be proved about some A_p. Then

$$CONFIG(jump, jump, joker, joker, joker)$$

holds in the database. Since Motorway$(joker, joker, \ldots, joker, A_p)$ holds and since *joker* is *red*, every fact of the form

$$CONFIG(run, Z, A_p, T', G')$$

can be proved in one derivation step if only
$TRULE(run, red, T', joker)$,
$GRULE_3(run, red, colour_0, joker, G')$,
$GRULE_3(run, red, colour_1, joker, G')$,
...
$GRULE_3(run, red, colour_{p-1}, joker, G')$,
$GTRULE(run, G', joker)$,
$GTRULE(run, T', joker)$. □

LEMMA 4.12. *If $C(g, 2)$ does not hold, then for each constant C there exist a database $\mathcal{D}$, and a fact*

$$CONFIG(run, run, A_0, T, G)$$

which can be proved, with the rule $\mathcal{S}$, in the database $\mathcal{D}$, but the proof requires more than C steps.

Proof. We proceed in a similar way as in the proof of Lemma 4.9, with the following differences:

(i) We no longer assume that the IDB input is empty. Instead, we require that there are the following $CONFIG$ facts in the input:

$$CONFIG(jump, jump, joker, joker, joker),$$

and, for each $x \leq C$,

$$CONFIG(jump, run, c_{px}, c_{px+2}, c_{px+2}).$$

(ii) We require that for each $x \leq C$,

$$\text{Motorway}(joker, joker, \ldots, joker, A_{px})$$

holds. This ends the proof of the following. □

TIGHT BOUNDS ON THE SIZE OF FAULT-TOLERANT MERGING AND SORTING NETWORKS WITH DESTRUCTIVE FAULTS[*]

TOM LEIGHTON[†] AND YUAN MA[‡]

Abstract. We study networks that can sort n items even when a large number of the comparators in the network are faulty. We restrict our attention to networks that consist of registers, comparators, and replicators. (*Replicators* are used to copy an item from one register to another, and they are assumed to be fault free.) We consider the scenario of both random and worst-case comparator faults, and we follow the general model of *destructive* comparator failure proposed by Assaf and Upfal [*Proc. 31st IEEE Symposium on Foundations of Computer Science*, St. Louis, MO, 1990, pp. 275–284] in which the two outputs of a faulty comparator can fail independently of each other.

In the case of random faults, Assaf and Upfal showed how to construct a network with $O(n \log^2 n)$ comparators that (with high probability) can sort n items even if a constant fraction of the comparators are faulty. Whether the bound on the number of comparators can be improved (to, say, $O(n \log n)$) for sorting (or merging) has remained an interesting open question. We resolve this question in this paper by proving that any n-item sorting or merging network which can tolerate a constant fraction of random failures has $\Omega(n \log^2 n)$ comparators.

In the case of worst-case faults, we show that $\Omega(kn \log n)$ comparators are necessary to construct a sorting or merging network that can tolerate up to k worst-case faults. We also show that this bound is tight for $k = O(\log n)$. The lower bound is particularly significant since it formally proves that the cost of being tolerant to worst-case failures is very high.

Both the lower bound for random faults and the lower bound for worst-case faults are the first nontrivial lower bounds on the size of a fault-tolerant sorting or merging network.

1. Introduction.

In the classic model of a *sorting circuit* analyzed by Knuth [6], Batcher [3], and Ajtai, Komlós, and Szemerédi [1], the circuit consists of n registers and a collection of comparators, where n is the number of items to be sorted. Each *register* holds one of the items to be sorted, and each *comparator* is a 2-input, 2-output device that outputs the two input items in sorted order. The comparators are partitioned into *levels* so that each register is involved in at most one comparison in each level. The *depth* of the circuit is defined to be the number of levels in the circuit, and the *size* of the circuit is defined to be the number of comparators in the circuit. For example, a 4-item sorting circuit with depth 5 and size 6 is shown in Figure 1.1.

Sorting circuits have numerous applications in the context of message routing and switching [9] and they have been intensively studied for several decades. In the past

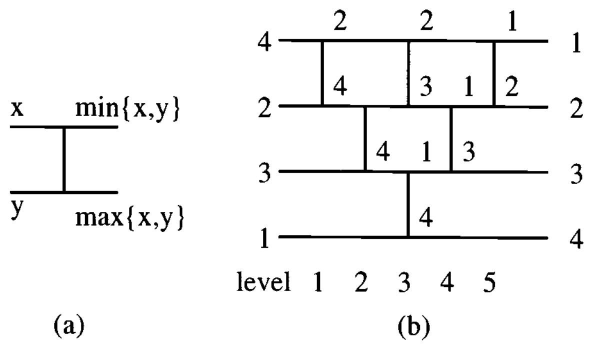

FIG. 1.1. (a) *A comparator.* (b) *A sorting circuit.*

several years, issues involving the fault-tolerance properties of sorting circuits have gained increased importance and attention (see [2, 4, 7, 10, 11, 12, 13, 14, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25]).

Thus far, the work on developing sorting circuits that are tolerant to faults has focussed on three basic types of failures: passive comparator faults, reversal comparator faults, and destructive comparator faults. In the *passive fault model*, a faulty comparator outputs its two input items in the same order in which they are input (i.e., without comparison). In the *reversal fault model*, a faulty comparator always outputs its input items in the wrong order but never loses any of the items.

In this paper, we consider the stronger "destructive" model of comparator failure proposed by Assaf and Upfal [2]. In the *destructive fault model*, a faulty comparator with inputs x and y can output $f(x,y)$ and $g(x,y)$, where f and g can be any of the following functions: x, y, $\min(x,y)$, or $\max(x,y)$. The destructive model of failure allows for any form of miswiring or short circuit. The only restriction is that each output be one of the inputs. (Without this constraint, it would not be possible to sort with high probability since for any circuit a single fault immediately before an output could make the output incorrect.)

In the destructive model of comparator failure, it is possible for one of the two inputs to a faulty comparator to be destroyed during the comparison. (For example, this happens to input y when $f(x,y) = g(x,y) = x$.) Hence, Assaf and Upfal made use of replicators when constructing networks that are tolerant to destructive faults. A *replicator* simply copies the content of one register to another. For example, a 2-item sorting network with replicators that is tolerant to any single fault is illustrated in Figure 1.2. In this paper (as in [2]), we will assume that the replicators are fault free. This is not a particularly unreasonable assumption since replicators can be hardwired and they do not contain any logic elements.

In [2], Assaf and Upfal described a general method for converting any sorting circuit into a sorting network (with replicators) that (with high probability) is tolerant to random faults in the comparators. In particular, given an n-item sorting circuit with depth d and size s, the fault-tolerant network produced by the Assaf–Upfal transformation has depth $O(d)$ and size $O(s \log n)$, and it is able to sort (with probability at least $1 - \frac{1}{n}$) even if each comparator independently suffers a destructive failure with some constant probability.[1] (The *size* of a network is defined to be the number of comparators. Asymptotically it makes no difference whether the replica-

[1]In this paper, all the logarithms are base 2 unless specified otherwise.

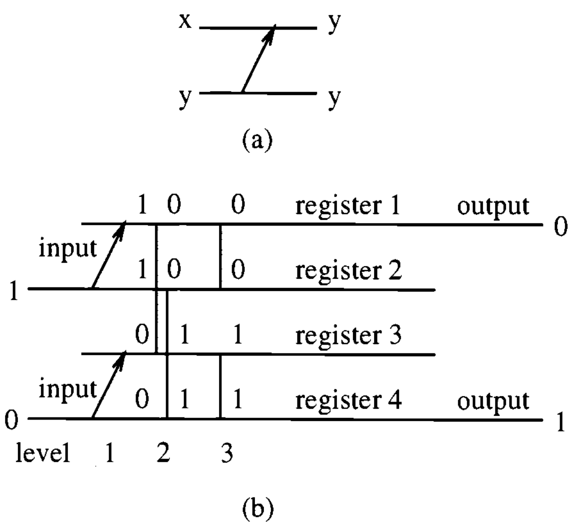

FIG. 1.2. (a) *A replicator.* (b) *A 2-item sorting network that tolerates any single fault.*

tors are counted since an optimal network should make copies of an item only if that item will be input to a comparator.) The network will also have width $O(n \log n)$, where the *width* of a network is defined to be the number of registers it contains. When used in conjunction with the AKS sorting circuit of [1], this provides a sorting network with depth $O(\log n)$, width $O(n \log n)$, and size $O(n \log^2 n)$ that is tolerant to random destructive comparator failures.

The Assaf–Upfal method proceeds by making $\Theta(\log n)$ copies of each item and replacing each comparator with $\Theta(\log n)$ comparators, followed by a majority-enhancing device that is constructed from an expander. As a consequence, the width and size of the resulting network are increased by a factor of $\Theta(\log n)$. Whether there is an alternative approach to fault tolerance that can avoid the $\Theta(\log n)$ factor blowup in width and/or size has remained an interesting open question. We resolve this question by showing that the width in the Assaf–Upfal network can be decreased, but only at the expense of a proportional increase in depth. In particular, for any $n \le w \le n \log n$, we show how to construct an n-item sorting network with width $O(w)$ and depth $O(\frac{n \log^2 n}{w})$ that can tolerate random destructive faults with high probability. More important, we show that any n-item sorting network that can tolerate random destructive faults (with any reasonable probability) has size $\Omega(n \log^2 n)$. (Somewhat surprisingly, we also show that the same lower bound holds for fault-tolerant merging networks.) These results provide tight bounds on the size and width of fault-tolerant sorting (and merging) networks, and they provide the first nontrivial lower bounds on the size of fault-tolerant sorting (and merging) networks. Compared with the recent results on passive and reversal faults [10, 13], our $\Omega(n \log^2 n)$ lower bound separates the size complexity of sorting and merging networks with destructive faults from those with passive or reversal faults.

We also consider the scenario of worst-case destructive faults. In particular, we prove a $\frac{(k+1)n \log n}{4}$ lower bound on the size of sorting and merging networks that can tolerate up to k worst-case destructive faults. This is the first nontrivial lower bound on sorting or merging networks that can tolerate worst-case faults, and it is tight (up to constant factors) for $k = O(\log n)$. Unfortunately, the lower bound means that building sorting and merging networks that are tolerant to worst-case faults is very costly. In particular, we must build the equivalent (in terms of size) of $\Omega(k)$ copies of an optimal sorting network in order to withstand k worst-case faults.

The remainder of the paper is organized into sections as follows. We start in section 2 by proving the $\Omega(kn \log n)$ lower bound on the size of merging networks that can tolerate up to k worst-case faults. We then extend this result in section 3 to prove the $\Omega(n \log^2 n)$ lower bound on the size of merging networks that are tolerant to random faults. The material in section 3 represents the most difficult and important contribution of the paper. The upper bound result on the width of fault-tolerant sorting networks is presented in section 4.

2. The lower bound on size for worst-case faults.

In this section, we prove a lower bound on the size of merging and sorting networks that are tolerant to worst-case faults. For ease of reference, we define a *k-destructive-fault-tolerant* sorting (or merging) network to be a network that is still a sorting (or merging) network even if any k (or fewer) comparators suffer any form of destructive failure. Our main result in this section is a proof of the following theorem.

THEOREM 2.1. *The size of any k-destructive-fault-tolerant merging (or sorting) network is at least* $\frac{(k+1)n \log n}{4}$.

We will prove Theorem 2.1 by showing a lower bound for merging networks. Without loss of generality, we will assume that n is an exact power of two. In what follows, we will use $\mathcal{M}$ to denote a k-destructive-fault-tolerant merging network that takes two sorted lists $X = (x_1 \le x_2 \le \cdots \le x_{n/2})$ and $Y = (y_1 \le y_2 \le \cdots \le y_{n/2})$ as input and that outputs the merged list. Without loss of generality, this means that $\mathcal{M}$ sorts lists of the form $(x_1, y_1, x_2, y_2, \ldots, x_{n/2}, y_{n/2})$ where $x_1 \le x_2 \le \cdots \le x_{n/2}$ and $y_1 \le y_2 \le \cdots \le y_{n/2}$.

To show that $\mathcal{M}$ has $\frac{(k+1)n \log n}{4}$ comparators, we need the following definitions and lemmas, some of which are extensions of those used by Floyd to prove that a fault-free merging network needs $\Omega(n \log n)$ comparators (see pages 230–232 of [6]).

Given a merging network $\mathcal{M}$ with *fault pattern* F (i.e., F specifies which comparators, if any, are faulty and how they fail) and a list of integer inputs $\Pi = (\pi_1, \pi_2, \ldots, \pi_n)$ to $\mathcal{M}$, we denote the *content* of a register r immediately after level t by $\mathcal{C}(r, t)$. For example, $\mathcal{C}(3, 1) = 0$ and $\mathcal{C}(3, 2) = \mathcal{C}(3, 3) = 1$ in Figure 1.2. We define the *history* of $\mathcal{M}$ given F and Π to be the collection of register contents $\mathcal{C}(r, t)$ taken over all registers and all levels. The following lemma shows how the history of a network computation can be influenced by a fault at a single output of a comparator.

LEMMA 2.2. *Given any* $\mathcal{M}$, Π, F, *and* F', *let* $\mathcal{C}(r, t)$ *denote the content of register* r *immediately after level* t *for* $\mathcal{M}$ *given* F *and* Π, *and let* $\mathcal{C}'(r, t)$ *denote the content of register* r *immediately after level* t *for* $\mathcal{M}$ *given* F' *and* Π. *If* F' *is identical to* F *except that one comparator* C *on level* l *with output registers* p *and* q *is modified in* F' *so that* $\mathcal{C}'(q, l) = \mathcal{C}(q, l)$ *and* $\mathcal{C}'(p, l) \ne \mathcal{C}(p, l)$, *then for all* r *and* t

(1) *if* $\mathcal{C}(r, t) < \mathcal{C}(p, l)$, *then* $\mathcal{C}'(r, t) \le \mathcal{C}(r, t)$,

(2) *if* $\mathcal{C}(r, t) > \mathcal{C}(p, l)$, *then* $\mathcal{C}'(r, t) \ge \mathcal{C}(r, t)$.

Proof. For simplicity, let $s = \mathcal{C}(p, l)$ and $s' = \mathcal{C}'(p, l)$. We will only prove the lemma for the case in which $s' < s$. The case in which $s' > s$ can be proved similarly.

We will think of F' as the result of modifying $\mathcal{C}$ in F and prove that some properties hold when such a modification is made. The network can be divided into two parts: the part before (and including) level l and the part after level l. The former part clearly remains unchanged after C is modified, and the latter part is changed as if one input item to that part were modified. Hence, it suffices to show that the following properties (a) and (b) hold when some input item is changed from s to some $s' < s$ but no comparator is modified. (We will use the term *register segment* to denote the part of a register that is between two consecutive levels.)

(a) The content of each register segment whose content was less than s before the modification is not increased.

(b) The content of each register segment whose content was greater than s before the modification remains unchanged.

In a given history, if an input item is changed from s to $s-1$ (but no comparator is modified), then all the input items that are neither s nor $s-1$ move in the network as they did before. Hence, all the register segments containing neither s nor $s-1$ before the modification now contain the same values as before. All the register segments containing $s-1$ before the modification now contain $s-1$, while some register segments containing s before the modification may contain $s-1$ now. This means that properties (a) and (b) hold when an input s is changed to $s-1$. If the new input item $s-1$ (the one that was s before) is further changed to $s-2$, then the only new change in the history is that some register segments containing $s-1$ before the modification may contain $s-2$ now. Overall, an input item has been changed from s to $s-2$ and properties (a) and (b) still hold. Since both s and s' are integers, this process can be continued until an input has been changed from s to s'. During the whole process, properties (a) and (b) are never violated. $\square$

Consider the history of $\mathcal{M}$ on a particular 0–1 input sequence π. A *crossing comparator* of $\mathcal{M}$ with respect to π is defined to be a comparator whose input contents are $\{0,1\}$ (i.e., they are not both 0 or both 1).[2] $\mathcal{M}_0(\pi)$, a subnetwork of $\mathcal{M}$ with respect to π, is constructed as follows. (The subscript 0 is used to denote that $\mathcal{M}_0(\pi)$ is the part of $\mathcal{M}$ that contains 0 on input sequence π.) Take all the register segments and replicators that contain 0 and all the comparators with both inputs containing 0. Replace each crossing comparator of $\mathcal{M}$ with respect to π by connecting directly its (unique) input containing 0 and its (unique) output containing 0. $\mathcal{M}_1(\pi)$ can be constructed in a similar fashion. For example, when $\mathcal{M}$ and π are as shown in Figure 1.2(b), $\mathcal{M}_0(\pi)$ and $\mathcal{M}_1(\pi)$ are as illustrated in Figure 2.1.

Unless specified otherwise, we will be particularly interested in the history of $\mathcal{M}$ (when there is *no* fault) on the input sequence

$$(\underbrace{0,0,\ldots,0}_{n/2},\underbrace{1,1,\ldots,1}_{n/2}). \tag{2.1}$$

Therefore, when we talk about crossing comparators, $\mathcal{M}_0$, and $\mathcal{M}_1$ without specifying π, π should be interpreted as the 0–1 sequence given in (2.1). In particular, to construct $\mathcal{M}_0$ and $\mathcal{M}_1$, we input the smallest $\frac{n}{2}$ items to the top half of $\mathcal{M}$ and the largest $\frac{n}{2}$ items to the bottom half of $\mathcal{M}$. Hence, when there is no fault, the smallest $\frac{n}{2}$ items should be contained in $\mathcal{M}_0$ and the largest $\frac{n}{2}$ items should be contained in $\mathcal{M}_1$. The motivation for defining crossing comparators, $\mathcal{M}_0$, and $\mathcal{M}_1$ can be found in the following lemmas.

LEMMA 2.3. *If $\mathcal{M}$ is an n-input k-destructive-fault-tolerant merging network, then both $\mathcal{M}_0$ and $\mathcal{M}_1$ are $\frac{n}{2}$-input k-destructive-fault-tolerant merging networks.*

[2]Here, the notion of a crossing comparator has nothing to do with any fault pattern. In the next section, however, the notion of a crossing comparator will be slightly modified so that it will be dependent on a fault pattern.

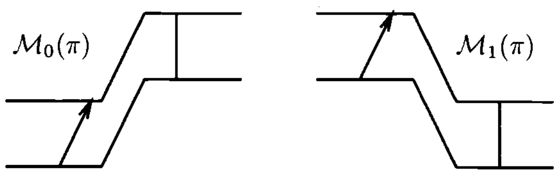

FIG. 2.1. *The decomposition of the network $\mathcal{M}$ in Figure* 1.2*, with respect to the input sequence therein, into $\mathcal{M}_0(\pi)$ and $\mathcal{M}_1(\pi)$. The sloping lines represent direct connections that replace crossing comparators.*

Proof. If we input to $\mathcal{M}$ any sequence

$$(x_1, y_1, x_2, y_2, \ldots, x_{n/4}, y_{n/4}, \underbrace{+\infty, \ldots, +\infty}_{n/2})$$

such that $x_1 \le x_2 \le \cdots \le x_{n/4}$ and $y_1 \le y_2 \le \cdots \le y_{n/4}$ and if none of the crossing comparators of $\mathcal{M}$ are faulty, then, by the definition of $\mathcal{M}_0$, the x's and y's should move within $\mathcal{M}_0$ only and $\mathcal{M}_1$ has no impact on them. Hence, $\mathcal{M}_0$ is a k-destructive-fault-tolerant merging network. (Note that an adversary can put no faults at crossing comparators and put up to k faults into $\mathcal{M}_0$.) By a similar argument, we can show $\mathcal{M}_1$ is also a k-destructive-fault-tolerant merging network. □

LEMMA 2.4. *If $\mathcal{M}$ is a k-destructive-fault-tolerant merging network, then $\mathcal{M}$ has at least $\frac{(k+1)n}{4}$ crossing comparators.*

Proof. We will focus on the history of $\mathcal{M}$ on input sequence

$$(1, +\infty, 2, +\infty, \ldots, n/2, +\infty).$$

According to the definition of $\mathcal{M}_0$, $1, 2, \ldots, \frac{n}{2}$ should all be output in the outputs of $\mathcal{M}_0$. In particular, $\frac{n}{4}+1, \ldots, \frac{n}{2}$ should be moved from $\mathcal{M}_1$ to $\mathcal{M}_0$. By definition, each crossing comparator has exactly one $\mathcal{M}_0$-input and one $\mathcal{M}_1$-input. (If an input (output) of a comparator is in $\mathcal{M}_0$, then we call it an $\mathcal{M}_0$-input (output); if an input (output) of a comparator is in $\mathcal{M}_1$, then we call it an $\mathcal{M}_1$-input (output).) Label each crossing comparator by its $\mathcal{M}_1$-input.

Assume for the purposes of contradiction that $\mathcal{M}$ contains less than $\frac{(k+1)n}{4}$ crossing comparators. Then there exists an integer s such that $\frac{n}{4}+1 \le s \le \frac{n}{2}$ and the total number of crossing comparators labeled by s is at most k.

Let C_1 be a crossing comparator labeled by s that is at the lowest level in $\mathcal{M}$. Since s cannot have gotten into $\mathcal{M}_0$ without using a crossing comparator labeled by s, we know that the $\mathcal{M}_0$-input to C_1 does not contain s. Moreover, since C_1 is not faulty in the fault-free network $\mathcal{M}$, one of its outputs contains s and the other output does not contain s. Hence, if we make C_1 be faulty by forcing the $\mathcal{M}_0$-input of C_1 to appear in both outputs of C_1, this will have the effect of replacing the value of s in one of the output registers with a value other than s, which is exactly the scenario described by Lemma 2.2. In addition, C_1 can no longer be used to move s from $\mathcal{M}_1$ to $\mathcal{M}_0$.

For any r and t, by Lemma 2.2 we know that if $C(r,t) \ne s$ before C_1 is made faulty, then $C(r,t) \ne s$ after C_1 is made faulty. Hence, the number of working crossing comparators labeled by s decreases by at least 1 when C_1 is made faulty.

We next relabel crossing comparators based on the new history when C_1 is faulty and proceed inductively (i.e., we select the next crossing comparator labeled by s, make it faulty, and so forth). The proceeding process terminates when there are no longer any functioning crossing comparators labeled by s. This is accomplished by making at most k crossing comparators faulty. Since there are no longer any crossing comparators that can move s from $\mathcal{M}_1$ to $\mathcal{M}_0$, the network does not successfully complete the merge. Hence, we can conclude that $\mathcal{M}$ has at least $\frac{(k+1)n}{4}$ crossing comparators. $\square$

Proof of Theorem 2.1. For any fixed k, let $S(n)$ denote the size of the smallest n-input k-destructive-fault-tolerant merging network. From the definition of crossing comparators, the construction of $\mathcal{M}_0$ and $\mathcal{M}_1$, and the fact that no crossing comparator in $\mathcal{M}$ appears as a comparator in either $\mathcal{M}_0$ or $\mathcal{M}_1$, we know that

$$\begin{aligned}\text{size}(\mathcal{M}) \geq\ & \text{size}(\mathcal{M}_0) + \text{size}(\mathcal{M}_1)\\ & + |\{\text{crossing comparators in } \mathcal{M}\}|.\end{aligned}$$

By Lemmas 2.3 and 2.4, this means that

$$S(n) \geq 2S(\frac{n}{2}) + \frac{(k+1)n}{4}$$

for $n \geq 4$. Solving the recurrence, we find that

$$S(n) \geq \frac{n}{2} \cdot S(2) + \frac{(k+1)n\log(n/2)}{4}.$$

Since $S(2) \geq k+1$, this means that $S(n) \geq \frac{(k+1)n\log n}{4}$, as claimed. $\square$

3. The lower bound on size for random faults. In this section, we prove a lower bound on the size of merging and sorting networks that are tolerant to random faults. For ease of reference, we define a (ρ, ϵ)-*destructive-fault-tolerant* sorting (or merging) network to be a network that is still a sorting (or merging) network with probability at least $1-\epsilon$ even if each comparator independently suffers a destructive failure with fixed probability ρ. When a destructive fault does occur, we will assume that each form of failure is equally likely. In other words, the probability that a particular form of failure appears at a comparator is $\rho_0 = \frac{\rho}{\alpha}$, where the constant α denotes the total number of possible ways that a comparator can fail. The main result in this section, which is also the main result in this paper, is a proof of the following theorem.

THEOREM 3.1. *The size of any (ρ, ϵ)-destructive-fault-tolerant merging (or sorting) network is*

$$\Omega\left(n\log n \frac{\log\frac{1}{\epsilon} + \log\sqrt{n} - \log\log_e\frac{1}{1-\epsilon}}{1-\log\rho}\right). \tag{3.1}$$

This theorem gives a good lower bound for a large range of ρ and ϵ and it does not require either ρ or ϵ to be a constant. The most interesting case, which people have studied most often, is that ρ is a nonzero constant and $\epsilon = 1/\text{poly}(n)$. In this case, the theorem gives a lower bound of $\Omega(n\log^2 n)$, which is tight [2]. Somewhat surprisingly, however, the theorem gives the same $\Omega(n\log^2 n)$ lower bound even when ϵ is not small. In particular, when ρ is a nonzero constant, the theorem implies the $\Omega(n\log^2 n)$ lower bound even for some extremely small success probability like $1-\epsilon = e^{-n^{\frac{1}{4}}}$. Hence, even networks that have a tiny chance of surviving the faults have $\Omega(n\log^2 n)$ comparators.

In fact, we will show a lower bound of the form

$$\Omega\left(n\log n\frac{\log\frac{1}{\epsilon}+\log\sqrt{n}-\log\log_e\frac{1}{1-\epsilon}}{\log\frac{1}{\rho_0}}\right), \tag{3.2}$$

where ρ_0 is the probability that a comparator suffers a particular form of destructive failure. (One can easily check that lower bound (3.2) implies lower bound (3.1). The term "1" in the denominator of (3.1) prevents the lower bound from going to $+\infty$ when ρ goes to 1.) We will prove lower bound (3.2) by showing a lower bound of

$$\frac{n\log n\log\epsilon}{4\log\rho_0} \tag{3.3}$$

and a lower bound of

$$\frac{n\log n(\log\sqrt{n}-\log\log_e\frac{1}{1-\epsilon})}{4\log\frac{1}{\rho_0}}. \tag{3.4}$$

When $\epsilon = o(1/\text{poly}(n))$, lower bound 3.4 is stronger, and when $\epsilon = \Omega(1/\text{poly}(n))$, lower bound 3.3 is stronger.

For worst-case faults, we have shown that a factor of $\Omega(k)$ in redundancy is necessary to tolerate k faults. In fact, if the size of the network is not large enough, then there exists a set of at most k comparators that are critical. If all these comparators fail in a particular way (and all other comparators work correctly), then the network will not work correctly. At first glance, one might think that this immediately implies that a factor of $\Omega(\frac{\log\epsilon}{\log\rho_0})$ in redundancy is required for the random fault case, since any set of $\Omega(\frac{\log\epsilon}{\log\rho_0})$ comparators will all fail in the necessary way with probability ϵ. If this were true, lower bound 3.3 would follow immediately. However, the problem for random faults is that we cannot assume that all "other" comparators work correctly. Indeed, it is likely that a large fraction of those "other" comparators will be faulty, and these faulty comparators might inadvertently help the network work correctly. One such interesting example is the butterfly-based fault-tolerant sorting circuit designed in [11] in which a fixed fraction of the comparator failures are crucial for the circuit to work! (To understand why fixed failure probability can be helpful, one can imagine that each comparator flips a coin to decide its behavior. Then the failures can be used as a source of randomness, which might be exploited in the network.)

In general, there are two types of lower bound results for random-fault-tolerant computation: one for the case of fixed failure probability and the other one for the case that only an upper bound is enforced on the failure probability. As argued by Pippenger [15] in the context of fault-tolerant Boolean circuits, the first type of lower bound is always stronger than the second type. Our proof technique for worst-case faults implies a lower bound of the second type for random faults. In order to get the stronger lower bound (of the first type) stated in Theorem 3.1, we need to do much more work.

As a direct application of the proof technique for worst-case faults, if the size of $\mathcal{M}$ does not satisfy lower bound 3.3, then, for any faulty $\mathcal{M}$, we can always produce another faulty network that does not work correctly by forcing at most $\log_{\rho_0}\epsilon = \frac{\log\epsilon}{\log_{\rho_0}}$ comparators to be faulty in a particular way. It is natural to ask if this property is strong enough to show that there is a large fraction of faulty networks that do not work correctly. This can be formulated as the following question. Let S be the set of all sequences with fixed length l and S_0 be a subset of S. (S will correspond to all fault patterns for a network $\mathcal{M}$, and S_0 will correspond to those fault patterns that keep $\mathcal{M}$ from being a merging network.) If the union of all the hamming balls with origins in S_0 and radius $\log_{\rho_0} \epsilon$ covers S, can we prove $\frac{|S_0|}{|S|} = \Omega(\epsilon)$? That is, if every fault pattern is within $\log_{\rho_0} \epsilon$ faults of a bad fault pattern, is the density of bad fault patterns $\Omega(\epsilon)$? Unfortunately, the answer to this question is in general "No." Hence, to prove our lower bound, we need a better understanding of the structure of the bad fault patterns.

Before proving the theorem, we first clarify some terminology to be used in the proof. We will use the terms *fault pattern* and *history* as defined in section 2. The notation $\mathcal{M}(F)$ will be used to denote the faulty network derived from $\mathcal{M}$ by setting the behavior of each comparator in $\mathcal{M}$ according to fault pattern F. In the proof, we will focus on a particular merging network $\mathcal{M}$ only. Hence there is a one-to-one correspondence between each fault pattern F and the faulty network $\mathcal{M}(F)$. We call a fault pattern F *good* if $\mathcal{M}(F)$ functions correctly as a merging network, and we call F *bad* otherwise. As in section 2, we want to decompose $\mathcal{M}$ into smaller networks and analyze the behavior of the comparators that connect these small networks. However, unlike in section 2, where we use the fault-free $\mathcal{M}$ to define these terminologies, we need to deal with different decompositions and different sets of crossing comparators for different fault patterns. We will use the history of $\mathcal{M}(F)$ on input sequence

$$(\underbrace{0, 0, \ldots, 0}_{n/2}, \underbrace{1, 1, \ldots, 1}_{n/2})$$

to redefine these terminologies as follows. A *crossing comparator* of $\mathcal{M}(F)$ is defined to be a comparator whose input contents are $\{0, 1\}$ (i.e., they are not both 0 or both 1). $\mathcal{M}(F)_0$ is constructed as follows. Take all the register segments and replicators that contain 0 and all the comparators with both inputs containing 0. For each crossing comparator with one output containing 0 and the other output containing 1, replace it in $\mathcal{M}(F)_0$ by directly connecting the (unique) input containing 0 to the (unique) output containing 0. For each crossing comparator with both outputs containing 0 (because of a fault), replace it in $\mathcal{M}(F)_0$ by a replicator that copies from the (unique) input register containing 0 to the other (output) register. (We do not include anything in $\mathcal{M}(F)_0$ to represent crossing comparators with both outputs containing 1.) $\mathcal{M}(F)_1$ can be constructed in a similar fashion.

Given $\mathcal{M}(F)_0$, we can construct $\mathcal{M}(F)_{00}$ and $\mathcal{M}(F)_{01}$, and given $\mathcal{M}(F)_1$, we can construct $\mathcal{M}(F)_{10}$ and $\mathcal{M}(F)_{11}$. Working recursively, we can construct $\mathcal{M}(F)_i$ in a similar way for any binary number i with less than $\log n$ bits.

For a fixed $\mathcal{M}$, we can define a partial order on the set of all the comparators in $\mathcal{M}$ by the following rule:

$$C_1 \prec C_2 \quad \text{if and only if} \quad \text{depth}(C_1) < \text{depth}(C_2).$$

We can extend this partial order into a total order. It does not matter how we extend, but we will stick to a fixed extension in the proof.

Proof of Theorem 3.1. We start by showing that for any (ρ, ϵ)-fault-tolerant merging network $\mathcal{M}$,

$$\text{size}(\mathcal{M}) \geq \frac{n \log n \log \epsilon}{4 \log \rho_0}. \tag{3.5}$$

Assume for the purposes of contradiction that (3.5) is not true for $\mathcal{M}$. Then we will prove that

$$\text{Prob}[F \text{ is bad for } \mathcal{M}] > \epsilon, \tag{3.6}$$

where F denotes a randomly generated fault pattern for $\mathcal{M}$. We will prove (3.6) by partitioning the space of all possible fault patterns into small groups and then showing that, within each group, a bad fault pattern will be generated with probability more than ϵ.

Now we will do the most difficult part of the proof, which is to find an appropriate partitioning of the space of the fault patterns. On any fault pattern F, we will use the following 3-step procedure to choose a characteristic set of F, which is denoted as *Char*(F). The set consists of comparators and it will be the basis for us to define the partition.

Step 1. List all the $\mathcal{M}(F)_i$'s as follows:

$$\mathcal{M}(F), \mathcal{M}(F)_0, \mathcal{M}(F)_1, \mathcal{M}(F)_{00}, \mathcal{M}(F)_{01}, \mathcal{M}(F)_{10}, \mathcal{M}(F)_{11}, \ldots. \tag{3.7}$$

That is, for any binary numbers i and j with strictly less than $\log n$ bits, we list $\mathcal{M}(F)_i$ before $\mathcal{M}(F)_j$ if i has fewer bits than j or if i and j have the same number of bits and $i < j$. Take the first network $\mathcal{M}(F)_i$ in list (3.7) that has strictly less than $\frac{1}{4} n_i \frac{\log \epsilon}{\log \rho_0}$ crossing comparators where $n_i = \frac{n}{2^{l(i)}}$ (where $l(i)$ is the length of i) is the total number of input items to $\mathcal{M}(F)_i$. (Such an integer i does exist since we have assumed that (3.5) is not true.)

By the way we create list (3.7) and the definition of n_i, we know that $n_i \geq 2$. In what follows, we will assume $n_i \geq 4$. The case when $n_i = 2$ is easily handled as a special case (or it can be ignored by replacing $\log n$ with $\log n - 1$ in the lower bound).

Step 2. Compute the history of $\mathcal{M}(F)_i$ on input

$$(1, +\infty, 2, +\infty, \ldots, i, +\infty, \ldots, n_i/2, +\infty),$$

and label each crossing comparator by its (unique) $\mathcal{M}(F)_{i1}$-input item (i.e., the item that is input from the subnetwork $\mathcal{M}(F)_{i1}$). Let $S(j)$ be the set of the crossing comparators labeled by j. Go through the list

$$S\left(\frac{n_i}{4} + 1\right), S\left(\frac{n_i}{4} + 2\right), \ldots, S\left(\frac{n_i}{2}\right)$$

and choose the first set $S(s)$ such that

$$\sum_{\frac{n_i}{4}+1 \leq j \leq s} |S(j)| < \left(s - \frac{n_i}{4}\right) \frac{\log \epsilon}{\log \rho_0}. \tag{3.8}$$

(Here, our assumption that $n_i \geq 4$ ensures that $\frac{n_i}{4}$ is an integer.) Such an s does exist, since, by the choice of i, $\mathcal{M}(F)_i$ contains less than $\frac{1}{4} n_i \frac{\log \epsilon}{\log \rho_0}$ crossing comparators, and therefore $s = \frac{n_i}{2}$ satisfies (3.8). (Note that our assumption $n_i \geq 4$ implies $\frac{n_i}{4} + 1 \leq \frac{n_i}{2}$.) By the minimality of s, we can conclude the following.

CLAIM 1. $|S(s)| < \frac{\log \epsilon}{\log \rho_0}$.

Step 3. We will continue to work on the history of $\mathcal{M}(F)_i$ on input

$$(1, +\infty, 2, +\infty, \ldots, i, +\infty, \ldots, n_i/2, +\infty),$$

and we will choose a characteristic set for F, $\mathit{Char}(F)$, from $S(s)$. List all the comparators in $S(s)$ as follows:

$$C_1 \prec C_2 \prec \cdots \prec C_t, \tag{3.9}$$

where $\prec$ is the depth-respecting total order described earlier. We first put comparator C_1 into $\mathit{Char}(F)$. Then we modify the behavior of C_1 (thereby making it faulty in a particular way) so as to make C_1 directly output its $\mathcal{M}(F)_{i0}$-input item to all its $\mathcal{M}(F)_{i0}$-outputs (if any), without changing any $\mathcal{M}(F)_{i1}$-output of C_1.

Before this modification, the $\mathcal{M}(F)_{i1}$-input of C_1 contained s and the $\mathcal{M}(F)_{i0}$-input of C_1 did not contain s since s could not have moved into $\mathcal{M}(F)_{i0}$ without using a comparator labeled by s. Moreover, if an $\mathcal{M}(F)_{i0}$-output of C_1 did not contain s (which is the $\mathcal{M}(F)_{i1}$-input content of C_1), it had to contain the $\mathcal{M}(F)_{i0}$-input content of C_1. Therefore, this modification has the effect of changing some output content of C_1 from s to non-s. By Lemma 2.2, this modification cannot cause any new crossing comparator to be labeled by s. Now C_1 is no longer capable of moving s from $\mathcal{M}(F)_{i1}$ to $\mathcal{M}(F)_{i0}$. Then we update the history accordingly. In the new history, $C_2, C_3, \ldots, C_t$ are the only remaining comparators that might move s from $\mathcal{M}(F)_{i1}$ to $\mathcal{M}(F)_{i0}$. In this remaining part of list (3.9), we choose the first comparator labeled by s in the new history. We put this comparator into $\mathit{Char}(F)$ and modify its behavior as we did for C_1. We then update the history again and continue in this fashion until all comparators in list (3.9) have been dealt with.

This completes the 3-step procedure and the construction of $\mathit{Char}(F)$. The final history, in which s is never moved into $\mathcal{M}(F)_{i0}$, corresponds to another fault pattern, and we will call this fault pattern $\tilde{F}$.

LEMMA 3.2. *For any fault pattern F,* (1) $\mathit{Char}(F) = \mathit{Char}(\tilde{F})$*,* (2) $\tilde{F}$ *is bad, and* (3)$|\mathit{Char}(F)| < \frac{\log \epsilon}{\log \rho_0}$.

Proof. To prove (1), we use the 3-step procedure to determine $\mathit{Char}(\tilde{F})$ and to show that it is the same as $\mathit{Char}(F)$.

We first note that $\mathcal{M}(\tilde{F})$ and $\mathcal{M}(F)$ have the same history on the input list

$$\Pi = (\underbrace{0, \ldots, 0}_{n/2}, \underbrace{1, \ldots, 1}_{n/2}).$$

This is because the changes made in comparators to produce $\tilde{F}$ from F do not affect the performance of $\mathcal{M}(F)$ on Π. In particular, the only changes from F to $\tilde{F}$ are made in Step 3 and they do not affect the history of $\mathcal{M}(F)$ on input Π, although they do affect the history of $\mathcal{M}(F)$ on input $(1, +\infty, 2, +\infty, \ldots, i, +\infty, \ldots, n_i/2, +\infty)$, as designed. (Recall that Step 3 lets an $\mathcal{M}(F)_{i0}$-output (or $\mathcal{M}(F)_{i1}$-output) remain so after the changes.) Hence, for all j such that $\mathcal{M}(F)_j$ is listed before or at $\mathcal{M}(F)_i$ in list (3.7), the structure of $\mathcal{M}(\tilde{F})_j$ is the same as the structure of $\mathcal{M}(F)_j$, although the functionality of some individual comparators may differ.[3] In addition, for all j such that $\mathcal{M}(F)_j$ is listed before or at $\mathcal{M}(F)_i$ in list (3.7), the crossing comparators for $\mathcal{M}(\tilde{F})_j$ are the same as the crossing comparators for $\mathcal{M}(F)_j$. Hence, the value of i for $\mathcal{M}(\tilde{F})$ selected in Step 1 is equal to that for $\mathcal{M}(F)$.

[3]To be precise, we say two networks have the same structure if and only if they look identical when they are drawn out in a picture like Figure 1.1(b), where we do not really care how the comparators work in presence of faults. That is, we care only about the topology of the network, not the functionalities of individual comparators.

Next, we show that we pick the same value of s for $\mathcal{M}(\tilde{F})_i$ and $\mathcal{M}(F)_i$ in Step 2. From the construction of $\tilde{F}$, we know that $\tilde{F}$ differs from F (at most) only in comparators that are labeled s in the history of $\mathcal{M}(F)_i$. More precisely, some outputs of these comparators (i.e., the $\mathcal{M}(F)_{i0}$-outputs) that contain s in the history of $\mathcal{M}(F)_i$ may contain non-s values in the history of $\mathcal{M}(\tilde{F})_i$. By Lemma 2.2, the effect of these changes is to make (possibly) some values that were s or less in the history of $\mathcal{M}(F)_i$ be smaller in the history of $\mathcal{M}(\tilde{F})_i$ and to make (possibly) some values that were s or greater in the history of $\mathcal{M}(F)_i$ be larger in the history of $\mathcal{M}(\tilde{F})_i$. Hence, the same value of s will be chosen in Step 2 for $\tilde{F}$ as for F. (The reason that we have used the cumulative threshold in Step 2 instead of simply selecting the smallest $S(s)$ should now be apparent.)

According to the description of the 3-step procedure, we can see that the starting history for $\tilde{F}$ at the beginning of the 3-step procedure is the same as the final history at the termination of Step 3 for F. (This can be shown inductively from the lowest level to the highest level.) Since the first two steps do not change any comparators, at the beginning of Step 3 for $\tilde{F}$ we have all the comparators in $\mathit{Char}(F)$ to start with. As we move along in the history of $\mathcal{M}(\tilde{F})_i$ on input $(1, +\infty, 2, +\infty, \ldots, n_i/2, +\infty)$, we will not make any real change on any comparator in $\mathit{Char}(F)$ since, at the termination of the 3-step procedure for F, all the comparators in $\mathit{Char}(F)$ have already output their $\mathcal{M}_{i0}$-inputs directly to their $\mathcal{M}_{i0}$-outputs. Furthermore, these comparators are all labeled by s in the history for $\tilde{F}$. Therefore, we have to put all the comparators in $\mathit{Char}(F)$ into the characteristic set for $\tilde{F}$. Hence, $\mathit{Char}(F) = \mathit{Char}(\tilde{F})$, as claimed.

To prove (2), we assume for the purposes of contradiction that $\tilde{F}$ is good. Then the proof technique of Lemma 2.3 implies that $\mathcal{M}(\tilde{F})_i$ functions correctly as a merging network. In particular, it should work correctly on both input

$$(\underbrace{0, \ldots, 0}_{n/2}, \underbrace{1, \ldots, 1}_{n/2})$$

and input $(1, +\infty, 2, +\infty, \ldots, n_i/2, +\infty)$. Hence, $\mathcal{M}(\tilde{F})_i$ successfully moves s from $\mathcal{M}(\tilde{F})_{i1}$ to $\mathcal{M}(\tilde{F})_{i0}$. However, in the history for $\tilde{F}$, no s can be moved from $\mathcal{M}(\tilde{F})_{i1}$ to $\mathcal{M}(\tilde{F})_{i0}$. This is a contradiction, which means that $\tilde{F}$ is bad.

The correctness of (3) follows from Claim 1. $\square$

We are now ready to describe the partition of the space of fault patterns. We group all the fault patterns by the following rule. We put F and F' in the same group if and only if (1) $\mathit{Char}(F) = \mathit{Char}(F')$ and (2) the fault patterns F and F' are identical on all the comparators not in $\mathit{Char}(F)$.

For any group G, take a fault pattern $F \in G$. By (1) in Lemma 3.2 and the construction of $\tilde{F}$, we know that $\tilde{F} \in G$. By (2) in Lemma 3.2, we know that $\tilde{F}$ is bad. By (1) and (3) in Lemma 3.2, we know that the probability that $\tilde{F}$ occurs is greater than ${\rho_0}^{\frac{\log \epsilon}{\log \rho_0}} = \epsilon$ times the probability that a fault pattern in G occurs. In other words, if a fault pattern in G occurs, there is a better than ϵ chance that it is $\tilde{F}$. Since this is true for all groups, we can thus conclude that the probability that a random fault pattern is bad is greater than ϵ.

This completes the proof of lower bound (3.5). We next show that

$$\mathit{size}(\mathcal{M}) \geq n \log n \frac{\log \sqrt{n} - \log \log_e \frac{1}{1-\epsilon}}{8 \log \frac{1}{\rho_0}}. \tag{3.10}$$

We will divide the network into blocks of size $\sqrt{n}$ and "pump up" the failure probability by showing that most of the blocks behave well in order for the overall circuit to work. In particular, we will partition the space of fault patterns into groups and use a conditional probabilistic argument.

For each fault pattern F, we can decompose $\mathcal{M}(F)$ into $\sqrt{n}$ networks such that each of them has $\sqrt{n}$ inputs and is of the form

$$\mathcal{M}(F)_i,$$

where $i \leq \sqrt{n}$ is a binary number with $\frac{\log n}{2}$ bits. By doing so, we have removed many comparators from $\mathcal{M}$. These comparators that we have removed are crossing comparators of many different networks that are larger than the networks with $\sqrt{n}$ inputs that we are currently interested in. We use *Cross*(F) to denote the set of all these removed crossing comparators. We put F and F' in the same group if and only if (1) *Cross*$(F) =$ *Cross*(F') and (2) F and F' are the same on all the comparators in *Cross*(F).

If, within each group G, the probability that a fault pattern $F \in G$ is good is less than $1-\epsilon$, then a randomly generated fault pattern will be good with probability less than $1-\epsilon$. This is a contradiction to the fact that a randomly generated F is good with probability at least $1-\epsilon$. Therefore, there exists a group G_0 such that

$$\text{Prob}[F \text{ is good} \mid F \in G_0] \geq 1-\epsilon.$$

Notice that the decomposition of $\mathcal{M}(F)$ is determined by the information about F in *Cross*(F) only. Hence, the fault patterns in the same group have the same decomposition. In particular, we can assume that, for any fault pattern $F \in G_0$ and any $i \leq \sqrt{n}$,

$$size(\mathcal{M}(F)_i) = \frac{\sqrt{n}\log\sqrt{n}x_i}{4\log\frac{1}{\rho_0}}, \tag{3.11}$$

where x_i depends on the group G_0 only (it does not depend on the individual F). By the proof technique of Lemma 2.3, we can see that each $\mathcal{M}(F)_i$ functions correctly as a merging network if F is good. Using lower bound (3.5) and (3.11), we have

$$\text{Prob}[\mathcal{M}(F)_i \text{ is good } \mid F \in G_0] \leq 1 - \frac{1}{2^{x_i}} \qquad \text{for } i \leq \sqrt{n}.$$

On the other hand, for a fault pattern F in group G_0, the behaviors of the $\mathcal{M}_i$'s ($i \leq \sqrt{n}$) are mutually independent. Hence,

$$\begin{aligned} 1-\epsilon &\leq \text{Prob}[F \text{ is good} \mid F \in G_0] \\ &\leq \text{Prob}[\mathcal{M}(F)_i \text{ is good } \forall i \mid F \in G_0] \\ &\leq \prod_{i\leq\sqrt{n}}\left(1-\frac{1}{2^{x_i}}\right) \\ &\leq e^{-\sum_{i\leq\sqrt{n}}(\frac{1}{2})^{x_i}}. \end{aligned}$$

Therefore,

$$\begin{aligned} -\log_e(1-\epsilon) &\geq \sum_{i\leq\sqrt{n}}\left(\frac{1}{2}\right)^{x_i} \\ &\geq \sqrt{n}\left(\frac{1}{2}\right)^{\frac{\sum_{i\leq\sqrt{n}}x_i}{\sqrt{n}}}, \end{aligned}$$

where the last inequality holds due to the concavity of function $(\frac{1}{2})^x$. Hence

$$\sum_i x_i \geq \sqrt{n}\left(\log\sqrt{n} - \log\log_e \frac{1}{1-\epsilon}\right).$$

Finally, we have

$$\begin{aligned} size(\mathcal{M}) &\geq \sum_{i\leq\sqrt{n}} size(\mathcal{M}(F)_i) \\ &\geq \frac{\sqrt{n}\log\sqrt{n}\sum_{i\leq\sqrt{n}} x_i}{4\log\frac{1}{\rho_0}} \\ &= \frac{n\log n(\log\sqrt{n} - \log\log_e\frac{1}{1-\epsilon})}{8\log\frac{1}{\rho_0}}. \end{aligned}$$

This proves (3.10) and completes the proof of Theorem 3.1. □

4. Trading depth for width. In this section, we show that there is a nice trade-off between the width and depth of fault-tolerant sorting networks. As in [2], we need to assume in this section that ρ is less than a constant strictly less than $\frac{1}{2}$. The proofs combine the COLUMN-SORT algorithm in [8] with the fault-tolerant sorting networks in [2].

THEOREM 4.1. *For any $n \leq w \leq n\log n$ and any ρ less than a constant strictly less than $\frac{1}{2}$, there exists an explicit construction of a $(\rho, 1/\text{poly}(n))$-destructive-fault-tolerant sorting network with width $O(w)$ and depth $O(\frac{n\log^2 n}{w})$.*

Proof. The COLUMN-SORT algorithm in [8] arranges all the items in an $r \times s$ matrix, where $r \geq 2s^2$, and it consists of 8 phases. Phases 1, 3, 5, 7 sort each column of the matrix and phases 2, 4, 6, 8 permute the matrix in a fixed manner. The only property of COLUMN-SORT that we need here is the fact that if we can sort all the columns of the matrix in T steps, then by applying COLUMN-SORT we can sort all the items in the matrix in $O(T)$ steps.

Assaf and Upfal [2] have shown how to build a $(\rho, 1/\text{poly}(n))$-destructive-fault-tolerant sorting network with width $O(n\log n)$ and depth $O(\log n)$. Hence, for a given w between n and $n\log n$, we can use a network with width w and depth $O(\log(\frac{w}{\log n})) = O(\log n)$ to sort $\frac{w}{\log n}$ items first. (At the same time, we need to keep all other items in some other registers. This can be done as long as we keep enough, say, $2n$, registers.) Then keep this sorted list of $\frac{w}{\log n}$ items in some registers and work on the next group of $\frac{w}{\log n}$ items, etc. We will have worked on all the groups after $O(\frac{n}{w/\log n}) = O(\frac{n\log n}{w})$ rounds. This finishes the first phase of COLUMN-SORT with depth $O(\frac{n\log^2 n}{w})$. To implement the second phase of COLUMN-SORT, we can hardwire in a permutation. We similarly finish the remaining phases. The overall depth is $O(\frac{n\log^2 n}{w})$. □

THEOREM 4.2. *For any $n \leq w \leq nk$ and $k = O(\log n)$, there exists an explicit construction of a k-destructive-fault-tolerant sorting network with width $O(w)$ and depth $O(\frac{nk\log n}{w})$.*

Proof sketch. In [2], Assaf and Upfal did not address the issue of worst-case faults. However, by following their method it is possible to construct a k-destructive-fault-tolerant sorting network with width $O(kn)$ and depth $O(\log n)$ when $k = O(\log n)$. Therefore we can use COLUMN-SORT, as we did in the proof of Theorem 4.1, to prove the theorem. □

5. Concluding remarks. We have shown lower bounds for merging and sorting networks that can tolerate destructive faults. Our lower bound for random faults is tight in the most interesting case where ρ is a constant and $1/\epsilon$ is a nonzero constant or a polynomial in n. Our lower bound for worst-case faults is tight when $k = O(\log n)$. In joint work with Kleitman [5], we have shown that there are better lower bounds for worst-case faults when k is very large, say, exponential in n.

Acknowledgment. We thank the anonymous referee for an outstanding job.

ROUTING WITH MINIMUM WIRE LENGTH IN THE DOGLEG-FREE MANHATTAN MODEL IS $\mathcal{NP}$-COMPLETE[*]

TIBOR SZKALICZKI[†]

Abstract. The present article concentrates on the dogleg-free Manhattan model where horizontal and vertical wire segments are positioned on different sides of the board and each net (wire) has at most one horizontal segment. While the minimum width can be found in linear time in the single row routing, apparently there was no efficient algorithm to find the minimum wire length. We show that there is no hope to find such an algorithm because this problem is $\mathcal{NP}$-complete even if each net has only two terminals. The results on dogleg-free Manhattan routing can be connected with other application areas related to interval graphs. In this paper we define the minimum value interval placement problem. There is given a set of weighted intervals and w rows and the intervals have to be placed without overlapping into rows so that the sum of the interval values, which is the value of a function of the weight and the row number assigned to the interval, is minimum. We show that this problem is $\mathcal{NP}$-complete. This implies the $\mathcal{NP}$-completeness of other problems including the minimum wire length routing and the sum coloring on interval graphs.

Key words. single row routing, VLSI, $\mathcal{NP}$-complete problems, minimum wire length, interval graph

1. Introduction.

The *routing problem* is to decide whether the problem instance is routable under specified restrictions and, if yes, to determine the routes of the wires that optimize certain criteria. The points to be interconnected are called *terminals*. Routing within a rectangle is a basic problem of the VLSI design. In case of *single row routing* all terminals appear only on one side of the rectangle. This is a special case of the *channel routing* where all terminals are located either at the upper or the lower boundary of the routing region. A *net* is a collection of terminals. An instance of the problem is a set of pairwise disjoint nets. The solution of a routing problem is a set of subgraphs (wires) where each subgraph connects all the terminals of the corresponding net under the conditions of the wiring model. In the *Manhattan model* wires run on a rectangular grid and horizontal and vertical wire segments are positioned on different sides of the board. In a restricted version of the Manhattan model each wire could occupy only one horizontal row (track). This model is called the *dogleg-free* model. We are interested in the complexity of finding the minimum wire length solution of the given routing problem in the dogleg-free model. Lengauer [5] presents a detailed exposition of the routing in the Manhattan model.

The minimum width can be found in linear time in the single row routing in the Manhattan model (Gallai [1]; see also Recski [7]). Szkaliczki [8] found an algorithm for the minimum wire length whose running time is linear in the length and super-polynomial in the width of the channel even in case of the channel routing. LaPaugh [4] proved that the channel routing problem is $\mathcal{NP}$-complete. We shall prove that

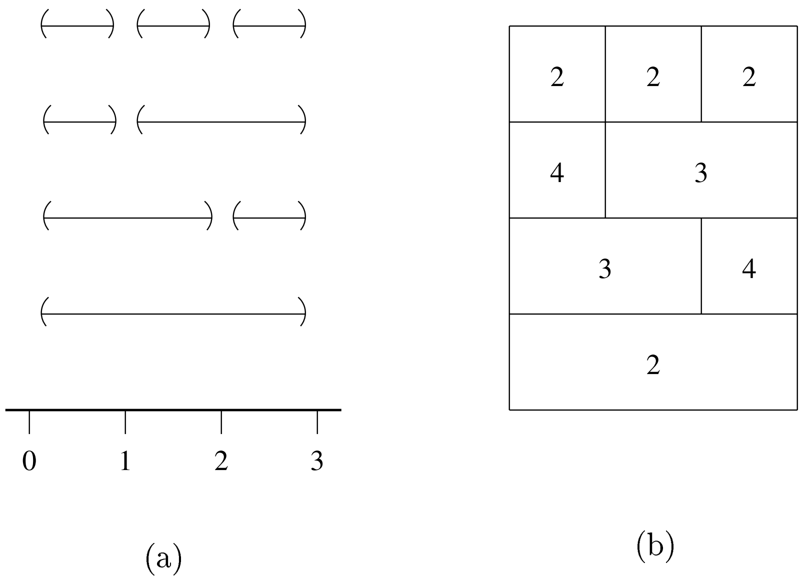

FIG. 1. *An instance of the interval placement problem:* (a) *interval representation,* (b) *rectangle representation.*

the minimum wire length single row routing in the dogleg-free Manhattan model is $\mathcal{NP}$-complete so there is no hope to find an algorithm which is polynomial both in length and width. This holds even if each net has only two terminals. Our result is that the minimum wire length routing is computationally difficult even in one of the simplest cases.

In this paper we define the minimum value interval placement problem. We prove that it is $\mathcal{NP}$-complete. We use this result to prove that finding the minimum wire length is $\mathcal{NP}$-complete in the single row routing in the dogleg-free Manhattan model. The minimum value interval placement can be applied to other areas such as graph coloring.

2. Interval placement problem.

The *interval placement problem* is as follows. Assume a finite set of intervals on a line and w rows. Each interval has to be placed into one of the rows in such a way that two intervals can be placed into the same row if and only if they have no common point. Several intervals can have the same end point. Figure 1(a) depicts an instance of the interval placement problem ($w = 4$). This figure not only gives the specification of the problem instance but also shows one of the solutions.

We often need an optimum solution. The minimum width, that is, the minimum number of necessary rows, can be found in linear time (Gallai [1]; see also Recski [7]). We define the value of a solution of an interval placement problem in the following way. A weight is assigned to each interval. The interval j has the weight l_j and in a solution it is placed into row r_j. The value of an interval is $r_j \cdot l_j$. The value (v) of a solution of the interval placement problem is the sum of the values of all intervals:

$$v = \sum r_j \cdot l_j. \tag{1}$$

If l'_i is the sum of the weights of the intervals in the ith row, then $v = \sum_{i=1}^{w} i \cdot l'_i$.

The *minimum value interval placement problem* is as follows: Is there a solution for the interval placement problem for which the value is at most k?

For simplicity, we assume that each interval is open, that is, two intervals placed into the same row can have common end points.

Figure 1(b) depicts the weighted version of the interval placement problem shown in Figure 1(a) using another notation. A rectangle corresponds to an interval. There are w rows and they have width in contrast with the notation in Figure 1(a). The height of each rectangle is equal to the width of the rows and their length is equal to the length of the corresponding interval. The rectangle is placed into the row assigned to the interval. The weights are denoted by the numbers written in the rectangles. We will use this notation because it is clear and it is suitable for the description of the solution as well as the specification of the interval placement problem.

We will deal with the saturated interval placement problem. We call an interval placement problem *saturated* if each point except the boundaries of intervals is inside either none of the intervals or exactly w intervals. Thus the intervals have to be placed continuously, without an empty place in each row. Therefore two intervals can be placed into the same row if and only if at the end of one of them is the starting point of the other or the section between them can be filled up with other intervals without an empty place.

3. Construction. We will reduce an $\mathcal{NP}$-complete problem to the minimum value interval placement problem in order to prove that this problem is $\mathcal{NP}$-complete as well. We shall show a transformation that translates an instance of a satisfiability problem of Boolean formulas (SAT; see Garey and Johnson [2]) into a saturated instance of the interval placement problem which has a solution with value k if and only if the original instance is satisfiable. The instance of SAT consists of n variables and m clauses. Without loss of generality, we assume that no clause contains the same variable more than once.

In this section, we consider each of the construction elements that correspond to the constituents of Boolean formulas (occurrence of a Boolean variable in a clause, Boolean variable, and clause). Using these elements we make a construction corresponding to the whole Boolean formula. We determine the proper weights of some additional intervals and the threshold value k for the instance of the minimum value interval placement problem. At last, we prove the $\mathcal{NP}$-completeness of the problem.

3.1. Occurrence of a variable. Figure 2 shows the part of the construction corresponding to an occurrence of a variable. Let us call it the *variable-occurrence element.* There are four different ways to place the intervals in four rows, as shown in Figure 2. If the rows in each of these figures are permuted, we do not consider the new solution to be essentially different. Obviously, in the optimal realization the sums of the weights of intervals in the same row are in decreasing order. Figure 2 depicts the four different realizations. The sum of the weights of the intervals in the rows and the value of the realization can be seen beside the realization. A variable-occurrence element has two different realizations with the minimum value. Let the realization Figure 2(a) (A) correspond to true and Figure 2(b) ($\overline{A}$) correspond to false.

3.2. Variable. Four adjacent rows correspond to a variable. Let us call them the *variable element*. They contain as many variable-occurrence elements as the number of occurrences of the variable in clauses. The variable in Figure 3 occurs in two clauses. We will determine the weights of the first intervals of the rows in section 3.5. The intervals with weight 2 located between two adjacent variable-occurrence elements

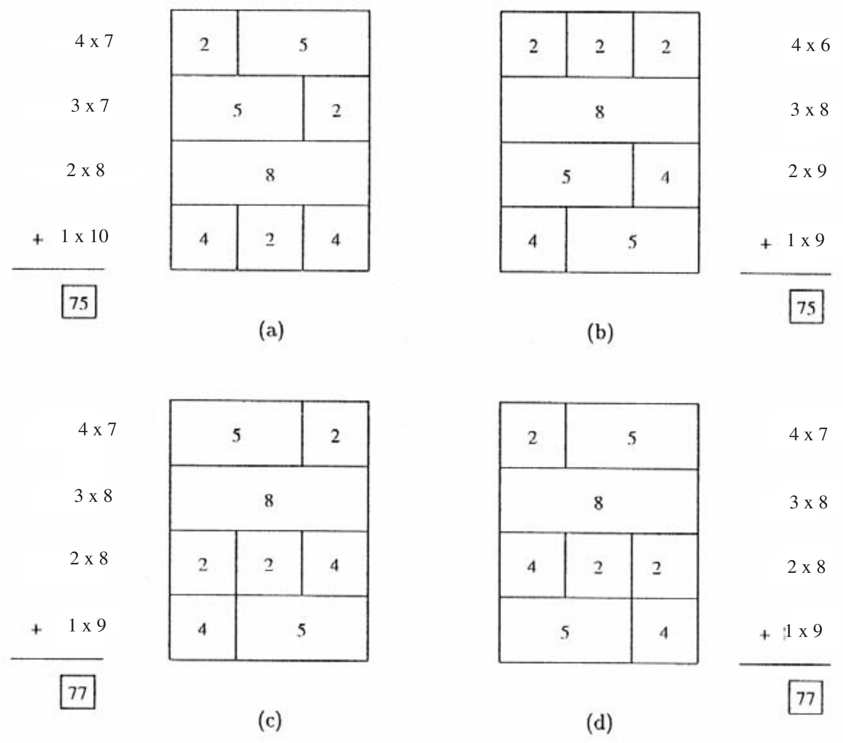

FIG. 2. *Element corresponding to an occurrence of a variable.*

and at the end of the rows are called *variable-connecting intervals*. An interval with weight 2 in the variable-occurrence element is lengthened because its exchange with an interval belonging to a clause will be permitted (see section 3.3 below), but further exchanges should be prevented. All the intervals with weight 8 belonging to the same variable and the variable-connecting intervals between them are merged into one long interval.

LEMMA 1. *The value of the variable element is minimum if and only if either realization A or $\overline{A}$ occurs at each element corresponding to an occurrence of the same variable.*

Proof. The realizations A and $\overline{A}$ of a variable-occurrence element are its minimum value realizations. The merged interval forces each element belonging to the same variable to have the same minimum value realization. □

3.3. Clause. The element corresponding to a clause is called the *clause element*. A specific example of a clause element is shown in Figure 4. The lower two rows are the *clause rows* and the rows above them are the *variable rows*. The intervals with weight t_1 and t_2 are placed between clause elements. They are called *clause-connecting intervals*. Notice that the two clause rows cannot be exchanged on a section within

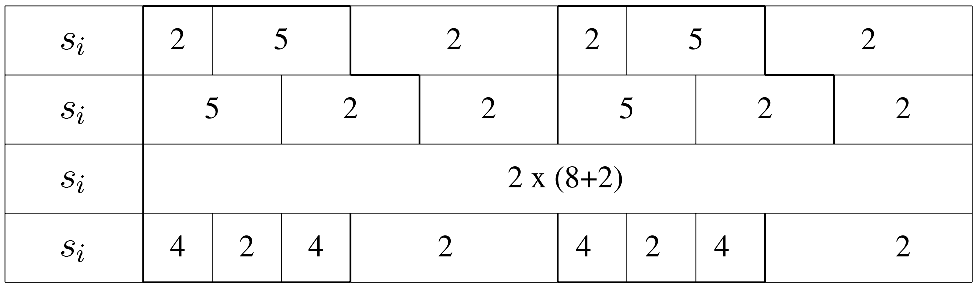

FIG. 3. *An element corresponding to a variable.*

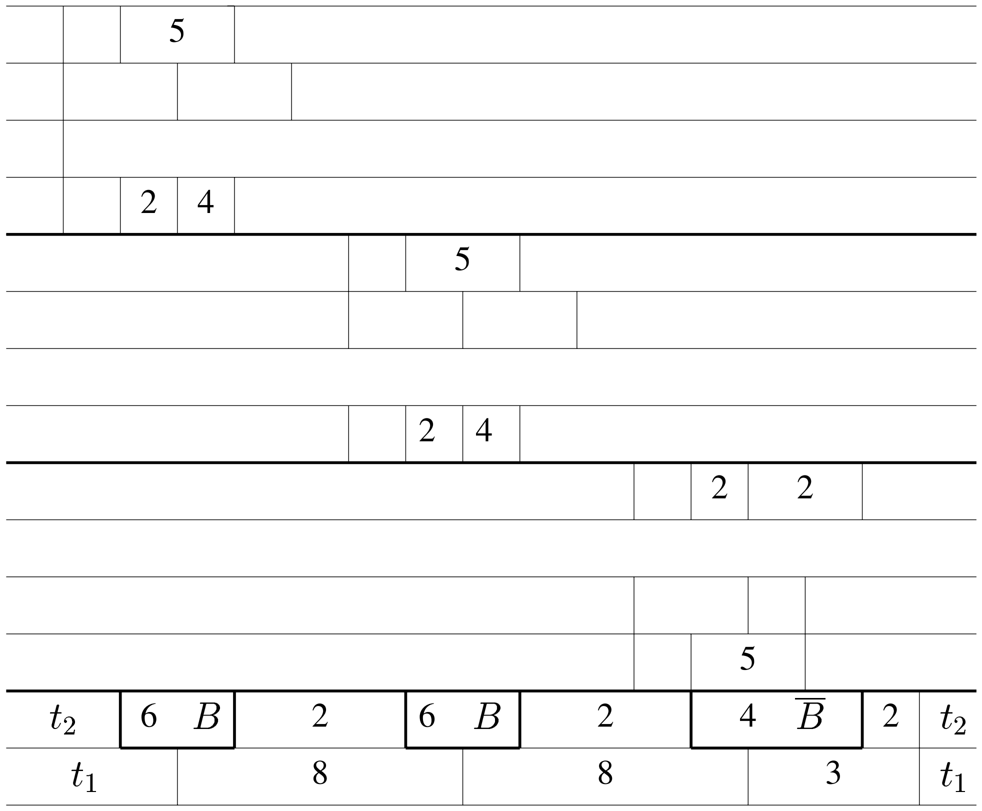

FIG. 4. *An element corresponding to the clause* $x_3 \vee x_2 \vee \overline{x}_1$.

a clause element because the intervals in different rows have no common end point. There are two types of intervals in clause rows that can be exchanged with the intervals in variable rows: B corresponds to a nonnegated variable and $\overline{B}$ to a negated variable. These intervals are marked with a thick border in the figure. The weight of B is 6 and its length is 2. The weight of $\overline{B}$ is 4 and its length is 3. There are as many variable-occurrence elements on the section of a clause element as there are variables included in the clause: each interval B and $\overline{B}$ is inside the section of exactly one variable-occurrence element corresponding to the variable included in the clause.

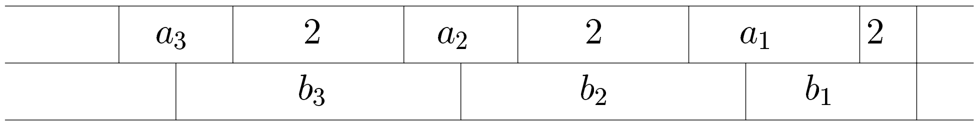

FIG. 5. *Weights of the intervals of a clause element.*

LEMMA 2. *If the clause-connecting intervals are in the lowest two rows, then among the intervals belonging to clauses only the intervals B and $\overline{B}$ can be placed into a higher row.*

Proof. Each interval belonging to a clause except B and $\overline{B}$ has a section where a variable-connecting interval is situated in each variable row. If one of these intervals is placed into a variable row, then a variable-connecting interval has to be placed into one of the clause rows. Each variable-connecting interval overlaps clause-connecting intervals. Thus at least one of the clause-connecting intervals has to be placed into a variable row, a contradiction. ▯

Figure 5 shows the clause element in the general case. a_i and b_i denote weights whose values depend on the concrete clause. We know that a_i (the weight of B or $\overline{B}$) is 4 or 6. Let

$$b_i = \begin{cases} a_i + 2 & \text{if } i > 1, \\ a_i - 1 & \text{if } i = 1. \end{cases}$$

There are two kinds of clause-connecting intervals. Let the longer interval with weight t_1 be placed into the lowest row and the shorter one with weight t_2 be placed into the second row from below. The clause rows can be exchanged with one another within a section containing clause elements together with clause-connecting intervals. The sum of weights of the intervals of a clause element in the first clause row is three plus that in the second row. Thus if $t_1 = t_2 + 4$, then the sum of weights of the intervals in the first row is greater than one in the second row, so it is not worth changing these rows in the minimum value solution. This is true even if some intervals of the clause rows are exchanged with intervals of the variable rows. The value of $t_2 = t$ will be determined in section 3.6.

Depending on the realization of the variable-occurrence element overlapping the intervals B and $\overline{B}$, we may say that realization A or $\overline{A}$ belongs to the intervals B and $\overline{B}$.

LEMMA 3. *Let us assume that the clause-connecting intervals are placed into the lowest two rows and the variable-occurrence elements together with the variable-connecting intervals belonging to the same variable are placed into adjacent rows. Then the placement of intervals belonging to them has the minimum value if and only if realization A belongs to interval B or realization $\overline{A}$ belongs to $\overline{B}$ at least at one occurrence of a variable at each clause.*

Proof. Let us suppose that each interval belonging to the clause is in the lowest two rows and each interval belonging to the occurrences of variables is in the corresponding variable rows, as Figure 4 shows. Now we examine how the value of this placement can be reduced. By Lemma 2, only intervals B or $\overline{B}$ can be placed into variable rows from clause rows.

Let us consider the minimum value placement if an interval B or $\overline{B}$ is placed into a variable row. If A is the realization of the variable, then the intervals with weight 2 and 4 can be exchanged with B in the clause row; however, there is no exchange

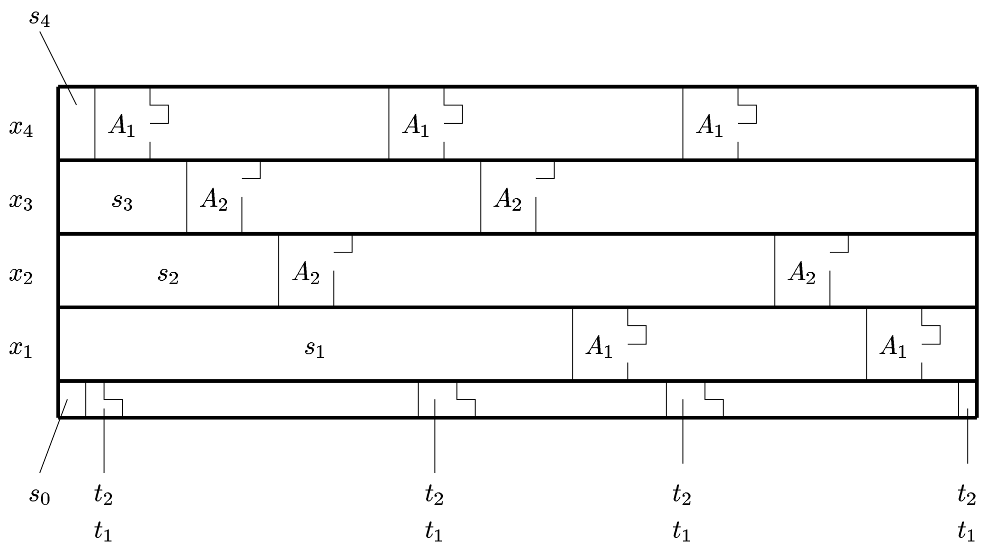

FIG. 6. *Outline of the construction corresponding to the formula* $(x_4 \vee x_3 \vee x_2) \wedge (x_4 \vee \overline{x}_3 \vee x_1) \wedge (\overline{x}_4 \vee \overline{x}_2 \vee \overline{x}_1)$.

with $\overline{B}$. If $\overline{A}$ is the realization of the variable, then two intervals with weight 2 can be exchanged with $\overline{B}$. The interval with weight 5 can be exchanged with B, but this is not worth doing because the total value increases and this exchange does not enable an additional exchange. The exchange of B or $\overline{B}$ with the appropriate intervals belonging to variables does not modify the total value of the placement but it enables the exchange of the two clause rows on a section, which reduces the total value by one. Let us call this exchange of clause rows an *improving exchange*. It does not matter whether one or more intervals belonging to the same clause are exchanged with intervals of variable rows because the total value can be reduced by one in each case.

It can easily be proved that this is the only way to reduce the value. For this reason, the value of a clause element cannot be reduced by more than one. Thus the value of a clause element can be reduced by one if and only if realization A belongs to interval B or realization $\overline{A}$ belongs to $\overline{B}$ at one or more occurrences of variables. The total value is minimum if this holds at each clause. □

3.4. Boolean formula. Now we know all the necessary elements to construct an instance of the interval placement problem that can be realized with a certain value if and only if the original Boolean formula is satisfiable. The structure of the whole construction is essentially the repetition of the block shown in Figure 4. Figure 6 depicts a construction in outline.

LEMMA 4. *If the clause-connecting intervals are in the lowest two rows and if the first intervals belonging to variables are in the corresponding variable rows, then none of the intervals belonging to variables are in rows belonging to other variables.*

Proof. The proof is indirect. Assume that some of the intervals belonging to variables are placed into rows belonging to other variables. A variable-connecting interval has to be moved in any case because each interval of a variable-occurrence element overlaps a variable-connecting interval or a fixed first interval in each row belonging to other variables. Let i denote the variable-connecting interval which is placed into a row belonging to another variable v, and its first point is the leftmost among the points of such variable-connecting intervals. Interval i cannot be placed into a clause row because each variable-connecting interval overlaps clause-connecting intervals fixed in the lowest two rows. There is an interval j which overlaps the beginning of interval i, belongs to variable v, and is placed into a row belonging to another variable. Notice that the beginning of each variable-connecting interval is overlapped only by variable-connecting intervals or by fixed first intervals in the rows belonging to other variables. If j is a variable-connecting interval, then this contradicts the assumption that i is the leftmost variable-connecting interval which is placed into a row belonging to another variable. If j is a first interval, then this contradicts the fact that the first intervals are fixed. $\square$

3.5. The weight of the first interval of a row. Let s_i be the weight of the first intervals belonging to the ith variable $(1 \le i \le n)$ and let s_0 belong to the clause rows. Let the weights of the first intervals belonging to the same variable be the same. Let l_{ia} $(1 \le i \le n, a = 1,2,3,4)$ be the sum of the weights of the intervals in the ath row of the ith variable and l_{0a} $(a = 1,2)$ be the sum of the weights of the intervals in the ath clause row. Let $l'_{ia} = l_{ia} - s_i$. Let l' be greater than any l'_{ia}, $i \ge 1$.

LEMMA 5. *If $s_i = (n+1-i)\cdot 12m$ $(0 \le i \le n)$ and the clause-connecting intervals are in the lowest two rows, then the first intervals belonging to the clauses are in the lowest two rows and the first intervals belonging to the ith variable are in the rows $4k-1$, $4k$, $4k+1$, $4k+2$ in the minimum value solution. (m is the number of the clauses and n is the number of the variables in the Boolean formula.)*

Proof. The sum of the weights of the intervals of a variable-occurrence element in one row and the weight of a variable-connecting interval is at most 12. By Lemma 2, if the clause-connecting intervals are in the lowest two rows, then only intervals B and $\overline{B}$ can be placed from the clause rows into the variable rows and these intervals do not increase the maximum sum of weights of a variable row. Thus the value $12m$ is appropriate for l'.

Let now $s_i = (n+1-i)\cdot 12m$. In this case if $j < i$, then $s_j > l' + s_i$ and so $l_{ja} > l_{ib}$ for each a and b. Thus the first interval with weight s_i is assigned to a higher row than that with weight s_j in the minimum value solution. Therefore the first intervals are placed into rows in decreasing order of their weights. $\square$

3.6. The weights of the clause-connecting intervals. Let the total value of the first intervals in all rows be v_1, the total value of the variable-occurrence elements be v_2, the total value of the variable-connecting intervals be v_3, the total value of the clause elements be v_4, and the total value of the clause-connecting intervals be v_5.

v'_i $(i = 1,2,3,4,5)$ denotes the corresponding values belonging to minimum value placement assuming that each clause-connecting interval is placed into the lowest two rows; v''_i $(i = 1,2,3,4,5)$ denotes the same values assuming that at least one of the clause-connecting intervals is not placed into the lowest two rows.

LEMMA 6. *If the weights $(t_1 = t+4, t_2 = t)$ of the clause-connecting intervals are at least $v'_2 + v'_3 + v'_4$, then there is a minimum value solution where these intervals are placed into the lowest two rows.*

Proof. If an interval is placed higher by one or more rows, then the value is increasing by at least the weight of the interval. Thus $v''_5 \ge v'_5 + t$. By Lemma 5, if the clause-connecting intervals are in the lowest two rows, then the first intervals are placed into rows in decreasing order of their weights. The value of their placement cannot be reduced; thus $v'_1 \leq v''_1$. Since $v''_i > 0$,

$$v'' = v''_1 + v''_2 + v''_3 + v''_4 + v''_5 \geq v''_1 + v''_5 \geq v'_1 + v'_5 + t \geq v'_1 + v'_5 + v'_2 + v'_3 + v'_4 = v'.$$

Thus if the clause-connecting intervals are placed into the lowest two rows, then the minimum value of the placement is not greater than the value of any placement containing at least one clause-connecting interval in the third or higher rows. ∎

3.7. Minimum value and $\mathcal{NP}$-completeness. We have shown a construction to assign a weighted interval set to each instance of SAT. We have to calculate an appropriate value for k which is contained by the instance of the minimum value interval placement problem as well and it is equal to the minimum value which can be achieved if and only if an improving exchange can be realized at each clause. Details are omitted, but it is necessary to note that k can be determined in polynomial time, because each weight and the value of each component of the optimum solution can be calculated in polynomial time. The equation for k is quite complicated:

$$k = 36(n+1)m + 4mn(n+1)(8n+19) + \sum_{i=1}^{n} j_i \cdot 95 \tag{2}$$

$$+ \sum_{i=1}^{n} j_i(4i-2)\cdot 40 + 24\sum_{i=1}^{m} p_i + 18\sum_{i=1}^{m} q_i - 4m + (m+1)(600mn^2+4).$$

Theorem 1. *The saturated minimum value interval placement problem is $\mathcal{NP}$-complete.*

Proof. The instance of SAT consists of n variables and m clauses, and o is the total number of occurrences of the variables. The dimensions of the instance of the interval placement problem are the following:

The number of rows: $4n+2$.

The number of variable-occurrence elements: o.

The number of clause elements: m.

The number of intervals: $12o + 2m + 5n + 4$.

The number of different interval boundaries: $5o + m + 2$.

The maximum weight: $200mn^2 + 4$.

$k < c(n^3m + n^2m^2)$, where c is an appropriate constant.

Each element of the construction can be determined in polynomial time in the size of the Boolean formula, and the whole construction applies a polynomial number of building elements. We can conclude that each instance of SAT can be translated into an instance of the minimum value interval placement problem in polynomial time.

We shall prove that the interval placement problem has a solution with value k if and only if the Boolean formula is satisfiable. By Lemma 6, the clause-connecting intervals are placed into the lowest two rows in the minimum value solution. By Lemma 5, the first intervals belonging to the variables are placed into fixed adjacent rows in the minimum value solution. Thus Lemmas 2 and 4 guarantee that each interval belonging to a variable except the intervals interchanged with B or $\overline{B}$ is placed into the corresponding variable row. By Lemma 1, the same realization belongs to each element corresponding to the occurrence of the same variable in the minimum value solution. By Lemma 3, the solution of the instance of the interval placement problem has the least value if and only if realization A belongs to interval B or realization $\overline{A}$ belongs to interval $\overline{B}$ at least at one occurrence of a variable in each clause element.

Suppose first that the placement of intervals can be realized with value k. If the variable element has a realization A or $\overline{A}$, let the corresponding Boolean variable be true or false, respectively. In this case each clause and the entire Boolean formula is satisfiable. Conversely, if the Boolean formula is satisfiable, apply realization A or $\overline{A}$ to the variable element depending on the value of the Boolean variable. In this case we can make an improving exchange in each clause element and we can achieve the placement value k. $\square$

4. Extensions and further results.

4.1. Unweighted case. The problem remains $\mathcal{NP}$-complete in the unweighted case, when the weight of each interval is 1 so the value of the interval j placed into the row r_j is simply r_j and the value of the solution is $v = \sum_j r_j$.

The saturated weighted case can be reduced to the unweighted case in the following way. Each interval with weight l_j has to be divided by $l_j - 1$ new points into l_j intervals in such a way that none of the new points coincides with an interval end point in the original problem instance and none of the new points coincides with another. In this case, all the intervals derived from the same weighted interval must be placed into the same row. Using this it can be shown that the unweighted interval placement problem is $\mathcal{NP}$-complete, too.

We still have to show that the transformation can be done in polynomial time. The only critical point is the number of divisions to be done. This is less than the product of the number of intervals in the original instance and the maximum weight. Unfortunately, the value of a weight is exponential in its length. However, the minimum value interval placement problem remains $\mathcal{NP}$-complete if all weights can be bounded from above by a polynomial in the number of intervals (see the expressions for the maximum weight and for the number of intervals in the proof of Theorem 1). For this, the number of divisions to be done can be bounded from above by a polynomial in the input length.

4.2. Maximization. Obviously, if we exchange the order of the rows of the minimum value solution, then we get the maximum value solution. Hence, this latter problem is $\mathcal{NP}$-complete, too.

4.3. Arbitrary width. We have assumed that the number w of the rows is given. We distinguish two new variants of the minimum value interval placement problem.

Let $\Pi(S, x)$ be the problem of deciding whether the weighted intervals in set S can be placed without overlapping with the total value at most x and with the minimum width.

Let $\Pi_0(S, x)$ be the problem of deciding whether the weighted intervals in set S can be placed without overlapping with the total value at most x and with arbitrary width.

Since the width in the construction in the proof of Theorem 1 is equal to the minimum width, $\Pi(S, x)$ is $\mathcal{NP}$-complete. $\Pi_0(S, x)$ is obviously in the class $\mathcal{NP}$. We shall prove that $\Pi_0(S, x)$ is $\mathcal{NP}$-complete, too. For this, we reduce $\Pi(S, x)$ to $\Pi_0(S, x)$ in polynomial time. We show that for each instant S, x there exists an instance S', x' so that $\Pi(S, x)$ is true if and only if $\Pi_0(S', x')$ is true.

This is not trivial because the minimum value placement may use more rows than the necessary minimum (see Figure 7). The minimum value is at most the value belonging to the situation when each interval would be placed into the highest row. Thus the total value v of a placement can be bounded from above by $k = y \cdot w + 1$,

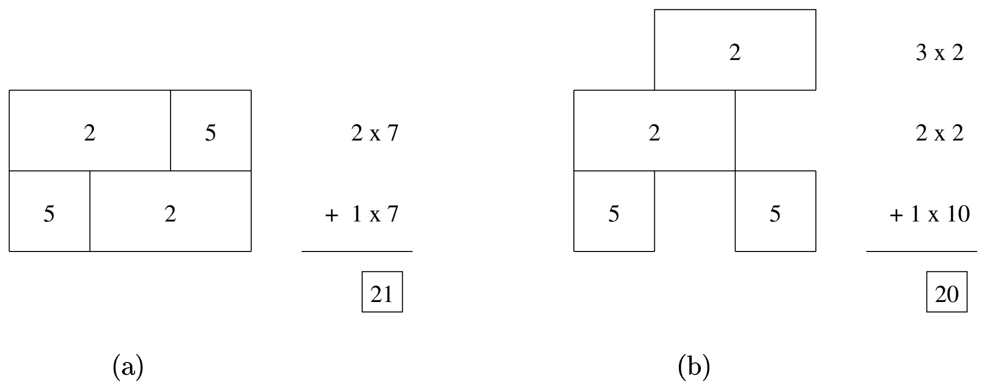

FIG. 7. *The minimum value and the minimum width placement problems are different.* (a) *A minimum value placement.* (b) *A minimum width placement.*

where y is the sum of the weights and w is the number of the rows (width). Therefore $v < k$. We get S' from S by adding k intervals with weight 1 which cover all the intervals in S. Let v' be $v + k \cdot (2w + 1 + k)/2$.

LEMMA 7. *The minimum value interval placement problem Π_0 with arbitrary width is $\mathcal{NP}$-complete.*

Proof. We have shown how to translate an instance of Π into an instance of Π_0. Now we show that the intervals in S' can be placed with the total value at most v' in any number of rows if and only if the intervals in S can be placed with the total value at most v and with minimum width w.

(if) The intervals from S are placed into the first w rows with the total value at most v. The new intervals are placed into the rows $w + 1$ through $w + k$. The total value of the new intervals is $k \cdot (2w + 1 + k)/2$.

(only if) Let us suppose that the intervals in S' can be placed with the total value at most v'. Let us note that the new intervals with weight 1 are placed into separate rows and these rows are the weakest ones; thus they are the highest rows. Let us suppose that the other intervals occupy at least $w + 1$ rows. Then the total value of the additional intervals with weight 1 is at least $k\cdot(2w+3+k)/2 = k+k\cdot(2w+1+k)/2 > v + k \cdot (2w + 1 + k)/2 = v'$. Consequently, the intervals from S use only the first w rows if the value is at most v' and the new intervals use the rows $w+1$ through $w+k$. In this case the total value of the new intervals is $k \cdot (2w + 1 + k)/2$. Since the total value of the intervals in S' is at most $v' = v + k \cdot (2w + 1 + k)/2$, the total value of the original intervals from S is at most v.

We have to check that this reduction can be done in polynomial time. For this, we show that k can be bounded from above by a polynomial in the length of the instance of Π. This length is proportional to the number i of the intervals. Clearly, $w \leq i$. Let us notice that our $\mathcal{NP}$-completeness result for problem Π holds even if all weights can be bounded from above by a polynomial in the number of the intervals. In this case, the sum y of all weights and k, which is calculated from the product of y and w, are less than a polynomial in the length of the problem instance. ∎

4.4. Graph coloring. The interval placement problem can be associated with interval graphs in the following way. The vertices of the interval graph correspond to the intervals and there is an edge between two vertices exactly if the corresponding intervals overlap. The weights of the intervals are assigned to the vertices.

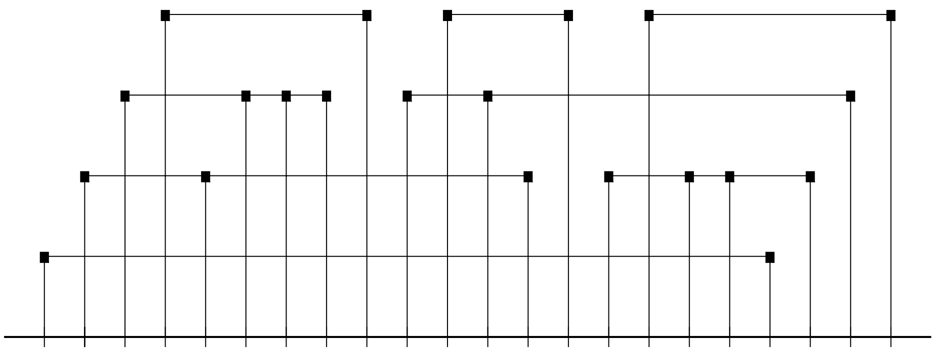

FIG. 8. *Single row routing corresponding to the interval placement in Figure* 1.

The coloring of the graph corresponds to the placement of the intervals if the colors correspond to the rows. The colors are numbered from 1 to w. The value of a vertex is the product of the color number and the weight of the vertex. We define the *minimum value graph coloring problem* to be the minimization of the sum of the values of each vertex. The minimum value coloring of an interval graph is tantamount to the minimum value interval placement problem, so it is also $\mathcal{NP}$-complete while the original coloring problem of an interval graph is polynomial.

We can apply our result to the chromatic sum problem. The chromatic sum of a graph is the minimum sum of the color numbers. The problem of determining the chromatic sum is known as the *chromatic sum problem* and the problem of producing a coloring where the sum of color numbers is equal to the chromatic sum is known as the *sum coloring problem.* These problems on arbitrary graphs are $\mathcal{NP}$-complete [3]. There is an approximation result on interval graphs [6]. Now, we can determine the complexity of these problems on interval graphs. The chromatic sum problem can be regarded as an unweighted version of the minimum value graph coloring problem. Similarly to the weighted case, the $\mathcal{NP}$-completeness of the chromatic sum problem and the sum coloring problem on interval graphs follows from the $\mathcal{NP}$-completeness of the unweighted version of the minimum value interval placement problem. If the number of colors is not fixed in the chromatic sum problem, first we reduce the unweighted version to the minimum value interval placement problem with arbitrary width, then the later problem is reduced to the chromatic sum problem.

5. Application to VLSI routing. The previous result implies the $\mathcal{NP}$-completeness of other problems. The constraint graph of an instance of the single row routing problem in the Manhattan model is an undirected graph such that its vertices correspond to the nets and two vertices are adjacent if and only if the nets overlap. This is an interval graph and can be used to describe the single row routing problems in the dogleg-free Manhattan model. An assignment of tracks to nets that represents a legal routing is a coloring of the constraint graph. The colors are track numbers and the vertices represent nets. Each instance of the coloring problem of the interval graphs can be transformed into an instance of the single row routing problem in the dogleg-free Manhattan model and vice versa. Lengauer [5] shows a transformation of a coloring problem into a routing problem. Figure 8 shows the routing problem constructed by translating the instance of the interval placement problem in Figure 1.

The minimum width (w) can be determined in linear time. Now we are interested in the minimum wire length. The total length of the horizontal segments is the same in any realization of the routing. Thus the minimization of the wire length is equivalent to the minimization of the vertical segment length.

How can the total vertical segment length be determined? If net j is placed into track r_j and it has l_j terminals ($l_j \geq 2$), then the vertical wire length of this net is $r_j \cdot l_j$. If there are t nets, then the total vertical wire length is

$$v = \sum_{i=1}^{t} r_j \cdot l_j. \tag{3}$$

If altogether l'_i terminals belong to the nets in the ith track, then $v = \sum_{i=1}^{w} i \cdot l'_i$.

The minimum wire length single row routing problem is equivalent to the following: Is there a realization of the given single row routing with width w in the dogleg-free Manhattan model for which the value defined in (3) is at most k?

Using this it is easy to see that each instance of the minimum value coloring problem of the interval graphs can be transformed into an instance of the minimum wire length single row routing in the dogleg-free Manhattan model if the weights of the vertices are integers greater than 1. The minimum value interval placement problem can be reduced to the minimum value coloring problem and it remains $\mathcal{NP}$-complete even if each weight is greater than 1 because the construction shown in the proof of the $\mathcal{NP}$-completeness uses such weights. Thus we managed to reduce an $\mathcal{NP}$-complete problem to the minimum wire length single row routing problem in the dogleg-free Manhattan model so it is $\mathcal{NP}$-complete.

THEOREM 2. *Single row routing with minimum wire length is $\mathcal{NP}$-complete in the dogleg-free Manhattan model.*

If each net has the same number of terminals, then the number of terminals can be eliminated from the expression in (3). Thus, the unweighted minimum value interval placement problem can be reduced to the restricted version of the minimum wire length single row routing problem when each net has the same number of terminals. Consequently, the minimum wire length single row routing problem is $\mathcal{NP}$-complete even if each net has only two terminals.

Similarly, an obvious consequence of Lemma 7 is $\mathcal{NP}$-completeness of the minimum wire length single row routing problem with arbitrary width in the dogleg-free Manhattan model.

Theorem 2 implies that routing with minimum wire length is $\mathcal{NP}$-complete in the dogleg-free Manhattan model in case of any shape of the routing region. This has been proved previously in cases of channel and switchbox routing [4]. However, this is a new result in cases of routing around a rectangle as well as in cases of gamma routing where terminals appear on two adjacent sides of a rectangular. For example, LaPaugh [4] presented a polynomial algorithm which finds a layout with minimum area in the Manhattan model if terminals are on four sides of a rectangular and the wires lie on the outside of the rectangle. However, there is no polynomial algorithm for optimizing the wire length. By Theorem 2, this problem is $\mathcal{NP}$-complete and thus there is no hope to find such an algorithm.

6. Conclusions. In this paper we assigned a value to a placement of intervals and proved that the minimum value interval placement problem is $\mathcal{NP}$-complete. This result could be applied to the interval graphs which are among the most useful mathematical structures for modeling real-world problems. Thus we proved that the minimum value coloring of interval graphs is $\mathcal{NP}$-complete. The routing problem is known to be $\mathcal{NP}$-complete in many cases. In this paper we have shown that finding the minimum wire length is computationally difficult even in one of the simplest cases—single row routing in the dogleg-free Manhattan model. This completes the previous results on complexity of routing with minimum wire length in the dogleg-free Manhattan model.

ON REGULAR TREE EMBEDDINGS*

WEIMIN CHEN† AND VOLKER TURAU‡

Abstract. Regular trees are a natural extension of finite trees, which have many applications. The path-embedding problem is to determine whether a regular tree S can be obtained from another regular tree T by deleting (probably infinitely many) subtrees of T. This paper explores efficient algorithms for the path-embedding problem in ordered and unordered trees. Given two regular trees S and T represented by rational graphs, our algorithms solve the ordered version of path-embedding problem in $O(|E_S||E_T|)$ time and the unordered version in $O(|E_S||E_T|D_SD_T)$ time. Here $|E_S|$ denotes the number of edges in the rational graph for S, and D_S denotes the maximum outdegree of a vertex in S. We also demonstrate that our approach can be applied to pattern matching problems for regular trees recently studied by Fu [*J. Algorithms*, 22 (1997), pp. 372–391].

1. Introduction.

A *labeled infinite tree* is a directed tree in which each node is assigned a unique label and each node has a finite number of children but the number of nodes in the tree may be infinite. Given a node v in a labeled infinite tree T, a *subtree* of T rooted at v is the tree induced by v and its descendants in T. A labeled infinite tree is called *regular* if it contains only finitely many distinct subtrees (two trees are regarded as distinct if they are not isomorphic). Further, a regular tree is called *ordered* (*unordered*) if the left-to-right order among siblings at each node is significant (insignificant, resp.). Figure 1 shows two examples of regular trees.

Regular trees are the basic tools for investigating tree automata, flow graphs [4], and type systems [2, 5]. In this paper we pose the following problem with respect to regular trees:

Given two regular trees S and T, can we obtain S from T by deleting (finitely or infinitely many) subtrees of T?

We call this problem the *ordered (unordered) regular tree path-embedding* problem if the regular trees S and T are ordered (unordered, resp.). The regular tree path-embedding problems are an extension of the finite tree path-embedding problems [7]. For ordered finite tree path-embedding problem, there is a simple $O(|S||T|)$ time algorithm [7], where S and T are the ordered finite trees. For the unordered finite tree path-embedding problem, efficient algorithms can be found in [8, 9, 11]. These algorithms run in $O(|S|^{3/2}|T|)$ time, where S and T both are unordered finite trees.

This paper explores efficient algorithms for the ordered and unordered regular tree embedding problems. The main idea of our approach is to treat the path-embedding algorithms as optimized procedures for finding a special solution of systems of boolean equations. By representing each regular tree as a finite rational graph [4], we solve the ordered version of the path-embedding in $O(|E_S||E_T|)$ time, and the unordered version in $O(|E_S||E_T|D_SD_T)$ time. Here, $|E_S|$ denotes the number of edges in the

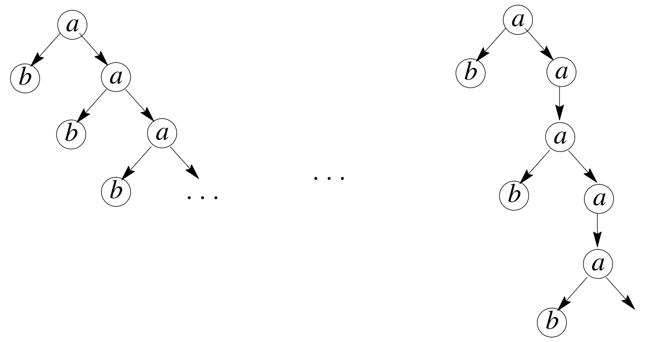

FIG. 1. *Two regular trees.*

rational graph for S, and D_S denotes the maximum outdegree of a vertex in S.

This paper is organized as follows. In section 2 we formally define the regular tree path-embedding problems and describe the data structure to represent regular trees. In sections 3 and 4, resp., we describe the ordered and unordered versions of our algorithms. Section 5 contains a comparison with related work. Finally, section 6 gives a short conclusion.

2. Basic definitions and rational graphs.

We give a formal definition for the path-embedding of ordered and unordered regular trees.

DEFINITION 2.1. *Let S and T be ordered regular trees. An injection $f : S \longrightarrow T$ is called an* ordered path-embedding *from S to T if*

(a) *f preserves roots, i.e., if r is the root of S, then $f(r)$ is the root of T;*
(b) *f preserves labels, i.e., $label(s) = label(f(s))$ for any node s of S;*
(c) *f preserves parents, i.e., if s_p is the parent of s, then $f(s_p)$ is the parent of $f(s)$;*
(d) *f preserves the order among siblings, i.e., if s_1 is a left sibling of s_2, then $f(s_1)$ is a left sibling of $f(s_2)$.*

Let $S \sqsubseteq^f T$ denote the fact that f is an ordered path-embedding of S into T.

For unordered regular trees S and T, an injective function $f : S \longrightarrow T$ is called an unordered path-embedding *of S into T if the above conditions* (a)–(c) *are satisfied. Let $S \sqsubseteq^f_{\mathrm{u}} T$ denote the fact that f is an unordered path-embedding of S into T.*

Further, let $S \sqsubseteq T$ and $S \sqsubseteq_{\mathrm{u}} T$, resp., denote that there exists a path-embedding f such that $S \sqsubseteq^f T$ and $S \sqsubseteq^f_{\mathrm{u}} T$.

In this paper we only consider the path-embedding problem and simply refer to it as the "embedding" problem.

Our first question is how to represent regular trees? Infinite regular trees can be expressed by finite systems. The natural approach is by means of rational graphs [4], defined as follows.

DEFINITION 2.2. *A* rational graph *$G = (V, E, r)$ is a finite directed graph, where V is the set of vertices, E is the set of edges, and $r \in V$ is the root such that*

(a) *all vertices of G are labeled over some alphabet;*
(b) *G may contain multiedges and loops;*
(c) *every vertex of G can be reached from the root r along a path of edges of G.*

A rational graph is called ordered (unordered)*, if the order of out-going edges at each vertex is significant (insignificant, resp.).*

Rational graphs are connected graphs. For completeness we show that an ordered regular tree can be expressed as an ordered rational graph, and vice versa. Let T be

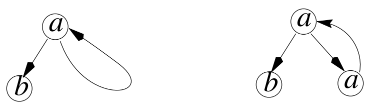

FIG. 2. *Rational graphs for regular trees in Figure* 1 *(top nodes are the roots).*

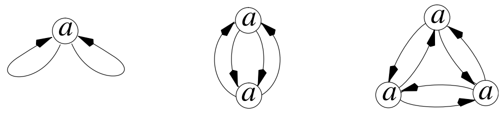

FIG. 3. *Rational graphs with multiedges for a full binary tree.*

an ordered regular tree and $S = \{T_1, \dots, T_s\}$ be the set of all distinct subtrees of T. The ordered rational graph $G = (V, E, r)$ of T can be constructed as follows. Let $V = \{v_1, \dots, v_s\}$, and let $label(v_i)$ equal to the label of the root of T_i. If $T_{i_1}, \dots, T_{i_l}$ (in S) are the directed subtrees of T_i from left to right, then $v_{i_1}, \dots, v_{i_l}$ are the successors of v_i from left to right. The root r is a vertex v_i such that T_i is equal to T. Conversely, given a rational graph $G = (V, E, r)$, a regular tree T can be constructed, level by level, by unfolding G starting at the root r (so T contains at most $|V|$ distinct subtrees). For example, the rational graphs in Figure 2 represent the regular trees in Figure 1.

Similarly, an unordered regular tree can be expressed as an unordered rational graph, and vice versa.

Note that a rational graph always represents a unique regular tree, but a regular tree may be represented by different rational graphs. Figure 3 depicts three different rational graphs (with multiedges) for the same regular tree.

We adopt the following notation to represent intervals of integers: Given integers a and b, let $[a..b]$ denote the set of integers n with $a \le n \le b$, and let $(a..b] = [a+1..b]$, $[a..b) = [a..b-1]$, and $(a..b) = [a+1..b-1]$.

3. Ordered embedding. Let S and T be ordered regular trees. Throughout this section let $G_S = (V_S, E_S, r_S)$ and $G_T = (V_T, E_T, r_T)$ denote the rational graphs for S and T. Given G_S and G_T, the task of the algorithm is to determine whether the relationship $S \sqsubseteq T$ holds.

For $(s, t) \in V_S \times V_T$, let $s \preceq t$ denote the following relation:

$$label(s) = label(t) \;\wedge\; d(s) \le d(t), \tag{1}$$

where $d(s)$ denotes the outdegree of vertex s. Furthermore, let $s \dot{\preceq} t$ be the abbreviation for

$$s \preceq t \;\wedge\; 0 < d(s).$$

The ith successor of s is denoted by $s[i]$. Let $\mathcal{B} = \{\mathbf{0}, \mathbf{1}\}$ denote the set of boolean values (represented in bold font).

Given a vertex v in rational graph G, let $tree(v)$ denote the regular tree obtained by unfolding G starting at v.

Before discussing the algorithm for the ordered regular tree embedding problem, let us look at the ordered finite tree embedding problem, which is also called the *ordered path inclusion* problem [7]. Suppose S and T both are ordered finite trees with roots r_S and r_T (so S and T can also be regarded as rational graphs). Let s and t be internal nodes in S and T (thus $\mathit{tree}(s)$ and $\mathit{tree}(t)$ are the subtrees rooted at s and t). To check whether $\mathit{tree}(s)$ can be embedded in $\mathit{tree}(t)$, the main idea behind the algorithm in [7] is to find a sequence of numbers $1 \le j_1 < j_2 < \cdots < j_{d(s)} \le d(t)$ such that $\mathit{tree}(s[i])$ can be embedded into $\mathit{tree}(t[j_i])$ for all $i \in [1..d(s)]$. Such a sequence can be found by scanning the children of s and t from left to right and thereby trying to find an embedding of the corresponding subtrees in a bottom-up fashion. The following function, *emb*, performs this operation, and a call of $\mathit{emb}(s,t)$ returns the value of the expression $\mathit{tree}(s) \sqsubseteq \mathit{tree}(t)$.

```
(e1)    function $\mathit{emb}(s,t)$ returns $\mathcal{B}$
        { if $s \not\preceq t$ then return 0
          $i \leftarrow j \leftarrow 1$
          while $i \le d(s) \wedge j \le d(t)$ do
(e2)      { if $\mathit{emb}(s[i], t[j])$ then $i \leftarrow i+1$
            $j \leftarrow j+1$
          }
          return $(i = d(s)+1)$
        }
```

Let $\mathit{tree}(s,i)$ denote the tree obtained from $\mathit{tree}(s)$ by removing subtrees $\mathit{tree}(s[k])$, for $k \in (i..d(s)]$. Thus, $\mathit{tree}(s,d(s)) = \mathit{tree}(s)$. To check the correctness of the above function *emb*, notice that the invariant of the while-loop is

$$\mathit{tree}(s,i-1) \sqsubseteq \mathit{tree}(t,j-1) \ \wedge\ \mathit{tree}(s,i) \not\sqsubseteq \mathit{tree}(t,j-1).$$

We attempt to extend the above algorithm to general rational graphs. The main obstacle is that in rational graphs the ancestorship of vertices does not form a partial order due to the cycles in the graphs, and, consequently, the above bottom-up matching approach cannot be applied to rational graphs.

For the pattern matching problem presented in [5], a similar obstacle occurs. However, pattern matching preserves degrees; the path-embedding problem relaxing this constraint further complicates the algorithm. A detailed comparison is given in section 5.

3.1. Transformation. The main idea of our approach is to transform the tree embedding problem into the problem of finding a specific solution in a system of boolean equations. First, it is easy to derive the following lemma.

LEMMA 3.1. *For $(s,t) \in V_S \times V_T$, $\mathit{tree}(s) \sqsubseteq \mathit{tree}(t)$ iff $s \preceq t$ and at least one of the following conditions holds:*

(a) $d(s) = 0$.

(b) *There exists a sequence of numbers $1 \le l_1 < l_2 < \cdots < l_{d(s)} \le d(t)$ such that $\mathit{tree}(s[i]) \sqsubseteq \mathit{tree}(t[l_i])$ for $i \in [1..d(s)]$.*

Let x_s^t be a boolean variable for each $(s,t) \in V_S \times V_T$. Consider the following system of boolean equations: $\forall (s,t) \in V_S \times V_T$,

$$x_s^t \;=\; s \preceq t \wedge \left((d(s)=0) \vee \bigvee_{1 \le l_1 < \cdots < l_{d(s)} \le d(t)} \bigwedge_{i=1}^{d(s)} x_{s[i]}^{t[l_i]} \right). \tag{2}$$

Lemma 3.1 guarantees that

$$x_s^t \;=\; (\mathit{tree}(s) \sqsubseteq \mathit{tree}(t)),\ \ (s,t) \in V_S \times V_T \tag{3}$$

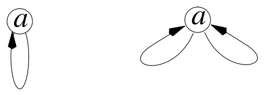

FIG. 4. *Two rational graphs.*

is a solution of (2). Hence we can ask how to find the solution (3) from (2). Note that (2) may have multiple solutions. For example, (2) corresponding to rational graphs shown in Figure 4 are $x_s^t = x_s^t \vee x_s^t$, for which there are two different solutions $x_s^t = \mathbf{0}$ and $x_s^t = \mathbf{1}$.

To obtain solution (3) from (2), we need the following concepts. Let $x_1, \ldots, x_n$ be boolean variables and $f_i : \mathcal{B}^n \longrightarrow \mathcal{B}$ for $i \in [1..n]$ boolean functions. Consider the following system of equations:

$$x_i = f_i(x_1, \ldots, x_n),\ \ i \in [1..n]. \tag{4}$$

DEFINITION 3.2. *A solution* $(a_1, \ldots, a_n)$ *for* (4) *is called the* maximum solution *if for any other solution* $(b_1, \ldots, b_n)$*,* $a_i \geq b_i$ *for all* $i \in [1..n]$*.*

Note that the maximum solution of (4) may not exist, but it is unique if it exists. Note that the above definition can be applied to (2) since they have the required form. This leads to the following result.

LEMMA 3.3. *The values of* x_s^t *given by expression* (3) *are the maximum solution of* (2)*.*

Proof. Lemma 3.1 proves that the values given in (3) are a solution of (2). Now we prove that they are the maximal solution. Let a_s^t with $(s,t) \in V_S \times V_T$ be any solution of (2). It suffices to show that $a_s^t \leq (\mathit{tree}(s) \sqsubseteq \mathit{tree}(t))$, i.e., if $a_s^t = \mathbf{1}$ then $\mathit{tree}(s) \sqsubseteq \mathit{tree}(t)$. We prove this by constructing a mapping f from $\mathit{tree}(s)$ to $\mathit{tree}(t)$ as follows. Let $f(s) = t$. The condition $a_s^t = \mathbf{1}$ implies that $s \preceq t$. If $d(s) = 0$, then $\mathit{tree}(s) \sqsubseteq \mathit{tree}(t)$. Now let $d(s) > 0$. Equations (2) guarantee the existence of numbers $1 \leq l_1 < l_2 < \cdots < l_{d(s)} \leq d(t)$ such that $a_{s[i]}^{t[l_i]} = \mathbf{1}$ for $i \in [1..d(s)]$. Applying the above argument with s and t replaced with $s[i]$ and $t[l_i]$, we define $f(s[i]) = t[l_i]$ for each $i \in [1..d(s)]$. Repeating this procedure level by level results in a mapping f from $\mathit{tree}(s)$ to $\mathit{tree}(t)$. Clearly, f satisfies all the conditions of Definition 2.1. Hence $\mathit{tree}(s) \sqsubseteq \mathit{tree}(t)$. ◻

The question is how to find the maximum solution of (2). It turns out that the answer to this question can be found by considering a more general problem. Consider the following definition.

DEFINITION 3.4. *A boolean function* $f : \mathcal{B}^n \longrightarrow \mathcal{B}$ *is called* monotonic*, if* $f(x_1, \ldots, x_n) \leq f(y_1, \ldots, y_n)$ *for all* $(x_1, \ldots, x_n)$ *and* $(y_1, \ldots, y_n) \in \mathcal{B}^n$ *with* $x_i \leq y_i$*,* $i \in [i..n]$*. Equations* (4) *are called* monotonic*, if all functions* f_i *are monotonic.*

The following theorem provides a key foundation of our algorithms for the ordered and unordered embedding problems.

THEOREM 3.5. *For monotonic* (4)*, the maximum solution exists and can be effectively found.*

Proof. We show that the maximum solution can be constructed by the following algorithm.

```
**algorithm R**
{ **foreach** $i \in [1..n]$ **do** $x_i \leftarrow \mathbf{1}$
  **while** $\exists i \in [1..n]$ **such that** $x_i > f_i(x_1, \ldots, x_n)$ **do** $x_i \leftarrow \mathbf{0}$
}
```

Suppose that the above while-loop takes k iterations; as each iteration of the while-loop changes the value of one variable x_i from $\mathbf{1}$ to $\mathbf{0}$, it follows that $k \leq n$. Below we show that $\mathbf{R}$ generates the maximum solution of (4). Without loss of generality, assume the while-loop sequentially updates the variables $x_1, x_2, \ldots, x_k$ in that order to $\mathbf{0}$. For simplicity, let $\bar{x}$ denote the vector $(x_1, \ldots, x_n)$, $f_i(\bar{x})$ denote the function $f_i(x_1, \ldots, x_n)$, and $\bar{e}_i$ denote the vector $(\mathbf{0}, \ldots, \mathbf{0}, \mathbf{1}, \ldots, \mathbf{1})$ of length n (the i leading entries are $\mathbf{0}$, and the remaining $n-i$ entries are $\mathbf{1}$). Thus, $\bar{x} = \bar{e}_k$ when $\mathbf{R}$ terminates.

First we show that $\bar{x} = \bar{e}_k$ is a solution of (4). Algorithm $\mathbf{R}$ guarantees that

$$f_i(\bar{e}_{i-1}) = \mathbf{0}, \ i \in [1..k]. \tag{5}$$

As f_i is monotonic, it follows that $f_i(\bar{e}_k) \leq f_i(\bar{e}_{i-1}) = \mathbf{0}$ for $i \in [1..k]$ and hence $x_i = f_i(\bar{e}_k) = \mathbf{0}$. On the other hand, for $i \in (k..n]$ we have $x_i = f_i(\bar{e}_k) = \mathbf{1}$.

Next it is shown that $\bar{x} = \bar{e}_k$ is the maximum solution. Suppose that $\bar{a} = (a_1, \ldots, a_n)$ is another solution of (4). Let i be the minimal subscript of $\bar{a}$ with $a_i = \mathbf{1}$ (i.e., $\bar{a} \leq \bar{e}_{i-1}$). It suffices to prove that $k < i$. This can be inferred from relations (5) and $f_i(\bar{e}_{i-1}) \geq f_i(a_1, \ldots, a_n) = a_i = \mathbf{1}$. $\square$

3.2. Algorithms. It is easy to verify that (2) are monotonic. Thus, algorithm $\mathbf{R}$ can be applied to (2) for finding the maximum solution (3). The cost for this application is as follows. Let $F(s,t)$ denote the function expressing the right-hand side of (2). Using an approach similar to function *emb*, $F(s,t)$ can be computed in $O(d(t))$ time (more exactly, the procedure to compute $F(s,t)$ can be obtained from function *emb* by changing the term *emb*(s,t) at line (e1) into $F(s,t)$ and term *emb*$(s[i], t[j])$ at line (e2) into $x_{s[i]}^{t[j]}$). As the while-loop of $\mathbf{R}$ iterates at most $|V_S||V_T|$ times, the total time-cost of $\mathbf{R}$ is thus $O(|V_S||V_T| \sum_{(s,t)\in V_S \times V_T} d(t)) = O(|V_S|^2|V_T||E_T|)$ and the required space is bounded by $O(|V_S||V_T|)$.

This section gives a refinement of $\mathbf{R}$ specifically for (2). The algorithm runs in $O(|E_S||E_T|)$ time and requires $O(|E_S||V_T| + |E_T|)$ space. First we introduce the following concepts.

DEFINITION 3.6. *Let x_s^t be boolean variables for $(s,t) \in V_S \times V_T$. Given $(s,t) \in V_S \times V_T$ with $s \preceq t$, a list $(l_1, \ldots, l_{d(s)})$ is called a* positive list *for (s,t), if*

- $1 \leq l_1 < \cdots < l_{d(s)} \leq d(t)$;
- $x_{s[i]}^{t[j]} = \mathbf{0}$ *for $i \in [1..d(s)]$ and $j \in (l_{i-1}..l_i)$ with $l_0 = 0$.*

A list $(l_1, \ldots, l_k)$ with $k \in [1..d(s)]$ is called a negative list *for (s,t), if*

- $1 \leq l_1 < \cdots < l_k = d(t) + 1$;
- $x_{s[i]}^{t[j]} = \mathbf{0}$ *for $i \in [1..k]$ and $j \in (l_{i-1}..l_i)$ with $l_0 = 0$.*

Clearly, for $s \dot{\preceq} t$, $F(s,t) = \mathbf{1}$ implies the existence of a positive list, but the converse is not true, because we don't make any assumption on the values $x_{s[i]}^{t[l_i]}$ of the positive list. For negative lists we have the following result.

LEMMA 3.7. *Let $(s,t) \in V_S \times V_T$ with $s \dot{\preceq} t$. If there exists a negative list for (s,t) then $F(s,t) = \mathbf{0}$.*

Proof. Assume $F(s,t) = \mathbf{1}$. Then there exists a list $(a_1, \ldots, a_{d(s)})$ such that $1 \leq a_1 < \cdots < a_{d(s)} \leq d(t)$ and $x_{s[i]}^{t[a_i]} = \mathbf{1}$ for $i \in [1..d(s)]$. Let $(l_1, \ldots, l_k)$ be a negative list for (s,t) and $i \in [1..k]$ minimal such that $a_i < l_i$ (the relation $a_k \leq d(t) < l_k$ implies the existence of such i). Thus, $a_i > a_{i-1} \geq l_{i-1}$, where $a_0 = l_0 = 0$. Therefore, $a_i \in (l_{i-1}..l_i)$ and hence $x_{s[i]}^{t[a_i]} = \mathbf{0}$, which leads to a contradiction. $\square$

The new algorithm $\mathbf{R}_o$ for ordered tree embeddings uses the following variables:

- x_s^t of type $\mathcal{B}$ for each $(s,t) \in V_S \times V_T$, to indicate the truth value for relation $\mathit{tree}(s) \sqsubseteq \mathit{tree}(t)$.
- $\mathit{pred}[s]$ of type **set of** $(V_S \times \mathbb{N})$ for each $s \in V_S$, to represent the set of predecessors of s in S.
- $\mathit{pred}[t]$ of type **set of** $(V_T \times \mathbb{N})$ for each $t \in V_T$, to represent the set of predecessors of t in T.
- l_s^t of type **array**$[1..d(s)]$ **of** $\mathbb{N}$ for each $(s,t) \in V_S \times V_T$, storing a positive list (if any existed) for (s,t).

The above variables are initialized by the following routine:

```
        routine $init()$
        { foreach $s \in V_S$ do $pred[s] \leftarrow \{(u,i) \mid u[i] = s\}$
          foreach $t \in V_T$ do $pred[t] \leftarrow \{(v,j) \mid v[j] = t\}$
          foreach $(s,t) \in V_S \times V_T$ do
          { $x_s^t \leftarrow \mathbf{1}$
(i1)        if $s \stackrel{\cdot}{\preceq} t$ then $(l_s^t[1], \ldots, l_s^t[d(s)]) \leftarrow (1, \ldots, d(s))$
          }
        }
```

The main body of algorithm $\mathbf{R}_o$ is as follows:

```
        algorithm $\mathbf{R}_o$
        { $init()$
          foreach $(s,t) \in V_S \times V_T$ such that $s \not\preceq t \wedge x_s^t = \mathbf{1}$ do $set\_zero(s,t)$
        }
```

The above algorithm needs to invoke the subroutine $\mathit{set\_zero}(s,t)$ that assigns x_s^t to $\mathbf{0}$ and recursively propagates this change of this value.

```
        routine $set\_zero(s,t)$
(s1)    { $x_s^t \leftarrow \mathbf{0}$
          foreach $((u,i),(v,j)) \in pred[s] \times pred[t]$ such that
(s2)              $u \preceq v \wedge x_u^v = \mathbf{1} \wedge l_u^v[i] = j$ do
(s3)        if $find(u,i,v) = \mathbf{0}$ then $set\_zero(u,v)$
        }
```

The routine *set_zero* needs to call function $\mathit{find}(u,i,v)$, which attempts to find a new positive list for (u,v) to reflect the change of the value of x_s^t (i.e., $x_{u[i]}^{v[l_i]}$) and to store this list in l_u^v. The function returns **1** if this task can be accomplished or returns **0** otherwise; in the latter case there exists a negative list for (u,v).

In the body of function $\mathit{find}(u,i,v)$, for simplicity, let l_j be the short-hand for the variable $l_u^v[j]$.

```
        function $find(u,i,v)$ returns $\mathcal{B}$
        { while 1 do
          { repeat $l_i \leftarrow l_i + 1$ until $l_i > d(v) \vee x_{u[i]}^{v[l_i]} = \mathbf{1}$
            if $l_i > d(v)$ then return 0
            if $i < d(u) \wedge l_i \geq l_{i+1}$ then $\{l_i \leftarrow l_{i+1};\ i \leftarrow i + 1\}$
            else return 1
          }
        }
```

Below we prove the correctness of algorithm $\mathbf{R}_o$. For convenience let $\langle l_u^v, +\rangle$ denote the fact that $(l_1, \dots, l_{d(u)})$ is a positive list (recall that l_j is the short-hand for $l_u^v[j]$), and let $\langle l_u^v, -\rangle$ denote that there exists $j \in [1..d(u)]$ such that $(l_1, \dots, l_j)$ is a negative list. Furthermore, we introduce global boolean variables ρ_s^t for $(s,t) \in V_S \times V_T$, which are only used in the proofs. Initially, assume $\rho_s^t = \mathbf{1}$ for all $(s,t) \in V_S \times V_T$. The value of ρ_u^v is set in line (s3) to the value of *find*(u,i,v). The following lemma analyzes function *find*.

LEMMA 3.8. *Let $(u,v) \in V_S \times V_T$ with $u \dot{\preceq} v$. Consider the call of function find(u,i,v) for some $i \in [1..d(u)]$. Assume that before the call $\langle l_u^v, +\rangle$ holds. The call of the function causes the following effect to the list $(l_1, \dots, l_{d(s)})$:* (I) *The values of $l_{i_0}, \dots, l_{i_1}$ are increased, where i_0 and i_1 denote the initial and final values of variable i;* (II) *the values of $l_j, j \notin [i_0..i_1]$ are not changed;* (III) *one of the following properties holds:*

(a) $\rho_u^v = \mathbf{1}$, $\langle l_u^v, +\rangle$, *and* $x_{u[j]}^{v[l_j]} = \mathbf{1}$ *for all increased* l_j*;*

(b) $\rho_u^v = \mathbf{0}$ *and* $\langle l_u^v, -\rangle$.

Proof. Notice that the function *find* is invoked only at line (s3), where the value of $x_{u[i]}^{v[l_i]}$ is set to $\mathbf{0}$ at line (s1).

The following invariant of the while-loop in the function *find* is easy to prove. When $i > i_0$,

- the values of $l_{i_0}, \dots, l_{i-1}$ are increased and the value of l_i is not decreased;
- the values of $l_j, j \notin [i_0..i_1]$ are not changed;
- $l_{i_0} < \cdots < l_{i-1} = l_i \le d(v)$;
- $\forall j \in [i_0..i) : x_{u[j]}^{v[p]}$ equals $\mathbf{1}$ if $p = l_j$ and equals $\mathbf{0}$ if $p \in (l_{i-1}..l_i)$.

The last round of the loop always increases the value of l_i. Properties (I) and (II) are obvious. For property (III), if the function returns $\mathbf{1}$, then (a) holds; if the function returns $\mathbf{0}$ then (b) holds and in this case $(l_1, \dots, l_i)$ forms a negative list. □

For the next lemma suppose that the execution of $\mathbf{R}_o$ produces a series of timestamps $\omega_1, \omega_2, \dots, \omega_n$, each of which corresponds either to the end of an invocation of function *find* or to the end of an execution of line (s1). Furthermore, let ω_0 denote the timestamp produced at the beginning of $\mathbf{R}_o$.

LEMMA 3.9. *At time ω_k, $k \in [0..n]$, for each $(u,v) \in V_S \times V_T$ with $u \dot{\preceq} v$ one of the following properties holds:*

(a) $\rho_u^v = \mathbf{1}$ *and* $\langle l_u^v, +\rangle$;

(b) $\rho_u^v = \mathbf{0}$ *and* $\langle l_u^v, -\rangle$.

Proof. The proof is by induction on k. Property (a) holds in the initial case $k = 0$. Now let $k > 0$. If ω_k is related to the execution of line (s1), then in the time interval between ω_{k-1} and ω_k, nothing is changed except that x_u^v is set to $\mathbf{0}$. However, the change of the value of x_u^v does not affect properties (a) and (b) in this time interval. Now assume ω_k is related to the invocation of *find*(s,i,t). If $(s,t) \neq (u,v)$, then ρ_u^v and l_u^v are not changed during the time interval between ω_{k-1} and ω_k. Now let $(s,t) = (u,v)$. By Lemma 3.8 it suffices to show that $\langle l_u^v, +\rangle$ at time ω_{k-1}. By induction hypothesis it is enough to show that $\rho_u^v = \mathbf{1}$ at time ω_{k-1}. Assume contrapositively that this is not true. Then ρ_u^v must be assigned to $\mathbf{0}$ by a call of *find*(u,i',v) which terminates at time $\omega_{k'}$ with $k' < k$. Consequently, x_u^v is set to $\mathbf{0}$ at time $\omega_{k'+1}$. Note that $k'+1 = k$ is impossible as ω_k is related to function *find*(u,i,v). Thus, $k'+1 < k$. Hence, $x_u^v = \mathbf{0}$ after ω_{k-1}, and by line (s2) the function *find*(u,i,v) cannot be invoked after ω_{k-1}. This leads to a contradiction. □

Now we are in a position to prove the correctness of algorithm $\mathbf{R}_o$.

THEOREM 3.10. *Algorithm* $\mathbf{R}_\text{o}$ *is correct. That is, once* $\mathbf{R}_\text{o}$ *terminates,* $x_s^t = (\mathit{tree}(s) \sqsubseteq \mathit{tree}(t))$ *for each* $(s,t) \in V_S \times V_T$.

Proof. By Lemma 3.3 and Theorem 3.5, it suffices to prove the equivalence of algorithms $\mathbf{R}$ and $\mathbf{R}_\text{o}$ for (2). Recall that $F(s,t)$ denotes the right-hand side of (2). Thus we need to prove

(a) the precondition to the call of *set_zero*(s,t) is $x_s^t > F(s,t)$;

(b) at time ω_n there exists no (s,t) such that $x_s^t > F(s,t)$.

Proof of (a). The routine *set_zero*(s,t) must be invoked either by the main routine or by another invocation of *set_zero*. In any case $x_s^t = \mathbf{1}$ holds before the call of *set_zero*(s,t). Below we show that $F(s,t) = \mathbf{0}$ before the call of *set_zero*(s,t). If *set_zero*(s,t) is invoked by the main routine, then $F(s,t) = \mathbf{0}$ is obvious as $s \not\preceq t$. Now assume that *set_zero*(s,t) is invoked by another invocation of *set_zero* and that *set_zero*(s,t) is invoked at time between ω_{k-1} and ω_k. Thus, time ω_{k-1} is related to an invocation of *find*(s,i,t) that returns $\mathbf{0}$, i.e., $\rho_s^t = \mathbf{0}$ at time ω_{k-1}. Lemma 3.9 shows that at time ω_{k-1}, $\langle l_s^t, -\rangle$ and hence, by Lemma 3.7, $F(s,t) = \mathbf{0}$.

Proof of (b). Let $x_s^t = \mathbf{1}$ at time ω_n. It suffices to show that $F(s,t) = \mathbf{1}$ at ω_n. Notice that in the course of $\mathbf{R}_\text{o}$ the following condition always holds:

$$s \preceq t \text{ and } \rho_s^t = \mathbf{1}, \tag{6}$$

as otherwise *set_zero*(s,t) would be invoked either at line (r1) or line (s3), and hence $x_s^t = \mathbf{0}$ at time ω_n.

In condition (6), if $s \preceq t$ and $d(s) = 0$, then $F(s,t) = \mathbf{1}$ is obvious. Below we assume $d(s) > 0$ (i.e., replace $\preceq$ by $\dot{\preceq}$ in (6)).

Now Lemma 3.9 with condition (6) guarantees that $\langle l_s^t, +\rangle$ at ω_n. To derive $F(s,t) = \mathbf{1}$ it suffices to further prove that for each $i \in [1..d(s)]$,

$$x_{s[i]}^{t[l_i]} = \mathbf{1} \text{ at time } \omega_n, \tag{7}$$

where $l_s^t[i]$ is abbreviated by l_i. Now fix $i \in [1..d(s)]$. Assume ω_k is the earliest timestamp such that l_i is not updated since ω_k. Surely *set_zero*$(s[i], t[l_i])$ is never called since ω_k, as otherwise the call of it would lead to a call of *find*(s,i,t) (due to condition (6)), in which the value of l_i would be increased again, by property (I) of Lemma 3.8. Thus, to prove (7) it suffices to prove that

$$x_{s[i]}^{t[l_i]} = \mathbf{1} \text{ at time } \omega_k. \tag{8}$$

If $k = 0$ (i.e., l_i is not updated since the initialization) then (8) is obvious. Now let $k > 0$. Surely ω_k is related to an invocation of *find*(s,i',t) in which the value of l_i is increased. By condition (6), Lemma 3.9 ensures that $\langle l_s^t, +\rangle$ holds at any time ω_p. Thus at time ω_k the property (a) of Lemma 3.8 holds and hence (8) holds (as l_i is increased). ◻

THEOREM 3.11. *Algorithm* $\mathbf{R}_\text{o}$ *runs in* $O(|E_S||E_T|)$ *time and requires* $O(|E_S||V_T| + |E_T|)$ *space.*

Proof. We express all set-typed variables *pred*$[s]$, *pred*$[t]$ by lists that take total $O(|E_S|+|E_T|)$ space. On the other hand, all arrays l_s^t use $O(|E_S||V_T|)$ space. Further, notice that the depth of the stack for (recursive) routine invocations *set_zero* never exceeds $|V_S||V_T|$.

For the time-cost, the routine *init* is accomplished in $O(|E_S||E_T|)$ time. Not counting the time for the invocations of *set_zero*, the main routine of $\mathbf{R}_\text{o}$ runs in time $O(|E_S||E_T|)$. Excluding the cost for the invocations of *find*, all invocations of *set_zero*(s,t) for all $(s,t) \in V_S \times V_T$ need time $O(\sum_{(s,t)\in V_S\times V_T}(d^-(s)d^-(t)+1)) = O(|E_S||E_T|)$, where $d^-(v)$ denotes the indegree of a vertex v.

It remains to count the cost for all invocations of the function *find*. Note that a call *find*(u,i,v) is performed at most once for a fixed triple (u,i,v). On the other hand, the function *find*(u,i,v) runs in time $O(\delta)$, where δ is the overall increment of entries $l_u^v[k]$, for $k \in [1..d(u)]$, caused by the function itself. Notice that during the course of the algorithm, every entry $l_u^v[k]$ is never decreased and its upper bound is $d(v)+1$. Thus, for a fixed pair (u,v), all calls of *find*(u,i,v) run in overall $O(d(u)d(v))$ time (here $d(u)d(v) > 0$ as $u \mathrel{\dot{\preceq}} v$). Consequently the total cost of all invocations of *find*(u,i,v) is again $O(|E_S||E_T|)$. $\square$

4. Unordered embedding. Having presented the algorithm for ordered embedding, we present in this section an algorithm for the unordered embedding problem. Analogous to the approach developed in the previous section, the unordered embedding problem is transformed into the problem of how to find the maximum solution of a system of boolean equations.

For every $(s,t) \in V_S \times V_T$, let

$$\Re_s^t = \left\{(l_1,\ldots,l_{d(s)}) \in [1..d(t)]^{d(s)} \;\middle|\; \forall i,j \in [1..d(s)] :\ i = j \vee l_i \neq l_j\right\}.$$

The following lemma is analogous to Lemma 3.1 and can be easily derived from Definition 2.1.

LEMMA 4.1. *Let $(s,t) \in V_S \times V_T$. Then tree$(s) \sqsubseteq_{\mathrm{u}}$ tree(t) iff $s \preceq t$ and at least one of the following conditions holds:*

(a) $d(s) = 0$.

(b) *There exists a sequence $(l_1,\ldots,l_{d(s)}) \in \Re_s^t$ such that tree$(s[i]) \sqsubseteq_{\mathrm{u}}$ tree$(t[l_i])$ for $i \in [1..d(s)]$.*

Now take into account the system of the following monotonic equations: $\forall (s,t) \in V_S \times V_T$,

$$x_s^t \;=\; s \preceq t \,\wedge\, \left((d(s)=0) \vee \bigvee_{(l_1,\ldots,l_{d(s)})\in\Re_s^t} \bigwedge_{i=1}^{d(s)} x_{s[i]}^{t[l_i]}\right). \tag{9}$$

Lemma 4.1 shows that

$$x_s^t = (tree(s) \sqsubseteq_{\mathrm{u}} tree(t)),\ \ (s,t) \in V_S \times V_T \tag{10}$$

is a solution of (9). Furthermore, the following lemma can be proved along the same lines as in Lemma 3.3.

LEMMA 4.2. *The values of x_s^t given by expression* (10) *are the maximum solution of* (9)*.*

Similar to the previous section, we present a refinement of algorithm **R** for monotonic (9). This refinement also benefits from the idea of unordered finite tree embedding algorithms [9, 11] that use an efficient algorithm to compute maximum matching in bipartite graphs to achieve a good efficiency. More concretely, a *matching* in a graph $G = (V,E)$ is a subset of E with no two edges incident upon the same vertex in V. A *maximum matching* is a matching with the maximum number of edges. A graph $G = (V,E)$ is *bipartite* if V can be partitioned into two disjoint sets X and Y such that $E \subseteq X \times Y$. Given a bipartite graph $G = (V,E)$, the Hopcroft–Karp algorithm [6] finds a maximum matching of G in $O(s^{1/2}|E|)$ time, where s is the size of maximum matching. Assume S and T both are unordered finite trees. The unordered finite tree embedding problem is to determine the relation $S \sqsubseteq_u T$ as defined in Definition 2.1. By the use of the above bipartite matching algorithm the unordered finite tree embedding problem can be solved in $O(|S|^{3/2}|T|)$ time [9, 11].

For the unordered regular tree embedding problem, however, the direct use of Hopcroft–Karp algorithm is not very efficient, as under our circumstance all bipartite graphs and their maximum matchings are incrementally maintained. For our problem it suffices to adopt a simple incremental algorithm. Detailed ideas will be presented later.

The following algorithm $\mathbf{R}_u$ is a refinement of $\mathbf{R}$ for (9) that uses the following variables:

- x_s^t of type $\mathcal{B}$ for each $(s,t) \in V_S \times V_T$;
- *pred*$[s]$ and *pred*$[t]$, resp., of type **set of** $(V_S \times \mathbb{N})$ and **set of** $(V_T \times \mathbb{N})$ for each $s \in V_S$ and $t \in V_T$.

The above variables are initialized by the following routine:

```
routine init()
{ foreach $s \in V_S$ do $pred[s] \leftarrow \{(u,i) \mid u[i] = s\}$
  foreach $t \in V_T$ do $pred[t] \leftarrow \{(v,j) \mid v[j] = t\}$
  foreach $(s,t) \in V_S \times V_T$ do $x_s^t \leftarrow \mathbf{1}$
  foreach $(s,t) \in V_S \times V_T$ such that $s \dot{\preceq} t$ do
    create a complete bipartite graph $G_s^t = (V_s^t, E_s^t)$, where
      $V_s^t = \{(s,1),\ldots,(s,d(s)),\ (t,1),\ldots,(t,d(t))\}$
      $E_s^t = \{(s,i) \rightarrow (t,j) \mid i \in [1..d(s)],\ j \in [1..d(t)]\}$
}
```

The main body of algorithm $\mathbf{R}_u$ is as follows:

```
algorithm $\mathbf{R}_u$
{ init()
  foreach $(s,t) \in V_S \times V_T$ such that $s \not\preceq t \wedge x_s^t = \mathbf{1}$ do set_zero(s,t)
}

routine set_zero(s,t)
{ $x_s^t \leftarrow \mathbf{0}$
  foreach $((u,i),(v,j)) \in pred[s] \times pred[t]$ do
  { remove edge $(u,i) \rightarrow (v,j)$ from $G_u^v$
    if $x_u^v = \mathbf{1}$ then
(s)    { compute $k$, the size of maximum matching on $G_u^v$
      if $k < d(u)$ then set_zero(u,v)
    }
  }
}
```

For the proof of the correctness of algorithm $\mathbf{R}_u$, assume the execution of $\mathbf{R}_u$ produces a series of timestamps $\omega_1,\ldots,\omega_n$, where ω_i corresponds to the start time for the ith call of routine *set_zero*. Also, let ω_{n+1} denote the timestamps produced at the end of algorithm $\mathbf{R}_u$.

LEMMA 4.3. *Let $(u,v) \in V_S \times V_T$, $u \dot{\preceq} v$, and $(i,j) \in [1..d(u)] \times [1..d(v)]$. At every time ω_k, $x_{u[i]}^{v[j]} = \mathbf{0}$ iff there exists no edge connecting (u,i) and (v,j) in G_u^v.*

Proof. It can be directly derived from routine *set_zero.* $\square$

THEOREM 4.4. *Algorithm $\mathbf{R}_{\mathrm{u}}$ is correct. That is, once $\mathbf{R}_{\mathrm{u}}$ terminates, $x_s^t = (tree(s) \sqsubseteq_{\mathrm{u}} tree(t))$ for each $(s,t) \in V_S \times V_T$.*

Proof. By Theorem 3.5 and Lemma 4.2, it suffices to prove the equivalence of algorithms $\mathbf{R}$ and $\mathbf{R}_{\mathrm{u}}$ for (9). Let $E(s,t)$ denote the expression at the right-hand side of (9). Now we must prove that

(a) the precondition to the call of *set_zero*(u,v) is $x_u^v > E(u,v)$;

(b) at time ω_{n+1} there exists no $(u,v) \in V_S \times V_T$ with $x_u^v > E(u,v)$.

Proof of (a). The routine *set_zero*(u,v) is invoked either by the main routine or recursively by itself. In the first case condition (a) is clearly satisfied. If *set_zero*(u,v) is called by another invocation of *set_zero*, then $x_u^v = \mathbf{1}$ and a maximum matching for bipartite graph G_u^v has less than $d(u)$ edges. Lemma 4.3 shows that $E(u,v) = \mathbf{0}$.

Proof of (b). Assume contrapositively that there exists (u,v) such that $x_u^v = \mathbf{1}$ and $E(u,v) = \mathbf{0}$ at time ω_{n+1}. Surely *set_zero*(u,v) is never called, so we have $u \dot{\preceq} v$ and $E(u,v) = \mathbf{1}$ at time ω_1. Consider the smallest $k > 1$ such that $E(u,v) = \mathbf{0}$ at ω_k. Thus $E(u,v) = \mathbf{1}$ at ω_{k-1}. In the time interval between ω_{k-1} and ω_k, *set_zero*$(u[i], v[j])$, for some i and j, must be called, and in this routine setting $x_{u[i]}^{v[j]}$ to $\mathbf{0}$ causes $E(u,v) = \mathbf{0}$ at time ω_k. By Lemma 4.3, the relation $E(u,v) = \mathbf{0}$ implies that the maximum matching of G_u^v has size less than $d(u)$. Consequently, *set_zero*(u,v) must be invoked in the call of *set_zero*$(u[i], v[j])$. This induces a contradiction. $\square$

The algorithm $\mathbf{R}_{\mathrm{u}}$ needs to incrementally compute the size of maximum matching on bipartite graphs G_u^v (line (s)). Kilpeläinen uses a similar incremental approach for the *unordered finite tree region inclusion* problem [7]. The basic idea in our context is as follows. After the routine *init* constructs the complete bipartite graphs G_u^v for $(u,v) \in V_S \times V_T$, some edges in these graphs are removed by routine *set_zero.* During the course of the algorithm, we keep a maximum matching M_u^v for each bipartite graph G_u^v. If an edge, say e, is removed from G_u^v, then the size of maximum matching of $G_u^v \backslash e$, the graph G_u^v after removing e, is reduced at most by one. With this property the maximum matching of $G_u^v \backslash e$ can be computed as follows. If $e \notin M_u^v$, then M_u^v is still the maximum matching of $G_u^v \backslash e$. If $e \in M_u^v$, then $M_u^v - \{e\}$ is a matching (but probably not the maximum one) of G_u^v, and it suffices to check the existence of an augmenting path[1] with respect to matching $M_u^v - \{e\}$ in $G_u^v \backslash e$, as each augmenting path extends the matching by one edge. It is known that an augmenting path can be computed in time linear to the size of the graph [10]. Thus, the maximum matching of graph $G_u^v \backslash e$ can be computed in $O(|E_u^v|)$ time, based on old matching M_u^v. Taking this strategy to compute maximum matching we obtain the following result.

THEOREM 4.5. *Algorithm $\mathbf{R}_{\mathrm{u}}$ runs in $O(|E_S||E_T|\, D_S\, D_T)$ time and requires $O(|E_S||E_T|)$ space, where D_S and D_T denote the maximum outdegrees in G_S and G_T.*

Proof. We represent the set-typed variables *pred*$[s]$, *pred*$[t]$ by lists, and represent the edges in each bipartite graph G_s^t by a $d(s) \times d(t)$ adjacency matrix.

The space requirement is dominated by the space needed to store the bipartite graphs. Each graph G_s^t requires $d(s)d(t)$ space. Hence the total space required is $O(|E_S||E_T|)$.

[1]An *augmenting path* with respect to a matching M in a bipartite graph $G = (V,E)$ is a simple path consisting of edges alternatively in M and $E - M$, while both endpoints of the path are not incident upon any edge in M.

To count the time-cost of $\mathbf{R}_{\mathrm{u}}$, we first measure the cost for all repeated computations of bipartite maximum matchings. Afterwards, it is easy to see that this cost dominates the cost for the other steps in $\mathbf{R}_{\mathrm{u}}$.

Assume after the routine *init* we construct a maximum matching M_s^t for each complete bipartite graph G_s^t in time $O(d(s))$. As there are at most $d(s)d(t)$ edges to be removed in G_s^t, the total time-cost of computing maximum matchings (and their sizes) in G_s^t is $O(d(s)^2\, d(t)^2)$. Thus, the time-cost for all repeated computations of bipartite maximum matching is

$$\sum_{(s,t)\in V_S\times V_T} O\bigl(d(s)^2 d(t)^2\bigr) \;=\; O\bigl(|E_S||E_T|D_S D_T\bigr). \tag{11}$$

It is easy to check that the time-cost for other steps in $\mathbf{R}_{\mathrm{u}}$ is dominated by (11). Especially, the routine *init* runs in $O(|E_S||E_T|)$ time. $\Box$

5. Comparisons with related work. Aside from previous work on the path-embedding for finite trees, there exists other related work on pattern matching for regular trees and graphs. Closely related work is due to Fu, who considers two kinds of problems for regular trees [5]. The first one, denoted $\mathbf{M}$, is a pattern matching problem. We say that an ordered regular tree S *matches* another one T if there is a injection $f : S \longrightarrow T$ that preserves roots, labels, degrees (except for the leaves of S), parents, and order of siblings. In other words, S matches T iff

$$S \sqsubseteq^f T \;\wedge\; (\forall s \in S : d(s) = 0 \vee d(s) = d(f(s))).$$

Given two ordered rational graphs $G_S = (E_S, V_S, r_S)$ and $G_T = (V_T, E_T, r_T)$, the ordered version of the problem $\mathbf{M}$, denoted $\mathbf{M}_{\mathrm{o}}$, is to determine if *tree*(r_S) matches *tree*(t) for each $t \in V_T$. The unordered version of $\mathbf{M}$ is denoted $\mathbf{M}_{\mathrm{u}}$; here the order among siblings is not necessarily preserved.

The difference between problem $\mathbf{M}$ and the path-embedding problem considered in this paper is the preservation of the degrees of the vertices. In problem $\mathbf{M}_{\mathrm{o}}$, the relation of whether s matches t can be checked recursively by the following condition:

$$\mathit{label}(s) = \mathit{label}(t) \;\wedge\; (d(s) = 0 \;\vee\; d(s) = d(t) \wedge \forall i \in [1..d(s)] : s[i] \text{ matches } t[i])\,.$$

Using this property Fu gives an $O(|E_S||V_T| + |E_T|)$ time and space algorithm for problem $\mathbf{M}_{\mathrm{o}}$. Note that the algorithm for $\mathbf{M}_{\mathrm{o}}$ does not need to search alternative positive lists as required in algorithm $\mathbf{R}_{\mathrm{o}}$ because of the condition to preserve degrees.

On the other hand, for problem $\mathbf{M}_{\mathrm{u}}$, the unordered version of $\mathbf{M}$, Fu asserts that it is NP-complete, but no proof is given. In fact, the problem $\mathbf{M}_{\mathrm{u}}$ can be solved by our algorithm $\mathbf{R}_{\mathrm{u}}$ with a slight modification of the relation $\preceq$ (originally defined in (1)) as follows: for $(s,t) \in V_S \times V_T$, $s \preceq t$ is defined as

$$\mathit{label}(s) = \mathit{label}(t) \;\wedge\; (d(s) = 0 \;\vee\; d(s) = d(t))\,. \tag{12}$$

Under this modification the proof of the correctness of algorithm $\mathbf{R}_{\mathrm{u}}$ is still valid for $\mathbf{M}_{\mathrm{u}}$. Also this modification does not alter the time and space complexities of the algorithm. As a result, the problem $\mathbf{M}_{\mathrm{u}}$ can be solved in polynomial time and space by the above variant of algorithm $\mathbf{R}_{\mathrm{u}}$ and Theorem 4.5.

Fu also considers another problem, denoted $\mathbf{E}$, that tests regular tree topological embedding. A regular tree S is *topological embeddable* in T if there is an injection

$f : S \longrightarrow T$ that preserves roots, labels, degrees (except for the leaves of S), and the following condition:

$$\forall s \in S \ \wedge \ i \in [1..d(s)] : f(s[i]) \in \mathit{tree}(f(s)[i]).$$

The ordered version of $\mathbf{E}$, denoted $\mathbf{E}_{\mathrm{o}}$, is to test whether $\mathit{tree}(r_S)$ is topological embeddable in $\mathit{tree}(t)$ for each $t \in V_T$. A similar argumentation can be applied to problem $\mathbf{E}_{\mathrm{u}}$, the unordered version of $\mathbf{E}$. Fu presents an $O(|V_S||E_T| + |E_S|)$ time and $O(|V_S||V_T| + |E_S| + |E_T|)$ space algorithm for problem $\mathbf{E}_{\mathrm{o}}$ and asserts the NP-completeness of problem $\mathbf{E}_{\mathrm{u}}$. Note that our algorithms $\mathbf{R}_{\mathrm{o}}$ and $\mathbf{R}_{\mathrm{u}}$ cannot be applied to problems $\mathbf{E}_{\mathrm{o}}$ and $\mathbf{E}_{\mathrm{u}}$ with trivial extensions.

Another related problem is the *directed subgraph isomorphism* problem, which tests whether a given unordered digraph is a subgraph (under isomorphism) of another one. This problem is NP-complete [3, 8]. The subgraph isomorphism problem takes a stronger condition than that in the unordered path-embedding problem. Concretely, if G_S is subgraph of G_T and s isomorphically corresponds to t, then $\mathit{tree}(s) \sqsubseteq_{\mathrm{u}} \mathit{tree}(t)$, but the converse is not true. For example, in Figure 3 all graphs represent the same regular tree but none of them is a subgraph of any of the others.

6. Conclusion. We presented two algorithms for the ordered and unordered regular tree path-embedding problems by treating the algorithms as optimized procedures to find the maximal solution of a system of boolean equations that describe the pairwise matches between the vertices in pattern and target trees. As a result, the ordered version of our algorithm runs in quadratic time (Theorem 3.11) and the unordered version in quartic time (Theorem 4.5).

Acknowledgment. Rimli Sengupta and the anonymous referees made helpful comments on a draft of this paper.

EQUIVALENCE OF MEASURES OF COMPLEXITY CLASSES[*]

JOSEF M. BREUTZMANN[†] AND JACK H. LUTZ[‡]

Abstract. The resource-bounded measures of complexity classes are shown to be robust with respect to certain changes in the underlying probability measure. Specifically, for any real number $\delta > 0$, any uniformly polynomial-time computable sequence $\vec{\beta} = (\beta_0, \beta_1, \beta_2, \dots)$ of real numbers (biases) $\beta_i \in [\delta, 1-\delta]$, and for any complexity class $\mathcal{C}$ (such as P, NP, BPP, P/Poly, PH, PSPACE, etc.) that is closed under positive, polynomial-time, truth-table reductions with queries of at most linear length, it is shown that the following two conditions are equivalent.

(1) $\mathcal{C}$ has p-measure 0 (respectively, measure 0 in E, measure 0 in E_2) relative to the coin-toss probability measure given by the sequence $\vec{\beta}$.

(2) $\mathcal{C}$ has p-measure 0 (respectively, measure 0 in E, measure 0 in E_2) relative to the uniform probability measure.

The proof introduces three techniques that may be useful in other contexts, namely, (i) the transformation of an efficient martingale for one probability measure into an efficient martingale for a "nearby" probability measure; (ii) the construction of a *positive bias reduction*, a truth-table reduction that encodes a positive, efficient, approximate simulation of one bias sequence by another; and (iii) the use of such a reduction to *dilate* an efficient martingale for the simulated probability measure into an efficient martingale for the simulating probability measure.

Key words. complexity classes, martingales, resource-bounded measure

1. Introduction.

In the 1990s, the measure-theoretic study of complexity classes has yielded a growing body of new, quantitative insights into various much-studied aspects of computational complexity. Benefits of this study to date include improved bounds on the densities of hard languages [15]; newly discovered relationships among circuit-size complexity, pseudorandom generators, and natural proofs [21]; strong new hypotheses that may have sufficient explanatory power (in terms of provable, plausible consequences) to help unify our present plethora of unsolved fundamental problems [18, 15, 7, 17, 14]; and a new generalization of the completeness phenomenon that dramatically enlarges the set of computational problems that are provably strongly intractable [13, 6, 2, 7, 8, 1]. See [12] for a survey of these and related developments.

Intuitively, suppose that a language $A \subseteq \{0,1\}^*$ is chosen according to a random experiment in which an independent toss of a fair coin is used to decide whether each string is in A. Then *classical* Lebesgue measure theory (described in [5, 20], for example) identifies certain *measure* 0 sets X of languages, for which the probability that $A \in X$ in this experiment is 0. *Effective* measure theory, which says what it means for a set of decidable languages to have measure 0 as a subset of the set of all such languages, has been investigated by Freidzon [4], Mehlhorn [19], and others. The *resource-bounded* measure theory introduced by Lutz [11] is a powerful generalization of Lebesgue measure. Special cases of resource-bounded measure include classical

Lebesgue measure; a strengthened version of effective measure; and most importantly, measures in $\mathrm{E} = \mathrm{DTIME}(2^{\mathrm{linear}})$, $\mathrm{E}_2 = \mathrm{DTIME}(2^{\mathrm{polynomial}})$, and other complexity classes. The *small* subsets of such a complexity class are then the measure 0 sets; the *large* subsets are the measure 1 sets (complements of measure 0 sets). We say that *almost every* language in a complexity class $\mathcal{C}$ has a given property if the set of languages in $\mathcal{C}$ that exhibit the property has measure 1 in $\mathcal{C}$.

All work to date on the measure-theoretic structure of complexity classes has employed the resource-bounded measure that is described briefly and intuitively above. This resource-bounded measure is based on the *uniform* probability measure, corresponding to the fact that the coin tosses are fair and independent in the above-described random experiment. The uniform probability measure has been a natural and fruitful starting point for the investigation of resource-bounded measure (just as it was for the investigation of classical measure), but there are good reasons to also investigate resource-bounded measures that are based on other probability measures. For example, the study of such alternative resource-bounded measures may be expected to have the following benefits.

(i) The study will enable us to determine which results of resource-bounded measure are particular to the uniform probability measure and which are not. This, in turn, will provide some criteria for identifying contexts in which the uniform probability measure is, or is not, the natural choice.

(ii) The study is likely to help us understand how the complexity of the underlying probability measure interacts with other complexity parameters, especially in such areas as algorithmic information theory, average case complexity, cryptography, and computational learning, where the variety of probability measures already plays a major role.

(iii) The study will provide new tools for proving results concerning resource-bounded measure based on the uniform probability measure.

The present paper initiates the study of resource-bounded measures that are based on nonuniform probability measures.

Let $\mathbf{C}$ be the set of all languages $A \subseteq \{0,1\}^*$. (The set $\mathbf{C}$ is often called *Cantor space.*) Given a probability measure ν on $\mathbf{C}$ (a term defined precisely below), section 3 of this paper describes the basic ideas of resource-bounded ν-measure, generalizing definitions and results from [11, 13, 12] to ν in a natural way. In particular, section 3 specifies what it means for a set $X \subseteq \mathbf{C}$ to have p-ν-measure 0 (written $\nu_{\mathrm{p}}(X) = 0$), p-ν-measure 1, ν-measure 0 in E (written $\nu(X|\mathrm{E}) = 0$), ν-measure 1 in E, ν-measure 0 in E_2, or ν-measure 1 in E_2. Intuitively, for example, a set $X \subseteq \mathbf{C}$ has p-ν-measure 0 if, when a language $A \in \mathbf{C}$ is chosen probabilistically according to the probability measure ν, the event "$A \in X$" has probability 0 in a strong sense that can be exploited by a polynomial-time betting algorithm.

Most of the results in the present paper concern a restricted (but broad) class of probability measures on $\mathbf{C}$, namely, coin-toss probability measures that are given by P-computable, strongly positive sequences of biases. These probability measures are described intuitively in the following paragraphs (and precisely in section 3).

Given a sequence $\vec{\beta} = (\beta_0, \beta_1, \beta_2, \dots)$ of real numbers (biases) $\beta_i \in [0,1]$, the *coin-toss probability measure* (also call the *product probability measure*) *given by* $\vec{\beta}$ is the probability measure $\mu^{\vec{\beta}}$ on $\mathbf{C}$ that corresponds to the random experiment in which a language $A \in \mathbf{C}$ is chosen probabilistically as follows. For each string s_i in the standard enumeration $s_0, s_1, s_2, \dots$ of $\{0,1\}^*$, we toss a special coin, whose probability is β_i of coming up heads, in which case $s_i \in A$, and $1 - \beta_i$ of coming up tails, in which case $s_i \notin A$. The coin tosses are independent of one another.

In the special case where $\vec{\beta} = (\beta, \beta, \beta, \dots)$, i.e., the biases in the sequence $\vec{\beta}$ are all β, we write μ^{β} for $\mu^{\vec{\beta}}$. In particular, $\mu^{\frac{1}{2}}$ is the uniform probability measure, which, in the literature of resource-bounded measure, is denoted simply by μ.

A sequence $\vec{\beta} = (\beta_0, \beta_1, \beta_2, \dots)$ of biases is *strongly positive* if there is a real number $\delta > 0$ such that each $\beta_i \in [\delta, 1-\delta]$. The sequence $\vec{\beta}$ is P-*computable* (and we call it a P-*sequences of biases*) if there is a polynomial-time algorithm that, on input $(s_i, 0^r)$, computes a rational approximation of β_i to within 2^{-r}.

In section 4, we prove the summable equivalence theorem, which implies that, if $\vec{\alpha}$ and $\vec{\beta}$ are strongly positive P-sequences of biases that are "close" to one another, in the sense that $\sum_{i=0}^{\infty} |\alpha_i - \beta_i| < \infty$, then for every set $X \subseteq \mathbf{C}$,

$$\mu_{\mathrm{p}}^{\vec{\alpha}}(X) = 0 \Longleftrightarrow \mu_{\mathrm{p}}^{\vec{\beta}}(X) = 0.$$

That is, the p-measure based on $\vec{\alpha}$ and the p-measure based on $\vec{\beta}$ are in absolute agreement as to which sets of languages are small.

In general, if $\vec{\alpha}$ and $\vec{\beta}$ are not in some sense close to one another, then the p-measures based on $\vec{\alpha}$ and $\vec{\beta}$ need not agree in the above manner. For example, if $\alpha, \beta \in [0,1]$, $\alpha \neq \beta$, and

$$X_{\alpha} = \left\{ A \in \mathbf{C} \middle| \lim_{n \to \infty} 2^{-n} |A \cap \{0,1\}^n| = \alpha \right\},$$

then a routine extension of the weak stochasticity theorem of [15] shows that $\mu_{\mathrm{p}}^{\alpha}(X_{\alpha}) = 1$, while $\mu_{\mathrm{p}}^{\beta}(X_{\alpha}) = 0$.

Notwithstanding this example, many applications of resource-bounded measure do not involve *arbitrary* sets $X \subseteq \mathbf{C}$, but rather are concerned with the measures of *complexity classes* and other closely related classes of languages. Many such classes of interest, including P, NP, co-NP, R, BPP, AM, P/Poly, PH, PSPACE, etc., are closed under positive, polynomial-time truth-table reductions ($\leq_{\mathrm{pos-tt}}^{\mathrm{P}}$-reductions), and their intersections with E are closed under $\leq_{\mathrm{pos-tt}}^{\mathrm{P}}$-reductions with linear bounds on the lengths of the queries ($\leq_{\mathrm{pos-tt}}^{\mathrm{P,lin}}$-reductions).

The main theorem of this paper is the bias equivalence theorem. This result, proven in section 8, says that, for every class $\mathcal{C}$ of languages that is closed under $\leq_{\mathrm{pos-tt}}^{\mathrm{P,lin}}$-reductions, the p-measure of $\mathcal{C}$ is somewhat robust with respect to changes in the underlying probability measure. Specifically, if $\vec{\alpha}$ and $\vec{\beta}$ are strongly positive P-sequences of biases and $\mathcal{C}$ is a class of languages that is closed under $\leq_{\mathrm{pos-tt}}^{\mathrm{P,lin}}$-reductions, then the bias equivalence theorem says that

$$\mu_{\mathrm{p}}^{\vec{\alpha}}(\mathcal{C}) = 0 \Longleftrightarrow \mu_{\mathrm{p}}^{\vec{\beta}}(\mathcal{C}) = 0.$$

To put the matter differently, for every strongly positive P-sequence $\vec{\beta}$ of biases and for every class $\mathcal{C}$ that is closed under $\leq_{\mathrm{pos-tt}}^{\mathrm{P,lin}}$-reductions,

$$\mu_{\mathrm{p}}^{\vec{\beta}}(\mathcal{C}) = 0 \Longleftrightarrow \mu_{\mathrm{p}}(\mathcal{C}) = 0.$$

This result implies that most applications of resource-bounded measure to date can be immediately generalized from the uniform probability measure (in which they were developed) to arbitrary coin-toss probability measures given by strongly positive P-sequences of biases.

The bias equivalence theorem also offers the following new technique for proving resource-bounded measure results. If $\mathcal{C}$ is a class that is closed under $\leq^{\mathrm{P,lin}}_{\mathrm{pos-tt}}$-reductions, then in order to prove that $\mu_{\mathrm{p}}(\mathcal{C}) = 0$, it suffices to prove that $\mu^{\vec{\beta}}_{\mathrm{p}}(\mathcal{C}) = 0$ for some conveniently chosen strongly positive P-sequence $\vec{\beta}$ of biases. (The bias equivalence theorem has already been put to this use in the forthcoming paper [16].)

The plausibility and consequences of the hypothesis $\mu_{\mathrm{p}}(\mathrm{NP}) \neq 0$ are subjects of recent and ongoing research [18, 15, 7, 17, 14, 3, 16]. The bias equivalence theorem immediately implies that the following three statements are equivalent.

(H1) $\mu_{\mathrm{p}}(\mathrm{NP}) \neq 0$.

(H2) For every strongly positive P-sequence $\vec{\beta}$ of biases, $\mu^{\vec{\beta}}_{\mathrm{p}}(\mathrm{NP}) \neq 0$.

(H3) There exists a strongly positive P-sequence $\vec{\beta}$ of biases such that $\mu^{\vec{\beta}}_{\mathrm{p}}(\mathrm{NP}) \neq 0$.

The statements (H2) and (H3) are thus new, equivalent formulations of the hypothesis (H1).

The proof of the bias equivalence theorem uses three main tools. The first is the summable equivalence theorem, which we have already discussed. The second is the martingale dilation theorem, which is proven in section 6. This result concerns martingales (defined in section 3), which are the betting algorithms on which resource-bounded measure is based. Roughly speaking, the martingale dilation theorem gives a method of transforming ("dilating") a martingale for one coin-toss probability measure into a martingale for another, perhaps very different, coin-toss probability measure, provided that the former measure is obtained from the latter via an "orderly" truth-table reduction.

The third tool used in the proof of our main theorem is the positive bias reduction theorem, which is presented in section 7. If $\vec{\alpha}$ and $\vec{\beta}$ are two strongly positive sequences of biases that are exactly P-computable (with no approximation), then the *positive bias reduction* of $\vec{\alpha}$ to $\vec{\beta}$ is a truth-table reduction (in fact, an orderly $\leq^{\mathrm{P,lin}}_{\mathrm{pos-tt}}$-reduction) that uses the sequence $\vec{\beta}$ to "approximately simulate" the sequence $\vec{\alpha}$. It is especially crucial for our main result that this reduction is efficient and positive. (The circuits constructed by the truth-table reduction contain AND gates and OR gates, but no NOT gates.)

The summable equivalence theorem, the martingale dilation theorem, and the positive bias reduction theorem are only developed and used here as tools to prove our main result. Nevertheless, these three results are of independent interest, and are likely to be useful in future investigations.

2. Preliminaries.

In this paper, $\mathbb{N}$ denotes the set of all nonnegative integers, $\mathbb{Z}$ denotes the set of all integers, $\mathbb{Z}^+$ denotes the set of all positive integers, $\mathbb{Q}$ denotes the set of all rational numbers, and $\mathbb{R}$ denotes the set of all real numbers.

We write $\{0,1\}^*$ for the set of all (finite, binary) *strings*, and we write $|x|$ for the length of a string x. The empty string, λ, is the unique string of length 0. The *standard enumeration* of $\{0,1\}^*$ is the sequence $s_0 = \lambda, s_1 = 0, s_2 = 1, s_3 = 00, \ldots,$ ordered first by length and then lexicographically. For $x, y \in \{0,1\}^*$, we write $x < y$ if x precedes y in this standard enumeration. For $n \in \mathbb{N}$, $\{0,1\}^n$ denotes the set of all strings of length n, and $\{0,1\}^{\leq n}$ denotes the set of all strings of length at most n.

If x is a string or an (infinite, binary) *sequence*, and if $0 \leq i \leq j < |x|$, then $x[i..j]$ is the string consisting of the ith through jth bits of x. In particular, $x[0..i-1]$ is the *i-bit prefix* of x. We write $x[i]$ for $x[i..i]$, the ith bit of x. (Note that the leftmost bit of x is $x[0]$, the 0th bit of x.)

If w is a string and x is a string or sequence, then we write $w \sqsubseteq x$ if w is a prefix of x, i.e., if there is a string or sequence y such that $x = wy$.

The *Boolean value* of a condition ϕ is $[\![\phi]\!] = \textbf{if } \phi \textbf{ then } 1 \textbf{ else } 0$.

In this paper we use both the binary logarithm $\log \alpha = \log_2 \alpha$ and the natural logarithm $\ln \alpha = \log_e \alpha$.

Many of the functions in this paper are real-valued functions on discrete domains. These typically have the form

$$f : \mathbb{N}^m \times \{0,1\}^* \longrightarrow \mathbb{R}, \tag{2.1}$$

where $m \in \mathbb{N}$. (If $m = 0$, we interpret this to mean that $f : \{0,1\}^* \longrightarrow \mathbb{R}$.) Such a function f is defined to be p-*computable* if there is a function

$$\hat{f} : \mathbb{N} \times \mathbb{N}^m \times \{0,1\}^* \longrightarrow \mathbb{Q} \tag{2.2}$$

with the following two properties.

(i) For all $r, k_1, \ldots, k_m \in \mathbb{N}$ and $w \in \{0,1\}^*$,

$$|\hat{f}(r, k_1, \ldots, k_m, w) - f(k_1, \ldots, k_m, w)| \leq 2^{-r}.$$

(ii) There is an algorithm that, on input $(r, k_1, \ldots, k_m, w)$, computes the value $\hat{f}(r, k_1, \ldots, k_m, w)$ in $(r + k_1 + \cdots + k_m + |w|)^{O(1)}$ time.

Similarly, f is defined to be p_2-*computable* if there is a function $\hat{f}$ as in (2.2) that satisfies condition (i) above and the following condition.

(ii′) There is an algorithm that, on input $(r, k_1, \ldots, k_m, w)$, computes the value $\hat{f}(r, k_1, \ldots, k_m, w)$ in $2^{\log(r+k_1+\cdots+k_m+|w|)^{O(1)}}$ time.

In this paper, functions of the form (2.1) always have the form

$$f : \mathbb{N}^m \times \{0,1\}^* \longrightarrow [0, \infty)$$

or the form

$$f : \mathbb{N}^m \times \{0,1\}^* \longrightarrow [0, 1].$$

If such a function is p-computable or p_2-computable, then we assume without loss of generality that the approximating function $\hat{f}$ of (2.2) actually has the form

$$\hat{f} : \mathbb{N} \times \mathbb{N}^m \times \{0,1\}^* \longrightarrow \mathbb{Q} \cap [0, \infty)$$

or the form

$$\hat{f} : \mathbb{N} \times \mathbb{N}^m \times \{0,1\}^* \longrightarrow \mathbb{Q} \cap [0, 1],$$

respectively.

3. Resource-bounded ν-measure. In this section, we develop basic elements of resource-bounded measure based on an arbitrary (Borel) probability measure ν. The ideas here generalize the corresponding ideas of "ordinary" resource-bounded measure (based on the uniform probability measure μ) in a straightforward and natural way, so our presentation is relatively brief. The reader is referred to [11, 12] for additional discussion.

We work in the *Cantor space* **C**, consisting of all languages $A \subseteq \{0,1\}^*$. We identify each language A with its *characteristic sequence*, which is the infinite binary sequence χ_A defined by

$$\chi_A[n] = [\![s_n \in A]\!]$$

for each $n \in \mathbb{N}$. Relying on this identification, we also consider **C** to be the set of all infinite binary sequences.

For each string $w \in \{0,1\}^*$, the *cylinder generated by* w is the set

$$\mathbf{C}_w = \{A \in \mathbf{C} \mid w \sqsubseteq \chi_A\}.$$

Note that $\mathbf{C}_\lambda = \mathbf{C}$.

We first review the well-known notion of a (Borel) probability measure on **C**.

Definition 3.1. *A* probability measure *on* **C** *is a function*

$$\nu : \{0,1\}^* \longrightarrow [0,1]$$

such that $\nu(\lambda) = 1$, and for all $w \in \{0,1\}^*$,

$$\nu(w) = \nu(w0) + \nu(w1).$$

Intuitively, $\nu(w)$ is the probability that $A \in \mathbf{C}_w$ when we "choose a language $A \in \mathbf{C}$ according to the probability measure ν." We sometimes write $\nu(\mathbf{C}_w)$ for $\nu(w)$.

Examples 3.2.

1. *The* uniform probability measure μ *is defined by*

$$\mu(w) = 2^{-|w|}$$

for all $w \in \{0,1\}^*$.

2. *A* sequence of biases *is a sequence* $\vec{\beta} = (\beta_0, \beta_1, \beta_2, \dots)$, *where each* $\beta_i \in [0,1]$. *Given a sequence of biases* $\vec{\beta}$, *the* $\vec{\beta}$*-coin-toss probability measure (also called the* $\vec{\beta}$-product probability measure*) is the probability measure* $\mu^{\vec{\beta}}$ *defined by*

$$\mu^{\vec{\beta}}(w) = \prod_{i=0}^{|w|-1} ((1-\beta_i)\cdot(1-w[i]) + \beta_i \cdot w[i])$$

for all $w \in \{0,1\}^*$.

3. *If* $\beta = \beta_0 = \beta_1 = \beta_2 = \cdots$, *then we write* μ^β *for* $\mu^{\vec{\beta}}$. *In this case, we have the simpler formula*

$$\mu^\beta(w) = (1-\beta)^{\#(0,w)} \cdot \beta^{\#(1,w)},$$

where $\#(b,w)$ *denotes the number of* b*'s in* w. *Note that* $\mu^{\frac{1}{2}} = \mu$.

Intuitively, $\mu^{\vec{\beta}}(w)$ is the probability that $w \sqsubseteq A$ when the language $A \subseteq \{0,1\}^*$ is chosen probabilistically according to the following random experiment. For each string s_i in the standard enumeration $s_0, s_1, s_2, \dots$ of $\{0,1\}^*$, we (independently of all other strings) toss a special coin, whose probability is β_i of coming up heads, in which case $s_i \in A$, and $1-\beta_i$ of coming up tails, in which case $s_i \notin A$.

Definition 3.3. *A probability measure* ν *on* **C** *is* positive *if, for all* $w \in \{0,1\}^*$, $\nu(w) > 0$.

Definition 3.4. *If ν is a positive probability measure and $u, v \in \{0,1\}^*$, then the* conditional ν-measure of u given v *is*

$$\nu(u|v) = \begin{cases} 1 & \text{if } u \sqsubseteq v, \\ \frac{\nu(u)}{\nu(v)} & \text{if } v \sqsubseteq u, \\ 0 & \text{otherwise.} \end{cases}$$

Note that $\nu(u|v)$ is the conditional probability that $A \in \mathbf{C}_u$, given that $A \in \mathbf{C}_v$, when $A \in \mathbf{C}$ is chosen according to the probability measure ν.

Most of this paper concerns the following special type of probability measure.

Definition 3.5. *A probability measure ν on $\mathbf{C}$ is* strongly positive *if* (ν *is positive and*) *there is a constant $\delta > 0$ such that, for all $w \in \{0,1\}^*$ and $b \in \{0,1\}$, $\nu(wb|w) \geq \delta$.*

Definition 3.6. *A sequence of biases $\vec{\beta} = (\beta_0, \beta_1, \beta_2, \dots)$ is* strongly positive *if there is a constant $\delta > 0$ such that, for all $i \in \mathbb{N}$, $\beta_i \in [\delta, 1-\delta]$.*

If $\vec{\beta}$ is a sequence of biases, then the following two observations are clear.

1. $\mu^{\vec{\beta}}$ is positive if and only if $\beta_i \in (0,1)$ for all $i \in \mathbb{N}$.
2. If $\mu^{\vec{\beta}}$ is positive, then for each $w \in \{0,1\}^*$,

$$\mu^{\vec{\beta}}(w0|w) = 1 - \beta_{|w|}$$

and

$$\mu^{\vec{\beta}}(w1|w) = \beta_{|w|}.$$

It follows immediately from these two things that the probability measure $\mu^{\vec{\beta}}$ is strongly positive if and only if the sequence of biases $\vec{\beta}$ is strongly positive.

In this paper, we are primarily interested in strongly positive probability measures ν that are p-computable in the sense defined in section 2.

We next review the well-known notion of a martingale over a probability measure ν. Computable martingales were used by Schnorr [23, 24, 25, 26] in his investigations of randomness, and have more recently been used by Lutz [11] in the development of resource-bounded measure.

Definition 3.7. *Let ν be a probability measure on $\mathbf{C}$. Then a ν-*martingale *is a function $d : \{0,1\}^* \longrightarrow [0, \infty)$ such that, for all $w \in \{0,1\}^*$,*

$$d(w)\nu(w) = d(w0)\nu(w0) + d(w1)\nu(w1). \tag{3.1}$$

*If $\vec{\beta}$ is a sequence of biases, then a $\mu^{\vec{\beta}}$-martingale is simply called a $\vec{\beta}$-*martingale*. A μ-martingale is even more simply called a* martingale. (*That is, when the probability measure is not specified, it is assumed to be the uniform probability measure μ.*)

Intuitively, a ν-martingale d is a "strategy for betting" on the successive bits of (the characteristic sequence of) a language $A \in \mathbf{C}$. The real number $d(\lambda)$ is regarded as the amount of money that the strategy starts with. The real number $d(w)$ is the amount of money that the strategy has after betting on a prefix w of χ_A. The identity (3.1) ensures that the betting is "fair" in the sense that, if A is chosen according to the probability measure ν, then the expected amount of money is constant as the betting proceeds. (See [23, 24, 25, 26, 27, 11, 13, 12] for further discussion.) Of course, the "objective" of a strategy is to win a lot of money.

DEFINITION 3.8. *A ν-martingale d* succeeds *on a language $A \in \mathbf{C}$ if*

$$\limsup_{n \longrightarrow \infty} d(\chi_A[0..n-1]) = \infty.$$

The success set *of a ν-martingale d is the set*

$$S^\infty[d] = \{A \in \mathbf{C} \mid d \textit{ succeeds on } A\}.$$

We are especially interested in martingales that are computable within some resource bound. (Recall that the p-computability and p_2-computability of real valued functions were defined in section 2.)

DEFINITION 3.9. *Let ν be a probability measure on $\mathbf{C}$.*

1. *A p-ν-*martingale *is a ν-martingale that is p-computable.*
2. *A p_2-ν-*martingale *is a ν-martingale that is p_2-computable.*

A p-$\mu^{\vec{\beta}}$-martingale is called a p-$\vec{\beta}$-martingale, a p-μ-martingale is called a p-martingale, and similarly for p_2.

We now come to the fundamental ideas of resource-bounded ν-measure.

DEFINITION 3.10. *Let ν be a probability measure on $\mathbf{C}$, and let $X \subseteq \mathbf{C}$.*

1. *X has p-ν-*measure 0*, and we write $\nu_\mathrm{p}(X) = 0$, if there is a p-ν-martingale d such that $X \subseteq S^\infty[d]$.*
2. *X has p-ν-*measure 1*, and we write $\nu_\mathrm{p}(X) = 1$, if $\nu_\mathrm{p}(X^c) = 0$, where $X^c = \mathbf{C} - X$.*

The conditions $\nu_{\mathrm{p}_2}(X) = 0$ and $\nu_{\mathrm{p}_2}(X) = 1$ are defined analogously.

DEFINITION 3.11. *Let ν be a probability measure on $\mathbf{C}$, and let $X \subseteq \mathbf{C}$.*

1. *X has ν-*measure 0 in *E, and we write $\nu(X|\mathrm{E}) = 0$, if $\nu_\mathrm{p}(X \cap E) = 0$.*
2. *X has ν-*measure 1 in *E, and we write $\nu(X|\mathrm{E}) = 1$, if $\nu(X^c|\mathrm{E}) = 0$.*
3. *X has ν-*measure 0 in E_2*, and we write $\nu(X|\mathrm{E}_2) = 0$, if $\nu_{\mathrm{p}_2}(X \cap \mathrm{E}_2) = 0$.*
4. *X has ν-*measure 1 in E_2*, and we write $\nu(X|\mathrm{E}_2) = 1$, if $\nu(X^c|\mathrm{E}_2) = 0$.*

Just as in the uniform case [11], the resource bounds p and p_2 of the above definitions are only two possible values of a very general parameter. Other choices of this parameter yield classical ν-measure [5], constructive ν-measure (as used in algorithmic information theory [29, 27]), ν-measure in the set REC, consisting of all decidable languages, ν-measure in ESPACE, etc.

The rest of this section is devoted to a very brief presentation of some of the fundamental theorems of resource-bounded ν-measure. One of the main objectives of these results is to justify the intuition that *a set with ν-measure* 0 *in* E *contains only a "negligibly small" part of* E (with respect to ν). For the purpose of this paper, it suffices to present these results for p-ν-measure and ν-measure in E. We note, however, that all these results hold *a fortiori* for p_2-ν-measure, rec-ν-measure, classical ν-measure, ν-measure in E_2, ν-measure in ESPACE, etc.

We first note that ν-measure 0 sets exhibit the set-theoretic behavior of small sets.

DEFINITION 3.12. *Let $X, X_0, X_1, X_2, \ldots \subseteq \mathbf{C}$.*

1. *X is a p-*union of the p-ν-measure 0 sets $X_0, X_1, X_2, \ldots$ *if $X = \cup_{k=0}^\infty X_k$ and there is a sequence $d_0, d_1, d_2, \ldots$ of ν-martingales with the following two properties.*
   (i) *For each $k \in \mathbb{N}$, $X_k \subseteq S^\infty[d_k]$.*
   (ii) *The function $(k, w) \mapsto d_k(w)$ is p-computable.*

2. *X is a* p-union of the sets $X_0, X_1, X_2, \ldots$ of ν-measure 0 in E *if* $X = \cup_{k=0}^{\infty} X_k$ *and there is a sequence* $d_0, d_1, d_2, \ldots$ *of* ν*-martingales with the following two properties.*
(i) *For each* $k \in \mathbb{N}$, $X_k \cap \mathrm{E} \subseteq S^\infty[d_k]$.
(ii) *The function* $(k, w) \mapsto d_k(w)$ *is p-computable.*

LEMMA 3.1. *Let* ν *be a probability measure on* $\mathbf{C}$, *and let* $\mathcal{I}$ *be either the collection of all p-*ν*-measure* 0 *subsets of* $\mathbf{C}$, *or the collection of all subsets of* $\mathbf{C}$ *that have* ν*-measure* 0 *in E. Then* $\mathcal{I}$ *has the following three closure properties.*
1. *If* $X \subseteq Y \in \mathcal{I}$, *then* $X \in \mathcal{I}$.
2. *If* X *is a finite union of elements of* $\mathcal{I}$, *then* $X \in \mathcal{I}$
3. *If* X *is a p-union of elements of* $\mathcal{I}$, *then* $X \in \mathcal{I}$.

Proof (sketch). Assume that X is a p-union of the p-ν-measure 0 sets $X_0, X_1, X_2, \ldots$, and let $d_0, d_1, d_2, \ldots$ be as in the definition of this condition. It suffices to show that $\nu_{\mathrm{p}}(X) = 0$. (The remaining parts of the lemma are obvious or follow directly from this.) The p-computability of the function $(k, w) \mapsto d_k(w)$ implies that there is a nondecreasing polynomial q such that, for all $k \in \mathbb{N}$ and $w \in \{0,1\}^*$, $d_k(w) \leq 2^{q(k+|w|)}$. Define

$$d : \{0,1\}^* \longrightarrow [0, \infty)$$
$$d(w) = \sum_{k=0}^{\infty} 2^{-q(2k)-k} d_k(w).$$

It is easily checked that d is a p-ν-martingale and that $X \subseteq S^\infty[d]$, so $\nu_{\mathrm{p}}(X) = 0$. □

We next note that, if ν is strongly positive and p-computable, then every singleton subset of E has p-ν-measure 0.

LEMMA 3.2. *If* ν *is a strongly positive*, *p-computable probability measure on* $\mathbf{C}$, *then for every* $A \in \mathrm{E}$,

$$\nu_{\mathrm{p}}(\{A\}) = \nu(\{A\}|\mathrm{E}) = 0.$$

Proof (sketch). Assume the hypothesis, and fix $\delta > 0$ such that, for all $w \in \{0,1\}^*$ and $b \in \{0,1\}$, $\nu(wb|w) \geq \delta$. Define

$$d : \{0,1\}^* \longrightarrow [0, \infty)$$
$$d(\lambda) = 1,$$
$$d(wb) = \frac{d(w)}{\nu(wb|w)} \cdot [\![b = [\![s_{|w|} \in A]\!]]\!].$$

It is easily checked that d is a p-ν-martingale and that, for all $n \in \mathbb{N}$, $d(\chi_A[0..n-1]) \geq (1-\delta)^{-n}$, whence $A \in S^\infty[d]$. □

Note that, for $A \in \mathrm{E}$, the "point-mass" probability measure

$$\pi_A : \{0,1\}^* \longrightarrow [0,1]$$
$$\pi_A(w) = \begin{cases} 1 & \text{if } w \sqsubseteq \chi_A, \\ 0 & \text{if } w \not\sqsubseteq \chi_A \end{cases}$$

is p-computable, and $\{A\}$ does *not* have p-π_A-measure 0. Thus, the strong positivity hypothesis cannot be removed from Lemma 3.2.

We now come to the most crucial issue in the development of resource-bounded measure. If a set X has ν-measure 0 in E, then we want to say that X contains only a "negligible small" part of E. In particular, then, it is critical that E itself not have ν-measure 0 in E. The following theorem establishes this and more.

THEOREM 3.3. *Let* ν *be a probability measure on* $\mathbf{C}$, *and let* $w \in \{0,1\}^*$. *If* $\nu(w) > 0$, *then* $\mathbf{C}_w$ *does not have* ν*-measure* 0 *in E.*

Proof (sketch). Assume the hypothesis, and let d be a p-ν-martingale. It suffices to show that $\mathbf{C}_w \cap \mathrm{E} \not\subseteq S^\infty[d]$.

Since d is p-computable, there is a function $\hat{d} : \mathbb{N} \times \{0,1\}^* \longrightarrow \mathbb{Q} \cap [0,\infty)$ with the following two properties.

(i) For all $r \in \mathbb{N}$ and $w \in \{0,1\}^*$, $|\hat{d}(r,w) - d(w)| \leq 2^{-r}$.

(ii) There is an algorithm that computes $\hat{d}(r,w)$ in time polynomial in $r + |w|$.

Define a language A recursively as follows. First, for $0 \leq i < |w|$, $[\![s_i \in A]\!] = w[i]$. Next assume that the string $x_i = \chi_A[0..i-1]$ has been defined, where $i \geq |w|$. Then

$$[\![s_i \in A]\!] = [\![\hat{d}(i+1, x_i1) \leq \hat{d}(i+1, x_i0)]\!].$$

With the language A so defined, it is easy to check that $A \in \mathbf{C}_w \cap \mathrm{E}$. It is also routine to check that, for all $i \geq |w|$,

$$\begin{aligned} d(x_{i+1}) &\leq \hat{d}(i+1, x_{i+1}) + 2^{-(i+1)} \\ &= \min\left\{\hat{d}(i+1, x_i0), \hat{d}(i+1, x_i1)\right\} + 2^{-(i+1)} \\ &\leq \min\{d(x_i0), d(x_i1)\} + 2^{-i} \\ &\leq d(x_i) + 2^{-i}. \end{aligned}$$

It follows inductively that, for all $n \geq |w|$,

$$\begin{aligned} d(x_n) &\leq d(w) + \sum_{i=|w|}^{n-1} 2^{-i} \\ &< d(w) + \sum_{i=|w|}^{\infty} 2^{-i} = d(w) + 2^{1-|w|}. \end{aligned}$$

This implies that

$$\limsup_{n \longrightarrow \infty} d(\chi_A[0..n-1]) \leq d(w) + 2^{1-|w|} < \infty,$$

whence $A \notin S^\infty[d]$. $\square$

As in the case of the uniform probability measure [11], more quantitative results on resource-bounded ν-measure can be obtained by considering the *unitary success set*

$$S^1[d] = \bigcup_{\substack{w \\ d(w) \geq 1}} \mathbf{C}_w$$

and the *initial value* $d(\lambda)$ of a p-ν-martingale d. For example, generalizing the arguments in [11] in a straightforward manner, this approach yields a measure conservation theorem for ν-measure (a quantitative extension of Theorem 3.3) and a uniform, resource-bounded extension of the classical first Borel–Cantelli lemma. As these results are not used in the present paper, we refrain from elaborating here.

4. Summable equivalence. If two probability measures on $\mathbf{C}$ are sufficiently "close" to one another, then the summable equivalence theorem says that the two probability measures are in absolute agreement as to which sets of languages have p-measure 0 and which do not. In this section, we define this notion of "close" and prove this result.

DEFINITION 4.1. *Let ν be a positive probability measure on $\mathbf{C}$, let $A \subseteq \{0,1\}^*$, and let $i \in \mathbb{N}$. Then the i*th conditional ν-probability along A *is*

$$\nu_A(i+1|i) = \nu(\chi_A[0..i] \mid \chi_A[0..i-1]).$$

DEFINITION 4.2. *Two positive probability measures ν and ν' on $\mathbf{C}$ are* summably equivalent, *and we write $\nu \approx \nu'$, if for every $A \subseteq \{0,1\}^*$,*

$$\sum_{i=0}^{\infty} |\nu_A(i+1|i) - \nu'_A(i+1|i)| < \infty.$$

It is clear that summable equivalence is an equivalence relation on the collection of all positive probability measures on $\mathbf{C}$. The following fact is also easily verified.

LEMMA 4.1. *Let ν and ν' be positive probability measures on $\mathbf{C}$. If $\nu \approx \nu'$, then ν is strongly positive if and only if ν' is strongly positive.*

The following definition gives the most obvious way to transform a martingale for one probability measure into a martingale for another.

DEFINITION 4.3. *Let ν and ν' be probability measures on $\mathbf{C}$ with ν' positive, and let d be a ν-martingale. Then the* canonical adjustment *of d to ν' is the ν'-martingale d' defined by*

$$d'(w) = \frac{\nu(w)}{\nu'(w)} d(w)$$

for all $w \in \{0,1\}^*$.

It is trivial to check that the above function d' is indeed a ν'-martingale. The following lemma shows that, for strongly positive probability measures, summable equivalence is a sufficient condition for d' to succeed whenever d succeeds.

LEMMA 4.2. *Let ν and ν' be strongly positive probability measures on $\mathbf{C}$, let d be a ν-martingale, and let d' be the canonical adjustment of d to ν'. If $\nu \approx \nu'$, then $S^\infty[d] \subseteq S^\infty[d']$.*

Proof. Assume the hypothesis, and let $A \in S^\infty[d]$. For each $i \in \mathbb{N}$, let

$$\nu_i = \nu_A(i+1|i), \quad \nu'_i = \nu'_A(i+1|i), \quad \tau_i = \nu_i - \nu'_i.$$

The hypothesis $\nu \approx \nu'$ says that $\sum_{i=0}^{\infty} |\tau_i| < \infty$. In particular, this implies that $\tau_i \longrightarrow 0$ as $i \longrightarrow \infty$, so we have the Taylor approximation

$$\ln \frac{\nu_i}{\nu'_i} = \ln\left(1 + \frac{\tau_i}{\nu'_i}\right) = \frac{\tau_i}{\nu'_i} + \mathrm{o}\left(\frac{\tau_i}{\nu'_i}\right)$$

as $i \longrightarrow \infty$. Thus $|\ln \frac{\nu_i}{\nu'_i}|$ is asymptotically equivalent to $\frac{|\tau_i|}{\nu'_i}$ as $i \longrightarrow \infty$. Since ν' is strongly positive, it follows that $\sum_{i=0}^{\infty} |\ln \frac{\nu_i}{\nu'_i}| < \infty$. Thus, if we let $w_k = \chi_A[0..k-1]$, then there is a positive constant c such that, for all $k \in \mathbb{N}$,

$$c \geq \sum_{i=0}^{k-1} \left(-\ln \frac{\nu_i}{\nu'_i}\right) = -\ln \prod_{i=0}^{k-1} \frac{\nu_i}{\nu'_i} = -\ln \frac{\nu(w_k)}{\nu'(w_k)},$$

whence

$$d'(w_k) = \frac{\nu(w_k)}{\nu'(w_k)} d(w_k) \geq e^{-c} d(w_k).$$

Since $A \in S^\infty[d]$, we thus have

$$\limsup_{k \longrightarrow \infty} d'(w_k) \geq \limsup_{k \longrightarrow \infty} e^{-c} d(w_k) = \infty,$$

so $A \in S^\infty[d']$. □

The following useful result is now easily established.

THEOREM 4.3 (summable equivalence theorem). *If ν and ν' are strongly positive, p-computable probability measures on* $\mathbf{C}$ *such that $\nu \approx \nu'$, then for every set $X \subseteq \mathbf{C}$,*

$$\nu_{\mathrm{p}}(X) = 0 \Longleftrightarrow \nu'_{\mathrm{p}}(X) = 0.$$

Proof. Assume the hypothesis, and assume that $\nu_{\mathrm{p}}(X) = 0$. By symmetry, it suffices to show that $\nu'_{\mathrm{p}}(X) = 0$. Since $\nu_{\mathrm{p}}(X) = 0$, there is a p-computable ν-martingale d such that $X \subseteq S^\infty[d]$. Let d' be the canonical adjustment of d to ν'. Since $d, \nu,$ and ν' are all p-computable, it is easy to see that d' is p-computable. Since $\nu \approx \nu'$, Lemma 4.2 tells us that

$$X \subseteq S^\infty[d] \subseteq S^\infty[d'].$$

Thus $\nu'_{\mathrm{p}}(X) = 0$. □

5. Exact computation. It is sometimes useful or convenient to work with probability measures that are rational-valued and efficiently computable in an exact sense, with no approximation. This section presents two very easy results identifying situations in which such probability measures are available.

DEFINITION 5.1. *A probability measure ν on* $\mathbf{C}$ *is* exactly p-computable *if $\nu : \{0,1\}^* \longrightarrow \mathbb{Q} \cap [0,1]$ and there is an algorithm that computes $\nu(w)$ in time polynomial in $|w|$.*

LEMMA 5.1. *For every strongly positive, p-computable probability measure ν on* $\mathbf{C}$, *there is an exactly p-computable probability measure ν' on* $\mathbf{C}$ *such that $\nu \approx \nu'$.*

Proof. Let ν be a p-computable probability measure on $\mathbf{C}$, and fix a function $\hat{\nu} : \mathbb{N} \times \{0,1\}^* \longrightarrow \mathbb{Q} \cap [0,1]$ that testifies to the p-computability of ν. Since ν is strongly positive, there is a constant $c \in \mathbb{N}$ such that, for all $w \in \{0,1\}^*$, $2^{-c|w|} \leq \nu(w) \leq 1 - 2^{-c|w|}$. Fix such a c and, for all $w \in \{0,1\}^*$, define

$$\nu'(w0|w) = \min\left\{1, \frac{\hat{\nu}((2c+1)|w|+3, w0)}{\hat{\nu}((2c+1)|w|+3, w)}\right\},$$

$$\nu'(w1|w) = 1 - \nu'(w0|w),$$

$$\nu'(w) = \prod_{i=0}^{|w|-1} \nu'(w[0..i] \big| w[0..i-1]).$$

It is clear that ν' is an exactly p-computable probability measure on $\mathbf{C}$.

Now let $w \in \{0,1\}^*$ and $b \in \{0,1\}$. For convenience, let

$$\begin{aligned} \delta &= 2^{-(1+c|w|)}, \\ \epsilon &= 2^{-(2c+1)|w|-3}, \\ a_1 &= \nu(wb), \\ a_2 &= \nu(w). \end{aligned}$$

Note that

$$\hat{\nu}((2c+1)|w|+3, w) \geq \nu(w) - \epsilon > \nu(w) - \delta \geq \delta.$$

It is clear by inspection that $\nu'(wb|w)$ can be written in the form

$$\nu'(wb|w) = \frac{a_1'}{a_2'},$$

where

$$|a_1' - a_1| \leq \epsilon \text{ and } |a_2' - a_2| \leq \epsilon.$$

We thus have

$$\begin{aligned} |a_1'a_2 - a_1a_2'| &\leq |a_1'a_2 - a_1a_2| + |a_1a_2 - a_1a_2'| \\ &\leq |a_1' - a_1| + |a_2' - a_2| \\ &\leq 2\epsilon, \end{aligned}$$

whence

$$\begin{aligned} |\nu'(wb|w) - \nu(wb|w)| &= \left| \frac{a_1'}{a_2'} - \frac{a_1}{a_2} \right| \\ &= \frac{|a_1'a_2 - a_1a_2'|}{a_2a_2'} \\ &\leq 2\epsilon\delta^{-2} \\ &= 2^{-|w|}. \end{aligned}$$

For all $A \subseteq \{0,1\}^*$, then, we have

$$\sum_{i=0}^{\infty} \left|\nu_A(i+1\middle|i) - \nu_A'(i+1\middle|i)\right| \;\leq\; \sum_{i=0}^{\infty} 2^{-i} \;=\; 2,$$

so $\nu \approx \nu'$. □

For some purposes (including those of this paper), the p-computability requirement is too weak, because it allows $\nu(w)$ to be computed (or approximated) in time polynomial in $|w|$, which is exponential in the length of the last string decided by w when we regard w as a prefix of a language A. In such situations, the following sort of requirement is often more useful. (We give only the definitions for sequences of biases, i.e., coin-toss probability measures, because this suffices for our purposes in this paper. It is clearly a routine matter to generalize further.)

DEFINITION 5.2.

1. *A P*-sequence of biases *is a sequence $\vec{\beta} = (\beta_0, \beta_1, \beta_2, \dots)$ of biases $\beta_i \in [0,1]$ for which there is a function*

$$\hat{\beta} : \mathbb{N} \times \mathbb{N} \longrightarrow \mathbb{Q} \cap [0,1]$$

   with the following two properties.
   (i) *For all $i, r \in \mathbb{N}$, $|\hat{\beta}(i,r) - \beta_i| \leq 2^{-r}$.*
   (ii) *There is an algorithm that, for all $i, r \in \mathbb{N}$, computes $\hat{\beta}(i,r)$ in time polynomial in $|s_i| + r$ (i.e., in time polynomial in $\log(i+1) + r$).*
2. *A P*-exact sequence of biases *is a sequence $\vec{\beta} = (\beta_0, \beta_1, \beta_2, \dots)$ of (rational) biases $\beta_i \in \mathbb{Q} \cap [0,1]$ such that the function $i \longmapsto \beta_i$ is computable in time polynomial in $|s_i|$.*

DEFINITION 5.3. *If $\vec{\alpha}$ and $\vec{\beta}$ are sequences of biases, then $\vec{\alpha}$ and $\vec{\beta}$ are* summably equivalent, *and we write $\vec{\alpha} \approx \vec{\beta}$, if $\sum_{i=0}^{\infty} |\alpha_i - \beta_i| < \infty$.*

It is clear that $\vec{\alpha} \approx \vec{\beta}$ if and only if $\mu^{\vec{\alpha}} \approx \mu^{\vec{\beta}}$.

LEMMA 5.2. *For every P-sequence of biases $\vec{\beta}$, there is a P-exact sequence of biases $\vec{\beta}'$ such that $\vec{\beta} \approx \vec{\beta}'$.*

Proof. Let $\vec{\beta}$ be a strongly positive P-sequence of biases, and let $\hat{\beta} : \mathbb{N} \times \mathbb{N} \longrightarrow \mathbb{Q} \cap [0,1]$ be a function that testifies to this fact. For each $i \in \mathbb{N}$, let

$$\beta'_i = \hat{\beta}(i, 2|s_i|),$$

and let $\vec{\beta}' = (\beta'_0, \beta'_1, \beta'_2, \dots)$. Then $\vec{\beta}'$ is a P-exact sequence of biases, and

$$\begin{aligned}\sum_{i=0}^{\infty} |\beta_i - \beta'_i| &\leq \sum_{i=0}^{\infty} 2^{-2|s_i|} \\ &\leq \sum_{i=0}^{\infty} 2^{-2\log(i+1)} \\ &= \sum_{i=0}^{\infty} \frac{1}{(i+1)^2} < \infty,\end{aligned}$$

so $\vec{\beta} \approx \vec{\beta}'$. □

6. Martingale dilation. In this section we show that certain truth-table reductions can be used to *dilate* martingales for one probability measure into martingales for another, perhaps dissimilar, probability measure on **C**. We first present some terminology and notation on truth-table reductions. (Most of this notation is standard [22], but some is specialized to our purposes.)

A truth-table reduction is a pair (f, g) of algorithms that, given a language A, is used to decide a language $B = F_{(f,g)}(A)$. Given a particular string x, the algorithm f specifies a list of membership queries regarding A, and the algorithm g specifies how the answers to these queries are to be used in deciding whether $x \in B$. The list of queries given by f is nonadaptive, i.e., the entire list is specified prior to the knowing of any of the answers to the queries. More formally, a *truth-table reduction* (briefly, a $\leq_{\text{tt}}$-reduction) is an ordered pair (f, g) of total recursive functions such that for each $x \in \{0,1\}^*$, there exists $n(x) \in \mathbb{Z}^+$ such that the following two conditions hold.

(i) $f(x)$ is (the standard encoding of) an $n(x)$-tuple $(f_1(x), \dots, f_{n(x)}(x))$ of strings $f_i(x) \in \{0,1\}^*$, which are called the *queries* of the reduction (f, g)

on input x. We use the notation $Q_{(f,g)}(x) = \{f_1(x), \ldots, f_{n(x)}(x)\}$ for the set of such queries.

(ii) $g(x)$ is (the standard encoding of) an $n(x)$-input, 1-output Boolean circuit, called the *truth table* of the reduction (f, g) on input x. We identify $g(x)$ with the Boolean function computed by this circuit, i.e.,

$$g(x) : \{0,1\}^{n(x)} \longrightarrow \{0,1\}.$$

A truth-table reduction (f, g) *induces* the function

$$F_{(f,g)} : \mathbf{C} \longrightarrow \mathbf{C}$$
$$F_{(f,g)}(A) = \left\{x \in \{0,1\}^* \ \mid g(x)\left([\![f_1(x) \in A]\!] \cdots [\![f_{n(x)}(x) \in A]\!]\right) = 1\right\}.$$

If A and B are languages and (f, g) is a $\leq_{\mathrm{tt}}$-reduction, then (f, g) *reduces B to A*, and we write

$$B \leq_{\mathrm{tt}} A \text{ via } (f, g),$$

if $B = F_{(f,g)}(A)$. More generally, if A and B are languages, then B is *truth-table reducible* (briefly, $\leq_{\mathrm{tt}}$-reducible) to A, and we write $B \leq_{\mathrm{tt}} A$, if there exists a $\leq_{\mathrm{tt}}$-reduction (f, g) such that $B \leq_{\mathrm{tt}} A$ via (f, g).

If (f, g) is a $\leq_{\mathrm{tt}}$-reduction, then the function $F_{(f,g)} : \mathbf{C} \longrightarrow \mathbf{C}$ defined above induces a corresponding function

$$F_{(f,g)} : \{0,1\}^* \longrightarrow \{0,1\}^* \cup \mathbf{C}$$

defined as follows. (It is standard practice to use the same notation for these two functions, and no confusion will result from this practice here.) Intuitively, if $A \in \mathbf{C}$ and $w \sqsubseteq A$, then $F_{(f,g)}(w)$ is the largest prefix of $F_{(f,g)}(A)$ such that w answers all queries in this prefix. Formally, let $w \in \{0,1\}^*$, and let

$$A_w = \left\{s_i \,\middle|\, 0 \leq i < |w| \text{ and } w[i] = 1\right\}.$$

If $Q_{(f,g)}(x) \subseteq \{s_0, \ldots s_{|w|-1}\}$ for all $x \in \{0,1\}^*$, then

$$F_{(f,g)}(w) = F_{(f,g)}(A_w).$$

Otherwise,

$$F_{(f,g)}(w) = \chi_{F_{(f,g)}(A_w)}[0..m-1],$$

where m is the greatest nonnegative integer such that

$$\bigcup_{i=0}^{m-1} Q_{(f,g)}(s_i) \subseteq \left\{s_0, \ldots, s_{|w|-1}\right\}.$$

Now let (f, g) be a $\leq_{\mathrm{tt}}$-reduction, and let $z \in \{0,1\}^*$. Then the *inverse image* of the cylinder $\mathbf{C}_z$ under the reduction (f, g) is

$$\begin{aligned} F^{-1}_{(f,g)}(\mathbf{C}_z) &= \left\{A \in \mathbf{C} \mid F_{(f,g)}(A) \in \mathbf{C}_z\right\} \\ &= \left\{A \in \mathbf{C} \mid z \sqsubseteq F_{(f,g)}(A)\right\}. \end{aligned}$$

We can write this set in the form

$$F^{-1}_{(f,g)}(\mathbf{C}_z) = \bigcup_{w \in I} \mathbf{C}_w,$$

where I is the set of all strings $w \in \{0,1\}^*$ with the following properties.

(i) $z \sqsubseteq F_{(f,g)}(w)$.

(ii) If w' is a proper prefix of w, then $z \not\sqsubseteq F_{(f,g)}(w')$.

Moreover, the cylinders $\mathbf{C}_w$ in this union are disjoint, so if ν is a probability measure on $\mathbf{C}$, then

$$\nu(F^{-1}_{(f,g)}(\mathbf{C}_z)) = \sum_{w \in I} \nu(w).$$

The following well-known fact is easily verified.

LEMMA 6.1. *If ν is a probability measure on $\mathbf{C}$ and (f,g) is a $\leq_{\mathrm{tt}}$-reduction, then the function*

$$\nu^{(f,g)} : \{0,1\}^* \longrightarrow [0,1],$$
$$\nu^{(f,g)}(z) = \nu(F^{-1}_{(f,g)}(\mathbf{C}_z))$$

is also a probability measure on $\mathbf{C}$.

The probability measure $\nu^{(f,g)}$ of Lemma 6.1 is called the *probability measure induced by ν and (f,g)*.

In this paper, we only use the following special type of $\leq_{\mathrm{tt}}$-reduction.

DEFINITION 6.1. *A $\leq_{\mathrm{tt}}$-reduction (f,g) is* orderly *if, for all $x,y,u,v \in \{0,1\}^*$, if $x < y$, $u \in Q_{(f,g)}(x)$, and $v \in Q_{(f,g)}(y)$, then $u < v$. That is, if x precedes y (in the standard ordering of $\{0,1\}^*$), then every query of (f,g) on input x precedes every query of (f,g) on input y.*

The following is an obvious property of orderly $\leq_{\mathrm{tt}}$-reductions.

LEMMA 6.2. *If ν is a coin-toss probability measure on $\mathbf{C}$ and (f,g) is an orderly $\leq_{\mathrm{tt}}$-reduction, then $\nu^{(f,g)}$ is also a coin-toss probability measure on $\mathbf{C}$.*

Note that, if (f,g) is an orderly $\leq_{\mathrm{tt}}$-reduction, then $F_{(f,g)}(w) \in \{0,1\}^*$ for all $w \in \{0,1\}^*$. Note also that the length of $F_{(f,g)}(w)$ depends only upon the length of w (i.e., $|w| = |w'|$ implies that $|F_{(f,g)}(w)| = |F_{(f,g)}(w')|$). Finally, note that for each $m \in \mathbb{N}$ there exists $l \in \mathbb{N}$ such that $|F_{(f,g)}(0^l)| = m$.

DEFINITION 6.2. *Let (f,g) be an orderly $\leq_{\mathrm{tt}}$-reduction.*

1. *An (f,g)-*step *is a positive integer l such that $F_{(f,g)}(0^{l-1}) \neq F_{(f,g)}(0^l)$.*
2. *For $k \in \mathbb{N}$, we let step(k) be the least (f,g)-step l such that $l \geq k$.*

The following construction is crucial to the proof of our main theorem.

DEFINITION 6.3. *Let ν be a positive probability measure on $\mathbf{C}$, let (f,g) be an orderly $\leq_{\mathrm{tt}}$-reduction, and let d be a $\nu^{(f,g)}$-martingale. Then the (f,g)-*dilation *of d is the function*

$$(f,g)\widehat{\ }d : \{0,1\}^* \longrightarrow [0,\infty)$$
$$(f,g)\widehat{\ }d(w) = \sum_{u \in \{0,1\}^{l-k}} d(F_{(f,g)}(wu))\nu(wu|w),$$

where $k = |w|$ and $l = $ step(k).

In other words, $(f,g)\widehat{\ }d(w)$ is the conditional ν-expected value of $d(F_{(f,g)}(w'))$, given that $w \sqsubseteq w'$ and $|w'| = $ *step*$(|w|)$. We do not include the probability measure ν in the notation $(f,g)\widehat{\ }d$ because ν (being positive) is implicit in d.

Intuitively, the function $(f,g)\widehat{\ }d$ is a strategy for betting on a language A, assuming that d itself is a strategy for betting on the language $F_{(f,g)}(A)$. The following theorem makes this intuition precise.

THEOREM 6.3 (martingale dilation theorem). *Assume that ν is a positive coin-toss probability measure on* $\mathbf{C}$, *(f,g) is an orderly $\leq_{\mathrm{tt}}$-reduction, and d is a $\nu^{(f,g)}$-martingale. Then $(f,g)\hat{}d$ is a ν-martingale. Moreover, for every language $A \subseteq \{0,1\}^*$, if d succeeds on $F_{(f,g)}(A)$, then $(f,g)\hat{}d$ succeeds on A.*

A very special case of the above result (for strictly increasing $\leq_{\mathrm{m}}^{\mathrm{P}}$-reductions under the uniform probability measure) was developed by Ambos-Spies, Terwijn, and Zheng [2] and made explicit by Juedes and Lutz [8]. Our use of martingale dilation in the present paper is very different from the simple padding arguments of [2, 8].

The following two technical lemmas are used in the proof of Theorem 6.3.

LEMMA 6.4. *Assume that ν is a positive coin-toss probability measure on* $\mathbf{C}$ *and (f,g) is an orderly $\leq_{\mathrm{tt}}$-reduction. Let $F = F_{(f,g)}$, let $w \in \{0,1\}^*$, and assume that $k = |w|$ is an (f,g)-step. Let $l = step(k+1)$. Then, for $b \in \{0,1\}$,*

$$\nu^{(f,g)}(F(w)b|F(w)) = \sum_{\substack{u \in \{0,1\}^{l-k} \\ F(wu) = F(w)b}} \nu(wu|w).$$

Proof. Assume the hypothesis. Then

$$\begin{aligned}\nu^{(f,g)}(F(w)b) &= \sum_{\substack{w' \in \{0,1\}^k \\ F(w') = F(w)}} \sum_{\substack{u \in \{0,1\}^{l-k} \\ F(w'u) = F(w')b}} \nu(w'u) \\ &= \sum_{\substack{w' \in \{0,1\}^k \\ F(w') = F(w)}} \nu(w') \sum_{\substack{u \in \{0,1\}^{l-k} \\ F(w'u) = F(w')b}} \nu(w'u|w').\end{aligned}$$

Now, since ν is a coin-toss probability measure, we have $\nu(w'u|w') = \nu(wu|w)$ for each $w' \in \{0,1\}^k$ such that $F(w') = F(w)$. Also, since (f,g) is orderly, the conditions $F(w'u) = F(w')b$ and $F(wu) = F(w)b$ are equivalent for each $u \in \{0,1\}^{l-k}$. Hence,

$$\begin{aligned}\nu^{(f,g)}(F(w)b) &= \sum_{\substack{w' \in \{0,1\}^k \\ F(w') = F(w)}} \nu(w') \sum_{\substack{u \in \{0,1\}^{l-k} \\ F(wu) = F(w)b}} \nu(wu|w) \\ &= \nu^{(f,g)}(F(w)) \sum_{\substack{u \in \{0,1\}^{l-k} \\ F(wu) = F(w)b}} \nu(wu|w). \qquad \square\end{aligned}$$

LEMMA 6.5. *Assume that ν is a positive coin-toss probability measure on* $\mathbf{C}$ *and (f,g) is an orderly $\leq_{\mathrm{tt}}$-reduction. Let $F = F_{(f,g)}$, and assume that d is a $\nu^{(f,g)}$-martingale. Let $w \in \{0,1\}^*$, assume that $k = |w|$ is an (f,g)-step, and let $l = step(k+1)$. Then*

$$d(F(w)) = \sum_{u \in \{0,1\}^{l-k}} d(F(wu))\nu(wu|w).$$

Proof. Assume the hypothesis. Since d is a $\nu^{(f,g)}$-martingale and $\nu^{(f,g)}(F(w))$ is positive, we have

$$d(F(w)) = \sum_{b=0}^{1} d(F(w)b)\nu^{(f,g)}(F(w)b|F(w)).$$

It follows by Lemma 6.4 that

$$\begin{aligned} d(F(w)) &= \sum_{b=0}^{1} d(F(w)b) \sum_{\substack{u \in \{0,1\}^{l-k} \\ F(wu) = F(w)b}} \nu(wu|w) \\ &= \sum_{b=0}^{1} \sum_{\substack{u \in \{0,1\}^{l-k} \\ F(wu) = F(w)b}} d(F(wu))\nu(wu|w) \\ &= \sum_{u \in \{0,1\}^{l-k}} d(F(wu))\nu(wu|w). \qquad \square \end{aligned}$$

Proof (Theorem 6.3). Assume the hypothesis, and let $F = F_{(f,g)}$.

To see that $(f,g)\widehat{\ }d$ is a ν-martingale, let $w \in \{0,1\}^*$, let $k = |w|$, and let $l = \mathit{step}(k+1)$. We have two cases.

Case 1. $\mathit{step}(k) = l$. Then

$$\begin{aligned} \sum_{b=0}^{1} (f,g)\widehat{\ }d(wb)\nu(wb) &= \sum_{b=0}^{1} \sum_{u \in \{0,1\}^{l-k-1}} d(F(wbu))\nu(wbu|wb)\nu(wb) \\ &= \sum_{b=0}^{1} \sum_{u \in \{0,1\}^{l-k-1}} d(F(wbu))\nu(wbu) \\ &= \sum_{u \in \{0,1\}^{l-k}} d(F(wu))\nu(wu) \\ &= (f,g)\widehat{\ }d(w)\nu(w). \end{aligned}$$

Case 2. $\mathit{step}(k) < l$. Then k is an (f,g)-step, so $(f,g)\widehat{\ }d(w) = d(F(w))$, whence by Lemma 6.5

$$(f,g)\widehat{\ }d(w)\nu(w) = \sum_{u \in \{0,1\}^{l-k}} d(F(wu))\nu(wu).$$

Calculating as in Case 1, it follows that

$$(f,g)\widehat{\ }d(w)\nu(w) = \sum_{b=0}^{1} (f,g)\widehat{\ }d(wb)\nu(wb).$$

This completes the proof that $(f,g)\widehat{\ }d$ is a ν-martingale.

To complete the proof, let $A \subseteq \{0,1\}^*$, and assume that d succeeds on $F(A)$. For each $n \in \mathbb{N}$, let $w_n = \chi_A[0..l_n - 1]$, where l_n is the unique (f,g)-step such that $|F(0^{l_n})| = n$. Then, for all $n \in \mathbb{N}$,

$$(f,g)\widehat{\ }d(w_n) = d(F(w_n)) = d(\chi_{F(A)}[0..n-1]),$$

so

$$\begin{aligned} \limsup_{k \longrightarrow \infty} (f,g)\widehat{\ }d(\chi_A[0..k-1]) &\geq \limsup_{n \longrightarrow \infty} (f,g)\widehat{\ }d(w_n) \\ &= \limsup_{n \longrightarrow \infty} d(\chi_{F(A)}[0..n-1]) \\ &= \infty. \end{aligned}$$

Thus $(f,g)\widehat{\ }d$ succeeds on A. $\square$

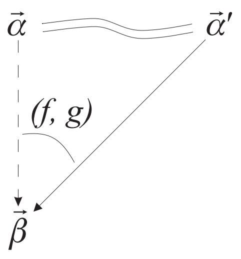

FIG. 1. *Schematic depiction of positive bias reduction.*

7. Positive bias reduction. In this section, we define and analyze a positive truth-table reduction that encodes an efficient, approximate simulation of one sequence of biases by another.

Intuitively, if $\vec{\alpha}$ and $\vec{\beta}$ are strongly positive sequences of biases, then the positive bias reduction of $\vec{\alpha}$ to $\vec{\beta}$ is a $\leq_{\mathrm{tt}}$-reduction (f, g) that "tries to simulate" the sequence $\vec{\alpha}$ with the sequence $\vec{\beta}$ by causing $\mu^{\vec{\alpha}}$ to be the probability distribution induced by $\mu^{\vec{\beta}}$ and (f, g). In general, this objective will only be approximately achieved, in the sense that the probability distribution induced by $\mu^{\vec{\beta}}$ and (f, g) will actually be a probability distribution $\mu^{\vec{\alpha}'}$, where $\vec{\alpha}'$ is a sequence of biases such that $\vec{\alpha}' \approx \vec{\alpha}$. This situation is depicted schematically in Figure 1, where the broken arrow indicates that (f, g) "tries" to reduce $\vec{\alpha}$ to $\vec{\beta}$, while the solid arrow indicates that (f, g) actually reduces $\vec{\alpha}'$ to $\vec{\beta}$.

The reduction (f, g) is constructed precisely as follows.

CONSTRUCTION 7.1 (positive bias reduction). *Let $\vec{\alpha}$ and $\vec{\beta}$ be strongly positive sequences of biases. Let*

$$\delta = \inf \{\alpha_i, 1 - \alpha_i, \beta_i, 1 - \beta_i \mid i \in \mathbb{N}\},$$

$$c = \left\lceil \frac{-4 \log e}{\log(1 - \delta^2)} \right\rceil.$$

For each $x \in \{0,1\}^*$ and $0 \leq n < 2^{c|x|}$, let $q(x, n) = xy$, where y is the nth element of $\{0,1\}^{c|x|}$, and let $j(x, n)$ be the index of the string $q(x, n)$, i.e., $s_{j(x,n)} = q(x, n)$. Then the positive bias reduction of $\vec{\alpha}$ to $\vec{\beta}$ is the ordered pair (f, g) of functions defined by the procedure in Figure 2. (For convenience, the procedure defines additional parameters that are useful in the subsequent analysis.)

The following general remarks will be helpful in understanding Construction 7.1.

(a) The boldface variables $\boldsymbol{v}_0, \boldsymbol{v}_1, \ldots$ denote Boolean inputs to the Boolean function $g(x)$ being constructed. The Boolean function $g(x)$ is an OR of $k(x)$ Boolean functions $h(x, k)$, i.e.,

$$g(x) = \bigvee_{k=0}^{k(x)-1} h(x, k).$$

The Boolean functions $g(x, 0), g(x, 1), \ldots$ are preliminary approximations of the Boolean function $g(x)$. In particular,

$$g(x, k) = \bigvee_{j=0}^{k-1} h(x, j)$$

```
begin
input $x = s_i$;
$n := 0$;
$g(x,0) := 0$; $\alpha'_i(0) = 0$;
$k := 0$;
while $\alpha'_i(k) < \alpha_i - (i+1)^{-2}$ do
        begin
        $h(x,k,0) := 1$; $\gamma_{i,k}(0) := 1$;
        $l := 0$;
        while $\alpha'_i(k) + \gamma_{i,k}(l) - \alpha'_i(k) \cdot \gamma_{i,k}(l) > \alpha_i$ do
                begin
                $h(x,k,l+1) := h(x,k,l)$ AND $v_n$;
                $\gamma_{i,k}(l+1) := \gamma_{i,k}(l) \cdot \beta_{j(x,n)}$;
                $l := l+1$;
                $n := n+1$;
                end ;
        $l(x,k) := l$;
        $h(x,k) := h(x,k,l(x,k))$;
        $\gamma_{i,k} := \gamma_{i,k}(l(x,k))$;
        $g(x,k+1) := g(x,k)$ OR $h(x,k)$;
        $\alpha'_i(k+1) := \alpha'_i(k) + \gamma_{i,k} - \alpha'_i(k) \cdot \gamma_{i,k}$;
        $k := k+1$
        end ;
$k(x) := k$;
$n(x) := n$;
$f(x) := (q(x,0), \ldots, q(x,n(x)-1))$;
$g(x) := g(x,k(x))$;
$\alpha'_i := \alpha'_i(k(x))$
end .
```

FIG. 2. *Construction of positive bias reduction.*

for all $0 \le k \le k(x)$. Thus $g(x,0)$ is the constant-0 Boolean function.

(b) The Boolean function $h(x,k)$ is an AND of $l(x,k)$ consecutive input variables. The subscript n is incremented globally so that no input variable appears more than once in $g(x)$. Just as $g(x,k)$ is the kth "partial OR" of $g(x)$, $h(x,k,l)$ is the lth "partial AND" of $h(x,k)$. Thus $h(x,k,0)$ is the constant-1 Boolean function.

(c) The input variables $\boldsymbol{v}_0$, $\boldsymbol{v}_1, \ldots$ of g correspond to the respective queries $q(x,0), q(x,1), \ldots$ of f. If $A = F_{(f,g)}(B)$, then we have $[\![x \in A]\!] = g(x)(\boldsymbol{v}_0 \cdots \boldsymbol{v}_{n(x)-1})$, where each $\boldsymbol{v}_n = [\![q(x,n) \in B]\!]$. If B is chosen according to the sequence of biases $\vec{\beta}$, then $\beta_{j(x,n)}$ is the probability that $\boldsymbol{v}_n = 1$, $\gamma_{i,k}$ is the probability that $h(x,k) = 1$, and α'_i is the probability that $g(x) = 1$. The while-loops ensure that $\alpha_i - (i+1)^{-2} \le \alpha'_i \le \alpha_i$.

The following lemmas provide some quantitative analysis of the behavior of Construction 7.1.

LEMMA 7.2. *In Construction* 7.1, *for all* $x \in \{0,1\}^*$ *and* $0 \le k \le k(x)$,

$$l(x,k) \le 1 + \frac{c|x|}{2\log e}.$$

Proof. Fix such x and k, and let $l^* = l(x,k)$. If $l^* = 0$, the result is trivial, so assume that $l^* > 0$. Then, by the minimality of l^*,

$$\alpha_i'(k) + \gamma_{i,k}(l^* - 1) > \alpha_i,$$

so

$$\gamma_{i,k}(l^* - 1) > \alpha_i - \alpha_i'(k) > (i+1)^{-2},$$

so

$$(i+1)^{-2} < \gamma_{i,k}(l^* - 1) \leq (1-\delta)^{l^*-1}.$$

It follows that

$$-2\log(i+1) \leq (l^* - 1)\log(1-\delta),$$

whence

$$\begin{aligned} l^* &\leq 1 - \frac{2\log(i+1)}{\log(1-\delta)} \\ &\leq 1 - \frac{2|x|}{\log(1-\delta^2)} \\ &\leq 1 + \frac{c|x|}{2\log e}. \qquad \square \end{aligned}$$

LEMMA 7.3. *In Construction* 7.1, *for all* $x \in \{0,1\}^*$, *and* $0 \leq k \leq k(x) - 1$,

$$\alpha_i - \alpha_i'(k) \leq (1-\delta^2)^k.$$

Proof. Fix such x and k with $k < k(x) - 1$, and let $l^* = l(x,k)$. Then $\gamma_{i,k}(l^* - 1) > \alpha_i - \alpha_i'(k)$, so $\gamma_{i,k} \geq \delta \cdot \gamma_{i,k}(l^* - 1) > \delta \cdot (\alpha_i - \alpha_i'(k))$, whence

$$\begin{aligned} \frac{\alpha_i - \alpha_i'(k+1)}{\alpha_i - \alpha_i'(k)} &= \frac{\alpha_i - (\alpha_i'(k) + \gamma_{i,k} - \alpha_i'(k)\cdot\gamma_{i,k})}{\alpha_i - \alpha_i'(k)} \\ &= \frac{\alpha_i - \alpha_i'(k) - \gamma_{i,k}(1 - \alpha_i'(k))}{\alpha_i - \alpha_i'(k)} \\ &< 1 - \delta\cdot(1-\alpha_i'(k)) \\ &\leq 1 - \delta\cdot(1-\alpha_i) \\ &\leq 1 - \delta^2. \end{aligned}$$

The lemma now follows immediately by induction. $\square$

LEMMA 7.4. *In Construction* 7.1, *for all* $x \in \{0,1\}^*$,

$$k(x) \leq 1 + \frac{c|x|}{2\log e}.$$

Proof. Fix $x \in \{0,1\}^*$. By Lemma 7.3 and the minimality of $k(x)$,

$$\alpha_i - (1-\delta^2)^{k(x)-1} \leq \alpha_i'(k(x)-1) < \alpha_i - (i+1)^{-2},$$

so

$$(1-\delta^2)^{k(x)-1} > (i+1)^{-2},$$

so

$$k(x) < 1 - \frac{2\log(i+1)}{\log(1-\delta^2)} \leq 1 + \frac{c|x|}{2\log e}. \qquad \square$$

LEMMA 7.5. *In Construction* 7.1, *for all* $x \in \{0,1\}^*$,

$$n(x) \leq \left(1 + \frac{c|x|}{2\log e}\right)^2 \leq 2^{c|x|}.$$

Proof. Let $x \in \{0,1\}^*$. Then

$$n(x) = \sum_{k=0}^{k(x)-1} l(x,k),$$

so by Lemmas 7.2 and 7.4, and the bound $1 + t \leq e^t$,

$$n(x) \leq \left(1 + \frac{c|x|}{2\log e}\right)^2 \leq e^{\frac{c|x|}{\log e}} = 2^{c|x|}. \qquad \square$$

DEFINITION 7.1. *Let* (f,g) *be a* $\leq_{\rm tt}$*-reduction.*

1. (f,g) *is* positive *(briefly, a* $\leq_{\rm pos-tt}$*-reduction) if, for all* $A, B \subseteq \{0,1\}^*$, $A \subseteq B$ *implies*$F_{(f,g)}(A) \subseteq F_{(f,g)}(B)$.
2. (f,g) *is* polynomial-time computable *(briefly, a* $\leq^{\rm P}_{\rm tt}$*-reduction) if the functions* f *and* g *are computable in polynomial time.*
3. (f,g) *is* polynomial-time computable with linear-bounded queries *(briefly, a* $\leq^{\rm P,lin}_{\rm tt}$-reduction*) if* (f,g) *is a* $\leq^{\rm P}_{\rm tt}$*-reduction and there is a constant* $c \in \mathbb{N}$ *such that, for all* $x \in \{0,1\}^*$, $Q_{(f,g)}(x) \subseteq \{0,1\}^{\leq c(1+|x|)}$.

Of course, a $\leq^{\rm P,lin}_{\rm pos-tt}$-reduction is a $\leq_{\rm tt}$-reduction with all the above properties.

The following result presents the properties of the positive bias reduction that are used in the proof of our main theorem.

THEOREM 7.6 (positive bias reduction theorem). *Let* $\vec{\alpha}$ *and* $\vec{\beta}$ *be strongly positive,* P*-exact sequences of biases, and let* (f,g) *be the positive bias reduction of* $\vec{\alpha}$ *to* $\vec{\beta}$*. Then* (f,g) *is an orderly* $\leq^{\rm P,lin}_{\rm pos-tt}$*-reduction, and the probability measure induced by* $\mu^{\vec{\beta}}$ *and* (f,g) *is a coin-toss probability measure* $\mu^{\vec{\alpha}'}$*, where* $\vec{\alpha} \approx \vec{\alpha}'$.

Proof. Assume the hypothesis. By inspection and Lemma 7.5, the pair (f,g) is an orderly $\leq^{\rm P,lin}_{\rm pos-tt}$-reduction. (Lemma 7.5 also ensures that $f(x)$ is well-defined.) The reduction is also positive, since only AND's and OR's are used in the construction of $g(x)$. Thus (f,g) is an orderly $\leq^{\rm P,lin}_{\rm pos-tt}$-reduction.

By remark (c) following Construction 7.1, the probability measure induced by $\mu^{\vec{\beta}}$ and (f,g) is the coin-toss probability measure $\mu^{\vec{\alpha}'}$, where $\vec{\alpha}' = (\alpha'_0, \alpha'_1, \dots)$ is defined in the construction. Moreover,

$$\sum_{i=0}^{\infty} |\alpha_i - \alpha'_i| \leq \sum_{i=0}^{\infty} (i+1)^{-2} < \infty,$$

so $\vec{\alpha} \approx \vec{\alpha}'$. $\square$

$$\begin{tikzcd}
\vec{\alpha} \arrow[r, no head, squiggly] & \vec{\alpha}' \arrow[r, no head, squiggly] \arrow[d, dashed] & \vec{\alpha}'' \arrow[r, no head, dashed] \arrow[dl, "(f,g)"'] & d \arrow[d, dashed] \\
\vec{\beta} \arrow[r, no head, squiggly] & \vec{\beta}' \arrow[rr, no head, dashed] & & (f,g)\hat{\ }d
\end{tikzcd}$$

FIG. 3. *Scheme of proof of the bias equivalence theorem.*

8. Equivalence for complexity classes. Many important complexity classes, including P, NP, co-NP, R, BPP, AM, P/Poly, PH, PSPACE, etc., are known to be closed under $\leq^{\mathrm{P}}_{\mathrm{pos-tt}}$-reductions, hence certainly under $\leq^{\mathrm{P,lin}}_{\mathrm{pos-tt}}$-reductions. The following theorem, which is the main result of this paper, says that the p-measure of such a class is somewhat insensitive to certain changes in the underlying probability measure. The proof is now easy, given the machinery of the preceding sections.

THEOREM 8.1 (bias equivalence theorem). *Assume that $\vec{\alpha}$ and $\vec{\beta}$ are strongly positive P-sequences of biases, and let $\mathcal{C}$ be a class of languages that is closed under $\leq^{\mathrm{P,lin}}_{\mathrm{pos-tt}}$-reductions. Then*

$$\mu^{\vec{\alpha}}_{\mathrm{p}}(\mathcal{C}) = 0 \Longleftrightarrow \mu^{\vec{\beta}}_{\mathrm{p}}(\mathcal{C}) = 0.$$

Proof. Assume the hypothesis, and assume that $\mu^{\vec{\alpha}}_{\mathrm{p}}(\mathcal{C}) = 0$. By symmetry, it suffices to show that $\mu^{\vec{\beta}}_{\mathrm{p}}(\mathcal{C}) = 0$.

The proof follows the scheme depicted in Figure 3. By Lemma 5.2, there exist P-exact sequences $\vec{\alpha}'$ and $\vec{\beta}'$ such that $\vec{\alpha} \approx \vec{\alpha}'$ and $\vec{\beta} \approx \vec{\beta}'$. Let (f,g) be the positive bias reduction of $\vec{\alpha}'$ to $\vec{\beta}'$. Then, by the positive bias reduction theorem (Theorem 7.6), (f,g) is an orderly $\leq^{\mathrm{P,lin}}_{\mathrm{pos-tt}}$-reduction, and the probability measure induced by $\mu^{\vec{\beta}}$ and (f,g) is $\mu^{\vec{\alpha}''}$, where $\vec{\alpha}' \approx \vec{\alpha}''$.

Since $\vec{\alpha} \approx \vec{\alpha}' \approx \vec{\alpha}''$ and $\mu^{\vec{\alpha}}_{\mathrm{p}}(\mathcal{C}) = 0$, the summable equivalence theorem (Theorem 4.3) tells us that there is a p-$\vec{\alpha}''$-martingale d such that $\mathcal{C} \subseteq S^{\infty}[d]$. By the martingale dilation theorem (Theorem 6.3), the function $(f,g)\hat{\ }d$ is then a $\vec{\beta}'$-martingale. In fact, it is easily checked that $(f,g)\hat{\ }d$ is a p-$\vec{\beta}'$-martingale.

Now let $A \in \mathcal{C}$. Then, since $\mathcal{C}$ is closed under $\leq^{\mathrm{P,lin}}_{\mathrm{pos-tt}}$-reductions, $F_{(f,g)}(A) \in \mathcal{C} \subseteq S^{\infty}[d]$. It follows by the martingale dilation theorem that $A \in S^{\infty}[(f,g)\hat{\ }d]$. Thus $\mathcal{C} \subseteq S^{\infty}[(f,g)\hat{\ }d]$. Since $(f,g)\hat{\ }d$ is a p-$\vec{\beta}'$-martingale, this shows that $\mu^{\vec{\beta}'}_{\mathrm{p}}(\mathcal{C}) = 0$. Finally, since $\vec{\beta} \approx \vec{\beta}'$, it follows by the summable equivalence theorem that $\mu^{\vec{\beta}}_{\mathrm{p}}(X) = 0$. ☐

It is clear that the bias equivalence theorem remains true if the resource bound on the measure is relaxed. That is, the analogs of Theorem 8.1 for p_2-measure, pspace-measure, rec-measure, constructive measure, and classical measure all immediately follow. We conclude by noting that the analogs of Theorem 8.1 for measure in E and measure in E_2 also immediately follow.

COROLLARY 8.2. *Under the hypothesis of Theorem* 8.1,

$$\mu^{\vec{\alpha}}(\mathcal{C}|\mathrm{E}) = 0 \Longleftrightarrow \mu^{\vec{\beta}}(\mathcal{C}|\mathrm{E}) = 0$$

and

$$\mu^{\vec{\alpha}}(\mathcal{C}|\mathrm{E}_2) = 0 \Longleftrightarrow \mu^{\vec{\beta}}(\mathcal{C}|\mathrm{E}_2) = 0.$$

Proof. If $\mathcal{C}$ is closed under $\leq^{\mathrm{P,lin}}_{\mathrm{pos-tt}}$-reductions, then so are the classes $\mathcal{C} \cap \mathrm{E}$ and $\mathcal{C} \cap \mathrm{E}_2$. □

9. Conclusion.

Our main result, the bias equivalence theorem, says that every strongly positive, P-computable, coin-toss probability measure ν is *equivalent* to the uniform probability measure μ, in the sense that

$$\nu_{\mathrm{p}}(\mathcal{C}) = 0 \Longleftrightarrow \mu_{\mathrm{p}}(\mathcal{C}) = 0$$

for all classes $\mathcal{C} \in \Gamma$, where Γ is a family that contains P, NP, co-NP, R, BPP, P/Poly, PH and many other classes of interest. It would be illuminating to learn more about which probability measures are, and which probability measures are not, equivalent to μ in this sense.

It would also be of interest to know whether the summable equivalence theorem can be strengthened. Specifically, say that two sequences of biases $\vec{\alpha}$ and $\vec{\beta}$ are *square-summably equivalent*, and write $\vec{\alpha} \approx^2 \vec{\beta}$, if $\sum_{i=0}^{\infty}(\alpha_i - \beta_i)^2 < \infty$. A classical theorem of Kakutani [9] says that, if $\vec{\alpha}$ and $\vec{\beta}$ are strongly positive sequences of biases such that $\vec{\alpha} \approx^2 \vec{\beta}$, then for every set $C \subseteq \mathbf{C}$, X has (classical) $\vec{\alpha}$-measure 0 if and only if X has $\vec{\beta}$-measure 0. A constructive improvement of this theorem by Vovk [28] says that, if $\vec{\alpha}$ and $\vec{\beta}$ are strongly positive, computable sequences of biases such that $\vec{\alpha} \approx^2 \vec{\beta}$, then for every set $X \subseteq \mathbf{C}$, X has constructive $\vec{\alpha}$-measure 0 if and only if X has constructive $\vec{\beta}$-measure 0. (The Kakutani and Vovk theorems are more general than this, but for the sake of brevity, we restrict the present discussion to coin-toss probability measures.) The summable equivalence theorem is stronger than these results in one sense, but weaker in another. It is stronger in that it holds for p-measure, but it is weaker in that it requires the stronger hypothesis that $\vec{\alpha} \approx \vec{\beta}$. We thus ask whether there is a "square-summable equivalence theorem" for p-measure. That is, if $\vec{\alpha}$ and $\vec{\beta}$ are strongly positive, p-computable sequences of biases such that $\vec{\alpha} \approx^2 \vec{\beta}$, is it necessarily the case that, for every set $X \subseteq \mathbf{C}$, X has p-$\vec{\alpha}$-measure 0 if and only if X has p-$\vec{\beta}$-measure 0? (Note: Kautz [10] has very recently answered this question affirmatively.)

Acknowledgments. We thank Giora Slutzki, Martin Strauss, and other participants in the ISU Information and Complexity Seminar for useful remarks and suggestions. We especially thank Giora Slutzki for suggesting a simplified presentation of Lemma 4.2. We also thank the referee for a very careful reading of our manuscript.

THE SWAPPING PROBLEM ON A LINE[*]

SHOSHANA ANILY[†], MICHEL GENDREAU[‡], AND GILBERT LAPORTE[‡]

Abstract. We consider the problem of optimally swapping objects between N workstations, which we refer to as nodes, located on a line. There are m types of objects, and the set of object-types is denoted by $S = \{1, \dots, m\}$. Object-type 0 is a dummy type, the *null object*. Each node v contains one unit of a certain object-type $a_v \in S \cup \{0\}$ and requires one unit of object-type $b_v \in S \cup \{0\}$. We assume that the total supply equals the total demand for each of the object-types separately. A vehicle of unit capacity ships the objects so that the requirements of all nodes are satisfied. The set of object-types is partitioned into two sets: objects that may be temporarily dropped at intermediate nodes before reaching their destination and objects that have to be shipped directly from their origin to their destination. The objective is to design a route that starts and ends at the depot and a feasible assignment of object-types to the route's arcs so that the total distance is minimized. We propose an $O(N^2)$ algorithm to compute the optimal solution for this problem.

Key words. the swapping problem, transshipment problem

1. Introduction.

A set V of N workstations, which we refer to as nodes, is located on a line. We are also given a set of m object-types $S = \{1, \dots, m\}$. Object-type 0 is the null object. Each workstation v contains one unit of a certain object $a_v \in S \cup \{0\}$ and requires one unit of object $b_v \in S \cup \{0\}$. $a_v = 0 (b_v = 0)$ means that no object is currently (required) at node v. For each object-type separately, the total supply (i.e., the number of nodes currently containing that object-type) equals the total demand (the number of nodes requiring that object-type). A vehicle of unit capacity that starts and ends at node $v_D \in V$ ships the objects from their initial locations so that the requirements of the workstations are satisfied. The objective is to design a feasible route of minimum length.

The set of object-types is partitioned into two sets $S = S_d \cup S_n$. Objects in S_d may be temporarily dropped at intermediate nodes before reaching their destination, while objects in S_n have to be shipped *directly* from their origin to their destination. One of these two sets may be empty. Clearly, the optimal solution when some of the objects may be dropped cannot be worse than in the case that $S = S_n$.

The general swapping problem where the workstations are the nodes of an undirected complete graph was studied by Anily and Hassin (1992). The authors show that the problem is NP-hard and prove the existence of an optimal solution that satisfies certain structural properties. They design two heuristics whose worst-case bounds are 2.5. The proposed heuristics are based on the composition of the optimal solutions to $m + 1$ matching problems, one for each object-type $i \in S \cup \{0\}$, where nodes v with $a_v = i$ are matched with nodes w with $b_w = i$. This step results in a set of disjoint cycles that are then patched into a single Eulerian tour. Except for Anily and Hassin (1992) and the current paper, the literature confines itself to systems containing one unit of each object-type, and moreover, all objects are in either S_n or

S_d. In the stacker-crane problem analyzed by Frederickson, Hecht, and Kim (1978) (see also Johnson and Papadimitriou (1985)), some directed arcs are given and the objective is to find a directed closed tour of minimum length containing these arcs. The stacker-crane problem is a special case of the swapping problem, where $S = S_n$, and there is one unit of each object-type. The authors propose a polynomial approximation for this problem whose worst-case bound is 9/5. Atallah and Kosaraju (1988) analyze the swapping problem on a line and on a circular track when there exists exactly one unit of each object-type in S. They consider the cases of $S = S_n$ (no drops) and $S = S_d$ (with drops). Their motivation to study the problem arises from the movement of a robot arm that is supposed to rearrange m objects among N stations. The robot arm consists of a single link that rotates around a fixed pivot. The link's length is variable since it can be extended in and out. A gripper that can grasp any of the objects is positioned at the end of the link. Minimizing the total distance traveled by the gripper is NP-hard. Instead, the authors focus separately on minimizing the total (a) telescoping motion, which corresponds to moving along a linear track, and (b) angular motion, which corresponds to moving along a circular track. The paper provides low polynomial algorithms for computing the optimal route: for the no-drop case the algorithm runs in $O(m + N\alpha(N))$ ($\alpha()$ is the inverse of Ackerman's function) for the linear track and in $O(m + N \log N)$ for the circular track (this last bound is further tightened in Frederickson (1993)). For the with-drop case the algorithm runs in $O(m + N)$ for both the linear and circular tracks. Frederickson and Guan (1992, 1993) studied the same problem as that of Atallah and Kosaraju (1988) when the objects are located on the vertices of a tree and the vehicle travels along its edges. For the with-drop case they present two algorithms that run in $O(m + Nq)$, where $q \leq \min\{m, N\}$. The no-drop case is shown to be NP-hard, and the authors provide two heuristics that run in low polynomial time with worst-case ratios of 1.5 and 1.25, respectively.

In this paper, we develop an $O(N^2)$-step algorithm for the linear track allowing no-drop and with-drop objects. Section 2 introduces the terminology, and section 3 establishes the necessary structural properties of any optimal solution. Finally, the main algorithm and its analysis is presented in section 4.

2. Notations and preliminaries.

$V = \{v_1, v_2, \ldots, v_N\}$ is a set of N workstations. Vertex $v_D, 1 \leq D \leq N$, is the depot where the vehicle starts and terminates the tour. The vertices are indexed according to their location on the line from left to right. $S = \{1, \ldots, m\}$ is a set of m object-types. Object-type 0 denotes the null object. Each vertex v is associated with a pair $(a_v, b_v) \in [S \cup \{0\}] \times [S \cup \{0\}]$, where a_v is the object-type currently at v and b_v is the object-type desired at v. Without loss of generality (w.l.o.g.) we assume that $a_v \neq b_v$. (If $a_D = b_D = 0$, then an equivalent problem can be defined such that $a_D \neq b_D$ by introducing a new node at the depot's location and a new object-type $m + 1$. Associate the depot with $(0, m + 1)$ and the new vertex with $(m + 1, 0)$.) The set S is partitioned into S_n, the set of *no-drop* objects-types, and S_d, the set of object-types that can be *dropped* at intermediate vertices. $d(u, v)$ is the distance between vertices u and v. $P^i \subseteq V$ are the supply vertices of object-type $i (i = 0, 1, \ldots, m)$, i.e., $P^i = \{v : a_v = i\}$. Let $P^i = \{p_{i1}, p_{i2}, \ldots, p_{ik(i)}\}$. $R^i \subseteq V$ are the vertices that require object-type $i (i = 0, 1, \ldots, m)$, i.e., $R^i = \{v : b_v = i\}$. Let $R^i = \{r_{i1}, r_{i2}, \ldots, r_{ik(i)}\}$. Let $V^i = P^i \cup R^i$, and $k(i) = |P^i| = |R^i|$ is the number of objects of type i in the system. Thus, $\sum_{i=0}^{m} k(i) = N$. The supply (demand) vertices of object-type i are indexed according to their location from left to right.

If $S = S_n$, then once we know which supply vertex in P^i serves each of the demand vertices in R^i for $i = 1, \ldots, m$, our problem reduces to the respective problem solved by Atallah and Kosaraju (1988).

DEFINITION 2.1. *A* path *is a sequence of directed arcs where the tail of one arc is the head of the preceding arc in the sequence, and all arcs in the sequence are assigned the same object-type* $i, 0 \leq i \leq m$.

DEFINITION 2.2. *If object-type* $i, 1 \leq i \leq m$, *that is initially located at vertex* p_{ih} *is used to supply the requirement of vertex* $r_{ih'}$, *then the path from* p_{ih} *to* $r_{ih'}$ *along which the object is shipped is called a* service path. *(See below for an extension of the definition for object-type* 0.*)*

Assume w.l.o.g. that objects are never dropped in order to pick up objects of the same type. Thus, in any feasible solution and any $v \in V$ with $a_v = i$, there exists a service path of object i initiating at v and ending at vertex u, $u \in V$ with $b_u = i$, $1 \leq i \leq m$. If $i \in S_n$, then the arcs of this path appear consecutively in the solution; i.e., the vehicle traverses the service path with no intermediate stops. If $i \in S_d$, then the arcs of this path appear in the solution in the same order as in the path, but not necessarily consecutively, meaning that the vehicle may drop the object and pick it up later.

DEFINITION 2.3. *A segment of the solution that the vehicle traverses empty is called a* deadheading.

According to Anily and Hassin (1992), if $a_v = 0$ for $v \in V$, then any feasible solution includes a path of deadheadings originating at v and ending at some vertex u with $b_u = 0$. Such a path is called a *service path* of the null object. Note that a feasible solution consists of $k(i)$ service paths for each object-type i, $i \in S \cup \{0\}$ and possibly some additional deadheadings.

DEFINITION 2.4. *The* end points *of a path starting at* u *and ending at* v, $u, v \in V$ *are the vertices* u *and* v.

DEFINITION 2.5. *A given arc is said to* cover *all points (not necessarily vertices) on the track in between its tail and its head including its end points. A path covers all points covered by its arcs.*

DEFINITION 2.6. *A path is* left-to-right (right-to-left) *if each of its arcs is directed to the right (left).*

DEFINITION 2.7. *Two paths are* intersecting in opposite directions *if* (a) *one path is left-to-right and other is right-to-left and* (b) *at least one end point of one path is covered by the other path.*

3. Structural properties of an optimal solution.

In this section we prove some theorems that ensure the existence of an optimal solution that satisfies some specified properties. The theorems hold for all the problem's variants discussed here.

THEOREM 3.1. *There exists an optimal solution that does not contain any pair of service paths for the same object-type* $i, 0 \leq i \leq m$, *that are intersecting in opposite directions.*

Proof. The proof is by contradiction. Suppose the theorem is false, i.e., any optimal routing contains service paths of the same object-type that are intersecting in opposite directions. Consider an optimal solution and let SP_1 and SP_2 be two such service paths for object-type i, $0 \leq i \leq m$. Suppose SP_1 connects $p_{ij(1)}$ to $r_{ih(1)}$ and SP_2 connects $p_{ij(2)}$ to $r_{ih(2)}$. W.l.o.g. let SP_1 be a left-to-right path. We show that there exists an alternative feasible solution that follows the same route and the only difference is with respect to the assignment of object i to the arcs of SP_1 and SP_2. Some arcs on these paths are assigned object i and the others are turned into deadheadings. As a consequence, the two new service paths are no longer intersecting in opposite directions. For the null object, the new solution is identical to the given one, but we distinguish differently between the service paths of object 0 and the deadheadings.

According to our assumptions, there exists a segment (u, v) that is covered by SP_1 and SP_2, where SP_1 is directed from u to v and SP_2 from v to u. The alternative solution is defined such that $r_{ih(1)}(r_{ih(2)})$ is served from $p_{ij(2)}(p_{ij(1)})$. It is easy to verify that the two new service paths consist of exactly those parts in SP_1 and SP_2 that do not cover (u, v) and their directions are consistent with the respective directions of SP_1 and SP_2. Also, the segment (u, v) on SP_1 and SP_2 is turned into a deadheading.

In the following, we derive additional properties satisfied by optimal paths.

DEFINITION 3.2. *$V^{\ell(i)} \subseteq V^i$ is* consecutive *if it consists of V^i nodes that appear consecutively on the line.*

DEFINITION 3.3. *A* consecutive partition *of V^i is a partition of V^i into consecutive disjoint subsets.*

DEFINITION 3.4. *A subset of vertices $V^{\ell(i)} \subseteq V^i$ is called* balanced *if it is consecutive and is of even cardinality, where half of its vertices are in P^i and the remaining are in R^i.*

DEFINITION 3.5. *A subset is* minimally balanced *if it is balanced and there does not exist any consecutive partition of the subset into two balanced subsets.*

DEFINITION 3.6. *The* consecutive minimally balanced partition (CMBP) *of V^i is the consecutive partition of V^i, where each of the subsets in the partition is minimally balanced.*

Note that any feasible solution is associated with $m + 1$ sets of service paths, one set for each object-type. The service paths of object i induce a consecutive balanced partition of V^i defined recursively as follows: (1) the two end points of a service path belong to the same subset in the partition; (2) all vertices of V^i covered by a certain service path belong to the same subset as the end points of the path; and (3) the subsets are minimal. It is easy to see that for a given solution the consecutive balanced partition of V^i induced by the service paths of object i is well defined. Moreover, if the solution does not contain any intersecting in opposite directions service paths for the same object-type, then all service paths within a set of this partition are in the same direction.

THEOREM 3.7. *In any optimal solution that does not contain intersecting in opposite directions service paths of object i, the service paths of this object-type* (1) *induce the CMBP of V^i and* (2) *have constant total length.*

Proof. Suppose Z is an optimal solution that satisfies the property of the theorem. The service paths of object-type i that are associated with solution Z induce a consecutive balanced partition of V^i. We want to show first that the subsets of this partition are *minimally balanced*. Assume w.l.o.g. that the leftmost vertex in V^i is a supply vertex $s_1 \in P^i$. Let $L_{i1} \subseteq V^i$ be the set induced by solution Z that contains s_1.

The proof is by induction on the cardinality of V^i. The minimum cardinality of V^i is two; i.e., V^i consists of a supply vertex and a demand vertex and the theorem is trivial. According to the inductive hypothesis, the theorem holds for any set of cardinality less than $|V^i|$. Suppose $|V^i| > 2$. We distinguish between two cases: (a) No consecutive partition of V^i into two balanced subsets exists. Thus, $L_{i1} = V^i$; i.e., the partition of V^i induced by the service paths of object-type i in Z is into a single set, which is the CMBP of V^i. (b) There exists a consecutive balanced partition of V^i into two subsets: let $V^i = V_{i1} \cup V_{i2}$ be a consecutive partition of V^i, where V_{i1} is a minimally balanced subset that contains s_1. We will show that $L_{i1} = V_{i1}$ and the rest will follow by the inductive hypothesis. Suppose that $V_{i1} \subset L_{i1}$ but $V_{i1} \neq L_{i1}$. Since s_1 is the leftmost supply vertex of object i on the line, it must serve a demand vertex to its right. As a consequence, all service paths within L_{i1} should be from left to right, otherwise there would be intersecting paths in opposite directions within L_{i1}, in contradiction to our assumption about Z. Since $V_{i1} \subset L_{i1}$ but $V_{i1} \neq L_{i1}$, there should be in Z a supply vertex $p \in V_{i1}$ that serves a demand vertex $r \in L_{i1} - V_{i1}$. In view of the fact that V_{i1} is balanced, at least one of the demand vertices r' in V_{i1} should be served according to Z by a supply vertex $s' \in L_{i1} - V_{i1}$. This contradicts the assumption that Z does not contain any service paths for object-type i that are intersecting in opposite directions.

In order to prove the second part of the theorem, we will show that the total length of the service paths of object i within any subset of the CMBP of V^i is constant. Suppose w.l.o.g. that we are given a minimally balanced subset of the CMBP of V^i for which all service paths are from left to right. Also suppose that x and y are consecutive vertices in V^i, where x is strictly to the left of y. Let $lp^i(z)(lr^i(z))$ denote the number of supply (demand) vertices from V^i within the subset that are located to the left or at the location of z. Then, the number of service paths of object i that cover the segment connecting x to y is $lp^i(x) - lr^i(x)$, which is strictly positive according to our assumptions. Accordingly, a simple calculation that depends only on the subset gives the total length of service paths within that subset.

4. The algorithm for the linear track case.

In this section we present an algorithm for finding an optimal policy for linear graphs. As a consequence of the previous section, an optimal solution exists in which the service paths of each object-type i, $0 \leq i \leq m$, induce the CMBP of V^i. Let $\{V_{i\ell}\}_{\ell=1,\dots,L(i)}$ denote the CMBP of V^i for $i = 0, \dots, m$. We now propose an algorithm for computing an optimal routing policy. The first step in the algorithm is to define a directed graph on V that consists of those arcs that must appear in such an optimal solution. Each arc in the graph connects two vertices in $V_{i\ell}$ for some $i = 0, \dots, m$ and $\ell = 1, \dots, L(i)$.

DEFINITION 4.1. *A set $V_{i\ell}$ of the CMBP of V^i is called a* left-set (right-set) *if the number of supply vertices is no smaller (no larger) than the number of demand vertices of object-type i in any consecutive subset of $V_{i\ell}$ that contains the leftmost vertex of $V_{i\ell}$.*

The directed graph G on V is defined by the following algorithm, called Basic Graph.

ALGORITHM BASIC GRAPH.

Step 0. For $i = 0, \dots, m$ and $\ell = 1, \dots, L(i)$ do steps 1 and 2:

Step 1. Let k be the number of demand vertices in $V_{i\ell}$. If $V_{i\ell}$ is a left-set (right-set), then index the demand vertices in $V_{i\ell}$ from left to right (right to left) as $\{r_1, r_2, \dots, r_k\}$. Let $G_{i\ell}$ initially be a graph with no arcs. Add to $G_{i\ell}$ a directed arc from each supply vertex in $P^i \cap V_{i\ell}$ toward the first demand vertex in $R^i \cap V_{i\ell}$ to its right (left), i.e., the first demand vertex it may serve.

Step 2. If $|V_{i\ell}| = 2$, then stop (the graph $G_{i\ell}$ contains a single arc). Otherwise, set $j = 1$; while $j < k$ do begin: Count the number of incoming arcs in $G_{i\ell}$ to r_j. Let this number be $in(j)$; add $in(j) - 1$ arcs to $G_{i\ell}$ all from r_j towards r_{j+1}. endwhile;

Step 3. Let graph G be the composition of all subgraphs $G_{i\ell}$ for $i = 0, \dots, m$ and $\ell = 1, \dots, L(i)$.

Remark. Note that in Step 2, $V_{i\ell}$ is a subset of the CMBP of V^i; thus $in(j) > 1$ for $j \leq k - 1$ and $in(k) = 1$.

LEMMA 4.1. *The in-degree equals the out-degree for any of the vertices of graph G.*

Proof. We have to show that the number of incoming arcs equals the number of outgoing arcs for any vertex $v \in V$. Let $v \in V$, and denote $(a_v, b_v) = (k, j)$ k, $j \in S \cup \{0\} k \neq j$. Also suppose that $v \in V_{k\ell} \cap V_{jh}$. The only arcs incident to v are arcs in the subgraphs $G_{k\ell}$ and G_{jh}. In $V_{k\ell}$, v is a supply vertex; thus exactly one arc exits from v in $G_{k\ell}$. In V_{jh}, v is a demand vertex; thus in G_{jh}, the number of outgoing arcs from v is one less than the number of incoming arcs to v. Thus overall, G satisfies the lemma.

A directed graph may be partitioned into a collection of equivalence classes such that vertices w and v are in the same class if and only if the graph contains directed paths from v to w and from w to v. (See section 5.5 in Aho, Hopcroft, and Ullman (1974).) The subgraph induced by a certain class consists of the vertices in the class as well as all edges in the graph that connect a pair of vertices in the class. These subgraphs are called the *strongly connected components* of the given graph. In light of Lemma 4.1, the union of the strongly connected components of G results in G itself.

We first demonstrate the algorithm when G is strongly connected: Since G is Eulerian, there exists an optimal solution that consists of G's arcs and does not use the drop option. This is observed by noting that if the number of incoming arcs to vertex v is k, $k > 1$, then *all* incoming arcs to v carry item b_v, where $k-1$ outgoing arcs carry item b_v. Thus, in $k-1$ of the k entrances to v the vehicle continues with the same item; at one entrance item b_v is unloaded and at one exit item a_v is loaded. Any Euler tour in G produces an optimal solution by starting at the depot. The complexity of finding such a tour is linear in the number of arcs of G. A simple calculation demonstrates that the number of arcs in G carrying item i is at most $k(i)(k(i)+1)/2$. Thus, G contains at most $\sum_{i=0}^{m} k(i)(k(i)+1)/2$ arcs. Since $\sum_{i=0}^{m} k(i) = N$, the maximum number of arcs in G is of order $O(N^2)$.

We continue with the general case when G is not necessarily strongly connected, i.e., G is the union of a number of strongly connected components where each is an Eulerian subgraph. Up to now, we have not used the fact that the vehicle is empty along arcs associated with the null object and we have not used the drop option. For that sake, we extend the term "connectivity:" It is not necessarily the case that for two different components of G none is reachable from the other, moreover it may well be that each is reachable from the other. An arc in G may cover intermediate vertices, thus it consists of a sequence of *basic arcs*, where a basic arc is defined as a directed arc connecting two consecutive vertices of V. We distinguish between three types of arcs in G: (1) arcs of object-type i, $i \in S_n$; (2) arcs of object-type i, $i \in S_d$; and (3) arcs of the null object. Arcs of no-drop objects should be followed continuously from their initial vertex to their terminal vertex; i.e., the respective sequence of basic arcs should occur in the solution consecutively. Arcs of drop-objects should be followed from their initial vertex to their terminal vertex with possible stops at intermediate vertices for drops; i.e., the respective basic arcs should be followed at the order they occur in the sequence, but not necessarily consecutively. The basic arcs of the null object occur in the solution with no restriction on their order.

DEFINITION 4.2. *Let C^s_ℓ and C^s_k be different strongly connected components of G. C^s_k is* directly reachable *from C^s_ℓ if at least one of the following conditions holds:* (1) *There exists an arc of the null object in G that covers vertices $v \in C^s_\ell$ and $w \in C^s_k$ and is directed from v to w; or* (2) *there exists an arc in G of object i, $i \in S_d$, whose tail is in $C^s_\ell \cap V^i$, and at least one vertex in C^s_k is covered by this arc. G's arcs that allow direct reachability of strongly connected components are called* reachability arcs.

DEFINITION 4.3. *Let $C_1^s, C_2^s, \dots, C_n^s$ be different strongly connected components of G. We say that C_n^s is* reachable *from C_1^s if C_k^s is directly reachable from C_{k-1}^s for $k = 2, \dots, n$.*

DEFINITION 4.4. *Two different strongly connected components of G, C_1^s and C_2^s, such that each is reachable from the other are said to be* weakly connected.

For practical purposes, a maximal weakly connected component is a connected component since *starting at any vertex* in the set there exists a closed tour that serves all vertices in the set, possibly by using the drop option. Therefore, we repartition V into rougher equivalence classes by grouping the strongly connected components of G according to the weak connectivity relation. Let $C_1^w, C_2^w, \dots, C_k^w$ be the weakly connected components of G, where the depot is assumed to be in C_1^w. In each of these components identify a closed feasible tour that serves all its vertices: This tour is a patching of the tours found in the strongly connected components, where the patching is done along reachability arcs. For that sake, we extend the reachability definition to weakly connected components.

DEFINITION 4.5. *C_h^w is said to be reachable from C_ℓ^w if C_h^w contains a strongly connected component that is reachable from a strongly connected component contained in C_ℓ^w, $\ell \neq h$.*

DEFINITION 4.6. *A weakly connected component of G that is not reachable from any other weakly connected component is said to be an* unreachable component. *Let C_1^w be an unreachable component independently of its reachability from other components as the tour should start at the depot.*

DEFINITION 4.7. *The* reachable set *of the unreachable component C_ℓ^w is the set of weakly connected components of G that are reachable from C_ℓ^w. (C_ℓ^w is said to be reachable from itself.) We note that a weakly connected component of G either may be an unreachable component or belongs to at least one reachable set of some unreachable component.*

If C_k^w is reachable from C_ℓ^w, then there exists a feasible closed tour that *starts* at C_ℓ^w and serves all vertices in $C_\ell^w \cup C_k^w$: The vehicle, while either carrying a droppable item loaded at C_ℓ^w or while being empty, traverses a reachability arc of G that connects two vertices of C_ℓ^w and covers a vertex of C_k^w; in the first case, the item may be dropped at such a vertex of C_k^w. The vehicle may then serve all vertices of C_k^w; in the first case the vehicle then reloads the droppable item. The vehicle then continues toward its destination in C_ℓ^w. Thus, a closed feasible tour that starts at the unreachable component (the tour starts in C_1^w at the depot) may be identified within each of the reachable sets such that all vertices within the set are served. In order to execute this step, no augmentation of the graph is needed, as it is a patching of the tours that have been found separately in each of the weakly connected components contained within the reachable set, where the patching is done along reachability arcs. Thus, if C_1^w is the only unreachable component, no augmentation of G is required, i.e., there exists an optimal solution with total length identical to the total length of G's arcs. Otherwise, G must be augmented in order to reach each of the unreachable components from C_1^w. Each augmentation arc added to G must be traversed twice, once in each direction. We next propose a minimum cost augmentation technique for G whose complexity time is $O(N^2 \log N)$; then we show how the complexity may be reduced to $O(N \log N)$ by using the fact that the vertices are located on a line.

Define a directed graph T on the set of vertices that correspond one-to-one to the unreachable components of G. Let node ℓ of T represent C_ℓ^w (node 1 of T corresponds to C_1^w). There exists a directed arc in T from node ℓ to node k, $k \neq 1$, if and only if there exists a pair of vertices v_j and v_h in V such that v_j is in the reachable set of C_ℓ^w and v_h is in the unreachable component C_k^w. The length of this arc, denoted by $\delta(\ell, k)$, is defined as the length of the shortest arc connecting the reachable set of C_ℓ^w and unreachable component C_k^w. The minimum cost augmentation of G may be found by solving a *minimum directed spanning tree* (MDST) on T rooted at node 1. The MDST was solved independently by Chu and Liu (1965), Edmonds (1967), and Bock (1971). The complexity of their algorithm on a general directed graph with N nodes and $|E|$ edges is $O(\min\{|E| \log N, N^2\})$. The number of nodes of T is the number of unreachable components which is at most $O(N)$. Thus, T contains at most $O(N^2)$ edges. Therefore, the complexity of the MDST algorithm on T is $O(N^2 \log N)$. Below we show that due to the linearity of G, we may apply the MDST algorithm on a subgraph of T that contains at most $O(N)$ edges. As a result the complexity of this step will be reduced to $O(N \log N)$.

DEFINITION 4.8. *A vertex $v_j \in V \cap S$, $j > 1$, is called* extreme to the left in S *if and only if $v_{j-1} \notin S$; a vertex $v_j \in V \cap S$, $j < N$, is called* extreme to the right in S *if and only if $v_{j+1} \notin S$. A vertex is called* extreme *if it is either extreme to the left or extreme to the right.*

Let v_j be an extreme to the left (right) vertex in the reachable set of the unreachable component C_ℓ^w. Let $v_h \in V$, $h < j (h > j)$, be the rightmost (leftmost) vertex that belongs to some unreachable component C_k^w, $k \notin \{1, \ell\}$. If such a vertex h exists, then we say that the extreme vertex v_j and the reachable set of C_ℓ^w have a neighboring unreachable component C_k^w. *Each extreme vertex may have at most two neighboring unreachable components (one to its left and one to its right), but a reachable set may have several neighboring unreachable components. Due to the linearity of the track, there exists a minimum cost augmentation of G using only those edges of T that connect reachable sets to* their neighboring *unreachable components. Indeed, it is sufficient to include in T only edges connecting a vertex ℓ to a vertex k if and only if C_k^w, $k \notin \{1, \ell\}$, is a neighboring unreachable component of the reachable set of C_ℓ^w. The length of such an edge is given by $\delta(\ell, k) = \min\{d(v, w)$: v* is an extreme vertex in the reachable set of *C_ℓ^w and $w \in C_k^w\}$. According to the new procedure, T now contains a subset of the arcs that were previously contained in T. An arc of T that is eliminated is not needed in the augmentation of G as it is too expensive and can be replaced by a cheaper sequence of those arcs that are left in T. It is easily verified that any unreachable component C_k^w can be reached from any reachable set C_ℓ^w, $k \notin \{1, \ell\}$, via those arcs that are left in T. This property ensures that T contains a directed spanning tree. The number of directed arcs in T is at most of size $O(N)$, as each extreme vertex may have at most two neighboring unreachable components.*

Let MDST(T) be the MDST length of T, and let $A(T)$ be its corresponding set of arcs on the line. Along the arcs of $A(T)$ the vehicle travels empty twice, once in each direction. There exists an optimal solution for the problem whose length is $L(G) + 2\text{MDST}(T)$, where $L(G)$ is the total length of all arcs in G. The complexity of the whole procedure is $O(N^2)$. Below we summarize the complete algorithm.

THE SWAPPING ALGORITHM FOR THE LINEAR TRACK CASE.

Step 1. Apply the Basic Graph algorithm on V. Let G be the resulting graph, and let $L(G)$ be its total length.

Step 2. Identify the strongly connected components of G.

Step 3. If the system contains the null object or $S_d \neq \emptyset$, then partition the strongly connected components into equivalence classes according to the weak connectivity relation. Let $C_1^w, C_2^w, \ldots, C_k^w$ be the weakly connected components, with the depot at C_1^w. Within each of them find a closed feasible tour that serves all its vertices, using only G's arcs where some of them may be broken into basic arcs. Identify the unreachable components, the reachable sets, and a corresponding set of reachability arcs.

Step 4. Define a directed graph T on the set of nodes that corresponds one-to-one to the unreachable components. A directed arc from node ℓ to node k in T, $k \neq 1$, exists if and only if the unreachable component C_k^w is a neighbor of some extreme vertex in the reachable set of the unreachable component C_ℓ^w. The distance between these nodes is determined by the minimum distance between an extreme vertex in the reachable set of C_ℓ^w and an extreme vertex in its neighboring unreachable component C_k^w. Let MDST(T) be the MDST length on T, and let $A(T)$ be the corresponding set of arcs in the linear track.

Step 5. Use two copies of $A(T)$'s arcs and reachability arcs that connect weakly connected components within the same reachable set to patch the closed tours associated with the weakly connected components. Along $A(T)$'s arcs the vehicle travels empty. Starting at the depot, follow a feasible closed tour that serves all vertices by traversing G's arcs and twice the arcs of $A(T)$ once in each direction. We conclude the paper with a proof that the above algorithm solves the swapping problem optimally.

THEOREM 4.9. *The swapping algorithm for the linear track case solves the swapping problem on a line optimally.*

Proof. Any feasible solution is the union of service paths for each object-type $i \in \{0, \dots, m\}$ and possibly some deadheadings; see Anily and Hassin (1992). As shown in Theorems 3.1 and 3.7, any feasible solution can be transformed into a feasible solution of the same cost, where the length of service paths of each object-type $i \in \{0, \dots, m\}$ is separately minimized and possibly some deadheadings. The minimum cost service paths are obtained by algorithm BASIC GRAPH G. A minimum cost set of deadheadings is found by applying the MDST procedure on T. Two copies of each such deadheading is added to the BASIC GRAPH G in order to preserve the final graph as Eulerian while making it connected.

HOW GOOD IS THE GOEMANS–WILLIAMSON MAX CUT ALGORITHM?[*]

HOWARD KARLOFF[†]

Abstract. The celebrated semidefinite programming algorithm for MAX CUT introduced by Goemans and Williamson was known to have a performance ratio of at least $\alpha = \frac{2}{\pi} \min_{0<\theta\leq\pi} \frac{\theta}{1-\cos\theta}$ ($0.87856 < \alpha < 0.87857$); the exact performance ratio was unknown. We prove that the performance ratio of their algorithm is exactly α. Furthermore, we show that it is impossible to add valid linear constraints to improve the performance ratio.

1. Introduction.

The *performance ratio* of a randomized algorithm for a maximization problem is defined as follows. Let $W(I)$ be the (random) weight of the feasible solution it produces on instance I and let $OPT(I)$ be the weight of the optimal solution for instance I. The performance ratio is then

$$\inf \frac{E[W(I)]}{OPT(I)},$$

where the infimum is over instances with $OPT(I)$ positive.

In 1994, M. X. Goemans and D. P. Williamson published a new approximation algorithm for MAX CUT, the NP-complete problem of finding a maximum cut in a nonnegatively weighted graph [GW]. (Readers unfamiliar with [GW] should read the description of the algorithm in section 1.1 before continuing.) Much of the mathematical programming community turned its attention to this new algorithm, not only because it improved the performance ratio for MAX CUT from 0.5 to at least 0.87856, but also because Goemans and Williamson's paper was the first use of semidefinite programming in the area of approximation algorithms. Naturally researchers asked how far semidefinite programming could go.

In this paper, we analyze MAX CUT and the semidefinite programming algorithm proposed by Goemans and Williamson, hereafter called *Algorithm GW.* Goemans and Williamson proved a lower bound of $\alpha = \frac{2}{\pi} \min_{0<\theta\leq\pi} \frac{\theta}{1-\cos\theta}$ ($0.87856 < \alpha < 0.87857$) on its performance ratio, a huge improvement over the 0.5 known before. But exactly how good is Algorithm GW? At no point did they prove an upper bound on the performance ratio of Algorithm GW. Conceivably the performance ratio of Algorithm GW substantially exceeded α. We will prove, in fact, that its performance ratio is exactly α.

In addition, we study the effect of the addition of linear constraints to the semidefinite program of [GW]. For example, several authors have proposed adding to the

semidefinite program a family of $4\binom{n}{3}$ linear constraints, in the hope of narrowing the gap between the optimal value of the semidefinite program and the weight of a maximum cut. These constraints, given in section 2 and called the *triangle constraints*, are valid for all cuts (that is, when the vector variables are actually the *integers* ± 1). It is known [BM] that with the triangle constraints, the optimal value of the semidefinite program is exactly the weight of a maximum cut if the input graph does not contain K_5 as a minor (in particular, if the input graph is planar).

We will prove that the addition of any family of constraints, which, like the triangle constraints, are linear in the dot products and valid for all cuts, cannot improve the performance ratio; it will be exactly α, even with those constraints.

A caveat to the reader: We analyze the performance ratio of Algorithm GW, which randomly produces one cut. Should we instead run Algorithm GW many times and output the *best* of the random cuts produced, the current analysis says nothing about the performance ratio of the new algorithm.

In addition to the performance ratio, another interesting quantity to study is the "integrality ratio": the minimum, over all weighted graphs, of the ratio between the weight of a maximum cut and the optimal value of the semidefinite relaxation for that graph. Unlike the performance ratio, which is affected both by the relaxation and the rounding procedures, the integrality ratio depends, of course, only on the relaxation. Goemans and Williamson did study the integrality ratio for their semidefinite relaxation, noting that it is particularly bad for the cycle C_5. We caution the reader that the results in the present paper say nothing about the integrality ratio. In fact, for the graphs we will construct, the weight of a maximum cut exactly equals the optimal value of the semidefinite program.

1.1. A description of Algorithm GW.

Here we describe the algorithm of Goemans and Williamson. For more details, see [GW].

The Goemans and Williamson algorithm applies to MAX CUT, the problem of partitioning the vertices of a weighted graph $G = (V, E)$, $V = \{1, 2, \ldots, n\}$, into two sets, so as to maximize the total weight of the edges across the cut. Let us use $w_{ij} \geq 0$ to denote the nonnegative weight of the edge between vertices i and j, with $w_{ij} = 0$ if $\{i, j\} \notin E$.

This problem can be rephrased as follows. Assign an integer $x_i \in \{-1, +1\}$ to each vertex i, -1 representing the left side of the cut and $+1$ the right side, so as to maximize the sum, over all $i < j$, of $w_{ij}(1 - x_i x_j)/2$. The reason this works is that $(1 - x_i x_j)/2$ is 1 if i and j are on opposite sides of the cut and 0 if they're on the same side. Since MAX CUT is NP-complete, clearly one cannot solve this problem exactly in polynomial time (unless P = NP). However, one can relax this program to a polynomial time-solvable one, as follows. Let v_i be an n-dimensional vector whose first component is x_i and whose others are 0. Clearly $||v_i|| = 1$ ($||v||$ being the Euclidean norm of v) and the objective function

$$\sum_{i<j} w_{ij} \frac{1 - x_i x_j}{2}$$

can be rewritten as

$$\sum_{i<j} w_{ij} \frac{1 - v_i \cdot v_j}{2}$$

for these vectors, where the usual multiplication of integers x_i and x_j has been replaced by the dot product of vectors v_i and $v_j \in \mathbb{R}^n$. Now consider the problem (SD): Find vectors $v_1, v_2, \ldots, v_n \in \mathbb{R}^n$ to

$$\max \sum_{i<j} w_{ij} \frac{1 - v_i \cdot v_j}{2}$$

and such that $||v_i|| = 1$ for all i.

Since the vectors v_i given above satisfy $||v_i|| = 1$, they are feasible for this program. This makes (SD) a relaxation of MAX CUT and thus the optimal value of this program is at least as large as the weight of a maximum cut in G.

Interestingly, (SD) can be (almost exactly) solved in polynomial time. Before we sketch how, let us describe what we can do with the solution $v_1, v_2, \ldots, v_n$, which we assume, for this summary, is the sequence of exactly optimal vectors. Somehow, we want to convert the sequence of n vectors into a cut (or into a sequence of n -1's and $+1$'s); that is, we want to *round* the vectors to an integral solution, so that the total weight of the edges across the cut is close to the value of the objective function in (SD).

The rounding procedure proposed by Goemans and Williamson is remarkably simple: just choose a random hyperplane through the origin, putting all the vertices on one side of the hyperplane on the "left" side L of the cut and the remainder on the "right" side R. More formally, choose a random unit vector r (the normal to the random hyperplane) and define $L = \{i | r \cdot v_i \leq 0\}$ and $R = \{i | r \cdot v_i > 0\}$. What is the expected weight of this cut? By linearity of expectation, the expected weight is the sum, over all $i < j$, of w_{ij} times the probability that i and j are on opposite sides of the cut. It is not hard to prove that the probability that i and j are on opposite sides of the cut is proportional to the angle $\arccos(v_i \cdot v_j)$ between v_i and v_j; in fact, the probability is exactly $\arccos(v_i \cdot v_j)/\pi$. Thus the expected value $E[W]$ of the weight W of the random cut is exactly

$$\sum_{i<j} w_{ij} \frac{\arccos(v_i \cdot v_j)}{\pi}.$$

However, the optimal value z_P^* of program (SD) (it does have an optimum) is exactly

$$\sum_{i<j} w_{ij} \frac{1 - v_i \cdot v_j}{2}.$$

Thus, by a term-by-term analysis, we have

$$\begin{aligned} \frac{E[W]}{z_P^*} &= \frac{\sum_{i<j} w_{ij} \arccos(v_i \cdot v_j)/\pi}{\sum_{i<j} w_{ij}(1 - v_i \cdot v_j)/2} \\ &\geq \min_{i<j} \frac{\arccos(v_i \cdot v_j)/\pi}{(1 - v_i \cdot v_j)/2}. \end{aligned}$$

Letting

$$\alpha = \frac{2}{\pi} \min_{0<\theta\leq\pi} \frac{\theta}{1 - \cos\theta}$$

(θ representing $\arccos(v_i \cdot v_j)$), we have

$$E[W] \geq \alpha \cdot z_P^*,$$

and, since z_P^* is at least as large as the weight OPT of a maximum cut, we have

$$E[W] \geq \alpha \cdot OPT.$$

Fortunately, $\alpha \in (0.87856, 0.87857)$. It follows that Algorithm GW is an α-approximation algorithm for MAX CUT.

Now we return to semidefinite programming. To understand semidefinite programming, one must understand what it means for an $n \times n$ symmetric matrix Y to be positive semidefinite. There are three equivalent definitions:

1. All the eigenvalues of Y are nonnegative. (Recall that the eigenvalues of any symmetric matrix are real.)
2. For any $x \in \mathbb{R}^n$, $x^T Y x \geq 0$.
3. There is an $n \times n$ matrix B such that $Y = B^T B$.

A *semidefinite program* is an optimization problem of the following sort. Find reals $y_{11}, y_{12}, \ldots, y_{nn}$ so as to maximize $c^T y$ (where $y = (y_{11}, y_{12}, y_{13}, \ldots, y_{nn})^T$) subject to a finite number of linear constraints $a_i^T y \geq b_i$ and such that the $n \times n$ matrix $Y = (y_{ij})$ is symmetric and positive semidefinite. The only differences between semidefinite programming and linear programming are the immaterial difference that the number of variables is a perfect square and the crucial difference that the matrix defined by the variables must be symmetric and positive semidefinite.

Semidefinite programs can be (almost exactly) solved in polynomial time; for more details, see [GW]. How does this help us? By the third definition of "positive semidefinite" we see that if Y is symmetric and positive semidefinite, then there is an $n \times n$ B such that $Y = B^T B$, and if B is an $n \times n$ matrix, then $Y = B^T B$ is positive semidefinite. To solve program (SD) on variables $v_1, v_2, \ldots, v_n \in \mathbb{R}^n$, we instead solve the following problem: Find a symmetric positive semidefinite matrix $Y = (y_{ij})$ to

$$\max \sum_{i<j} w_{ij} \frac{1 - y_{ij}}{2}$$

such that $y_{ii} = 1$ for all i.

Given Y, we can find a B such that $Y = B^T B$ in polynomial time. Letting v_i be the ith column of B, we have $v_i \cdot v_j = y_{ij}$ and $||v_i|| = 1$, exactly what we wanted. Conversely, given vectors $v_1, v_2, \ldots, v_n \in \mathbb{R}^n$, each of Euclidean length 1, we can build a matrix B whose ith column is v_i and then let $Y = B^T B$; we will have Y symmetric and positive semidefinite, $v_i \cdot v_j = y_{ij}$ and $y_{ii} = 1$ again. Thus, program (SD) can be phrased as a semidefinite program and thus (almost exactly) solved in polynomial time.

2. Bounds on the performance ratio. The troublesome graphs for the Goemans–Williamson algorithm are the graphs $J(m, t, b)$ defined as follows. The vertex set of $J(m, t, b)$ is the set of all $\binom{m}{t}$ t-element subsets of $\{1, 2, \ldots, m\}$, two t-subsets S, T being adjacent if and only if $|S \cap T| = b$ and $S \neq T$. (These graphs are similar to the Kneser graphs $K(m, t, b)$ used in [KMS], which have the same vertex set but with S and T adjacent if and only if $|S \cap T| \leq b$.) It will become clear that the smallest eigenvalue of the adjacency matrix of $J(m, m/2, b)$ plays a crucial role, so we now study the eigenvalues of $J(m, t, b)$. For $s = 0, 1, 2, \ldots, t$, let

$$\alpha_s = \sum_{r \geq 0} (-1)^{s-r} \binom{s}{r} \binom{t-r}{b-r} \binom{m-t-s+r}{t-b-s+r}$$

with the usual convention that $\binom{u}{v} = 0$ if $v < 0$.

THEOREM 2.1. *Let $0 \le t \le m/2$ and $0 \le b \le t$. Then for $s = 0, 1, 2, \dots, t$, α_s occurs as an eigenvalue of $J(m, t, b)$ with multiplicity $\binom{m}{s} - \binom{m}{s-1}$.*

See [Knuth] for a beautiful proof of this theorem, or see [Delsarte]. Notice that since $\sum_{s=0}^{t}[\binom{m}{s} - \binom{m}{s-1}] = \binom{m}{t}$, these are all the eigenvalues of $J(m, t, b)$.

In fact, we will need only $J(m, m/2, b)$ for even positive m's.

COROLLARY 2.2. *If m is an even positive integer, $0 \le b \le m/2$, then the eigenvalues of $J(m, m/2, b)$ are $\beta_0, \beta_1, \dots, \beta_{m/2}$ (each with some positive multiplicity), where*

$$\beta_s = \sum_{r \ge 0} (-1)^{s-r} \binom{s}{r} \binom{m/2 - r}{b - r} \binom{m/2 - s + r}{b}.$$

The next theorem gives the exact value of the smallest eigenvalue of $J(m, m/2, b)$.

THEOREM 2.3. *Let m be an even positive integer and let $0 \le b \le m/12$. The smallest eigenvalue of $J(m, m/2, b)$ is*

$$\binom{m/2}{b}^2 \left[\frac{4b}{m} - 1\right].$$

We defer the proof of Theorem 2.3. For now, let us say only that a simple calculation gives $\beta_1 = \binom{m/2}{b}^2 \left[\frac{4b}{m} - 1\right]$; thus proving Theorem 2.3 is the same as proving that β_1 is the smallest of all the β_s's.

The Goemans–Williamson semidefinite program to approximately solve the MAX CUT instance with edge weight w_{ij} between edges i and j ($w_{ij} = w_{ji}$ for all i, j and $w_{ii} = 0$ for all i) is, as mentioned above, program (SD): Find reals y_{ij} to

$$\max z_P = \sum_{i<j} w_{ij} \frac{1 - y_{ij}}{2},$$

subject to $y_{ii} = 1$ for all i and $Y = (y_{ij})$ is $n \times n$ and symmetric positive semidefinite.

In our case, we use $w_{ij} = 1$ if the ith set S is adjacent in $J(m, m/2, b)$ to the jth set T (and $i \ne j$), and 0 otherwise. Alternatively, $w_{S,T} = 1$ if $|S \cap T| = b$ (and $S \ne T$), and 0 otherwise. Thus the matrix of weights is exactly the adjacency matrix of $J(m, m/2, b)$.

Each vertex in $J(m, m/2, b)$, being a subset S of $\{1, 2, \dots, m\}$ of weight $m/2$, can be represented by an m-vector of $+1$'s and -1's, with the ith component $+1$ if $i \in S$ and the ith component -1 if $i \notin S$, then scaled by $1/\sqrt{m}$, so that the resulting m-vector v_S has unit length. Now, from the v_S's, build an $m \times n$ matrix B with the column indexed by S being the vector v_S; then set $Y = B^T B$. Y is symmetric positive semidefinite, is $n \times n$, and has $y_{ii} = 1$ for all i. Therefore Y is a feasible solution to (SD).

In fact, Y is an *optimal* solution to (SD), if $b \le m/12$.

THEOREM 2.4. *If $b \le m/12$ and m is even, then $Y = B^T B$ is an optimal solution to (SD).*

Proof. To show that a feasible solution to a semidefinite program is optimal, we use the dual of the semidefinite program [GW]. Let $A = (w_{ij})$ be the matrix of weights on the edges of the n-vertex graph. Let $W_{tot} = \sum_{1 \le i < j \le n} w_{ij}$. The dual to the semidefinite program (SD) is the semidefinite program (D), as follows. Find reals

$\gamma_1, \gamma_2, \ldots, \gamma_n$ to

$$\min z_D = \frac{1}{2} W_{tot} + \frac{1}{4} \sum_{i=1}^{n} \gamma_i,$$

such that

$$A + \operatorname{diag}(\gamma_1, \gamma_2, \ldots, \gamma_n)$$

is positive semidefinite, where $\operatorname{diag}(\gamma_1, \gamma_2, \ldots, \gamma_n)$ is the diagonal matrix whose ith diagonal entry is γ_i. It is known [GW] that $z_P \leq z_D$ for any pair of respectively (primal, dual) feasible solutions. In fact, (SD) and (D) attain optimal values z_P^* and z_D^*, respectively, and $z_P^* = z_D^*$.

Therefore, to prove that a particular feasible solution Y for (SD) is optimal, it suffices to exhibit a feasible solution $(\gamma_1, \gamma_2, \ldots, \gamma_n)$ to (D) such that $z_P = z_D$. Let γ be the negation of the smallest eigenvalue of $J(m, m/2, b)$. By Theorem 2.3, $\gamma = \binom{m/2}{b}^2 \left[1 - \frac{4b}{m}\right]$. A symmetric matrix being positive semidefinite if and only if its eigenvalues are nonnegative, the choice of γ guarantees that $\gamma_i = \gamma$ for all i is a feasible solution to (D).

Let z_P be the (primal) cost of the primal feasible Y given above and let z_D be the (dual) cost of dual feasible $(\gamma, \gamma, \gamma, \ldots, \gamma)$. We prove that $z_P = z_D$, so that both are optimal.

In this formulation,

$$\begin{aligned} z_P &= \frac{1}{4} \sum_{|S|=|T|=m/2} w_{S,T}(1 - v_S \cdot v_T) \\ &= \frac{1}{4} \sum_{|S|=|T|=m/2, |S \cap T|=b} (1 - v_S \cdot v_T). \end{aligned}$$

By symmetry, we can take $S = \{1, 2, \ldots, m/2\}$ and infer that

$$\begin{aligned} z_P &= \frac{1}{4} n \sum \left[1 - \frac{1}{\sqrt{m}} (\underbrace{1, 1, \ldots, 1}_{m/2}, \underbrace{-1, -1, \ldots, -1}_{m/2}) \cdot v_T \right] \\ &= \frac{1}{4} n \left[\binom{m/2}{b}^2 - \frac{1}{\sqrt{m}} \sum (\underbrace{1, \ldots, 1}_{m/2}, \underbrace{-1, \ldots, -1}_{m/2}) \cdot v_T \right] \end{aligned}$$

(where both summations are over all T such that $|T| = m/2$ and $|T \cap \{1, 2, \ldots, m/2\}| = b$)

$$\begin{aligned} &= \frac{1}{4} n \left[\binom{m/2}{b}^2 - \frac{1}{\sqrt{m}} \binom{m/2}{b}^2 \frac{1}{\sqrt{m}} (4b - m) \right] \\ &= \frac{n}{2} \binom{m/2}{b}^2 \left[1 - \frac{2b}{m} \right]. \end{aligned}$$

Also,

$$z_D = \frac{1}{2} W_{tot} + \frac{1}{4} \sum_{i=1}^{n} \gamma_i$$

$$= \frac{1}{4}n\binom{m/2}{b}^2 + \frac{1}{4}n\gamma$$

$$= \frac{n}{4}\binom{m/2}{b}^2 + \frac{n}{4}\binom{m/2}{b}^2\left[1 - \frac{4b}{m}\right]$$

$$= \frac{n}{2}\binom{m/2}{b}^2\left[1 - \frac{2b}{m}\right].$$

It follows that $z_P = z_D$ and that, by the discussion earlier in this proof, both are optimal. $\square$

Now let us study in more detail the optimal system of vectors v_S given above. Define $y_S = v_S\sqrt{m}$. Since the lth component of v_S is $\pm 1/\sqrt{m}$, each component of y_S is ± 1. Let us define a sequence of cuts $\mathcal{C}_l = (\mathcal{S}_l, \bar{\mathcal{S}}_l)$, $1 \le l \le m$, with $\mathcal{S}_l = \{S | S \ni l, |S| = m/2\}$. Letting $(y_S)_l$ denote the lth component of vector y_S, notice that for all S

$$S \in \mathcal{S}_l \iff l \in S \iff (y_S)_l = +1.$$

When we solve the semidefinite program, we hope that the optimal vectors have the following property: There is an l such that each vector is ± 1 in component l, and 0 elsewhere; such vectors correspond naturally to cuts, and any solution of that form would be a maximum cut, since its weight would equal that of the optimum of the semidefinite program. Of course, the vectors y_S given above have ± 1 in *every* coordinate. This means that each vector v_S is the sum, over $l = 1, 2, 3, \ldots, m$, of a vector which is ± 1 in component l and 0 elsewhere (and then scaled down to unit length). The optimal family (v_S) can be viewed as an "average" of families of vectors representing the cuts $\mathcal{C}_1, \mathcal{C}_2, \ldots, \mathcal{C}_m$. This motivates the following.

LEMMA 2.5. *If $b \le m/12$, then the optimal value z_P^* of the semidefinite program is the average of the weights of cuts $\mathcal{C}_1, \mathcal{C}_2, \ldots, \mathcal{C}_m$.*

Proof. Where $(v_S)_l$ and $(y_S)_l$ denote the lth coordinates of v_S and y_S, respectively, we have

$$z_P^* = \frac{1}{2}\sum_{S,T} w_{S,T}\frac{1 - v_S \cdot v_T}{2}$$

$$= \frac{1}{2}\sum_{S,T} w_{S,T}\frac{1}{m}\sum_{l=1}^{m}\left[\frac{1 - m(v_S)_l(v_T)_l}{2}\right]$$

$$= \frac{1}{m}\frac{1}{2}\sum_{S,T} w_{S,T}\sum_{l=1}^{m}\left[\frac{1 - (y_S)_l(y_T)_l}{2}\right]$$

$$= \frac{1}{m}\sum_{l=1}^{m}\left[\frac{1}{2}\sum_{S,T} w_{S,T}\left[\frac{1 - (y_S)_l(y_T)_l}{2}\right]\right].$$

Since the weight of cut $\mathcal{C}_l$ is exactly

$$\frac{1}{2}\sum_{S,T} w_{S,T}\left[\frac{1 - (y_S)_l(y_T)_l}{2}\right],$$

we are done. $\square$

LEMMA 2.6. *Each cut $\mathcal{C}_l$ is a maximum cut (if $b \le m/12$).*

Proof. Because (SD) is a relaxation of MAX CUT, z_P^* is an upper bound on the weight of any cut. If any cut $\mathcal{C}_l$ were not a maximum cut, its weight would be strictly less than z_P^* and so would the average weight of these cuts. $\square$

We have proven the following theorem.

THEOREM 2.7. *The weight of a maximum cut in $J(m, m/2, b)$ is exactly*

$$z_P^* = \frac{n}{2}\binom{m/2}{b}^2\left[1 - \frac{2b}{m}\right]$$

if m is even and $b \le m/12$.

Now we study what happens when additional constraints are added to the semidefinite program. The results on this subject were obtained in collaboration with Uri Feige, who showed how the author's original argument, which applied only to the triangle constraints, could be generalized.

Where a_{ij}, $1 \le i < j \le n$, and b are reals, let us call a constraint

$$\sum_{i<j} a_{ij}(z_i \cdot z_j) \ge b$$

valid if it is satisfied whenever each z_i is the *integer* ± 1. (Whether a linear constraint is valid doesn't depend, of course, on the w_{ij}'s.)

If

$$b' = \frac{-b + \sum_{i<j} a_{ij}}{2},$$

then by a simple linear transformation,

$$\sum_{i<j} a_{ij}(z_i \cdot z_j) \ge b \iff \sum_{i<j} a_{ij}\frac{1 - z_i \cdot z_j}{2} \le b'.$$

Now build a complete graph H_a on $\{1, 2, \ldots, n\}$ with the (possibly negative) weight of edge $\{i, j\}$ being a_{ij}. Validity of the constraint is equivalent to saying that the weight of a maximum cut in H_a is at most b' (where we are including the trivial cut with one empty side as a cut).

Now suppose that $n = \binom{m}{m/2}$ for some positive even m. Label the vectors v_S above as $v_1, v_2, \ldots, v_n$ arbitrarily. Define $y_i = v_i\sqrt{m}$.

THEOREM 2.8. *Let a_{ij}, for all vertices $1 \le i < j \le n$, and b be reals such that the constraint*

$$\sum_{i<j} a_{ij}(z_i \cdot z_j) \ge b$$

is valid. Then the constraint is necessarily satisfied when $z_i = v_i$ for all i.

Proof.

$$\begin{aligned}\sum_{i<j} a_{ij}(v_i \cdot v_j) &= \sum_{i<j} a_{ij}\sum_{l=1}^{m}(v_i)_l(v_j)_l \\ &= \frac{1}{m}\sum_{l=1}^{m}\left(\sum_{i<j} a_{ij}(y_i)_l(y_j)_l\right).\end{aligned}$$

Clearly $(y_i)_l \in \{-1, +1\}$ for all vertices i. Therefore

$$\sum_{i<j} a_{ij}(y_i)_l(y_j)_l \geq b.$$

Hence

$$\frac{1}{m}\sum_{l=1}^{m}\sum_{i<j} a_{ij}(y_i)_l(y_j)_l \geq \frac{1}{m}\sum_{l=1}^{m} b = b. \qquad \square$$

Theorem 2.8 has the following consequence. Since the vectors $v_1, \ldots, v_n$ satisfy all valid constraints and happen to be optimal for the semidefinite program (SD) associated with $J(m, m/2, b)$ (at least if $0 \leq b \leq m/12$), they are obviously optimal in the augmented program for $J(m, m/2, b)$ (if $b \leq m/12$). Of course, the procedure that rounds the v_i's will proceed as before. However badly the algorithm rounded the vectors (v_i) beforehand, it will round them just as badly afterward.

For example, consider the triangle constraints (see [FG, GW] as well as [DL, Chapter 27] and the references therein). For each triple (i, j, k) of vertices, $1 \leq i < j < k \leq n$,

$$\begin{aligned}
+z_i \cdot z_j + z_i \cdot z_k + z_j \cdot z_k &\geq -1,\\
-z_i \cdot z_j - z_i \cdot z_k + z_j \cdot z_k &\geq -1,\\
-z_i \cdot z_j + z_i \cdot z_k - z_j \cdot z_k &\geq -1,\\
+z_i \cdot z_j - z_i \cdot z_k - z_j \cdot z_k &\geq -1.
\end{aligned}$$

The second, third, and fourth constraints in each block of four are obtained from the first one by negating z_i, z_j, or z_k, respectively. The reader can verify that these four constraints are valid. (The key is that given any three integers in $\{-1, +1\}$, not all three pairwise products can be -1.) It follows from Theorem 2.8, if $n = \binom{m}{m/2}$, that the vectors $z_i = v_i$ satisfy these vector constraints.

For another example, suppose we augment (SD) by adding all infinitely many possible valid constraints. That is, for each $a = (a_{ij})$, $1 \leq i < j \leq n$, we build a weighted complete graph H_a on $\{1, 2, \ldots, n\}$, with weight a_{ij} on edge $\{i, j\}$. We then calculate the maximum weight b' of a (possibly trivial) cut in H_a and add a constraint

$$\sum_{i<j} a_{ij}\frac{1 - v_i \cdot v_j}{2} \leq b'.$$

This constraint is evidently valid, and furthermore, by looking at all a's, we are including all possible valid constraints (except that we are using the best possible right-hand side for each a). By Theorem 2.8, if $n = \binom{m}{m/2}$, then the vectors $v_1, v_2, \ldots, v_n$ will satisfy all the infinitely many additional constraints (of which the triangle constraints are but a subset) and, being optimal for (SD) for $J(m, m/2, b)$, will still be optimal afterward (if $b \leq m/12$).

Now let us calculate just how badly Algorithm GW performs on $J(m, m/2, b)$, keeping in mind that the addition of more valid inequalities would not improve the outcome.

LEMMA 2.9. *The expected value of the weight W of the random cut produced from Y and the v_S's is exactly*

$$\frac{n}{2}\binom{m/2}{b}^2 \frac{1}{\pi}\arccos\left[\frac{4b}{m} - 1\right].$$

Proof. The expected weight of the cut is

$$E[W] = \frac{1}{2} \sum_{S,T:|S|=|T|=m/2} w_{S,T} \cdot \arccos(v_S \cdot v_T)/\pi$$
$$= \frac{1}{2} \sum_{S,T:|S|=|T|=m/2,|S\cap T|=b} \arccos(v_S \cdot v_T)/\pi.$$

By symmetry, we can take $S = \{1, 2, \ldots, m/2\}$ and get

$$E[W] = \frac{1}{2} n \sum \frac{1}{\pi} \arccos\left(v_S \cdot v_T\right),$$

where the summation is over all T such that $|T| = m/2$ and $|T \cap \{1, 2, \ldots, m/2\}| = b$. Thus

$$E[W] = \frac{n}{2} \binom{m/2}{b}^2 \frac{1}{\pi} \arccos\left[\frac{4b-m}{m}\right]. \qquad \square$$

Since we know that a maximum cut has weight exactly

$$\frac{n}{2} \binom{m/2}{b}^2 \left[1 - \frac{2b}{m}\right]$$

if $b \le m/12$, by Lemma 2.9 the ratio of $E[W]$ to the weight of a maximum cut is exactly

$$\frac{\frac{1}{\pi} \arccos\left[\frac{4b}{m} - 1\right]}{1 - \frac{2b}{m}}.$$

Where $\theta = \arccos[\frac{4b}{m} - 1]$, the ratio is $\frac{2}{\pi} \frac{\theta}{1-\cos\theta}$. But $\alpha = \min_{0<\theta\le\pi} \frac{2}{\pi} \frac{\theta}{1-\cos\theta}$. By choosing b, m, and hence θ auspiciously, we will approach the α of [GW].

THEOREM 2.10. *For each $\epsilon > 0$, there are b and m, m even and positive and $0 \le b \le m/12$, such that the expected weight of the cut produced by Algorithm GW applied to $J(m, m/2, b)$ is at most $\alpha + \epsilon$ times the weight of a maximum cut.*

Proof. A simple calculation shows that the unique θ^* that achieves the minimum value in the right-hand side of $\alpha = \min_{0<\theta\le\pi} \frac{2}{\pi} \frac{\theta}{1-\cos\theta}$ corresponds to a value of b which is less than $m/12.5$ and hence is safely away from $m/12$. Because $\frac{2}{\pi} \frac{\theta}{1-\cos\theta}$ is continuous, we can find a $\delta > 0$ so that if $\theta \in [\theta^* - \delta, \theta^* + \delta]$, then $\frac{2}{\pi} \frac{\theta}{1-\cos\theta} \le \alpha + \epsilon$. We can certainly choose a rational $\gamma < \frac{1}{12.5}$ such that $\theta = \arccos(4\gamma - 1)$ lies in $[\theta^* - \delta, \theta^* + \delta]$. Then we choose m even such that $b = \gamma m$ is an integer. But $\frac{2}{\pi} \frac{\theta}{1-\cos\theta}$ is precisely the ratio between $E[W]$ and the weight of a maximum cut. $\square$

Last, we prove Theorem 2.3.

Proof. We must prove that the smallest eigenvalue of $J(m, m/2, b)$ is

$$\binom{m/2}{b}^2 \left[\frac{4b}{m} - 1\right],$$

provided that m is even and that $0 \le b \le m/12$. Recall from Corollary 2.2 that the eigenvalues of $J(m, m/2, b)$ are $\beta_0, \beta_1, \ldots, \beta_{m/2}$, where

$$\beta_s = \sum_r (-1)^{s-r} \binom{s}{r} \binom{m/2-r}{b-r} \binom{m/2-s+r}{b}.$$

Since

$$\beta_1 = \binom{m/2}{b}^2 \left[\frac{4b}{m} - 1\right],$$

we must show that $\beta_1 \le \beta_s$ for $s = 0, 1, 2, \ldots, m/2$.

Fix s, $0 \le s \le m/2$. Given r, let

$$t_r = \binom{m/2 - r}{b - r}\binom{m/2 - s + r}{b} \ge 0$$

so that

$$\beta_s = (-1)^s \sum_r (-1)^r \binom{s}{r} t_r.$$

If s is even, then

$$\beta_s \ge -\sum_{r \text{ odd}} \binom{s}{r} t_r,$$

and if s is odd, then

$$\beta_s \ge -\sum_{r \text{ even}} \binom{s}{r} t_r.$$

Let us assume that $b \le m/2 - s + r$ and that $b \ge r$, for otherwise $t_r = 0$. Then

$$\frac{t_r}{\binom{m/2}{b}^2} = \frac{(m/2 - r)!}{(m/2)!}\frac{(m/2 - s + r)!}{(m/2)!}\frac{b!}{(b-r)!}\frac{(m/2 - b)!}{(m/2 - s + r - b)!}. \tag{2.1}$$

The product of the first and third fractions equals

$$\left[\frac{b(b-1)(b-2)\cdots(b-r+1)}{(\frac{m}{2})(\frac{m}{2}-1)(\frac{m}{2}-2)\cdots(\frac{m}{2}-r+1)}\right], \tag{2.2}$$

while the product of the second and fourth equals

$$\left[\frac{(\frac{m}{2}-b)(\frac{m}{2}-b-1)(\frac{m}{2}-b-2)\cdots(\frac{m}{2}-s+r-b+1)}{(\frac{m}{2})(\frac{m}{2}-1)(\frac{m}{2}-2)\cdots(\frac{m}{2}-s+r+1)}\right]. \tag{2.3}$$

It is easy to verify that for $0 \le i < m/2$,

$$\frac{b-i}{\frac{m}{2}-i} \le \frac{b}{\frac{m}{2}}$$

and

$$\frac{\frac{m}{2}-b-i}{\frac{m}{2}-i} \le \frac{\frac{m}{2}-b}{\frac{m}{2}}.$$

Therefore

$$\frac{t_r}{\binom{m/2}{b}^2} \le \left(\frac{2b}{m}\right)^r \left(1 - \frac{2b}{m}\right)^{s-r}.$$

This is true whether $b \le m/2 - s + r$ and $b \ge r$ or not. Let $\gamma = b/m \le 1/12$. Then

$$\frac{t_r}{\binom{m/2}{b}^2} \le (2\gamma)^r (1-2\gamma)^{s-r}.$$

For any p, let

$$x = \sum_{\text{odd } r} \binom{s}{r} p^r (1-p)^{s-r}$$

and

$$y = \sum_{\text{even } r} \binom{s}{r} p^r (1-p)^{s-r}.$$

Then $x + y = 1$ and $-x + y = (-p + (1-p))^s = (1-2p)^s$. It follows that

$$y = 1/2 + (1/2)(1-2p)^s$$

and

$$x = 1/2 - (1/2)(1-2p)^s.$$

Hence

$$\sum_{\text{odd } r} \binom{s}{r} (2\gamma)^r (1-2\gamma)^{s-r} = 1/2 - (1/2)(1-4\gamma)^s$$

and

$$\sum_{\text{even } r} \binom{s}{r} (2\gamma)^r (1-2\gamma)^{s-r} = 1/2 + (1/2)(1-4\gamma)^s.$$

Now

$$\frac{t_r}{\binom{m/2}{b}^2} \le (2\gamma)^r (1-2\gamma)^{s-r}.$$

So, if s is even,

$$\begin{aligned}
\beta_s &\ge -\left[\sum_{\text{odd } r} \binom{s}{r} (2\gamma)^r (1-2\gamma)^{s-r}\right] \binom{m/2}{b}^2 \\
&= -\left[\frac{1}{2} - \frac{1}{2}(1-4\gamma)^s\right] \binom{m/2}{b}^2 \\
&\ge -\left[\frac{1}{2} + \frac{1}{2}(1-4\gamma)^s\right] \binom{m/2}{b}^2;
\end{aligned}$$

if s is odd we have

$$\beta_s \ge -\left[\frac{1}{2} + \frac{1}{2}(1-4\gamma)^s\right] \binom{m/2}{b}^2.$$

So, in either case,

$$\beta_s \geq -\left[\frac{1}{2} + \frac{1}{2}(1-4\gamma)^s\right]\binom{m/2}{b}^2.$$

Now we need a technical fact.

FACT 2.11. *If $p \in [0, 1/3]$ and $s \geq 4$, then $(1-p)^s \leq 1-2p$.*

Proof (sketch). Let $f(p) = (1-p)^s/(1-2p)$ for $p \in [0, 1/3]$. Clearly $f(0) = 1$. It is not hard to see that $f'(p) \leq 0$ if and only if $p \leq \frac{s-2}{2s-2}$, and $s \geq 4$ implies that $(s-2)/(2s-2) \geq 1/3$. □

By the fact, because $\gamma \leq 1/12$, $(1-4\gamma)^s \leq 1-8\gamma$ if $s \geq 4$. Thus

$$\begin{aligned}\beta_s &\geq -\left[\frac{1}{2} + \frac{1}{2}(1-8\gamma)\right]\binom{m/2}{b}^2 \\ &= (4\gamma - 1)\binom{m/2}{b}^2 \\ &= \left[\frac{4b}{m} - 1\right]\binom{m/2}{b}^2,\end{aligned}$$

and we are finished, in the case $s \geq 4$.

Now we must dispense with $s = 0, 1, 2, 3$ by showing that $\beta_s \geq \beta_1 = \binom{m/2}{b}^2\left[\frac{4b}{m} - 1\right]$ for $s = 0, 1, 2, 3$. Notice that if $b = 0$, then for any even m, $\beta_s = (-1)^s$. This means that the smallest eigenvalue is -1, as it should be. In what follows, we assume that $m \geq 12$, for otherwise $b \leq m/12$ makes $b = 0$.

The $s = 0$ case is first. $\beta_0 = \binom{m/2}{b}^2$, the degree of a vertex in $J(m, m/2, b)$. Since this is positive and $\binom{m/2}{b}^2\left[\frac{4b}{m} - 1\right]$ is negative, this part is easy.

The $s = 1$ case is trivial.

The $s = 2$ case is still not hard.

$$\frac{\beta_2}{\binom{m/2}{b}^2} = \frac{(\frac{m}{2} - b)}{\frac{m}{2}}\frac{(\frac{m}{2} - b - 1)}{\frac{m}{2} - 1} - 2\frac{b}{\frac{m}{2}}\frac{(\frac{m}{2} - b)}{\frac{m}{2}} + \frac{b}{\frac{m}{2}}\frac{(b-1)}{(\frac{m}{2} - 1)}.$$

Since $\beta_1 = \binom{m/2}{b}^2\left[\frac{4b}{m} - 1\right] < 0$, it suffices to prove that

$$\frac{(\frac{m}{2} - b)}{\frac{m}{2}}\frac{(\frac{m}{2} - b - 1)}{\frac{m}{2} - 1} \geq 2\frac{b}{\frac{m}{2}}\frac{(\frac{m}{2} - b)}{\frac{m}{2}}.$$

That

$$\frac{\frac{m}{2} - b - 1}{\frac{m}{2} - 1} \geq \frac{2b}{\frac{m}{2}}$$

holds follows from $b \leq m/12$ and $m \geq 12$. This means that

$$\frac{(\frac{m}{2} - b)}{\frac{m}{2}}\frac{(\frac{m}{2} - b - 1)}{\frac{m}{2} - 1} \geq 2\frac{b}{\frac{m}{2}}\frac{(\frac{m}{2} - b)}{\frac{m}{2}},$$

and the proof of the case $s = 2$ is complete.

Now we attack $s = 3$. Since $t_r \geq 0$ for all r and

$$\beta_3 = -\sum_{r=0}^{3}(-1)^r\binom{3}{r}t_r,$$

the only possibly negative terms are the ones having $r = 0$ or $r = 2$. Using the formula for $t_r/\binom{m/2}{b}^2$ from (2.1) and using (2.2) and (2.3), it suffices to prove that

$$-\frac{(\frac{m}{2}-b)}{(\frac{m}{2})}\frac{(\frac{m}{2}-b-1)}{(\frac{m}{2}-1)}\frac{(\frac{m}{2}-b-2)}{(\frac{m}{2}-2)} - 3\frac{b}{\frac{m}{2}}\frac{(b-1)}{(\frac{m}{2}-1)}\frac{(\frac{m}{2}-b)}{\frac{m}{2}} \geq \frac{4b}{m} - 1.$$

Simple calculations yield that

$$-\left(\frac{\frac{m}{2}-b}{\frac{m}{2}}\right)^3 \leq -\frac{(\frac{m}{2}-b)}{\frac{m}{2}}\frac{(\frac{m}{2}-b-1)}{\frac{m}{2}-1}\frac{(\frac{m}{2}-b-2)}{\frac{m}{2}-2}$$

and that

$$-3\frac{b}{\frac{m}{2}}\frac{b}{\frac{m}{2}}\frac{(\frac{m}{2}-b)}{\frac{m}{2}} \leq -3\frac{b}{\frac{m}{2}}\frac{(b-1)}{(\frac{m}{2}-1)}\frac{(\frac{m}{2}-b)}{\frac{m}{2}}.$$

This means that it is sufficient to prove that

$$-\left(\frac{\frac{m}{2}-b}{\frac{m}{2}}\right)^3 - 3\left(\frac{b}{\frac{m}{2}}\right)^2\frac{\frac{m}{2}-b}{\frac{m}{2}} \geq \frac{4b}{m} - 1.$$

Let $\gamma = b/m$. The left-hand side equals

$$-(1-2\gamma)^3 - 3(2\gamma)^2(1-2\gamma) = -1 + 4\gamma - 16\gamma^2 + 2\gamma - 8\gamma^2 + 32\gamma^3.$$

Now

$$-1 + 6\gamma - 24\gamma^2 + 32\gamma^3 \geq 4\gamma - 1 \iff (2\gamma)(16\gamma^2 - 12\gamma + 1) \geq 0.$$

The roots of $16\gamma^2 - 12\gamma + 1 = 0$ are $(3 \pm \sqrt{5})/8$. Since $(3-\sqrt{5})/8 > 1/12 \geq \gamma \geq 0$, we are finished. $\square$

Although we don't need it, this paper wouldn't be complete without the following conjecture.

CONJECTURE 2.12. *For all even $m > 0$, for all $0 \leq b < m/4$, the smallest eigenvalue of $J(m, m/2, b)$ is exactly*

$$\beta_1 = \binom{m/2}{b}^2\left[\frac{4b}{m} - 1\right].$$

Possibly this is already known.

Acknowledgments. I am deeply grateful to David Williamson. David originally suggested the problem of analyzing the effect of the triangle constraints on the performance of Algorithm GW. And without David's help in finding a maximum cut and solving (SD) for a particular graph, this paper wouldn't exist. I thank him also for his comments on an earlier draft of this paper.

For the far more general result on the power of additional inequalities than what appeared in an earlier draft, for allowing me to include the result, and for his comments on an earlier draft, I am very thankful to Uri Feige.

For his pointers to the literature on algebraic graph theory, I am grateful to Neil Calkin. I thank Leonard Schulman and Cristina Fernandes for their help in studying the eigenvalues and eigenvectors of the $J(m, t, b)$'s. And I am thankful to Don Knuth for writing his notes on combinatorial matrices.

SOLVABILITY IN ASYNCHRONOUS ENVIRONMENTS II: FINITE INTERACTIVE TASKS[*]

BENNY CHOR[†] AND LEE-BATH NELSON[‡]

Abstract. Identifying what problems can be solved in a given distributed system is a central question in distributed computing. In this series of works, we study this question in the context of asynchronous fault tolerant systems that can execute consensus. These systems can be those executing deterministic protocols with access to a consensus routine or those running randomized error-free protocols. A previous work handled the class of distributed decision tasks. In these tasks, each processor receives one local input and has to respond with one local output.

In an *interactive distributed task* each of n processors receives a sequence of local inputs and has to respond *on line* with an output for every new input (before getting its next input). Different processors can be at different stages concurrently, so that additional inputs are received by fast processors while slow processors are still working on early inputs. An interactive task is called finite if the number of local inputs (and outputs) is finite. Interactive tasks can neither be described as a single huge decision task nor be decomposed into distinct, independent decision tasks.

The main result of this work is an exact characterization of the finite interactive tasks which can be solved by t-resilient protocols in either of the above two models. The major tool we use in the characterization is a directed acyclic graph that is associated with an interactive task. Properties of this graph are used to determine the resiliency of the task and to devise a "generic" resilient algorithm which solves such tasks. This generic algorithm can be viewed as a repeated, deterministic reduction to a consensus subroutine. This implies that any finite interactive task is solvable by randomized error-free protocols iff it is solvable by deterministic protocols with access to consensus.

Key words. solvability, asynchronous distributed systems, fault tolerance, randomized algorithms, consensus, interactive tasks, decision tasks, adversary scheduler

1. Introduction.

1.1. Background.

A central question in distributed computing is identifying what problems can be solved by a given distributed system. In typical systems, each one of n processors starts with some local input and communicates with other processors in order to produce globally meaningful outputs. If the system is perfect, in the sense that all processors are reliable and communication is error-free and is instantaneously relayed, then every well-defined task can be solved (assuming, as usual, that the processors are not computationally limited). However, perfect systems are either rare or nonexistent. Communication links tend to introduce errors and delays. Processors may become slow, stop operating, or even exhibit malevolent behavior.

One of the more popular models of distributed computing is the asynchronous crash failure model. Here, processors may crash without supplying any warning be-

forehand. Asynchrony implies that there is no way to distinguish a failed processor from a very slow one. An alternative way to describe this is that there is an adversary scheduler that decides which processor moves when. Thus the scheduler controls the pace and failure of processors. A task is called *t-resilient* if it is solvable by a protocol, withstanding up to t processor crash failures. In addition to the important fault-tolerance aspect, crash resilient protocols have other merits: the more resilient the protocol, the less faster processors are delayed by waiting for slower ones. In particular, in a system with n processors, $n-1$ resilient protocols are *wait-free*—every processor can run at its maximum speed [19, 17].

A key result in this area was given by Fischer, Lynch, and Paterson [16], who have shown that the consensus problem is not even 1-resilient in the message passing model with respect to *deterministic* protocols. This result has been extended to the shared memory model [15, 21, 11]. (The conference version of the last reference proves this explicitly for a system of two processors.) This impossibility has motivated the study of *randomized* consensus protocols. A host of consensus protocols for various types of adversaries has been found for both the message passing model (e.g., [7, 24, 12, 6]) and the shared memory model (e.g., [11, 2, 1, 9, 3]). In particular, consensus has efficient *wait-free* (i.e., $n-1$ resilient) solutions in the shared memory model and $\lfloor \frac{n-1}{2} \rfloor$-resilient solutions in the message-passing model, even in the presence of a "strong adversary" [2, 6].

Consensus is an important problem, and in a certain sense it is a complete task, as follows from our results. Still, in order to understand the power and limitations of error-free randomization with respect to arbitrary distributed tasks, consensus alone does not suffice. To clarify this point, it is helpful to compare consensus with the *parity* task. In this latter task, each processor is required to output the XOR (parity) of all n inputs. Error-free randomization is powerful enough to overcome the coordination problems which prevent a deterministic solution to consensus, but it is of no help when facing problems of missing information. In the parity task, any irrevocable output by one processor (before knowing the inputs of all other $n-1$ processors) may later turn out to be inconsistent with additional inputs. Our work suggests a formal framework to capture these notions of missing and consistent/inconsistent inputs. Another aspect of fault tolerant models that is exemplified in this paper is that it is important for the adversary to have adequate powers. In particular, the adversary needs to be able to "resurrect" a processor, thereby turning a processor that previously may have appeared faulty into a merely slow one. Also, the adversary must be able to fail a processor that was previously active.

We study asynchronous fault tolerant systems that execute protocols of either of the following two types:

- deterministic protocols with access to consensus,
- randomized error-free protocols.

While we present most of our results in terms of *randomized error-free protocols*, the proof implies that in fact any finite interactive task is t-resilient in one model iff it is t-resilient in the other. In terms of what can and cannot be solved, it suffices to restrict the use of randomization to consensus. Thus if a consensus mechanism is built in, no randomization at all is needed. (Of course, randomization might still be used to speed up computations.)

This paper is the second in a series of three papers which study solvability by randomized error-free protocols, operating in asynchronous crash failure environments. The first paper in this series [13] deals with distributed decision tasks. The characterization there (as well as in the present work) is of combinatorial nature. Despite the added power of randomization, the characterizations and their proofs are fairly simple and yield effective procedures for testing solvability. This stands in sharp contrast to the recent works on deterministic solvability [8, 18, 27], which develop a methodology for characterizing decision tasks that are t-resilient with respect to deterministic protocols (*without* built-in consensus). These works are fairly complicated, use topological tools, and do not seem to yield effective characterization procedures. To the best of our knowledge, solvability of interactive tasks has not been addressed in the deterministic model.

A different line of research in deterministic solvability has dealt with *initial faults.* In the initial faults model, each processor either is initially crashed or remains active forever. Taubenfeld, Katz, and Moran [28] and Taubenfeld and Moran [29] have characterized t-resilience of distributed decision tasks with respect to deterministic protocols in the initial fault model. Interestingly, the characterization is the same as t-resilience with respect to randomized error-free protocols in the regular crash failure model [13]. This raises the question whether the two models have the same capabilities when richer classes of tasks are considered. In this work, we demonstrate a negative answer to this question. We describe a two-stage task that is solvable in the initial fault model but not in the regular crash failure model. The initial fault model enables the election of a "leader" who collects inputs and assigns outputs in a centralized fashion (and is not allowed to fail while doing this). While for the one round, decision tasks, randomization can be used to yield the effect of a leader, this is no longer the case when two-stage interactive tasks are involved. Intuitively, the models are different because in the initial faults model the adversary's powers are seriously limited.

1.2. Finite interactive tasks—motivation. Finite interactive tasks are an extension of distributed decision tasks [22, 13] (where each processor gets a single input and produces a single output). The number of rounds, namely the number of inputs received by each processor, is specified as part of the task. While one round corresponds to decision tasks, even tasks with two rounds constitute a nontrivial generalization. What distinguishes interactive tasks is the on-line character of the interaction. Each new local input is given only after the corresponding processor has irrevocably produced its previous output. Fast processors can work on late inputs while slower ones are still working on earlier inputs. For example, P_1 can work on its third input, P_2 on its fifth input, and P_3 on its first input concurrently. This implies that interactive tasks can neither be described as a single huge decision task nor be decomposed into distinct, independent decision tasks. Sequential systems as defined by Herlihy [17] and by Plotkin [23], such as stacks and queues, can also be formulated as interactive distributed tasks. (Finite interactive tasks will model such systems that are restricted to a bounded number of accesses per processor.)

We give several examples that should help clarify the expressive power of finite interactive tasks. Consider a multiround task where in each round the processors have to select a unique leader among all candidates. We indicate a processor's candidacy, in a given round, by inputting 1, while 0 indicates that the processor is not a candidate. The selected processor outputs 1 in the appropriate round, while all others output 0. (If there are no candidates in a given round, then nobody is selected.) So far, this leader selection problem can be viewed and solved as a collection of independent decision tasks. However, it may be useful to prevent a fast processor from taking permanent control of the system. Thus we add the requirement that no processor is selected twice. This gives rise to different finite interactive tasks, characterized by the total number of "selection campaigns" (or, equivalently, rounds). In the kth task in this list each processor has k inputs and k outputs. In this revised task, a processor that was selected in some round will output 0 in all subsequent rounds, *even if there are no other candidates.* It is not hard to see (and follows easily from our characterization) that the k round task is $(n-1)$-resilient for any $k \geq 1$. (The task is well defined for any k, although after everyone is selected, it becomes quite boring.)

The second example is a variant of the first. Here, in every round every processor receives as input a "priority," which is a positive integer in case the processor is a candidate and 0 if it is not. A leader can be selected if there are at least ℓ other processors with smaller priorities, among all processors that were not chosen already. (If nobody is interested, then every relevant processor gets a 0 and all inputs are among the least ℓ priorities, and in this case everyone outputs a 0 to indicate nonleadership.) As before, the unique selection is indicated by a 1 in the appropriate output. The selection process is repeated k times. How resilient is this task? For $k = 1$, a prospective leader must see at least ℓ other inputs before "fighting" for candidacy. This argument can be formalized to see that for $k = 1$, the task is $(n-\ell-1)$-resilient. Now consider $k = 2$. At the second round, the prospective candidate must still wait for ℓ other processors, but now these could come from a pool of only $n-1$ processors. This argument can be formalized to see that the task now is $(n-\ell-2)$-resilient. For general k and ℓ, it can be shown that this finite interactive task is $(n-\ell-k)$-resilient. This example can be extended further to describe cases where the selection of the ith round leader may depend on inputs from the $(i+1)$st round (e.g., if future inputs of previous leaders can act as tie breakers for the choice of the current leader), and so on.

As a final example, we now describe a different task, which can be viewed as a resource allocation problem. There are m resources $(m < n)$, denoted by 1 through m. At each of k rounds, any number of no more than m of the n processors can announce their interest in getting one of the resources (it does not matter which specific resource) by receiving an input of 1 (otherwise the processor gets 0). If the processor is allocated resource number j, then its output for that round is j. If no resource is allocated, the processor's output is 0. Once a resource is allocated, the processor can retain it by continuing to get input 1. To release a resource, the processor must get input 0. The task specifies that no resource is allocated at the same round to more than one processor. In addition, all requests should be granted. This task is related to a continued renaming problem [5]. For $k = 1$, it is not hard to see that the task is $(n-1)$-resilient (notice the difference from the deterministic case where the name range has to be larger than m). But this is no longer the case if $k > 1$. Consider a fast processor who was not interested in a resource at round 1 but became interested in one at round 2. This processor cannot simply grab a resource, despite the fact that it is guaranteed that such resource will eventually be freed for round 2: up to m tardy processors can wake up and ask for resources at the first round, and only one of them may release its resource in the second round. Our fast processor must wait until at least $m-1$ of the first round users announce their input, and only then can the processor grab a resource. This will be either one of the resources released by one of the $m-1$ processors or the remaining resource, in case all these processors retained their resource. This implies that if m resources were claimed at round 1, the processor may have to wait for the second round inputs of $m-1$ of them before giving an output in the second round. This argument leads to realizing that for $k \geq 2$, this resource allocation problem is 1-resilient but not 2-resilient.

The examples we give demonstrate the versatility of the finite interactive task formulation. We conclude that this is a rich class of tasks which constitutes a meaningful extension to the class of distributed decision tasks.

1.3. Highlights of the characterization. Denote by ISM_t (resp., IMP_t) the class of finite distributed interactive tasks that are solvable in the asynchronous shared memory (resp., message passing) model by a terminating t-resilient randomized protocol, which never errs and works in the presence of a strong adversary scheduler [2, 6]. (A protocol is terminating if each processor stops participating and halts after producing its last output.) Our main results are necessary and sufficient combinatorial conditions which determine membership in ISM_t (for $0 \leq t < n$) and IMP_t (for $0 \leq t \leq \lfloor \frac{n-1}{2} \rfloor$). A similar characterization, for nonterminating protocols, is also given. These results subsume the previous results of [13], which characterized resiliency of distributed decision tasks. We remark that the proof methods in the present work are substantially more involved than those in [13], due to the more general nature of interactive tasks.

We show that what determines resiliency in the randomized error-free model is the amount of information available (at every possible step) to the active processors and whether this information suffices to make moves that are compatible with every potential future development. In order to capture these properties, we associate every finite interactive task T with a directed acyclic graph (DAG), whose nodes represent states of the distributed system. It turns out that the DAG is a convenient tool with which to express the properties we need. In this subsection we outline how the DAG is defined and used for the characterization (while omitting some of the noncrucial details).

The nodes in the DAG contain partial vectors of (multi) input and (multi) output values that are globally known in the system. (For a concrete example, see section 4.) The nodes are first examined according to their "legality" and "consistency." Legality depends only on the indices in the partial vectors (these are the "S vectors" of section 3) and not on the values themselves. It means that no processor has produced an output in a given round before producing all the outputs of earlier rounds and getting all the inputs of earlier and the current rounds. Consistency is related to the task T and does depend on the values in the partial vector (these are the "Q vectors" of section 3). It means that for every possible completion of input values there is a corresponding completion of output values, such that the complete multi-input multi-output vector belongs to the task T.

We put a directed edge from node v_1 to node v_2 in the graph if v_2 extends the values in v_1 and contains exactly one additional input value. (It may contain one additional output, several additional outputs, or none.) We partition the nodes in the DAG into equivalence classes. Two nodes are called *equivalent* if they have the same sets of indices of revealed *inputs* (output indices do not matter here). This definition is useful in situations when there are directed edges from v to both u_1 and u_2 and the latter two nodes are *nonequivalent*. This implies that u_1 and u_2 extend v in different input indices, implying that two different processors have read an additional input in the corresponding moves.

We further refine each equivalence class and say that two equivalent nodes are *input equal* if the *values* of their revealed inputs are the same (output indices and values may still differ). With these definitions, we can describe the notion of a t-*founded* node (relative to the task T). This notion is central to our characterization.

Essentially, we think of a t-founded node as a "good" node from which there exists a strategy to advance while facing up to t crashes without getting stuck or making errors (relative to the task T).

The definition of t-founded is recursive, and we will now briefly describe its main points while omitting some special cases that correspond to the "boundaries" (where at least $n-t$ processors have already terminated). A node v in the DAG is t-founded if it is either a complete multi-input multioutput vector that belongs to the task T or a nonboundary partial vector which satisfies the following condition: there are at least $t+1$ nonequivalent nodes in the DAG, $u_1, \dots, u_t, u_{t+1}$, such that there is a directed edge from v to each u_j, and all u_j's are t-founded. In addition, for every u with a directed edge from v to u there exists an input equal node u' that also has a directed edge from v to it, and u' is t-founded. (The definition of t-founded for boundary nodes is slightly modified, especially in the requirement for the number of nonequivalent sons.)

Having $t+1$ nonequivalent sons of v essentially implies that even if an adversary scheduler crashes t processors, the remaining ones can still make progress. The second condition (regarding input equal sons) guarantees that the system can advance along a path of consistent nodes (with respect to the task T) no matter which processor is active next. The main theorem states that a finite interactive task T has a t-resilient protocol iff the root of the DAG (the partial vector with no inputs and no outputs) is t-founded.[1]

We show that the condition is necessary by the following argument. Suppose T is a task where the root of the DAG is not t-founded and $\mathcal{A}$ is an algorithm for the task that is claimed to withstand t crashes. We demonstrate a strategy for an adversary scheduler that enables it to force the system to advance (with positive probability) along a path of nodes that are not t-founded. We show that such a path leads to an inconsistent node. This means that the adversary can force the algorithm $\mathcal{A}$ to err (with nonzero probability). Notice that in order to be able to force the processors down this path, the adversary needs to be able to fail a previously active processor as well as cause the processors to think that a slow processor may be faulty.

To show that the condition is sufficient, we design a generic protocol which guarantees that all processors take a coordinated walk along a path of t-founded nodes in the DAG. When all processors terminate, this path must lead to a complete vector that is in T. Such coordination is achieved by applying a consensus subroutine to every step in the walk.

We use randomized consensus algorithms as given by [2, 1, 3, 9, 26] for the shared memory model and by [6] for the message passing model. It is interesting to observe that randomization is needed only for consensus and gives no extra power beyond that. This follows from our generic algorithm, which can be viewed as a repeated *deterministic reduction* of an arbitrary interactive task to consensus (which itself requires randomized solutions). Therefore, our characterizations also can be applied to deterministic systems that have a built-in consensus mechanism, and in this case no randomization at all will be needed (see section 7 for additional discussion).

1.4. Organization. The remainder of this paper is organized as follows. Section 2 describes the computation models. In section 3 we formally define interactive tasks and related notions used in this paper. In section 4 we describe the DAG associated

[1]As stated, the theorem holds for the shared memory model. A slight variation, which corresponds mainly to the final stages of an execution, makes it applicable to the message passing model (the variation is termed *t-valid*).

with an interactive task. This graph plays a central role in section 5, where the characterization theorem for the shared memory model is stated and proven. Section 6 contains the characterization for the message passing model. Finally, in section 7 we present some concluding remarks, including the equivalence of error-free randomized model and the deterministic model with access to consensus.

2. The models. In this section we define the models of asynchronous computation which we use in the sequel, as well as the class of appropriate schedulers (or adversaries) that control our systems.

An asynchronous concurrent system is a collection of n processors. Each processor, P, is a (not necessarily finite) state automaton with an internal input register in_P and an internal output register out_P. The set of all states of the processor P is denoted by S_P. The input register contains a value v taken from a set IN, while the output register has initially the value $\perp$. The value in the output register can be changed to any value in the set OUT ($\perp \notin OUT$). For every input value that the processor gets, it must change the value of the output register (possibly to the same value as before) exactly once before receiving the next input or terminating (after the last input).

The two models we consider differ in the way that processors communicate among themselves. In the *shared memory model*, processors communicate via *shared registers*. Every shared register r is associated with a set of processors R_r, $\mid R_r \mid > 0$, that can read from the register and a set of processors W_r, $\mid W_r \mid > 0$, that can write into the register. These registers are atomic with respect to the read and write operations. (Although our protocols use only the simpler, multireader single-writer registers, the necessity of our conditions holds in the more general setting, presented here.)

In the second model, the *message passing model*, there is a communication link between every two processors. Processors may send and receive messages via these links. The links are atomic with respect to the send-message and receive-message operations, but there is no guarantee on the order in which the messages are received once they are sent.

Processors execute their programs by taking steps. An atomic step consists of one of the following:

1. An internal operation, possibly involving coin tosses.
2. Getting information from other processors (reading from a shared register in the shared memory model, or receiving a message from a link in the message passing model).
3. Giving information to other processors (writing into a shared register in the shared-memory model, or sending via a link in the message passing model).
4. Getting a new local input.
5. Giving a new local output.

Formally, every processor P takes steps according to its *transition function*, T_P. In case the step taken was a read (or receive), the new state of P depends not only on its old state but also on the value read (received) by this action. The transition function T_P could be either deterministic or nondeterministic. In the latter case, the actual step taken is decided via coin tosses (in a nondeterministic step the only difference between the old and new states is the coin toss, and no communication occurs in such a step). Given an asynchronous system as specified above, a *protocol* is a collection of n transition functions $T_1, \dots, T_n$, one per processor.

A *configuration* C of the system, in the shared memory (message passing) model, consists of the state of each processor together with the contents of the shared registers (communication links). In an *initial configuration*, every processor is in an initial state, and all shared registers and output registers contain the default value $\perp$ (all the links are empty). The set of all configurations will be denoted by $\mathcal{C}$. A *step* takes one configuration to another by activating a single processor P. A *run* of length ℓ is a sequence of ℓ steps. Each run has an associated *schedule* which is a sequence of ℓ processors, numbered according to the order of processors that take steps in that run. We denote schedules, finite or infinite, by a list of processor numbers, e.g., $(2, 3, 3, 2, 1)$. We say that processor P is activated k times in a run if P appears k times in the run's schedule. The *history* $\mathcal{H}$ of a run is the sequence obtained by interleaving the sequence of configurations with the steps in the run, starting with the initial configuration. For a finite run, we refer to the last configuration in its history as the *current* configuration.

A *scheduler* $\mathcal{S}$ is a mapping from $\mathcal{H}$ into the set of n processors. Given the configuration of the system, the scheduler picks the next processor that is to take a step. The scheduler could be either a deterministic mapping or a randomized one. The scheduler can be viewed as an adversary which tries to prevent the system from reaching its goal. Under this definition, the adversary is very strong: it has complete knowledge of the state of every processor and of the contents of the shared registers (communication links) during the entire history. In case the processors are randomized, the scheduler could also base its choices on the outcome of past coin flips as well as the current coin flip (if the next step is randomized). We do not allow it, though, to be able to predict *future* randomized moves of the processors. This is a necessary requirement if randomization is to be helpful at all, and it is used in all algorithms where randomization is employed, e.g., [25, 20, 7]. In addition, the scheduler picks the inputs to be given to the processors (from the possible legal inputs).

Finally, we note that both models are asynchronous, meaning that there is no global clock in the system and each processor runs at its own pace. In the message passing model this also means that messages can be delivered with arbitrary delays (and possibly out of order).

In each one of these models there are two submodels according to the nature of the processors. All the processors can be of one of two types:

1. Terminating processors that terminate and halt once their final output has been given.
2. Nonterminating processors that continue to operate even after giving their final output. These processors may help and coordinate among the slower processors that have not yet finished their task.

The second type of processor yields a more robust system, which could solve any task solvable by processors of the first type.

In this work we study the resiliency of tasks in these two models.[2] There is a resiliency parameter, t, that denotes the extent of resiliency required. The *t-resiliency* requirement imposes restrictions both on the scheduler and on the protocol. In every infinite schedule under the scheduler, S, at least $n - t$ processors will be activated infinitely many times. We will call such a scheduler a *t-bounded scheduler*. Intuitively, this means that the scheduler may fail-stop at most t processors.

A *round* of a t-bounded schedule is a minimal schedule of the processors (starting from any configuration) in which at least $n - t$ processors are scheduled at least once.

[2]Most of our results are developed for terminating processors. Once these results are obtained, the case of nonterminating processors is easy to handle. The results for the nonterminating model are stated in section 7.

Each processor which is scheduled in the round is said to be *active* in it. Notice that after $n - t$ processors have terminated, a schedule in which all the terminated processors are scheduled (and thus no move will be made) is also a round.

DEFINITION 1. *We say that an algorithm, A, is a t-resilient algorithm for a task, T, if the following conditions hold:*

- *Safety. For every legal input for T, for any t-bounded scheduler, S, and for any execution of A, if all n processors terminate (or in the nonterminating models, if all n processors have given their last output), then the resulting output is correct with respect to the input for T (see Definition 2).*
- *Liveness. There is a constant, M, such that for every processor the* expected *number of rounds in which it is active, before producing its final output, is bounded by M. For terminating processors this requirement implies that after $n-t$ processors have terminated, the expected number of* steps *taken by each of the remaining t processors in order to terminate is bounded by M (no matter how the steps of this individual processor are interleaved with steps of other processors).*

It should be noticed that we require that protocols never err. Although there could be a positive probability for very long nonterminating runs, this probability should be very small (converging to 0 with the length of the run).

3. Basic definitions.

In this section we define finite interactive tasks and what it means for such a task to be t-resilient. We introduce the notation of partial vectors and use this notation to express states of systems that implement interactive tasks and transitions between such states.

Distributed interactive tasks are a generalization of distributed decision tasks. A decision task is a collection of input-output pairs (each pair is an n-vector). Analogously, we define an *interactive$_k$ task* as a collection of k pairs. Each element of every pair is an n-vector. The first element represents an input vector and the second an output vector. The following formulation turns out to be convenient for our purposes.

DEFINITION 2. *An interactive$_k$* task *(or k-*stage distributed interactive task*), T, is a collection of $2k$-tuples of the form $\langle I^1, \ldots, I^k, O^1, \ldots, O^k\rangle$. Each I^j and O^j is an n-component vector over an arbitrary alphabet, corresponding to the n inputs and n outputs of the jth stage, respectively. The* legal inputs *for T (denoted $IN(T)$) are all the k-tuples of n-component vectors $\langle I^1, \ldots, I^k\rangle$ such that there exists $\langle O^1, \ldots, O^k\rangle$ for which $\langle I^1, \ldots, I^k, O^1, \ldots, O^k\rangle \in T$.*

When an execution of an interactive$_k$ task starts, a processor P_i gets the input for the first stage. After it submits the output for this stage (which is irrevocable) it receives the input for the second stage, and so on. In general, each processor, P_j, gets its input for stage $i + 1$ only after submitting its output for stage i, for all $1 \le i \le k - 1$. Different processors may be in different stages simultaneously. At a certain point during an execution, it is possible that there will already be, for example, seven outputs for the first stage, five for the second, two for the third, and none for the fourth.

We will represent the states in an instance of an algorithm using partial vectors which contain input and output values. If we take a vector $\vec{V}$ of length n over a certain alpha-beth, Σ, and a set of indices, J, where $J \subseteq \{1, \ldots, n\}$, then the partial vector $\vec{V_J}$ is defined as follows:

- If $i \in J$, then $V_J(i) = V(i)$, the ith coordinate of $\vec{V}$.
- Otherwise $V_J(i) = \perp$, where $\perp$ is an agreed sign for "don't know yet."

This means that we know only the values of $\vec{V}$ at the indices indicated by J. Typically,

$\vec{V}_J$ is compatible with more than one vector $\vec{V}$, namely, there may be a $\vec{V}'$ such that $\vec{V}' \neq \vec{V}$ but still $\vec{V}'_J = \vec{V}_J$. For example, the partial vector $\vec{V}_\phi$ is compatible with every vector of the same length.

One property of a $2k$-tuple, representing the state of an interactive$_k$ task, corresponds to the temporal order in which input and output indices are revealed. This property is formalized in the next definition, which uses the notion of *corresponding partial input and output.* We say that a partial input and output $Q = \langle I^1_{A_1}\ ,\ \ldots\ ,\ I^k_{A_k}\ ,\ O^1_{B_1}\ ,\ \ldots\ ,\ O^k_{B_k}\rangle$ corresponds to the $2k$-tuple $S = \langle A_1\ ,\ \ldots\ ,\ A_k\ ,\ B_1\ ,\ \ldots\ ,\ B_k\rangle$ if the revealed indices in Q match the index-sets in S.

DEFINITION 3. *Let $S = \langle A_1, \ldots, A_k, B_1, \ldots, B_k\rangle$ be a $2k$-tuple of index-sets. S will be called a* legal 2k-tuple *if the following conditions are satisfied:*

- *For all i, $1 \le i \le k$, it holds that $B_i \subseteq A_i$ and $A_i, B_i \subseteq \{1, ..., n\}$.*
- *For all i, $1 \le i \le k-1$, it holds that $A_{i+1} \subseteq B_i$.*

Let Q be a partial input and output vector, corresponding to S. We say that Q is a legal partial input–output vector *if S is a legal $2k$-tuple.*

The requirements ensure that S represents a possible state of revealed inputs and outputs in an instance of an algorithm for an interactive$_k$ task. By demanding that $B_i \subseteq A_i$ we guarantee that no processor will produce its ith output before receiving its ith input. By demanding that $A_{i+1} \subseteq B_i$ we guarantee that no processor will get its $(i+1)$st input before producing its ith output. However, the legality requirement does not suffice. We also want to guarantee that the "input output contents" matches a state that can fit the requirements of the task itself. This property is stated in the next definition.

DEFINITION 4. *Let $Q = \langle I^1_{A_1}\ ,\ \ldots\ ,\ I^k_{A_k}\ ,\ O^1_{B_1}\ ,\ \ldots\ ,\ O^k_{B_k}\rangle$ be a legal $2k$-tuple of partial vectors. Q will be called* T-consistent *if for every extension I^1 to I^k, of $I^1_{A_1}$ to $I^k_{A_k}$ such that $\langle I^1, \ldots, I^k\rangle \in IN(T)$, there exist extensions O^1 to O^k, of $O^1_{B_1}$ to $O^k_{B_k}$ such that $\langle I^1\ ,\ \ldots\ ,\ I^k\ ,\ O^1\ ,\ \ldots\ ,\ O^k\rangle \in T$.*

We will say that output o^i_j is a consistent output *for the $2k$-tuple $\langle I^1_{A_1}\ ,\ \ldots\ ,\ I^k_{A_k}$, $O^1_{B_1}\ ,\ \ldots\ ,\ O^k_{B_k}\rangle$ if the $2k$-tuple $\langle I^1_{A_1}\ ,\ \ldots\ ,\ I^k_{A_k}\ ,\ O^1_{B'_1}\ ,\ \ldots\ ,\ O^k_{B'_k}\rangle$, is T-consistent, $B'_k = B_k$ for every $k \neq i$, $B'_i = B_i \cup \{j\}$, and the jth coordinate of $O_{B'_i}$ equals o^i_j.*

An inconsistent $2k$-tuple corresponds to a state where the scheduler, by giving legal inputs, can force the algorithm to err. Thus, intuitively, consistency is a property that the processors wish to maintain.

Let us now formalize the notion of a "one-step" advancement from a legal $2k$-tuple of partial input-output vectors to another legal one. Intuitively, a one-step advancement corresponds to one additional input read by one processor and possibly a resulting extension of one or more outputs. If the new input is from the ith stage $(i \ge 2)$, then, by our convention, the reading processor has already given its $(i-1)$st output. There is an exception to this intuition, which occurs toward the end of a run, when only t or fewer processors still have unrevealed inputs. In this case, a single additional output is also considered an advancement, as the remaining t or fewer processors might be faulty and thus we cannot insist on input extensions here. We first formally define these early and late parts in a run.

DEFINITION 5. *The earlier parts of a run of an algorithm, where the set of processors that have already read their last input, A_k, satisfies $|A_k| < n-t$, are called the* main phase. *The final parts of a run of an algorithm, where $|A_k| \ge n-t$, are called the* concluding phase.

The definition of a one-step advancement is as follows.

DEFINITION 6. *Let*

$$S = \langle A_1, \ldots, A_k, B_1, \ldots, B_k \rangle, S' = \langle A'_1, \ldots, A'_k, B'_1, \ldots, B'_k \rangle$$

be two legal $2k$-tuples and let

$$Q = \langle I^1_{A_1}, \ldots, I^k_{A_k}, O^1_{B_1}, \ldots, O^k_{B_k} \rangle,$$

$$Q' = \langle I^1_{A'_1}, \ldots, I^k_{A'_k}, O^1_{B'_1}, \ldots, O^k_{B'_k} \rangle$$

*be partial inputs and outputs corresponding to S and S', respectively. The pair $[S', Q']$ will be called a t-*subsequent *of the pair $[S, Q]$ if the following three conditions hold:*

- *For all i, $1 \le i \le k$ it holds that $B_i \subseteq B'_i$.*
- *Exactly one of the following is true:*
  1. *There is exactly one i ($1 \le i \le k$) and one j ($j \in \{1, \ldots, n\}$) such that $j \notin A_i$, $j \in B_{i-1}$, $A'_i = A_i \cup \{j\}$, and for all $m \ne i$ it holds that $A'_m = A_m$.*
  2. *The system is in the concluding phase ($|A_k| \ge n - t$) and there is exactly one i ($1 \le i \le k$) and one j ($j \in \{1, \ldots, n\}$) such that $j \notin B_i$, $B'_i = B_i \cup \{j\}$, for all $m \ne i$ it holds that $B'_m = B_m$, and for all $1 \le \ell \le k$ it holds that $A_\ell = A'_\ell$. This corresponds to a single new output, given by P_j in the ith stage.*
- *Q' is an extension of Q and there exists $< I^1, \ldots, I^k > \in IN(T)$ such that $< I^1, \ldots, I^k >$ is an extension of $< I^1_{A'_1}, \ldots, I^k_{A'_k} >$.*

When $[S', Q']$ is a t-subsequent of $[S, Q]$ and j is the unique index extending A_i (in case 1) or B_i (in case 2), we say that P_j is the processor associated with the t-advancement.

The number of possible failures, t, is a parameter in the definition. An additional input is considered an advancement in both the main and the concluding phases, while an additional output (on its own) is considered an advancement only in the concluding phase. Notice that this definition can be used independently of consistency.

In [17], Herlihy studied concurrent implementations of sequential data objects. Finite versions of such objects may be represented as interactive$_k$ tasks. This can be done by taking the set of all possible sequences of correct operations on the object. For example, consider a concurrent implementation of a stack. The processors in this implementation are servers that receive in their input one of two possible requests:

- *push(value)*: push the parameter *value* onto the top of the stack and return (output) ℓ, where ℓ is the level of the stack in which the value was put (1 when the stack contains one element, 2 when the stack contains two elements, etc.). In our example the stack level is required as output mainly for didactic reasons.
- *pop*: pop the top of the stack and return (output) its value ("empty" if the stack is empty).

Obviously the outcome of a request given to a processor may depend on previous requests to some of the other processors. We will use the example of a three-processor stack as implemented by an interactive$_2$ task (two requests per processor) to illustrate the definitions. The resiliency parameter will be $t = 2$. Assume that in the first stage P_1 will be requested to push 5, P_2 will be requested to pop, and P_3 will be requested to push 7. These will be the inputs (but the processors do not know them initially). From the initial configuration, where no inputs and no outputs are known, we can advance in one step to a state where one input is known (e.g., P_1 has "push 5" as input) or to a state where one input and one output are known (for instance, P_1 with the input "push 5" and with output "1," or P_2 with input "pop" and output "empty").

4. The corresponding DAG. In this section we define the DAG associated with an interactive$_k$ task. A run of an algorithm can be viewed as a sequence of $2k$-tuples of indices with their corresponding $2k$-tuples of partial inputs and outputs. We associate this sequence with a path in a DAG. There is a directed edge from v to u if u is a possible state representing a one-step advancement from v (namely, u is a t-subsequent of v). More formally, we have the following definition.

DEFINITION 7. *Let T be an interactive$_k$ task. The* DAG associated with T, *which we denote by $D(T)$, has the set of nodes*

$$V = \{[S, Q] | S = \langle A_1 \,,\, \dots \,,\, A_k \,,\, B_1 \,,\, \dots \,,\, B_k \rangle, Q = \langle I^1_{A_1}, \,\dots, \, I^k_{A_k}, \, O^1_{B_1}, \,\dots, \, O^k_{B_k} \rangle,$$

S is a legal $2k$-tuple, Q corresponds to S, and there exists $\langle I^1, \dots, I^k \rangle \in IN(T)$ such that $\langle I^1, \dots, I^k \rangle$ is an extension of $\langle I^1_{A_1} \,,\, \dots \,,\, I^k_{A_k} \rangle\}$. The set of directed edges, E, is the set of all (v_1, v_2) where $v_1 = [S_1, Q_1]$ and $v_2 = [S_2, Q_2]$, such that v_2 is a t-subsequent of v_1 and v_2 is T-consistent.

The root of the DAG is the node $[\langle \phi, \dots, \phi, \phi, \dots, \phi \rangle, \langle I^1_\phi, \dots, I^k_\phi, O^1_\phi, \dots, O^k_\phi \rangle]$. The leaves (nodes from which there are no outgoing edges) are either nodes containing a complete $2k$-tuple of indices ($A_1 = \cdots = A_k = B_1 = \cdots B_k = \{1, \dots, n\}$) with the corresponding full inputs and outputs, or nodes whose $2k$-tuple of indices is incomplete but do not have T-consistent sons. In general, we think of a node in the DAG as representing a possible state of the published input and agreed-upon output values at some point during a possible execution. An edge represents a transition according to the t-subsequency relation. Notice that one can "label" an edge from u to v according to the processor P_j which is associated with the t-advancement.

In our example of the stack, there will be an edge from the node representing the initial state, $[\langle \phi \,,\, \phi \,,\, \phi \,,\, \phi \rangle, \langle I^1_\phi \,,\, I^2_\phi \,,\, O^1_\phi \,,\, O^2_\phi \rangle]$, to the node representing the state where P_1 has seen the input "push 5," which is the node $[\langle \{1\}, \phi, \phi, \phi \rangle, \langle \{\text{"push(5)"}, \perp, \perp\}, I^2_\phi, O^1_\phi, O^2_\phi \rangle]$. There will also be an edge from the initial node to the node representing the state where P_2 has seen "pop" and returned "empty." This node is $[\langle \{2\}, \phi, \{2\}, \phi \rangle, \langle \{\perp, \text{"pop"}, \perp\}, I^2_\phi, \{\perp, \text{"empty"}, \perp\}, O^2_\phi \rangle]$.

The DAG represents all the possible advancements for all possible inputs. It is useful to group the vertices into equivalence classes according to the amount of information in them, disregarding the actual input and output values. This leads to the definition of *t-equivalent* nodes in the DAG.

DEFINITION 8. *Let*

$$v = [\langle A_1 \,,\, \dots \,,\, A_k \,,\, B_1 \,,\, \dots \,,\, B_k \rangle, \langle I^1_{A_1} \,,\, \dots \,,\, I^k_{A_k} \,,\, O^1_{B_1} \,,\, \dots \,,\, O^k_{B_k} \rangle]$$

and

$$v' = [\langle A'_1 \,,\, \dots \,,\, A'_k \,,\, B'_1 \,,\, \dots \,,\, B'_k \rangle, \langle I^1_{A'_1} \,,\, \dots \,,\, I^k_{A'_k} \,,\, O^1_{B'_1} \,,\, \dots \,,\, O^k_{B'_k} \rangle]$$

be two nodes in the DAG corresponding to an interactive$_k$ task, T. These two nodes will be called t-equivalent *if the following two conditions are satisfied:*

- *For all i, $1 \le i \le k$, it holds that $A_i = A'_i$.*
- *If $|A_k| \ge n - t$, then for all i, $1 \le i \le k$, it holds that $B_i = B'_i$.*

In the equivalence relation we are concerned only with the *indices* of the revealed inputs/outputs, while the values in these indices do not matter. From the definition it follows that two nodes are *non-t-equivalent* in one of two cases: either they do not have the same indices of input revealed or they are both in the concluding phase, and their revealed output indices are different (for some i it holds that $B_i \neq B'_i$). As with the definition of t-subsequents, we take the outputs into consideration only in the concluding phase.

In our example, when examining whether the task is 2-resilient ($t = 2$), the nodes

$$v_1 = [\langle \{1,2,3\}, \phi, \{1,2,3\}, \phi\rangle, \\ \langle\{\text{“push(17)”, “push(27)”, “push(37)”}\}, I^2_\phi, \{1,3,2\}, O^2_\phi\rangle]$$

and

$$v_2 = [\langle \{1,2,3\}, \phi, \{1,3\}, \phi\rangle, \\ \langle\{\text{“push(57)”, “push(67)”, “push(87)”}\}, I^2_\phi, \{2,\perp,1\}, O^2_\phi\rangle]$$

are 2-equivalent (both nodes have $A_1 = \{1,2,3\}, A_2 = \phi$). While the nodes

$$u_1 = [\langle \{1,2\}, \{2\}, \{1,2\}, \phi\rangle, \\ \langle\{\text{“push(17)”, “push(27)”}, \perp\}, \{\perp, \text{“pop”}, \perp\}, \{2,1,\perp\}, O^2_\phi\rangle]$$

and

$$u_2 = [\langle \{1,2\}, \{2\}, \{1,2\}, \{2\}\rangle, \\ \langle\{\text{“push(17)”, “push(27)”}, \perp\}, \{\perp, \text{“pop”}, \perp\}, \{1,2,\perp\}, \{\perp, 27, \perp\}\rangle]$$

are *non*-2-equivalent. (These nodes have $|A_2| = 1 = 3 - 2$, but their B_2 sets are not the same.)

Notice that two nodes (collections of partial vectors) with the same input indices are revealed, but different values revealed in these indices *are* equivalent. The reason they are defined as equivalent is that in a specific run we are interested only in the input for this run, which cannot be compatible with both. We refine the t-equivalence relation, thereby partitioning the equivalence classes into subclasses, such that all the nodes in the same subclass will have the same *input values* (not just indices). The nodes in this subclass will be called *input-equal.* Input-equal nodes may differ both in their output indices and in their output values (provided they remain t-equivalent).

DEFINITION 9. *Let*

$$v = [\langle A_1, \dots, A_k, B_1, \dots, B_k\rangle, \langle I^1_{A_1}, \dots, I^k_{A_k}, O^1_{B_1}, \dots, O^k_{B_k}\rangle]$$

and

$$v' = [\langle A'_1, \dots, A'_k, B'_1, \dots, B'_k\rangle, \langle I^1_{A'_1}, \dots, I^k_{A'_k}, O^1_{B'_1}, \dots, O^k_{B'_k}\rangle]$$

be two nodes of the DAG corresponding to an interactive$_k$ task, T. Let t be a resiliency parameter. The nodes v and v' will be called input-equal if the following conditions hold:

- *v and v' are t-equivalent.*
- *For all i, $1 \leq i \leq k$, it holds that $I^i_{A_i} = I^i_{A'_i}$ (which implies $A_i = A'_i$ as well).*

In the example of the stack, assume that the inputs in the first stage are "push 21" for P_1, "push 22" for P_2, and "push 23" for P_3. Now suppose that the input in the second stage for all three processors is "pop." In this situation, the nodes

$$v_1 = [\langle \{1,2,3\}, \{1,2,3\}, \{1,2,3\}, \{2\}\rangle, \langle \{\text{“push(21)”}, \text{“push(22)”}, \text{“push(23)”}\}, \{\text{“pop”}, \text{“pop”}, \text{“pop”}\}, \{2,1,3\}, \{\perp, 23, \perp\}\rangle]$$

and

$$v_2 = [\rangle \{1,2,3\}, \{1,2,3\}, \{1,2,3\}, \{2\}\rangle, \langle \{\text{“push(21)”}, \text{“push(22)”}, \text{“push(23)”}\}, \{\text{“pop”}, \text{“pop”}, \text{“pop”}\}, \{3,2,1\}, \{\perp, 21, \perp\}\rangle]$$

(which correspond to two different schedulings of the same input values) are input-equal.

5. Characterization for the shared memory model. In this section we state and prove the characterization theorem for t-resilient interactive$_k$ tasks in the shared memory model. The following claim will be useful in the proof of the main theorem for this model.

DEFINITION 10. *We say that an algorithm A is an* immediate-input *algorithm if the first step of every processor after writing an output in its private output register (as long as this is not the last (kth) output) is reading the next input from its private input register.*

CLAIM 1. If a distributed interactive$_k$ task, T, is solvable by a t-resilient algorithm, A, in the shared memory model, then T is also solvable by a t-resilient immediate-input algorithm, A'.

Proof. We show how to construct such an immediate-input algorithm, A', on the basis of the given algorithm, A. The algorithm A' will have all the shared registers of A plus an array of k Boolean multireader single-writer registers per processor (one bit for every input in T). The bits in all n arrays are initialized to "false." The state of a processor will consist of a pair (s_A, s_{add}), where s_A is a state of the processor in A and s_{add} reflects the additional parts, performed by A'. The algorithm A' will simulate algorithm A (changing s_A according to algorithm A) except at the following points:

- After a processor, P, writes the ℓth output ($\ell < k$), P's next step is to read the next, $(\ell+1)$st, input. However, P will leave the indicator corresponding to the $(\ell+1)$st input with the value "false," meaning that it did not want to read its input yet (in A). This will change only s_{add}, not s_A.
- When P is supposed to read its input (according to algorithm A) it will, instead, change the indicator corresponding to this input to "true." It will also change s_A according to algorithm A (and the value of this input).

It is not hard to verify that if A is t-resilient, then so is A'. ∎

We now define the notion of a t-founded node relative to a task T. Intuitively, a t-founded node is a "good" node from which a t-resilient algorithm can progress to correct outputs, regardless of the scheduling and of future revealed inputs. The definition of t-foundedness will be recursive.

DEFINITION 11. *Let*

$$v = [\langle A_1, \ldots, A_k, B_1, \ldots, B_k\rangle, \langle I^1_{A_1}, \ldots, I^k_{A_k}, O^1_{B_1}, \ldots, O^k_{B_k}\rangle]$$

be a node in the DAG. The node v will be called t-founded *relative to the interactive$_k$ task T if*

- *the node v is a "completed leaf" $v = [\langle\{1,\ldots,n\}_1, \ldots, \{1,\ldots,n\}_{2k}\rangle, \langle I^1,\ldots,I^k,O^1,\ldots,O^k\rangle]$ and $\langle I^1,\ldots,I^k,O^1,\ldots,O^k\rangle \in T$,*

or

- *the node $v = [\langle A_1, \ldots, A_k, B_1, \ldots, B_k\rangle, \langle I^1_{A_1}, \ldots, I^k_{A_k}, O^1_{B_1}, \ldots, O^k_{B_k}\rangle]$ is not a completed leaf (namely $B_k \neq \{1,\ldots,n\}$), and the following conditions hold:*
  1. *The node v has at least α non-t-equivalent sons, where $\alpha = min\,(t+1\,,\, n-|B_k|)$.*
  2. *For every possible t-subsequent, u, of v (u is not necessarily T-consistent), there exists an input-equal node u' that is a t-founded son of v.*

As we mentioned earlier, t-equivalent nodes have the same input indices revealed. Therefore, if two nodes are t-equivalent sons of some node, then the same processor made the t-advancement to both sons. Since the scheduler may fail up to t processors, t-resiliency necessitates, in the main phase, at least $t+1$ processors that can advance from any given situation. However, during the concluding phase there may be fewer than t active processors. (These are the processors that have not yet submitted their final output.) The number of processors able to make a t-advancement surely cannot exceed the number of active processors. This argument motivates the definition of α. If we require that there be at least α processors that are able to advance (i.e., at least α non-t-equivalent sons), some processor will always be able to advance from this state, no matter what the scheduling sequence is.

In addition, we need to have a legal consistent step available no matter what the input *values* are. This is embodied in the requirement for a t-founded input-equal son for every possible t-subsequent. Notice that the specific input values in a run cannot be chosen by the processors, while the output values *are* chosen by the processors. We remark that by the definition of t-foundedness, every path in the DAG which starts at the root, ends at some leaf, and proceeds only through t-founded nodes must end in a leaf belonging to T.

We are now in position to state and prove the characterization theorem for the shared memory model.

THEOREM 1. *In the terminating shared memory model, for $0 \leq t \leq n-1$, an interactive$_k$ task T is t-resilient iff the root of its DAG is t-founded relative to T.*

Proof. First we prove the $\Rightarrow$ direction: if the root of the DAG, $R_0 = [\langle\phi,\ldots,\phi, \phi,\ldots,\phi\rangle, \langle I^1_\phi, \ldots, I^k_\phi, O^1_\phi, \ldots, O^k_\phi\rangle]$ is *non*-t-founded relative to T, then T is not t-resilient. A high-level description of the proof is as follows: Assume that the root of the DAG is non-t-founded and yet there exists a t-resilient algorithm for the task T. We will show how the scheduler can force the system to make transitions along a sequence, s, of non-t-founded nodes in the DAG. Each node in s reflects the input values that were read and the output values that were produced by the processors. In every transition, at least one new input is read or one new output is produced. Since the number of inputs and outputs is finite, $2nk$, the number of such transitions will also be finite. This process will terminate either at a leaf of the DAG that is non-t-founded or in a state that is not represented by a node in the DAG. In the latter case, the inputs and outputs represent an inconsistent state. In either case, the scheduler has forced the algorithm to err.

A processor that had either terminated or read an input for which it has not yet given an output will be called a *nonreading* processor. Let v be a node in the sequence s. The scheduler's strategy will preserve two invariants regarding v:

1. The node v is non-t-founded, and every node in the DAG, u, that is input-equal to v is either inconsistent or is both consistent and non-t-founded.
   Notice that this invariant holds at the root, as we assume that the root is non-t-founded and there are no other nodes that are input-equal to the root.
2. The node, v, belongs to one of the following two categories:
   (a) The state represented by v is in the main phase and the number of non-reading processors in this state is smaller than $n - t$. (Notice that this invariant holds at the root, as there are no nonreading processors at the root.)
   (b) The state represented by v is in the concluding phase and at least $n - t$ processors have terminated (given their final output).

The scheduler will allow the system to advance by making a t-advancement while keeping these invariants. We will denote them as advancements from node R_ℓ to node $R_{\ell+1}$ ($\ell = 0$ at the root). In such an advancement there are two possibilities.

1. In the main phase, a t-advancement corresponds to an additional input and possibly several additional outputs.
2. In the concluding phase an advancement can be either an additional single input (only) or a single additional output.

We now present the detailed proof. Suppose, by way of contradiction, that T *is* t-resilient, namely, there exists a t-resilient algorithm, A, which implements T. By Claim 1 we can assume that this algorithm is an immediate-input algorithm. The root of the DAG corresponding to T, R_0, is *non*-t-founded. By Definition 11 there are two possible reasons for a node R_ℓ to be non-t-founded:

(A) R_ℓ has less than α non-t-equivalent sons.
(B) R_ℓ has a t-subsequent, $R'_{\ell+1}$, such that for every $R_{\ell+1}$ which is input-equal to $R'_{\ell+1}$ and is a son of R_ℓ in the DAG, $R_{\ell+1}$ is *non*-t-founded.

We describe an adversary scheduler which, as long as the system is at a node that is non-t-founded due to possibility (B), will force the algorithm to advance by choosing one of the non-t-founded input-equal sons. Notice that when the system moves from R_ℓ to $R_{\ell+1}$, the first invariant is maintained. ($R_{\ell+1}$ is non-t-founded and all of it's input-equals are either inconsistent (not a node in the DAG) or consistent (in the DAG) but non-t-founded.)

Let P_i be the processor associated with the t-advancement from R_ℓ to $R'_{\ell+1}$ (Definition 6). If the system is in the main phase, this advancement corresponds to P_i reading an input. If the system is in the concluding phase, this advancement corresponds to either P_i reading an input or P_i writing an output (case 2 of Definition 6).

In case P_i's step is reading an input, in the concluding phase, the adversary scheduler will activate P_i once and P_i will read this input, since A is an immediate-input algorithm. The resulting configuration will be $R_{\ell+1}$. In case P_i's step is reading an input in the main phase, the scheduler activates P_i (which reads its input) as above, but then the scheduler may perform additional activations according to the following cases.

If $n-t$ or more inputs of the final stage are known, then the scheduler will activate the $n - t$ processors that have read their final input (say, in round-robin order) until *all* of them give an output and terminate. By Definition 1, within a finite expected number of steps all $n-t$ processors will give outputs and terminate. The configuration reached after all $n - t$ processors have given their final output is $R_{\ell+1}$. Notice that this case preserves invariant 2(b), as we reach the concluding phase not only with

$n-t$ inputs of the final stage but also with $n-t$ outputs and terminated processors.

If, however, there are fewer than $n-t$ inputs of the final stage, then we know that the system remains in the main phase. In this case, let S_p denote the set of nonreading processors (after the read step of P_i). Notice that by invariant 2(a) it holds that $|S_p| \leq n-t$ because before P_i read its input, there were fewer than $n-t$ nonreading processors. The scheduler will do one of the following:

1. If $|S_p| < n-t$, then the resulting configuration is $R_{\ell+1}$ (no additional activations). In this case, the second invariant holds ($R_{\ell+1}$ is in the main phase and $|S_p| < n-t$).
2. If $|S_p| = n-t$, then the scheduler will activate the processors in S_p (say, in round-robin order) until exactly one of them gives an output. By Definition 1, such an output will be given within a finite expected number of steps. The resulting configuration will be $R_{\ell+1}$. This configuration adheres to the second invariant as now there are only $n-t-1$ nonreading processors.

When examining $R_{\ell+1}$ we see there are now two possibilities. The first is that the outputs given were inconsistent, in which case the algorithm has erred. The second possibility is that $R_{\ell+1}$ is consistent. The configurations $R_{\ell+1}$ and $R'_{\ell+1}$ are input equal. $R_{\ell+1}$ is a son of R_ℓ in the DAG. Since we assumed R_ℓ is non-t-founded due to (B), this implies that $R_{\ell+1}$ is non-t-founded.

The other t-advancement possible is that P_i's step in advancing from R_ℓ to $R'_{\ell+1}$ is writing an output. In this case the system must be in the concluding phase, and due to the second invariant we know that $n-t$ processors have already terminated. By Definition 1, since A is assumed to be a t-resilient algorithm, P_i will write an output, with probability 1, after being scheduled a finite number of times. Thus, the scheduler will activate P_i until it writes an output. In this case, the resulting configuration is the desired $R_{\ell+1}$. Again, if $R_{\ell+1}$ is inconsistent the algorithm has erred and otherwise, $R_{\ell+1}$ is non-t-founded (since all the t-advancements made by P_i in this case are input equal and thus non-t-founded). As the system was in the concluding phase and the second invariant was true before the advancement, it will also hold after the advancement.

Hence, in all cases, within a finite expected number of steps the scheduler can force the system to reach $R_{\ell+1}$ without failing any processor. The system is now at a non-t-founded node, $R_{\ell+1}$. The argument used for R_ℓ applies to $R_{\ell+1}$ as well, and can therefore be repeated.

Since the depth of the DAG is finite, after a finite number of such t-advancements we will reach a node R_f that is non-t-founded due either to possibility (A) or to the fact that it is a complete leaf which is not in T ($\langle I^1, \ldots, I^k, O^1, \ldots, O^k \rangle \notin T$).

In the main phase, a node v cannot be non-t-founded due to possibility (A): from the second invariant, less than $n-t$ processors are nonreading. Therefore, at least $t+1$ processors can read an additional input and thus v must have at least α non-t-equivalent sons. (Remember that $\alpha \leq t+1$ and that due to Definition 4 an additional input preserves consistency.)

If R_f is a completed leaf not in T, then the algorithm has erred, contradicting the assumption that algorithm A implements T without erring. Otherwise, R_f is non-t-founded due to possibility (A). This means that R_f has less than α non-t-equivalent sons. As $\alpha \leq t+1$, we know that at most t processors can be associated with a (consistent) t-advancement from R_f (Definitions 11 and 7). Denote the set of these processors by C_f.

For every output that is consistent for R_f (Definition 4) there exists a consistent son of R_f which includes this output. Therefore, in the concluding phase when it holds that $n - t$ processors have already terminated (due to the second invariant), the fact that there are fewer than α processors able to make a t-advancement implies that the number of these processors is smaller than the number of active processors ($\alpha = min\,(t+1\ ,\ n - |B_k|)$, Definition 11). It follows that there exists at least one additional active processor (not in C_f) which cannot give a consistent output. Our adversary scheduler will activate all the processors not in C_f. Since the algorithm is t-resilient, one of the remaining (activated) processors must give an output within a finite expected number of steps. However, this processor's output is not consistent (the processor is not in C_f). This means that with this output, the system is at an inconsistent state and therefore (by Definition 4) there is an input that the scheduler can give the system for which it will err.

We have shown that the scheduler can force the system to advance along a sequence of non-t-founded nodes, and hence we have arrived at a contradiction in every possible case. This proves the $\Rightarrow$ direction of the theorem.

Now we will prove the $\Leftarrow$ direction; namely, if the root of the DAG corresponding to T is t-founded, then T is a t-resilient task. This is proven by presenting a generic t-resilient algorithm which implements T. In this algorithm, every processor will publish (in a shared register that the rest of the processors can read) its input as soon as it reads it and will also publish the output that it has chosen just before writing it in the output register. The frame of this algorithm will be a walk along a path in the DAG starting at its root, proceeding according to the inputs revealed and the produced outputs, and ending at a legal leaf that represents a full $2k$-tuple in T. This walk is executed commonly by all processors, and the way to achieve this is by applying consensus to every move.

There is a certain difference between the use of the DAG in this direction and its use in the previous direction. While in the first direction the current node represented the system's current state, in this direction the node represents a state the system "aspires" to. If a certain node, v, was agreed upon, it means that v represents input values that were published. However, not all the output values in v have necessarily been decided upon (and published) because they could belong to dormant processors. Such outputs will be decided upon and published by the respective processors when they are activated.

The algorithm we present uses as a subroutine an *extended consensus* protocol. This protocol allows consensus among processors when some of the participating processors do not offer a value but rather adopt one of the values offered by other processors. Processors that do not suggest values for the extended consensus protocol are called *passive processors* while processors that do offer a value for the extended consensus protocol are called *agile processors*. Given an $n-1$ resilient consensus protocol, and allowing β passive processors, we can build a $n-1-\beta$-resilient extended consensus protocol as follows:

- An agile processor will publish its offered value in a shared register and then proceed to execute the wait-free consensus protocol.
- A passive processor will wait until some agile processor suggests a value, adopt that value as its own, and then join the execution of the wait-free consensus protocol.

The algorithm will be carried out in "virtual rounds." In round $r+1$ each processor starts with node v_r, the t-founded node (in the DAG) that was agreed upon in round r (via consensus). Each processor then proceeds to pick, according to the DAG, a son of v_r representing a $2k$-tuple, S_{i+1}. This node, u_r, is a t-subsequent of v_r, is t-founded, and includes the processor's new input, if such an input is available (i.e., P_i has not yet published its jth input even though it has given its $(j-1)$st output). If the system is in the concluding phase and no such node, u_r, exists, the processor P will look for a t-founded son of v_r that includes an additional output for P. The processor proposes the node it has found to the rest of the processors to agree upon. Then, the processors run consensus to agree on one of the proposed options. Since the option includes outputs (not necessarily outputs of the originating processor, i.e., the one whose option was chosen), each processor now checks the agreed node to see if it is required to output a value. Each of the relevant processors will output its required value immediately after receiving the result, v_{r+1}, of the $(r+1)$st consensus. The processor then proceeds to the next virtual round. Formally the algorithm for processor P_i is as follows:

```
INIT:
  $v_r \leftarrow$ root(DAG).          /* $v_r$ is the current node in virtual round number $r$ */
  $a \leftarrow 1$                                      /* $a$ holds $P_i$'s current stage */
  $r \leftarrow 1$                                                    /* round counter */
  $in_i \leftarrow input$

VIRTUAL ROUNDS:
  do while $a \le k$
    denote $v_r$'s components by $< I^1_{A_1}, \dots, I^k_{A_k}, O^1_{B_1}, \dots, O^k_{B_k} >= v_r$
      if there exists $u_r =< I^1_{A'_1}, \dots, I^k_{A'_k}, O^1_{B'_1}, \dots, O^k_{B'_k} >$ s.t.
        $u_r$ is a son of $v_r$ and $u_r$ is $t$-founded
        and
          ( either
              $I^a_{A'_a} = I^a_{A_a} \cup \{in_i\}$     /* main or concluding phase - $in_i$ is $P_i$'s input */
              and $A'_j = A_j \;\; j \ne a$
              and $B_j \subseteq B'_j \;\; \forall j$
          or
              $B'_a = B_a \cup \{i\}$               /* concluding phase - only another output */
              and $B'_j = B_j \;\; j \ne a$
              and $A'_j = A_j \;\; \forall j$
          )
        then $v_{r+1} \leftarrow extended\text{-}consensus(u_r, r)$
        else $v_{r+1} \leftarrow extended\text{-}consensus(passive, r)$
      if $i \in B'_a$                     /* an additional output of $P_i$ was decided upon */
        then
          output($O^a_{\{i\}}$)                          /* output the corresponding value */
          if $a = k$
            then terminate
          $a \leftarrow a + 1$
          $in_i \leftarrow input$
      $r \leftarrow r + 1$
    end                                                              /* of while */
```

The different consensus rounds are separate and use separate sets of registers. We will use a multivalue consensus protocol with the addition of "passive inputs" (belonging to passive processors). The requirement from the protocol is that its output will be the input of one of the agile processors. Any known wait-free protocol for consensus (e.g., [1, 2, 9, 26]) can easily be modified to comply with this requirement. Notice that if up to β processors can be passive in a given round, then the modified consensus protocol is $(n-\beta-1)$-resilient. In the concluding phase, it is possible that the processors that have missing inputs are faulty, and so every remaining processor must be able to advance on its own (without waiting for values offered by other processors).

Let us now prove that the given algorithm is correct and t-resilient. According to the remark from the end of section 4, following a t-founded path leads to a leaf in T. This means (by the definition of a t-founded leaf in Definition 11) that the outputs given by the system match the inputs it received, according to the task T. Hence the algorithm always gives correct outputs for any legal input. As every call to the consensus subroutine takes bounded expected time, and the other operations are finite, within bounded expected time the algorithm will terminate. Therefore the algorithm is correct.

To show t-resiliency we will show that the system can always advance (even if t processors have failed, as long as some processor is active), i.e., there will always be an agile processor that can find a u_r as required. Notice that v_r is always t-founded (the root is t-founded by the assumption, and only t-founded nodes are chosen by the algorithm during the execution). Also, for a given node, the number of passive processors is less than $n-\alpha$ as at least α processors can find a u_r as required. Now let us show that there are indeed enough agile processors. We will do this for two different cases, according to the phase that the system is in:

- In the main phase and in the concluding phase when less than $n-t$ processors have terminated, $\alpha = t+1$. Therefore, even if t processors have failed, there exists at least one additional processor that can make a t-advancement from this t-founded node. This processor will be agile in the consensus round for v_r and thus the extended consensus will be computed (in bounded expected time) in this round.
- In the concluding phase when $n-t$ processors have already terminated, α equals the number of not-yet-terminated processors. Therefore, every processor that has not yet terminated and will be activated can find a u_r as required. Such a processor will be agile in the respective extended consensus round.

Altogether, we have shown that for every node on the path there are enough processors that can make a t-advancement from it. Thus, the algorithm is t-resilient, as claimed. ▯

6. Characterization for message passing. In this section we will examine the resiliency of interactive tasks in the message passing model, where it is possible to perform t-resilient consensus only for $t \leq \left\lfloor \frac{n-1}{2} \right\rfloor$. In the terminating message passing model a processor terminates after giving its final output. After $n-t$ processors have terminated, the remaining t processors could be disconnected from each other by the scheduler, and thus will have no way of "coordinating" amongst themselves. The disconnection is possible since all t processors might be faulty and so no processor can wait for a message from another processor. (Recall that in an asynchronous system the processors have no way of distinguishing between a slow and a faulty processor.) Each of the t slow processors will know what the fast $n-t$ processors have decided but will have no way of knowing what any one of the other slow processors has decided. In order for a task to be t-resilient, the slow processors must be able to decide on their value in a "consistent" manner, each without knowing the others' decisions. Notice that a particularly slow processor may be at the beginning of its work, i.e., it has not yet read even its first input. Such a processor must be able to function correctly through *all* the stages of the task. Following these considerations, we focus on nodes in the DAG, $D(T)$, that have at least $n-t$ outputs of the final stage revealed. We call these nodes *semiterminal* nodes. In these nodes each additional input *or* output is considered a t-advancement (by Definition 6). Notice that for semiterminal nodes we require at least $n-t$ *outputs* of the final stage, while in the concluding phase we required only $n-t$ *inputs* of the final stage.

DEFINITION 12. *A tree R_i that is a subgraph of $D(T)$ will be called* terminal *for P_i if the following conditions hold:*

- *The root of R_i, $v=[S,Q]$ where $S=\langle A_1 , \dots , A_k , B_1 , \dots , B_k\rangle$ and $Q=\langle I^1_{A_1}, \dots, I^k_{A_k}, O^1_{B_1}, \dots, O^k_{B_k}\rangle$, is a semiterminal node ($|B_k|\geq n-t$) such that $i\notin B_k$. (Processor P_i has not yet terminated.)*
- *Let ℓ denote the last stage for which P_i gave an output. When we look at the inputs and outputs for processor P_i, the following condition holds: For every input for the $(\ell+1)$st stage there is an output for the $(\ell+1)$st stage such that for every input for the $(\ell+2)$nd stage there is ... for every input for the kth stage there is an output for the kth stage such that the t-advancements corresponding to these inputs and outputs form a path in R_i. In the case that the $(\ell+1)$st input is already given in v, then the condition starts with the existence of an output for the $(\ell+1)$st stage such that for every input for the $(\ell+2)$nd stage, etc.*

Intuitively, the tree R_i represents a possible strategy for P_i to react to every possible sequence of inputs presented to it, when the system is at the state represented by the root, v. The next definition captures the requirement that terminal trees of different processors should be compatible.

DEFINITION 13. *Let v be a semiterminal node and let $\{i_1,\dots,i_j\}=\{1,\dots,n\}\backslash B_k$ (i.e., the set of processors that have not yet terminated in v). Let $R_{i_1},\dots,R_{i_j}$ be j terminal trees for processors $P_{i_1},\dots,P_{i_j}$, respectively. These trees are called T-compatible if the following conditions hold:*

- *$R_{i_1},\dots,R_{i_j}$ have the same semiterminal root v:*
  $v=[\langle A_1 , \dots , A_k , B_1 , \dots , B_k\rangle,\langle I^1_{A_1} , \dots , I^k_{A_k} , O^1_{B_1} , \dots , O^k_{B_k}\rangle]$.
- *For every $\langle I^1,\dots,I^k\rangle\in IN(T)$ which is an extension of $\langle I^1_{A_1},\dots,I^k_{A_k}\rangle$, the outputs produced along the set of paths (one path per tree) that correspond to this input give a full output vector $\langle O^1,\dots,O^k\rangle$ such that $\langle I^1,\dots,I^k, O^1,\dots,O^k\rangle\in T$ and $\langle O^1,\dots,O^k\rangle$ is an extension of $\langle O^1_{B_1} , \dots , O^k_{B_k}\rangle$.*

We use these definitions to describe our "building block," t-validity. It will play the role that t-foundedness played in the shared memory model (section 5).

DEFINITION 14. *Let*

$$v=[\langle A_1 , \dots , A_k , B_1 , \dots , B_k\rangle,\langle I^1_{A_1} , \dots , I^k_{A_k} , O^1_{B_1} , \dots , O^k_{B_k}\rangle]$$

be a node in the DAG $D(T)$, and let $\alpha=min\,(t+1 , n-|B_k|)$. We say that v is t-valid *relative to the task T when*

- *The node v is a leaf ($v=[\langle\{1,\dots,n\}_1 , \dots , \{1,\dots,n\}_{2k}\rangle, \langle I^1,\dots,I^k, O^1,\dots,O^k\rangle]$), and $\langle I^1,\dots,I^k,O^1,\dots,O^k\rangle\in T$;*

or

- *The node v is an internal node (not a leaf) and the following conditions hold:*
  1. *v has at least α non-t-equivalent sons.*

2. *For every t-subsequent, u, of v there exists an input-equal node u' that is a t-valid son of v.*
3. *If v is semiterminal, then for every $i \notin B_k$ there exists a terminal tree, R_i, for P_i, such that the trees $\{R_i\}_{i \notin B_k}$ are T-compatible. We will call one of these sets, say, the first in canonical order that complies with the above condition, the* chosen set *for v, denoted by $ch(v)$.*

The characterization theorem is formulated in the same way as Theorem 1, but the different definitions of t-foundedness versus t-validity make the difference between the shared memory and the message passing models. The additional requirement (3) explains why certain tasks, solvable in the shared memory model, cannot be solved in the message passing model.

THEOREM 2. *Consider the terminating message passing model, and let t satisfy $t \leq \lfloor \frac{n-1}{2} \rfloor$. An interactive$_k$ task, T, is t-resilient iff the root of its corresponding DAG is t-valid relative to T.*

Proof. The proof follows the proof of Theorem 1 closely. The differences between these proofs are due to the nature of the communication model. For the $\Rightarrow$ direction, we use an algorithm which, starting at a t-valid node, proceeds along a path of t-valid nodes until a semiterminal node is reached. The algorithm uses an *extended consensus* subroutine (see proof of Theorem 1) which guarantees that all the processors agree on the same nodes along the path. In the message passing model, the resiliency of the extended consensus protocol is $min(\lfloor \frac{n-1}{2} \rfloor, n-1-\beta)$, where β is an upper bound on the number of passive processors (processors that take part in the consensus protocol but do not suggest a value). In our algorithm, no processor terminates before a semiterminal node is reached. That is, no processor writes its final (kth) output before a node which includes the final outputs of at least $n-t$ processors has been agreed upon. This precaution guarantees that at least $n-t$ processors remain active throughout the main phase of the algorithm. This number is large enough to enable each round of the extended consensus algorithm to terminate, as there is at least one agile processor in each round, and at least $\lfloor \frac{n+1}{2} \rfloor$ processors take part in the sequence of consensus executions until a semiterminal node is reached and agreed upon.

We associate with every t-valid semiterminal node, v, its chosen set, $ch(v)$ (the existence of this set follows from Definition 14). Once the system reaches and agrees upon such a semiterminal node, all processors P_i with $i \in B_k$ can produce their final output and terminate. Each remaining processor can now produce a local output as a response to every new local input it receives by proceeding along the corresponding path in its tree. This requires no communication and coordination with the remaining processors. The compatibility of the terminal trees guarantees that this process leads to a leaf satisfying the input-output relations of the task T. In order to simplify the algorithm, we will use a pruned DAG, denoted by $D'(T)$. This DAG will be the same as D(T) for all nodes that are not semiterminal. For semiterminal nodes, $D'(T)$ will include only their chosen set. That is, for semiterminal node v, $D'(T)$ will include only $ch(v)$ (and not other alternative advancements from v). The algorithm will run on $D'(T)$ rather than $D(T)$.

Formally, the algorithm for P_i is as follows.

```
INIT:
  $v_r \leftarrow$ root($D'(T)$).          /* $v_r$ is the current node in virtual round number $r$ */
  $a \leftarrow 1$                                          /* $a$ holds $P_i$'s current stage */
  $r \leftarrow 1$                                                        /* round counter */
  $in_i \leftarrow input$
```

```
VIRTUAL ROUNDS:
 do while $a \leq k$
   denote $v_r$'s components by $< I^1_{A_1}, \ldots, I^k_{A_k}, O^1_{B_1}, \ldots, O^k_{B_k} >= v_r$
     if there exists $u_r =< I^1_{A'_1}, \ldots, I^k_{A'_k}, O^1_{B'_1}, \ldots, O^k_{B'_k} >$ s.t.
       $u_r$ is a son of $v_r$ and $u_r$ is $t$-valid
       and
         ( either
             $I^a_{A'_a} = I^a_{A_a} \cup \{in_i\}$          /* main phase - $in_i$ is the new input */
             and $A'_j = A_j$  for all $j$, $j \neq a$
             and $B_j \subseteq B'_j$ for all $j$
         or
             $B'_a = B_a \cup \{i\}$          /* concluding phase - only another output */
             and $B'_j = B_j$ for all $j$, $j \neq a$
             and $A'_j = A_j$ for all $j$
         )
       then if $|B_k| < n - t$/* consensus is possible until $n - t$ processors terminate */
             then $v_{r+1} \leftarrow extended - consensus(u_r, r)$
             else $v_{r+1} \leftarrow u_r$        /* no consensus - proceed along terminal tree */
       else $v_{r+1} \leftarrow extended - consensus(passive, r)$   /* this case is only possible
                                                                   in the main phase */
     if $i \in B'_a$                 /* an additional output of $P_i$ was decided upon */
       then (if $a < k$
           then
             output($O^a_{\{i\}}$)                  /* output the corresponding value */
             $a \leftarrow a + 1$
             $in_i \leftarrow input$
           elseif $|B'_k| \geq n - t$
             then
               output($O^a_{\{i\}}$)                /* output the corresponding value */
               terminate
     $r \leftarrow r + 1$
   end                                                              /* of while */
```

The consensus protocol used by the extended consensus must be $\lfloor \frac{n-1}{2} \rfloor$-resilient and terminating. The different consensus rounds are separate and use separate message numbers. (Any consensus protocol that complies with these requirements can be used as a subroutine. Examples of such consensus protocols are [7, 6]). Notice that passive processors are counted for the number of processors participating in the consensus as they can "help out." However, at least one agile processor must participate in the consensus (to suggest the next value). There will always be such a processor for the same reasons as in the shared memory model (in the main phase at least $\alpha = t+1$ processors can find the required u_r as the current node is always t-valid, and in the concluding phase there is no need for consensus).

The $\Leftarrow$ direction is also similar to the shared memory case. As in Claim 1, we can assume that the algorithms used are immediate input algorithms. (The proof for the message passing model is identical to that of the shared memory case.) We present a scheduler that forces the system to always remain in a non-t-valid node. By Definition 14, the possible cases at node v (which is non-t-valid) are

0. v is a non-t-valid leaf;
1. v has less than α non-t-equivalent sons;
2. v has a t-subsequent, v_1, such that for every u' that is input-equal to v_1 and is a son of v, it holds that u' is *non-t*-valid;
3. v is semiterminal and one of the following is true:
   (a) There exists $i \notin B_k$ for which there is no terminal tree rooted at v.
   (b) Every collection of terminal trees $\{R_i\}_{i \notin B_k}$ rooted at v is not compatible.

As in the shared memory model, let us assume toward a contradiction that there exists a t-resilient immediate-input algorithm for T. We will start at the root of the DAG and the processors will follow this algorithm. As long as the node representing the system's current state, v, is non-t-valid due to possibility 2, the scheduler forces the processors to advance to a state represented by u' that is input-equal to v_1. This will continue until we reach a node v_f that is non-t-valid either due to possibility 1 or possibility 3 or because v_f is a non-t-valid leaf. If v_f is non-t-valid due to possibility 1 or is a leaf, then for exactly the same reasons as in the proof for the shared memory model we have shown a contradiction.

It remains to show that the other alternative (non-t-validity due to possibility 3) also leads to contradiction. The first case is when there exists an i for which there is no terminal tree. By Definition 12, this means that there exists a strategy for the scheduler (supplying inputs) such that every strategy for the processor P_i leads to a partial $2k$-tuple which is not a partial vector of any full $2k$-tuple in T. This contradicts the correctness of the algorithm.

The second case is when each selection of terminal trees is not compatible (i.e., every set of terminal trees, one for each active processor, is incompatible). In this case the scheduler activates these active processors and withholds all messages sent between them. Now each one must act on its own. Let us now show that there is a strategy for the scheduler which causes the processors to err with positive probability. In order to do that we will construct one set of terminal trees for all the remaining active processors, using a "roll-back" technique. The construction starts with the system at the state in which it arrived at the semiterminal node v. Now for every processor P_i where $i \notin B_k$, the tree T_i is built recursively, as follows: For every node, u, in the tree (starting the recursion at v), the scheduler determines the son by presenting the processor P_i with a legal input at u and the grandson by activating P_i until it produces an output (which must happen within bounded time, by the requirements of t-resilient algorithms). The process is repeated in the next recursion level, with respect to the grandson. To determine the continuation from u with respect to other inputs, the scheduler "rolls back" the system to the same state it was in u and then supplies another input. This process is done with respect to every legal input for P_i at u. The end of the recursion along each path is when P_i supplies its last (kth) output.

This process builds a set of terminal trees. Every branch along each tree represents a strategy for the corresponding processor, which is used with positive probability. Probabilities of different processors are independent, since their random inputs are independent, and the processors cannot communicate. By our assumption, the terminal trees are incompatible. Therefore, there exist input sequences (one per processor) such that the output sequences resulting by following the corresponding trees yield a full input-output $2k$-tuple that is not in T. The scheduler will supply these inputs and then the processors will give incorrect answers (due to the definition of incompatible terminal trees) with positive probability. This contradicts the assumption that the algorithm implements T with no error. Therefore the condition in the theorem is necessary. $\square$

7. Concluding remarks. Denote by REF the class of randomized error-free protocols and by DC the class of deterministic protocols with access to consensus. Since consensus has wait-free REF solution, it follows that any finite interactive task solvable in the DC model is also solvable in the REF model. The proof of Theorems 1 (for the shared memory model) and 2 (for the message passing model) implies that any finite interactive task solvable in the REF model is also solvable in the DC model. Stated formally, we have the following theorem.

THEOREM 3. *Consider the following two families of protocols:*

- *deterministic protocols with access to consensus (DC),*
- *randomized error-free protocols (REF).*

An interactive$_k$ task T is t-resilient in the DC family iff it is t-resilient in the REF family, where the range of t is

- $0 \leq t \leq n-1$ *in the terminating shared memory model,*
- $0 \leq t \leq \left\lfloor \frac{n-1}{2} \right\rfloor$ *in the terminating message passing model.*

Results concerning the structure of the "resiliency hierarchy" in both the shared memory and the message passing models can easily be inferred from our characterizations. They extend similar results for decision tasks, proven by Chor and Moscovici in [13]. Some of these implications are as follows:

- Shared memory is strictly more powerful than message passing for the same resiliency (except at the two lowest resiliencies): $IMP_t \subsetneq ISM_t$ $(1 < t < n)$, while $IMP_0 = ISM_0$ and $IMP_1 = ISM_1$.
- With respect to difference resiliencies, message passing and shared memory, namely IMP_t and ISM_{t+i}, are incompatible for $0 < i < n-t$. (The results in [13] already prove this.)
- In the range of resiliency where network partition is not possible ($t \leq \left\lfloor \frac{n-1}{2} \right\rfloor$), *nonterminating* protocols in the shared memory and message passing models have the same capabilities: namely, nonterminating $IMP_t =$ nonterminating $ISM_t = ISM_t$. For t in the range $\frac{n}{2} \leq t \leq n-1$, nonterminating $ISM_t = ISM_t$.

7.1. Related work. Bar-Noy and Dolev [6], and consequently Attiya, Bar-Noy and Dolev [4], have investigated emulation strategies of shared memory in nonterminating message passing systems. One consequence of their work is that $ISM_{n-1} \subseteq$ nonterminating $IMP_{\left\lfloor \frac{n-1}{2} \right\rfloor}$. In fact, their construction yields the stronger result $ISM_{\left\lfloor \frac{n-1}{2} \right\rfloor} \subseteq$ nonterminating $IMP_{\left\lfloor \frac{n-1}{2} \right\rfloor}$. However, no characterization can be derived from their techniques. Also, it is not clear if their "local" approach can be extended to yield the equality between these classes (which does follow from our characterization).

Plotkin [23] and Herlihy [17] have studied the implementation of concurrent objects in the shared memory model. They have shown that every sequential system has a concurrent wait-free implementation, given access to a wait-free consensus subroutine. We note that our results give a natural way to implement finite versions of concurrent objects, and so they shed light on the use of randomization for wait-free concurrent objects. In fact, the concurrent objects in [17] refer to $t = n-1$ (wait-free objects) while interactive tasks can implement a wider range of fault-tolerance.

Taubenfeld, Katz, and Moran [28] and Taubenfeld and Moran [29] have studied a weaker type of crash failures—initial faults. In the initial faults model, each processor either is initially crashed or remains active forever. Taubenfeld, Katz, and Moran found necessary and sufficient conditions for solvability of distributed *decision* tasks with respect to deterministic protocols in the initial fault message passing and shared memory models. Surprisingly, the characterization is the same as the one for general crash faults using randomized protocols [13]. Indeed, these equalities no longer remain valid when interactive, rather than decision, tasks are considered. This is due to the scheduler's limited powers in the initial faults model. Therefore, it is not surprising that there are interactive tasks that are t-resilient in the initial fault model but are not t-resilient for general crash faults. As an example, consider the following interactive$_2$ task: Inputs for both stages are all binary n-vectors. The value in each component of the first output equals the sum of the first inputs over some subset S of size $n - t$ (the subset is not predetermined). The value in each component of the second output equals the sum of the second inputs over the *same* subset S. It is easily seen that this task is resilient to t *initial* faults but is not in ISM_t since in ISM_t the scheduler can fail a previously active processor, thus leaving the second input unknown. This confirms the intuition that initial faults alone are not sufficient to represent a realistic fault model. (In the other direction, every task in ISM_t can be solved in a system with at most t crashes that can implement a consensus subroutine. Since consensus is solvable deterministically in the initial faults model, this implies that ISM_t is strictly contained in the class of t initial faults.)

The modular way in which consensus is used implies that our characterization is also a sufficient condition for t-resilience in *deterministic* systems augmented with *stronger* mechanisms that make consensus possible, for example, the failure detectors of Chandra and Toueg [10]. However, the question whether our conditions are also necessary requires a closer look. For example, suppose one has at his possession an accurate and reliable failure detector. If the detector announces that a processor has crashed, then we are guaranteed this processor will not become active later. In such a case we may be able to solve a natural modification of, for example, the parity task. We assign $\perp$ as the input of processors that crashed before supplying an input, and the $\perp$ values do not influence the output. Under such conditions, the parity is no longer unsolvable in the presence of one failure. This example implies that exact characterization of resilience in the presence of failure detectors strongly depends on the specific properties of the detector.

Despite substantial differences, there is a common feature to the initial faults model and the one with strong failure detectors. In both, the power of the adversary is severely restricted, further than what is "needed" to enable deterministic consensus. Any task which satisfies our characterization for t-resilience will also be t-resilient in these restricted adversary models. But whether the condition is also necessary crucially depends on the strength (or weakness) of the adversary.

Acknowledgments. Thanks to Hagit Attiya and Oded Goldriech for helpful discussions and suggestions and for their comments on earlier versions of this manuscript, to Moshi Molcho for his help and support, and to the anonymous referees for helpful comments.

WEAKLY TRIANGULATED COMPARABILITY GRAPHS[*]

ELAINE ESCHEN[†], RYAN B. HAYWARD[‡], JEREMY SPINRAD[§], AND R. SRITHARAN[¶]

Abstract. The class of weakly triangulated comparability graphs and their complements are generalizations of interval graphs and chordal comparability graphs. We show that problems on these classes of graphs can be solved efficiently by transforming them into problems on chordal bipartite graphs. We show that recognition and independent set on weakly triangulated comparability graphs can be solved in $O(n^2)$ time in this manner, and that the number of weakly triangulated comparability graphs is $2^{\Theta(n\log^2 n)}$. We also give algorithms to compute transitive closure and transitive reduction in $O(n^2\log\log n)$ time if the underlying undirected graph of the transitive closure is a weakly triangulated comparability graph.

Key words. weakly triangulated, comparability, partial orders, algorithm

1. Introduction.

A variety of interesting graph classes correspond to requiring that the graph and/or its complement be a triangulated or a comparability graph. For example, permutation graphs are equal to graphs which are both comparability and cocomparability graphs, split graphs correspond to triangulated cotriangulated graphs, and interval graphs are exactly the chordal cocomparability graphs. These two properties are one of the themes which unify Golumbic's book on perfect graph classes [17]. We extend the study of the intersection of pairs of properties by generalizing from triangulated graphs to weakly triangulated graphs.

Triangulated graphs [28], also known as chordal graphs, are those graphs which contain no induced cycles of length greater than three. Weakly triangulated graphs allow induced four-cycles but do not allow any induced cycles of length greater than four in either the graph or its complement. We refer to an induced cycle of length five or more as a *hole*. We refer to the complement of a hole as an *antihole*. Weakly triangulated graphs properly contain chordal graphs and are a subclass of perfect graphs [18]. The fastest known recognition algorithm for weakly triangulated graphs takes $O(n^4)$ time [30]. The best algorithms for clique, independent set, chromatic number, and clique cover on weakly triangulated graphs also take $O(n^4)$ time [19, 3].

Comparability graphs [16], also known as transitively orientable graphs, are undirected graphs with the property that directions can be assigned to edges in such a way that whenever there is an edge from x to y and from y to z in the directed graph, there is also an edge from x to z. This assignment of direction to edges is called a

transitive orientation. Comparability graphs are also a subset of perfect graphs. The fastest known recognition algorithm for comparability graphs has two distinct stages. It is possible to find an orientation which is transitive if and only if the input is a comparability graph in $O(n+m)$ time [25]. However, it is not known how to determine whether this orientation is actually transitive faster than performing a matrix multiplication, for which the current asymptotically fastest algorithm takes $O(n^{2.376})$ time [7]. There are $O(n+m)$ algorithms for clique and chromatic number [17, 25] on comparability graphs, if a transitive orientation is given. Maximum independent set on comparability graphs is essentially equivalent to bipartite matching [13], for which the best known algorithms have complexities of $O(n^{1.5}\sqrt{m/\log n})$ [2] and $O(\frac{n^{2.5}}{\log n})$ [11].

One of the most famous classes of intersection graphs is the class of interval graphs [4, 5]. A graph G is an interval graph if and only if both G is a chordal graph and the complement of G is a comparability graph [16]. Since weakly triangulated graphs are a natural generalization of triangulated graphs, we are interested to see whether the weakly triangulated cocomparability graphs are well behaved. Since weakly triangulated graphs are closed under complementation, this class is exactly the complement of weakly triangulated comparability graphs.

Weakly triangulated comparability graphs generalize the triangulated comparability graphs, studied in [23]. We note that both triangulated comparability graphs and triangulated cocomparability graphs can be recognized in linear time, which is faster than the algorithm obtained by separately testing whether G is triangulated and whether G is comparability/cocomparability. For weakly triangulated comparability and weakly triangulated cocomparability graphs, we give recognition algorithms which are faster than testing either whether G is weakly triangulated or whether G is a comparability/cocomparability graph.

Another class contained in the weakly triangulated comparability graphs is the class of permutation graphs [17]. This follows from the fact that cocomparability graphs cannot contain induced cycles of length greater than four [15], and permutation graphs are equal to graphs which are both comparability and cocomparability graphs.

Both the classes of comparability graphs and triangulated graphs contain $2^{\Theta(n^2)}$ graphs on n vertices, but the classes of triangulated comparability graphs and triangulated cocomparability graphs contain $2^{\Theta(n\log n)}$ graphs on n vertices. We show that the number of weakly triangulated comparability graphs on n vertices is $2^{\Theta(n\log^2 n)}$, which makes this class much smaller, for example, than the triangulated cotriangulated graph class, which has $2^{\Theta(n^2)}$ members.

The primary method used here to design efficient algorithms for weakly triangulated comparability graphs is to convert them into bipartite graphs and use the property that this transformation yields a chordal bipartite graph. The ideas are similar to those used in recognizing circular-arc graphs [10] and trapezoidal graphs [24] efficiently. Chordal bipartite graphs, studied in [21], are bipartite graphs in which every cycle of length greater than four has a chord. The bipartite adjacency matrix of a graph is the 0/1 matrix formed by making one color class the rows, the other color class the columns, and placing a 1 at row x column y if and only if (x,y) is an edge of G. A 0/1 matrix has a Γ if there is some pair of rows $r_1 < r_2$ and columns $c_1 < c_2$ such that $(r_1,c_1) = (r_1,c_2) = (r_2,c_1) = 1$, while $(r_2,c_2) = 0$. The crucial theorem for this paper is that a graph is chordal bipartite if and only if the rows and columns of the bipartite adjacency matrix can be permuted to form a Γ-free matrix, and this ordering can be found in $O(m\log n)$ or $O(n^2)$ time [21, 27, 32].

2. Recognition. Let G be an arbitrary directed graph. Consider the undirected bipartite graph G' formed by making two copies x_1, x_2 of each vertex x and adding an edge from u_1 to v_2 if and only if there is an edge from u to v in G. We will call G' the *bipartite transformation* of G. Identical constructions have been made frequently; the most closely related work that uses this construction is due to Ford and Fulkerson [13], who use it for solving the independent set problem on partially ordered sets.

THEOREM 1. *If G is a transitively oriented graph, then the underlying undirected graph of G is weakly triangulated if and only if the bipartite transformation G' of G is chordal bipartite.*

Proof. First, we note that complements of comparability graphs cannot have induced cycles of length greater than four [15]. Thus, we do not have to be concerned with long antiholes in the underlying undirected graph of G.

Suppose that the underlying undirected graph of G is weakly triangulated. Consider a chordless cycle C of length at least six in G'. There cannot be a vertex x such that both x_1 and x_2 are in C; otherwise, there would be edges (y_1,x_2) and (x_1,u_2) in C, where $u_2 \neq y_2$ and (y_1,u_2) is not in C, and thus transitivity in G would imply that C has the chord (y_1,u_2). If x_1 and y_1 are both in C, then there cannot be an edge from x to y in G; otherwise, since G is transitively oriented, the neighborhood of x_1 would contain the neighborhood of y_1, and the vertices could not be part of the same chordless cycle. Similarly, if x_2 and y_2 are both in C, then there cannot be an edge from x to y in G. There cannot be any nonadjacent vertices u_1, v_2 in C such that there is an edge from v to u in G; otherwise, the edge (w_1,v_2) of C would imply an edge from w to u in G. Therefore, any chordless cycle C of G' corresponds to a chordless cycle of the same length in the underlying undirected graph of G; if the underlying graph of G is weakly triangulated, then G' must be chordal bipartite.

Suppose that G' is chordal bipartite. Let C be a chordless cycle in the underlying undirected graph of G. No vertex of C can have an edge directed to vertex u of C and an edge directed into it from vertex v of C, since v would have an edge to u by transitivity of the orientation. Let 1 be a vertex of C with edges directed to other vertices of C. If the cycle is $1, 2, \ldots, k$, then $1, 3, \ldots$ have edges directed outward with respect to other vertices of C, while $2, 4, \ldots$ have edges directed towards them. There will be a chordless cycle $1_1,\ 2_2,\ 3_1,\ 4_2, \ldots,\ (k-1)_1, k_2, 1_1$ in G', contradicting our assumption that G' is chordal bipartite. $\square$

Theorem 1 immediately reduces the complexity of weakly triangulated comparability graph recognition to the time of comparability graph recognition and orientation plus the time of chordal bipartite graph recognition. Since comparability graphs can be recognized and transitively oriented in $O(n^{2.376})$ time using matrix multiplication [31], and chordal bipartite graphs can be recognized in $O(n^2)$ time [21, 27, 32], we have an $O(n^{2.376})$ algorithm for recognizing weakly triangulated comparability graphs. If fast matrix multiplication is not desired due to its complexity, we get an $O(n^3)$ recognition algorithm. These time complexities are an improvement over existing algorithms, since the best known algorithms for recognizing weakly triangulated graphs take $\Theta(n^4)$ time [30].

However, we can improve on these time bounds using properties of the comparability graph recognition algorithm. It is possible to find a transitive orientation of a comparability graph in $O(n+m)$ time [25]; the reason that this does not give a linear time algorithm for recognizing comparability graphs is that the algorithm will assign some direction to edges, even if no transitive orientation is possible. Therefore, we will use the following strategy for recognizing weakly triangulated comparability graphs.

We find an orientation of the graph which is transitive if and only if the graph has a transitive orientation. We determine whether the bipartite transformation of the directed graph is chordal bipartite; if not, then we know that G is either not a comparability graph or G is not weakly triangulated. We then use properties of chordal bipartite graphs, and use the bipartite transformation to verify that the orientation is transitive. If the orientation is transitive, we use Theorem 1 to answer that G is a weakly triangulated comparability graph.

We construct a Γ-free ordering of the bipartite transformation, which can be done in $O(n^2)$ time [32]. Algorithms for constructing a Γ-free ordering work by using a technique called doubly lexical ordering of the matrix. Details of the procedure are not important to this paper, but if the neighborhood of a vertex x properly contains the neighborhood of vertex y, then doubly lexical ordering guarantees that the column or row corresponding to x comes after the column or row corresponding to y in the Γ-free ordering of the bipartite adjacency matrix.

THEOREM 2. *Suppose that the bipartite transformation of a directed graph G gives a chordal bipartite graph G'. We can determine whether G is transitive in* $O(n^2)$ *time.*

Proof. For each pair of vertices x, y we can determine whether there is a transitivity violation $x \to y \to z$ in constant time. If x does not have an edge to y, clearly no such violation exists. So suppose there is an edge from x to y and x_1 comes before y_1 in the doubly lexical ordering of G'. There must be a vertex z such that $y \to z$ while x has no edge to z, or the neighborhood of y_1 would be properly contained in the neighborhood of x_1 (the containment is proper since x_1 has an edge to y_2 while y_1 does not), so we can immediately answer that G is not transitive. Now suppose that x_1 comes after y_1 in the ordering. Let z_2 be the first column of the Γ-free ordering of G' which has a 1 in row y_1. If x_1 does not have a 1 in this position, there is a transitivity violation $x \to y \to z$. If there is a 1 in this position, then there is no transitivity violation $x \to y \to u$, or the rows x_1, y_1 and columns z_2, u_2 would form a Γ. ◻

COROLLARY 3. *Weakly triangulated comparability graphs can be recognized in* $O(n^2)$ *time.*

Proof. Given a graph G, we find an orientation of the edges which is transitive if and only if G is a comparability graph using the algorithm of [25, 31]. We construct the bipartite transformation G' of the directed version of G. By Theorem 1, if G is in the class, then G' must be a chordal bipartite graph; we test this in $O(n^2)$ time using the algorithms in [21, 32]. If G' is chordal bipartite, we use Theorem 2 to test whether the orientation is actually transitive. If the orientation is transitive and G' is chordal bipartite, we use Theorem 1 to conclude that G is a weakly triangulated comparability graph. ◻

COROLLARY 4. *The number of weakly triangulated comparability graphs is* $2^{\Theta(n \log^2 n)}$.

Proof. Every chordal bipartite graph G is clearly a weakly triangulated comparability, since there are no induced cycles of length greater than four in G, and there cannot be any set of three vertices from a single color class in any hole of the complement. Any weakly triangulated comparability graph G can be reconstructed from the bipartite transformation of the transitive orientation of G, which is a chordal bipartite graph on $2n$ vertices. Therefore, the number of weakly triangulated comparability graphs on n vertices is some number between the number of chordal bipartite graphs on n vertices and the number of chordal bipartite graphs on $2n$ vertices. Since there are $2^{\Theta(n \log^2 n)}$ chordal bipartite graphs on n vertices [29], the result follows. ◻

3. Independent set, transitive closure, and transitive reduction. We know that there are polynomial algorithms for solving the clique, independent set, chromatic number, and clique cover problems on weakly triangulated comparability graphs, since such algorithms exist for these problems on both comparability graphs and weakly triangulated graphs. Clique and chromatic number can be solved in linear time on comparability graphs [17, 25], so we cannot hope to do better for these problems. Since these graphs are perfect, and the size of the largest independent set in G is equal to the clique cover number of G, we will consider only the independent set problem.

The best known algorithm for solving independent set on weakly triangulated graphs has time complexity $\Theta(n^4)$ [3, 19] and the best algorithm for computing the maximum independent set on comparability graphs has the same time complexity as finding a maximum matching in a bipartite graph [13], as described below. We show that this problem can be solved in $\mathrm{O}(n^2)$ time on weakly triangulated comparability graphs, as a simple consequence of Theorem 1. We note that it will be difficult to improve the time bound for independent set on general comparability graphs, since every bipartite graph is a comparability graph, and any improvement in the time complexity of computing maximum independent set on comparability graphs will improve the time complexity of computing the cardinality of a maximum matching in bipartite graphs.

The best algorithm for solving the independent set problem on comparability graphs is most easily phrased as solving the vertex cover problem on the class; to solve the maximum independent set problem, we simply take the vertices which are not part of the minimum vertex cover.

The algorithm for solving this problem takes a transitive orientation of the graph G, performs the bipartite transformation, and solves the vertex cover problem on the bipartite transformation G' using well known ideas for transforming bipartite vertex cover problem to bipartite matching problem. A vertex x is placed in the vertex cover of G if and only if either x_1 or x_2 is in the minimum vertex cover of G'; this will be the minimum vertex cover of G. The bottleneck step is solving the maximum matching problem on G'; the current best time bounds are $\mathrm{O}(n^{1.5}\sqrt{m/\log n})$ [2] and $\mathrm{O}(\frac{n^{2.5}}{\log n})$ [11].

For weakly triangulated comparability graphs, we make the same transformation, but instead of using a general matching algorithm we use the fact that G' is chordal bipartite, and use a simpler matching algorithm for G'. It is known that a maximum cardinality matching in a chordal bipartite graph can be found in linear time, given a Γ-free ordering of the bipartite adjacency matrix of the graph [6]. We include the algorithm here for the sake of completeness.

LEMMA 5. *The maximum cardinality matching problem on a chordal bipartite graph can be solved in* $\mathrm{O}(n^2)$ *time.*

Proof. We create a Γ-free ordering of the bipartite adjacency matrix for the chordal bipartite graph. We match the vertex corresponding to the first row with the vertex whose column corresponds to the first 1 entry in that row (if such a column exists), and delete that row and column. We then continue to the next row and repeat until all the rows and columns have been deleted. Consider any row r and column c which we choose for our matching. Suppose that we cannot choose to match these in a maximum cardinality matching that includes all previous matches. If r or c is unmatched in the optimal matching, then matching r with c cannot decrease the size of the matching. If r is matched with c_2 and c is matched with r_2, there must be an edge (r_2, c_2) or rows r, r_2 and c, c_2 induce a Γ. Therefore, we can match r with c and r_2 with c_2 and still get an optimum matching. ☐

COROLLARY 6. *The independent set problem can be solved in* $O(n^2)$ *time for weakly triangulated comparability graphs.*

Proof. Use Ford and Fulkerson's transformation [13] to reduce this to bipartite matching. Theorem 1 shows that this yields a chordal bipartite graph, and Lemma 5 lets us solve this problem in $O(n^2)$ time. ☐

Transitive closure is normally defined on a directed acyclic graph G; an edge from x to y is part of the transitive closure of G if there is a directed path of length ≥ 1 from x to y in G. The best algorithms known for general transitive closure involve matrix multiplication; relationships between matrix multiplication and transitive closure are examined in [12, 14, 26].

We will solve the transitive closure problem efficiently for any directed acyclic graph G with the property that the underlying undirected graph of the transitive closure is a weakly triangulated comparability graph. This problem can be solved in $O(n+m_t)$ time for chordal comparability graphs [23], where m_t is the number of edges of the transitive closure. We show that the problem can be solved in $O(n^2\log\log n)$ time for weakly triangulated comparability graphs.

The algorithm most closely resembles the algorithm for transitive closure of two dimensional partial orders [22]. The fundamental idea is to use divide and conquer. The set of vertices is partitioned into two sets S_1, S_2 of size $\frac{n}{2}$ with the property that no edge goes from S_2 to S_1; the transitive closure is solved recursively within each set. The key task is to add edges which are implied by transitivity from S_1 to S_2; this is done by using the fact that the transitive closures of the two pieces can be transformed to chordal bipartite graphs using the bipartite transformation.

LEMMA 7. *Suppose that G is a directed acyclic graph such that the underlying undirected graph is a weakly triangulated comparability graph. Assume that we are given the doubly lexical ordering of the bipartite transformation of G, and adjacency lists of each vertex ordered by column number in the ordering. Let x be a vertex which has edges to some vertices of G. We can find all edges out of x in the transitive closure of $\{x\} \cup G$ in* $O(n\log\log n)$ *time.*

Proof. Let $Y = y_1, y_2, \ldots, y_k$ be the vertices of G which have an edge from x. We place the vertices of Y in a priority queue, where the value associated with y_i is the column number of the first 1 in row y_i.

We repeatedly look at the vertex y_i with the smallest value in the priority queue; let z be the vertex with the column number that is currently associated with y_i. Suppose there is another vertex y_j on the queue with the same priority value as y_i. One of the vertices $\{y_i, y_j\}$ has smaller row number in the bipartite transformation; call the vertex with smaller row number y_a and the vertex with larger row number y_b. Since we are given a Γ-free ordering, for any vertex z' which comes after z in the ordering, if y_a has an edge to z', then y_b has an edge to z'. Therefore, we can eliminate y_a from our priority queue when looking for later edges implied by transitivity from x.

Therefore, the algorithm is as follows. Remove from the priority queue the vertex y_i with the smallest value. Let z be as above and suppose z's column number is k. Add an edge from x to z. Next examine the current smallest value on the queue. Suppose it is associated with the vertex y_j. If the value associated with y_j is also k, remove y_j from the priority queue and eliminate from further consideration whichever of y_i and y_j has the smaller row number. Repeat this step until the current smallest value in the queue is greater than k. The vertex with the largest row number among those with priority value k is then added back to the priority queue with associated value equal to the column index of the next 1 after column k in its row. Repeat this entire process until the priority queue is empty.

There are $\mathrm{O}(n)$ operations which correspond to adding an edge from x, and each priority queue operation which does not add an edge from x must delete one vertex from the priority queue. Therefore, the number of priority queue operations is $\mathrm{O}(n)$. If the priority queue is a heap, each operation takes $\mathrm{O}(\log n)$ time, and the total time spent is $\mathrm{O}(n \log n)$. However, each value in the queue is an integer in the range $1, \ldots, n$, which allows us to use van Emde Boas's data structure [33] with cost $\mathrm{O}(\log\log n)$ per operation. Therefore, all edges can be added in $\mathrm{O}(n \log\log n)$ time. $\square$

A similar procedure can be used to add a new vertex y with edges into it from vertices of G, and to add all edges implied by transitivity in $\mathrm{O}(n\log\log n)$ time.

THEOREM 8. *If the underlying undirected graph of the transitive closure of a directed acyclic graph G is a weakly triangulated comparability graph, then the transitive closure of G can be found in* $\mathrm{O}(n^2 \log\log n)$ *time.*

Proof. Let T be a topological sort of G. Divide the vertices of G into two sets S_1, S_2, where S_1 consists of the first $\frac{n}{2}$ vertices in T and S_2 is the remainder. Recursively find the transitive closures C_1, C_2 of the subgraphs induced by S_1 and S_2. Construct the Γ-free matrix of the bipartite transformation of C_1 and C_2, and order the adjacency lists of each vertex of C_1 and C_2 so that vertices appear in increasing order of their columns in the Γ-free ordering.

For each vertex x in S_1, add all edges implied by transitivity of the form $x \to y_1 \to y_2$, where y_1 and y_2 are in S_2. By Lemma 7, this step takes $\mathrm{O}(n^2\log\log n)$ time overall. For each vertex y in S_2, add all edges implied by transitivity of the form $x_1 \to x_2 \to y$, x_1, $x_2 \in S_1$; this also takes $\mathrm{O}(n^2\log\log n)$ time.

At this point, we claim that we have the transitive closure of G. Consider any path from x to y in G. If x and y are both in S_1 or both in S_2, then the path must be entirely within S_1 or within S_2 as we divided vertices along a topological sort of G, and therefore, the edge from x to y will be added in the recursive step. Consider a path of G from x in S_1 to y in S_2. Let x_2 be the last vertex of S_1 on the path, and let y_2 be the first vertex of S_2 on the path. There must be an edge from x to x_2 in C_1, and an edge from y_2 to y in C_2. When we are adding edges implied by transitivity from x_2, we will add an edge from x_2 to y. When we are adding edges implied by transitivity into y, since the edge from x_2 to y has already been added, we will add an edge from x to y.

The running time of this algorithm is governed by the recurrence relation $\mathrm{T}(n) = 2\mathrm{T}(\frac{n}{2}) + \mathrm{O}(n^2\log\log n)$. $\mathrm{T}(n)$ can be shown to be $\mathrm{O}(n^2\log\log n)$; one automatic method for proving this can be found in [8]. $\square$

The transitive reduction of a directed acyclic graph G is formed by removing from G all edges $x \to z$ such that there exists a path of length greater than 1 from x to z in the transitive closure of G. The relationship between computing transitive closure and computing transitive reduction is discussed in [1]. We show that Lemma 7 can be used to find the transitive reduction of G in $\mathrm{O}(n^2\log\log n)$ time in the case that the underlying undirected graph of G's transitive closure is a weakly triangulated comparabilty graph.

THEOREM 9. *If the underlying undirected graph of the transitive closure of a directed acyclic graph G is a weakly triangulated comparability graph, then the transitive reduction of G can be found in* $\mathrm{O}(n^2\log\log n)$ *time.*

Proof. We first find the transitive closure of G and find a Γ-free ordering of the bipartite transformation of the transitive closure. Consider any vertex x. Let $y_1, y_2, \ldots, y_k$ be the vertices which have edges in from x in G. Consider adding a new vertex z which has edges to these same vertices. By Lemma 7, we can find all edges implied by transitivity from z in $\mathrm{O}(n\log\log n)$ time. An edge $x \rightarrow w$ of the transitive closure is implied by transitivity and therefore is not in the transitive reduction of G if and only if the edge $z \rightarrow w$ is found by the procedure of Lemma 7. Therefore, repeating the procedure for each vertex x in G, the transitive reduction of G can be found in $\mathrm{O}(n^2\log\log n)$ time. ∎

If the input graph is an arbitrary directed acyclic graph, Corollary 3 and Theorem 9 give us an $\mathrm{O}(n^2\log\log n)$-time algorithm which either finds the transitive reduction or declares that the underlying undirected graph of transitive closure of the input is not a weakly triangulated comparability graph. While computing the transitive closure of the input graph, we simply verify at each recursive step that the underlying undirected graph of the transitive closure of each subgraph is a weakly triangulated comparability graph.

4. Conclusions and open problems.

We have shown that weakly triangulated comparability graphs can be dealt with more efficiently than either of the classes weakly triangulated or comparability individually, by transforming problems on these graphs to an associated chordal bipartite graph. This technique allows us to recognize and find maximum independent set in $\mathrm{O}(n^2)$ time for graphs in the class and to find transitive closure and reductions in $\mathrm{O}(n^2\log\log n)$ time if the transitive closure is in the class.

It would be interesting to find a geometric intersection model for the class of graphs or its complement. Extensions of the models for the subclasses of permutation graphs and interval graphs are possible, but the fact that there are $2^{\Theta(n\log^2 n)}$ weakly triangulated comparability graphs means that the models would have to be made considerably more complex.

Weakly triangulated cocomparability graphs are natural extensions of interval graphs, using the fact that a graph G is an interval graph if and only if G is a chordal cocomparability graph. Interval graphs are also equivalent to chordal asteroidal triple-free graphs [20], and cocomparability graphs are a proper subset of asteroidal triple-free graphs [9]. Thus, it also seems natural to consider weakly triangulated asteroidal triple-free graphs to see whether problems remain tractable on this larger class.

ON APPROXIMATELY COUNTING COLORINGS OF SMALL DEGREE GRAPHS [*]

RUSS BUBLEY[†], MARTIN DYER[†], CATHERINE GREENHILL[†], AND MARK JERRUM[‡]

Abstract. We consider approximate counting of colorings of an n-vertex graph using rapidly mixing Markov chains. It has been shown by Jerrum and by Salas and Sokal that a simple random walk on graph colorings would mix rapidly, provided the number of colors k exceeded the maximum degree Δ of the graph by a factor of at least 2. We prove that this is not a necessary condition for rapid mixing by considering the simplest case of 5-coloring graphs of maximum degree 3. Our proof involves a computer-assisted proof technique to establish rapid mixing of a new "heat bath" Markov chain on colorings using the method of path coupling. We outline an extension to 7-colorings of triangle-free 4-regular graphs. Since rapid mixing implies approximate counting in polynomial time, we show in contrast that exact counting is unlikely to be possible (in polynomial time). We give a general proof that the problem of exactly counting the number of proper k-colorings of graphs with maximum degree Δ is $\#P$-complete whenever $k \geq 3$ and $\Delta \geq 3$.

Key words. graph colorings, rapidly mixing Markov chains, approximate counting, transportation problems

1. Introduction.

The problem of properly coloring the vertices of an n-vertex graph with some given number of colors k has been widely studied [19]. Of equal theoretical interest has been the problem of *counting the number* of proper k-colorings of a graph, the values of the so-called *chromatic polynomial* [19, p. 247]. Unfortunately this is a $\#P$-hard counting problem, even for graphs with a fixed bound Δ on the vertex degrees. (See section 6 for a proof of this fact in the context of this paper.) Consequently, exact counting is unlikely to be possible, and attention turns to *approximate* counting, to some given proportional error ε. It is well known [15] that *randomized* approximate counting in this sense is equivalent to *approximate uniform generation* of a coloring; it is this problem we address here, using the *Monte Carlo Markov chain* (MCMC) method [14]. The use of the MCMC method originated in statistical physics (see, for example, [5, 9, 17]), but rigorous analysis of the method has been a more recent development, with notable contributions from the computer science community [6, 13]. This analysis involves using one of a few available methods to prove that a Markov chain converges quickly to its stationary distribution.

In this context, Jerrum [12] and Salas and Sokal [18] independently proved that a simple random walk on the k-colorings of an n-vertex graph would mix rapidly, provided the number of colors k exceeded the maximum degree Δ of the graph by a factor of more than 2. These proofs were based on entirely different techniques, *coupling* and *Dobrushin uniqueness*, respectively. The two results had different merits.

Jerrum's result was subsequently extended (but with an $\Omega^*(n^2)$[1] increase in running time) to the case $k = 2\Delta$, whereas Salas and Sokal's result was extended to the closely related *Potts model* [3]. However, the similarity of these bounds led to a natural question: whether the condition $k \geq 2\Delta$ is necessary for rapid mixing of the underlying Markov chain on colorings. (Note that the chain is known to converge eventually for $k \geq \Delta + 2$.) There is still no general refutation of this question. Here we examine only specific cases.

In a recent paper, Bubley and Dyer [3], using a new technique called *path coupling*, showed how a coupling proof could be extended to the Potts model (and beyond). Subsequently, Dyer and Greenhill [8] used this technique to analyze a more rapidly mixing chain on colorings. This reduces the running time for the case $k = 2\Delta$ by an $\Omega^*(n^2)$ factor, but still does not demonstrate rapid mixing with fewer than 2Δ colors.

Here we show that it is possible to have rapid mixing with fewer than 2Δ colors by considering the simplest case of 5-coloring graphs of maximum degree 3. To establish our result we analyze a new Markov chain on colorings, from the so-called *heat bath* family, using the technique of path coupling. The proof idea is somewhat novel in this area: we establish the existence of certain required couplings by solving a large number of large linear programs (in fact, *transportation problems*). The analysis therefore cannot be carried out "by hand" and requires the use of linear programming software to solve the many subproblems. Thus our analysis is a "computer proof" of a mathematical theorem (in the spirit of [2, 4]).

We also extend our results to 7-colorings of *triangle-free* 4-regular graphs, again demonstrating rapid mixing with fewer than 2Δ colors. (Observe that this includes the physically relevant case of planar grids.) However, our methods are subject to combinatorial explosion in terms of Δ, and we have currently not succeeded in pushing them further.

Using results presented in [7] it is possible to deduce that the simple Jerrum/Salas–Sokal Markov chain of colorings is rapidly mixing for the same values of k and the same families of graphs as our new chains; that is, when $k = 5$ and the graphs have maximum degree 3 or when $k = 7$ and the graphs are triangle-free and 4-regular. (Note, however, that the mixing rate which is established in this way, while still polynomial, is much larger than the mixing rate of our chains.)

The plan of the paper is as follows. In section 1.1 of the paper we review the path coupling method, and in section 1.2 we briefly review recent work on approximately counting colorings. In section 2 we give a rigorous mathematical definition of a *heat bath Markov chain.* (As far as we are aware, this is the first general definition of this concept.) In section 3 we show that the analysis of a heat bath Markov chain can be reduced (using path coupling) to the task of solving a set of related transportation problems. This leads to a computational method for analyzing heat bath Markov chains. In section 4 this approach is applied to a Markov chain on 5-colorings of graphs of maximum degree 3. A table needed for the computation is provided. In section 5, we outline the extension to 7-colorings of triangle-free 4-regular graphs. Finally, in section 6 we prove that the problem of exactly counting the number of proper k-colorings of graphs with maximum degree Δ is $\#P$-complete when $k \geq 3$ and $\Delta \geq 3$.

1.1. Path coupling. Let Ω be a finite set and let $\mathcal{M}$ be a Markov chain with state space Ω, transition matrix P, and unique stationary distribution π. If the initial

[1]$\Omega^*(\cdot)$ is the notation which hides factors of $\log n$.

state of the Markov chain is x, then the distribution of the chain at time t is given by $P_x^t(y) = P^t(x,y)$. The *total variation distance* of the Markov chain from π at time t with initial state x is defined by

$$\mathrm{d_{TV}}(P_x^t, \pi) = \frac{1}{2}\sum_{y\in\Omega} |P^t(x,y) - \pi(y)|.$$

A Markov chain is only useful in terms of almost uniform sampling or approximate counting if its total variation distance tends to zero relatively quickly from some (easily obtainable) initial state. Let $\tau_x(\varepsilon)$ denote the least value T such that $\mathrm{d_{TV}}(P_x^t, \pi) \leq \varepsilon$ for all $t \geq T$. The *mixing rate*[2] of $\mathcal{M}$, denoted by $\tau(\varepsilon)$, is defined by $\tau(\varepsilon) = \max\{\tau_x(\varepsilon) : x \in \Omega\}$. A Markov chain is said to be *rapidly mixing* if the mixing rate is bounded above by some polynomial in n and $\log(\varepsilon^{-1})$, where n is a measure of the size of the elements of Ω. All logarithms are to the base e.

There are relatively few methods available to prove that a Markov chain is rapidly mixing. One such method is *coupling*. A *coupling* for $\mathcal{M}$ is a stochastic process (X_t, Y_t) on $\Omega \times \Omega$ such that each of (X_t), (Y_t), considered independently, is a faithful copy of $\mathcal{M}$. The coupling lemma (see, for example, Aldous [1]) states that the total variation distance of $\mathcal{M}$ at time t is bounded above by $\mathrm{Prob}[X_t \neq Y_t]$, the probability that the process has not coupled. The difficulty in applying this result lies in obtaining an upper bound for this probability. In the *path coupling* method, introduced by Bubley and Dyer [3], one need only define and analyze a coupling on a subset S of $\Omega \times \Omega$. Choosing the set S carefully can simplify considerably the arguments involved in proving rapid mixing of Markov chains by coupling. The path coupling method is described in the next lemma (taken from [8]). We use the term *path* to refer to a sequence of elements of Ω, which need not be a path of possible transitions in the Markov chain.

LEMMA 1.1. *Let δ be an integer-valued metric defined on $\Omega \times \Omega$ which takes values in $\{0, \ldots, D\}$. Let S be a subset of $\Omega \times \Omega$ such that for all $(X_t, Y_t) \in \Omega \times \Omega$ there exists a path*

$$X_t = Z_0, Z_1, \ldots, Z_r = Y_t$$

between X_t and Y_t where $(Z_l, Z_{l+1}) \in S$ for $0 \leq l < r$ and $\sum_{l=0}^{r-1} \delta(Z_l, Z_{l+1}) = \delta(X_t, Y_t)$. Define a coupling $(X, Y) \mapsto (X', Y')$ of the Markov chain $\mathcal{M}$ on all pairs $(X, Y) \in S$. Suppose that there exists $\beta < 1$ such that

$$\mathbf{E}\left[\delta(X', Y')\right] \leq \beta\, \delta(X, Y)$$

for all $(X, Y) \in S$. Then the mixing rate $\tau(\varepsilon)$ of $\mathcal{M}$ satisfies

$$\tau(\varepsilon) \leq \frac{\log(D\varepsilon^{-1})}{1-\beta}.$$

Remark 1. The set S is often taken to be

$$S = \{(X, Y) \in \Omega \times \Omega : \delta(X, Y) = 1\}.$$

Here a coupling only need be defined for pairs at distance 1 apart.

Remark 2. Notice that Lemma 1.1 does not assume that the Markov chain $\mathcal{M}$ is reversible.

[2]Elsewhere, the *mixing rate* is sometimes defined to be $\tau_x(\varepsilon)$ for some fixed x.

1.2. Colorings of graphs. Let $G = (V, E)$ be a graph on n vertices and let Δ be the maximum degree of G. Let k be a positive integer and let C be a set of size k. A map from V to C is called a *k-coloring*. A vertex v is said to be *properly colored* in the coloring X if v is colored differently from all of its neighbors. A coloring X is called *proper* if every vertex is properly colored in X. A necessary and sufficient condition for the existence of a proper k-coloring of all graphs with maximum degree Δ is $k \geq \Delta + 1$. Denote by $\Omega_k(G)$ the set of all proper k-colorings of G. The color assigned to a vertex v in the coloring X is denoted by $X(v)$.

Jerrum [12] and Salas and Sokal [18] independently defined a Markov chain with state space $\Omega_k(G)$ which is irreducible for $k \geq \Delta + 2$ and rapidly mixing for $k \geq 2\Delta$. One version of this chain has the following transition procedure: from current state X, choose a vertex v uniformly at random and choose a color c uniformly at random from the set of those colors which properly color v in X. Then recolor v with c to give the new state. A new Markov chain of colorings, denoted by $\mathcal{M}_1(\Omega_k(G))$, was introduced in [8]. This new chain is irreducible for $k \geq \Delta+1$ and is also rapidly mixing for $k \geq 2\Delta$. Moreover, the new chain is provably faster than the Jerrum chain when G is Δ-regular or (after a slight adjustment to the chain) when $2\Delta \leq k \leq 3\Delta - 1$. When $k = 2\Delta$ the new chain is $\Omega^*(n^2)$ times faster than the Jerrum chain (see [8]). The transitions of $\mathcal{M}_1(\Omega_k(G))$ are defined by the following procedure: choose an edge $\{v, w\}$ uniformly at random from E and choose an ordered pair of colors $(c(v), c(w))$ uniformly at random from the set of all those such that both v and w are properly colored when v is recolored $c(v)$ and w is recolored $c(w)$. The resulting coloring is the new state.

2. Definition of a heat bath Markov chain. The notation is adapted from that used in [3]. Let V and C be finite sets and let Ω be a subset of C^V, the set of functions from V to C. Let L be a subset of the power set of V. We shall refer to the elements of L as *lines*. For $X \in \Omega$, $\ell \in L$, and $c \in C^\ell$, let $X_{\ell\to c}$ denote the element of C^V defined by

$$X_{\ell\to c}(u) = \begin{cases} c(u) & \text{if } u \in \ell, \\ X(u) & \text{otherwise.} \end{cases}$$

If $X_{\ell\to c} \in \Omega$ then we say that c is *acceptable* at ℓ in X. Finally let $\mathcal{S}_X(\ell)$ be the set of all elements of C^ℓ which are acceptable at ℓ in X. Let π be a distribution on Ω and, for all $\ell \in L$ and all $X \in \Omega$, let $\pi^*_X(\ell)$ be defined by

$$\pi^*_X(\ell) = \sum_{c\in\mathcal{S}_X(\ell)} \pi(X_{\ell\to c}).$$

The set of lines L and the distribution π can be used to define a Markov chain $\mathcal{M}(L, \pi)$ with state space Ω. The transition procedure from the current state X is as follows:

1. choose ℓ uniformly at random from L,
2. choose $c \in \mathcal{S}_X(\ell)$ with probability $\pi(X_{\ell\to c})/\pi^*_X(\ell)$ and move to $X_{\ell\to c}$.

Clearly the Markov chain $\mathcal{M}(L, \pi)$ is aperiodic.

The definition of a heat bath Markov chain can now be stated.

DEFINITION 2.1. *A Markov chain $\mathcal{M}$ with state space $\Omega \subseteq C^V$ is said to be a heat bath Markov chain if there exists a set of lines L and a distribution π on Ω such that $\mathcal{M} = \mathcal{M}(L, \pi)$.*

Suppose that $\mathcal{M}(L, \pi)$ satisfies Definition 2.1. The transition matrix P of $\mathcal{M}(L, \pi)$ has entries

$$P(X, Y) = \pi(Y) \sum_{\ell\supseteq D} \left(|L||\pi^*_X(\ell)|\right)^{-1},$$

where $D = \{v \in V : X(v) \neq Y(v)\}$. If $\ell \supseteq D$, then $\mathcal{S}_X(\ell) = \mathcal{S}_Y(\ell)$ and $\pi^*_X(\ell) = \pi^*_Y(\ell)$. Therefore P is reversible with respect to π. If $\mathcal{M}(L, \pi)$ is also irreducible, then it is an ergodic chain with stationary distribution π. Say that the set of lines L is *sufficient* if $\mathcal{M}(L, \pi)$ is irreducible.

In the special case that π is the uniform distribution on Ω we will write $\mathcal{M}(L)$ instead of $\mathcal{M}(L, \pi)$. Here the transition procedure of $\mathcal{M}(L)$ involves choosing a line $\ell \in L$ uniformly at random and a color map $c \in \mathcal{S}_X(\ell)$ uniformly at random and making a transition to $X_{\ell \to c}$. All the heat bath Markov chains considered in this paper involve the uniform distribution. Two examples are the two Markov chains of k-colorings of a graph described in section 1.2. Both fit Definition 2.1, where π is the uniform distribution on $\Omega_k(G)$. For the Jerrum/Salas–Sokal chain the set L of lines is merely the set of singleton vertices. In the case of the chain $\mathcal{M}_1(\Omega_k(G))$ the set of lines L is the edge set E. In both cases, the set of lines L is sufficient, so the corresponding Markov chain is ergodic.

Let $H(X, Y)$ denote the *Hamming distance* between X and Y, defined by

$$H(X, Y) = |\{v \in V : X(v) \neq Y(v)\}|.$$

Suppose we want to analyze the mixing rate of $\mathcal{M}(L)$ using path coupling on pairs at Hamming distance 1 apart. Let X and Y be two elements of Ω which differ only at $v \in V$. A coupling $(X, Y) \mapsto (X', Y')$ must be defined for every $\ell \in L$. Call a coupling at ℓ *optimal* if it minimizes the expected value of $H(X', Y')$. Note that the *optimal* coupling defined here is not the same as the *maximal* coupling which is referred to elsewhere in the literature. Refer to $\mathbf{E}\,[H(X', Y') - 1]$ as the *cost* of the coupling. If $\mathcal{S}_X(\ell) = \mathcal{S}_Y(\ell)$, then an optimal coupling at ℓ is obtained by choosing the same element $c \in \mathcal{S}_X(\ell)$ in both X and Y. Here $H(X', Y') = 0$ if v lies on the line ℓ and $H(X', Y') = 1$ otherwise. Suppose now that $\mathcal{S}_X(\ell) \neq \mathcal{S}_Y(\ell)$; it follows that $v \notin \ell$. Given $c_X \in \mathcal{S}_X(\ell)$ and $c_Y \in \mathcal{S}_Y(\ell)$, let $P(c_X, c_Y)$ denote the probability that the pair (c_X, c_Y) is chosen by the coupling and let

$$h(c_X, c_Y) = |\{u \in \ell : c_X(u) \neq c_Y(u)\}|,$$

the number of elements of ℓ which are assigned different values by c_X and c_Y. Then the expected value of $H(X', Y') - 1$ is given by

$$\sum P(c_X, c_Y) h(c_X, c_Y),$$

where the sum is over all $(c_X, c_Y) \in \mathcal{S}_X(\ell) \times \mathcal{S}_Y(\ell)$.

3. The related transportation problems. In this section it will be shown that an optimal coupling for a heat bath Markov chain is equivalent to the optimal solutions of a related set of *transportation problems.* (For more information on transportation problems see, for example, [16].) Let m and n be positive integers and let K be an $m \times n$ matrix of nonnegative integers (the *cost matrix*). Let a be a vector of m positive integers and let b be a vector of n positive integers such that $\sum_{i=1}^m a_i = \sum_{j=1}^n b_j = N$. An $m \times n$ matrix Z of nonnegative numbers is a solution of the transportation problem defined by a, b, and K if $\sum_{j=1}^n Z_{i,j} = a_i$ for $1 \leq i \leq m$ and $\sum_{i=1}^m Z_{i,j} = b_j$ for $1 \leq j \leq n$. The *cost* of this solution is measured by $\sum_{i=1}^m \sum_{j=1}^n K_{i,j} Z_{i,j}$. The elements of a are called *row sums* and the elements of b are called *column sums.* An *optimal solution* of this transportation problem is a solution which minimizes the cost. Every entry of an optimal solution is a nonnegative integer. Efficient algorithms exist for solving transportation problems.

Returning to the problem of defining an optimal coupling for the heat bath Markov chain $\mathcal{M}(L)$ at the line ℓ, let $N_X = |\mathcal{S}_X(\ell)|$ and $N_Y = |\mathcal{S}_Y(\ell)|$. Let a be the N_X-dimensional vector with each entry equal to N_Y and let b be the N_Y-dimensional vector with each entry equal to N_X. Let K be the matrix with N_X rows and N_Y columns, corresponding to the elements of $\mathcal{S}_X(\ell)$ and $\mathcal{S}_Y(\ell)$, respectively, such that the (c_X, c_Y)th entry of K is $h(c_X, c_Y)$. A coupling at ℓ defines an $N_X \times N_Y$ matrix Z with (c_X, c_Y)th entry given by

$$N_X N_Y \operatorname{Prob}\left[X' = X_{\ell \to c_X}, Y' = Y_{\ell \to c_Y}\right].$$

The matrix Z is a solution of the transportation problem defined by a, b, and K. An optimal solution of this transportation problem corresponds to a optimal coupling at ℓ. The cost of an optimal solution equals $N_X N_Y$ times the cost of an optimal coupling. Therefore one can attempt to prove that $\mathcal{M}(L)$ is rapidly mixing by adapting the path coupling method as follows. Here “nonisomorphic” means “nonisomorphic in some appropriate sense.”

1. Compile a complete list of nonisomorphic pairs (X, Y) such that $H(X, Y) = 1$.
2. For each such pair, calculate the contribution of all lines ℓ such that $\mathcal{S}_X(\ell) = \mathcal{S}_Y(\ell)$.
3. For all other lines ℓ, solve the corresponding transportation problem to find the cost of the optimal coupling.
4. Combine all this information to determine whether the expected value of $H(X', Y') - 1$ is negative in all cases. If this is the case, then let the maximum of these values be $\beta - 1$. The mixing time $\tau(\varepsilon)$ of $\mathcal{M}(L)$ satisfies
$$\tau(\varepsilon) \leq \frac{\log(n\varepsilon^{-1})}{1 - \beta}$$
by Lemma 1.1. If $1 - \beta$ is only polynomially small, then $\mathcal{M}(L)$ is rapidly mixing.

Remark 3. In order to prove that the Markov chain is rapidly mixing it may not be necessary to find an optimal solution in each case. Instead, it may be sufficient to find a solution with a low enough cost in each case.

Remark 4. Certainly the list of pairs (X, Y) used in the above procedure must contain at least one element from each isomorphism class so that the calculations are conclusive. If the list is a transversal, then no unnecessary calculations are performed. In many cases, however, the amount of effort required to find a transversal of the isomorphism classes is prohibitive and ruling out obviously isomorphic pairs will suffice. Moreover, in most cases one need only consider a certain “neighborhood” around the line ℓ rather than the entire maps X, Y.

4. Five-coloring degree-three graphs.

Let G be a graph with maximum degree 3 and let $\Omega_k(G)$ denote the set of proper k-colorings of G. The two known Markov chains on k-colorings described in section 1.2 are rapidly mixing for $k \geq 6$. In this section a Markov chain on $\Omega_5(G)$ is defined and a computational proof that the chain is rapidly mixing is given following the method described in section 3.

Let $C = \{1, \ldots, 5\}$ be the color set and let $\mathcal{M}$ be the following Markov chain on $\Omega_5(G)$. If w is a vertex with degree d then let the neighbors of w be denoted by $u_1(w), \ldots, u_d(w)$. Denote by $\tilde{w}$ the set defined by

$$\tilde{w} = \{w, u_1(w), \ldots, u_d(w)\}.$$

Define the set of lines L by

$$L = \{\tilde{w} : w \in V\}.$$

Then $\mathcal{S}_X(\tilde{w})$ is

$$\mathcal{S}_X(\tilde{w}) = \left\{c \in C^{\tilde{w}} : X_{\tilde{w}\to c} \in \Omega_5(G)\right\}. \tag{4.1}$$

The Markov chain $\mathcal{M} = \mathcal{M}(L)$ is a heat bath Markov chain in the sense of Definition 2.1, where π is the uniform distribution on $\Omega_5(G)$. The transitions of $\mathcal{M}$ from current state X follow the pattern described in section 2: a line $\tilde{w} \in L$ is chosen uniformly at random, a corresponding color mapping $c \in \mathcal{S}_X(\tilde{w})$ is chosen uniformly at random, and a transition is made to $X_{\tilde{w}\to c}$. The chain $\mathcal{M}$ is irreducible; for example, it can perform all the moves of the Jerrum/Salas–Sokal chain. Therefore the set of lines L is sufficient and the chain $\mathcal{M}$ is ergodic with uniform stationary distribution.

The mixing rate of $\mathcal{M}$ will now be analyzed using path coupling on pairs at Hamming distance 1 apart. Let $X, Y \in \Omega_5(G)$ and let $d = H(X, Y)$. It is not always possible to form a path

$$X = Z_0, Z_1, \ldots, Z_d = Y$$

of length d between $X, Y \in \Omega_5(G)$ where $H(Z_l, Z_{l+1}) = 1$ for $0 \le l < d$ and $Z_l \in \Omega_5(G)$ for $0 \le l \le d$; however, we can always form such a path where $Z_l \in C^V$ for $0 \le l \le d$. If $X \in \Omega_5(G)$, then the definition of the set $\mathcal{S}_X(\tilde{w})$ given in (4.1) is equivalent to the following definition:

$$\mathcal{S}_X(\tilde{w}) = \left\{c \in C^{\tilde{w}} : \text{ all elements of } \tilde{w} \text{ are properly colored in } X_{\tilde{w}\to c}\right\}.$$

The latter definition makes sense for all $X \in C^V$. Using the latter definition, we can extend the chain $\mathcal{M}$ to act on the state space C^V. It is easy to see that the extended chain has the stationary distribution

$$\pi(X) = \begin{cases} |\Omega_5(G)|^{-1} & \text{if } X \in \Omega_5(G), \\ 0 & \text{otherwise.} \end{cases}$$

The extended chain is no longer reversible; however, by Remark 2 we may apply Lemma 1.1 to the extended chain. If the extended chain is rapidly mixing, then the original chain is also rapidly mixing with the same upper bound on the mixing rate. This follows since mixing time is defined as the maximum over all initial states, and the original chain involves only a subset of these.

Now suppose that X and Y are two colorings which differ only at v. Without loss of generality, suppose that $X(v) = 1$ and $Y(v) = 2$. Denote the degree of v by d_v. Let w be a vertex for which $\tilde{w}$ corresponds to the line chosen in the transition procedure. If $w = v$ or $\{w, v\} \in E$, then $\mathcal{S}_X(\tilde{w}) = \mathcal{S}_Y(\tilde{w})$. Therefore the same choice of c may be made in X and Y. It follows that these vertices contribute $-(d_v+1)/n$ to the expected value of $H(X', Y') - 1$. The only other lines which may make nonzero contributions to the expected value of $H(X', Y') - 1$ are those corresponding to vertices w which satisfy the following criteria:

1. $w \ne v$ and $\{w, v\} \notin E$,
2. there exists $u \in V$ such that $\{w, u\} \in E$ and $\{u, v\} \in E$.

Call such a vertex a *critical* vertex. Define the *multiplicity* $\mu(w)$ of a critical vertex w to be the number of neighbors of w which are neighbors of v. Now w may have up to three neighbors. If w has degree 2 or 3, then label its second neighbor by z_1; if w has degree 3, then label its third neighbor by z_2. If z_i is present, then it may have up to three neighbors, for $i = 1, 2$. Let the second and third neighbors of z_i be labeled $z_{i,1}$, $z_{i,2}$, if they are present, for $i = 1, 2$. Finally u may have a third neighbor

which we denote by z_3 if it is present. There are 15 nonisomorphic configurations on these vertices, depending on the degree of w and on whether the edges

$$\{v, z_1\}, \{v, z_2\}, \{z_1, z_2\}, \{z_1, u\}$$

are present or absent in E. The details are given in Table 4.1, where the second column holds the degree of w and the third column holds a string of four characters, each equal to "Y" or "N." The characters refer to the four edges listed above—in that order—and "Y" indicates that the edge is present in E while "N" indicates that it is absent. The fourth column of Table 4.1 holds $\mu_i(w)$, the multiplicity of w in the ith configuration. The last two columns of Table 4.1 are explained below. Note that any identification or edges between the vertices $z_{1,1}, z_{1,2}, z_{2,1}, z_{2,2}, z_3$ can be ignored, as this situation can be modeled by coloring the affected vertices with the same (respectively, different) colors. The only vertices which affect the sets $\mathcal{S}_X(\tilde{w})$, $\mathcal{S}_Y(\tilde{w})$ are the vertices

$$v, z_3, z_{1,1}, z_{1,2}, z_{2,1}, z_{2,2}.$$

Call these vertices the *rim vertices* and call an assignation of colors to these vertices a *rim coloring*. Following Remark 4, it suffices to consider a complete list of nonisomorphic rim colorings for each configuration. Let λ_i be the number of nonisomorphic rim colorings of the ith configuration, $1 \leq i \leq 15$. These values are listed in the fifth column of Table 4.1, while a complete list of the nonisomorphic rim colorings for each configuration can be found in Table 4.2. Each rim coloring is shown as a list of six characters representing the colors of the six rim vertices in the order given above. If a rim vertex equals v, then its color is given as 0. Similarly, if a rim vertex equals u, z_1, or z_2, then its color is given as ρ. If a rim vertex is absent, then its color is given as ω. The first element of each rim coloring is always 0, but it is included so that any symmetry in the configuration is apparent.

Suppose that in a given configuration the vertex z_1 is present and is not joined by an edge to v, u (or z_2 if present). Then it suffices to assume that z_1 has degree 3, as follows. If z_1 has degree 2, then its third neighbor $z_{1,2}$ may be added and colored with the same color as $z_{1,1}$ without affecting the sets $\mathcal{S}_X(\tilde{w})$, $\mathcal{S}_Y(\tilde{w})$. If z_1 has degree 1, then the sets $\mathcal{S}_X(\tilde{w})$, $\mathcal{S}_Y(\tilde{w})$, respectively, contain exactly four times as many elements as those obtained in the case that vertex z_1 is not present. Let a, b, and K be the

row sums, column sums, and cost matrix obtained when z_1 is absent and let a', b', and K' be those obtained when z_1 is present. Then K' has the block form

$$K' = \begin{pmatrix} K & * & * & * \\ * & K & * & * \\ * & * & K & * \\ * & * & * & K \end{pmatrix}$$

and the vector a' (respectively, b') consists of four copies of the vector $4a$ (respectively, $4b$) concatenated together. It is not hard to see that the cost of an optimal solution of the transportation problem defined by a', b', and K' is bounded above by $16k$, where k is the cost of an optimal solution of the transportation problem defined by a, b, and K. Therefore the cost of an optimal coupling when z_1 is present is bounded above by the cost of an optimal coupling when z_1 is absent. The same argument holds with the roles of z_1 and z_2 reversed and reduces the number of rim colorings for certain configurations.

For each rim coloring of a given configuration the sets $\mathcal{S}_X(\tilde{w})$, $\mathcal{S}_Y(\tilde{w})$ can be formed. From these the matrix K of costs can be obtained and given as input to an algorithm for the transportation problem. The cost of an optimal solution corresponds to the value of $N_X N_Y \mathbf{E}\,[H(X',Y')-1]$ for an optimal coupling of X and Y at w. Let $M_i(w)$ be the greatest cost of an optimal coupling over all possible rim colorings for the ith configuration, $1 \le i \le 15$. These values are listed in the sixth column of Table 4.1. These results lead to the following theorem.

THEOREM 4.1. *The Markov chain $\mathcal{M}$ is rapidly mixing with mixing rate*

$$\tau(\varepsilon) \le \frac{161}{144} n \log(n\varepsilon^{-1}).$$

Proof. The maximum contribution of a critical vertex in the ith configuration is denoted by $M_i(w)$. These values were calculated using an algorithm for the transportation problem and are listed in Table 4.1. Denote by d_v the degree of the vertex v. If $d_v = 0$, then the expected value of $H(X',Y')-1$ is $-1/n$. If $d_v > 0$, then the expected value of $H(X',Y')-1$ in the ith configuration is given by

$$\mathbf{E}\,[H(X',Y')-1] \le -\frac{(d_v+1)}{n} + \sum_w \frac{M_i(w)}{n}$$

for $1 \le i \le 15$, where the sum is over all critical w. By inspection of Table 4.1 it is clear that

$$M_i(w) < \frac{2\mu_i(w)}{3} \le \frac{(d_v+1)\mu_i(w)}{2d_v}$$

for $1 \le i \le 15$. Therefore the expected value of $H(X',Y')-1$ is less than

$$\frac{(d_v+1)}{2d_v n}\left(\sum_w \mu_i(w) - 2d_v\right) \le 0$$

for $1 \le i \le 15$. To compute an upper bound for the mixing rate, let

$$T = \max\left\{M_i(w)/\mu_i(w) : 1 \le i \le 15\right\}.$$

By inspection of Table 4.1 one can see that $T = 250/483$, corresponding to configuration 12. Then

$$\mathbf{E}\,[H(X',Y')-1] \le -\frac{4}{n} + \frac{6T}{n} = -\frac{144}{161n}.$$

Therefore, by Lemma 1.1 the mixing rate of $\mathcal{M}$ is as stated. $\square$

Remark 5. In order to prove that $\mathcal{M}$ is rapidly mixing, it suffices to establish the inequality $T < 2/3$, as shown in the proof of Theorem 4.1. To show this, the exact value of $M_i(w)$ was calculated for $1 \le i \le 15$. As mentioned in Remark 3, much calculation can be saved by halting the algorithm for the transportation problem in each case as soon as a feasible solution with low enough cost has been found. In two separate calculations using different heuristics, the authors established the two bounds $T \leq 1174/1767$ and $T \leq 515/966$ using this method. The first gives rise to the upper bound

$$\tau(\varepsilon) \leq \frac{589}{8} n \log(n\varepsilon^{-1})$$

on the mixing rate of $\mathcal{M}$, which is more than 65 times greater than the bound given in Theorem 4.1. This illustrates that the increased efficiency which results in this way may incur a significant loss of tightness in the bound on the mixing rate. However, the second calculation gives rise to the bound

$$\tau(\varepsilon) \leq \frac{161}{129} n \log(n\varepsilon^{-1}),$$

which is very close to the bound provided by Theorem 4.1.

5. Further applications. In principle it is not difficult to extend the result of section 4 to graphs of larger (bounded) degree—the algorithm for generating all the nonisomorphic configurations readily extends to this case. However, there is a problem that prevents us from doing this: the number of rim colorings suffers from combinatorial explosion, as does the size of the transportation problems to be solved. This may be offset in some fashion by restricting attention to smaller classes of graphs. The high degree of symmetry inherent in lattice graphs makes these ideal candidates.

It would be interesting to see just how general these classes of graphs can be made before the computation becomes intractable. Determining the cut-off point is a largely subjective matter and dependent on available resources. One additional computation that we discovered to be tractable is the proof of rapid mixing of $\Omega_7(G)$, where G is a 4-regular, triangle-free graph. It should be clear where the simplifications arise from these two additional restrictions over the case considered in section 4: the regularity condition ensures that we need not consider the cases where some of the rim vertices are absent, and demanding that the graph is triangle-free means that we do not need to consider the cases where some of the rim vertices are adjacent to the critical vertex that they rim.

To further save on the amount of computational time needed, we did not actually find the optimum solutions of the transportation problems. Instead we made use of Remark 3, since it transpired that using the matrix minimum heuristic was sufficient.

We will use some of the notation of section 4 for the remainder of this section.

In order to ensure that the chain was rapidly mixing, we needed to show that we had

$$\mathbf{E}\left[H(X', Y') - 1\right] \leq -\frac{5}{n} + \sum_{w} \frac{M_i(w)}{n}$$

for all critical vertices w. (The 5 arises from the fact that there are five choices of vertex, v and all of its neighbors, whose choice would ensure that $H(X', Y') = 0$.)

It is sufficient therefore to show that for each rim coloring Q we have

$$\text{cost}(Q) \times \frac{12}{\mu(w)} - 5 \leq 0, \quad \text{i.e., } \text{cost}(Q) \leq \frac{5}{12}\mu(w), \tag{5.1}$$

where $\text{cost}(Q)$ is the cost of the optimal solution to the transportation problem associated with Q.

0 3 4 0 3 5 0 3 6 0 4 7	4	1212/997

It was necessary to consider 42574 nonisomorphic rim colorings. The worst cases for the different values of $\mu(w)$ are listed in Table 5.1. Each rim coloring is shown as a list of 12 numbers in four groups of three. Each group of three numbers corresponds to a neighbor z of w and represents the colors of the neighbors of z other than w. The notation for the colors is as explained in section 4 (although here the set of colors is $\{1, \ldots, 7\}$, with seven elements). By inspection, all of these worst-case rim colorings satisfy (5.1), from which the rapid mixing result follows.

The mixing rate may be bounded by considering the largest value of the proven bound over $\mu(w)$ in Table 5.1. This is 62/189. Thus $\mathbf{E}\left[H(X', Y') - 1\right] \leq -67/63n$. It follows then from Lemma 1.1 that the Markov chain $\mathcal{M}$ is rapidly mixing with mixing rate bounded above by

$$\frac{63}{67} n \log(n\varepsilon^{-1}).$$

Remark 6. A method is outlined in [7] whereby, under certain conditions, the rapid mixing of a given Markov chain can be used to deduce the rapid mixing of a second Markov chain with the same state space and stationary distribution as the first. Using this and the results of section 4 it is possible to prove that the simple Jerrum/Salas–Sokal chain is rapidly mixing when $k = 5$ for graphs of maximum degree 3. Similarly, using the results of this section it is possible to prove that the simple chain is rapidly mixing when $k = 7$ for triangle-free 4-regular graphs. The mixing rate of the Jerrum/Salas–Sokal chain is bounded above by $O(n^8 \log(n))$ in both cases.

6. A #*P*-completeness proof.

In this section we present a proof that the problem of counting the number of k-colorings of graphs with maximum degree Δ is #P-complete for fixed k, Δ such that $k \geq 3$ and $\Delta \geq 3$. First we must establish a preliminary result involving the path with $r+1$ vertices $u_1, \ldots, u_{r+1}$ and edges $\{u_i, u_{i+1}\}$ for $1 \leq i \leq r$.

LEMMA 6.1. *Let C_r denote the path with $r+1$ vertices $u_1, \ldots, u_{r+1}$ and r edges $\{u_i, u_{i+1}\}$ for $1 \leq i \leq r$. Let γ, γ' be two fixed, distinct colors and let σ_r, δ_r be defined by*

$$\sigma_r = |\{X \in \Omega_k(C_r) : X(u_1) = \gamma,\ \ X(u_{r+1}) = \gamma\}|,$$
$$\delta_r = |\{X \in \Omega_k(C_r) : X(u_1) = \gamma,\ \ X(u_{r+1}) = \gamma'\}|$$

for $r \geq 1$. *Then*

$$\sigma_r = \frac{(k-1)^r - (-1)^{r-1}(k-1)}{k} \qquad \textit{and} \qquad \delta_r = \frac{(k-1)^r + (-1)^{r-1}}{k}$$

for $r \geq 1$.

Proof. This result follows easily by induction, using the following observations. When $r = 1$, the equations give the correct values $\sigma_1 = 0$ and $\delta_1 = 1$. If $r > 1$, then

$$\sigma_r = (k-1)\delta_{r-1} \qquad \text{and} \qquad \delta_r = \sigma_{r-1} + (k-2)\delta_{r-1},$$

giving the inductive step. □

We now show that it is $\#P$-complete to count the number of proper k-colorings of arbitrary graphs of maximum degree Δ when $k \geq 3$ and $\Delta \geq 3$.

THEOREM 6.2. *Denote by* $\#kColMaxDeg\Delta$ *the problem of computing* $|\Omega_k(G)|$ *for an arbitrary graph* G *of maximum degree* Δ. *If* $k \geq 3$ *and* $\Delta \geq 3$, *then the problem* $\#kColMaxDeg\Delta$ *is* $\#P$*-complete.*

Proof. Let $\#kCol$ denote the problem of computing the number of proper k-colorings for an arbitrary graph. If $k \geq 3$, then by an immediate corollary of Vertigan's thesis (see [11]) the problem $\#kCol$ is $\#P$-complete.

Let Π be the problem which takes as an instance a graph G with maximum degree Δ and bipartition of the edge set $E = M \cup B$, and asks how many k-colorings of G are there which make every edge in M monochromatic and every edge in B bichromatic. There is an easy reduction from $\#kCol$ to Π, which we now describe. Given an instance H of $\#kCol$, define an instance G of Π as follows. Let the vertex set of G equal the vertex set of H initially and let B equal the edge set of H, $M = \emptyset$. Let Δ' be the maximum degree of H. Suppose first that $\Delta' > \Delta$. Then replace each vertex v with degree greater than Δ by a path of new vertices, each of degree at most Δ, joined together by edges in M. Ensure that each neighbor of v in H is connected (by an edge in B) to exactly one of these new vertices and that at least one of the new vertices has degree Δ. Next suppose that $\Delta' < \Delta$. In this case choose a vertex v of degree Δ' in H and make v a vertex of degree Δ in G, as follows. Add $\Delta - \Delta'$ vertices w to the vertex set of G, and make each new vertex a neighbor of v by adding the edge $\{v, w\}$ to M. The number of k-colorings of G which make all edges in M monochromatic and all edges in B bichromatic is given by $|\Omega_k(H)|$. This shows that $\#kCol$ is polynomial-time reducible to Π, so Π is $\#P$-complete.

We now give a polynomial-time reduction of Π to $\#kColMaxDeg\Delta$. Let H be an instance of Π with edge bipartition $E = M \cup B$. Let $m = |M|$ and let C_r be the path with $r+1$ vertices and r edges, as in Lemma 6.1. For $r \geq 1$, let G_r be the r-stretch of H with respect to M. That is, G_r is obtained from H by replacing each edge $\{v, w\}$ in M by a copy of the path C_r, with the identifications $u_1 = v$, $u_{r+1} = w$. Let N_s be the number of k-colorings of H where s edges in M are monochromatic and the remaining $m - s$ edges in M (together with all edges in B) are bichromatic. Then

$$|\Omega_k(G_r)| = \sum_{s=0}^{m} N_s \, {\sigma_r}^s \, {\delta_r}^{m-s} = {\delta_r}^m \sum_{s=0}^{m} N_s \, {x_r}^s, \tag{6.1}$$

where $x_r = \sigma_r/\delta_r$. We may express (6.1), for $1 \leq r \leq m+1$, as a matrix equation

$$\begin{pmatrix} {\delta_1}^{-m}|\Omega_k(G_1)| \\ {\delta_2}^{-m}|\Omega_k(G_2)| \\ \vdots \\ {\delta_{m+1}}^{-m}|\Omega_k(G_{m+1})| \end{pmatrix} = \begin{pmatrix} 1 & x_1 & \cdots & {x_1}^m \\ 1 & x_2 & \cdots & {x_2}^m \\ \vdots & \vdots & \ddots & \vdots \\ 1 & x_{m+1} & \cdots & {x_{m+1}}^m \end{pmatrix} \begin{pmatrix} N_0 \\ N_1 \\ \vdots \\ N_m \end{pmatrix}. \tag{6.2}$$

Now, using Lemma 6.1,

$$x_r = 1 - \frac{k}{(k-1)(1-k)^{r-1}+1}.$$

It follows that the values x_r are distinct. If we know the values $|\Omega_k(G_r)|$, for $1 \leq r \leq m+1$, then the values $N_0, N_1, \dots, N_m$ may be obtained in polynomial time by inverting the Vandermonde matrix in (6.2). Since N_m is the answer which satisfies Π, this completes the reduction. Therefore $\#kColMaxDeg\Delta$ is $\#P$-complete. □

By Theorem 6.2, the counting problem associated with the Jerrum/Salas–Sokal chain [12, 18] and the Dyer–Greenhill chain [8] is $\#P$-complete. Also, by Theorem 6.2 with $\Delta = 3$ and $k = 5$, the counting problem associated with the Markov chain of section 4 is $\#P$-complete.

Further $\#P$-completeness results for graph colorings can be found in [10]. For example, we show that the problem of counting k-colorings in graphs with maximum degree Δ remains $\#P$-complete when restricted to triangle-free Δ-regular graphs, so long as $k \geq 3$ and $\Delta \geq 3$. Thus, the specific counting problem associated with the Markov chain of section 5 is $\#P$-complete.

RANKING PRIMITIVE RECURSIONS: THE LOW GRZEGORCZYK CLASSES REVISITED*

STEPHEN J. BELLANTONI† AND KARL-HEINZ NIGGL‡

Abstract. Traditional results in subrecursion theory are integrated with the recent work in "predicative recursion" by defining a simple ranking ρ of all primitive recursive functions. The hierarchy defined by this ranking coincides with the Grzegorczyk hierarchy at and above the linear-space level. Thus, the result is like an extension of the Schwichtenberg–Müller theorems. When primitive recursion is replaced by recursion on notation, the same series of classes is obtained except with the polynomial time computable functions at the first level.

Key words. subrecursion, computational complexity, predicativity, ramified recursion, Heinermann classes, polynomial time, linear space

1. Introduction.

A variety of restricted recursion schemes has been successfully used to characterize some common complexity classes; see, e.g., Clote [6] for a survey. At first characterized using explicit bounds on the value computed by a recursion, some of these function classes were later characterized by restricting the way in which values can be accessed during the recursion. These latter schemes are called "predicative recursion" [4] or "ramified recurrence" [11] schemes; the phrase "safe recursion" has also been used. Taking the predicative viewpoint, one has two types of values: values which are known in their entirety and which therefore can be examined completely, e.g., by being recursed upon; and those values which are still emerging and which therefore can be accessed only in a more restricted way, e.g., by examining a few low-order bits. One then develops a class of functions over these two types. Although one can develop a formal mechanism having more types of values, doing so does not usually allow one to define more functions: Leivant showed that strictly predicative systems having more than two types collapse to the system having only two types [11].

A different way to look at ramification is in terms of the amount or structure of the recursions performed. One thinks of a loose analogy with the number of comprehension levels used to define a particular set in ramified set theory. A definition of the function is given first, then one examines that definition to see how many "ramification levels" are used by it. In this sense, ramification is "implicit" in the derivation of the function as built up from the initial functions of the class using the derivation rules of composition and recursion. Rather than explicitly controlling the type or quality of the values appearing during the calculation, one measures the amount or structure of the work that, implicitly, must have been performed in order to produce the value. Of course, in order to use this approach one must restrict attention to func-

tion definitions for which one can always ascribe ramification levels; in the present work, the primitive recursive functions are used. A major purpose of this paper is to propose a specific way of measuring the amount or structure of primitive recursive derivations. The measure should classify derivations by specifying the number of ramification levels that are implicitly used.

An obvious proposal for such a classification would be, according to the minimal degree of derivations of the function, using an idea which dates back to the early 1960s: the degree, *deg*, of a derivation concluded by a recursion rule is one more than the maximum degree of the subderivations; for a composition rule the degree is just the maximum of the degrees of the subderivations. This simple definition has the advantage of coinciding with the Grzegorczyk hierarchy $\mathcal{E}^r$ at and above the elementary functions: $\mathcal{E}^{r+1} = \mathcal{D}^r$ for $r \geq 2$, where $\mathcal{D}^r$ are the primitive recursive derivations with degree at most r. As discussed by Clote [6], the characterization for $r \geq 3$ was shown by Schwichtenberg [23], and later the case of $r = 2$ was shown by Müller [15]. Another possible classification was given prior to Müller's result by Parsons [20], who examined whether the step function (i.e., the function h in $f(x+1) = h(x, f(x))$) accesses the critical value. This result also characterized the Grzegorczyk hierarchy at the elementary functions and above. A more detailed discussion of other earlier work is given after the statement of the results in section 4.

In this paper we propose a new ranking ρ of the primitive recursive functions. Like *deg*, the ranking ρ characterizes the Grzegorczyk hierarchy at and above the elementary level; but at level 1 it characterizes the linear-space computable functions —by Ritchie's result [22], this is $\mathcal{E}^2$. Thus, $\mathcal{E}^{r+1} = \mathcal{PR}_1^r$ for $r \geq 1$, where $\mathcal{PR}_1^r$ consists of the primitive recursive derivations with rank at most r. In this sense, the result is like an extension of the Schwichtenberg–Müller theorems. Unlike the Schwichtenberg and Müller proofs, the proof of this result does not refer directly to any computation model. A natural series of classes $\mathcal{PR}_2^r$ is also obtained down to the first level, when primitive recursion is replaced with recursion on notation. In fact, $\mathcal{E}^{r+1} = \mathcal{PR}_2^r$ for $r \geq 2$, but $\mathcal{PR}_2^1$ characterizes the polynomial-time computable functions.

The μ measure of Niggl [17], a slight modification of [16], provides similar characterizations of the complexity classes discussed here with respect to classes $\mathcal{R}_1^n$ and $\mathcal{R}_2^n$. The former are based on primitive recursion, the latter on recursion on notation. In fact, the μ measure operates on algorithms given as lambda terms over ground-type variables. The measure μ accounts for redundant input positions and therefore is able to distinguish between proper and improper recursions, i.e., recursions in which the critical input position of the recurrence function is not used. Thus μ does not require any initial functions other than zero and its successor. Remarkably, the proofs of $\mathcal{R}_2^1 = \text{FPTIME}$ and $\mathcal{E}^{r+1} = \mathcal{R}_1^n$ for $r \geq 1$ use the same method, thus emphasizing the uniform method of determining the computational complexity of primitive recursive algorithms.

The measure ρ is convenient because it classifies derivations in an arguably more natural way than *deg* does. For example, the natural derivation of the multiplication function uses two recursions. The Schwichtenberg–Müller approach classifies this derivation in the same way as the exponential, as level 2. Although there is a derivation of multiplication that has *deg* equal to 1, one typically must pass through a Turing machine simulation in order to find it. In contrast, the ranking ρ proposed here classifies the natural derivation of multiplication as level 1, and exponentiation as level 2.

A parallel of these developments can be carried out in the setting of formal logic.

This paper is a companion to [1], which shows how to define weak subsystems of arithmetic by defining the "rank" of proofs instead of by bounding the induction formulas. Rank r functions turn out to be exactly those having a rank r proof of convergence. The intuition of ramification levels is made more precise by the model-theoretic analysis in [1]; also see Leivant [10].

The results of this paper should be of some interest to complexity theorists as well as recursion theorists. Complexity characterizations based on the structure of recursive derivations, without explicit bounds on time or memory resources, can help to ground the concepts of computational complexity by providing a reference point other than the original resource-based definitions.

Notation. Iterations of a function f are defined by $f^{(0)}(x) = x$ and $f^{(n+1)}(x) = f(f^{(n)}(x))$. The binary length of x is $|x| = (\mu n \geq 0)(p^{(n)}(x) = 0)$, where $p(x) \equiv \lfloor x/2 \rfloor$. Vector notation is used freely throughout this work; for example, $|\vec{x}|$ means the vector $|x_1|, \ldots, |x_m|$, where m is the number of elements (perhaps zero) in vector $\vec{x}$. Sometimes vectors are treated as if they were sets, and vice versa. When $\vec{x}$ is the empty vector, one assumes $\max \vec{x} = 0$. The arity of function f is indicated by m_f. Throughout, the domain and range are assumed to be the nonnegative numbers. We avoid writing λ and instead casually use expressions such as "2^x" to mean the function $\lambda x.2^x$.

2. Existing subrecursive classes. First we would like to review some basic and well-known facts about subrecursive function classes defined over the nonnegative integers.

The primitive recursive functions, $\mathcal{D}$, are usually defined by closing the set of initial functions 0, $Sx = x + 1$, and $\pi^n_k(\vec{x}) = x_k$ (for $1 \leq k \leq n$, all $n \geq 0$) under the following primitive recursion and composition rules. Let $P(x) = \max(0, x - 1)$.

• Composition: given h and $g_1, \ldots, g_m$ with $m = m_h \geq 1$, derive f such that $f(\vec{x}) = h(g_1(\vec{x}), \ldots, g_m(\vec{x}))$.

• Primitive recursion: given g and h, derive f such that $f(0, \vec{y}) = g(\vec{y})$ and $f(x, \vec{y}) = h(Px, \vec{y}, f(Px, \vec{y}))$ for $x \neq 0$.

Researchers have frequently used definitions similar to the following degree *deg* for function derivations in $\mathcal{D}$. The definition of *deg* can be applied equally well to the classes $\mathcal{PR}_1$ and $\mathcal{PR}_2$ defined later in this paper.

• If f is an initial function, then $deg(f) = 0$.

• If f is defined by (any form of) composition from h and $g_1, \ldots, g_m$, then $deg(f) = \max\{deg(h), deg(g_1), \ldots, deg(g_m)\}$.

• If f is defined by (any form of) recursion with step function h and base function g, then $deg(f) = \max\{deg(g), 1 + deg(h)\}$.

Let $\mathcal{D}^r = \{f \in \mathcal{D} : deg(f) \leq r\}$, the primitive recursive derivations with *deg* at most r.

The degree of functions is closely related to the Grzegorczyk hierarchy, with classes $\mathcal{E}^n$. The definition of $\mathcal{E}^n$ refers to the Ackermann branches $A_n(x, y) = A(n, x, y)$, where A is the Ackermann function

$$\begin{aligned} A(0, x, y) &= y + 1, \\ A(n + 1, x, 0) &= \text{"if } n = 0, \text{ then } x \text{ else if } n = 1, \text{ then } 0 \text{ else } 1\text{"} \\ A(n + 1, x, y + 1) &= A(n, x, A(n + 1, x, y)). \end{aligned}$$

Note that $A_0(x, y) = Sy$, $A_1(x, y) = x + y$, $A_2(x, y) = x \cdot y$, and $A_3(x, y) = x^y$. Let $\mathcal{E}^r$ consist of the initial functions 0, π^n_k, S, and A_r closed under composition and "bounded primitive recursion," stated next. For later use we also define "bounded recursion on notation."

• Bounded primitive recursion: given g, h, and k, obtain f such that $f(0,\vec{y}) = g(\vec{y})$ and $f(x,\vec{y}) = h(Px,\vec{y},f(Px,\vec{y}))$ for $x \neq 0$, provided that for all $x,\vec{y},\ f(x,\vec{y}) \leq k(x,\vec{y})$.

• Bounded recursion on notation: given g, h_0, h_1, and k, obtain f such that $f(0,\vec{y}) = g(\vec{y})$ and $f(x,\vec{y}) = h_i(px,\vec{y},f(px,\vec{y}))$ for $x \neq 0$, where $i = (x \bmod 2)$, provided that for all $x,\vec{y},\ f(x,\vec{y}) \leq k(x,\vec{y})$.

The following central results were established early on. See Clote [6] for a definition of the Kalmar elementary functions and for discussion of these theorems.

THEOREM 2.1 (see Schwichtenberg [23]; Müller [15]). *For $r \geq 2$, $\mathcal{E}^{r+1} = \mathcal{D}^r$.*

THEOREM 2.2 (see Ritchie [22]). *$\mathcal{E}^2$ consists of the linear-space computable functions.*

THEOREM 2.3 (see Cobham [7]). *The polynomial-time computable functions are exactly those in the class obtained from the initial functions 0, π_i^n, $s_0x = 2x$, $s_1x = 2x+1$, and $x\#y \equiv 2^{|x|\cdot|y|}$ using composition and the rule of bounded recursion on notation.*

THEOREM 2.4 (see Grzegorczyk [8]). *$\mathcal{E}^3$ consists of the Kalmar elementary functions.*

3. Ranking recursions.

The development begins by defining function classes $\mathcal{PR}_1$ and $\mathcal{PR}_2$.

Let I_1 consist of the following initial functions: constant 0; successor $Sx = x+1$; predecessor $P(x) = \max(0, x-1)$; and conditional $C(x,y,z) =$ "if $x = 0$, then y else z."

Let I_2 consist of constant 0; successors $s_0x = 2x$ and $s_1x = 2x+1$; predecessor $p(x) = \lfloor x/2 \rfloor$; and conditional $c(x,y,z) =$ "if $x \bmod 2 = 0$, then y else z."

Define $\mathcal{PR}_1$ to be the smallest set of function derivations containing a derivation for each function in I_1 and closed under the following rules of "full" composition and recursion. These full closure rules differ slightly from the ordinary ones stated earlier; this minor difference will be compensated for by the difference in the initial functions. We use the full rules in order to simplify the definition of ρ and to improve the similarity between $\mathcal{PR}_2$ and $\mathcal{PR}_1$.

• Full composition: given derivations h and $g_1,\ldots,g_m$ with $m = m_h \geq 1$, derive f such that $f(\vec{x}) = h(g_1(\vec{x}^1),\ldots,g_m(\vec{x}^m))$, where each $\vec{x}^j$ is a vector consisting of elements from the vector $\vec{x}$ (possibly with repetitions, omissions, or changes in order).

• Full primitive recursion: given derivations g and h, derive f such that $f(0,\vec{y}) = g(\vec{y})$ and $f(x,\vec{y}) = h(x,\vec{y},f(Px,\vec{y}))$ for $x \neq 0$.

Similarly, define $\mathcal{PR}_2$ to be the least set of function derivations containing I_2 and closed under the same rules, except using p instead of P in the recursion rule (now called "full recursion on notation" instead of "full primitive recursion").

For convenience, we have defined $\mathcal{PR}_1$ and $\mathcal{PR}_2$ to be sets of derivations rather than sets of functions, because we will be working most often with the derivation rather than the function itself. Given a derivation f, we sometimes ambiguously also use f to refer to the function defined by the derivation.

Now we assign a *rank*, $\rho(f,i)$, for each derivation f and for each position $1 \leq i \leq m_f$. The rank of an input position is supposed to be an indication of the amount of recursion on that input; or, it is the number of ramification levels of "knowledge" about that input which are required in order to "know" the result of the function. In defining ρ, one uses the idea that when f is derived from subfunctions $\vec{h}$, then there is some sense in which the rank of input positions of $\vec{h}$ contributes to the rank of input positions of f. For example, if $f(x) = h(0, g(x))$, then one requires $\rho(f,1) \geq \rho(h,2)$ and $\rho(f,1) \geq \rho(g,1)$. The key point is that recursion makes it strictly more difficult to understand how a value is used. If $f(x) = h(x, f(px))$, then one requires $\rho(f,1) \geq 1 + \rho(h,2)$ as well as $\rho(f,1) \geq \rho(h,1)$.

The rank $\rho(f,i)$ is defined for both $\mathcal{PR}_2$ and $\mathcal{PR}_1$ as follows:

• If f is an initial function, then $\rho(f,i) = 0$ for $1 \leq i \leq m_f$.

• If f is defined by the full composition $h(g_1(\vec{x}^1), \ldots, g_m(\vec{x}^m))$, then $\rho(f,i) = \max(\{\rho(h,k) : x_i \in \vec{x}^k\} \cup \{\rho(g_k, j) : x_i \equiv (\vec{x}^k)_j\})$ for $1 \leq i \leq m_f$.

• If f is defined by full recursion from base function g and step function h, then $\rho(f,1) = \max\{\rho(h,1),\, 1 + \rho(h, m_h)\}$ and $\rho(f,i) = \max\{\rho(h,i),\, \rho(h,m_h),\, \rho(g,i-1)\}$ for $2 \leq i \leq m_f$.

Define the rank of function derivations f by $\rho(f) = \max\{\rho(f,i) : 1 \leq i \leq m_f\}$.

Define $\mathcal{PR}_1^r = \{f \in \mathcal{PR}_1 : \rho(f) \leq r\}$ and $\mathcal{PR}_2^r = \{f \in \mathcal{PR}_2 : \rho(f) \leq r\}$.

One can see that the formulation of full composition has been designed to give rank 0 to input positions that appear in the defined function $f(\vec{x})$ but which do not appear in any of the sublists $\vec{x}^1, \ldots, \vec{x}^m$. A spuriously higher rank would have been assigned if we had used projection functions and ordinary composition.

It is shown below that, without loss of generality, every $\mathcal{PR}_i^r$ function derivation has all subderivations also in $\mathcal{PR}_i^r$. On the other hand, $\mathcal{PR}_i^r$ is closed under full composition, because the rank of a function defined by full composition is bounded by the greater of the ranks of the subderivations. It follows that $\mathcal{PR}_i^r$ is equivalent to the least class of function derivations containing the initial functions and closed under full composition and the following rule:

• r-safe recursion: given g and h, derive f by full recursion, provided that $\rho(f) \leq r$. This generalizes the rule of safe recursion ($r = 1$) in [4].

Rank differs from "tiers" (Leivant [11]) because rank, as defined by ρ, is not a type system. This is not merely a syntactic distinction, as the present system admits more instances of composition and recursion than the stricter system in [11]. In particular, the systems $\mathcal{PR}_1$ and $\mathcal{PR}_2$ contain all the primitive recursive functions and separates at all levels, while the system in [11] collapses to level 2. However, the philosophical underpinning of rank is similar to that of tiers: by stratifying or ramifying the definition of a function, one obtains at the same time a more predicative definition and a more computationally tractable one.

LEMMA 3.1 (ρ-normalization). *If f is a derivation whose conclusion has rank r, then there is a derivation f' defining the same function with the same input ranks, in which every subderivation has rank at most r.*

Proof. Essentially, the rank of a derivation can be reduced only by composing a constant into a recursion position. Such a constant-depth recursion can be unrolled as a sequence of compositions; the compositions do not increase the rank above the rank of the subderivations.

Say that a derivation f' is *equivalent* to another derivation f if the functions defined by f' and f are the same, and $\rho(f',i) = \rho(f,i)$ for $1 \leq i \leq m_f$. We prove the following strengthened statement: any derivation $f^{\vec{a}}$ obtained by substituting zero or more constants $\vec{a}$ for some of the inputs of a derivation f has an equivalent derivation f' in which every subderivation has rank at most $\rho(f^{\vec{a}})$. The proof is by induction on the derivation f.

Technically, $f^{\vec{a}}$ is obtained from f by a full composition in which each g_i is either some a_j or else is the rank 0 identity function, either $P(S(x_i))$ or $p(s_0(x_i))$. This use of the identity function does not affect the rank; therefore we omit discussion of it below.

The strengthened statement is trivial for the initial functions, since their derivations have no subderivations. Next, consider f defined by recursion from g and h. We consider two subcases.

The first subcase is when a constant a is substituted for the recursion variable and, without loss of generality, other constants $\vec{c}$ are substituted for the subsequent non-recursion variables, i.e., $f^{a,\vec{c}}(\vec{y}) = f(a, \vec{c}, \vec{y})$. Using the induction hypothesis on g and h for each constant $1 \leq j \leq a$, one has derivations g' and h'_j equivalent to $g^{\vec{c}}(\vec{y}) = g(\vec{c}, \vec{y})$ and $h^{j,\vec{c}}(\vec{y}, z) = h(j, \vec{c}, \vec{y}, z)$, such that g' and h'_j have all subderivations of rank at most $\rho(g^{\vec{c}})$ and $\rho(h^{j,\vec{c}})$, respectively. If $a \neq 0$, then define $f'(\vec{y})$ by a compositions of h'_j $(1 \leq j \leq a)$ starting on g' (in the case of $\mathcal{PR}_1$, or by $|a|$ compositions in the case of $\mathcal{PR}_2$). But if $a = 0$, define $f'(\vec{y}) = C(0, g'(\vec{y}), h'_1(\vec{y}, g'(\vec{y})))$ (for $\mathcal{PR}_1$, or use conditional c instead of conditional C for $\mathcal{PR}_2$). The latter construction defines the same function as $g^{\vec{c}}$ but provides the same rank as in $f^{a,\vec{c}}$ for inputs $\vec{y}$. In either case, the defined f' is equivalent to $f^{a,\vec{c}}$ and subderivations have the required rank.

The second subcase is when no constant is substituted into the recursion position of f, e.g., $f^{\vec{a}}(x, \vec{y}) = f(x, \vec{a}, \vec{y})$. Here, the induction hypothesis is applied to both g and h with respect to $\vec{a}$ to get suitable functions g' and h'. Then defining f' by recursion on these gives the required equivalent derivation.

Consider a function $f^{\vec{a}}$, obtained from a function $f(\vec{x}) = h(g_1(\vec{x}^1), \ldots, g_m(\vec{x}^m))$ by substituting arbitrary constants $\vec{a}$ for some of the inputs. Let $g_j^{\vec{a}}$ be g_j with some of the inputs replaced by the constants among $\vec{a}$ that are selected by the list $\vec{x}^j$. Observe that by the definition of ρ, $\rho(g_j^{\vec{a}}) \leq \rho(f^{\vec{a}})$. Applying the induction hypothesis on each $g_j^{\vec{a}}$ gives equivalent functions g'_j in which the rank of every subderivation is at most $\rho(f^{\vec{a}})$. Now let $\vec{c}$ be constants equal to the values of the constant expressions, if any, among $g'_1, \ldots, g'_m$. Applying the induction hypothesis to h with constants $\vec{c}$, one obtains an equivalent function h'. Again all subderivations have rank at most $\rho(h, \vec{c}) \leq \rho(f^{\vec{a}})$. Finally, f' is obtained by composing h' with the remaining (non-constant) functions g'_j. This defines f' equivalent to $f^{\vec{a}}$ with all subderivations of rank at most $\rho(f^{\vec{a}})$. $\square$

Of course, the translation defined by this proof could result in a serious blow-up of the derivation size, but this is not a concern in the current work.

4. Consolidated characterizations. The main results are stated here in a consolidated form and they are compared to previous work. Like *deg*, the ranking ρ characterizes $\mathcal{E}^{r+1}$ for $r \geq 2$. However, it also characterizes $\mathcal{E}^2$. Furthermore, ρ gives natural characterizations when recursion on notation is considered.

Among other characterizations, the following theorem gives $\mathcal{PR}_1^2 = \mathcal{PR}_2^2 = \mathcal{E}^3 =$ the Kalmar elementary functions, and $\mathcal{PR}_1^1 = \mathcal{E}^2 =$ FLINSPACE (the linear-space computable functions).

THEOREM 4.1.

1. $\mathcal{PR}_1^r = \mathcal{E}^{r+1}$ *for* $r \geq 1$.
2. $\mathcal{PR}_2^r = \mathcal{E}^{r+1}$ *for* $r \geq 2$.
3. $\mathcal{PR}_2^1 =$ FPTIME *(the polynomial-time computable functions).*
4. $\mathcal{PR}_1 = \mathcal{PR}_2 = \mathcal{D}$ *(the primitive recursive functions).*

Proof. Each part of items 1–3 is restated and proved as one of the theorems in section 6.

Item 4 is an easy corollary. By items 1 and 2 one obtains $\mathcal{PR}_2 = \mathcal{PR}_1$. The equivalence of $\mathcal{PR}_1$ and $\mathcal{D}$ is obtained by straightforward simulations. For example, the projection functions are computed in $\mathcal{PR}_1$ by the full composition $\pi_i(\vec{x}) = C(0, C(x_i, x_i, x_i), 0)$. $\square$

Oitavem [19] has shown that the Kalmar functions are obtained by adding s_0 as an initial function to the definition of $\mathcal{PR}_1^1$. In the current work, extra rank is used instead: the Kalmar functions are shown to equal $\mathcal{PR}_1^2$ (and $\mathcal{PR}_2^2$). The use of extra rank locates the Kalmar functions above the linear-space functions in a hierarchy.

The Kalmar functions were given a resource-free recursive characterization by Leivant [14] using higher-type recurrence. The present results do not use higher-type recursion.

This work extends the polynomial-time characterization of Bellantoni and Cook [4]. That result is listed above, but it is seen from a new perspective. Rather than defining a restricted class (FPTIME) using the rule of 1-safe recursion, one instead considers all recursion-on-notation derivations and then classifies them according to ρ. The set of derivations f such that $\rho(f) = 1$ are derivations of all the FPTIME functions.

A linear-space characterization similar to the current one was first proved by Bellantoni in his thesis [3, p. 49], at the suggestion of S. Cook; related linear-space results were proved independently by Handley [9] and Leivant [11]. The characterization was adapted and reproved by Nguyen [18] in her work on linear-space reasoning.

The current characterizations of $\mathcal{E}^{r+1}$ can also be compared to Leivant's characterization of Grzegorczyk classes using "coerced recurrence"; see [12, section 4]. Coerced recurrence seems to be more powerful than stratified recurrence. To restrict it, Leivant uses an approach similar to Parson's earlier definition ([20, p. 358]): one separately determines whether the step function uses the critical term. Leivant defined a hierarchy by putting the predicative recurrence rules at levels 0 and 1, together with the Parsons-like rules at levels 2 and above (see [12, section 4]). This hierarchy, which is similar to the present one, has desirable properties: it characterizes an interesting class at level 1, and it corresponds to the Grzegorczyk classes at and above the elementary level. Despite these desirable features, the definition by itself does not seem to integrate the lower levels with the higher ones. One can argue that ρ provides a more integrated definition. The characterization using ρ also differs in that it is type free, requires only one recursion scheme rather than two (stratified and coerced), and does not determine whether the step function uses the critical term.

Predicative recursion results for some other space-bounded complexity classes are available (see Oitavem [19]; Bellantoni [2]; Leivant and Marion [13]; Bloch [5]). With respect to parallel complexity classes, current results using unbounded recursion schemes (Bloch [5]; Leivant and Marion [13]; Bellantoni [3, p. 69] and [2]) are either unable to characterize the computationally interesting class NC or else require awkward constructions to do so.[1]

If ρ is taken as determining a fundamental hierarchy, then one discards classes $\mathcal{E}^0$ and $\mathcal{E}^1$ in favor of $\mathcal{PR}_1^0$. Functions in the class $\mathcal{PR}_1^0$ are compositions of the initial functions, i.e., functions computable in constant time, counting one time step for each initial function application. This seems to be quite a bit less than the functions in $\mathcal{E}^0$ or $\mathcal{E}^1$, which are defined by arbitrary amounts of bounded primitive recursion (albeit with a small size bound).

[1]Note added in press: A more satisfactory characterization recently appeared in D. Leivant, *A characterization of NC by tree recurrence*, in Proceedings of the 1998 IEEE Symposium on Foundations of Computer Science, IEEE, 1998, pp. 716–724.

The remainder of the paper is devoted to proving the results. We introduce Grzegorczyk polynomials and prove some simple facts about them. The statement of the key bounding lemma uses Grzegorczyk polynomials as the bounding functions. The required characterizations items 1–3 can be derived based on the bounding lemma.

5. Grzegorczyk polynomials. Bounding terms will be defined using an analogue, at each level of the Grzegorczyk hierarchy, of the successor, addition, and multiplication functions. These functions, indicated by S^r, $+^r$, and $\times^r$ for $r \geq 1$, are defined by

$$\begin{aligned}
S^1(x) &= S(x),\\[1ex]
0 +^r a &= a,\\
x +^r a &= S^r(Px +^r a) \quad \text{for } x \neq 0,\\[1ex]
0 \times^r y &= 0,\\
x \times^r y &= y +^r (Px \times^r y) \quad \text{for } x \neq 0,\\[1ex]
S^{r+1}(x) &= S^r((x +^r x) \times^r (x +^r x)).
\end{aligned}$$

Thus, $x +^r a$ is x applications of S^r starting at a and $x \times^r y$ is x applications of $y+^r$ starting at 0, that is, $x \cdot y$ applications of S^r starting at 0. Equivalently, $x \times^r y = (x \cdot y) +^r 0$. Under these definitions, S^1 is the ordinary successor function, and $+^1$ and $\times^1$ are ordinary addition and multiplication. At the next level, $+^2$ and $\times^2$ are elementary. Observe that all the functions $S^r, +^r, \times^r$ are monotone increasing. They are also monotone with respect to the level r; e.g., if $r' \leq r$, then $x +^{r'} y \leq x +^r y$ for all x and y.

A Grzegorczyk polynomial, or simply a polynomial, is an expression built up from nonnegative integer constants, input variables, and the functions $+^r$ for $r \geq 1$, $\times^r$ for $r \geq 1$, and max. All these functions are definable in $\mathcal{PR}_1$, but in considering Grzegorczyk polynomials we mean to use them as initial functions and then perform compositions.

Definition 5.1. *Define rank for polynomials as follows. For the primitives (with $r \geq 1$)*

$$\begin{aligned}
&\nu(x,1) = 0 \textit{ for variable } x,\\
&\nu(\max,1) = \nu(\max,2) = 0,\\
&\nu(+^r,1) = r \textit{ and } \nu(+^r,2) = r-1,\\
&\nu(\times^r,1) = \nu(\times^r,2) = r.
\end{aligned}$$

If the polynomial $q(\vec{x})$ is given by the expression $q_0(q_1(\vec{x}^1), \ldots, q_k(\vec{x}^k))$ (where each $\vec{x}^k \subseteq \vec{x}$), then define

$$\nu(q,i) = \max\{\, \nu(q_0,k),\, \nu(q_k,j) : \ \vec{x}_i \equiv (\vec{x}^k)_j \}.$$

When z is the ith variable in the list $\vec{x}$, we may write $\nu(q,z)$ for $\nu(q,i)$.

Intuitively, ν is very much like ρ, except that max is considered an initial function.

When we see that the outermost operation of a polynomial is $\times^r$, we know that all variables have rank at least r. But when we see that the outermost operation is $+^r$, we know that variables in the left subterm have rank at least r, and those in the right have at least $r-1$.

Grzegorczyk polynomials are a way of lifting ordinary polynomials into all levels of the Grzegorczyk hierarchy. The lifted functions do not have all the properties of the ordinary functions, such as commutativity of $+$. However, they do have many desirable properties, allowing us to generalize the proofs of [4] to all levels of the Grzegorczyk hierarchy. Some desirable properties of Grzegorczyk polynomials are as follows: (1) a restricted kind of associativity for $+$; (2) the fact that rank r polynomials are definable in $\mathcal{E}^{r+1}$; (3) the fact that $+^{r+1}$ grows faster than any polynomial of rank r; and (4) the ability to "separate" any polynomial q at any level r to get $q \le q' +^{r+1} \max \vec{x}^*$, where $\vec{x}^*$ are the variables in q of rank at most r, and where q' does not refer to $\vec{x}^*$. These facts are proved in the remainder of this section.

Lemma 5.2 (semiassociativity). *$x +^{r'} (y +^r z) \le (x +^{r'} y) +^r z$ for all x, y, and z and all $r' \le r$.*

Proof. The assertion is proved by calculating $x +^{r'} (y +^r z) = (S^{r'})^{(x)}((S^r)^{(y)}(z)) \le (S^r)^{(x)}((S^r)^{(y)}(z)) = (S^r)^{(x+y)}(z) \le (S^r)^{(x+^{r'}y)}(z) = (x +^{r'} y) +^r z$. ∎

Lemma 5.3 (definability). *Every Grzegorczyk polynomial q belongs to $\mathcal{E}^{\nu(q)+1}$.*

Proof. We first show by induction on $r \ge 1$ that $S^r \in \mathcal{E}^r$, and $+^r, \times^r \in \mathcal{E}^{r+1}$. In the base case, one has $S^1 \equiv S \in \mathcal{E}^0$, $+^1 \in \mathcal{E}^1$, and $\times^1 \in \mathcal{E}^2$, as the latter two are ordinary addition and multiplication. For the step case, the induction hypothesis yields $S^r \in \mathcal{E}^r$ and $+^r, \times^r \in \mathcal{E}^{r+1}$. This implies $S^{r+1} \in \mathcal{E}^{r+1}$ by definition of S^{r+1}. It is well known from [23] that any function defined by primitive recursion from functions in $\mathcal{E}^n$, $n \ge 2$, belongs to $\mathcal{E}^{n+1}$. Thus $+^{r+1} \in \mathcal{E}^{r+2}$. Since $x \times^{r+1} y = (x \cdot y) +^{r+1} 0$, we can define $\times^{r+1} \in \mathcal{E}^{r+1}$ using $+^{r+1}$. This concludes the induction showing $S^r \in \mathcal{E}^r$ and $+^r, \times^r \in \mathcal{E}^{r+1}$.

Now consider a Grzegorczyk polynomial q, and let $r = \nu(q)$. We define q in $\mathcal{E}^{r+1}$ by induction on the structure of q. If q is a constant or a variable, then it is easily defined in $\mathcal{E}^{r+1}$. If q is defined by $q_1 +^s q_2$ or $q_1 \times^s q_2$ for $s \le r$, or by $\max(q_1, q_2)$, then we are done using the induction hypothesis and using the closure of $\mathcal{E}^{r+1}$ under composition (note $\max \in \mathcal{E}^1$). If q is $q_1 +^s q_2$ or $q_1 \times^s q_2$ for $s \ge r+1$, then either q does not contain any variables or q is of the form $c +^{r+1} q_2$ for a constant c. For the case of q having the form $c +^{r+1} q_2$ for a constant c, we can define q in $\mathcal{E}^{r+1}$ using c compositions of S^{r+1} onto the definition of q_2, using $q_2 \in \mathcal{E}^{r+1}$ by the induction hypothesis. ∎

Lemma 5.4 (domination). *For every Grzegorczyk polynomial $q(\vec{x})$ there is a constant c_q satisfying $q(\vec{x}) \le c_q +^{\nu(q)+1} \max \vec{x}$ for all $\vec{x}$.*

Proof. The proof is by induction on the structure of q. If q is a constant, then the result is immediate using q as the required constant c_q; if q is a variable, then it is immediate using $c_q = 0$. Otherwise, $q(\vec{x}) = q_1(\vec{x}^1) \circ q_2(\vec{x}^2)$, where $\circ$ is either $+^s$, $\times^s$, or max. Let $r = \nu(q)$.

Suppose that $\circ$ is $+^s$ or $\times^s$ with $s \le r$, or $\circ$ is max. In these cases, observe that for every y, $y \circ y \le S^r((y +^r y) \times^r (y +^r y)) = S^{r+1}(y)$. Applying the induction hypothesis to obtain c_{q_1} and c_{q_2}, define $c = \max(c_{q_1}, c_{q_2})$ so that

$$\begin{aligned} q(\vec{x}) &\le (c +^{r+1} \max \vec{x}) \circ (c +^{r+1} \max \vec{x}) \\ &\le S^{r+1}(c +^{r+1} \max \vec{x}) \\ &= (c+1) +^{r+1} \max \vec{x}. \end{aligned}$$

If $\circ$ is $+^s$ with $s \ge r+2$, or is $\times^s$ with $s \ge r+1$, then both $\vec{x}^1$ and $\vec{x}^2$ are empty (since otherwise these variables would have rank greater than r, by the definition of ν). In these cases q is a constant expression and the result is easy.

If $\circ$ is $+^s$ with $s = r+1$, then $\vec{x}^1$ is empty, again by definition of ν. In this case, q_1 is a constant expression and $q(\vec{x})$ is equivalent to $c +^{r+1} q_2(\vec{x}^2)$ for some constant c. Applying the induction hypothesis on q_2, one obtains $q(\vec{x}) \le c +^{r+1} (c_{q_2} +^{r+1} \max \vec{x}^2) \le (c +^{r+1} c_{q_2}) +^{r+1} \max \vec{x}$. ◻

LEMMA 5.5 (separation). *Let q be a polynomial over $\vec{x}$, let r be a nonnegative integer, and define $\vec{x}' = \langle x_i : \nu(q, x_i) \ge r+1\rangle$ and $\vec{x}^* = \langle x_i : \nu(q, x_i) \le r\rangle$. Then there is a polynomial q' over $\vec{x}'$ such that*

$$q(\vec{x}) \le q'(\vec{x}') +^{r+1} \max \vec{x}^*, \tag{1}$$

$$\nu(q', z) = \nu(q, z) \text{ for } z \in \vec{x}'. \tag{2}$$

Proof. The proof is by structural induction on q. For q a constant or variable, note $\vec{x}' \equiv \langle\rangle$ and $\vec{x}^* \equiv \vec{x}$ because all the inputs to q are rank 0. So if q is a constant, defining $q' = c$ will do. Otherwise, q is a variable and we can define $q' = 0$; the statements (1) and (2) follow directly.

For the step case of the induction, one has $q(\vec{x}) = q_1(\vec{x}^1) \circ q_2(\vec{x}^2)$, where $\circ$ is either $+^s$ or $\times^s$ or max, and where $\vec{x}^1 \cup \vec{x}^2 \subseteq \vec{x}$. Consider cases on $\circ$.

Suppose $\circ$ is $\times^s$ for some $s \ge r+1$. Then $\vec{x}' = \vec{x}$ and $\vec{x}^* = \langle\rangle$ because for each $z \in \vec{x}$ one has $\nu(q_1 \times^s q_2, z) \ge s \ge r+1$. Defining $q'(\vec{x}') = q(\vec{x})$, the properties (1) and (2) follow trivially.

For a more difficult case, suppose $\circ$ is $+^s$ for some $s \ge r+1$. If $s > r+1$, then again $\vec{x}' = \vec{x}$ and $\vec{x}^* = \langle\rangle$ because for $z \in \vec{x}^1$ one has $\nu(q_1 +^s q_2, z) \ge s > r+1$ and for $z \in \vec{x}^2$ one has $\nu(q_1 +^s q_2, z) \ge s-1 \ge r+1$. Otherwise, $s = r+1$. Then $\vec{x}^1 \subseteq \vec{x}'$ because all the variables in the subexpression $q_1(\vec{x}^1)$ obtain rank at least $r+1$ due to their appearance on the left side of $+^{r+1}$. Applying the induction hypothesis to $q_2(\vec{x}^2)$, one obtains $q_2'((\vec{x}^2)')$, where $(\vec{x}^2)'$ are the rank at least $r+1$ variables in q_2. Defining $q'(\vec{x}') = q_1(\vec{x}^1) +^{r+1} q_2'((\vec{x}^2)')$ one has

$$\begin{aligned} q(\vec{x}) &\le q_1(\vec{x}^1) +^{r+1} (q_2'((\vec{x}^2)') +^{r+1} \max(\vec{x}^2)^*) \\ &\le (q_1(\vec{x}^1) +^{r+1} q_2'((\vec{x}^2)')) +^{r+1} \max \vec{x}^* \end{aligned}$$

as required for statement (1) of the lemma. Statement (2) for q' follows by statement (2) of the induction hypothesis on q_2 together with the definition of ν.

If $\circ$ is $+^s$ for $s \le r$, then we apply the induction hypothesis to both q_1 and q_2 with r, to obtain $q_1(\vec{x}^1) \le q_1'((\vec{x}^1)') +^{r+1} \max(\vec{x}^1)^*$ and $q_2(\vec{x}^2) \le q_2'((\vec{x}^2)') +^{r+1} \max(\vec{x}^2)^*$. Using the domination lemma on the polynomial $y +^s z$ and the fact that $r+1 \ge s+1$, let c be such that $c +^{r+1} \max(y, z) \ge y +^s z$ for all y, z. Then

$$\begin{aligned} q(\vec{x}) &\le (q_1'((\vec{x}^1)') +^{r+1} \max(\vec{x}^1)^*) +^s (q_2'((\vec{x}^2)') +^{r+1} \max(\vec{x}^2)^*) \\ &\le c +^{r+1} \max(q_1'((\vec{x}^1)') +^{r+1} \max(\vec{x}^1)^*, q_2'((\vec{x}^2)') +^{r+1} \max(\vec{x}^2)^*) \\ &\le c +^{r+1} (\max(q_1((\vec{x}^1)'), q_2((\vec{x}^2)')) +^{r+1} \max((\vec{x}^1)^* \cup (\vec{x}^2)^*)) \\ &\le (c +^{r+1} \max(q_1((\vec{x}^1)'), q_2((\vec{x}^2)'))) +^{r+1} \max((\vec{x}^1)^* \cup (\vec{x}^2)^*). \end{aligned}$$

Observing that rank $r+1$ or greater variables in q_1 or q_2 are also rank $r+1$ or greater in q, and that rank at most r variables in q_1 and q_2 are also rank at most r in q, one has $(\vec{x}^1)' \cup (\vec{x}^2)' \subseteq \vec{x}'$ and $(\vec{x}^1)^* \cup (\vec{x}^2)^* \subseteq \vec{x}^*$. Defining then $q'(\vec{x}') = c +^{r+1} \max(q_1'((\vec{x}^1)'), q_2'((\vec{x}^2)'))$, we have demonstrated property (1) and must verify property (2). By the induction hypothesis, every variable of rank at least $r+1$ in q_1

or q_2 has the same rank in q'_1 or q'_2, respectively. In q the subterms are combined with $+^s$, which does not change the rank of any of these variables, since these variables all have rank at least $r+1 > s$. In q' the subterms are combined with max, which also does not change the rank of any variable in the subterms. Property (2) follows.

For $\times^s$ with $s \le r$, one proceeds in the same way as for the case of $+^s$ with $s \le r$. A similar proof also works for max. ◻

6. Bounding lemma. The bounding lemma proved in this section is central to all the results, as it shows how the recursive layering indicated by ρ corresponds to bounded function growth rate. The latter in turn corresponds to bounds on the space or time of a computation.

One can just as well prove the bounding lemma at the same time for $\mathcal{PR}_2^r$ as for $\mathcal{PR}_1^r$. The proofs differ in the size measure used: the relevant measures are $\|x\|_1 \equiv x$ for $\mathcal{PR}_1$ and $\|x\|_2 \equiv |x|$ for $\mathcal{PR}_2$. In the following, one uses the fact that $S\|Px\|_1 = \|x\|_1$, or correspondingly $S\|px\|_2 = \|x\|_2$, for $x \neq 0$. We write $\|\cdot\|$ to mean either $\|\cdot\|_1$ or $\|\cdot\|_2$, depending on the class under discussion. The vector notation $\|\vec{x}\|$ means $\langle \|x_1\|, \dots, \|x_m\| \rangle$, where m is the number of elements in $\vec{x}$.

LEMMA 6.1 (bounding). *For every $f \in \mathcal{PR}_i$ $(i \in \{1,2\})$ there is a Grzegorczyk polynomial q_f over m_f variables such that $\|f(\vec{x})\|_i \le q_f(\|\vec{x}\|_i)$ and for $1 \le i \le m_f$, $\rho(f,i) = \nu(q_f,i)$.*

Proof. If f is one of the initial functions, then one assigns $q_f(\vec{x}) = 1 +^1 \max(\vec{x})$, and the required properties follow directly.

If f is defined by full composition, say $f(\vec{x}) = h(g_1(\vec{x}^1), \dots, g_n(\vec{x}^n))$, then one correspondingly defines q_f so that $q_f(\|\vec{x}\|) = q_h(q_{g_1}(\|\vec{x}^1\|), \dots, q_{g_n}(\|\vec{x}^n\|))$ using the polynomials obtained by the induction hypothesis. The statement of the lemma follows using monotonicity of polynomials to achieve the bounding expression and using the definitions of ρ and ν to achieve the equality of the ranks.

The last case is when f is defined by full recursion, say in $\mathcal{PR}_2$,

$$\begin{aligned} f(0,\vec{y}) &= g(\vec{y}), \\ f(x,\vec{y}) &= h(x,\vec{y}, f(px,\vec{y})) \quad \text{for } x \neq 0. \end{aligned}$$

The induction hypothesis gives $q_g(\vec{v})$ and $q_h(u,\vec{v},w)$ with input ranks equal to the input ranks of g and h. Letting $r = \rho(h, m_h)$, one applies the separation lemma to obtain q'_h such that

$$q_h(u,\vec{v},w) \le q'_h((u\vec{v})') +^{r+1} \max((u\vec{v})^*, w),$$

where $(u\vec{v})'$ is a sublist corresponding to input positions of h (or q_h) having rank at least $r+1$, and $(u\vec{v})^*, w$ is a sublist corresponding to the input positions of h (or q_h) having rank at most r. The separation lemma also gives equality between the ranks of the inputs that are in both q_h and q'_h. Now define q_f by

$$q_f(u,\vec{v}) = (u \times^{r+1} q'_h((u\vec{v})')) +^{r+1} \max((u\vec{v})^*, q_g(\vec{v})).$$

To prove the bound (1) for f, one uses induction on $\|x\|$, where the base case follows from $\|f(0,\vec{y})\| \le q_g(\|\vec{y}\|) \le q_f(\|0,\vec{y}\|)$. For the step case,

$$\begin{aligned} \|f(x,\vec{y})\| &\le q_h(\|x,\vec{y}, f(px,\vec{y})\|) \\ &\le q'_h(\|x,\vec{y}\|') +^{r+1} \max(\|x,\vec{y}\|^*, q_f(\|px,\vec{y}\|)) \\ &\le q'_h(\|x,\vec{y}\|') +^{r+1} \big((\|px\| \times^{r+1} q'_h(\|px,\vec{y}\|')) +^{r+1} \max(\|x,\vec{y}\|^*, q_g(\|\vec{y}\|))\big) \\ &\le \big(\|x\| \times^{r+1} q'_h(\|x,\vec{y}\|')\big) +^{r+1} \max(\|x,\vec{y}\|^*, q_g(\|\vec{y}\|)) \\ &\le q_f(\|x,\vec{y}\|). \end{aligned}$$

All that remains is to show that the ranks of variables in q_f are the same as in f.

First consider u. If $u \in (u\vec{v})'$, then $\nu(q'_h, 1) = \nu(q_h, 1) \geq r+1$ by the definition of $(u\vec{v})'$ and (2) of the separation lemma. Using the induction hypothesis on h, this gives $\rho(h,1) = \nu(q_h, 1) \geq r+1$. In this case, applying ν to q_f gives $\nu(q_f, 1) = \nu(q'_h, 1)$; also, applying ρ to f gives $\rho(f,1) = \rho(h,1)$. Thus $\rho(f,1) = \nu(q_f,1)$ in this case. The other case concerning the induction variable is when $u \in (u\vec{v})^*$, that is, $\rho(h,1) = \nu(q_h,1) \leq r$. In this case, $\rho(q_f, 1) = r+1$ due to the presence of u on the left side of $+^{r+1}$ in the definition of q_f. Correspondingly, $\rho(f,1) = \max(\rho(h,1), r+1) = r+1$ by the definition of ρ. This finishes the proof of $\rho(f,1) = \nu(q_f,1)$.

Now consider one of the parameter positions, $2 \leq i \leq m_f = m_h - 1$, where an input v_{i-1} appears in q_f. If $v_{i-1} \in (u\vec{v})'$, then $\nu(q_h, i) \geq r+1$. Using the equality of ranks in q_h with ranks in q'_h, one has $\nu(q_f, i) = \max(\nu(q_h, i), \nu(q_g, i-1))$ by the definition of ν on q_f. By the induction hypothesis, $\nu(q_h, i) = \rho(h,i)$ and $\nu(q_g, i-1) = \rho(g, i-1)$, leading to $\nu(q_f, i) = \max(\rho(h,i), \rho(g,i-1)) = \rho(f,i)$ by the definition of $\rho(f,i)$ with $\rho(h,i) \geq r+1 > \rho(h, m_h)$. The remaining case is when v_{i-1} does not appear in $(u\vec{v})'$, that is, $\nu(q_h, i) \leq r$. By the induction hypothesis on h, one has $\rho(h,i) = \nu(q_h,i) \leq r$, leading to $\rho(f,i) = \max(\rho(g,i-1), r)$. By the induction hypothesis on g this value is $\max(\nu(q_g, i-1), r)$. The definition of ν on q_f, using the fact that $v_{i-1} \notin (u\vec{v})'$, gives $\max(\nu(q_g, i-1), r) = \nu(q_f, i)$. This finishes the proof that $\rho(f,i) = \nu(q_f,i)$ for $2 \leq i \leq m_f$. $\square$

7. Proofs of characterization theorems. In this section we prove the characterizations which were summarized in section 4. The Schwichtenberg–Müller theorem is generalized. One direction uses the bounding lemma proved above, while the other direction is obtained by generalizing the simulation lemmas of [4] and [3] to all levels of the Grzegorczyk hierarchy. Finally, concerning $\mathcal{PR}_2^1$, we rely on the results of [4]. It is of some interest that the proofs for $r \geq 2$ do not refer to any computation model, unlike the Schwichtenberg and Müller proofs.

LEMMA 7.1 ($\mathcal{E}$-bounding). *For $r \geq 0$, every $f \in \mathcal{E}^{r+2}$ has a monotone increasing bound $b_f \in \mathcal{PR}_1^{r+1}$.*

Proof. Since S, $+^1$, and $\times^1$ are defined in $\mathcal{PR}_1^1$, we already have that A_0, A_1, and A_2 are in $\mathcal{PR}_1^1$. In fact, under these derivations, $\rho(A_2, 1) = \rho(A_2, 2) = 1$. Now note that for $r \geq 0$,

$$A_{r+3}(x, 0) = 1,$$
$$A_{r+3}(x,y) = A_{r+2}(x, A_{r+3}(x, Py)) \quad \text{for } y \neq 0.$$

It follows by induction on r that A_{r+3} is defined in $\mathcal{PR}_1$ with $\rho(A_{r+3}, 1) = r+1$ and $\rho(A_{r+3}, 2) = r+2$. Next note that max is definable in $\mathcal{PR}_1^1$ by $\max(x,y) = C(Sy \dot{-} x, x, y)$, where cutoff subtraction is defined by $x \dot{-} 0 = x$ and $x \dot{-} y = P(x \dot{-} Py)$ for $y \neq 0$. By a theorem in [23, p. 87], every $f \in \mathcal{E}^{r+2}$ satisfies $f(\vec{x}) \leq A_{r+3}(\max(2, \vec{x}), c_f)$ for some constant c_f. Since A_{r+3} is defined in $\mathcal{PR}_1$ with $\rho(A_{r+3}, 1) = r+1$, the composition $A_{r+3}(\max(2,\vec{x}), c_f)$ gives a bounding function for $f(\vec{x})$ in $\mathcal{PR}_1^{r+1}$. $\square$

LEMMA 7.2 (generalized simulation). *For every $f \in \mathcal{E}^{r+2}$ there is a derivation $f^* \in \mathcal{PR}_1^1$ and a monotone increasing function $w_f \in \mathcal{PR}_1^{r+1}$ such that $f^*(w, \vec{x}) = f(\vec{x})$ for all $w \geq w_f(\vec{x})$. In fact, $\rho(f^*, 1) \leq 1$ and for $2 \leq i \leq m_f$, $\rho(f^*, i) = 0$.*

Proof. The proof is by induction on the definition of $f \in \mathcal{E}^{r+2}$. If f is one of the initial functions $0, S, \Pi_i^n$, then $f^*(w, \vec{x}) = f(\vec{x})$ and $w_f(\vec{x}) = 0$ will do.

If f is the initial function A_{r+2}, then observe that f is definable in $\mathcal{E}^{r+2}$ using A_{r+2} itself to bound the recursions. Therefore, to obtain the statement of the lemma for A_{r+2}, one can apply the method below for compositions and bounded recursions to the definition of A_{r+2}.

Suppose that f is defined by a composition in $\mathcal{E}^{r+2}$, say $f(\vec{x}) = h(g_1(\vec{x}), \ldots, g_m(\vec{x}))$. The induction hypothesis provides suitable simulations $h^*, g_1^*, \ldots, g_m^*$ with monotone increasing functions $w_h, w_{g_1}, \ldots, w_{g_m} \in \mathcal{PR}_1^{r+1}$. By the $\mathcal{E}$-bounding lemma, there is a function $b \in \mathcal{PR}_1^{r+1}$ which is a monotone increasing bound on all $g_1, \ldots, g_m$. Therefore one defines $f^*(w, \vec{x}) = h^*(w, g_1^*(w, \vec{x}), \ldots, g_m^*(w, \vec{x}))$ and $w_f(\vec{x}) = w_h(b(\vec{x}), \ldots, b(\vec{x})) + \sum_j w_{g_j}(\vec{x})$.

Consider f defined by a bounded recursion in $\mathcal{E}^{r+2}$, such as $f(0, \vec{y}) = g(\vec{y})$, $f(x + 1, \vec{y}) = h(x, \vec{y}, f(x, \vec{y}))$, and $f(x, \vec{y}) \le k(x, \vec{y})$; where $g, h, k \in \mathcal{E}^{r+2}$. First note that the characteristic function $x \le y$ can be defined by $C(Sy \dot{-} x, 1, 0)$ with $\rho(\le, 1) = 1$ and $\rho(\le, 2) = 0$. Using the induction hypothesis, let

$$\begin{aligned} \hat{f}(0, w, x, \vec{y}) &= g^*(w, \vec{y}), \\ \hat{f}(v, w, x, \vec{y}) &= \text{if } v \le x, \text{ then } h^*(w, Pv, \vec{y}, \hat{f}(Pv, w, x, \vec{y})) \text{ else } \hat{f}(Pv, w, x, \vec{y}) \ (v \ne 0). \end{aligned}$$

Also define $w_f(x, \vec{y}) = w_h(x, \vec{y}, b(x, \vec{y})) + w_g(\vec{y}) + x$, where $b \in \mathcal{PR}_1^{r+1}$ is a monotone increasing bound on k obtained from the $\mathcal{E}$-bounding lemma. Given the ranks of the input position for $\le$ and for h' and g', we have $\rho(\hat{f}, 1) = \rho(\hat{f}, 2) = 1$ and $\rho(\hat{f}, i+2) = 0$ for $1 \le i \le m_f$. Moreover, if $w \ge w_f(x, \vec{y})$, then a subsidiary induction on v shows that $\hat{f}(v, w, x, \vec{y}) = f(v, \vec{y})$ for $v \le x$ and $\hat{f}(v, w, x, \vec{y}) = f(x, \vec{y})$ for $v \ge x$. Thus, the lemma is finished by defining $f^*(w, x, \vec{y}) = \hat{f}(w, w, x, \vec{y})$. $\square$

Finally, we can prove the main results.

THEOREM 7.3 (characterization). *For* $n \ge 1$, $\mathcal{E}^{r+1} = \mathcal{PR}_1^r$.

Proof. One direction follows from the generalized simulation lemma: given $f \in \mathcal{E}^{r+1}$ with $r \ge 1$, we obtain f^* such that $f(\vec{x}) = f^*(w_f(\vec{x}), \vec{x})$, where $f^* \in \mathcal{PR}_1^1$ and $w_f \in \mathcal{PR}_1^r$. Thus $f \in \mathcal{PR}_1^r$ as desired.

In the other direction, we are given a derivation $f \in \mathcal{PR}_1^r$ and need to show that the function computed by f is in $\mathcal{E}^{r+1}$. First we apply the ρ-normalization lemma to f, to ensure that all subderivations are also in $\mathcal{PR}_1^r$. Now we proceed by induction on the structure of f. In the initial cases $0, S, P$, we have $f \in \mathcal{E}^0$ and $C \in \mathcal{E}^1$. In the case of a full composition of h and $\vec{g}$, the ranks of h and $\vec{g}$ are at most r (by ρ-normalization) and therefore this case follows from the induction hypothesis, using composition in $\mathcal{E}^{r+1}$ with the projection functions. Finally, if f is defined by full recursion from g and h, the induction hypothesis gives g and h in $\mathcal{E}^{r+1}$. By the bounding lemma and the definability lemma, f is bounded by a function in $\mathcal{E}^{r+1}$. Thus f is definable by bounded primitive recursion in $\mathcal{E}^{r+1}$. $\square$

THEOREM 7.4 (see Bellantoni and Cook [4]). $\mathcal{PR}_2^1 =$ FPTIME.

Proof. Essentially this was proved in [4], to which the reader should refer. The definition of $\mathcal{PR}_2^1$ corresponds closely to the definition of the class B in [4], with rank 0 input positions being "safe" and rank 1 input positions being "normal." Although there are slight differences in the details of the formulations, such as the use of full composition instead of ordinary composition, these are inessential. $\square$

THEOREM 7.5 (equivalence of higher levels). *For* $r \ge 2$, $\mathcal{PR}_2^r = \mathcal{PR}_1^r$.

Proof. The first part of the lemma is to show $\mathcal{PR}_1^r \subseteq \mathcal{PR}_2^r$, for $r \ge 2$. First define, in $\mathcal{PR}_2^2$, the concatenation function $\oplus$ and the unary conversion function $u(x) = 2^x - 1$:

$$\begin{aligned} x \oplus 0 &= x, \\ x \oplus y &= c(y, s_0(x \oplus py), s_1(x \oplus py)), \\ u(0) &= 0, \\ u(x) &= c(x, u(px) \oplus u(px), s_1(u(px) \oplus u(px))). \end{aligned}$$

Under this definition, $|u(x)| = x$, and the number of steps in a full recursion on notation on $u(x)$ is the same as the number of steps in a full primitive recursion on x. Also, $p(u(x)) = u(Px)$. We write $u(\vec{x})$ for $u(x_1), \dots, u(x_m)$, where m is the number of elements in $\vec{x}$.

To show $\mathcal{PR}_1^r \subseteq \mathcal{PR}_2^r$, one proceeds by induction on the structure of a $\mathcal{PR}_1$ derivation f, defining a corresponding $\mathcal{PR}_2$ derivation f' such that $f'(u(\vec{x})) = u(f(\vec{x}))$ for all $\vec{x}$, and such that $\rho(f', i) = \rho(f, i)$ for all i. Each case of the induction is straightforward: for initial functions $0, S, P, C$ we use $0, s_1, p, c$ (note $u(x) = 2^x - 1$); if f is defined by full primitive recursion on g and h, then f' is defined by full recursion on notation on g' and h' (note $p(u(x)) = u(Px)$); and for full compositions in $\mathcal{PR}_1$ we use full compositions in $\mathcal{PR}_2$. Having finished the structural induction, one can observe that $f(\vec{x}) = |f'(u(\vec{x}))|$ is a computation of f in $\mathcal{PR}_2^{\max(\rho(f),2)}$, because $u \in \mathcal{PR}_2^2$ and $|\cdot| \in \mathcal{PR}_2^1 =$ FPTIME.

The second part is to show $\mathcal{PR}_2^r \subseteq \mathcal{PR}_1^r$, for $r \geq 2$. Using the characterization theorem, $\mathcal{E}^{r+1} \subseteq \mathcal{PR}_1^r$ for $r \geq 2$, so it is enough to show that for $r \geq 2$, $\mathcal{PR}_2^r \subseteq \mathcal{E}^{r+1}$.

Let f be any derivation in $\mathcal{PR}_2$, and let $r = \rho(f)$; we show that the function computed by f is in $\mathcal{E}^{\max(3,r+1)}$. Applying the ρ-normalization lemma, we can assume that all subderivations of f are in $\mathcal{PR}_2^r$. If f is an initial function, i.e., s_0, s_1, p, or c, then the same function is defined in FLINSPACE $= \mathcal{E}^2$. If f is defined by a full composition $h(g_1(\vec{x}^1), \dots, g_m(\vec{x}^m))$, then by ρ-normalization and the induction hypothesis we can compute h and $\vec{g}$ in $\mathcal{E}^{\max(3,r+1)}$, and therefore by composition $f \in \mathcal{E}^{\max(3,r+1)}$. The last case is when f is defined by full recursion on notation, say, $f(0, \vec{y}) = g(\vec{y})$ and $f(x, \vec{y}) = h(x, \vec{y}, f(px, \vec{y}))$ for $x \neq 0$. In this case, a function to extract the high-order n bits of a value x is defined by $e(x, n) = p^{(|x| \dot{-} n)}(x)$ (where "$\dot{-}$" is the cutoff subtraction defined earlier). The e function, as well as the length function $|\cdot|$ and comparison $\leq$, is in FLINSPACE $= \mathcal{E}^2$. The induction hypothesis yields $g, h \in \mathcal{E}^{\max(3,r+1)}$. Now define a function $\hat{f}$ by $\hat{f}(0, x, \vec{y}) = g(\vec{y})$ and $\hat{f}(n, x, \vec{y}) =$ "if $n \leq |x|$, then $h(e(x, n), \vec{y}, \hat{f}(Pn, x, \vec{y}))$ else $\hat{f}(Pn, x, \vec{y})$" for $n \neq 0$. An induction on n, for $0 \leq n \leq |x|$, shows that $\hat{f}(n, x, \vec{y}) = f(e(x, n), \vec{y})$. For $n \geq |x|$, one has $\hat{f}(n, x, \vec{y}) = f(x, \vec{y}) = f(e(x, n), \vec{y})$ due to the "else" clause. Thus the definition $f(x, \vec{y}) = \hat{f}(|x|, x, \vec{y})$ will complete the proof, provided that the recursion defining $\hat{f}$ can be carried out in $\mathcal{E}^{\max(3,r+1)}$, that is, provided we have a bounding function for $\hat{f}$ in $\mathcal{E}^{\max(3,r+1)}$. Since $\hat{f}(n, x, \vec{y}) \leq f(e(x, n), \vec{y})$ and $e \in \mathcal{E}^2$, a bound on f is sufficient to give a bound on $\hat{f}$. By the bounding lemma for $\mathcal{PR}_2^r$, one has a Grzegorczyk polynomial q of rank r such that $|f(\vec{x})| \leq q(|\vec{x}|)$. Therefore $f(\vec{x}) \leq 2^{q(|\vec{x}|)}$. By the definability lemma, $q \in \mathcal{E}^{r+1}$. Since exponentiation is in $\mathcal{E}^3$, we have $2^{q(|\vec{x}|)} \in \mathcal{E}^{\max(3,r+1)}$. Therefore, f is bounded by an $\mathcal{E}^{\max(3,r+1)}$ function. □

8. Conclusion. A detailed analysis of the nesting of recursions has yielded benefits at the low levels of the Grzegorczyk hierarchy. Ramified recursion has been reframed in the traditional context of counting the nesting of recursions. Computationally interesting classes are seen to be characterized by this "structural" analysis of function derivations, which is based on a novel way of counting recursions. This integrates older characterizations at and above the elementary level with newer characterizations below the elementary level.

All the results obtained here are for recursions in type level 0, i.e., the value computed by the recursion is an integer. An extension of these results to higher-type recursion would be of interest.

COMMUNICATION-EFFICIENT PARALLEL SORTING[*]

MICHAEL T. GOODRICH[†]

Abstract. We study the problem of sorting n numbers on a p-processor bulk-synchronous parallel (BSP) computer, which is a parallel multicomputer that allows for general processor-to-processor communication rounds provided each processor sends and receives at most h items in any round. We provide parallel sorting methods that use internal computation time that is $O(\frac{n \log n}{p})$ and a number of communication rounds that is $O(\frac{\log n}{\log(h+1)})$ for $h = \Theta(n/p)$. The internal computation bound is optimal for any comparison-based sorting algorithm. Moreover, the number of communication rounds is bounded by a constant for the (practical) situations when $p \leq n^{1-1/c}$ for a constant $c \geq 1$. In fact, we show that our bound on the number of communication rounds is asymptotically optimal for the full range of values for p, for we show that just computing the "or" of n bits distributed evenly to the first $O(n/h)$ of an arbitrary number of processors in a BSP computer requires $\Omega(\log n / \log(h+1))$ communication rounds.

Key words. parallel algorithms, parallel sorting, parallel processing

1. Introduction.

Most of the research on parallel algorithm design in the 1970s and 1980s was focused on fine-grain massively parallel models of computation (e.g., see Akl [4], Bitton et al. [7], JáJá [26], Karp and Ramachandran [28], Leighton [32], and Reif [43]), where the ratio of memory to processors is fairly small (typically $O(1)$), and this focus was independent of whether the model of computation was a parallel random-access machine (PRAM) or a network model, such as a mesh-of-processors model. However, as more and more parallel computer systems are being built, researchers are realizing that processor-to-processor communication is a prime bottleneck in parallel computing (e.g., see Aggarwal, Chandra, and Snir [2], Bilardi and Preparata [6], Culler et al. [13], Kruskal, Rudolph, and Snir [30], Mansour, Nisan, and Vishkin [34], Mehlhorn and Vishkin [35], Papadimitriou and Yannakakis [38], and Valiant [47, 46]). The real potential of parallel computation, therefore, will most likely be realized only for coarse to medium-grain parallel systems, where the ratio of memory to processors is unbounded, for such systems allow an algorithm designer to balance communication latency with internal computation time. Indeed, this realization has given rise to several new computation models for parallel algorithm design, which all use what Valiant [46] calls "bulk synchronous" processing. In such a model an input of size n is distributed evenly across a p-processor parallel computer. In a single computation *round* (which Valiant calls a *superstep*) each processor may send and receive h messages and then perform an internal computation on its internal memory cells using the messages it has just received. The amount of additional "internal time" is allowed to be greater than h. To avoid any conflicts that might be caused by asynchronies in the network (whose topology is left undefined) the messages sent out in a round t by some processor cannot depend upon any messages that a processor

receives in round t (but, of course, they may depend upon messages received in round $t-1$). We refer to this model of computation as the bulk-synchronous parallel (BSP) model.

1.1. The BSP computer. As with the PRAM family of computer models,[1] the BSP model is distinguished by the broadcast and combining abilities of the network connecting the various processors. In the weakest version, which is the only version Valiant [46] considers, the network may not duplicate or combine messages but instead may only realize h-relations between the processors. We call this the exclusive-read exclusive-write (EREW) BSP model, noting that it is essentially the same as a model Valiant elsewhere [47] calls the XPRAM and one that Gibbons [21] calls the EREW phase-PRAM. It is also the communication structure assumed by the LogP model [13, 29], which is the same as the BSP model except that the LogP model does not explicitly require bulk-synchronous processing.

It is also natural to allow for a slightly more powerful bulk-synchronous model, which we call the weak–concurrent-read exclusive-write (CREW) BSP model. In this model we assume processors are numbered 1, 2, . . ., p and that messages can be duplicated by the network so long as the destinations for any message are a contiguous set of processors $\{i, i+1, \ldots, j\}$. This is essentially the same as a model Dehne et al. [16] and Dehne, Fabri, and Rau–Chaplin [17] refer to as the coarse-grain multicomputer. In designing an algorithm for this model one must take care to ensure that, even with message duplication, the number of messages received by a processor in a single round is at most h. Nevertheless, as we demonstrate in this paper, this limited broadcast capability can sometimes be employed to yield weak-CREW BSP algorithms that are conceptually simpler than their EREW BSP counterparts.

We can also define more powerful instances of the BSP model, such as a CREW BSP model, which allows for arbitrary broadcasts, or even a concurrent-read concurrent-write (CRCW) BSP model, which also allows for messages to the same location to be combined (using some rule). These models correspond to models Gibbons [21] calls the CREW phase-PRAM and CRCW phase-PRAM. In fact, Nash et al. [36] consider even more-powerful bulk-synchronous models in which messages can be combined using more-powerful combining functions (such as "add" or "bitwise-and"). We personally feel that anything more powerful than a weak-CREW BSP computer is probably not a realistic parallel model, given the possible asynchronies a network may possess; hence, we restrict our attention in this paper to the EREW and weak-CREW versions of the BSP model.

The running time of a BSP algorithm is characterized by two parameters: T_C, the number of communication rounds, and T_I, the internal computation time, that is, the sum, taken over all rounds of the algorithm, of the maximum amount of internal computation time taken by any processor in that round. A prime goal in designing a BSP algorithm is to minimize both of these parameters. Alternatively, by introducing additional characterizing parameters of the BSP model, we can combine T_I and T_C into a single running time parameter, which we call the *combined running time*. Specifically, if we let L denote the latency of the network—that is, the worst-case time needed to send one processor-to-processor message—and we let g denote the time "gap" between consecutive messages received by a processor in a communication round, then we can characterize the total running time of a BSP computation as

[1]Indeed, a PRAM with the same number of processors and memory cells is a BSP model with $h = 1$, as is a *module parallel computer* (MPC) [35], which is also known as a *distributed-memory machine* (DMM) [27], for any memory size.

$O(T_I + (L + gh)T_C)$. Incidentally, this is also the running time of implementing a BSP computation in the analogous[2] LogP model [13, 29].

The goal of this paper is to further the study of bulk-synchronous parallel algorithms by addressing the fundamental problem of sorting n elements distributed evenly across a p-processor BSP computer.

1.2. Previous work on parallel sorting. Let us, then, briefly review a small sample of the work previously done for parallel sorting. Batcher [5] in 1968 gave what is considered to be the first parallel sorting scheme, showing that in a fine-grained parallel sorting network one can sort in $O(\log^2 n)$ time using $O(n)$ processors. Since this early work there has been much effort directed at fine-grain parallel sorting algorithms (e.g., see Akl [4], Bitton et al. [7], JáJá [26], Karp and Ramachandran [28], and Reif [43]). Nevertheless, it was not until 1983 that it was shown, by Ajtai, Komlós, and Szemerédi [3], that n elements can be sorted in $O(\log n)$ time with an $O(n \log n)$-size network (see also Paterson [39]). In 1985 Leighton [31] extended this result to show that one can produce an $O(n)$-node bounded-degree network capable of sorting in $O(\log n)$ steps, based upon an algorithm he called "columnsort." In 1988 Cole [11] gave simple methods for optimal sorting in the CREW and EREW PRAM models in $O(\log n)$ time using $O(n)$ processors, based upon an elegant "cascade mergesort" paradigm using arrays, and this result was recently extended to the Parallel Pointer Machine by Goodrich and Kosaraju [22]. Thus, one can sort optimally in these fine-grained models.

These previous methods are not optimal, however, when implemented in bulk-synchronous models. Nevertheless, Leighton's columnsort method [31] can be used to design a bulk-synchronous parallel sorting algorithm that uses a constant number of communication rounds, provided $p^3 \leq n$. Indeed, there is a host of published algorithms for achieving such a result when the ratio of input size to number of processors is as large as this. For example, a randomized strategy, called sample sort, achieves this result with high probability [8, 19, 20, 24, 25, 33, 42, 44], as do deterministic strategies based upon regular sampling [18, 37, 45, 48]. These methods based upon sampling do not seem to scale nicely for smaller n/p ratios, however. If columnsort is implemented in a recursive fashion, then it yields an EREW BSP algorithm that uses $T_C = O([\log n/\log(n/p)]^\delta)$ communication rounds and internal computation time that is $O(T_C(n/p)\log(n/p))$, where $\delta = 2/(\log 3 - 1)$, which is approximately 3.419. Using an algorithm they call "cubesort," Cypher and Sanz [14] show how to improve the T_C term in these bounds to be $O((25)^{(\log^* n - \log^*(n/p))}[\log n/\log(n/p)]^2)$, and Plaxton [40] shows how cubesort can be modified to achieve $T_C = O([\log n/\log(n/p)]^2)$. Indeed, Plaxton [41] can modify the "sharesort" method of Cypher and Plaxton [15] to achieve $T_C = O((\log n/\log(n/p))\log^2(\log n/\log(n/p)))$. Finally, Chvátal [10] describes an approach of Ajtai, Komlós, Paterson, and Szemerédi for adapting the sorting network of Ajtai, Komlós, and Szemerédi [3] to achieve a depth of $O(\log n/\log(n/p))$ where the basic unit in the network is a "black box" that can sort $\lceil n/p \rceil$ elements. An effective method for constructing such a network is not included in Chvátal's report, however, for the method he describes is a nonuniform procedure based upon the probabilistic method. In addition, the constant factor in the running time appears to be fairly large. Incidentally, these latter methods [10, 15, 14, 31, 40] are actually defined for more-restrictive BSP models where the data elements cannot be duplicated and each

[2]There is also an o parameter in the LogP model, but it would be redundant with L and g in this bound.

internal computation must be a sorting of the internal-memory elements.

The only previous sorting algorithms we are aware of that were designed with the BSP model in mind are recent methods of Adler, Byers, and Karp [1] and Gerbessiotis and Valiant [20]. The method of Adler, Byers, and Karp runs in a combined time that is $O(\frac{ng\log n}{p} + pg + gL)$, provided $p \leq n^{1-\delta}$ for some constant $0 < \delta < 1$. They do not define their algorithm for larger values of p, but they do give a slightly better implementation of their method in the LogP model so as to achieve a running time of $O(\frac{ng\log n}{p} + pg + L)$ for p similarly bounded. Gerbessiotis and Valiant give several randomized methods,[3] the best of which runs with a combined time of $O(\frac{n\log n}{p} + gp^{\epsilon} + gn/p + L)$, with high probability, for any constant $0 < \epsilon < 1$, provided $p \leq n^{1-\delta}$, where δ is a small constant depending upon ϵ.

1.3. Our results. Given a set S of n items distributed evenly across p processors in a weak-CREW BSP computer we show how S can be sorted in $O(\log n/\log(h+1))$ communication rounds and $O((n\log n)/p)$ internal computation time, for $h = \Theta(n/p)$. The method is fairly simple and the constant factors in the running time are fairly small. Moreover, we also show how to extend our result to the EREW BSP model while achieving the same asymptotic bounds on the number of communication rounds and internal computation time. Our bounds on internal computation time are optimal for any comparison-based parallel algorithm. In addition, we achieve a deterministic combined running time that is $O(\frac{n\log n}{p} + (L + gn/p)(\log n/\log(n/p)))$, which is valid for all values of p and improves the best bounds of Adler, Byers, and Karp [1] and Gerbessiotis and Valiant [20] even when $p \leq n^{1-\delta}$ for some constant $0 < \delta < 1$, in which case our method sorts in a constant number of communication rounds. In fact, if $p^3 \leq n$, then our method essentially amounts to a sample sort (with regular sampling). If $p = \Theta(n)$, then our method amounts to a pipelined parallel mergesort, achieving the same asymptotic performance as the fine-grained algorithms of Cole [11] and Goodrich and Kosaraju [22]. Thus, our method provides a sorting method that is fully scalable over all values of p while achieving an optimal internal computation time over this entire range.

Indeed, we show that our bounds on the number of communication rounds needed to sort n elements on a BSP computer are also worst-case optimal for this entire range of values of p. We establish this by showing that simply computing the "or" of n bits distributed evenly across $\Theta(n/h)$ processors requires $\Omega(\log n/\log(h+1))$ number of communication rounds, where each processor can send and receive h messages in a CREW BSP computer. This lower bound holds even if the number of additional processors and the number of additional memory cells per processor are unbounded. Since this lower bound is independent of the total number of processors and amount of memory in the multicomputer, it joins lower bounds of Mansour, Nisan, and Vishkin [34] and Adler, Byers, and Karp [1] in giving further evidence that the prime bottleneck in parallel computing is communication, not the number of processors nor the memory size.

2. A weak-CREW BSP sorting algorithm.

Let S be a set of n items distributed evenly in a p-processor weak-CREW BSP computer. We sort the elements of S using a d-way parallel mergesort, pipelined in a way analogous to the binary parallel mergesort procedures of Cole [11] and Goodrich and Kosaraju [22].

[3]They also give an alternate BSP sorting method that has a combined running time of $O([(n/p)\log^{a+1} p + L\log^2 p + g\log^{a+2} p + g(n/p)\log p]/\log\log p)$, with high probability, provided $p < n/\log^{a+1} p$.

Specifically, we choose $d = \max\{\lceil\sqrt{n/p}\rceil, 2\}$ and let T be a d-way rooted, complete, balanced tree such that each leaf is associated with a subset $S_i \subseteq S$ of size at least $\lfloor n/p \rfloor$ and at most $\lceil n/p \rceil$. For each node v in T define $U(v)$ to be the sorted list of elements stored at descendants of v in T, where we define v to be a descendant of itself if it is a leaf. Note that if $\{w_1, w_2, \ldots, w_d\}$ denote the children of a node v in T, then $U(v) = U(w_1) \cup U(w_2) \cup \cdots \cup U(w_d)$. Our goal, then, is to construct $U(root(T))$. We may assume, without loss of generality, that the elements are distinct, for otherwise we can break ties using the original positions of the elements of S.

We perform this construction in a bottom-up pipelined way. In particular, we perform a series of *stages*, where in stage t we construct a list $U_t(v) \subseteq U(v)$ for each node v that we identify as being *active*. A node is *full* in stage t if $U_t(v) = U(v)$, and a node is *active* if $U_t(v) \neq \emptyset$ and v was not full in stage $t-3$. Likewise, we say that a list A stored at a node v in T is *full* if $A = U(v)$. Initially, each leaf of T is full and active, whereas each internal node is initially inactive.

We say that a list B is a *k-sample* of a list A if B consists of every kth element of A. For each active node v in T we define a sample $L_t(v)$ as follows:

- If v is not full, then $L_t(v)$ is a d^2-sample of $U_t(v)$.
- If v first became full in stage t, then we define $L_t(v)$ to be a d^2-sample of $U_t(v) = U(v)$; we define $L_{t+1}(v)$ to be a d-sample of $U_t(v)$; and we define $L_{t+2}(v) = U(v)$ (i.e., $L_{t+2}(v)$ is full).

We then define

$$U_t(v) = L_{t-1}(w_1) \cup L_{t-1}(w_2) \cup \cdots \cup L_{t-1}(w_d),$$

where, again, $\{w_1, w_2, \ldots, w_d\}$ denote the children of node v in T. Note that by our definition of $L_t(v)$, if a node v becomes full in stage t, then v's parent becomes full in stage $t+3$. Thus, assuming we can implement each stage with a constant number of communication rounds using the p processors, we will be able to sort the elements of S, by constructing $U(root(T))$, in just $O(\log_d n) = O\left(\frac{\log n}{\log(h+1)}\right)$ communication rounds, for $h = \Theta(n/p)$. Before we give the details for implementing each stage in our algorithm, however, we establish the following bounds.

LEMMA 2.1. *If at most k elements of $U_t(v)$ are in an interval $[a, b]$, then at most $dk + 2d^2$ elements of $U_{t+1}(v)$ are in $[a, b]$.*

Proof. Our proof is by induction on t. Suppose there are k elements of $U_t(v)$ in an interval $[a, b]$. Since the claim is clearly true if v is full (which is the base case), let us suppose further that v is not full. Then $U_t(v) = L_{t-1}(w_1) \cup L_{t-1}(w_2) \cup \cdots L_{t-1}(w_d)$, where $\{w_1, w_2, \ldots, w_d\}$ denote the children of v. Let j_i denote the number of elements of $L_{t-1}(w_i)$ in the interval $[a, b]$ and let k_i denote the number of elements of $U_{t-1}(w_i)$ in the interval $[a, b]$. Likewise, let j'_i denote the number of elements of $L_t(w_i)$ in the interval $[a, b]$ and let k'_i denote the number of elements of $U_t(w_i)$ in the interval $[a, b]$. Finally, let k' denote the number of elements of $U_{t+1}(v)$ in the interval $[a, b]$. Then

$$k = \sum_{i=1}^{d} j_i$$

and

$$\left\lfloor \frac{k_i}{d^2} \right\rfloor \leq j_i \leq \left\lceil \frac{k_i}{d^2} \right\rceil$$

by our definition of $L_t(w_i)$, with similar relationships holding, respectively, for k' and the k'_i values. Therefore,

$$\begin{aligned}
k' &= \sum_{i=1}^{d} j'_i \\
&\le \sum_{i=1}^{d} \left\lceil \frac{k'_i}{d^2} \right\rceil \\
&\le \sum_{i=1}^{d} \left\lceil \frac{dk_i + 2d^2}{d^2} \right\rceil \qquad \text{(by our induction hypothesis)} \\
&= \sum_{i=1}^{d} \left(\left\lceil \frac{k_i}{d} \right\rceil + 2 \right) \\
&\le 2d + \sum_{i=1}^{d} \left\lceil \frac{d^2(j_i+1)}{d} \right\rceil \\
&= 2d + \sum_{i=1}^{d} d(j_i+1) \\
&= 2d + d^2 + d\sum_{i=1}^{d} j_i \\
&= 2d + d^2 + dk \\
&\le dk + 2d^2,
\end{aligned}$$

provided $d \ge 2$, which will always be the case for our algorithm. ∎

Intuitively, this lemma says that $U_{t+1}(v)$ will not be wildly different from $U_t(v)$. Similarly, we have the following corollary that relates $L_{t+1}(v)$ and $L_t(v)$.

COROLLARY 2.2. *If at most k elements of $L_t(v)$ are in an interval $[a, b]$, then at most $d(k + 1) + 2$ elements of $L_{t+1}(v)$ are in $[a, b]$.*

Proof. Suppose there are k elements of $L_t(v)$ in an interval $[a, b]$. The corollary is immediately true if v is full, so let us suppose that v is not full. Then there are at most $d^2(k + 1)$ elements of $U_t(v)$ in $[a, b]$; hence, by Lemma 2.1, there are at most $d^3(k + 1) + 2d^2$ elements of $U_{t+1}(v)$ in $[a, b]$. Thus, there are at most $d(k + 1) + 2$ elements of $L_{t+1}(v)$ in $[a, b]$. ∎

Having given this important lemma and its corollary, let us now turn to the details of implementing each stage in our pipelined procedure using just a constant number of communication rounds.

2.1. Implementing each stage using a constant number of communication rounds.

We say that a list A is *ranked* [11, 22] into a list B if, for each element $a \in A$, we know the rank of a's predecessor in B (based upon the ordering of elements in $A \cup B$). If A is ranked in B and B is ranked in A, then A and B are *cross ranked.* The generic situation at the end of any stage t is that we have the following conditions satisfied at each node v in T.

Induction invariants.

1. $L_t(v)$ is ranked into $L_{t-1}(v)$.
2. If v is not full, then $L_{t-1}(w_i)$ is ranked into $U_t(v)$, for each child w_i of v in T.

3. $L_t(v)$ is ranked into $U_t(v)$.

We maintain copies of the lists $L_{t-1}(v)$, $L_t(v)$, $U_{t-1}(v)$, and $U_t(v)$ for each active node v in T, and we do not maintain any other lists during the computation. As we shall show, this will allow us to implement the entire computation efficiently using just p processors. In order to implement each stage in our computation using just $O(1)$ communication rounds we also maintain the following important load-balancing invariant at each node v in T.

Load-balancing invariant.

- If a list A is not full, then A is partitioned into contiguous subarrays of size d each, with each subarray stored on a different processor.
- If a list A is full, then A is partitioned into contiguous subarrays of size d^2 each, with each subarray stored on a different processor.

We assume that the names of the nodes of v in T and the four lists stored at each node v are defined so that given an index, i, into one of these lists, A, one can determine the processor holding $A[i]$ as a local computation (not needing a communication step). For example, we could number the nodes in T using the level-order labeling (e.g., see Goodrich and Tamassia [23]) and number each contiguous subarray of an array A consecutively. Since the arrays stored at the same level in T are all within one element of being the same size, such a numbering scheme would allow us to compute in $O(1)$ time the processor number holding any subarray $A[i..j]$ of an array A simply by knowing the index for $A[i..j]$ and the level-order number of the node holding $A[i..j]$.

Given that the induction and load-balancing invariants are satisfied for each node v in T, we can construct $U_{t+1}(v)$ at each active node, with the above invariants satisfied for it, as follows.

Computation for stage $t + 1$.

1. For each element a in $L_t(w_i)$, let $b(a)$ and $c(a)$, respectively, be the predecessor and successor of a in $L_{t-1}(w_i)$. We can determine $b(a)$ and $c(a)$ in $O(1)$ communication rounds, for each such a, since $L_t(w_i)$ is ranked in $L_{t-1}(w_i)$ by induction invariant 1. In fact, if $L_t(w_i) = U(w_i)$, then this is essentially a local computation. Moreover, by our load-balancing invariant and Corollary 2.2, even in the general case, each processor (storing a portion of some $L_{t-1}(w_i)$) will receive (and then send) at most $d(d+1)+2 = \Theta(h)$ messages to implement this step.
2. Determine the location (rank) of $b(a)$ and $c(a)$ in $U_t(v)$. This can also be easily implemented with a $O(1)$ communication rounds, as in the previous step.
3. Broadcast a (and its rank in $L_t(w_i)$) to all processors holding elements of $U_t(v)$ between $b(a)$ and $c(a)$. Note that this step may require usage of the weak-CREW capability, since there may be many processors holding such elements and, if so, these processors will be consecutively numbered. By our load-balancing invariant and Lemma 2.1 we can guarantee that each processor will receive at most $3d^2 + d = \Theta(h)$ messages to implement this step (each processor receives at least one element from each child of v plus as many elements as fall in its interval of $U_t(v)$); hence, this step can be implemented in $O(1)$ communication rounds.
4. Each processor assigned to a contiguous portion $[e, f)$ of $U_t(v)$ receives elements sent in the previous round and merges them via a simple d-way merge-sort procedure to form a sublist of $U_{t+1}(v)$ of size $O(d^2) = O(h)$. It is im-

portant to observe that the processor for $[e, f)$ receives at least one element from each child of v so as to include all the elements that may intersect the interval $[e, f)$, even if none actually fall inside $[e, f)$. This allows us to accurately compute the rank of each element in $U_{t+1}(v)$ locally; hence, it gives us $U_t(v)$ cross ranked with $U_{t+1}(v)$. Moreover, this step can be accomplished in $O(1)$ communication rounds and $O(d^2 \log d) = O((n/p)\log(n/p))$ internal computation time.

5. For each element a in $U_{t+1}(v)$ send a message to the processor holding $a \in L_t(w_i)$ informing that copy of a of its rank in $U_{t+1}(v)$. This step can easily be accomplished in $O(1)$ communication rounds and gives us induction invariant 2.
6. Determine the sample $L_{t+1}(v)$ and rank it into $U_{t+1}(v)$, giving us induction invariant 3. Also, use the cross ranking of $U_{t+1}(v)$ and $U_t(v)$ to rank $L_{t+1}(v)$ into $L_t(v)$, giving us induction invariant 1. This step can easily be accomplished in $O(1)$ communication rounds.
7. Finally, partition the four lists stored at each node v so as to satisfy the load-balancing invariant. That is, we partition each list in T into the appropriately sized sublists and ship sublists to processors according to our numbering scheme. Assuming the total size of all the nonfull lists in T is $O(n/d)$, this can easily be performed in $O(1)$ communication rounds using $p = \Theta(n/d^2)$ processors.

Therefore, given the above assumption regarding the total size of all the lists, in a constant number of communication rounds and an internal computation time that is $O((n/p)\log(n/p))$ we can build the set $U_{t+1}(v)$ and establish the induction and load-balancing invariants so as to repeat this procedure in stage $t + 2$.

Let us therefore analyze the total size of all the lists stored at nodes in T. Clearly, the size of all the full lists in T is $O(n)$. Moreover, each such list contributes at most $1/d$ of its elements to the next higher level in T, and from then on up T each list on a level l contributes at most $1/d^2$ of its elements to lists on the next higher level in T. Thus, the total size of all nonfull $U_{t-1}(v)$ or $U_t(v)$ lists forms a geometric series that sums to be $O(n/d)$, which is what we require. In addition, any sample $L_t(v)$ or $L_{t-1}(v)$ that is not full can contain at most $1/d$ of the elements of $U(v)$; hence, the total space needed for all these lists is also $O(n/d)$. This establishes the following.

THEOREM 2.3. *Given a set S of n items stored $O(n/p)$ per processor on a p-processor weak-CREW BSP computer, one can sort S in $O(\log n/\log(h+1))$ communication steps and $O((n \log n)/p)$ internal computation time, where $h = \Theta(n/p)$.*

In achieving this result we exploited the broadcast capability of the weak-CREW BSP model (in step 3). In the next section we show how to match the asymptotic performance of Theorem 2.3 without using such a capability.

3. An EREW BSP sorting algorithm.

Suppose we are now given a set S of n items, which are distributed evenly across the p processors of an EREW BSP computer. Our goal is to sort S in $O(\log n/\log(h+1))$ communication rounds and $O(n \log n/p)$ internal computation time without using any broadcasts, for $h = \Theta(n/p)$. We achieve this result using a cascading method similar to one used by Cole [11], which itself is similar to the general fractional cascading technique of Chazelle and Guibas [9].

Let T be a complete rooted d-way tree with each of its leaves associated with a sublist $S_i \subset S$ of size at most $\lceil n/p \rceil$, where $d = \max\{\lceil (n/p)^{1/7} \rceil, 2\}$ (the reason for this choice will become apparent in the analysis). Our method proceeds in a series of stages, as in the weak-CREW BSP algorithm, with us constructing the set $U_t(v)$ in each stage, as before:

$$U_t(v) = \bigcup_{i=1}^{d} L_{t-1}(w_i),$$

where each $L_t(v)$ list is defined to be a sample of $U_t(v)$ as in our weak-CREW algorithm.

In order to perform this construction so as to avoid broadcasts, however, we will accomplish this by constructing a larger, augmented list, $A_t(v)$, such that $U_t(v) \subseteq A_t(v)$. We also define a list $D_t(v)$ to be a d^2-sample of $A_t(v)$. For each active node v, with parent u and children $w_1, w_2, \ldots, w_d$, we then define

$$A_t(v) = D_{t-1}(u) \cup \bigcup_{i=1}^{d} L_{t-1}(w_i),$$

i.e., $A_t(v) = D_{t-1}(u) \cup U_t(v)$. Intuitively, the D_t lists communicate information "down" the tree T in a way that allows us to avoid broadcasts. Indeed, once a copy of an element begins to traverse down the tree, it will never again traverse up (since the D lists are sent only to children).

Still, although we are assuming, without loss of generality, that the elements of S are distinct, this definition may create duplicate entries of an element in the same list, with some traversing down and at most one traversing up. We resolve any ambiguities this may create by breaking comparison ties based upon an upward-traversing element always being greater than any downward-traversing element, and any comparison between downward-traversing elements is resolved based upon the level in T where the elements first began traversing down (where level numbers increase as one traverses down T).

The goal of each stage t in the computation, then, is to construct $A_t(v)$ and $U_t(v)$, together with their respective samples $D_t(v)$ and $L_t(v)$. In order to prove that each stage of our algorithm can indeed be performed in a constant number of communication rounds on an EREW BSP computer we must establish the following bounds.

LEMMA 3.1. *If at most k elements of $A_t(v)$ are in an interval $[a, b]$, then at most $(d+1)k + 2(d+1)^2$ elements of $A_{t+1}(v)$ are in $[a, b]$.*

Proof. The proof is essentially the same as that for Lemma 2.1 except that the expansion coefficient is now $d + 1$, instead of d, for each nonfull active node now receives elements from all $d + 1$ of its neighbors in T, not just its children. ∎

This immediately implies the following.

COROLLARY 3.2. *If at most k elements of $D_t(v)$ are in an interval $[a, b]$, then at most $(d+1)(k+1) + 3$ elements of $D_{t+1}(v)$ are in $[a, b]$.*

Proof. Suppose there are k elements of $D_t(v)$ in an interval $[a, b]$. Then there are at most $d^2(k + 1)$ elements of $A_t(v)$ in $[a, b]$; hence, by Lemma 3.1, there are at most $(d + 1)d^2(k + 1) + 2(d + 1)^2$ elements of $A_{t+1}(v)$ in $[a, b]$. Thus, there are at most $(d + 1)(k + 1) + 3$ elements of $D_{t+1}(v)$ in $[a, b]$. ∎

In addition, we can also show the following.

LEMMA 3.3. *For any two consecutive elements b and c in $A_t(v)$ let b' and c', respectively, be the predecessor of b and the successor of c in $A_t(u)$, where u is the parent of v in T. There are at most $(d+1)(d^2+1) + 2(d+1)^2 + 2$ elements of $A_t(u)$ in the interval $[b', c']$.*

Proof. By construction, $A_t(v)$ contains $D_{t-1}(u)$ as a subset, and $D_{t-1}(u)$ is a d^2-sample of $A_{t-1}(u)$. Thus, there can be at most d^2+1 elements of $A_{t-1}(u)$ in the interval $[b,c]$. By Lemma 3.1, then, there will be at most $(d+1)(d^2+1)+2(d+1)^2$ elements of $A_t(u)$ in the interval $[b,c]$; hence, there will be at most $(d+1)(d^2+1)+2(d+1)^2+2$ elements of $A_t(u)$ in the interval $[b',c']$. □

Finally, we have the following.

LEMMA 3.4. *For any two consecutive elements b and c in $D_{t-1}(u)$ there are at most $(d+1)^2(d^4+5)$ elements of $A_t(v)$ in the interval $[b,c]$, where u is the parent of v in T.*

Proof. By construction, $D_{t-1}(u)$ is a d^2-sample of $A_{t-1}(u)$, which in turn contains $L_{t-2}(v)$ as a subset. Thus, there are at most d^2+1 elements of $L_{t-2}(v)$ in the interval $[b,c]$. This implies that there are at most d^4+1 elements of $A_{t-2}(v)$ in the interval $[b,c]$. The lemma follows then by two applications of Lemma 3.1. □

As will become apparent in our algorithm description, these bounds are all crucial for establishing that our algorithm runs in the EREW BSP model using a constant number of communication rounds per stage. In order to perform the computation for stage $t+1$ using a constant number of communication rounds we assume that we maintain the following induction invariants for each active node v in T.

Induction invariants.
1. $A_t(v)$ is ranked into $U_t(v)$.
2. $A_t(v)$ and $D_{t-1}(u)$ are cross ranked, where u is the parent of v.
3. $A_{t-1}(v)$ is ranked into $A_t(v)$.
4. $D_t(v)$ is ranked in $D_{t-1}(v)$.

We also maintain a load-balancing invariant, similar to the one we used in our weak-CREW BSP algorithm, except that we now define a list A stored at a node v to be *full* if $A \supseteq U(v)$.

Load-balancing invariant.
- If a list A is not full, then A is partitioned into contiguous subarrays of size d^6 each, with each subarray stored on a different processor.
- If a list A is full, then A is partitioned into contiguous subarrays of size d^7 each, with each subarray stored on a different processor.

Given that the induction and load-balancing invariants hold after the completion of stage t, our method for performing stage $t+1$ is as follows.

Computation for stage $t+1$. For each child w_i of v we perform the following computation:
1. For each element a in $A_t(w_i)$ use the ranking of $A_t(w_i)$ in $U_t(w_i)$ to determine if a is also in $L_t(w_i)$ (together with its rank in $L_t(w_i)$ if so). No communication is necessary for this step, given induction invariant 1.
2. For each such element a in $L_t(w_i)$ use the ranking of $A_t(w_i)$ in $D_{t-1}(v)$ to determine the ranks of the predecessor, $b(a)$, of a and successor, $c(a)$, of a in $D_{t-1}(v)$. No communication is necessary for this step either, given induction invariant 2.
3. For each a in $L_t(w_i)$, use the ranks of the processor(s) for $b(a)$ and $c(a)$ in $D_{t-1}(v)$ to determine the respective ranks of $b(a)$ $c(a)$ in $A_{t-1}(v)$. No communication is necessary for this step.
4. For each a in $L_t(w_i)$, request that the processor(s) for $b(a)$ and $c(a)$ in $A_{t-1}(v)$ send(s) the processor for a the name of predecessor, $b'(a)$, of $b(a)$ and the name of successor, $c'(a)$, of $b(a)$ in $A_t(v)$, using invariant 3. By Lemma 3.1 and

our load-balancing invariant, each processor will receive and send at most $(d+1)d^6 + 2(d+1)^2 = \Theta(h)$ messages to implement this step.

5. Send a (together with its rank in $L_t(w_i)$) to the processor(s) assigned to elements of $A_t(v)$ between $b'(a)$ and $c'(a)$ to be merged with all other elements of $A_{t+1}(v)$ that fall in this range. As with the previous step, by Lemma 3.1 and our load-balancing invariant each processor will receive at most $(d+1)d^6 + 2(d+1)^2 = \Theta(h)$ messages to implement this step. More importantly, by Lemma 3.3, each processor will send an element a to at most $\lceil((d+1)(d^2+1) + 2(d+1)^2 + 2)/d^6\rceil + 1 = O(1)$ other processors. Thus, no broadcasting is needed in order to implement this step.

At the parent u of v we assume a similar (but simpler) computation is being performed:

1. For each element a in $D_t(u)$, determine the ranks of $b(a)$ and $c(a)$, the respective predecessor and successor of a in $D_{t-1}(u)$. No communication is necessary for this step, given induction invariant 4.
2. Request that the processor(s) for the copies of $b(a)$ and $c(a)$ in $D_{t-1}(u)$ return the ranks of $b(a)$ and $c(a)$ in $A_t(v)$, which are available because of induction invariant 2. By Corollary 3.2 and our load-balancing invariant, this step can be implemented with each processor receiving and sending at most $(d+1)(d^6+1) + 3 = \Theta(h)$ messages.
3. Send a (together with its rank in $D_t(u)$) to the processor(s) assigned to elements of $A_t(v)$ between $b(a)$ and $c(a)$ to be merged with all other elements of $A_{t+1}(v)$ that fall in this range. By Lemma 3.4 each processor will send an element a to at most $\lceil(d+1)^2(d^4+5)/d^6\rceil + 1 = O(1)$ other processors; hence, no broadcasting is needed. Moreover, each processor will send d such copies of a, which, by our load-balancing invariant, implies that a processor will send $O(h)$ messages. Likewise, each processor will receive at most $O(h)$ messages.

Finally, at node v we perform the following computation:

1. For each interval $[e, f)$ of elements of $A_t(v)$ assigned to a single processor, merge all the elements coming from the parent u and children $w_1, w_2, \ldots, w_d$ to form $A_{t+1}(v)$. Such a processor will receive at least one element from each node adjacent to v, plus as many elements of $A_{t+1}(v)$ as fall in $[e, f)$, for a total of at most $d + 1 + (d+1)d^6 + 2(d+1)^2 = \Theta(h)$. This mergesort computation amounts to a $(d+1)$-way mergesort and can easily be implemented in $O(d^7 \log(d+1)) = O((n/p)\log(n/p))$ internal steps.
2. Likewise, for each interval $[e, f)$ of elements of $A_t(v)$ assigned to a single processor, merge all the elements coming just from v's children $w_1, w_2, \ldots, w_d$ to form $U_{t+1}(v)$ (and $A_{t+1}(v)$ ranked in $U_{t+1}(v)$, which gives us induction invariant 1).
3. Use the rank information derived from the previous two steps to rank $A_{t+1}(v)$ in $D_t(u)$, giving us half of induction invariant 2. Also, rank $A_t(v)$ in $A_{t+1}(v)$, giving us invariant 3 and by an additional calculation a ranking of $D_{t+1}(v)$ in $D_t(v)$, which is invariant 4. Finally, send a message to each element a in $D_t(u)$ informing it of its rank in $A_{t+1}(v)$ so as to complete the other half of invariant 2. To implement this step requires that each processor send at most h messages and each processor receive at most $d^6(d) = O(h)$ messages.
4. Finally, repartition the lists at each node v so as to satisfy the load-balancing invariant. Assuming that the total size of all nonfull lists is $O(n/d)$ and the size of all full lists is $O(n)$, this step can easily be implemented in $O(1)$ communication rounds.

Let us, therefore, analyze the space requirements of this algorithm. The total size of all the $U(v)$ lists on the full level clearly is $O(n)$. Each such list causes at most $\lceil |U(v)|/d \rceil$ elements to be sent to v's parent, u. Now the inclusion of these elements in u causes at most $(d+1)\lceil |U(v)|/d^3 \rceil$ elements to be sent to nodes at distance 1 from u (including v itself). However, once an element starts traversing down the tree T it never is sent up again. We can repeat this argument to establish that the existence of $U(v)$ causes at most $(d+1)^2 \lceil |U(v)|/d^5 \rceil$ elements to be sent to nodes at distance 2 from u, and so on. Thus, the number of all of these elements that originate from u sum to be a geometric series that is $O(n/d)$. Therefore, the total size of all the nonfull lists is $O(n/d)$. Likewise, the total size of all the lists (and hence the lists on the full level) is $O(n)$. This gives us the following theorem.

THEOREM 3.5. *Given a set S of n items stored $O(n/p)$ per processor on a p-processor EREW BSP computer, one can sort S in $O(\log n/\log(h+1))$ communication rounds and $O(n \log n/p)$ internal computation time, for $h = \Theta(n/p)$.*

This immediately implies the following.

COROLLARY 3.6. *Given a set S of n items stored $O(n/p)$ per processor, one can sort S on an EREW BSP computer with a combined running time that is $O(\frac{n \log n}{p} + (L + gn/p)(\log n/\log(n/p)))$.*

This bound also applies to the LogP model.

4. A lower bound for BSP computations.

In this section we show that our upper bounds on the number of communication rounds needed to sort n numbers on a p-processor BSP computer are optimal. Specifically, we show that $\Omega(\log n/\log(h+1))$ communication steps are needed to compute the "or" of n bits using an arbitrary number of processors in a CREW BSP computer, where h is the number of messages that can be sent and received by a single processor in a single communication round.

Let us begin by formalizing the framework for proving our lower bound. Assume we have a set S of n Boolean values $x_1, x_2, \ldots, x_n$ initially placed in memory locations $m_1, m_2, \ldots, m_n$ with memory cells $m_{(i-1)h+1}, \ldots, m_{ih}$ stored in the local memory of processor p_i, for $i \in \{1, 2, \ldots, \lceil n/h \rceil\}$. This, of course, implies that we have at least $\lceil n/h \rceil$ processors, but for the sake of the lower bound we allow for an arbitrary number of processors. Moreover, we place no upper bound on the amount of additional memory cells that each processor may store internally. The goal of the computation is that after some T steps the "or" of the values in S should be stored in memory location m_1.

Our lower bound proof will be an adaptation of a lower bound proof of Cook, Dwork, and Reischuk [12] for computing the "or" of n bits on a CREW PRAM. In performing this adaptation there are several difficulties that must be overcome. The primary difficulty comes from the fact that each processor in a BSP computer can send h messages in each communication round, rather than just a single value, because this complicates arguments that bound the amount of information processors can communicate by *not* sending messages.

Each processor p_i is assumed initially to be in a starting state, q_1^i, taken from a possibly unbounded set of states. At the beginning of a round t processor p_i is assumed to be in some state q_t^i. A round begins with each processor sending up to h messages, some of which may be (arbitrary) partial broadcasts, and simultaneously receiving up to h messages from other processors. Without loss of generality, each message may be assumed to be the contents of one of the memory cells associated with the sending processor, since we place no constraints on the amount of information that may be stored in a memory cell nor on the number of memory cells that a processor may contain. A processor then enters a new state q^i_{t+1} that depends upon its previous state q^i_t and the values of the messages it has received. A round completes with a processor possibly writing new values to some of its internal memory cells based upon its new state q^i_{t+1}.

Before analyzing the most general situation, let us first prove a lower bound for the *oblivious* case, where the determination of whether a processor p_i will send a message to processor p_j in round t depends upon only the value of p_i and t and not on the input. Of course, the contents of such a message could depend upon the input. For input string $I = (x_1, x_2, \ldots, x_n)$ of Boolean values, let $I(k)$ denote the input string $(x_1, x_2, \ldots, \bar{x}_k, \ldots, x_n)$, where $\bar{x}_k$ denotes the complement of Boolean value x_k. I is a *critical input* for function $f(I)$ if $f(I) \neq f(I(k))$ for all $k \in \{1, 2, \ldots, n\}$. (Note that $I = (0, 0, \ldots, 0)$ is a critical input for the "or" function.) Say that input index k *affects* [12] processor p_i in round t with input I if the state of p_i on input I after round t differs from the state of processor p_i on input $I(k)$ after round t. Likewise, say that input index k affects memory cell m_i in round t with input I if the contents of m_i on input I after round t differs from the contents of m_i on input $I(k)$ after round t.

THEOREM 4.1. *If $f : \{0,1\}^n \to \{0,1\}$ has a critical input, then any oblivious CREW BSP computer that computes f requires $\Omega(\log n / \log(h+1))$ communication rounds.*

Proof. Let $K(p_i, t, I)$ (respectively, $L(m_i, t, I)$) be the set of input indices that affect processor p_i (respectively, memory cell m_i) in round t with input I. Further, let K_t and L_t satisfy the following recurrence equations:

$$K_0 = 0, \tag{4.1}$$

$$L_0 = 1, \tag{4.2}$$

$$K_{t+1} = K_t + hL_t, \tag{4.3}$$

$$L_{t+1} = K_{t+1} + L_t = K_t + (h+1)L_t. \tag{4.4}$$

Note that it suffices to prove that $|K(p_i, t, I)| \leq K_t$ and $|L(p_i, t, I)| \leq L_t$, for K_t and L_t are both at most $[2(h+1)]^t$, and if I is a critical input for f, then every one of the input indices must affect memory cell m_1. That is, if $m_1 = f(I)$, then $|L(m_1, T, I)| = n$, which implies that T is $\Omega(\log n / \log(h+1))$.

We establish the bounds on $|K(p_i, t, I)|$ and $|L(p_i, t, I)|$ by induction on t. First, note that $K(p_i, t, I)$ is empty in round $t = 0$, and $L(m_i, 0, I) = \{i\}$ if $i \in \{1, 2, \ldots, n\}$ and otherwise $L(m_i, 0, I)$ is empty. In round $t+1$ each processor p_i receives the contents of up to h memory locations; hence, $K(p_i, t+1, I) \subseteq K(p_i, t, I) \cup \bigcup_{j \in \mathcal{I}} L(m_j, t, I)$ for some index set $\mathcal{I}$ with $|\mathcal{I}| \leq h$. Thus, $|K(p_i, t+1, I)| \leq K_{t+1}$ by the induction hypothesis. After a processor p_i receives the values of these memory locations it may, at its option, write to any of its internal memory cells based upon its new state. Therefore, for any memory cell m_j internal to processor p_i, $L(m_j, t+1, I) \subseteq K(p_i, t+1, I) \cup L(m_j, t, I)$; hence, by the induction hypothesis and (4.3), $|L(m_j, t+1, I)| \leq L_{t+1}$. $\square$

The main difficulty in generalizing this result to nonoblivious computations is that in the non oblivious case a processor p_i can receive information from a processor p_j by p_j *not* sending a message to p_i. Still, as we show in the next theorem, this ability cannot alter the asymptotic performance of a CREW BSP computer by more than a constant factor for computing the value of a function with a critical input.

THEOREM 4.2. *If $f : \{0,1\}^n \to \{0,1\}$ has a critical input, then any CREW BSP computer that computes f requires $\Omega(\log n / \log(h+1))$ communication rounds.*

Proof. Let $K(p_i, t, I)$ and $L(m_i, t, I)$ be as in the proof of Theorem 4.1. But now let K_t and L_t be defined by the following recurrence relations:

$$K_0 = 0, \tag{4.5}$$

$$L_0 = 1, \tag{4.6}$$

$$K_{t+1} = (6h+1)K_t + hL_t, \tag{4.7}$$

$$L_{t+1} = K_{t+1} + L_t = (6h+1)K_t + (h+1)L_t. \tag{4.8}$$

As in the previous proof, it suffices to show that $|K(p_i, t, I)| \le K_t$ and $|L(m_i, t, I)| \le L_t$, for K_t and L_t are both at most $[7(h+1)]^t$.

We establish these bounds on $|K(p_i, t, I)|$ and $|L(p_i, t, I)|$ by induction on t. First, note that $K(p_i, t, I)$ is empty in round $t = 0$, and $L(m_i, 0, I) = \{i\}$ if $i \in \{1, 2, \ldots, n\}$ and otherwise $L(m_i, 0, I)$ is empty. At the beginning of round t a processor p_i receives the contents of at most h memory locations, and it also receives information by noting that some processors did not send p_i a message. Still, after it incorporates this information into its new state q^i_{t+1}, it optionally writes to its local memory, as in the previous proof. Thus, if we can establish (4.7), then (4.8) immediately follows.

Say that input index k *possibly causes* a processor p_j to send a message to processor p_i in round t with I if p_j sends a message to processor p_i in round t on input $I(k)$. Using this notion we bound $K(p_i, t+1, I)$ as a subset of

$$K(p_i, t, I) \cup \bigcup_{j \in \mathcal{I}} L(m_j, t, I) \cup Y(p_i, t, I),$$

for some index set $\mathcal{I}$ with $|\mathcal{I}| \le h$, where $Y(p_i, t, I)$ denotes the set of all indices k that possibly cause some processor p_j to send a message to p_i with I. Thus, we must bound $r = |Y(p_i, t, I)|$. So, let $Y = Y(p_i, t, I) = \{k_1, k_2, \ldots, k_r\}$ be the set of indices that possibly cause a processor to send a message to p_i with I. Further, for each k_j, let $p(k_j)$ denote a specific processor that would send p_i a message in round t on $I(k_j)$, and let P denote the set of all such processors, i.e., define $P = \{p(k_j)\colon k_j \in Y\}$. Note that if $r \le hK_t$, then we have established (4.7), so for the remainder of this proof let us assume that $r > hK_t$. We will show that if this is the case, then $r \le 6hK_t$.

As done by Cook, Dwork, and Reischuk [12], we employ a combinatorial graph argument to derive a bound on $r = |Y|$. Consider a bipartite graph G whose two node sets are Y and P. Let there be an edge between k_j in Y and $p(k_l)$ in P if k_j affects $p(k_l)$ in round t with $I(k_l)$. Let e denote the number of edges in G. The degree of any node $p(k_j)$ is at most $|K(p(k_j), t, I(k_j))|$, which, by our induction hypothesis, is bounded by K_t. Thus, $e \le |P|K_t \le rK_t$.

We can also derive a lower bound on e. To this end let us define a second graph H, which is defined on the elements in Y. Say that two indices k_j and k_l in Y are adjacent in H if there is, in G, an edge from k_j to $p(k_l)$ or an edge from k_l to $p(k_j)$. That is, for each edge (k_j, k_l) in H there is at least one corresponding edge in G, indicating that either k_j affects $p(k_l)$ with $I(k_l)$ or k_l affects $p(k_j)$ with $I(k_j)$. Say that a subset $Y' \subseteq Y$ is *processor-disjoint* if, for any k_j and $k_{j'}$ in Y', $p(k_j) \ne p(k_{j'})$.

Claim A. If $Y' \subseteq Y$ is a processor-disjoint independent set in H, then $|Y'| \le h$.

Proof of Claim A. Let $Y' = \{k_{j_1}, k_{j_2}, \ldots, k_{j_m}\}$. Suppose, for the sake of a contradiction, that $m > h$. Since Y' is an independent set in H, then no index k_j in Y' affects the processor associated with any other index k_l in Y' (i.e., $p(k_l)$). Thus, since Y' is processor-disjoint, on input $I(k_{j_1})(k_{j_2}) \cdots (k_{j_m})$ there would be more than h different messages sent to processor p_i. However, this would contradict the communication bandwidth assumptions of the BSP model. $\square$

Claim B. There are at least $r/2$ nodes in H with degree at least $r/2h - K_t$.

Proof of Claim B. Suppose, for the sake of contradiction, that there are at least $r/2$ nodes in H with degree less than $r/2h - K_t$. To reach a contradiction we will construct a processor-disjoint independent set in H of size more than h. We begin by placing the nodes of H into equivalence classes such that the nodes in the same class are all associated with the same processor, i.e., k_j and k_l are in the same class if and only if $p(k_j) = p(k_l)$. Note that there are at most K_t nodes in any class. Now consider a simple greedy algorithm for constructing a processor-disjoint independent Y' set in H:

1. Go to any node v in H of degree less than $r/2h - K_t$ and place v into Y'.
2. Having placed v into Y', delete from H all the nodes in the same class as v as well as all nodes in H that are adjacent to v.
3. If there are nodes left in H, repeat the above two steps.

This, of course, removes less than $r/2h - K_t + K_t = r/2h$ nodes in each iteration. Thus, we can repeat this process for strictly more than

$$\frac{r/2}{r/2h} = h$$

iterations. By construction, there are no edges in H between any of the nodes in Y', and each node in Y' is in a different equivalence class. However, this implies a processor-disjoint independent set $Y' \subseteq Y$ in H such that $|Y'| > h$, which contradicts Claim A. $\square$

Claim B implies that there at least $(r/2)(r/2h - K_t)$ edges in H; hence there are at least this many edges in G. Therefore, $(r/2)(r/2h - K_t) \leq rK_t$. Noting that this implies $r \leq 6hK_t$ completes the proof of the theorem. $\square$

5. Conclusion. We have studied the power and limitations of parallel computing with particular attention paid to the importance of communication in parallel algorithm design, which is an issue gaining prominence in both theory and practice. We gave BSP algorithms for sorting that are optimal in terms of both the internal computation times and the number of communication rounds. Admittedly, the algorithm we derived for the EREW BSP model is considerably more complicated than that we derived for the weak-CREW BSP model. Thus, it is not actually clear which one would be more efficient in practice. A weak-CREW BSP computer would be easier to program but would require the switching hardware in the network to be more sophisticated than what would be required by our EREW BSP algorithm.

Acknowledgments. We would like to thank Bob Cypher, Faith Fich, S. Rao Kosaraju, Greg Plaxton, Mikael Sundström, and Les Valiant for several helpful conversations and e-mail exchanges regarding topics related to this paper.

PROXIMITY IN ARRANGEMENTS OF ALGEBRAIC SETS[*]

J. H. RIEGER[†]

Abstract. Let X be an arrangement of n algebraic sets X_i in d-space, where the X_i are either parametrized or zero-sets of dimension $0 \leq m_i \leq d-1$. We study a number of decompositions of d-space into connected regions in which the distance-squared function to X has certain invariances. Each region is contained in a single connected component of the complement of the bifurcation set $\mathcal{B}$ of the family of distance-squared functions or of certain subsets of $\mathcal{B}$. The decompositions can be used in the following proximity problems: given some point, find the k nearest sets X_i in the arrangement, find the nearest point in X, or (assuming that X is compact) find the farthest point in X and hence the smallest enclosing $(d-1)$-sphere. We give bounds on the complexity of the decompositions in terms of n, d, and the degrees and dimensions of the algebraic sets X_i.

Key words. k nearest points, Voronoi regions, bifurcation sets, critical points, symbolic computation

1. Introduction.

Let X be the union of n algebraic sets X_i of dimension $0 \leq m_i \leq d-1$ in d-space which are defined either by parametrizations or, more generally, as zero-sets. The dimension d of the ambient space is assumed to be arbitrary but fixed. Given a point $p \in \mathbb{R}^d$ with rational or, more generally, with algebraic number coordinates and a set of defining polynomials of X with rational coefficients, we would like to do the following:

1. find the k nearest sets X_i;
2. find the nearest point in X;
3. and, provided that X is compact, find the farthest point in X (and hence the smallest sphere with center p enclosing X).

For all of these proximity problems it is convenient to decompose d-space into certain connected regions, depending on X, in which the distance-squared function to X has certain invariances. A number of such decompositions are possible. Some decompositions have many invariants but also many regions, and it is of interest to bound the number of regions in terms of n, d, and the degrees and dimensions of the algebraic sets X_i. For example, the coarsest decomposition considered below consists of the first-order Voronoi regions, and the finest consists of the regions in the complement of the bifurcation set of the family of all distance-squared functions on X. However, all the decompositions studied here have the property that the proximity problems above can be solved in $O(\log n) \cdot P$ time (discarding the preprocessing time for constructing the decomposition), where P is a polynomial in the degrees and coefficient sizes of both the defining polynomials of X and the minimal polynomials of the algebraic number coordinates of p (from section 4 on we shall often concentrate on the combinatorial complexity, where the degrees and coefficient sizes of these polynomials are assumed to be bounded by some constant independent of n). Decompositions of

d-space into regions made of points having certain proximity properties with respect to some collection of submanifolds of $\mathbb{R}^d$ have been studied both in computational geometry and in singularity theory, but there hasn't been much interaction between these fields.

Most of the works in computational geometry consider either the classical, first-order, Voronoi diagram of sets of isolated points or extensions to arrangements of linear subspaces of $\mathbb{R}^d$. The relation between higher-order Voronoi diagrams in $\mathbb{R}^d$ and arrangements in $\mathbb{R}^{d+1}$ is investigated by Edelsbrunner and Seidel [12]. A few works also consider Voronoi diagrams of arrangements of curved objects. First-order Voronoi diagrams of disjoint convex semialgebraic sites in d-space are studied in the book of Sharir and Agarwal [22]. Alt and Schwarzkopf [1] study first-order Voronoi diagrams of parametrized (semialgebraic) curve-segments and points in the plane. These authors are also interested in the local geometry of Voronoi edges: for example, they point out that end-points of self-Voronoi-edges (in the singularity theory literature known as symmetry sets) correspond to centers of osculating circles at curvature extrema of a planar curve and also to a cusp singularity of the evolute (or focal set). The local geometry of such symmetry sets and of evolutes has been studied in great detail in a number of singularity theory works.

One of the main topics of singularity theory is the classification of stable and unstable singularities of functions and maps, and of the bifurcation sets in the parameter space of families of functions and maps. The bifurcation set of a family of functions $F : \mathbb{R}^d \times \mathbb{R}^m \to \mathbb{R}^d \times \mathbb{R}$, $(p, x) \mapsto (p, f(p, x))$ consists of all points p in parameter space $\mathbb{R}^d$ for which the function $x \mapsto f(p, x)$ has an unstable (degenerate) singularity. The family of distance-squared functions from any point $p \in \mathbb{R}^d$ to a parametrized m-dimensional surface X in d-space is a particular example of such a family, and the bifurcation set of this family is precisely the union of the evolute and the symmetry set of X. Porteous [16, 17] has used the classification of families of functions by Thom (from the early 1960s) to study the relation between the geometry of evolutes and the curvature of surfaces. Bruce, Giblin, and Gibson [6] have classified the singularities of symmetry sets of planar curves and of surfaces and space-curves in $\mathbb{R}^3$; see also the recent paper by Bruce [5]. Symbolic algorithms for computing bifurcation sets of families of projection maps have been studied by Rieger [19, 20] and these algorithms can also be used, with some minor modifications, to compute other bifurcation sets, such as evolutes and symmetry sets.

1.1. Assumptions and some notation. Let $X := \cup X_i \subset \mathbb{R}^d$ be a collection of n closed algebraic sets X_i and set $m_i := \dim X_i$ $(0 \le m_i \le d-1)$ and $m := \sup m_i$. For parametrized algebraic m_i-surfaces $x \mapsto X_i(x)$ we denote the maximal degree of the d component functions of $X_i(x)$ by δ_i, and set $\delta := \sup \delta_i$ $(1 \le i \le n)$. For the more general case of zero-sets $X_i = h_i^{-1}(0)$, where $h_i := (h_i^1, \dots, h_i^{d-m_i}) : \mathbb{R}^d \to \mathbb{R}^{d-m_i}$, we assume that X_i, or rather its complexification, is a complete intersection (i.e., its codimension is equal to the number of defining equations) and we set $\Delta_i := \Pi_j \deg h_i^j = \deg X_i$ and $\Delta := \sup \Delta_i$ (geometrically, $\deg X_i$ is the number of real and complex intersection points, including those "at infinity," of X_i and a "generic" linear subspace of $\mathbb{R}^d$ of dimension $d - m_i$).

The following notation will be used in this paper: $Z(I)$ denotes the zero-set of an ideal I, $I(Z)$ the ideal of polynomials vanishing on Z, $I : J$ the ideal quotient, and cl$Z$ denotes the closure of the set Z. Also, $\langle g_1, \dots, g_s \rangle$ denotes the ideal generated by the g_i, $1 \le i \le s$. The components of a vector $x = (x^1, \dots, x^d)$ are denoted by superscripts, so that subscripts can be used to enumerate elements of sets; and $(x^d)^3$

denotes the third power of the dth component.

Next, we need some notation from singularity theory. For most parts of this paper (sections 2 to 5), it is enough to remember the following notations: a nondegenerate critical point of a function, where the matrix of second derivatives has maximal rank, is of type A_1 (or of Morse type), a pair of A_1 points having the same critical values is denoted by A_1^2, and the least degenerate of the degenerate critical points is of type A_2. The bifurcation set $\mathcal{B} \subset \mathbb{R}^d$ of a family of distance-squared functions is a generally singular hypersurface whose regular components correspond to (codimension 1) singularities of type A_2 or A_1^2 of the distance-squared function. However, in section 6 we need to count the strata of the singular locus of $\mathcal{B}$ corresponding to more degenerate types of singularities (of codimension ≥ 2). The following notation for these singularities is more or less standard (for more details on the classification of functions up to $\mathcal{K}$- and $\mathcal{R}$-equivalence see chapter 8 of Dimca's book [10]). A function $f : \mathbb{R}^d \to \mathbb{R}$, $x := (x^1, \ldots, x^d) \mapsto f(x)$ has an A_k-singularity at $x = 0$ if there exists a smooth coordinate change $h : \mathbb{R}^d \to \mathbb{R}^d$, defined in the neighborhood of $x = 0$, such that $f \circ h(x) = c + (x^1)^{k+1} + \sum_{i=2}^d \epsilon_i (x^i)^2$, where c is some constant and $\epsilon_i = \pm 1$; see [2]. In other words, A_k denotes an equivalence class of function-germs (we consider pm;u f and h near $x = 0$), and the formula above describes a particular representative of this class. The equivalence classes A_k are orbits of the Mather groups $\mathcal{K}$ and $\mathcal{R}$. We shall abuse the notation $A_{\geq k}$ slightly: it will denote *all* classes of singularities in the closure of the A_k orbit, not just the orbits represented by $c + (x_1)^{\geq k+1} + \sum \epsilon_i (x^i)^2$. Finally, the function f has an $A_{\geq 1}^r$-singularity at a set of points $\{x_1, \ldots, x_r\}$, if it has an $A_{\geq 1}$-singularity at each $x_i \in \mathbb{R}^d$ and the r critical values $f(x_i)$ coincide.

Throughout this paper, $d^k f(p, x)[v_1, \ldots, v_l]$ will always denote the kth differential of a function f with respect to the variables $x \in \mathbb{R}^m$ and not with respect to the parameter $p \in \mathbb{R}^d$, and this k-linear form $d^k f$ should be multiplied with the vectors $v_i \in \mathbb{R}^m$, $1 \leq i \leq l$. Occasionally, we shall omit the parameters and variables (p, x).

Given a hypersurface $M \subset \mathbb{R}^d$, we denote the arrangement cut-out by M by $\mathcal{A}(M)$. We denote by $|\mathcal{A}(M)|$ the size of this arrangement, that is, the number of i-cells, $0 \leq i \leq d$, in $\mathcal{A}(M)$. Note that the connected regions of $\mathbb{R}^d \setminus M$ are the d-cells in $\mathcal{A}(M)$.

The Voronoi diagram of order k of a set $S := \{X_1, \ldots, X_n\}$ of algebraic sets $X_i \subset \mathbb{R}^d$ is defined as follows. Set $\mu_p(X_i) := \inf_{q \in X_i} \|q - p\|^2$ and let $\tilde{S} \subset S$ be a subset with k elements, $1 \leq k \leq n - 1$. Then

$$V_k(\tilde{S}) := \{p \in \mathbb{R}^d : \mu_p(X_i) < \mu_p(X_j), \text{for all } (X_i, X_j) \in \tilde{S} \times (S \setminus \tilde{S})\}$$

is the kth-order Voronoi cell of $\tilde{S}$ (which, in general, is not connected). The kth-order Voronoi surface V_k of S is the union of the boundaries of such Voronoi cells, i.e., $V_k := \cup_{\tilde{S} \subset S} \partial V_k(\tilde{S})$, and the kth-order Voronoi diagram is the arrangement $\mathcal{A}(V_k)$.

1.2. Contents of following sections. In section 2 we study the bifurcation set $\mathcal{B}$ of the family of distance-squared functions on an arrangement of m_i-surfaces X_i in $\mathbb{R}^d$ which are parametrized by polynomial maps. In particular, we give bounds for the number of regions in the complement of $\mathcal{B}$ (and, in fact, for $|\mathcal{A}(\mathcal{B})|$) and describe certain invariants which characterize these regions. We also obtain a result on the local topology of $\mathcal{B}$ that yields a priori information on how the semialgebraic components of $\mathcal{B}$ are glued together. This result is valid both for parametrized surfaces X_i and for zero-sets and does not assume that the family of distance-squared functions is versal (this is a common assumption in singularity theory works on this subject that does not necessarily hold for "almost all" algebraic surfaces X_i of some bounded degree).

In section 3 we consider the more general case of arrangements of algebraic zero-sets X_i (note that most zero-sets do not have a global parametrization given as the image of some polynomial map). For zero-sets we exploit the geometric characterization of the singularities of the distance-squared function in terms of the contact order (or intersection multiplicity) of X_i with certain $(d-m_i)$-spheres, where $m_i = \dim X_i$. This avoids the problem of finding local parametrizations of the X_i given by analytic maps (working with polynomials is much more convenient). The more classical case of contact between hypersurfaces X_i and osculating circles is treated in subsection 3.1; the more complicated case of contact between algebraic sets X_i of codimension $d - m_i \geq 2$ and $(d - m_i)$-spheres is studied in subsection 3.2.

In section 4 we describe an algorithm for determining the regions in the complement of the bifurcation set $\mathcal{B}$. This algorithm is similar, in its overall structure, to the algorithms in [19, 20] and uses standard techniques from computational algebra. We also describe solutions to the proximity problems 1 to 3 stated at the beginning of this introduction, which are based on the decomposition of d-space into regions in the complement of $\mathcal{B}$ or of certain subsets of $\mathcal{B}$.

In section 5 we present a few examples of these decompositions for curves and points in the plane, which have been computed with the methods described in section 4.

Finally, in section 6, we compare the combinatorial complexities of the arrangements $\mathcal{A}(\mathcal{B})$ and of the kth-order Voronoi diagrams $\mathcal{A}(V_k)$. Note that the boundaries V_k of the Voronoi regions of order k are subsets of $\mathcal{B}$, and the bounds in sections 2 and 3 are therefore upper bounds for the complexity of the kth-order Voronoi diagram of arrangements of algebraic sets in terms of n, d, and the degrees and dimensions of these sets. A comparison of the combinatorial complexities of the bifurcation set $\mathcal{B}$ and of the Voronoi boundaries V_k for the more special arrangements studied in [1] and [22] shows that there is a considerable gap, which can be partially understood by studying the combinatorial complexity of certain intermediate sets $V_k \subset R_k \subset \mathcal{B}$. Even so, for general arrangements of algebraic sets, an asymptotically tight bound (at least in terms of combinatorial complexity) for the number of regions of $\mathbb{R}^d \setminus V_k$ remains a widely open problem (for n intersecting hypersurfaces in $\mathbb{R}^d$ we show, for example, that $|\mathcal{A}(V_1)| \sim O(n^{d+1})$ and $|\mathcal{A}(V_1)| \sim \Omega(n^d)$).

2. The complement of the bifurcation set $\mathcal{B}$ of a family of distance-squared functions.

In this section the algebraic m_i-surfaces X_i of the arrangement are parametrized by polynomial maps $x \mapsto X_i(x)$, where $x = (x^1, \ldots, x^{m_i}) \in \mathbb{R}^{m_i}$. The necessary modifications in the (more general) case of zero-sets will be described in section 3. The family of distance-squared functions on X_i is defined by

$$F_i : \mathbb{R}^d \times \mathbb{R}^{m_i} \to \mathbb{R}^d \times \mathbb{R}, \quad (p, x) \mapsto (p, f_i(p, x) := \|X_i(x) - p\|^2).$$

Recall that an element of this d-parameter family of functions in m_i variables is a Morse function if its critical points are nondegenerate (i.e., the corresponding matrix of second derivatives has maximal rank) and have distinct critical values. The bifurcation set $\mathcal{B}_i \subset \mathbb{R}^d$ of the family F_i is the set of "bad" parameters p for which $x \mapsto f_i(p, x)$ fails to be a Morse function. The set $\mathcal{B}_i$ is the union of the local bifurcation set

$$\mathcal{E}_i := \{p \in \mathbb{R}^d : \exists x : df_i(p, x) = 0, \text{rank } d^2 f_i(p, x) < m_i\},$$

consisting of $A_{\geq 2}$-singularities, and the level bifurcation set

$$\mathcal{S}_i := \mathrm{cl}\{p \in \mathbb{R}^d : \exists x \neq \bar{x} : df_i(p,x) = df_i(p,\bar{x}) = 0, f_i(p,x) = f_i(p,\bar{x})\},$$

consisting of $A_{\geq 1}^{\geq 2}$-singularities. (The notation $\mathcal{E}_i$ and $\mathcal{S}_i$ indicates that, from a classical differential geometry point of view, the local and level bifurcation sets are evolutes and symmetry sets, respectively; see section 3. Also, recall that in all functions depending on the parameters $p \in \mathbb{R}^d$, the differentials are with respect to the remaining variables.)

The bifurcation set $\mathcal{B}$ of the arrangement associated to $X = \cup X_i$ is the union of the bifurcation sets $\mathcal{B}_i$ of the X_i and the following intersurface level bifurcation sets:

$$\mathcal{S}_{i,j} := \{p \in \mathbb{R}^d : \exists x, \bar{x} : df_i(p,x) = df_j(p,\bar{x}) = 0, f_i(p,x) = f_j(p,\bar{x})\},$$

that is,

$$\mathcal{B} := \bigcup_{1\leq i\leq n} \mathcal{E}_i \cup \bigcup_{1\leq i\leq n} \mathcal{S}_i \cup \bigcup_{1\leq i<j\leq n} \mathcal{S}_{i,j}.$$

This definition of $\mathcal{B}$ assumes that $1 \leq \dim X_i \leq d-1$, but it can be extended easily to include isolated points $X_i = \{q_i\}$. For a point q_i the sets $\mathcal{E}_i$ and $\mathcal{S}_i$ are defined to be empty, for a point pair q_i, q_j the set $\mathcal{S}_{i,j}$ is defined to be the hyperplane perpendicular to $q_j - q_i$ through $(q_i + q_j)/2$, and for surface-point pairs X_i ($\dim X_i \geq 1$), $X_j = \{q_j\}$ we define

$$\mathcal{S}_{i,j} := \{p \in \mathbb{R}^d : \exists x : df_i(p,x) = 0, f_i(p,x) = \|q_j - p\|^2\}.$$

The definitions of the local bifurcation sets $\mathcal{E}_i$ and of the intersurface level bifurcation sets $\mathcal{S}_{i,j}$ are fairly straightforward from a computational point of view. The definition of the intrasurface level bifurcation sets $\mathcal{S}_i$ is less straightforward: the inequalities $x \neq \bar{x}$, together with the defining equations appearing in the definition, yield semialgebraic sets $\mathcal{S}'_i \subset \mathbb{R}^d \times \mathbb{R}^{2m_i}$ which are not closed. It is, however, possible to close up the sets $\mathcal{S}'_i$ by adding a set of boundary points $\partial\mathcal{S}'_i$ on the diagonal $\{x = \bar{x}\} \subset \mathbb{R}^{2m_i}$ (see below). Furthermore, the closed sets $\tilde{\mathcal{S}}_i := \mathcal{S}'_i \cup \partial\mathcal{S}'_i$ can be defined by polynomial equations (inequations are not required), which is a big advantage from a computational algebra point of view.

Let $\bar{\mathcal{S}}_i \subset \mathbb{R}^d \times \mathbb{R}^{2m_i}$ denote the set defined by the defining equations of $\mathcal{S}'_i$ (omitting the inequalities $x \neq \bar{x}$); this is a closed set which coincides with $\mathcal{S}'_i$ away from the diagonal, but has too high dimension on the diagonal. Then the vanishing ideal of the closure of $\mathcal{S}'_i$ is given by the ideal quotient

$$I(\bar{\mathcal{S}}_i) : (I(\bar{\mathcal{S}}_i) + \langle x^1 - \bar{x}^1, \ldots, x^{m_i} - \bar{x}^{m_i}\rangle),$$

whose generators can be determined using Gröbner basis methods (see, for example, [3, Chapter 6.2]). For zero-sets X_i of codimension ≥ 2 we actually close up the sets $\mathcal{S}'_i$ in this way (see section 3.2). However, for arrangements of parametrized sets (and of zero-sets of codimension 1; see section 3.1) the defining equations of the closure of $\mathcal{S}'_i$ can be constructed in a more direct way that avoids the expensive computation of Gröbner bases and also yields some useful information about the topology of the

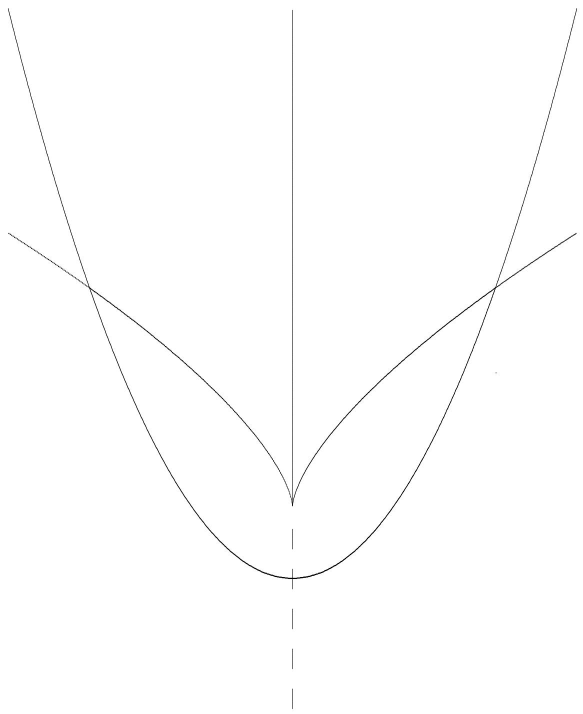

FIG. 1. *The bifurcation set $\mathcal{B}_i$ of a single parabola X_i: the local bifurcation set $\mathcal{E}_i$ is the cusp-shaped curve and the level bifurcation set $\mathcal{S}_i$ is the solid half-line whose boundary $\partial\mathcal{S}_i$ in the union $\hat{\mathcal{S}}_i$ of the solid and dashed vertical line coincides with the cusp point. The distance-squared function to X_i from points of $\mathcal{B}_i$ has the following singularities: A_3 at the cusp, A_2 for all other points of $\mathcal{E}_i$, and A_1^2 for all other points of $\mathcal{S}_i$.*

bifurcation set $\mathcal{B}_i$. We first give an outline of this construction and its topological consequences; more detailed statements follow in Proposition 2.1 and its proof.

To find the defining equations of the closure of $\mathcal{S}'_i$, we first "blow up" the diagonal $\{x = \bar{x}\} \subset \mathbb{R}^{2m_i}$ by a change of coordinates β that replaces the pair of points $(x, \bar{x})$ by $(x, x + \lambda \cdot \omega)$, where $\lambda \in \mathbb{R}$ and $\omega \in \mathbb{P}^{m_i - 1}$ (i.e., we represent the point $\bar{x}$ by moving it some distance λ along a ray through x and direction ω). The map β is an isomorphism for $\lambda \neq 0$ "blowing down" the hyperplane $\{\lambda = 0\}$ to the diagonal $\{x = \bar{x}\}$, which is a linear subspace of $\mathbb{R}^{2m_i}$ of codimension m_i. Next, we choose a certain set of generators of $I(\bar{\mathcal{S}}_i)$ and divide them by suitable powers of λ. The modified generators define a closed algebraic set $\tilde{\mathcal{S}}_i$ that coincides with the sets $\bar{\mathcal{S}}_i$ and $\mathcal{S}'_i$ in the complement of the diagonal $\{\lambda = 0\}$. The set of boundary points of $\mathcal{S}'_i$ on the diagonal is given by $\partial\mathcal{S}'_i = \tilde{\mathcal{S}}_i \cap \{\lambda = 0\}$. Using the defining equations of the sets $\tilde{\mathcal{S}}_i$, $\mathcal{S}'_i$, and $\bar{\mathcal{S}}_i$ and excluding a Zariski closed subset of X_i in the space of all algebraic sets (where m_i, δ_i, and d are fixed) one easily checks the following properties. The set $\mathcal{S}'_i$ has dimension $d-1$, and "almost all" of its points $(p, x, \bar{x})$ correspond to pairs of A_1-singularities of the distance-squared function having the same critical values $f_i(p, x) = f_i(p, \bar{x})$. The set $\partial\mathcal{S}'_i$ has dimension $d-2$ and almost all of its points correspond to A_3-singularities. (By contrast, most points of $\bar{\mathcal{S}}_i \cap \{\lambda = 0\}$ merely correspond to A_1-singularities and form a $d+m_i$-dimensional set.) It therefore follows that the projection of $\partial\mathcal{S}'_i$ into the parameter space $\mathbb{R}^d$ is contained in the local bifurcation set $\mathcal{E}_i$ (which corresponds to

$A_{\geq 2}$-singularities). The projection of $\partial\mathcal{S}_i'$, denoted by $\partial\mathcal{S}_i$, also forms the boundary of the semialgebraic level bifurcation set $\mathcal{S}_i \subset \mathbb{R}^d$ in the smallest real algebraic set $\hat{\mathcal{S}}_i$ containing $\mathcal{S}_i$: moving along a generic path from $\mathcal{S}_i$ to $\hat{\mathcal{S}}_i \setminus \mathcal{S}_i$ we first get a pair of real A_1-singularities having the same critical value, which coalesce in an A_3-singularity as we cross the boundary $\partial\mathcal{S}_i$ and then become complex. Figure 1 illustrates this situation in the simple case of a single parabola $X_i(x) = (x, x^2)$ in the plane. We can now give a more precise description of this construction.

PROPOSITION 2.1.

(i) *For all $(p, x, x) \in \partial\mathcal{S}_i'$, the distance-squared function $x \mapsto f_i(p, x)$ has an $A_{\geq 3}$-singularity at x. This implies that $\pi(\partial\mathcal{S}_i') \subset \mathcal{E}_i$, where $\pi : \mathbb{R}^d \times \mathbb{R}^{2m_i} \to \mathbb{R}^d$ denotes the projection onto the first factor.*

(ii) *The degree of $\partial\mathcal{S}_i'$ is of order $\delta_i^{2m_i+1}$ and that of $\cup\partial\mathcal{S}_i'$ of order $n \cdot \delta^{2m+1}$.*

Proof. (i) The proof of the first part of the proposition follows the construction outlined above. Set $A := (a^1, \ldots, a^{m_i-1}, 1)$, then the map given by

$$\beta : \mathbb{R}^{2m_i} \to \mathbb{R}^{2m_i}, \quad (x, \lambda, A) \mapsto (x, x + \lambda \cdot A)$$

"blows down" the hyperplane $\{\lambda = 0\}$ to the diagonal $\{x = \bar{x}\}$ and has maximal rank for $\lambda \neq 0$. Note that we have replaced the space of directions $\omega \in \mathbb{P}^{m_i-1}$ by the affine chart of vectors A in $\mathbb{R}^{m_i}$ whose last component is equal to 1. To cover all of $\mathbb{P}^{m_i-1}$, m_i such charts are required, but it is easy to check that the arguments below do not depend on the choice of chart. We then claim that the set $\tilde{\mathcal{S}}_i$ can be defined by the following three equations (omitting the inequality $\lambda \neq 0$): by $df_i(p, x) = 0$ (as before), and by

$$U_i(p, x, \lambda, A) := \lambda^{-1}\big(df_i(p, x + \lambda \cdot A) - df_i(p, x)\big) = 0,$$

and by

$$V_i(p, x, \lambda, A) := \lambda^{-3}\Big(f_i(p, x + \lambda \cdot A) - f_i(p, x) - \lambda df_i(p, x)[A] - \frac{\lambda^2}{2}\langle U_i, A\rangle\Big) = 0.$$

It is easy to see that, away from the diagonal $\{\lambda = 0\}$,

$$df_i(p, x) = U_i(p, x, \lambda, A) = V_i(p, x, \lambda, A) = 0$$

and the original system

$$df_i(p, x) = df_i(p, x + \lambda \cdot A) = f_i(p, x) - f_i(p, x + \lambda \cdot A) = 0$$

define the same zero-sets $\mathcal{S}_i' \subset \mathbb{R}^d \times \mathbb{R}^{2m_i} \setminus \{\lambda = 0\}$. Furthermore, the right-hand sides of U_i and V_i are divisible by λ and λ^3 (by Taylor's theorem); hence $df_i = U_i = V_i = 0$ defines a closed algebraic variety $\tilde{\mathcal{S}}_i := \mathcal{S}_i' \cup \partial\mathcal{S}_i' \subset \mathbb{R}^d \times \mathbb{R}^{2m_i}$.

In fact, $\tilde{\mathcal{S}}_i$ is the smallest closed set containing $\mathcal{S}_i'$, and the boundary $\partial\mathcal{S}_i' := \tilde{\mathcal{S}}_i \cap \{\lambda = 0\}$ of $\mathcal{S}_i'$ in $\tilde{\mathcal{S}}_i$ corresponds to $A_{\geq 3}$-singularities of the distance-squared function $x \mapsto f_i(p, x)$. The boundary $\partial\mathcal{S}_i'$ is defined by the following equations:

$$\begin{aligned} df_i(p, x) &= 0, \\ U_i(p, x, 0, A) = d^2 f_i(p, x)[A] &= 0, \\ V_i(p, x, 0, A) = -\frac{1}{12} d^3 f_i(p, x)[A^3] &= 0. \end{aligned}$$

This system "recognizes" an $A_{\geq 3}$-singularity of $x \mapsto f_i(p,x)$ at x—the condition for an $A_{\geq 3}$-singularity is precisely that $df_i = 0$ and $d^2 f_i[v] = 0$, $d^3 f_i[v^3] = 0$ for some nonzero vector v (see, for example, Porteous [18, p. 397]).

(ii) The degree of the variety $\partial \mathcal{S}'_i$ defined by the above system of equations is at most of order $\delta_i^{2m_i+1}$ (by Bezout's theorem), so that the degree of the union of n such varieties is of order $\sum_{i=1}^{n} \delta_i^{2m_i+1} \leq n \cdot \delta^{2m+1}$. ∎

Remarks. 1. Patching together the $\tilde{\mathcal{S}}_i$ in the m_i affine charts in the proof of part i yields a variety $V \subset \mathbb{R}^d \times \mathbb{R}^{m_i+1} \times \mathbb{P}^{m_i-1}$ whose projection π onto $\mathbb{R}^d$ is the intrasurface level bifurcation set $\mathcal{S}_i$. To compute the defining equations of $\mathcal{S}_i$ it is sufficient to use a single "good" affine chart for $\mathbb{P}^{m_i-1}$: for example, $(a^1, \dots, a^{m_i-1}, 1)$ is good if $\dim V > \dim(V \cap \{a^{m_i} = 0\})$. In this case, the missing component of V "at infinity" will be closed up by the projection π.

2. Part i of the proposition also holds locally for germs of C^∞-submanifolds X_i of dimension m_i (note that the proof merely depends on the Taylor expansion of f_i at $(p,x) = (p_0, x_0)$). In particular, it also holds for algebraic zero-sets of dimension m_i (which will be studied in section 3), because these sets have a parametrization which is even analytic.

3. For $m = 1$ and $d = 2$, the set $\cup \partial \mathcal{S}'_i$ consists of isolated points $(p_l, x_l) \in \mathbb{R}^2 \times \mathbb{R}$ (this can be checked by a simple dimensional argument), and there are at most $O(n \cdot \delta^3)$ such endpoints by the proposition above. The projections p_l of these points into the plane are possible endpoints of the level-bifurcation set $\mathcal{S} = \cup \mathcal{S}_i$. However, their projections x_l onto $\mathbb{R}$ correspond to curvature extrema of X_i and each curvature extremum corresponds to one endpoint. But $X = \cup X_i$ has at most $O(n \cdot \delta)$ curvature extrema.

PROPOSITION 2.2. *For all points p in a single connected region of $\mathbb{R}^d \setminus \cup \mathcal{E}_i$ the collection of distance-squared functions $\{x \mapsto f_i(p,x) : 1 \leq i \leq n\}$ has a constant number, c, of critical points, where*

$$n \leq c \leq \sum_{i=1}^{n} (2\delta_i - 1)^{m_i} \sim O(n \cdot \delta^m).$$

Proof. From the definition of the local bifurcation sets $\mathcal{E}_i$ we see that the distance-squared functions $x \mapsto f_i(p,x)$ have isolated critical points (of multiplicity 1) for all $p \in \mathbb{R}^d \setminus \cup \mathcal{E}_i$. Each f_i is nonnegative and has degree $2\delta_i$. Hence, each f_i has at least one local minimum and at most $(2\delta_i - 1)^{m_i}$ critical points; this yields the desired bounds for c. ∎

Remark. For arrangements of hypersurfaces X_i (i.e., $m_i = d-1$) the number of critical points c has the following geometrical interpretation: it is equal to the number of normal lines of $X = \cup X_i$ passing through the point p.

PROPOSITION 2.3. *The number of connected regions of $\mathbb{R}^d \setminus \mathcal{B}$ (and, in fact, the size of $\mathcal{A}(\mathcal{B})$) are at most of order $n^{2d} \cdot \delta^{(2m+1)d}$. Furthermore, let $p \in \mathbb{R}^d \setminus \mathcal{B}$, and let*

$$\xi_{1,\nu_1}(p), \xi_{2,\nu_2}(p), \dots, \xi_{c,\nu_c}(p)$$

denote the critical points $\xi_{l,\nu_l}(p)$ of the collection of distance-squared functions $x \mapsto f_{\nu_l}(p,x)$, where $\nu_l \in \{1, \dots, n\}$, ordered by increasing distance. That is, $f_{\nu_l}(p, \xi_{l,\nu_l}(p)) < f_{\nu_{l+1}}(p, \xi_{l+1,\nu_{l+1}}(p))$. For all points p in a single connected region of $\mathbb{R}^d \setminus \mathcal{B}$ we have the following: (i) *the numbers $\nu_1, \dots, \nu_c$ are invariant, and* (ii) *the maps $p \mapsto \xi_{l,\nu_l}(p)$ are continuous for $1 \leq l \leq n$.*

Proof. The bifurcation set $\mathcal{B}$ is a semialgebraic subset of a closed real algebraic set $\hat{\mathcal{B}} \subset \mathbb{R}^d$, and the number of connected regions cut out by $\mathcal{B}$ is less than or equal to the number of regions cut out by $\hat{\mathcal{B}}$. The number of connected regions of $\mathbb{R}^d \setminus \hat{\mathcal{B}}$ is equal to the $(d-1)$st Betti number of $\hat{\mathcal{B}}$ plus 1 (see below), and the desired upper bound follows at once from a result of Milnor [15] (which says that the sum of the Betti numbers of $\hat{\mathcal{B}}$ is of order $(\deg \hat{\mathcal{B}})^d$) and the bound for the degree of $\hat{\mathcal{B}}$ derived below. (On the other hand, the singular stratification of $\hat{\mathcal{B}}$ has $O((\deg \hat{\mathcal{B}})^d)$ strata and $|\mathcal{A}(\mathcal{B})| \leq |\mathcal{A}(\hat{\mathcal{B}})|$, which yields the bound for $|\mathcal{A}(\mathcal{B})|$.)

The (linear) formula for the number of connected components of $\mathbb{R}^d \setminus \hat{\mathcal{B}}$ in terms of the $(d-1)$st Betti number of $\hat{\mathcal{B}}$ follows from standard duality results in algebraic topology: roughly speaking, either from Lefschetz duality (which yields an isomorphism between the zeroth homology group H_0 of $\mathbb{R}^d \setminus \hat{\mathcal{B}}$ and the dth cohomology group H^d of the pair $(\mathbb{R}^d, \hat{\mathcal{B}})$) and the isomorphism $H_d(\mathbb{R}^d, \hat{\mathcal{B}}) \cong H_{d-1}(\hat{\mathcal{B}})$ (coming from the standard exact homology sequence of the pair $(\mathbb{R}^d, \hat{\mathcal{B}})$); or, more directly, one can use Alexander duality to get an isomorphism between H_0 of $\mathbb{R}^d \setminus \hat{\mathcal{B}}$ and H^{d-1} of $\hat{\mathcal{B}}$. The more precise argument (included in parentheses below) is a bit more complicated, due to the possible noncompactness of $\hat{\mathcal{B}}$ and the appearance of reduced homology groups and might be skipped. (Let $S^d = \mathbb{R}^d \cup \{\infty\}$ and $\hat{\mathcal{B}}^c = \hat{\mathcal{B}} \cup \{\infty\}$ denote 1-point compactifications; then the Alexander duality yields the following isomorphism of reduced (co)homology groups $\tilde{H}_0(S^d \setminus \hat{\mathcal{B}}^c) \cong \tilde{H}^{d-1}(\hat{\mathcal{B}}^c)$. (See [11, Section 8.15, Chapter VIII]). The set $\hat{\mathcal{B}}$ is a closed real algebraic set; hence $\tilde{H}_0(S^d \setminus \hat{\mathcal{B}}^c) \cong \tilde{H}_0(\mathbb{R}^d \setminus \hat{\mathcal{B}})$ and $b_i(\hat{\mathcal{B}}^c) = b_i(\hat{\mathcal{B}})$, for all $i > 0$. Finally, note that the rank of the zeroth homology group is one plus that of the reduced one.)

We claim that the degree of $\hat{\mathcal{B}}$ is of order $n^2\delta^{2m+1}$. The set $\hat{\mathcal{B}}$ is the union of $\binom{n}{2}$ (real algebraic) sets $\hat{\mathcal{S}}_{i,j}$, n sets $\hat{\mathcal{S}}_i$, and n sets $\hat{\mathcal{E}}_i$. The orders of the degrees of the $\hat{\mathcal{S}}_i$ and the $\hat{\mathcal{E}}_i$ are lower than those of the $\hat{\mathcal{S}}_{i,j}$; hence it suffices to estimate the degree of $\hat{\mathcal{S}}_{i,j}$. So let $\tilde{\mathcal{S}}_{i,j} \subset \mathbb{R}^d \times \mathbb{R}^{m_i+m_j}$ be the real algebraic set defined by the defining equations of $\mathcal{S}_{i,j}$ (omitting the existential quantifier). The restriction of the projection $\pi : \mathbb{R}^d \times \mathbb{R}^{m_i+m_j} \to \mathbb{R}^d$ to $\tilde{\mathcal{S}}_{i,j}$ yields the semialgebraic set $\mathcal{S}_{i,j}$. Complexifying the defining equations of $\tilde{\mathcal{S}}_{i,j}$ and taking the real part of the projection π onto $\mathbb{C}^d$ of the resulting zero-set yields a closed real algebraic set $\hat{\mathcal{S}}_{i,j} \subset \mathbb{R}^d$ which contains the semialgebraic set $\mathcal{S}_{i,j}$. Suppose that $\operatorname{codim}\hat{\mathcal{S}}_{i,j} = 1$ (otherwise the complement of $\hat{\mathcal{S}}_{i,j}$ is connected, and we are finished), and let $\mathcal{L} \subset \mathbb{R}^d$ be any line. Now there are two cases: (1) the set $A := \pi^{-1}(\mathcal{L}) \cap \tilde{\mathcal{S}}_{i,j}$ consists of isolated points (the "generic case") and (2) $\dim A = e > 0$. Let $\bar{\pi} : \mathbb{R}^d \times \mathbb{R}^{m_i+m_j} \to \mathbb{R}^{m_i+m_j}$ denote the projection onto the second factor, let $\bar{\mathcal{L}} \subset \mathbb{R}^{m_i+m_j}$ be any linear subspace of codimension e such that $\bar{\pi}^{-1}(\bar{\mathcal{L}})$ is not contained in A and set $\bar{A} := A \cap \bar{\pi}^{-1}(\bar{\mathcal{L}})$. The sets A in case 1 and $\bar{A}$ in case 2 are discrete point sets, and the restriction of π to these point sets onto the set of intersection points $\hat{\mathcal{S}}_{i,j} \cap \mathcal{L}$ is surjective. The degree of $\hat{\mathcal{S}}_{i,j}$ is therefore bounded by the number of points of A (or $\bar{A}$ in case 2). Inspecting the defining equations of these sets, we get from Bezout's theorem that

$$\deg \hat{\mathcal{S}}_{i,j} \leq (2\delta_i - 1)^{m_i} \cdot (2\delta_j - 1)^{m_j} \cdot 2\max(\delta_i, \delta_j)$$

(counting both real and complex roots with their multiplicities).

For the proof of the second part of the proposition, consider the following real algebraic set:

$$\Sigma_{F_i} := \{(p, x) : df_i(p, x) = 0\} \subset \mathbb{R}^d \times \mathbb{R}^{m_i}.$$

The set Σ_{F_i} is the critical set of the family F_i of all distance-squared functions f_i on X_i. The fibers $\pi^{-1}(p) \cap \Sigma_{F_i}$ of the projection $\pi : \mathbb{R}^d \times \mathbb{R}^{m_i} \to \mathbb{R}^d$ correspond to the critical points of f_i from p. The restriction of π to Σ_{F_i} is a covering map whose branch-locus is the (preimage of the) evolute $\mathcal{E}_i$ and which is finite-to-one off the branch-locus. The number of points in each fiber $\pi^{-1}(p) \cap \Sigma_{F_i}$ is therefore finite and constant for all points p in a connected region of $\mathbb{R}^d \setminus \mathcal{E}_i$. The same is true for the total number c of critical points of a collection $\{f_i\}_{1 \le i \le n}$ of distance-squared functions on $X := \cup X_i$ for all p in a single connected region of $\mathbb{R}^d \setminus \cup\mathcal{E}_i$. Furthermore, the indices $\nu_1, \dots, \nu_c$ are invariant within a connected region of $\mathbb{R}^d \setminus (\cup\mathcal{E}_i) \cup (\cup\mathcal{S}_{i,j})$, because c is constant and permutations of indices can only occur along the intersurface level bifurcation sets $\mathcal{S}_{i,j}$. Finally, let U be any connected region of $\mathbb{R}^d \setminus \cup\mathcal{E}_i$ and consider the union of the n bundles $\cup_{i=1}^n \pi^{-1}(U) \cap \Sigma_{F_i}$. This is a semialgebraic set consisting of c disjoint components of dimension d, and these components are the graphs of continuous maps $h_j : U \to \mathbb{R}^{m_i}$, $1 \le j \le c$ (these facts are established by arguments that are quite similar to the proof of the first main structure theorem in [4, Chapter 2.2]; in fact, most stratification schemes of semialgebraic sets seem to be based on some version of this theorem). The composition of the h_j with the projection $\bar{\pi} : \mathbb{R}^d \times \mathbb{R}^{m_i} \to \mathbb{R}^{m_i}$ is a continuous map, which implies that the c critical points of the collection of distance-squared functions $x \mapsto f_i(p,x)$, $1 \le i \le n$, vary continuously with $p \in U$. The continuity of the maps $p \mapsto \xi_{l,\nu_l}(p)$ for all p within a single connected region of $\mathbb{R}^d \setminus \mathcal{B}$ then follows from the results above and the fact that the permutation of the critical points of a single function $x \mapsto f_i(p,x)$ can only occur on $\mathcal{S}_i$. □

3. Contact of X with spheres and the definition of $\mathcal{B}$ for zero-sets X.

The fibers of the distance-squared function from a point $p \in \mathbb{R}^d$ are $(d-1)$-spheres of varying radius r, given by $\{x \in \mathbb{R}^d : \|x - p\|^2 - r^2 = 0\}$. The conditions for an A_k-singularity of the distance-squared function, which appear in the definition of the bifurcation set $\mathcal{B}$, can be reformulated in more geometric terms involving the contact between a family of such spheres and a collection $X = \cup X_i$ of algebraic sets. Using these more geometric conditions, we can easily define, and compute, the bifurcation set $\mathcal{B}$ in the case of algebraic sets X_i given as zero-sets of polynomials $h_i^j \in \mathbb{Q}[x] = \mathbb{Q}[x^1, \dots, x^d]$, $1 \le j \le d - m_i$.

We first consider the special case of algebraic hypersurfaces (codimension 1) where the local and level bifurcation sets of the distance-squared function are the well-known evolutes and symmetry sets of classical differential geometry (section 3.1). In section 3.2 we consider the more general case of arrangements of algebraic sets X_i of codimension $1 \le d - m_i \le d - 1$ which are complete intersections (i.e., are defined by $d - m_i$ polynomials). Note that the case of points X_i (of codimension d) can be handled as in section 2.

3.1. Arrangements of hypersurfaces, evolutes, and symmetry sets.

First, recall that a hypersurface X_i in d-space has $d-1$ (not necessarily distinct) principal curvatures κ_j and directions d_j which are the eigenvalues and eigendirections of the Weingarten map. (The Weingarten map $W_p : T_pX_i \to T_pX_i$, $v \mapsto -\nabla_v N$ measures the rate of change of the normal direction N along a direction v in the tangent space of X_i at p.) A $(d-1)$-sphere is a curvature sphere at $x \in X_i$ if its center lies on the normal line through x and its radius r is the inverse of one of the principal curvatures of X_i at x. The unique great circle in this curvature sphere whose tangent line at x is oriented along the principal direction associated to $1/r$ is an osculating circle. The evolute (or focal surface) $\mathcal{E}_i$ of X_i is the locus of centers of such osculating circles and of the curvature spheres containing them (for each surface patch of X_i there are generically $d-1$ sheets of the evolute, one for each principal curvature).

The distance-squared function from $p \in \mathbb{R}^d$ to X_i has an A_k-singularity ($k \geq 1$) at $x \in \mathbb{R}^d$ if and only if there exists a circle with center p having $(k+1)$-point contact with X_i at x. The order of contact is ≥ 2 if p lies on the normal line to X_i at x and ≥ 3 if, in addition, the circle is an osculating circle. The local bifurcation set $\mathcal{E}_i$ consists of points p for which the distance-squared function to X_i has an $A_{\geq 2}$-singularity; such points are centers of osculating circles (and of curvature spheres). The local bifurcation set $\mathcal{E}_i$ is therefore the evolute of X_i. The relation between singularities of the distance-squared function, normal singularities of submanifolds (i.e., singularities of the exponential map of the normal bundle), and the possible types of contact between these submanifolds and spheres was first studied by Porteous; see [16] and [17].

The intra- and intersurface level bifurcation sets $\mathcal{S}_i$ and $\mathcal{S}_{i,j}$ are loci of centers of bitangent spheres touching $X = \cup X_i$ in two distinct points (the spheres can shrink to a point as their centers tend to the self-intersection locus of X). If both points of tangency lie on a single surface X_i then the center belongs to $\mathcal{S}_i$, otherwise it belongs to $\mathcal{S}_{i,j}$. Clearly, the distance-squared function from a center of a bitangent sphere has the two points of tangency as its critical points, and the corresponding critical values are given by the square of the radius of the bitangent sphere. The locus of centers of bitangent spheres of a hypersurface is known as symmetry set in the differential geometry literature, and the singularities of such symmetry sets of plane curves and of surfaces in 3-space have been classified by Bruce, Giblin, and Gibson [6]. (In the pattern recognition literature, the symmetry set of a plane curve is also known under the names skeleton, medial axis, and symmetric axis transform.)

Using these geometrical descriptions of the local bifurcation sets $\mathcal{E}_i$ and of the level bifurcation sets $\mathcal{S}_i$ and $\mathcal{S}_{i,j}$, we can now define the bifurcation set of the distance-squared functions for arrangements of algebraic hypersurfaces given as zero-sets $X_i = h_i^{-1}(0)$. Below, $V \| W$ denotes the condition that the pair of vectors V, W in $\mathbb{R}^d$ is parallel (obviously, this condition involves the vanishing of $d-1$ functions involving the components of the vectors), and $S(p,x,r) := \|x-p\|^2 - r^2$ defines a $(d-1)$-sphere with center p and radius r. The fact that (at least) one of the principal curvatures of X_i at x is equal to $1/r$ is equivalent to the vanishing of the following two equations:

$$Q_i(x,u) := \det \begin{pmatrix} (d^2 h_i(x) - u \cdot I) & dh_i(x) \\ (dh_i(x))^t & 0 \end{pmatrix}$$

(where I denotes the $d \times d$ identity matrix) and

$$R_i(x,u,r) := u^2 r^2 - \|dh_i(x)\|^2.$$

(The condition $Q_i = R_i = 0$ can be deduced easily from the standard formula for the principal curvatures of a hypersurface defined as zero-set; see, e.g., [23, p. 204]. Note that the derivation of this formula [23, pp. 202–204] is for hypersurfaces in 3-space, but the d-dimensional case ($d \geq 2$) is analogous.)

Using this notation, the local bifurcation sets (evolutes) are defined as follows:

$$\begin{aligned} \mathcal{E}_i := \{p \in \mathbb{R}^d : \exists x, u, r : & h_i(x) = S(p,x,r) = Q_i(x,u) = R_i(x,u,r) = 0, \\ & dh_i(x) \| dS(p,x,r)\}. \end{aligned}$$

The level bifurcation sets (symmetry sets) are given by

$$\begin{aligned} \mathcal{S}_i := \mathrm{cl}\{p \in \mathbb{R}^d : \exists x_1 \neq x_2 : & h_i(x_k) = 0, dh_i(x_k) \| (x_k - p), k = 1, 2; \\ & \|x_1 - p\|^2 = \|x_2 - p\|^2\} \end{aligned}$$

and

$$\begin{aligned}\mathcal{S}_{i,j} := \{p \in \mathbb{R}^d : \exists x_i, x_j : & h_k(x_k) = 0, dh_k(x_k) \| (x_k - p), k = i, j; \\ & \|x_i - p\|^2 = \|x_j - p\|^2\}.\end{aligned}$$

The estimates in Propositions 2.1, 2.2, and 2.3 for arrangements of parametrized surfaces, in terms of n and δ, have the following analogues, (i)–(iii) of 3.1, in the case of $(d-1)$-dimensional zero-sets.

PROPOSITION 3.1. *Let $\mathcal{B}$ denote the bifurcation set of the family of distance-squared functions on a collection $X = \cup_{i=1}^n X_i$ of algebraic hypersurfaces of maximal degree Δ. Then the following holds:* (i) *the degree of $\cup \partial \mathcal{S}'_i$ is at most of order $n \cdot \Delta^{2d}$;* (ii) *the number of critical points of the distance-squared function from any point $p \in \mathbb{R}^d \setminus \cup \mathcal{E}_i$ to X is at most of order $n \cdot \Delta^d$; and* (iii) *the number of connected regions of $\mathbb{R}^d \setminus \mathcal{B}$ and the size of $\mathcal{A}(\mathcal{B})$ are at most of order $n^{2d} \cdot \Delta^{2d^2}$.*

Proof. For statement (i), we modify the defining equations of $\mathcal{S}_i$, as in the case of parametrized sets X_i, by blowing up the diagonal $\{x_1 = x_2\} \subset \mathbb{R}^{2d}$ by setting $x_2 := x_1 + \lambda \cdot \omega$, where $\omega \in \mathbb{P}^{d-1}$, and by dividing certain generators of the resulting ideal by suitable powers of λ. Let $\tilde{\mathcal{S}}_i$ be the zero-set of these modified defining equations and let $\mathcal{S}'_i$ denote the semialgebraic set that coincides with $\tilde{\mathcal{S}}_i$ off the diagonal $\{\lambda = 0\}$; then again $\partial \mathcal{S}'_i = \tilde{\mathcal{S}}_i \cap \{\lambda = 0\}$ (see the proof of Proposition 2.1). For statements (ii) and (iii) we simply follow the proofs of Propositions 2.2 and 2.3 using the new definitions of the components of $\mathcal{B}$. □

3.2. Arrangements of algebraic sets of higher codimension. Let $X_i = h_i^{-1}(0)$ be the m_i-dimensional zero-set of a polynomial map $h_i := (h_i^1, \ldots, h_i^{d-m_i}) : \mathbb{R}^d \to \mathbb{R}^{d-m_i}$. The distance-squared function from p to X_i has an A_k-singularity at x if and only if there exists a $(d-m_i)$-sphere with center p having $(k+1)$-point contact with X_i at x. Algebraically, the order of contact (or intersection multiplicity) between X_i and a $(d-m_i)$-sphere, with defining equations $s^1(\xi) = \cdots = s^{m_i}(\xi) = 0$, at x is equal to the dimension of the vector space

$$\mathbb{R}[\xi]/\langle h_i^1(\xi - x), \ldots, h_i^{d-m_i}(\xi - x), s^1(\xi - x), \ldots, s^{m_i}(\xi - x)\rangle.$$

It is easy to see that such a sphere has at least 2-point contact with X_i at x if its center p lies in the normal space $N_x X_i = x + \operatorname{span}\{dh_i^1(x), \ldots, dh_i^{d-m_i}(x)\}$ of X_i at x (this assumes that x is a regular point of X_i, but the algebraic definition of the intersection multiplicity above is also valid for the singular locus of X_i).

We can now define the local bifurcation set $\mathcal{E}_i$ for complete intersections X_i and give an estimate for its degree. The point p lies in the normal space of X_i at x if $x - p \in \operatorname{span}\{dh_i^1(x), \ldots, dh_i^{d-m_i}(x)\}$, which means that all $(d-m_i+1) \times (d-m_i+1)$ minors of $\binom{dh_i(x)}{x-p}$ have to vanish. Note that only m_i of these minors are independent and that each of them has degree $O(\Delta_i)$. Let $\mathcal{M}_i := (\mathcal{M}_i^1, \ldots, \mathcal{M}_i^{m_i}) : \mathbb{R}^d \times \mathbb{R}^d \to \mathbb{R}^{m_i}$ be a d-parameter family of polynomial maps, depending on the variables x and parameters p, whose component functions are such independent minors. Then $\varphi_i := (h_i, \mathcal{M}_i) : \mathbb{R}^d \times \mathbb{R}^d \to \mathbb{R}^d$, $(p, x) \mapsto \varphi_i(p, x)$ is a d-parameter family of polynomial maps from $\mathbb{R}^d$ to $\mathbb{R}^d$. Using the algebraic definition of the intersection multiplicity, one checks that the simple roots in x of φ_i correspond to points of X_i having 2-point contact with $(d-m_i)$-spheres with center p through x. Roots of higher multiplicity correspond to points x in which the order of contact is at least 3-point; hence we define

$$\mathcal{E}_i := \{p \in \mathbb{R}^d : \exists x : \varphi_i(p,x) = \det d\varphi_i(p,x) = 0\}.$$

The product of the degrees of these defining equations of $\mathcal{E}_i$ is at most $O(\Delta_i^{2(m_i+1)})$.

The level bifurcation set of the family of all distance-squared functions to a pair of complete intersections $X_i = h_i^{-1}(0)$ and $X_j = h_j^{-1}(0)$ of dimension m_i and m_j is given by

$$\mathcal{S}_{i,j} := \{p \in \mathbb{R}^d : \exists x, \bar{x} : \varphi_i(p,x) = \varphi_j(p,\bar{x}) = 0, \|x-p\|^2 = \|\bar{x}-p\|^2\}$$

and has degree at most $O(\Delta_i^{m_i+1}\Delta_j^{m_j+1})$. The level bifurcation set of a single set X_i is given by

$$\mathcal{S}_i := \mathrm{cl}\{p \in \mathbb{R}^d : \exists x \neq \bar{x} : \varphi_i(p,x) = \varphi_i(p,\bar{x}) = 0, \|x-p\|^2 = \|\bar{x}-p\|^2\}$$

and has degree at most $O(\Delta_i^{2(m_i+1)})$. Recall that $\mathcal{S}_i$ is the projection of the algebraic set $\tilde{\mathcal{S}}_i := \mathcal{S}_i' \cup \partial\mathcal{S}_i'$. The set $\tilde{\mathcal{S}}_i$ is the closure of the difference of two algebraic sets $U \setminus V$, where U is the zero-set of the defining equations of $\mathcal{S}_i$, omitting the inequations $x \neq \bar{x}$, and where V is defined by the equations of $\mathcal{S}_i$ and by $x = \bar{x}$. Hence, $\tilde{\mathcal{S}}_i = Z(I(U) : I(V))$ is an algebraic set of degree at most $\deg U \sim O(\Delta_i^{2(m_i+1)})$, and its projection $\mathcal{S}_i$ is a semi-algebraic subset of an algebraic set of degree $O(\Delta_i^{2(m_i+1)})$.

Next recall that the boundary $\mathcal{S}_i'$ of $\tilde{\mathcal{S}}_i$ is contained in the diagonal $E := \{x = \bar{x}\} \subset \mathbb{R}^{2d}$. The subspace E is linear which implies that $\deg \tilde{\mathcal{S}}_i \cap E = \deg \tilde{\mathcal{S}}_i$ and that $\mathcal{S}_i' \subset \tilde{\mathcal{S}}_i \cap E$ has degree at most $O(\Delta_i^{2(m_i+1)})$.

Finally, note that the number of critical points of the distance-squared function from some fixed point $p \in \mathbb{R}^d \setminus \mathcal{E}_i$ is finite and bounded above by the degree of the map φ_i, which is $O(\Delta_i^{m_i+1})$. Summing up, we have the following proposition.

PROPOSITION 3.2. *Let $\mathcal{B}$ denote the bifurcation set of the family of distance-squared functions on a collection $X = \cup_{i=1}^n X_i$ of algebraic sets of maximal degree Δ and maximal dimension m. Then the following holds:* (i) *the degree of $\cup\partial\mathcal{S}_i'$ is at most of order $O(\Delta^{2(m+1)})$;* (ii) *the number of critical points of the distance-squared function from any point $p \in \mathbb{R}^d \setminus \cup\mathcal{E}_i$ to X is at most of order $n \cdot \Delta^{m+1}$; and* (iii) *the number of connected regions of $\mathbb{R}^d \setminus \mathcal{B}$ and the size of $\mathcal{A}(\mathcal{B})$ are at most of order $n^{2d} \cdot \Delta^{2(m+1)d}$*

Remarks. 1. Note that the estimates i, ii, and iii yield in the case of hypersurfaces $(m = d-1)$ the same estimates as in Proposition 3.1 (i), (ii), and (iii).

2. The estimate (i) implies for arrangements of plane curves (where $m = 1$) that there are at most $O(n \cdot \Delta^4)$ endpoints of the level bifurcation set. But, again using the fact that these endpoints correspond to curvature extrema of the curves X_i, one checks that actually there are at most $O(n \cdot \Delta)$ such endpoints.

3. It is also interesting to compare these estimates for arrangements of zero-sets with the corresponding bounds in the special case of parametrized m_i-surfaces given in section 2. Not surprisingly, the combinatorial complexities (fixing the degrees Δ or δ) are the same. However, in terms of algebraic complexity, the estimates in Propositions 2.1, 2.2, and 2.3 for arrangements of parametrized surfaces are sharper than the corresponding ones in Proposition 3.2 This can be seen using the following fact.

LEMMA 3.3. *The degree Δ_i of a parametrized m_i-surface X_i given by*

$$x \mapsto X_i(x) := (X_i^1(x), \dots, X_i^d(x)), \quad \delta_i := \sup_j \deg X_i^j$$

is of order $\delta_i^{m_i}$ (which implies, for arrangements of such surfaces, that $\Delta \sim O(\delta^m)$).

Proof. Let $\mathcal{L}$ be a $(d - m_i)$-dimensional linear subspace of $\mathbb{R}^d$ not contained in X_i, and let $\mathcal{L}$ be given as zero-set of some linear map $L = (L_1, \dots, L_{m_i}) : \mathbb{R}^d \to \mathbb{R}^{m_i}$. By Bézout's theorem, $L \circ X_i : \mathbb{R}^{m_i} \to \mathbb{R}^{m_i}$ has at most $\delta_i^{m_i}$ roots (counting multiplicities, complex roots, and roots at infinity), hence $|\mathcal{L} \cap X_i| \sim O(\delta_i^{m_i})$. $\square$

4. Determining the connected regions of $\mathbb{R}^d \setminus \mathcal{B}$, and applications to proximity queries. This section consists of two parts: in subsection 4.1 we sketch the exact symbolic computation of connected regions of $\mathbb{R}^d \setminus \mathcal{B}$ of constant description size for arrangements of algebraic sets defined by polynomials with rational coefficients. And in subsection 4.2 we discuss how this partition of $\mathbb{R}^d$ can be used to efficiently answer proximity queries for points with algebraic number coordinates. In terms of combinatorial complexity (where the degrees and coefficient sizes of the defining polynomials of the algebraic sets are bounded by some constant), computing the partition takes $O(n^{4d-6+\epsilon})$ (for $d \geq 3$) or $O(n^{4+\epsilon})$ (for $d = 2$) expected time (here ϵ is some small positive constant), and answering a proximity query takes $O(\log n)$ time. In dimensions 2 and 3, the time for computing the partition almost matches the number of regions of $\mathbb{R}^d \setminus \mathcal{B}$ (in the worst case), but in higher dimensions the computation time is much larger than the number of regions. In section 6 we shall study certain partitions, cut out by subsets of $\mathcal{B}$, which have a lower combinatorial complexity but can still be used for the same proximity problems.

4.1. Determining the partition. The bifurcation set $\mathcal{B}$ of the family of distance-squared functions between points $p \in \mathbb{R}^d$ and a collection of algebraic sets is a semi-algebraic set which is the projection of a real algebraic set $\tilde{\mathcal{B}} \subset \mathbb{R}^d \times \mathbb{R}^a$, where $a \leq 2m$ (for parametrized m_i-surfaces, $m := \sup m_i$) or $a = 2d$ (for zero-sets). The defining equations of the components $\tilde{\mathcal{E}}_i$, $\tilde{\mathcal{S}}_i$, $\tilde{\mathcal{S}}_{ij}$ of $\tilde{\mathcal{B}}$ are described in sections 2 and 3 and are polynomials with rational coefficients (we assume that the X_i are defined by polynomials over $\mathbb{Q}$). If π denotes the restriction to $\tilde{\mathcal{B}}$ of the obvious projection from $\mathbb{R}^d \times \mathbb{R}^a$ to $\mathbb{R}^d$ and if $\hat{\mathcal{B}} \subset \mathbb{R}^d$ is a closed real algebraic set containing $\mathcal{B}$, then we have the following set-up for the algorithm below (which consists of three steps):

$$\begin{tikzcd}
\tilde{\mathcal{B}} \arrow[d, "\pi"] & \subset \mathbb{R}^d \times \mathbb{R}^a \\
\mathcal{B} & \subset \hat{\mathcal{B}} \subset \mathbb{R}^d
\end{tikzcd}$$

1. Eliminate $x^1, \dots, x^a$ between the defining equations of $\tilde{\mathcal{B}}$. Result: the defining equations of the real algebraic set $\hat{\mathcal{B}} \subset \mathbb{R}^d$.
2. Decompose $\mathbb{R}^d$ into connected regions (of constant combinatorial complexity) such that each such region lies in a single component of $\mathbb{R}^d \setminus \hat{\mathcal{B}}$ (and hence of $\mathbb{R}^d \setminus \mathcal{B}$).
3. Optional step: determine the connected regions of $\mathbb{R}^d \setminus \mathcal{B}$ by deleting the "branches" of $\hat{\mathcal{B}} \setminus \mathcal{B}$ from $\hat{\mathcal{B}}$.

In these steps we use known techniques; here we discuss their complexity and give some references.

Step 1. The set $\tilde{\mathcal{B}}$ has $2n + \binom{n}{2}$ components; the combinatorial complexity of the elimination is therefore $O(n^2)$. Next, we consider the algebraic complexity. Recall from section 3.2 that, for zero-sets X_i of codimension ≥ 2, the generators of the ideals $I(\tilde{\mathcal{S}}_i)$ have to be precomputed from certain ideal quotients. In all other cases the defining equations of the components of $\tilde{\mathcal{B}}$ are already known. For parametrized surfaces one has to eliminate m_i (for $\tilde{\mathcal{B}}_l = \tilde{\mathcal{E}}_i$), $2m_i$ (for $\tilde{\mathcal{B}}_l = \tilde{\mathcal{S}}_i$), or $m_i + m_j$ variables (for $\tilde{\mathcal{B}}_l = \tilde{\mathcal{S}}_{i,j}$). During the elimination, which can use either multipolynomial resultants (see, for example, [7]) or Gröbner bases, one can remove repeated factors, because the later steps of the algorithm only require information about the radicals of the elimination ideals $I(\hat{\mathcal{B}}_l) := I(\tilde{\mathcal{B}}_l) \cap \mathbb{Q}[p]$. (Note that the worst-case computation time is $D^{O(v)}$ for the multipolynomial resultant and $D^{2^{O(v)}}$ for Gröbner bases, where $D \leq \delta$ or Δ is the maximal degree of the input polynomials and $v = d + a$ the number of variables.)

Step 2. We mention two algorithms in (i) and (ii) below which can be used to compute a partition of $\mathbb{R}^d$ into connected regions, of constant combinatorial complexity, in the complement of $\hat{\mathcal{B}}$. The first is the classical one and has been used to compute the examples shown in section 5; the second is more efficient. Recall that $\hat{\mathcal{B}}$ is the union of the zero-sets of $N \sim O(n^2)$ polynomials of maximal degree $D \sim O(\delta^{2m+1})$ (for parametrized X_i) or $O(\Delta^{2(m+1)})$ (for zero-sets X_i).

(i) The cylindrical algebraic decomposition of Collins [9] yields at most $(ND)^{2^d}$ d-cells in the complement of $\mathbb{R}^d \setminus \hat{\mathcal{B}}$. The cells are diffeomorphic to open d-cubes (so that the number of lower dimensional cells in their closure is independent of N) and can be determined in $L^3(ND)^{2^d}$ time (where L denotes the maximal coefficient size of the input polynomials).

(ii) Chazelle et al. [8] (see also [22, Theorem 8.23]) describe a stratification which yields d-cells in the complement of $\hat{\mathcal{B}}$ whose closure contains a number of lower dimensional cells which does not depend on N. Assuming that the maximal degree D and the bit lengths of all polynomials arising during the computation are bounded by some constant, this stratification consists of at most $O(N^{2d-3+\epsilon})$ (for $d \geq 3$) or $O(N^{2+\epsilon})$ (for $d = 2$) cells which can be determined deterministically in $O(N^{2d+1})$ time or by a randomized algorithm in $O(N^{2d-3+\epsilon})$ (for $d \geq 3$) or $O(N^{2+\epsilon})$ (for $d = 2$) expected time (here ϵ denotes an arbitrarily small positive constant). Furthermore, given some point $p \in \mathbb{R}^d$, the cell containing p can be determined in $O(\log N)$ time. The drawback of this stratification procedure is that, considering the degree D as a variable, the number of cells and the running time become doubly exponential in d with base D.

Remark. The algorithm of Grigor'ev and Vorobjov [14] can be used to find the representative points of a partition of $\mathbb{R}^d \setminus \hat{\mathcal{B}}$ into connected regions, and this algorithm produces at most $(ND)^{d^2}$ such points in $L^{O(1)}(ND)^{O(d^2)}$ time. But it is not clear whether the number of lower-dimensional cells in the closure of each of these regions is independent of N (also, some extra work would be required to compute the region boundaries).

Step 3. The algorithms in Rieger [19, 20] can be adapted to determine the connected regions in the complement of $\mathcal{B}$. The adapted algorithm is based on a very coarse "stratification" (in which the strata can have singularities) of $\hat{\mathcal{B}}$ consisting of $O(n^2) \cdot P$ "branches" (where P is a polynomial in the degrees of the X_i) such that each "branch" either lies entirely in $\mathcal{B}$ or in $\hat{\mathcal{B}} \setminus \mathcal{B}$. Picking a "good" sample point q in each "branch," one can count the number k of real roots of the specialization $I(\tilde{\mathcal{B}})_{p=q}$

(using results from real algebra): if $k > 0$, then the "branch" belongs to $\mathcal{B}$, otherwise we delete it. The running time of this procedure is quadratic in n and polynomial in the remaining parameters. However, a region in the complement of $\hat{\mathcal{B}}$ could have up to $O(N) = O(n^2)$ "branches" of $\hat{\mathcal{B}}$ in its closure, and in the proximity queries discussed next it is important that the regions have a constant number of cells in their closures.

4.2. Answering proximity queries. We now discuss how the decompositions above can be used to answer proximity queries exactly (i.e., without numerical errors). Let $p \in \mathbb{R}^d$ be a point whose coordinates $(\alpha^1, \dots, \alpha^d)$ are algebraic numbers, represented by minimal polynomials $m^j(t) = 0$ and isolating intervals with rational endpoints. Given p and a set of defining polynomials of X with rational coefficients we would like to do the following:

1. find the k nearest sets X_i;
2. find the nearest point in X;
3. and, provided that X is compact, find the farthest point in X (and hence the smallest sphere with center p enclosing X).

For all three problems we first decompose $\mathbb{R}^d$ into regions which lie in a single connected component in the complement of $\cup\mathcal{S}_{i,j}$ (or $\mathcal{B}$ or $\hat{\mathcal{B}}$—the latter two possibilities yield finer decompositions but with the same "leading term" with respect to the asymptotic complexity in the number of regions). For problem 1 we store for each region the k nearest X_i (for any sample point in the region), for problem 2 the nearest X_i, and for problem 3 the farthest. This completes the preprocessing.

Next, given p, we use the algorithm in [8] to find the region containing p. This takes $O(\log n)$ time, assuming that the degrees and coefficient sizes of the defining polynomials of X and of the minimal polynomials m^j are bounded by some constant. This solves problem 1 already. In the case of problem 2 (respectively, 3) we now know the set X_i in the arrangement that contains the nearest (respectively, farthest) point $q \in X$ from p.

The only remaining task, then, is to determine the coordinates $(\beta^1, \dots, \beta^d)$ of the point $q \in X_i$. The coordinates are algebraic numbers, and we want to compute their minimal polynomials and isolating intervals. We know from sections 2 and 3 that the critical points of the distance-squared function from p to X_i are either the real roots of $df_i^1(p, x) = \cdots = df_i^{m_i}(p, x) = 0$, where $df_i^j \in \mathbb{Q}(\alpha^1, \dots, \alpha^d)[x]$, (for parametrized m_i-surfaces X_i) or of $\varphi_i^1(p, x) = \cdots = \varphi_i^d(p, x) = 0$, where $\varphi_i^j \in \mathbb{Q}(\alpha^1, \dots, \alpha^d)[x]$, (for zero-sets X_i). The real roots $\xi_1, \dots, \xi_s$ of these systems are isolated and have algebraic coordinates whose minimal polynomials and isolating intervals can be determined by computing a diagonal basis of the systems and by isolating the roots of univariate polynomials with algebraic coefficients (using primitive element methods and the modified Uspenski algorithm). For parametrized surfaces X_i we have to determine the root ξ_j, $1 \le j \le s$, for which the algebraic number $f_i(p, \xi_j)$ is minimal (problem 2) or maximal (problem 3); and the result is $q = X_i(\xi_j)$, whose coordinates are algebraic numbers. For zero-sets X_i we have to determine the ξ_j for which $\|\xi_j - p\|^2$ is minimal or maximal; and the result is $q = \xi_j$.

Remarks. 1. The decomposition of d-space into connected regions in the complement of $Y := \cup\mathcal{S}_{i,j}$ is finer than it needs to be for answering the above queries. In section 6 we study certain subsets R_k and $\tilde{R}_k$ of Y which cut out far fewer regions (see

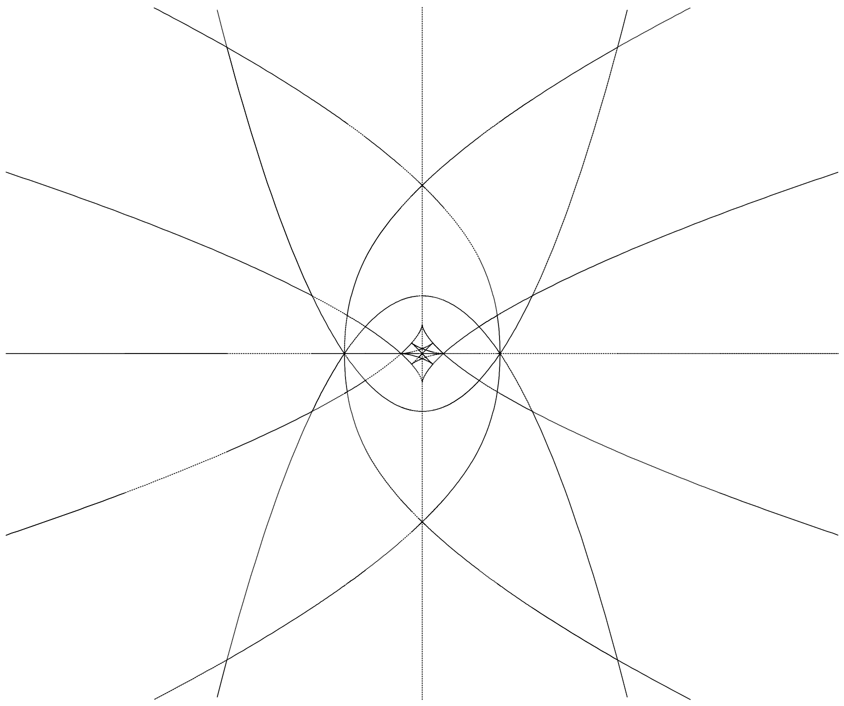

FIG. 2. *The set $\hat{\mathcal{B}}$ for a pair of parabolas.*

Proposition 6.1 for precise statements). Using the above exact symbolic methods, one can replace Y by the following sets: in problem 1 by R_k, in problem 2 by R_1, and in problem 3 by $\tilde{R}_1$.

2. However, in problems 2 and 3, if one replaces the exact symbolic computation of the nearest and farthest point $q \in X$ from p by the numerical curve-tracing procedure sketched below, then the decomposition into regions of $\mathbb{R}^d \setminus Y$ is too coarse, and one must replace Y by the full bifurcation set $\mathcal{B}$! The numerical procedure consists of the following: determine one sample point p' for each region in the complement of $\mathcal{B}$ (or $\hat{\mathcal{B}}$) and the corresponding nearest or farthest point $q' \in X$. After determining the region containing p (as before), one knows that any path in this region joining its sample point p' with p corresponds to a unique path in X joining the corresponding nearest/farthest points q' and q. This follows from the fact that the critical points of the distance-squared function are isolated in the complement of $\mathcal{B}$ and the continuity of the map which assigns to p its nearest/farthest point in X (Proposition 2.3). This would not be the case if we replace $\mathcal{B}$ by Y.

5. Some examples for arrangements in the plane. The first example, in Figure 2, shows a pair of parabolas $X_1(x) = (x, x^2 - 1)$, $X_2(x) = (x, 1 - x^2)$ together with the set $\hat{\mathcal{B}}$ which contains the bifurcation set $\mathcal{B}$. It should be noted that most curves in Figure 2, except for the intercurve level bifurcation set, are already known from Figure 1: the first parabola X_1 and the sets $\hat{\mathcal{E}}_1 = \mathcal{E}_1$ (a cusp-shaped curve) and $\hat{\mathcal{S}}_1$ (a vertical line) are exactly as shown in Figure 1, and turning Figure 1 upside down yields X_2, $\mathcal{E}_2$, and $\hat{\mathcal{S}}_2$ ($\hat{\mathcal{S}}_2$ coincides with $\hat{\mathcal{S}}_1$). The set $\hat{\mathcal{S}}_{1,2}$, which contains the intercurve level bifurcation set $\mathcal{S}_{1,2}$ (but we do not know whether it is equal to it), consists of a horizontal line through the origin and the zero-set Z of an irreducible

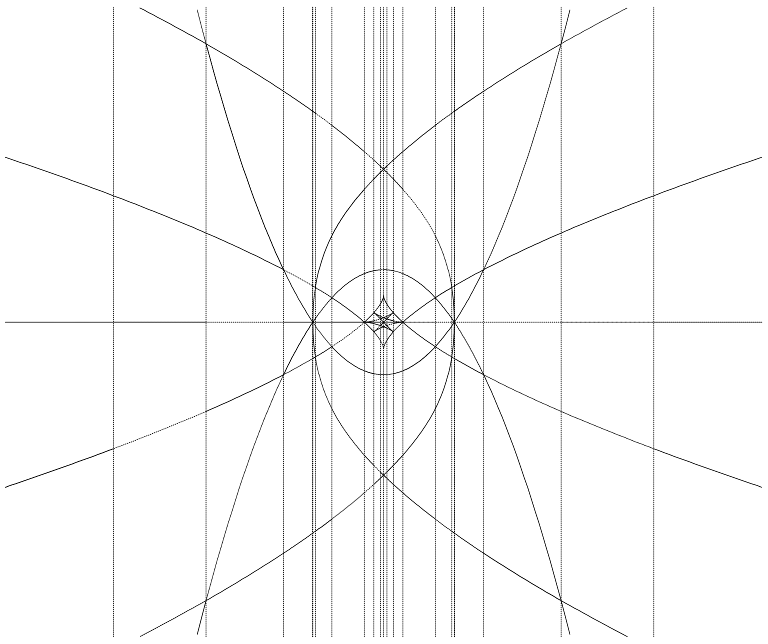

FIG. 3. *Cylindrical algebraic decomposition of $\hat{\mathcal{B}}$ and a pair of parabolas.*

(over $\mathbb{Q}$) degree 12 polynomial. The set Z has three real components: a compact curve with 6 cusps and a pair of nonsingular curves passing through the intersection points of the parabolas. Figure 3 shows a cylindrical algebraic decomposition of the plane into regions in the complement of $\mathbb{R}^2 \setminus \hat{\mathcal{B}} \cup X_1 \cup X_2$, which are arranged in "vertical cylinders." The cylinders are bounded by vertical tangent lines or by vertical lines passing through singular points. The regions within a cylinder $I \times \mathbb{R}$, where I is an interval on the x-axis, are separated by nonintersecting function graphs over I.

The second example, in Figure 4, shows the set $\hat{\mathcal{S}}_{1,2}$ for a parabola $X_1(x) = (x, x^2)$ and a point $X_2 = (1, 2)$. Note that the Voronoi diagram of X_1, X_2 consists of just two regions: the region cut out by $\hat{\mathcal{S}}_{1,2}$ containing the point X_2 and the complement of the closure of this region. The curve $\hat{\mathcal{S}}_{1,2}$ has 2 cusps, which correspond to centers of osculating circles of X_1 which pass through the point X_2. Figure 5 illustrates this fact: the cusps of $\hat{\mathcal{S}}_{1,2}$ lie on the evolute $\mathcal{E}_1 = \hat{\mathcal{E}}_1$ of the parabola X_1 (and hence are centres of osculating circles having A_2-contact with X_1).

6. Regions of $\mathbb{R}^d \setminus \mathcal{B}$ and Voronoi regions.

The estimates in sections 2 and 3 for the size of $\mathcal{A}(\mathcal{B})$ (in terms of n, d, and the degrees and dimensions of the X_i) yield upper bounds for the complexity of the kth-order Voronoi diagram. They also bound the complexity of Voronoi diagrams of collections $X^s := \cup_i X_i^s$ of closed semialgebraic sets $X_i^s \subset \mathbb{R}^d$, each given as unions and intersections of $O(1)$ "elementary" sets of the form $\{x \in \mathbb{R}^d : h(x) \ ?\ 0\}$, where $? \in \{=, <, >, \leq, \geq\}$ (actually, any such X_i^s can be defined by choosing $? \in \{=, <\}$). For each X_i^s we can define a real algebraic set $X_i \supset X_i^s$, using the $O(1)$ polynomials h, such that $\dim X_i = \dim X_i^s$. If $\mathcal{B}^s$ and $\mathcal{B}$ are the bifurcation sets of X^s and $X := \cup_i X_i$, then $\mathcal{B}^s \subset \mathcal{B}$; in fact $\mathcal{B} \setminus \mathcal{B}^s$ consists of the closure of certain $(d-1)$-cells of $\mathcal{B}$. The size of the arrangement $\mathcal{A}(\mathcal{B}^s)$ (and hence of the kth-order Voronoi diagram of X^s) is therefore bounded above by $|\mathcal{A}(\mathcal{B})|$.

A comparison of the bounds for the size of $\mathcal{A}(\mathcal{B})$ and of Voronoi diagram $\mathcal{A}(V_k)$

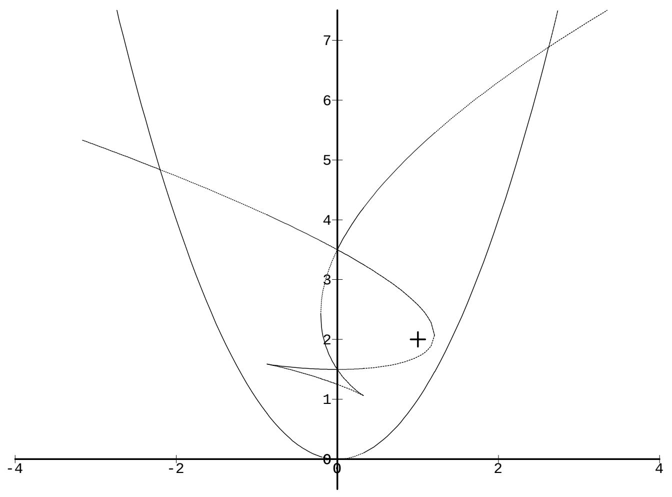

FIG. 4. *The set $\hat{\mathcal{S}}_{1,2}$ for a parabola X_1 and the point $X_2 = (1, 2)$ (marked by a cross).*

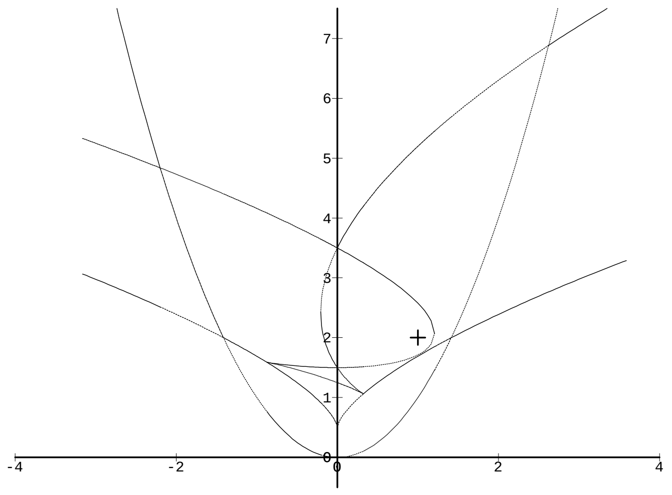

FIG. 5. *The sets $\hat{\mathcal{S}}_{1,2}$ and $\hat{\mathcal{E}}_1$ for a parabola X_1 and the point $X_2 = (1, 2)$.*

reveals, however, a considerable gap—at least in the special cases where something about the complexity of the Voronoi diagram is known. The works on Voronoi diagrams of arrangements of (semi-)algebraic sets study the combinatorial complexity (i.e., assume that the degrees of the algebraic sets in an arrangement are bounded above by some constant). In this case, $|\mathcal{A}(\mathcal{B})| \sim O(n^{2d})$. On the other hand, Sharir and Agarwal show in [22, Appendix 7.1] that the size of the first-order Voronoi diagram of n disjoint convex semialgebraic sets of "constant description size" (i.e., defined by $O(1)$ polynomial (in)equations of bounded degree and coefficient size) in d-space is $O(n^{d+\epsilon})$ (for any $\epsilon > 0$). And Alt and Schwarzkopf [1] show that the first-order Voronoi diagram of n points and disjoint parametrized algebraic curve segments in the plane, which also do not have self-intersections, has $O(n)$ size and can be constructed by a randomized algorithm in $O(n \log n)$ (expected) time. Their algorithm concentrates on the combinatorial aspect of the problem and assumes that the semialgebraic level bifurcation sets $\mathcal{S}_i$ and $\mathcal{S}_{i,j}$ (in our notation) can be determined by some numerical polynomial equation solver. We have seen in previous sections that the bifurcation set can also be determined by exact symbolic methods.

On the other hand, the first-order Voronoi diagram of the $dn \sim \Theta(n)$ intersecting hyperplanes $X_{ij} := \{x^i = j\}$, where $1 \leq i \leq d$ and $1 \leq j \leq n$, has $\Theta(n^d)$ connected d-dimensional regions (recall that $(x^1, \ldots, x^d)$ are coordinates in $\mathbb{R}^d$). Hence we have the lower bound $|\mathcal{A}(V_1)| \sim \Omega(n^d)$.

The goal of the present section, then, is to study the gap in the combinatorial complexities of $\mathcal{A}(\mathcal{B})$ and of $\mathcal{A}(V_k)$. To this end, we shall derive a bound for the combinatorial complexity of certain intermediate sets $V_k \subset R_k \subset \mathcal{B}$, which we are going to define next.

Roughly speaking, the sets R_k are constructed by deleting from the intersurface level bifurcation set $Y := \cup_{1 \leq i < j \leq n} \mathcal{S}_{i,j} \subset \mathcal{B}$ certain "branches" that cannot belong to V_k. In order to describe this construction, we need the following notation. Recall the notation for an $A^r_{\geq 1}$-singularity of the distance squared-function (see section 1.1). For a family of distance-squared functions $f(p, x)$ parametrized by the coordinates of the points $p \in \mathbb{R}^d$, we denote the set of points p for which f has a singularity of type $A^r_{\geq 1}$ by $\mathcal{L}(A^r_{\geq 1})$. Geometrically, it is the locus of centers of r-tangent spheres (i.e., spheres touching the algebraic set X in r distinct points). Now set

$$Y_r := Y \cap \mathcal{L}(A^r_{\geq 1}).$$

Furthermore, let $Y_{r_1,\ldots,r_s}$ denote the locus of common intersection points of s such sets Y_{r_i}. In order to avoid redundancies, let us agree that the indices are nonincreasing, i.e., $r_i \geq r_{i+1}$. It is also convenient to define the "closure" of $Y_{r_1,\ldots,r_s}$ as

$$\bar{Y}_{r_1,\ldots,r_s} := \bigcup \{Y_{a_1,\ldots,a_t} : t \geq s, a_i \geq r_i, 1 \leq i \leq s\}. \qquad (*)$$

Note that the points p of the s-fold self-intersection locus of $Y_{r_1,\ldots,r_s}$ of $Y = \bar{Y}_2$ are centers of s concentric r_i-tangent spheres (where $r_i \geq 2$). Also note that $p \in \bar{Y}_{r_1,\ldots,r_s} \setminus Y_{r_1,\ldots,r_s}$ if and only if there are more than s such spheres or some sphere has more than r_i points of tangency. To save breath, we shall often refer to the "k smallest r_i-tangent spheres" with common center $p \in Y_{r_1,\ldots,r_s}$, $k \leq s$, rather than to the "subset of the set of s simultaneous $A^r_{\geq 1}$-singularities with the k smallest critical values." Finally, let $S_{c_1,\ldots,c_t}$ be the locus of common intersections of t sets X_i of codimension $c_i := d - m_i$, which corresponds to the intersection locus of $\binom{t}{2}$ branches of Y, and define its "closure" $\bar{S}_{c_1,\ldots,c_t}$ as in $(*)$. Each branch consists of centers of spheres tangent to a pair of intersecting sets X_i, X_j whose radius tends to zero as the center approaches $X_i \cap X_j$, such spheres will be called *vanishing spheres*. We are now ready to construct the sets R_k.

First, we decompose the intersurface level bifurcation set Y into certain branches which, for generic arrangements X, will be $(d-1)$-dimensional. Let $B(Y)$ denote the set of connected components (branches) of $Y \setminus \bar{Y}_3 \cup \bar{S}_{1,1}$. Note that all points of such a branch lie either in $V_k \subset Y$ or in $Y \setminus V_k$, because for all these points we have a pair of critical points of the distance-squared function whose critical value is distinct from all other critical values.

Next, we decompose the self-intersection locus of Y into connected components of i-fold intersections, $i = 2, 3, \ldots, s$ and compare the radii of ≥ 2-tangent spheres associated to the i branches of $B(Y)$ passing through an i-fold intersection point. Let us call the set of $X_j \in \{X_1, \ldots, X_n\}$ containing the r points of tangency of an r-tangent sphere the *support set* of this sphere and the smallest sphere among a set of concentric r-tangent spheres with the same support set the *minimal sphere*. We also consider any vanishing sphere to be minimal. If, at any point p of the self-intersection locus, the ≥ 2-tangent sphere associated with some branch of $B(Y)$ does not belong to the k smallest minimal spheres with center p (including the vanishing sphere if $p \in S_{c_1,\ldots,c_t}$) and distinct support sets, then this branch cannot belong to V_k. Deleting all such branches from Y yields the set R_k. To be a bit more precise, let L be the set of "strata" of the "stratification" (the reason for the quotes will be explained in the remark below) of the self-intersection locus of Y into connected components of $Y_{r_1,\ldots,r_s}$ $(s, r_i \geq 2)$, $S_{c_1,\ldots,c_t}$ $(t \geq 2)$, and $S_{c_1,\ldots,c_t} \cap Y_{r_1,\ldots,r_s}$ $(t, r_i \geq 2,\ s \geq 1)$. For any $l \in L$, let l_k denote the set of branches $b \in B(Y)$ passing through l which correspond to the k smallest minimal $\geq$ 2-tangent spheres with center in l, which by definition have distinct support sets (if there are fewer than k minimal spheres with distinct radius, then l_k contains all branches through l that correspond to some minimal sphere). We can now define

$$R_k := \{b \in B(Y) : b \in l_k, \text{for all } l \in L : l \subset \text{cl} b\} \cup \bar{Y}_3 \cup \bar{S}_{1,1}.$$

The principal result of the present section is based on an enumeration of the connected components of the self-intersection locus of Y, on the one hand, and of those components that also belong to R_k, on the other hand. We give an outline of our enumeration technique. Given an arrangement $X = \cup_{i=1}^n X_i$, there are $\Pi_{i=1}^s \binom{n}{r_i}$ sets $\bar{Y}_{r_1,\ldots,r_s}$, and each of them has a constant number of connected components (recall that the maximal degree of the defining equations of X and the ambient dimension are assumed to be fixed). The number of connected components of $Y_{r_1,\ldots,r_s}$ depends on the number of connected components of all the (lower dimensional) sets

$$Y_{a_1,\ldots,a_t} \subset \bar{Y}_{r_1,\ldots,r_s} \setminus Y_{r_1,\ldots,r_s}$$

in its boundary. For "large enough" s and $r_1, \ldots, r_s$ (see more precise statements below), the boundary of $Y_{r_1,\ldots,r_s}$ will be empty, so that $Y_{r_1,\ldots,r_s}$ has as many connected components as $\bar{Y}_{r_1,\ldots,r_s}$. We call a connected component of such a nonempty set $Y_{r_1,\ldots,r_s}$, whose boundary is empty, a *maximal component*, and $Y_{r_1,\ldots,r_s}$ a *maximal set*. (Note that its index set $r_1, \ldots, r_s$ is maximal, with respect to the natural partial order of $\mathbb{N}^s$, among the nonempty sets $Y_{a_1,\ldots,a_s}$. Among these nonempty sets, however, it will be the one with minimal dimension.) Likewise, the combinatorial complexity of the closures of the sets $S_{c_1,\ldots,c_t}$ and $S_{c_1,\ldots,c_t} \cap Y_{r_1,\ldots,r_s}$ is $O(n^t)$ and $O(n^{t+\Sigma r_i})$, respectively, and the complexity of the interiors of these sets will depend on the number of components in their boundary (for Σr_i and Σc_j sufficiently large we get, again, maximal sets with empty boundary). By inductively deleting the lower dimensional boundary components from $Y = \bar{Y}_2$, beginning with the maximal components, whose boundary is empty, we obtain a "stratification" of Y whose "strata" are the connected components of the sets $Y_{r_1,\ldots,r_s}$, $S_{c_1,\ldots,c_t}$ and their intersections. The number of strata obtained in this way is of the order of the number of maximal sets (recall that a given maximal set has $O(1)$ connected components, in terms of combinatorial complexity).

Remarks (refining stratification to get genuine stratification). 1. First, the rough idea. The strata of this stratification of Y can have singularities along the intersection of Y with the local bifurcation set $\mathcal{E} := \cup\mathcal{E}_i$. For example, the intersurface level bifurcation curve Y in Figure 2 has a component C with six cusps contained in $Y \cap \mathcal{E}$ (C is the small compact curve in the center of the figure). So what is going on here? The strata of C are connected components of $Y_{r_1,\ldots,r_s}$ and correspond to points $p \in \mathbb{R}^d$ for which the distance-squared function to X has s simultaneous singularities of type $A^{r_i}_{\geq 1}$. But any r-tuple of singular points with the same critical values belongs to $A^{r}_{\geq 1}$: for example, the regular branches of C in Figure 2, which are of type $A_1^2 = \{A_1, A_1\}$, but also the cusps, which are of type $\{A_2, A_1\}$. Roughly speaking, one can further subdivide the components (i.e., the strata) of Y into submanifolds (i.e., genuine strata) by requiring that its singular points $\Sigma_1, \ldots, \Sigma_{r_i}$, $1 \leq i \leq s$, are of the same local type (for example, we distinguish A_1 from A_2 points). For each original stratum we then obtain $O(1)$ genuine "equisingular" strata (the number of local types on a given stratum depends on the degree of the X_i and the ambient dimension, but not on n). With this understood, we shall no longer make the distinction between a stratification and its genuine refinement.

2. The meaning of equisingular (for readers familiar with singularity theory). We are considering, in general, nonversal d-parameter families of functions. As d increases, the standard groups of equivalences for functions, such as $\mathcal{R}$ and $\mathcal{K}$, will quickly yield an infinite number of equisingular strata (due to the appearance of moduli). Recall that a $\mathcal{K}$-orbit consists, in general, of several $\mathcal{R}$-orbits; we can only expect for the class of quasi-homogeneous functions that the $\mathcal{K}$- and $\mathcal{R}$-orbits coincide (by a result of Saito [21]). The appropriate definition of equisingular stratum, which yields a finite number of smooth strata, therefore involves the union of $\mathcal{K}$-modular strata (minus certain exceptional strata of higher codimension).

We can now state the main result of section 6.

PROPOSITION 6.1. *For any arrangement of parametrized or implicitly defined algebraic sets (whose degrees are bounded by some constant) in d-space consisting of n elements of any positive codimension the following hold:*

(i) $V_k \subset R_k \subset Y \subset \mathcal{B}$, $1 \leq k \leq n-1$.

(ii) *The size of* $\mathcal{A}(R_k)$ *and hence the number of connected regions of* $\mathbb{R}^d \setminus R_k$ *are bounded above by* $O(\min(n^{d+k}, n^{2d}))$.

(iii) *The combinatorial complexity of* $Y_{2,\ldots,2}$ *(d twos) is* $\Pi_{j=1}^{d}\binom{n}{2} \sim O(n^{2d})$ *and represents the "leading term" in the combinatorial complexity of* $\mathcal{A}(\mathcal{B})$.

Proof. Statement (i) simply follows from the definitions of these sets. For the proof of statements (ii) and (iii) it is convenient to distinguish generic and nongeneric arrangements X, which are defined as follows. Let $\mathcal{X}$ be the space of arrangements $X \subset \mathbb{R}^d$ of n zero-sets X_i of codimension c_i of maximal degree Δ (or of n m_i-surfaces X_i parametrized by polynomials ofdegree $\leq \delta$). $\mathcal{X}$ can be identified with some semialgebraic subset of the finite dimensional space of coefficients of $\sum_{i=1}^n c_i$ polynomials in d variables of degree $\leq \Delta$ (or of nd polynomials in $\sum_{i=1}^n m_i$ variables of degree $\leq \delta$). (Note that not all choices of coefficients yield m_i-dimensional real algebraic sets X_i.) Now define W to be the union of the following sets (corresponding to degenerate X for which Y has "excess intersection"):

$$\left\{X \in \mathcal{X} : \exists s \geq 1, \exists r_i \geq 2 : \dim Y_{r_1,\dots,r_s} > d + s - \sum_{i=1}^{s} r_i\right\},$$

$$\left\{X \in \mathcal{X} : \exists t \geq 2, \exists c_i \geq 1 : \dim S_{c_1,\dots,c_t} > d - \sum_{i=1}^{t} c_i\right\},$$

and

$$\left\{X \in \mathcal{X} : \exists s, c_i \geq 1, \exists t, r_j \geq 2 : \dim(S_{c_1,\dots,c_t} \cap Y_{r_1,\dots,r_s}) > d + s - \sum_{i=1}^{t} c_i - \sum_{j=1}^{s} r_j\right\}.$$

(Note that X denotes both a subset of $\mathbb{R}^d$ as well as a point of $\mathcal{X}$, but the meaning of X should be clear from the context.) One shows, using the defining equations of these sets, that W is a Zariski closed subset of $\mathcal{X}$. We shall therefore say that an element X in $\mathcal{X} \setminus W$ is generic and one in W nongeneric.

First, assume that X is generic and consider the following two stratifications of $\mathbb{R}^d$. In the first, take as strata of dimension 0 to $d-1$ the connected components of the sets $Y_{r_1,\dots,r_s}$, $S_{c_1,\dots,c_t}$, $S_{c_1,\dots,c_t} \cap Y_{r_1,\dots,r_s}$ and as d-dimensional strata the connected components in the complement of $Y = Y_2$. In the second stratification, we discard the connected components of $Y_{r_1,\dots,r_s}$ that do not belong to R_k and take the connected components of $\mathbb{R}^d \setminus R_k$ as d-dimensional strata.

For the 0-dimensional maximal sets $Y_{r_1,\dots,r_s}$ we have, by the genericity of X, the relation $\Sigma_{i=1}^s r_i = d + s$. For the 0-dimensional maximal sets $S_{c_1,\dots,c_t}$ and $S_{c_1,\dots,c_t} \cap Y_{r_1,\dots,r_s}$ we have in the worst case of hypersurface arrangements (where all $c_i = 1$) the relations $t = d$ and $t + \Sigma r_i = d + s$. Hence, there are at most $\Pi_{i=1}^s \binom{n}{r_i} \sim O(n^{d+s})$ such maximal sets, and each of them has $O(1)$ connected components. For the first stratification (whose union of strata of dimension less than d is Y), the relation $\Sigma r_i = d + s$, where all $r_i \geq 2$, implies that $s \leq d$. For the second stratification (whose union of strata of dimension $< d$ is R_k) we have, by the definition of R_k, $s \leq \min(k, d)$. Let e_i denote the number of i-dimensional strata. Then, for all $0 \leq i \leq d-1$, $e_i \sim O(n^{2d})$ (for the stratification of Y) and $e_i \sim O(n^{\min(d+k,2d)})$ (for the stratification of R_k).

For statement (ii) of the proposition we now consider the second stratification. We claim that the number e_d of connected regions of $\mathbb{R}^d \setminus R_k$ is also $O(n^{\min(d+k,2d)})$. Taking a 1-point compactification $S^d = \mathbb{R}^d \cup \{\infty\}$ and adding at most $O(n^{\min(d+k,2d)})$ cells to the induced stratification of R_k in the d-sphere, we get a cell complex K whose Euler characteristic is equal to $\chi(S^d) = 1 + (-1)^d$. Note that e_d is bounded above by the number of d-cells of K; this implies (ii).

For statement (iii), note that $Y_{2,\dots,2}$ (with d twos) is the maximal set of the highest combinatorial complexity in the stratification of Y satisfying the relation $\Sigma r_i = d + s$, and its number of connected components is of order n^{2d}.

For nongeneric arrangements $X \in W$, we consider a "linear deformation" X_t, $t \in (-\epsilon, +\epsilon)$, of $X = X_0$ such that X_0 is the only nongeneric element—linear in the sense that $t \mapsto X_t$ defines a line in the space of coefficients which can be identified with $\mathcal{X}$. (Such a deformation can be obtained, for example, by constructing a stratification of the semialgebraic set W and by restricting a line in the normal space of the stratum containing X to some sufficiently small open neighborhood.) Consider the union U of any of the semialgebraic sets $U_t = Y_t$ or $(R_k)_t$ associated to X_t; U is a semialgebraic subset of $\mathbb{R}^d \times (-\epsilon, +\epsilon)$. We claim that the combinatorial complexity of the degenerate arrangement $\mathcal{A}(U_0)$ is of the same order as that of its generic deformation $\mathcal{A}(U_t)$, for small $t \neq 0$, which implies the desired bounds in the degenerate case.

The claim follows from the following argument. First, we want to check that all strata of U_0 lie in the closure of some stratum of $U \setminus U_0$. Given a pair of closed, connected subsets $A, B \subset \mathbb{R}^d$ and any point $q \in A$ there exists a sphere tangent to A at q and to B in some point q'. Let A_t and B_t be subsets of $X_t \subset \mathbb{R}^d \times (-\epsilon, +\epsilon)$ such that A_0, B_0 are connected subsets of $X = X_0$. Our assumptions about the algebraic set X imply that the dimensions of A_t and B_t are constant for t in some open neighborhood I of 0 (in particular the sets remain nonempty over the reals). By the geometric fact above, there exist points $q_t \in A_t$ and $q'_t \in B_t$ supporting bitangent spheres with centers p_t, such that the sets $\{q_t : t \in I\}$, $\{q'_t : t \in I\}$, and $\{p_t : t \in I\}$ are connected and p_0 is any point of U_0. Next, let $\epsilon > 0$ be small enough such that U is transverse to all hyperplanes $t = c$, for any constant $|c| < \epsilon$, except $t = 0$. (U is, in general, a singular semialgebraic set, and transverse means that the hyperplane in question is transverse to all the strata of a suitable stratification of U, e.g., a stratification satisfying the Whitney condition (b). See the book by Goresky and MacPherson [13, Part I, Chapters 1.2–1.8] for a good introduction to stratification theory.) So the numbers of strata of dimension $0 \leq i \leq d$ in $\mathcal{A}(U_t)$ are locally constant for $t \in (-\epsilon, 0)$ and $t \in (0, \epsilon)$; denote these numbers by r_- and r_+, respectively. Hence there are $r_- + r_+$ strata in $\mathcal{A}(U \setminus U_0)$ and therefore at most that many strata of $\mathcal{A}(U_0)$. $\square$

Remarks. 1. For compact arrangements $X = \cup X_i$ we can define regions analogous to the usual kth-order Voronoi regions, such that for all points within each region the farthest k sets in the arrangement do not change. If $\tilde{V}_k$ is the union of the boundaries of these regions and $\tilde{R}_k$ the set analogous to R_k, except that the k smallest minimal spheres are replaced by the k largest maximal spheres, then Proposition 6.1 above holds for $\tilde{R}_k$ and $\tilde{V}_k$ in place of R_k and V_k.

2. One can get a sharper bound for the (expected) size of $\mathcal{A}(V_k)$, where $k \sim O(1)$, in the average case. Set $\mu_p(X_i) := \inf_{q \in X_i} \|q - p\|^2$. The sets $Y_{r_1,\dots,r_s} \cap R_k$ and $(Y_{r_1,\dots,r_s} \cap S_{c_1,\dots,c_t}) \cap R_k$, $s \leq k$, can only belong to V_k if the critical values of the s $A^{r_i}_{\geq 1}$-singularities of the distance-squared function from $p \in Y_{r_1,\dots,r_s}$ are smaller than all but $k - s \sim O(1)$ of the minima $\mu_p(X_j)$ of the $O(n)$ sets X_j that do not belong to the support sets of one of these $A^{r_i}_{\geq 1}$-singularities (for $p \in \cap_{i=1}^t X_i$, we include the intersecting X_i in the support set). Now suppose for the moment that there exists a "good" probability measure on the space $\mathcal{X}$ of arrangements (definition follows below) such that if we pick some $X = \cup X_i \in \mathcal{X}$ "at random," then $\Pr[\mu_p(X_i) < \mu_p(X_j)] = 1/2$ (actually it is enough if this probability is different from 0 and 1). One then checks that the probability that the critical values of all s $A^{r_i}_{\geq 1}$-singularities are smaller than $O(n)$ minima $\mu_p(X_j)$ is $O(n^{-s})$. Looking at the proof of Proposition 6.1 we now see the following: if M sets X are picked independently from some "good" distribution on $\mathcal{X}$ then, as $M \to \infty$, the expected size of $\mathcal{A}(V_k)$ is $O(n^d)$.

The "good" probability measures on $\mathcal{X}$ are defined as follows. Let $\mathcal{X}^{m_i}$ denote the space of real algebraic sets of dimension m_i of some bounded degree (recall that $\mathcal{X}^{m_i}$ can be identified with a semialgebraic subset of the space of coefficients of the defining polynomials of such sets); then $\mathcal{X} := \times_{i=1}^{n} \mathcal{X}^{m_i}$. Let $\mathcal{M}_i$ be a probability measure on $\mathcal{X}^{m_i}$ (for example, the uniform distribution on some compact subset B of $\mathcal{X}^{m_i}$ of bounded coefficients). We say that the collection of probability measures $\mathcal{M}_i$, $1 \leq i \leq n$, is "good" if the following hold. 1. For each pair $(\mathcal{M}_i, \mathcal{M}_j)$, the Lebesgue measure on $\mathcal{X}^{m_i} \times \mathcal{X}^{m_j}$ is *absolutely continuous* with respect to the product measure $\mathcal{M}_i \times \mathcal{M}_j$. 2. For any given $p \in \mathbb{R}^d$ and all ordered pairs i, j the sets $\{(X_i, X_j) : \mu_p(X_i) < \mu_p(X_j)\}$ have non-zero Lebesgue measure in $\mathcal{X}^{m_i} \times \mathcal{X}^{m_j}$. Conditions 1 and 2 imply that $\Pr[\mu_p(X_i) < \mu_p(X_j)] \neq 0, 1$, but seem quite strong. Note, however, that the conditions are trivially satisfied in an important special case: if all sets X_i in an arrangement have the same dimension and are chosen from a single, but arbitrary, distribution, then, by symmetry, $\Pr[\mu_p(X_i) < \mu_p(X_j)] = 1/2$.

Acknowledgments. I am very grateful to the referees for their detailed comments that contained several corrections and many other useful suggestions. The author acknowledges financial support from the Max–Planck Gesellschaft and the research foundation FAPESP, São Paulo, Brazil.

BETTER BOUNDS FOR ONLINE SCHEDULING[*]

SUSANNE ALBERS[†]

Abstract. We study a classical problem in online scheduling. A sequence of jobs must be scheduled on m identical parallel machines. As each job arrives, its processing time is known. The goal is to minimize the makespan. Bartal et al. [*J. Comput. System Sci.*, 51 (1995), pp. 359–366] gave a deterministic online algorithm that is 1.986-competitive. Karger, Phillips, and Torng [*J. Algorithms*, 20 (1996), pp. 400–430] generalized the algorithm and proved an upper bound of 1.945. The best lower bound currently known on the competitive ratio that can be achieved by deterministic online algorithms is equal to 1.837. In this paper we present an improved deterministic online scheduling algorithm that is 1.923-competitive; for all $m \geq 2$. The algorithm is based on a new scheduling strategy, i.e., it is not a generalization of the approach by Bartal et al. Also, the algorithm has a simple structure. Furthermore, we develop a better lower bound. We prove that, for general m, no deterministic online scheduling algorithm can be better than 1.852-competitive.

1. Introduction.

We study a classical problem in online scheduling. A sequence of jobs must be scheduled on m identical parallel machines. Whenever a job arrives, its processing time is known in advance, and the job must be scheduled immediately on one of the machines without knowledge of any future jobs. Preemption of jobs is not allowed. The goal is to minimize the *makespan*, i.e., the completion time of the last job that finishes.

Algorithms for this scheduling problem are used in multiprocessor scheduling. Moreover, the problem is important because it is the root of many problem variants where, for instance, preemption is allowed, precedence constraints exist among jobs, or machines run at different speeds. The problem was first investigated by Graham [10]. In fact, Graham also studied the *offline* version of the problem, when all jobs are known in advance. The problem of computing an optimal offline schedule for a given job sequence is NP-hard [9]. Graham gave a fast scheduling heuristic that achieves a good approximation ratio. He developed the well-known *List* algorithm that takes the given jobs one by one and always schedules them on the least loaded machine. Clearly, *List* is also an online algorithm.

Following [13], we call a deterministic online scheduling algorithm A *c-competitive* if, for all job sequences $\sigma = J_1, J_2, \ldots, J_n$,

$$A(\sigma) \leq c \cdot OPT(\sigma),$$

where $A(\sigma)$ is the makespan of the schedule produced by A and $OPT(\sigma)$ is the makespan of an optimal schedule for σ.

Graham's *List* algorithm is $(2 - \frac{1}{m})$-competitive. Galambos and Woeginger [8] presented an algorithm that is $(2 - \frac{1}{m} - \epsilon_m)$-competitive, where $\epsilon_m > 0$, but ϵ_m tends to 0 as m goes to infinity. It was unknown for a long time whether there was an algorithm that achieves a competitive ratio of c, $c < 2$, for general m. Bartal, et al. [3] then gave an algorithm that is 1.986-competitive, for all $m \geq 70$. Karger, Phillips, and Torng [11] generalized the algorithm and proved a competitive ratio of 1.945, for all m. This has been the best upper bound known so far for general m. For the special case $m = 4$, Chen, van Vliet, and Woeginger [6] developed an algorithm that is 1.733-competitive. With respect to lower bounds, Faigle, Kern, and Turan [7] showed that no deterministic online algorithm can have a competitive ratio smaller than $(2 - \frac{1}{m})$ for $m = 2$ and $m = 3$. Thus, for these values of m, *List* is optimal. Faigle, Kern, and Turan [7] also proved that no deterministic online algorithm can be better than 1.707-competitive, for any $m \geq 4$. The best lower bound known so far for general m is due to Bartal, Karloff, and Rabani [4], who showed that no deterministic online algorithm can have a competitive ratio smaller than 1.837, for $m \geq 3454$. For more work on related online scheduling problems see, for instance, [1, 2, 5, 12, 14].

In this paper we present an improved deterministic online algorithm for the scheduling problem defined above. The algorithm is 1.923-competitive, for all $m \geq 2$. Our algorithm is based on a new scheduling strategy, i.e., it is not a generalization of the approach by Bartal et al. [3]. Moreover, the algorithm has a simple structure. At any time, the algorithm maintains a set S_1 of $\lfloor \frac{m}{2} \rfloor$ machines with a low load and a set S_2 of $\lceil \frac{m}{2} \rceil$ machines with a high load. Every job is either scheduled on the least loaded machine in S_1 or on the least loaded machine in S_2. The decision about which of the two machines to choose depends on the ratio of the load on machines in S_1 to the load on machines in S_2. A description of the algorithm is given in section 2. A detailed analysis follows in section 3. We also develop a better lower bound for online scheduling. In section 4 we show that if a deterministic online scheduling algorithm is c-competitive for all $m \geq 80$, then $c \geq 1.852$.

2. The new scheduling algorithm.

For the description of the algorithm we need some definitions. Let the *load* of a machine be the sum of the processing times of the jobs already assigned to it. At any time, the algorithm maintains a list of the machines sorted in nondecreasing order by the current load. Let M_i^t denote the machine with the ith smallest load, $1 \leq i \leq m$, after exactly t jobs have been scheduled. In particular, M_1^t is the machine with the smallest load and M_m^t is the machine with the largest load. We denote by l_i^t the load of machine M_i^t, $1 \leq i \leq m$. Note that the load l_m^t of the most loaded machine is always equal to the current makespan.

As with previous algorithms [3, 11], our new scheduling strategy tries to prevent schedules in which the load on all machines is about the same. If all machines have the same load, with all previous jobs being very small, an adversary can present an additional large job and force a competitive ratio of $(2 - \frac{1}{m})$. This is the worst-case scenario for *List*.

Our new algorithm, called $M2$, always tries to maintain k machines with a low load and $m - k$ machines with a high load, where $k = \lfloor \frac{m}{2} \rfloor$. The goal is to always have a schedule in which the total load L_l on the k lightly loaded machines is at most α times the total load L_h on the $m - k$ heavily loaded machines, for some α to be specified later. A schedule satisfying $L_l \leq \alpha L_h$ is always prepared to handle a large incoming job and can easily maintain a competitive ratio of c, where c is 1.923.

Algorithm $M2$ always schedules a new job J_t with processing time p_t on the least loaded machine as long as $L_l \leq \alpha L_h$ is satisfied after the assignment. Note that during this assignment, the load L_l on the lightly loaded machines does not necessarily increase by p_t because the least loaded machine might become one of the machines M_i^t, $k < i \leq m$. If an assignment of J_t to the least loaded machine results in $L_l > \alpha L_h$, then $M2$ considers scheduling J_t on the machine with the $(k+1)$st smallest load. However, if this assignment increases the makespan and the new makespan exceeds $c \cdot (L_l + L_h)/m$, then J_t is finally scheduled on the least loaded machine, ignoring the violation of $L_l \leq \alpha L_h$. Note that $L_l + L_h$ is the sum of the processing times of all jobs that have arrived so far, and thus $(L_l + L_h)/m$ is a lower bound on the optimum makespan.

Algorithm *M2*. Set $c = 1.923$, $k = \lfloor \frac{m}{2} \rfloor$, and $j = 0.29m$. Set $\alpha = \frac{(c-1)k - j/2}{(c-1)(m-k)}$. Every new job J_t is scheduled as follows. Let L_l be the sum of the loads on machines $M_1^t, \ldots, M_k^t$ if J_t is scheduled on the least loaded machine. Similarly, let L_h be the sum of the loads on machines $M_{k+1}^t, \ldots, M_m^t$ if J_t is scheduled on the least loaded machine. Let λ_m^t be the makespan, i.e., the load of the most loaded machine, if J_t is scheduled on the machine with the $(k+1)$st smallest load. Recall that l_m^{t-1} is the makespan before the assignment of J_t.

Schedule J_t on the least loaded machine if one of the following conditions holds.

(a) $L_l \leq \alpha L_h$.
(b) $\lambda_m^t > l_m^{t-1}$ and $\lambda_m^t > c \cdot \frac{L_l + L_h}{m}$.

Otherwise schedule J_t on the machine with the $(k+1)$st smallest load.

Theorem 1. *Algorithm M2 is 1.923-competitive for all $m \geq 2$.*

Before analyzing the algorithm in the next section, we discuss the choice of α. First observe that $0 < \alpha < 1$ for $m \geq 2$. The inequality $0 < \alpha$ holds because $c - 1 > 1/2$ and $k > j$; thus $(c-1)k - j/2 > 0$. Inequality $\alpha < 1$ holds because $(c-1)k \leq (c-1)(m-k)$ and $j/2 > 0$. In fact, for even m, $\alpha = \frac{(c-1) - j/m}{c-1} \approx 0.686$ and, for odd m, α tends to this value as m goes to infinity. Always setting $\alpha = 0.686$ in the algorithm $M2$ asymptotically results in the same competitive ratio of 1.923. Choosing $\alpha = \frac{(c-1)k - j/2}{(c-1)(m-k)}$ has two advantages. (1) We can prove a competitiveness of 1.923 for even small m. (2) In the analysis we can do symbolic calculations where a fixed $\alpha = 0.686$ would require numeric calculations.

3. Analysis of the algorithm.

We present a detailed proof of Theorem 1. The analysis presented by Graham [10] for the *List* algorithm, combined with the observation that algorithm $M2$ only schedules a job on the machine with the $(k+1)$st smallest load if the resulting makespan does not exceed 1.923 times the optimum makespan, shows that $M2$ is c-competitive, where $c = \max\{(2 - \frac{1}{m}), 1.923\}$, for all $m \geq 2$. This gives the desired bound for small m. For $m \geq 8$, the following analysis applies.

Consider an arbitrary job sequence $\sigma = J_1, J_2, \ldots, J_n$. Let p_t be the processing time of J_t, $1 \leq t \leq n$. We will show that $M2$ schedules every job J_t, $1 \leq t \leq n$, such that

$$M2(\sigma_t) \leq 1.923 \cdot OPT(\sigma_t),$$

where $M2(\sigma_t)$ is the makespan of the schedule produced by $M2$ on the subsequence $\sigma_t = J_1, J_2, \ldots, J_t$ and $OPT(\sigma_t)$ is the makespan of an optimal schedule for σ_t.

3.1. The basic analysis. Suppose that $M2$ has already scheduled the first $t-1$ jobs and that a competitive ratio of $c = 1.923$ was maintained at all times. Let

$$L = \sum_{s=1}^{t} p_s.$$

L is the sum of the loads on all machines after J_t is assigned.

If the makespan does not change during the assignment of J_t, then by the induction hypothesis there is nothing to show. Also, if the makespan changes but is bounded from above by $c\frac{L}{m}$, then we are done because $\frac{L}{m}$ is a lower bound on the optimum makespan for σ_t.

Thus we concentrate on the case where, during the assignment of J_t, the makespan increases and exceeds $c\frac{L}{m}$. Condition (b) in Algorithm $M2$ implies that J_t is scheduled on the least loaded machine. Let $l_1 = l_1^{t-1}$ be the load of the least loaded machine immediately before J_t is assigned.

First we consider the case where $l_1 \le (c-1)\frac{L}{m} = 0.923\frac{L}{m}$. We have

$$M2(\sigma_t) = l_1 + p_t \le (c-1)\tfrac{L}{m} + p_t.$$

If $p_t \le \frac{L}{m}$, then

$$M2(\sigma_t) \le (c-1)\tfrac{L}{m} + \tfrac{L}{m} \le c\tfrac{L}{m} \le c \cdot OPT(\sigma_t).$$

If $p_t = (1+\delta)\frac{L}{m}$, for some positive δ, then

$$\begin{aligned} M2(\sigma_t) &= l_1 + p_t \\ &\le (c-1)\tfrac{L}{m} + (1+\delta)\tfrac{L}{m} \\ &\le c \cdot (1+\delta)\tfrac{L}{m} = c \cdot p_t \\ &\le c \cdot \max_{1 \le s \le t} p_s \le c \cdot OPT(\sigma_t). \end{aligned}$$

Here we use the fact that $\max_{1\le s\le t} p_s$ is also a lower bound on the optimum makespan.

In the remainder of this proof we will study the situation that the load on the least loaded machine is greater than $(c-1)\frac{L}{m}$, i.e., $l_1 = (c-1+\epsilon)\frac{L}{m}$ for some positive ϵ. Since l_1 cannot be greater than $\frac{L}{m}$, we have $0 < \epsilon \le 2 - c = 0.077$. Note that all machines must have a load of at least $(c-1+\epsilon)\frac{L}{m}$. Since J_t is assigned to the least loaded machine and the makespan after the assignment is greater than $c\frac{L}{m}$, we have $p_t > c\frac{L}{m} - l_1 \ge (1-\epsilon)\frac{L}{m} \ge (\frac{1}{2}+\epsilon)\frac{L}{m}$. Our goal is to show that the sequence $\sigma_{t-1} = J_1, J_2, \ldots, J_{t-1}$ contains m jobs, each with a processing time of at least $(\frac{1}{2}+\epsilon)\frac{L}{m}$. Then there are $m+1$ jobs with a processing time of at least $(\frac{1}{2}+\epsilon)\frac{L}{m}$, two of which must be scheduled on the same machine in an optimal schedule. Thus

$$OPT(\sigma_t) \ge (1+2\epsilon)\tfrac{L}{m}.$$

If $p_t \le \frac{L}{m}$, then

$$\begin{aligned} M2(\sigma_t) = l_1 + p_t &\le (c-1+\epsilon)\tfrac{L}{m} + \tfrac{L}{m} \\ &\le c(1+\epsilon)\tfrac{L}{m} \le c \cdot OPT(\sigma_t). \end{aligned}$$

If $p_t = (1+\delta)\frac{L}{m}$ for some positive δ, then

$$\begin{aligned} M2(\sigma_t) &= (c-1+\epsilon)\tfrac{L}{m} + p_t \le (c+\epsilon+\delta)\tfrac{L}{m} \\ &\le c \cdot \max\{(1+2\epsilon),\ (1+\delta)\}\tfrac{L}{m} \\ &\le c \cdot OPT(\sigma_t). \end{aligned}$$

In each case, Theorem 1 is proved. It remains to show that the sequence $\sigma_{t-1} = J_1, J_2, \ldots, J_{t-1}$ does contain m jobs, each with a processing time of at least $(\frac{1}{2}+\epsilon)\frac{L}{m}$.

3.2. Identifying large jobs. We have to analyze jobs in the sequence σ_{t-1}. Let *time* s, $1 \le s \le t$, denote the point of time immediately after J_s is scheduled. (Time 0 is the point of time before any jobs are scheduled.) For any time s, $1 \le s \le t$, let L_s be the total load on the m machines, i.e.,

$$L_s = \sum_{r=1}^{s} p_r.$$

Note that $L_t = L$.

DEFINITION 1. *At any time s, $1 \le s \le t$, the schedule constructed by $M2$ is called* steady *if the total load on the k lightly loaded machines $M_1^s, \ldots, M_k^s$ is at most α times the total load on the $m-k$ heavily loaded machines $M_{k+1}^s, \ldots, M_m^s$.*

In the following, when referring to machines $M_1^s, \ldots, M_m^s$, we will often drop s when the meaning is clear.

LEMMA 1. *At time $t-1$, i.e., immediately before J_t is scheduled, $M2$'s schedule is not steady.*

Proof. Immediately before J_t is scheduled, the total load on the machines $M_1, \ldots, M_k$ is at least

$$\begin{aligned} \overline{L}_l &= k(c-1+\epsilon)\tfrac{L}{m} \\ &> k(c-1)\tfrac{L}{m} \\ &= ((c-1)k - \tfrac{j}{2})\tfrac{L}{m} + \tfrac{j}{2}\tfrac{L}{m} \\ &= \alpha(c-1)(m-k)\tfrac{L}{m} + \tfrac{j}{2}\tfrac{L}{m}. \end{aligned}$$

If $M2$'s schedule was steady, then the total load on machines $M_{k+1}, \ldots, M_m$ would be at least $\frac{1}{\alpha}\overline{L}_l$. Thus the total load before the assignment of J_t would be at least

$$\begin{aligned} L_{t-1} &\ge (1+\tfrac{1}{\alpha})\overline{L}_l \\ &> k(c-1)\tfrac{L}{m} + (m-k)(c-1)\tfrac{L}{m} + \tfrac{1}{\alpha}\tfrac{j}{2}\tfrac{L}{m}. \end{aligned}$$

Here we used the facts $\overline{L}_l > k(c-1)\frac{L}{m}$ and $\overline{L}_l > \alpha(c-1)(m-k)\frac{L}{m} + \frac{j}{2}\frac{L}{m}$. Thus

$$\begin{aligned} L_{t-1} &> (c-1)L + \tfrac{j}{2\alpha}\tfrac{L}{m} \\ &= L + (c-2)L + \tfrac{j}{2\alpha}\tfrac{L}{m} \\ &> L \end{aligned}$$

because $\alpha = \frac{(c-1)k-j/2}{(c-1)(m-k)} \le \frac{(c-1)-j/m}{c-1} \le \frac{7}{10}$ and hence $(c-2)L + \frac{j}{2\alpha}\frac{L}{m} > -0.077L + 0.2L > 0$. We have a contradiction. ∎

3.2.1. Analyzing load.

Definition 2. *At any time s, $1 \leq s \leq t$, a machine is called* full *if its load is at least* $(c-1+\epsilon)\frac{L}{m}$.

Recall that at time $t-1$, all machines have a load of at least $(c-1+\epsilon)\frac{L}{m}$ and, thus, are full.

For $i = 1, \ldots, m$, let t_i be the most recent time when exactly i machines were full. Note that

$$t_1 < t_2 < \cdots < t_m = t-1.$$

Of particular interest to us will be the time $t_{m-\lfloor j \rfloor}$ when exactly $m - \lfloor j \rfloor$ machines were full. Let t', $t_{m-\lfloor j \rfloor} \leq t' < t-1$, be the most recent time when *M*2's schedule was steady. If *M*2's schedule was not steady during the time interval $[t_{m-\lfloor j \rfloor}, t-1]$, then let $t' = t_{m-\lfloor j \rfloor}$. Let f be the number of machines that are full at time t'.

Our goal is to show that at time t', the total load on the nonfull machines $M_1, \ldots, M_{m-f}$ in *M*2's schedule is at most $(c-1.5)(m-f)\frac{L}{m}$. We will show this using the following two lemmas. Let

$$X = \tfrac{(c-1)}{c}L,$$
$$Y = \tfrac{(c-1)^2}{c}L - \tfrac{j}{2}\tfrac{L}{m}.$$

Lemma 2. *If at time t' the total load on the nonfull machines $M_1, \ldots, M_{m-f}$ in M2's schedule were greater than $(c-1.5)(m-f)\frac{L}{m}$, then the total load at time t would satisfy $L > X + Y(1-\frac{c}{m})^{-(\lfloor j \rfloor+1)}$.*

The proof of Lemma 2 is presented in the appendix.

Lemma 3. $X + Y(1-\frac{c}{m})^{-(\lfloor j \rfloor+1)} \geq L$.

Proof. We have

$$\left(1-\frac{c}{m}\right)^{-(\lfloor j \rfloor+1)} \geq \left(1-\frac{c}{m}\right)^{-j} \geq e^{cj/m}.$$

The first inequality follows because $\lfloor j \rfloor + 1 \geq j$. Thus,

$$\begin{aligned} X + Y(1-\tfrac{c}{m})^{-(\lfloor j \rfloor+1)} &\geq \tfrac{(c-1)}{c}L + (\tfrac{(c-1)^2}{c}L - \tfrac{j}{2m}L) \cdot e^{cj/m} \\ &= (1-\tfrac{1}{1.923})L + (\tfrac{0.923^2 - 1.923 \cdot 0.145}{1.923}L) \cdot e^{0.29 \cdot 1.923}. \end{aligned}$$

Evaluating the last expression gives that it is at least $1 \cdot L$. □

We summarize the results of Lemmas 2 and 3.

Lemma 4. *At time t', the total load on the nonfull machines $M_1, \ldots, M_{m-f}$ is at most $(c-1.5)(m-f)\frac{L}{m}$.*

3.2.2. Tracing the assignment of large jobs. We now identify jobs with a processing time of at least $(\frac{1}{2}+\epsilon)\frac{L}{m}$.

Lemma 5. *During the time interval $(t_{m-k}, t']$, $f-m+k$ jobs, each of size at least $(\frac{1}{2}+\epsilon)\frac{L}{m}$, are scheduled.*

Proof. At time t_{m-k}, $m-k$ machines are full. At time t', f machines are full, where $f \geq m - \lfloor j \rfloor$. Consider the $f-m+k$ steps in $(t_{m-k}, t']$ at which the number of full machines increases. Since at least $m-k$ machines are full, the number of full machines can increase only if a job is scheduled on the least loaded machine. By Lemma 4, at time t', the total load on the $m-f$ least loaded machines is at most

$(c-1.5)(m-f)\frac{L}{m}$. This implies that at time t', the load on the least loaded machine is at most $(c-1.5)\frac{L}{m}$. Thus, at any of the $f-m+k$ steps in $(t_{m-k}, t']$ at which the number of full machines increases, the load on the least loaded machine is at most $(c-1.5)\frac{L}{m}$. Hence jobs of size at least $(c-1+\epsilon)\frac{L}{m} - (c-1.5)\frac{L}{m} = (\frac{1}{2}+\epsilon)\frac{L}{m}$ are introduced. ◻

LEMMA 6. *At time t_{m-k}, each of the machines $M_1, \ldots, M_{f-m+k+1}$ has a load of at most $(c-1.5)\frac{L}{m}$. The total load on the machines $M_{f-m+k+1}, \ldots, M_k$ is at most $(c-1.5)(m-f)\frac{L}{m}$.*

Proof. The machine with the $(f-m+k+1)$st smallest load at time t_{m-k} becomes the least loaded machine no later than time t', when f machines are full. Thus, if at time t_{m-k}, machine $M_{f-m+k+1}$ (or any machine M_i with $i \le f-m+k$) had a load greater than $(c-1.5)\frac{L}{m}$, then the load of the least loaded machine at time t' would be greater than $(c-1.5)\frac{L}{m}$. Lemma 4 implies that this is impossible. Similarly, if at time t_{m-k}, machines $M_{f-m+k+1}, \ldots, M_k$ had a total load of at least $(c-1.5)(m-f)\frac{L}{m}$, then the total load on $M_1, \ldots, M_{m-f}$ at time t' would be at least $(c-1.5)(m-f)\frac{L}{m}$. Again, Lemma 4 gives the desired statement. ◻

LEMMA 7. *During the time interval $(t', t-1]$, $m-f$ jobs of size at least $(\frac{1}{2}+\epsilon)\frac{L}{m}$ are scheduled.*

Proof. By the definition of t', $M2$'s schedule is not steady during $[t'+1, t-1]$. Let $s \in [t'+1, t-1]$ be any of the $m-f$ time steps in $[t'+1, t-1]$ at which the number of full machines has just increased. If the load on the least loaded machine is at most $(c-1.5)\frac{L}{m}$ when J_s is scheduled, then $p_s \ge (c-1+\epsilon)\frac{L}{m} - (c-1.5)\frac{L}{m} = (\frac{1}{2}+\epsilon)\frac{L}{m}$.

Suppose that immediately before the assignment of J_s, the least loaded machine has a load greater than $(c-1.5)\frac{L}{m}$. Let l_{k+1}^{s-1} be the load of machine M_{k+1} and suppose $l_{k+1}^{s-1} = (c-1+\epsilon+\delta)\frac{L}{m}$ for some nonnegative δ. By the definition of t', at least $m - \lfloor j \rfloor$ machines are full at any time in $[t', t-1]$. Thus,

$$\begin{aligned} L_{s-1} &\ge (m-\lfloor j\rfloor)(c-1+\epsilon)\tfrac{L}{m} + \lfloor j\rfloor(c-1.5)\tfrac{L}{m} + (m-k)\delta\tfrac{L}{m} \\ &\ge (c-1)L - \tfrac{1}{2}\lfloor j\rfloor\tfrac{L}{m} + (m-\lfloor j\rfloor)\epsilon\tfrac{L}{m} + \tfrac{\delta}{2}L \\ &\ge (c-1)L - \tfrac{j}{2}\tfrac{L}{m} + (m-j)\epsilon\tfrac{L}{m} + \tfrac{\delta}{2}L. \end{aligned}$$

The second inequality follows because $m-k \ge \frac{1}{2}m$. Since $M2$'s schedule is not steady, $M2$ would prefer to schedule J_s on machine M_{k+1} but cannot because

$$l_{k+1}^{s-1} + p_s > c(L_{s-1} + p_s)/m.$$

Hence,

$$\begin{aligned} p_s &\ge (\tfrac{c}{m}L_{s-1} - l_{k+1}^{s-1})/(1-\tfrac{c}{m}) \\ &\ge \tfrac{c}{m}L_{s-1} - l_{k+1}^{s-1} \\ &\ge c(c-1-\tfrac{j}{2m})\tfrac{L}{m} - (c-1)\tfrac{L}{m} + c(1-\tfrac{j}{m})\epsilon\tfrac{L}{m} - \epsilon\tfrac{L}{m} + \tfrac{c\delta}{2}\tfrac{L}{m} - \delta\tfrac{L}{m}. \end{aligned}$$

The load $l_{k+1}^{s-1} = (c-1+\epsilon+\delta)\frac{L}{m}$ cannot be greater than $(3-c-\epsilon)\frac{L}{m}$ since otherwise we would have, at time $t-1$, $m-k$ machines each with a load greater than $(3-c-\epsilon)\frac{L}{m}$ and k machines each with a load of at least $(c-1+\epsilon)\frac{L}{m}$, resulting in a total load greater than L. Thus, $\delta \le 4-2c-2\epsilon$ and

$$p_s \ge ((c-1)^2 - \tfrac{cj}{2m})\tfrac{L}{m} + (c-1-\tfrac{cj}{m})\epsilon\tfrac{L}{m} + 2(\tfrac{c}{2}-1)(2-c-\epsilon)\tfrac{L}{m}$$

$$= ((c-1)^2 - (c-2)^2 - \tfrac{cj}{2m})\tfrac{L}{m} + (1 - \tfrac{cj}{m})\epsilon\tfrac{L}{m}$$
$$\geq 0.567\tfrac{L}{m} + 0.442\epsilon\tfrac{L}{m}$$
$$\geq (\tfrac{1}{2} + \epsilon)\tfrac{L}{m}$$

for all $\epsilon \leq 0.12$. Recall that our ϵ is at most $2 - c = 0.077$. □

We now consider the time $t_{m-k-\lfloor j\rfloor}$ when exactly $m - k - \lfloor j\rfloor$ machines are full. Let t'' be the earliest point of time in the interval $[t_{m-k-\lfloor j\rfloor}, t_{m-k}]$ at which the machine with the $(k+1)$st smallest load has a load greater than $(c-1.5)\frac{L}{m}$.

LEMMA 8. *During the time interval $(t'', t_{m-k}]$, every job is scheduled on the least loaded machine.*

Proof. We first show that at any time $s \in [t'', t_{m-k}]$, *M*2's schedule is steady. Lemma 6 implies that at time s the total load on the lightly loaded machines $M_1, \ldots, M_k$ is at most $\overline{L}_l = k(c-1.5)\frac{L}{m}$. By the definition of t'', the total load on the heavily loaded machines $M_{k+1}, \ldots, M_m$ at time s is at least

$$\begin{aligned}\overline{L}_h &= (m-k-\lfloor j\rfloor)(c-1)\tfrac{L}{m} + \lfloor j\rfloor(c-1.5)\tfrac{L}{m}\\ &= (m-k)(c-1)\tfrac{L}{m} - \tfrac{\lfloor j\rfloor}{2}\tfrac{L}{m}.\end{aligned}$$

We show that at time s, the total load on the lightly loaded machines is at most α times the load on the heavily loaded machines. This holds if $\overline{L}_l \leq \alpha\overline{L}_h$, i.e., if

$$k(c-1.5)\tfrac{L}{m} \leq \tfrac{k(c-1)-j/2}{(c-1)(m-k)}((m-k)(c-1)\tfrac{L}{m} - \tfrac{\lfloor j\rfloor}{2}\tfrac{L}{m}),$$

which is equivalent to

$$(c-1)(k\lfloor j\rfloor + (m-k)j) - j\tfrac{\lfloor j\rfloor}{2} \leq (c-1)k(m-k).$$

This in turn holds if

$$jm - \tfrac{j^2}{2(c-1)} \leq k(m-k).$$

The left-hand side is at most $0.245m^2$, and the right-hand side is $\frac{1}{4}m^2$ for even m and at least $0.246m^2$ for odd $m \geq 9$. Thus, at time s, *M*2's schedule is steady.

Now consider job J_{s+1} scheduled at time $s+1$. Let l_1^s be the load on the least loaded machine at time s. We have $l_1^s \leq (c-1.5)\frac{L}{m}$. Let p be a processing time such that $l_1^s + p = (c-1.5)\frac{L}{m}$. The property stated in Lemma 6 must also hold at time s because the load on the lightly loaded machines $M_1, \ldots, M_k$ can only be smaller. Thus, if J_{s+1} has a processing time of at most p, scheduling J_{s+1} on the least loaded machine results in a total load of at most $k(c-1.5)\frac{L}{m}$ on machines $M_1, \ldots, M_k$. Since the total load on machines $M_{k+1}, \ldots, M_m$ is at least $(m-k)(c-1)\frac{L}{m} - \frac{\lfloor j\rfloor}{2}\frac{L}{m}$, the calculations of the preceding paragraph show that *M*2's schedule must be steady after the assignment.

Suppose that J_{s+1} has a processing time $p_{s+1} > p$ and that scheduling J_{s+1} on the least loaded machine results in a load of $k(c-1.5)\frac{L}{m} + \delta\frac{L}{m}$ on machines $M_1, \ldots, M_k$, for some $\delta > 0$. This implies that at time $s+1$, the load on any of the machines $M_{k+1}, \ldots, M_{k+\lfloor j\rfloor}$ must be at least $(c-1.5+\delta)\frac{L}{m}$. With the above definitions of $\overline{L}_l$ and $\overline{L}_h$, we conclude that after the assignment of J_{s+1} to the least loaded machine, the total load on $M_1, \ldots, M_k$ is at most $\overline{L}_l + \delta\frac{L}{m}$ and the total load on $M_{k+1}, \ldots, M_m$ is at least $\overline{L}_h + \lfloor j\rfloor\delta\frac{L}{m}$. Since, for $m \geq 8$, we have $\lfloor j\rfloor \geq 2$ and $\alpha \geq \frac{1}{2}$, *M*2's schedule must be steady. ∎

LEMMA 9. *At time $t'' - 1$, the load on machine M_{k+1} is at most $(c - 1.5)\frac{L}{m}$.*

Proof. If $t'' > t_{m-k-\lfloor j \rfloor}$, then the lemma follows from the definition of t''. We show that t'' cannot be equal to $t_{m-k-\lfloor j \rfloor}$. Recall that $f \geq m - \lfloor j \rfloor$. Thus, Lemma 6 implies that at time t_{m-k}, machine $M_{k-\lfloor j \rfloor+1}$ has a load of at most $(c-1.5)\frac{L}{m}$. If $t'' = t_{m-k-\lfloor j \rfloor}$, then there are $\lfloor j \rfloor$ steps in $(t'', t_{m-k}]$ at which the number of full machines increases. By Lemma 8, at all these steps, the jobs are assigned to the least loaded machine. Thus at time t'', the load of machine M_{k+1} cannot be greater than the load of machine $M_{k-\lfloor j \rfloor+1}$ at time t_{m-k}. This means that M_{k+1} has a load of at most $(c-1.5)\frac{L}{m}$ at time t'', contradicting the choice of t''. ∎

LEMMA 10. *During time interval $(0, t_{m-k}]$, $m - k$ jobs of size at least $(\frac{1}{2} + \epsilon)\frac{L}{m}$ are scheduled.*

Proof. Let i be the number of machines that are full at time t''. Consider the i steps in $(0, t'']$ at which the number of full machines increases. At any of these steps, before the assignment of the job, the load on M_1 and M_{k+1} is at most $(c-1.5)\frac{L}{m}$ each; see Lemma 9. Thus jobs of size at least $(c - 1 + \epsilon)\frac{L}{m} - (c-1.5)\frac{L}{m} \geq (\frac{1}{2} + \epsilon)\frac{L}{m}$ must be scheduled. At the $m - k - i$ steps in $(t'', t_{m-k}]$ at which the number of full machines increases, jobs are scheduled on the least loaded machine (Lemma 8). The least loaded machine has a load of at most $(c-1.5)\frac{L}{m}$ and we conclude again that jobs of size at least $(\frac{1}{2} + \epsilon)\frac{L}{m}$ must be scheduled. ∎

Lemma 5 as well as Lemmas 7 and 10 imply the following statement.

LEMMA 11. *During time interval $(0, t-1]$, m jobs of size at least $(\frac{1}{2} + \epsilon)\frac{L}{m}$ are scheduled.*

By the discussion immediately preceding section 3.2, the proof of Theorem 1 is complete.

4. The lower bound. We develop an improved lower bound for deterministic scheduling algorithms.

THEOREM 2. *Let A be a deterministic online scheduling algorithm. If A is c-competitive for all $m \geq 80$, then $c \geq 1.852$.*

Proof. We will construct a job sequence σ such that $A(\sigma) \geq 1.852 \cdot OPT(\sigma)$. The job sequence consists of several rounds. We assume that m is a multiple of 40.

Round 1: m jobs with a processing time of $w = 0.01$.
Round 2: m jobs with a processing time of $x = 0.06$.
Round 3:
- Subround 3.1: $\frac{19}{20}m$ jobs with a processing time of $y_1 = 0.282$.
- Subround 3.2: $\frac{1}{20}m$ jobs with a processing time of $y_2 = 0.4$.

Round 4:
- Subround 4.1: $\frac{1}{2}m$ jobs with a processing time of $z_1 = 0.5$.
- Subround 4.2: $\frac{1}{4}m$ jobs with a processing time of $z_2 = 1 - y_2 = 0.6$.
- Subround 4.3: $\frac{3}{40}m$ jobs with a processing time of $z_3 = 1 - y_1 = 0.718$.
- Subround 4.4: $\frac{3}{40}m$ jobs with a processing time of $z_4 = 0.84$.
- Subround 4.5: $\frac{1}{10}m + 1$ jobs with a processing time of $z_5 = 1$.

Note that in the fourth round, $m + 1$ jobs have to be scheduled.

In the following, when analyzing the various subrounds, we will often compare the makespan produced by an online algorithm A in a subround to the optimum makespan at the end of the subround. It is clear that the optimum makespan during the subround can only be smaller.

Analysis of Round 1: Clearly, in order to maintain 1.852-competitiveness, online algorithm A must schedule the m jobs in Round 1 on different machines.

Analysis of Round 2: Algorithm A must schedule the m jobs in Round 2 on different machines. Otherwise, A's makespan would be at least $w + 2x = 0.13$. Since the optimum makespan during the round is always at most $w + x = 0.07$ and $\frac{0.13}{0.07} > 1.857$, A would not be 1.852-competitive. At the end of the second round, A has a load of $l_2 = w + x = 0.07$ on each of its machines.

Analysis of Round 3: At the end of Subround 3.1, the optimum makespan is at most $x + y_1 = 0.342$. On each of $\frac{19}{20}m$ machines, OPT schedules an x-job and a y_1-job. The remaining $\frac{1}{20}m$ machines have an x-job and 20 jobs of size w. If A does not schedule the jobs in Subround 3.1 on different machines, then its makespan is at least $w + x + 2y_1 = 0.634 > 1.853(x + y_1)$. The optimum makespan after Subround 3.2 is $y_1 + 2x = 0.402$. In an optimal schedule, $\frac{1}{20}m$ machines have a y_2-job, $\frac{1}{2}m$ machines have a y_1-job and two x-jobs. The remaining machines have a y_1-job and at most three w-jobs. Online algorithm A must schedule the jobs of Subround 3.2 on different machines and these machines may not contain any y_1-jobs since otherwise A's makespan is at least $w+x+y_1+y_2 = 0.752 > 1.87(y_1+2x)$. At the end of Round 3, the least loaded machine in A's schedule has a load of $l_3 = w + x + y_1 = 0.352$.

Analysis of Round 4: *Subround* 4.1: After Subround 4.1, the optimum makespan is $y_1 + y_2 = 0.682$. In an optimal schedule, $\frac{1}{20}m$ machines contain a y_1 and a y_2. $\frac{1}{2}m$ machines contain a z_1, two w and two x. $\frac{9}{20}m$ machines contain two y_1. Algorithm A must schedule all z_1-jobs on different machines. Otherwise its makespan would be at least $l_3 + 2z_1 = 1.352 > 1.98(y_1 + y_2)$.

Subround 4.2: At the end of the subround, the optimum makespan is $y_1 + z_1 = 0.782$. In OPT's schedule, $\frac{1}{2}m$ machines have a y_1 and a z_1. $\frac{1}{20}m$ machines have a y_1 and a y_2. $\frac{1}{5}m$ machines have two y_1, three w, and three x. $\frac{1}{4}m$ machines have a z_2 and some of them have two additional w and x. Algorithm A must schedule each z_2-job on a machine not containing any z_1 or z_2 jobs. Otherwise its makespan would be at least $l_3 + z_1 + z_2 = 1.452$, which is greater than $1.856(y_1 + z_1)$.

Subround 4.3: The optimum makespan after the subround is $3y_1 = 0.846$. In an optimal schedule $\frac{1}{2}m$ machines have a y_1, a z_1, and an x. $\frac{1}{4}m$ machines have a z_2, two x, and four w. $\frac{3}{40}m$ machines have a z_3. $\frac{3}{20}m$ machines have three y_1. $\frac{1}{40}m$ machines have two y_2. As before, A may not schedule any z_3-jobs on a machine containing a z_1, a z_2, or a z_3 because this would result in a makespan of at least $l_3 + z_1 + z_3 = 1.57 > 1.855(3y_1)$.

Subround 4.4: The optimum makespan is $y_2 + z_1 = 0.9$. In OPT's schedule, all the z-jobs are scheduled on different machines. $\frac{1}{20}m$ machines having a z_1 also contain a y_2. $(\frac{1}{2} - \frac{1}{20})m$ machines containing a z_1 also have a y_1, an x, and up to three w. The $\frac{1}{4}m$ machines having a z_2 also have a y_1. Machines having a z_3 also have three x. Machines having a z_4 also have an x. At this point, OPT is left with $\frac{1}{10}m$ machines on which it has to schedule $\frac{1}{4}m$ jobs with a processing time of x and $\frac{1}{4}m$ jobs with a processing time of y_1. This can be done by scheduling (a) $\frac{1}{40}m$ machines with 10 x and one y_1 each and (b) $\frac{3}{40}m$ machines with three y_1. As usual, A may not schedule a z_4-job on a machine already having any z-jobs; otherwise its makespan is at least $l_3 + z_1 + z_4 = 1.692 = 1.88(y_2 + z_1)$.

Subround 4.5: The online algorithm A must schedule one of the z_5-jobs on a machine already containing another z-job, because a total of $m + 1$ jobs have to be scheduled in Round 4. This gives a makespan of at least $w + x + y_1 + z_1 + z_5 = 1.852$.

We will show that OPT can schedule all the jobs with a makespan of 1 if $m \geq 80$. An optimal schedule is as follows. $\frac{1}{10}m$ machines have a z_5. $\frac{1}{4}m$ machines have two z_1. $\frac{3}{40}m$ machines have a z_4, two w, and two x. $\frac{3}{40}m$ machines have a z_3 and a y_1. $\frac{1}{5}m$ machines have a z_2, one y_1, two w, and one x. $\frac{1}{20}m$ machines have a z_2 and a y_2. $\frac{9}{40}m$ machines have three y_1, two w, and two x. OPT has $\frac{1}{40}m$ machines left on which it has to schedule one z_5 job and $\frac{1}{5}m$ jobs of size x. This can be done if at least two machines are left, i.e., if $m \geq 80$. OPT can use one machine for the z_5-job and the remaining machines for the x-jobs. ▯

5. Open problems. An interesting problem is to formulate and analyze a generalization of the algorithm $M2$ that, at any time, is allowed to schedule a new job on any of the m machines. In such an algorithm, the ratio of the load on the ith smallest machine to the load on the $(i+1)$st smallest machine has to be bounded by some α_i, $1 \leq i \leq m-1$. The problem is to specify α_i's and a proper scheduling rule that is able to maintain these values. A first step in this direction is to maintain three sets S_1, S_2, and S_3 of $m/3$ machines with low, medium, and high loads, respectively.

More generally, with respect to the scheduling problem studied here, a fundamental open problem is to develop randomized online algorithms that achieve a competitive ratio smaller than the deterministic lower bound for all m.

Appendix. We prove Lemma 2. For convenience, we state the lemma again.

LEMMA A.1. *If at time t', the total load on the nonfull machines $M_1, \ldots, M_{m-f}$ in $M2$'s schedule were greater than $(c-1.5)(m-f)\frac{L}{m}$, then the total load at time t would satisfy $L > X + Y(1-\frac{c}{m})^{-(\lfloor j \rfloor+1)}$.*

Proof. In order to prove the lemma, we have to keep track of the load on the m machines during the entire time interval $[t', t]$. For $i = f, \ldots, m+1$, let

$$Z_i = X + Y(1-\tfrac{c}{m})^{-(i-m+\lfloor j \rfloor)}.$$

We will show by induction on i that for $i = f, \ldots, m$,

$$L_{t_i} - \Phi_{t_i} > Z_i, \tag{1}$$

where Φ is a nonnegative potential that we will define in a moment. Using the inequality $L_{t_m} - \Phi_{t_m} > Z_m$, we will then prove $L > Z_{m+1}$.

We first explain the purpose of the potential. We want to show that during the time interval $(t', t-1]$, every time another machine becomes full, a job J with a large processing time p must be scheduled. Since, by the definition of t', $M2$'s schedule is not steady in $(t', t-1]$, $M2$ would prefer to assign J to machine M_{k+1}. However, $M2$ schedules J on the least loaded machine, causing another machine to become full. This implies that an assignment of J to machine M_{k+1} results in an increased makespan that exceeds c times the average load on the machines, i.e., J's processing time p must be large. In some cases, when M_{k+1} has a high load, we will not be able to argue that J's processing time is greater than a certain value. In these cases we will pay some "missing processing time" out of the potential. This way we can ensure that J's *amortized processing time* is greater than the desired value. J's amortized processing time is the actual processing time plus the change in potential.

Formally, the potential Φ is defined as follows. At time t', we *color* some of the load in $M2$'s schedule. More precisely, on each of the machines $M_1, \ldots, M_{k+m-f}$ we color the load that is above level $(c-1)\frac{L}{m}$. We can imagine that we draw a horizontal line at level $(c-1)\frac{L}{m}$ across $M2$'s schedule and color the load on machines

$M_1, \dots, M_{k+m-f}$ that is above this line. Note that this way a job might be partially colored. During time interval $(t', t]$, the colored load is updated as follows.

1. Whenever $M2$ schedules a job that causes one more machine to become full, we choose the least loaded machine with colored load among $M_{k+1}, \dots, M_m$ and remove the color from its load.
2. Whenever a job is assigned to a machine with colored load, we color that job.
3. After the final job J_t is scheduled, the color is removed from all machines.

At any time, let $I = \{i | M_i \text{ has colored load}\}$ and let c_i, $i \in I$ be the amount of the load that is colored on M_i. Define

$$\Phi = \sum_{i \in I} c_i.$$

During the interval $(t', t-1]$, the following invariants hold.

I1. Whenever $M2$ schedules a job that causes one more machine to become full, there is a machine in $\{M_{k+1}, \dots, M_m\}$ with colored load.
I2. If a machine has colored load, then all its load above level $(c-1)\frac{L}{m}$ is colored.
I3. At any time, if machine M_{k+1} has load $(c-1+\delta)\frac{L}{m}$ for some positive δ, then $c_i \geq \delta \frac{L}{m}$ for all $i \in I$ with $i \geq k+1$.
I4. At any time, there exists a machine among $M_1, \dots, M_k$ with colored load at least $\epsilon \frac{L}{m}$.

Invariant I1 holds because at time t' there are $m-f$ machines in $\{M_{k+1}, \dots, M_m\}$ with colored load, exactly $m-f$ more jobs are scheduled in $(t', t-1]$ that cause a machine to become full, and every time this happens, by update rule 1, the number of machines in $\{M_{k+1}, \dots, M_m\}$ with colored load is reduced by exactly 1. Invariant I2 follows from update rule 2. Invariant I3 is immediate from I2. Invariant I4 holds because initially, at time t', we color loads on the k lightly loaded machines that are full and these machines remain in the set of lightly loaded machines during $(t', t-1]$.

Base of the induction. In order to prove inequality (1) for $i = f$, we have to evaluate $L_{t'}$, the total load on the m machines at time t'. We will show that

$$L_{t'} - \Phi_{t'} > Z_f. \tag{2}$$

This implies that inequality (1) holds for $i = f$ because, between time t' and time t_f, the number of full machines remains the same and, whenever the load on the m machines increases by p, the potential increases by at most p (see update rule 2).

If $M2$'s schedule is not steady at time t', i.e., $t' = t_{m-\lfloor j \rfloor}$ and $f = m - \lfloor j \rfloor$, then

$$Z_f = X + Y = (c-1)L - \tfrac{j}{2}\tfrac{L}{m} \leq (c-1)L - \tfrac{\lfloor j \rfloor}{2}\tfrac{L}{m}. \tag{3}$$

By assumption, at time t', the load on the nonfull machines is greater than $(c-1.5)(m-f)\frac{L}{m} = (c-1.5)\lfloor j \rfloor \frac{L}{m} = (c-1)\lfloor j \rfloor \frac{L}{m} - \frac{\lfloor j \rfloor}{2}\frac{L}{m}$. The load on the full machines is at least $(c-1)f\frac{L}{m} + \Phi_{t'} = (c-1)(m - \lfloor j \rfloor)\frac{L}{m} + \Phi_{t'}$. We obtain

$$L_{t'} - \Phi_{t'} > (c-1)L - \tfrac{\lfloor j \rfloor}{2}\tfrac{L}{m}. \tag{4}$$

Inequalities (3) and (4) give the desired bound.

We study the case where $M2$'s schedule is steady at time t'. The total load on the nonfull machines is greater than $(c-1.5)(m-f)\frac{L}{m}$. The load on each machine

$M_{m-f+1},\ldots,M_k$ is at least $(c-1+\epsilon)\frac{L}{m}$. Thus the total load $\overline{L}_l$ on the k lightly loaded machines $M_1,\ldots,M_k$ is

$$\begin{aligned}\overline{L}_l &> (c-1+\epsilon)(k-m+f)\tfrac{L}{m} + (c-1.5)(m-f)\tfrac{L}{m}\\ &= (c-1)k\tfrac{L}{m} - \tfrac{1}{2}(m-f)\tfrac{L}{m} + (k-m+f)\epsilon\tfrac{L}{m}\\ &\geq (c-1)k\tfrac{L}{m} - \tfrac{j}{2}\tfrac{L}{m} + \tfrac{1}{2}(f-m+\lfloor j\rfloor)\tfrac{L}{m} + (k-m+f)\epsilon\tfrac{L}{m}.\end{aligned}$$

Note that the load $(k-m+f)\epsilon\frac{L}{m}$ will go into the potential. Since the schedule is steady, the total load $\overline{L}_h$ on the heavily loaded machines $M_{k+1},\ldots,M_m$ is at least $\frac{1}{\alpha}$ times the above expression. Neglecting the term $\frac{1}{\alpha}(k-m+f)\epsilon\frac{L}{m}$, we obtain

$$\overline{L}_h > (c-1)(m-k)\tfrac{L}{m} + \tfrac{1}{2\alpha}(f-m+\lfloor j\rfloor)\tfrac{L}{m}.$$

The load $(c-1)(m-k)\frac{L}{m}$ can fill the machines $M_{k+1},\ldots,M_m$ up to a level of $(c-1)\frac{L}{m}$. Of the additional load $\frac{1}{2\alpha}(f-m+\lfloor j\rfloor)\frac{L}{m}$, at least a fraction of $\frac{f-k}{m-k}$ is located on machines $M_{k+m-f+1},\ldots,M_m$ and does not go into the potential. Thus,

$$\begin{aligned}L_{t'} - \Phi_{t'} &= \overline{L}_l + \overline{L}_h - \Phi_{t'}\\ &> (c-1)L - \tfrac{j}{2}\tfrac{L}{m} + \tfrac{1}{2}(f-m+\lfloor j\rfloor)(1+\tfrac{1}{\alpha}\tfrac{f-k}{m-k})\tfrac{L}{m}\\ &= X + Y + \tfrac{1}{2}(f-m+\lfloor j\rfloor)(1+\tfrac{1}{\alpha}\tfrac{f-k}{m-k})\tfrac{L}{m}.\end{aligned}$$

We have to show that

$$\tfrac{1}{2}(f-m+\lfloor j\rfloor)(1+\tfrac{1}{\alpha}\tfrac{f-k}{m-k})\tfrac{L}{m} \geq Y((1-\tfrac{c}{m})^{-(f-m+\lfloor j\rfloor)}-1) \tag{5}$$

holds for every $f \in \{m-\lfloor j\rfloor,\ldots,m\}$. This proves inequality (2).

We define functions

$$g(x) = \tfrac{1}{2}(x-m+\lfloor j\rfloor)(1+\tfrac{1}{\alpha}\tfrac{x-k}{m-k})\tfrac{L}{m},$$

$$h(x) = Y((1-\tfrac{c}{m})^{-(x-m+\lfloor j\rfloor)}-1).$$

The function $g(x)$ is a polynomial of degree 2, and $h(x)$ is an exponentially increasing function. Obviously, $g(m-\lfloor j\rfloor) = h(m-\lfloor j\rfloor) = 0$. We will show that

$$g'(m-\lfloor j\rfloor) > h'(m-\lfloor j\rfloor) \tag{6}$$

and

$$g(y) > h(y) \quad \text{for some } y > m. \tag{7}$$

This implies that $g(x) > h(x)$ must hold for all $x \in (m-\lfloor j\rfloor, m]$. (If $g(z) \leq h(z)$ were true for some $z \in (m-\lfloor j\rfloor, m]$, then $g(x) < h(x)$ for all $x > z$.)

Recall that, as mentioned in the proof of Lemma 1, $\alpha \leq \frac{7}{10}$. Also, evaluating Y with its actual parameters gives $Y \leq 0.299L$. We have

$$\begin{aligned}g'(m-\lfloor j\rfloor) &= \tfrac{1}{2}(1+\tfrac{1}{\alpha}\tfrac{m-\lfloor j\rfloor-k}{m-k})\tfrac{L}{m}\\ &\geq \tfrac{1}{2}(1+\tfrac{10}{7}\cdot\tfrac{m-k-\lfloor j\rfloor}{m-k})\tfrac{L}{m}\\ &\geq (\tfrac{17}{14}-\tfrac{10}{7}\tfrac{j}{m})\tfrac{L}{m}\\ &= 0.8\tfrac{L}{m}.\end{aligned}$$

The last inequality holds because $\lfloor j \rfloor \le j$ and $m - k \ge m/2$. Also, $h'(m - \lfloor j \rfloor) = Y \ln((1 - \frac{c}{m})^{-1}) \le 0.299\frac{L}{m} \ln((1 - \frac{c}{m})^{-m}) < 0.79\frac{L}{m}$. The last inequality holds because $\ln((1-\frac{c}{m})^{-m})$ is decreasing in m and evaluates to less than 2.63 for $m \ge 4$. This shows (6). For the proof of (7), let $y = m + j - \lfloor j \rfloor$. Then $g(y) \ge \frac{1}{2}0.29m(1 + \frac{10}{7})\frac{L}{m} \ge 0.35L$. Also, $h(y) = Y((1 - \frac{c}{m})^{-0.29m} - 1) \le 0.299L((1 - \frac{c}{m})^{-0.29m} - 1)$. The last expression is decreasing in m and less than $0.341L$ for all $m \ge 4$. The proof of inequality (5) is complete.

Induction step. We show that if inequality (1) holds for $i-1$, then it also holds for i. Let s_i be the earliest point of time when exactly i machines are full. We have $t_{i-1} < s_i \le t_i$. For all $s \in [t_{i-1}, s_i - 1]$,

$$L_s - \Phi_s > Z_{i-1}. \tag{8}$$

This is because of the induction hypothesis and the fact that if the load on the m machines increases by p between time t_{i-1} and time $s_i - 1$, then the potential increases by at most p.

Let L_{s_i-1} be the total load on the m machines at time $s_i - 1$ and let $l = l_{k+1}^{s_i-1}$ be the load on machine M_{k+1} at time $s_i - 1$. Suppose $l = (c - 1 + \delta)\frac{L}{m}$ for some $\delta > 0$. The job J_{s_i} that causes the ith machine to become full is scheduled on the least loaded machine. Since *M*2's schedule is not steady at time s_i, *M*2 would prefer to schedule J_{s_i} on machine M_{k+1}. Since this is not possible, condition (b) in Algorithm *M*2 implies that the processing time p_{s_i} of J_{s_i} must satisfy

$$l + p_{s_i} > \frac{c(L_{s_i-1} + p_{s_i})}{m},$$

which is equivalent to

$$p_{s_i} > (\tfrac{c}{m} L_{s_i-1} - l)/(1 - \tfrac{c}{m}).$$

Consider the change in potential during the assignment of J_{s_i}. Update rule 1 and invariants I1–I3 imply that the potential drops by at least $\delta \frac{L}{m}$.

$$\begin{aligned}
p_{s_i} - \Delta\Phi &> (\tfrac{c}{m} L_{s_i-1} - l)/(1 - \tfrac{c}{m}) + \delta \tfrac{L}{m} \\
&\ge (\tfrac{c}{m}(Z_{i-1} + \Phi_{s_i-1}) - l)/(1 - \tfrac{c}{m}) + \delta \tfrac{L}{m} \\
&\ge (\tfrac{c}{m} Z_{i-1} + \tfrac{c\delta}{m}\tfrac{L}{m} - (c - 1 + \delta)\tfrac{L}{m})/(1 - \tfrac{c}{m}) + \delta \tfrac{L}{m} \\
&= (\tfrac{c}{m} Z_{i-1} - (c-1)\tfrac{L}{m})/(1 - \tfrac{c}{m}) \\
&= \tfrac{cY}{m}(1 - \tfrac{c}{m})^{-(i-m+\lfloor j \rfloor)}.
\end{aligned}$$

The second inequality follows because of inequality (8). The third inequality holds because at time $s_i - 1$, there is at least one machine in $\{M_{k+1}, \dots, M_m\}$ with colored load, i.e., $\Phi_{s_i-1} \ge \delta \frac{L}{m}$. Thus,

$$\begin{aligned}
L_{s_i} - \Phi_{s_i} &\ge L_{s_i-1} - \Phi_{s_i-1} + p_{s_i} - \Delta\Phi \\
&> Z_{i-1} + \tfrac{cY}{m}(1 - \tfrac{c}{m})^{-(i-m+\lfloor j \rfloor)} \\
&= X + Y(1 - \tfrac{c}{m})^{-(i-m+\lfloor j \rfloor)} \\
&= Z_i.
\end{aligned}$$

The induction step is complete because during time interval $(s_i, t_i]$ the inequality is maintained.

We finally have to prove

$$L > Z_{m+1}. \tag{9}$$

Our inductive proof shows $L_{t-1} - \Phi_{t-1} > Z_m$. Job J_t is scheduled on the least loaded machine and by assumption $l_1 + p_t > \frac{c(L_{t-1}+p_t)}{m}$, where $l_1 = (c-1+\epsilon)\frac{L}{m}$ is the load of the least loaded machine at time $t-1$, i.e., immediately before J_t is scheduled. Recall that at time t we remove the color from the load in $M2$'s schedule. Invariant I4 implies that the potential at time t must decrease by at least $\epsilon\frac{L}{m}$. Calculations identical to that in the inductive step show inequality (9). □

TIGHT BOUNDS FOR ON-LINE TREE EMBEDDINGS[*]

SANDEEP BHATT[†], DAVID GREENBERG[‡], TOM LEIGHTON[§], AND PANGFENG LIU[¶]

Abstract. Tree-structured computations are relatively easy to process in parallel. As leaf processes are recursively spawned they can be assigned to independent processors in a multicomputer network. However, to achieve good performance the on-line mapping algorithm must maintain load balance, i.e., distribute processes equitably among processors. Additionally, the algorithm itself must be distributed in nature, and process allocation must be completed via message-passing with minimal communication overhead.

This paper investigates bounds on the performance of deterministic and randomized algorithms for on-line tree embeddings. In particular, we study trade-offs between computation overhead (load imbalance) and communication overhead (message congestion). We give a simple technique to derive lower bounds on the congestion that any on-line allocation algorithm must incur in order to guarantee load balance. This technique works for both randomized and deterministic algorithms. We prove that the advantage of randomization is limited. Optimal bounds are achieved for several networks, including multidimensional grids and butterflies.

1. Introduction.

Tree-structured computations arise naturally in diverse applications of the divide-and-conquer paradigm, for example, N-body simulations, the evaluation of functional expressions, backtrack searches, and branch-and-bound procedures. As the computation evolves, the corresponding tree grows and shrinks. Each node of the tree can recursively spawn subprocesses and communicate with its parent. The most significant feature of tree computations is that each node can spawn children independently of and therefore in parallel with other nodes.

How do we exploit this inherent parallelism on a multicomputer network containing as few as 2 or as many as 100,000 processors? For maximum speedup, the processes must be evenly distributed in the network. If neither the structure nor the size of the tree can be predicted at compile time, then a reasonable strategy might be to assign each newly spawned process to a randomly chosen processor. This gives even load distribution with high probability. Unfortunately, it also causes large congestion; many processes are spawned simultaneously and each sends startup information to its assigned processor over a long distance in the network. For any given network,

one might reasonably suspect a trade-off between computational overhead (poor load distribution) and communication overhead (high congestion).

For the boolean hypercube and its derivative networks, e.g., the butterfly and cube-connected-cycle networks, simple and efficient algorithms have recently been developed and analyzed [1, 4]. These algorithms map processes to randomly chosen processors, but the random choice is confined to processors within a short distance from the spawning processor. In particular, every N-node tree can be dynamically spawned within the N-node hypercube so that, with high probability, each processor receives $O(1)$ tree nodes and such that the maximum congestion in the network is $O(1)$ [4]. Using this randomized tree embedding technique for butterfly, Ranade showed that optimal speedup can be achieved for backtrack search problems [6].

For the complete network Karp and Zhang showed that by assigning newly generated branch-and-bound tree nodes to random processors, the parallel branch-and-bound algorithm achieves linear speedup with high probability [3, 10]. The analysis in [3] was later simplified by Ranade [5].

In this paper we extend our study of on-line embeddings to additional multicomputer networks. We derive lower bounds on the congestion that any on-line, deterministic algorithm must incur in order to guarantee load balance. The bounds are tight, to within constant factors, for several networks, including multidimensional grids and butterflies. The deterministic lower bound for butterflies contrasts sharply with previous randomized upper bounds [4]. We also adapt the techniques of [4] to develop a randomized algorithm for grids and show that its performance is better than the deterministic lower bound. Finally, we give tight lower bounds on the expected congestion for randomized algorithms.

Our lower bounds are all based on the simpler problem of allocating tree nodes to two processors. It is well known that bounded-degree trees have small separators, and this seems to suggest that only a small amount of communication should be needed to distribute tree nodes evenly. Nevertheless, we show that, even in the simple case of two processors, large communication overhead is inevitable for balanced on-line embeddings.

The remainder of this paper is organized as follows. Section 2 defines the on-line embedding model and the cost measures studied in this paper. Section 3 presents lower bounds for deterministic algorithms. Section 4 discusses a deterministic off-line algorithm that embeds dynamic trees under a strict balance requirement. Section 5 presents randomized algorithms with improved performance. Section 6 presents lower bounds for randomized algorithms. Section 7 concludes the paper.

2. Models. We model the problem of growing trees on networks as an on-line embedding problem. Informally, the on-line tree embedding problem may be described as follows. We start with the root of a binary tree placed at some node of a multicomputer network. At any instant, each node with 0 or 1 child may choose to spawn a new child. Each newly spawned child must be assigned to a network node, and a path in the network must be chosen from the parent node to the child node. Furthermore, the decision of where to place the newly spawned child must be entirely local, i.e., the embedding algorithm can perform only local computations and no global data structures are allowed.

The on-line embedding algorithm is further constrained in that processes cannot migrate. Once embedded, a tree node cannot subsequently be moved to a different node in the network. These requirements are critical for fine-grain multicomputers [8]. Disallowing process migration is a common policy in practice; migration can conceivably lead to thrashing and thus cripple a large multicomputer network.

This framework for maintaining a dynamically evolving tree differs substantially from a model studied recently by Wu and Kung [9]. The latter model allows for a global data structure which all processors can access simultaneously. Moreover, newly spawned nodes do not need to be assigned processors immediately; the allocation can be deferred until some processor becomes idle. While the arguments and techniques used to prove tight upper and lower bounds are not affected drastically, the resulting bounds are substantially different.

2.1. Growth sequences. Although many tree nodes can spawn children simultaneously, it will suffice for our lower bound arguments to assume that the tree grows one node at a time. Formally, an instance of the on-line tree embedding problem is a sequence of directed edges, $e_i = (w_j, w_i)$, $1 \leq j < i$, in which w_i is the ith node spawned and has parent w_j. Node w_1 is the root. A *growth sequence* is a sequence of edges such that for each k the set $\{e_i : i \leq k\}$ of edges forms a directed tree with each node having outdegree at most two.

The restriction to binary trees is arbitrary, any bounded degree would do, but since the networks we consider have bounded degree, trees with unbounded fanout lead, uninterestingly, to poor worst-case performance.

2.2. Embeddings and their quality. An embedding of a tree T in a network H is a mapping of nodes of T to vertices of H, together with a mapping from edges of T to paths in H. The mapping of nodes is not required to be one-to-one; multiple processes can share the same processor. An on-line embedding induced by a growth sequence is a sequence of embeddings in which each embedding is an extension of the previous one. This enforces the policy of disallowing process migration.

Two standard measures of the quality of an embedding are dilation and congestion. The *dilation* of an embedding is the maximum path length in the network corresponding to an edge of T. The *congestion* of an embedding is the maximum number of edges of T whose images traverse any edge in H.

An embedding of a k-node tree is said to be *α-balanced*, $\alpha \geq 1$, if no more than $\alpha\lceil k/P \rceil$ tree nodes are assigned to any of the P nodes of H. The overloading factor, α, is typically a small constant, independent of P, the size of the network.

In some tree-structured computations, the computational activity is limited to the leaves of the tree. In such cases, it is important only to evenly distribute the leaves within the network. An on-line embedding of a tree with ℓ leaves is said to be *α-balanced on the leaves*, $\alpha \geq 1$, if no more than $\alpha\lceil \ell/P \rceil$ leaves are assigned to any of the P processors of the network.

Finally, an on-line embedding for a growth sequence ρ is *continuously α-balanced* if for every i the ith embedding (induced by the first i elements of ρ) is α-balanced. On the other hand, if only the final embedding in the sequence is α-balanced, then we say that the on-line embedding is *terminally α-balanced*. Obviously, terminal balance is a weaker requirement than continuous balance. Also note that in order to distinguish the two balance requirements under the on-line model, the length of the growth sequence will be given to the embedding algorithms.

3. Deterministic lower bounds. For a given embedding of a tree T, an edge $e = (u, v)$ in T is said to be a *cut edge* if the end points u and v of e are mapped to distinct processors. Each cut edge corresponds to a child spawned at a remote processor, thus requiring communication through the network. The number of cut edges can critically affect congestion.

3.1. Lower bound on two processor cut edges. Given a deterministic on-line algorithm we show how to construct an N-node binary tree for which the algorithm either requires $\Theta(N)$ cut edges or fails to achieve terminally α-balanced for $\alpha < 2$. We describe an *adversary* which progressively grows a tree such that if the algorithm does not use many cut edges, then the final embedding will not be balanced.

On-line allocation for two processors is equivalent to coloring each tree node either black or white. Without loss of generality, suppose that the root is colored *black*. The adversarial tree construction works in phases. In the first phase, we spawn two children from every black node. This phase ends when all the leaves are white. Phase 2 continues with this strategy of spawning from one color only, spawning two children from every white node until all the leaves are black. The tree is grown in this "layer-by-layer" method, producing leaves of alternating colors at the ends of successive phases.

Since the two-coloring algorithm is deterministic, the color committed on-line to each newly spawned node is "known," i.e., computable by the adversary constructing the growth sequence. Thus for each possible deterministic algorithm the adversary can produce a well-defined tree.

We will show that the number of cut edges grows linearly with the size of the adversarial tree under the requirement of terminal balance. The proof is based on the following observation. At the end of every phase, each leaf is connected to its parent by a cut edge. Since every internal node has two children, more than half the edges of the tree (those incident to leaves) are cut edges.

We use the following terminology. A tree node is in layer i if the path from the root to the node contains $i-1$ cut edges. Let n_i be the number of nodes in layer i. Each node spawned during phase i lies either in layer i or in layer $i+1$.

LEMMA 3.1. *For every deterministic algorithm $\mathcal{A}$, $\alpha < 2$, and $\epsilon < (2-\alpha)/4$ there exists a growth sequence ρ of length $N > \alpha/(2-\alpha-4\epsilon)$ such that if the on-line embedding of ρ is terminally α-balanced, then the number of cut edges is greater than ϵN.*

Proof. We consider two cases: either the embedding of ρ is completed before phase 1 terminates or the embedding is completed in a later phase.

The embedding is completed before phase 1 *terminates.* In this case every white node is a leaf and the number of cut edges equals the number of white leaves. In order to maintain terminal balance, there must be at least $N - \alpha\lceil N/2\rceil$ white nodes. This number is greater than $N-\alpha(N/2+1/2)$, which exceeds ϵN when $N > \alpha/(2-\alpha-4\epsilon)$. Therefore there are at least ϵN cut edges.

The embedding is completed during phase k, $k > 1$. Let n_i be the number of nodes in layer i. We again distinguish between two subcases: either $\sum_1^{k-1} n_i \geq \epsilon N$ or $\sum_1^{k-1} n_i < \epsilon N$.

When $\sum_1^{k-1} n_i \geq \epsilon N$.

We first observe that every node in layer $k-1$ is an internal node. Together with the fact that every internal node has two children, we conclude that there are $1 + \sum_1^{k-1} n_i$ cut edges, each connecting a node in layer $k-1$ to a node in layer k. Thus, in this subcase the number of cut edges is greater than ϵN.

When $\sum_1^{k-1} n_i < \epsilon N$.

In this subcase $n_k+n_{k+1} > N(1-\epsilon)$. From the terminal balance condition, we also have $n_k < \alpha\lceil N/2\rceil$. These two imply that $n_{k+1} > N(1-\epsilon) - \alpha\lceil N/2\rceil > N(1-\epsilon-\alpha/2) - \alpha/2 > \epsilon N$ when $N > \alpha/(2-4\epsilon-\alpha)$. Since the embedding terminated during phase k, and before phase $k+1$ began, it follows that every node in layer $k+1$ is a leaf that is connected to its parent by a cut edge. From the preceding argument, it again follows that the number of cut edges is greater than ϵN. □

Lemma 3.1 implies that every deterministic, on-line, load-balancing algorithm requires a linear number of cut edges on some finite sequence. This lower bound for terminally balanced algorithms holds for continuously balanced algorithms as well.

3.2. Multiple processors. As we show in this section, Lemma 3.1 can be extended in a straightforward manner to any bounded number of processors. With P colors (processors) instead of two, we use a construction similar to the one in Lemma 3.1. The only difference is that each phase grows only one subtree, rooted at a leaf grown in the previous phase. Each phase ends when all the leaves grown during that phase are colored differently from the root of the subtree. We also use the same terminology. A tree node is in the layer i if the path from the node to the root contains $i-1$ cut edges. The symbol n_i denotes the number of nodes in layer i.

LEMMA 3.2. *For every deterministic algorithm $\mathcal{A}$, $P \geq 2$, $\alpha < P$, and $\epsilon < \frac{1}{2}(1-\alpha/P)$ there exists a growth sequence ρ of length $N > \alpha/(1-2\epsilon-\alpha/P)$ such that if the on-line embedding of ρ is terminally α-balanced among P processors, then the number of cut edges is greater than ϵN.*

Proof. We consider two cases: the construction of ρ ends either in the first phase or in a later phase.

The construction ends in the first phase. In this case every node in the second layer has a cut edge to its parent. In order to maintain terminal α-balance, the number of nodes in the second layer must be at least $N - \alpha\lceil N/P\rceil$. Therefore the number of cut edges is at least $N-\alpha\lceil N/P\rceil > N-\alpha(N/P+1) > \epsilon N$ when $N > \alpha/(1-2\epsilon-\frac{\alpha}{P})$.

The construction ends during the kth phase for $k > 1$. Let T_k be the subtree constructed during the kth phase, and let $r \in T_k$ be the root of T_k. T_k is partitioned into two subsets, L and R. L is the set of nodes which are in layer $k+1$ and $R = T_k - L$. Notice that L contains only leaves of T_k since ρ ends in phase k.

Every node in the tree induced by $\rho - T_k$ has 0 or 2 children (except the parent of r); hence the number of leaves in $\rho - T_k$ is $\frac{1}{2}(N - |T_k|)$. Additionally, every *leaf* in $(\rho - T_k) \cup L$ has a cut edge to its parent, so the number of cut edges is at least $\frac{1}{2}(N-|L|-|R|) + |L| \geq \frac{1}{2}(N-|R|)$. Therefore, by bounding the size of R we get a lower bound on the number of cut edges. The size of R is at most $\alpha\lceil\frac{N}{P}\rceil$ because it consists of only one color (the color of r). Therefore the number of cut edges is at least $\frac{1}{2}(N-|R|) \geq \frac{1}{2}(N-\alpha\lceil\frac{N}{P}\rceil) \geq \frac{1}{2}(N-\alpha(\frac{N}{P}+1)) \geq \frac{N}{2}(1-\alpha/P) - \frac{\alpha}{2} > \epsilon N$ when $N > \alpha/(1-\frac{\alpha}{P}-2\epsilon)$. □

As mentioned in the previous section, in some tree-structured computations it is important to evenly distribute only the leaves of the tree. We next generalize Lemma 3.2 to get a lower bound on the number of cut edges when only the leaves need to be terminally balanced.

LEMMA 3.3. *For every deterministic algorithm $\mathcal{A}$, $P \geq 2$, $\alpha < P$, and $\epsilon < \frac{1}{2}(1-\frac{\alpha}{2P})$ there exists a growth sequence ρ of length $N > 2\alpha/(1-\frac{\alpha}{P}-2\epsilon)$ such that if the on-line embedding of ρ is terminally α-balanced on the leaves, then the number of cut edges is greater than ϵN.*

Proof. We use the adversarial strategy in Lemma 3.2 to grow a tree with N nodes, $N > 2\alpha/(1-\frac{\alpha}{P}-2\epsilon)$. In order to simplify the calculation, we assume, without loss of generality, that N is even so that there are exactly $N/2$ leaves in the N-node tree.

In the N-node tree grown by the adversary, let S denote the set of leaves which have the same color as their parents. Every leaf that has the same color as its parent must have been spawned in the last phase. Every leaf not in S is connected to its parent by a cut edge so that the number of cut edges is at least $N/2 - |S|$.

Since all leaves in S are grown in the same phase, they have the same color as the root of the subtree that is grown during that phase. In order to satisfy the terminal α-balance requirement on the leaves, the size of S is at most $\alpha\lceil \frac{N}{2P} \rceil$. Hence the number of cut edges is at least $N/2 - |S| \geq N/2 - \alpha(\frac{N}{2P} + 1) \geq N(\frac{1}{2} - \frac{\alpha}{2P}) - \alpha \geq \epsilon N$ when $N > 2\alpha/(1 - \frac{\alpha}{P} - 2\epsilon)$. $\square$

3.3. Lower bounds on network congestion and dilation. The lower bound of Lemma 3.2 on the number of cut edges required by any deterministic algorithm for P processors can be used to derive lower bounds on the worst-case congestion and dilation in different networks. In this section we derive tight lower bounds for multidimensional grids and butterfly networks.

We partition the given P-processor network into B blocks of equal size. We refer to an edge that connects processors in different blocks as a *cross-link*. An α-balanced embedding of an N-node tree assigns at most $\alpha N/B$ tree nodes per block; for convenience we let N be a multiple of P so that all divisions are exact. For any specified α, we choose B such that $\alpha/B < 1$ so that each block in the partition can receive at most a small fraction of the tree nodes.

By Lemma 3.2, in the worst case, $\Omega(N)$ edges of the tree must be cut. If there are C cross-links in the network partition, then some cross-link must accommodate $\Omega(N/C)$ cut edges of the tree, causing congestion $\Omega(N/C)$. Observe that an upper bound on C yields a lower bound on congestion.

By removing the edges in every $\sqrt{P}/B$th column, the P-node two-dimensional grid can be partitioned into B blocks of equal size with $B\sqrt{P}$ cross-links. Consequently, the congestion is $\Omega(N/\sqrt{P})$. For the P-node butterfly $C = O(P/\log P)$ when the edges at every $O((\log P)/B)$th level are removed; therefore, the congestion is $\Omega(\frac{N \log P}{P})$.

It is equally easy to obtain lower bounds on dilation. For a partition of the network into blocks, define the *boundary* of a block to be the set of processors incident to cross-links. Furthermore, let n_d be the number of processors within distance d from the boundary. Observe that in any embedding with dilation d every tree node incident to a cut edge must lie within distance d from a boundary node of some block. Since there are $\Omega(N)$ cut edges in the worst case, the total number of network nodes within distance d of boundary nodes must be large enough to accommodate $\Omega(N)$ tree nodes.

By removing the edges in every $\sqrt{P}/B$th column, the P-node two-dimensional grid can be partitioned into B blocks of equal size so that $n_d = \Theta(d\sqrt{P})$ for each block. From the balance constraint each processor has at most $\alpha\lceil N/P \rceil$ tree nodes. In order to accommodate $\Omega(N)$ tree nodes, it follows that $d = \Omega(\sqrt{P})$. Similarly, by removing the edges at every $O((\log P)/B)$th level, the P-node butterfly can be partitioned so that $n_d = \Theta(dP/\log P)$. It follows that for the butterfly, $d = \Omega(\log P)$.

These lower bounds can be matched by deterministic algorithms, which map tree nodes to processors in a round-robin manner so that the tree nodes are evenly distributed. First, we observe that the lower bound on dilation is already a constant factor of the diameters of the corresponding networks; therefore the dilation upper bounds immediately follow. Next, we choose the route that connects adjacent tree nodes. For the two-dimensional grids the algorithm picks the direct route from a parent tree node to its children that makes at most one turn in the grid. As a result a tree edge whose image goes through a horizontal network link will have at least one endpoint embedded in the same row of processors as the communication link. Since the number of tree nodes embedded into a row of processors is $O(N/\sqrt{P})$ from the balance requirement, we conclude that the congestion on every horizontal link is $O(N/\sqrt{P})$. A similar argument holds for vertical links, and the congestion bound follows. For butterfly networks we use standard off-line routing algorithms to meet the $O(\frac{N \log P}{P})$ congestion bounds.

The lower bounds on congestion and dilation for two-dimensional grids discussed above extend in a straightforward manner to grids with multiple dimensions. We summarize our observations in the following theorem.

THEOREM 3.4. *For every deterministic algorithm $\mathcal{A}$ and constant $\alpha > 1$, there exists a growth sequence ρ of length N (N sufficiently large) such that if the on-line embedding of ρ is terminally α-balanced, then* (1) *on the P-node, k-dimensional grid (constant k) the dilation is $\Omega(P^{1/k})$ and the congestion is $\Omega(N/P^{1-1/k})$, and* (2) *on the P-node butterfly the dilation is $\Omega(\log P)$ and the congestion is $\Omega(\frac{N \log P}{P})$.*

3.4. Infinite growth sequences. In the previous sections we have shown that every deterministic, balanced (either terminally or continuously) algorithm is required to make $\Omega(N)$ cuts on some growth sequences of sufficiently large length N. Turning the question around, one is led to ask if there is a growth sequence which is universally bad in the sense that every balanced algorithm is forced to make linearly many cuts.

As we will see in the next section, for every length-N growth sequence there is an *off-line* algorithm which is continuously α-balanced between two processors for $1 < \alpha < 2$ and requires only $O(\log^2 N)$ cut edges. However, in this section we show the existence of an infinite growth sequence on which every *on-line* continuously balanced algorithm requires, infinitely often, linearly many cut edges. Formally, we establish the following theorem.

THEOREM 3.5. *There exists an infinite growth sequence ϕ^* such that for every overloading factor $1 < \alpha < 2$ every on-line deterministic algorithm $\mathcal{A}$ which produces a continuously α-balanced embedding on two processors will, on infinitely many prefixes $\phi_1, \phi_2, \ldots$ of lengths $N_1, N_2, \ldots$, make at least ϵN_i cuts with $\epsilon = \alpha(2-\alpha)/4(2+\alpha)$.*

Before proceeding to the proof of the above theorem, we explain the idea behind the proof. The infinite sequence is constructed using a standard diagonalization argument that invokes Lemma 3.1 repeatedly. We begin with an enumeration, $(\mathcal{A}_1, \mathcal{A}_2, \ldots)$ of all algorithms as a sequence in which every algorithm appears infinitely often.

The universal growth sequence is constructed in stages. The portion constructed in phase i is denoted ϕ_i, and the entire growth sequence at the end of phase i is denoted $\mathcal{G}_i$ so that $\mathcal{G}_0$ consists of the root of the tree and $\mathcal{G}_i = \mathcal{G}_{i-1} \circ \phi_i$ for $i > 0$ (the symbol $\circ$ denotes concatenation). The idea is to construct ϕ_i such that algorithm $\mathcal{A}_i$ requires linearly many cuts on $\mathcal{G}_i$. Since the number of cuts made by $\mathcal{A}_i$ on the initial prefix $\mathcal{G}_{i-1}$ can be very small, we make ϕ_i large enough so that the number of cut edges forced in ϕ_i is a fraction of the length of $\mathcal{G}_i$. This latter idea is formalized in the following lemma.

LEMMA 3.6. *Suppose that $\mathcal{A}$ is a continuously α-balanced, deterministic algorithm ($\alpha < 2$) and that ϕ is a growth sequence of length n. Then for every $N > 2\alpha n/(2-\alpha)$ there is a growth sequence $\phi \circ \rho$ of length $n + N$ on which $\mathcal{A}$ makes at least $\epsilon(N+n)$ cut edges, where $\epsilon = \alpha(2-\alpha)/4(2+\alpha)$.*

Proof. For ease of exposition, we assume that $N + n$ is even. We use Lemma 3.1 to grow the sequence ρ of length N from a leaf of ϕ. We define layers on the subtree induced by ρ as in Lemma 3.1 and use n_i to denote the number of nodes in layer i of ρ.

We consider two cases: either the embedding of ρ is complete before phase 1 terminates or the embedding is completed during phase k, $k > 1$.

The embedding is complete before phase 1 *terminates.* In this case, every node in the second layer is incident to a cut edge, so the number of cut edges in ρ equals n_2. In order to maintain α-balance, the number of nodes n_2 must be at least $N - \alpha\lceil \frac{N+n}{2} \rceil$. Therefore, the number of cut edges is at least $N - \alpha(\frac{N+n}{2})$. Since $N > 2\alpha n/(2-\alpha)$, we have that $N > 2\alpha(N+n)/(2+\alpha)$ so that the number of cut edges is greater than $\alpha(2-\alpha)(N+n)/2(2+\alpha) = 2\epsilon(N+n)$.

The embedding is complete after phase 1 *terminates.* We further divide the second case into two subcases, depending on whether $\sum_1^{k-1} n_i \geq \epsilon(N+n)$ or $\sum_1^{k-1} n_i < \epsilon(N+n)$.

When $\sum_1^{k-1} n_i \geq \epsilon(N+n)$.

In this subcase, every node in the first $k-1$ layers is an internal node and has two children, so the number of cut edges between layers k and $k-1$ equals $\sum_1^{k-1} n_i + 1$, which exceeds $\epsilon(N+n)$.

When $\sum_1^{k-1} n_i < \epsilon(N+n)$.

In this subcase $n_k + n_{k+1} > N - \epsilon(N+n)$. From the balance condition we have that $n_k \leq \alpha\lceil \frac{N+n}{2} \rceil$ so that $n_{k+1} > N - \epsilon(N+n) - \frac{\alpha}{2}(N+n)$. Using the inequality $N > 2\alpha(N+n)/(2+\alpha)$, it follows that $n_{k+1} > (\frac{2\alpha}{2+\alpha} - \epsilon - \frac{\alpha}{2})(N+n)$, which exceeds $\epsilon(N+n)$. ∎

Proof of Theorem 3.5. Theorem 3.5 follows from applying Lemma 3.6 in the diagonalization argument outlined earlier with $\epsilon = \alpha(2-\alpha)/4(2+\alpha)$. ∎

4. Deterministic algorithm for off-line model.

In the off-line model the entire growth sequence is given in advance. The off-line embedding algorithm can preprocess this sequence to produce a sequence of embeddings. Since bounded-degree trees have small separators, terminal balance is easy to guarantee between two processors. The more interesting case is when the off-line algorithm is required to be continuously balanced.

Our off-line upper bound contrasts sharply with the on-line lower bound. An N-node binary tree can be partitioned into two subsets, each containing at least $\lfloor N/3 \rfloor$ nodes, by removing a single edge. Therefore an embedding algorithm can, by making a single cut edge, guarantee terminal $\frac{4}{3}$ balance between two processors. Of course, this is possible only if each edge has a distinct identity which can be recognized by the algorithm when the child node adjacent to the edge is spawn.

Less trivially, we can show that for every α, every length-N growth sequence can be *continuously* α-balanced between two processors with $O(\log^2 N)$ cuts for any $1 < \alpha < 2$. This is achieved using multicolor bisectors [2].

LEMMA 4.1 (see [2]). *The nodes of every N-node binary tree, each of whose nodes has one of k distinct colors, can be bisected into two equal-size (to within one) subsets by removing at most $k \log N$ edges. Furthermore, for each of the k colors the set of all nodes of the same color are divided equally (to within one) between the two subsets in the bisection.*

The algorithm first partitions the input growth sequence ρ into groups of consecutively spawned nodes. The partition $\{V_i\}$ with V_i of size N_i is determined as follows: The first N_1 nodes in the growth sequence are placed in the first partition V_1. The number N_1 is chosen to be an even number greater than $2/\gamma$, where $\gamma = \frac{2\alpha-2}{2-\alpha}$. The second group V_2 contains the next N_2 nodes; N_2 is chosen to be the largest even number no greater than γN_1. In general, V_i contains N_i tree nodes, where N_i is the largest even number no greater than $\gamma \sum_{j=1}^{i-1} N_j$.

Once the partition is formed, the off-line algorithm applies Lemma 4.1 to the input tree in which every node in V_i has color i. When the tree is processed on-line, edge by edge, the new child is allocated depending on whether the current edge lies in the separator set S. If it does, the child is placed in the remote processor; otherwise, it is placed in the same processor as the parent.

We now show that this algorithm maintains continuous α-balance. We first bound the number of groups in the partition. To this end, define a sequence, $\{M_i\}$, such that $M_1 = N_1$ and $M_i = \gamma \sum_{j=1}^{i-1} M_j$ for all $i \geq 2$.

LEMMA 4.2. *$M_i = \gamma N_1 (1+\gamma)^{i-2}$ for $i \geq 2$.*

Proof. This lemma is proved by induction on i. Since $M_2 = \gamma N_1$, the basis $i = 2$ is established. For the inductive step

$$\begin{aligned} M_{i+1} &= \gamma \sum_{j=1}^{i} M_j \\ &= \gamma \sum_{j=1}^{i-1} M_j + \gamma M_i \\ &= M_i + \gamma M_i \\ &= (1+\gamma) M_i \\ &= \gamma N_1 (1+\gamma)^{i-1}. \qquad \square \end{aligned}$$

Since for every $i \geq 2$, N_i equals the largest even integer no greater than M_i, we can bound each N_i from below as follows.

LEMMA 4.3. *$N_i > M_i - 2(1+\gamma)^{i-2}$ for $i \geq 2$.*

Proof. This lemma is proved by induction on i. Again, $N_2 > M_2 - 2$ by definition, so the basis is established. For the inductive step,

$$\begin{aligned} N_{i+1} &> \gamma \sum_{j=1}^{i} N_j \, - \, 2 \\ &> \gamma \sum_{j=1}^{i} M_j - \gamma \sum_{j=2}^{i} 2(1+\gamma)^{j-2} \, - \, 2 \\ &= \gamma \sum_{j=1}^{i} M_j - 2\gamma \sum_{j=0}^{i-2} (1+\gamma)^j \, - \, 2 \\ &= M_{i+1} - 2(1+\gamma)^{i-1}. \qquad \square \end{aligned}$$

LEMMA 4.4. *The above off-line algorithm partitions any length-N growth sequence into $O(\log N)$ groups and produces $O(\log^2 N)$ cut edges.*

Proof. From Lemmas 4.2 and 4.3, we conclude that $N_i > (\gamma N_1 - 2)(1+\gamma)^{i-2}$ for all $i \geq 2$. With $N_1 > 2/\gamma$, it follows that the sequence $\{N_i\}$ increases exponentially, so the number of groups in the partition is bounded by $O(\log N)$. Since the number of colors is bounded by $O(\log N)$, the resulting bisector S contains $O(\log^2 N)$ edges as seen in Lemma 4.1. $\square$

We formally establish the continuously balancing property for the above off-line algorithm in the following theorem.

THEOREM 4.5. *For every growth sequence ρ of length N and $1 < \alpha < 2$, the off-line algorithm requires at most $O(\log^2 N)$ cut edges and is continuously α-balanced between two processors for all prefixes of ρ of length $M > N_1$ (where N_1 is as defined above).*

Proof. The number of cut edges is bounded in Lemma 4.4. Since exactly half of the tree nodes in every V_i are assigned to each processor, the numbers of nodes in both processors are always equal at the end of every V_i; therefore we need to show only that the algorithm gives a continuously α-balanced embedding while processing every V_i. First, every V_j, $1 \le j \le i-1$, is perfectly balanced, so the number of white nodes equals the number of black nodes just before V_i is processed. Second, the number of white nodes in V_i equals the number of black nodes. Independent of the order in which the white and black nodes within V_i appear, we claim that α-balance is always guaranteed. To see this, consider the extreme case in which all the black nodes appear before the white nodes. The total number of black nodes after half the nodes in V_i appear equals $\frac{1}{2}(\sum_{j=1}^{i-1} N_j) + \frac{1}{2}N_i$. We claim that this is no more than the quantity allowed under α-balance, which equals $\frac{\alpha}{2}(\sum_{j=1}^{i-1} N_j + N_i/2)$. To see this, consider the difference

$$\begin{aligned}
&\frac{\alpha}{2}\left(\sum_{j=1}^{i-1} N_j + N_i/2\right) - \frac{1}{2}\left(\sum_{j=1}^{i-1} N_j\right) - \frac{1}{2}N_i \\
&= \frac{\alpha-1}{2}\sum_{j=1}^{i-1} N_j - \frac{1-\alpha/2}{2}N_i \\
&\ge \frac{\alpha-1}{2}\sum_{j=1}^{i-1} N_j - \frac{2-\alpha}{4}\cdot\frac{2\alpha-2}{2-\alpha}\sum_{j=1}^{i-1} N_j \\
&= 0. \qquad \square
\end{aligned}$$

5. Randomized algorithms.

5.1. *n*-way balancing. The key tool for our randomized algorithms is the *n-way balancing transformation* [4], which evenly distributes a binary tree of size N into a ring of $n = \log N$ processors. The n-way balancing transformation works as follows. A tree node is *distinguished* if it is in level $i \equiv 0 \bmod n/3$. For each distinguished node v we pick a random number $S(v)$ between 0 and $n/3$ as the *stretch count.* The transformation inserts a single dummy node in each edge in the subtree of height $S(v)$ rooted at v. The resulting tree after this transformation is denoted by $B(T)$. Define *level set* i to be the set of all tree nodes in a level congruent to i modulo n. Let the processors of the ring be p_0, p_1,..., p_{n-1} in clockwise order. The algorithm embeds the tree nodes in level set i of $B(T)$ into processor p_i. Figure 5.1 illustrates an example of six-way balancing.

This transformation embeds every sufficiently large binary tree into a ring evenly with high probability and with dilation two, since at most one dummy node will be inserted into each edge in T.

LEMMA 5.1 (see [4]). *With probability $1 - N^{-c}$, $c > 0$, the above $\log N$-way balancing algorithm dynamically embeds every N-node tree into the $\log N$-node ring so that $O(N/\log N)$ tree nodes are mapped to any ring node.*

When the number of processors in the ring is less than $\log N$, we instead map a virtual $\log N$-length ring onto our smaller ring. In particular, with two processors the

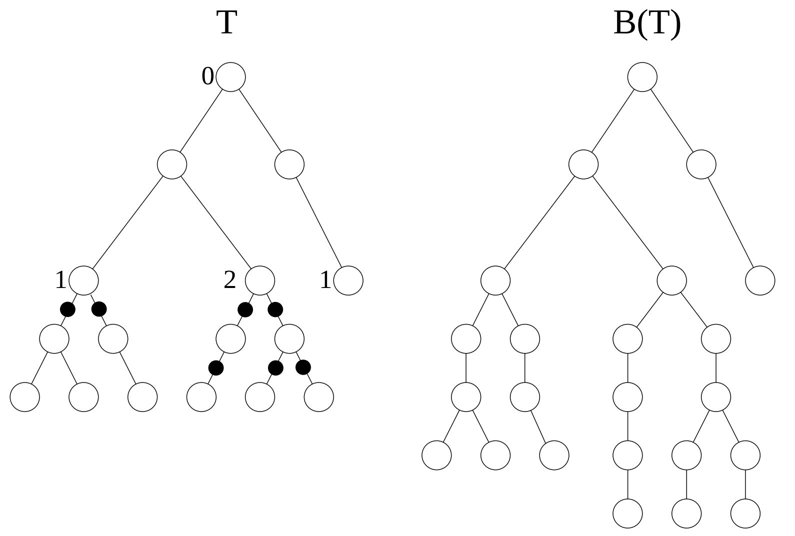

FIG. 5.1. *A 6-way balancing example taken from* [6]. *The solid circles indicate where the dummy nodes will be inserted, and the numbers next to the distinguished nodes are the stretch counts.*

first half of the virtual ring is mapped to one node and the second half to the other. Since the dilation of the mapping on the virtual ring is two, only the eight nodes of the virtual ring within distance two of the breaks contribute to the cut edges. Since these eight nodes contain at most $O(N/\log N)$ tree nodes, the number of cut edges is bounded by $O(N/\log N)$.

When the number of processors in the ring exceeds $\log N$, we divide the ring into $\log N$ groups, each containing an equal number of consecutive processors. We use $\log N$-way balancing to assign tree nodes to groups, and a deterministic strategy is used within each group to distribute nodes evenly in a group. For the P-node ring, the dilation is bounded by $O(P/\log N)$ because each tree edge traverses at most three groups. The bound on dilation is optimal; any mapping of the N-node complete binary tree on the P-node ring requires dilation $\Omega(P/\log N)$. From the dilation result, for any link l in the ring, only those processors that are within distance $O(P/\log N)$ can contribute congestion on l. Each processor can have at most $O(N/P)$ tree nodes in a balanced embedding, and each tree node has at most three edges; therefore, the congestion is $O(N/\log N)$ for any link in the ring. The congestion is a factor of $\log N$ less than the worst-case lower bound for deterministic on-line algorithms and matches the lower bound, shown in section 6, on the expected value of the congestion for any randomized algorithms.

5.2. Cut-edges reduction. Suppose that we wish to equitably allocate the tree nodes on-line among P processors with the goal of minimizing the total number of cut edges. When P is any fixed constant, the strategy mentioned above uses $O(N/\log N)$ cuts. However, when P is $\log N$, each of the $N-1$ edges is cut. By modifying the $\log N$-way balancing technique slightly, we can reduce the total number of cuts to $O(N/\log \frac{N}{P})$. As we will see in the next section, this bound is the best possible.

We modify the algorithm so that we choose ϵ so $1 > \epsilon > 0$, and for each node in every $\epsilon \log \frac{N}{P}$th level set of the transformed tree, we map it to a processor chosen uniformly at random among the P processors. We call these nodes *leaders*. Those nodes not in these level sets are embedded into the processor where their parents are embedded. We show that with high probability this algorithm gives balanced embedding and optimal number of cut edges when $P = O(N/\log^{\frac{1}{1-\epsilon}} N)$.

We need the following lemma [4], which states that with high probability the sum of independent random variables is at most a constant times their expected sum.

LEMMA 5.2 (see [4]). *Let $x_1, \dots, x_m$ be independent random variables in the range from 0 to V with $E(x_i) = \mu_i$. Let $X = \sum x_i$, and let $\mu = \sum_{i=1}^m \mu_i = E(X)$. Then for any constant β, $Pr(X \geq \beta\mu) \leq \exp(-\beta\frac{\mu}{V})$.*

THEOREM 5.3. *With probability $1 - N^{-c}$, $c > 0$, the above algorithm dynamically embeds every N-node binary tree into P processors, where $P = O(N/\log^{\frac{1}{1-\epsilon}} N)$ so that $O(N/P)$ tree nodes are mapped to any processor and the number of cut edges is $O(N/\log\frac{N}{P})$.*

Proof. First we estimate the number of cut edges. Since only edges at every $\epsilon\log\frac{N}{P}$th level of $B(T)$ are cut, from Lemma 5.1 the total number of cut edges is $O(N/\log\frac{N}{P})$. This bound matches the lower bound on the expected number of cut edges, as we will see in the next section.

Let $l = \epsilon\log\frac{N}{P}$. The transformed tree is divided into m subtrees, $t_1, \dots, t_m$, by cutting the edges between levels $k\,l$ and $k\,l-1$ (for any integral k). Each t_i is rooted at a leader, and every node in t_i will follow this leader to a processor. Let M_i be the number of nodes in t_i and $x_{i,p}$ be the number of tree nodes in t_i that will be mapped into a particular processor p. We denote the total number of tree nodes assigned to p by $X_p = \sum_{i=1}^m x_{i,p}$.

The contributions from each subtree to any processor are independent and occur with equal probability. Therefore for all i, $1 \leq i \leq m$, $E(x_{i,p}) = M_i/P$ and $E(X_p) = N/P$. Moreover, all $x_{i,p}$'s are mutually independent, and since each tree contains at most the number of nodes in a complete binary tree of height $\epsilon\log\frac{N}{P}$, all $x_{i,p} \leq 2^{\epsilon\log\frac{N}{P}} = \frac{N}{P}^{\epsilon}$. Applying Lemma 5.2 we get

$$\begin{aligned} Pr\left(X \geq \alpha\frac{N}{P}\right) &= Pr(X \geq \alpha E(X)) \\ &\leq \exp\left(-\alpha\frac{(\frac{N}{P})}{(\frac{N}{P})^{\epsilon}}\right) \\ &= \exp\left(-\alpha(\frac{N}{P})^{1-\epsilon}\right) \\ &\leq \exp(-c'(\log^{\frac{1}{1-\epsilon}} N)^{1-\epsilon}) \\ &< N^{-c'}. \end{aligned}$$

With probability $1 - PN^{-c'} \geq 1 - N^{-c}$, every processor receives $O(N/P)$ tree nodes when $P = O(N/\log^{\frac{1}{1-\epsilon}} N)$. For larger values of P, the same bound is achievable, but the algorithm becomes more complicated and requires global information. ◻

5.3. Two-dimensional grids. Any embedding of the N-node complete binary tree in the P-node two-dimensional grid with at most $O(N/P)$ tree nodes per grid node requires dilation $\Omega(\sqrt{P}/\log N)$ [7]. This follows from the fact that in any such embedding, some pair of tree nodes must be mapped distance $\Omega(\sqrt{P})$ apart, while the distance in the tree between the two nodes is $O(\log N)$. This lower bound on dilation is tight for off-line embeddings. In the previous section we saw that every on-line deterministic algorithm that balances the load requires dilation $\Omega(\sqrt{P})$ in the worst case. In this section we present a randomized algorithm which achieves the $O(\sqrt{P}/\log N)$ bound.

We shall see in section 6 that the expected value of the congestion is $\Omega(\frac{N}{\sqrt{P}\log N})$. The randomized algorithm presented here will meet this bound.

5.3.1. Randomized algorithm for two-dimensional torus. For convenience, we work with the two-dimensional torus instead of the grid. Since the two-dimensional torus can be embedded efficiently within the grid, our bounds for the torus are tight to within a constant factor for the grid.

Our randomized algorithm for the torus extends the previous algorithm for rings. We partition the P-node torus into $\log^2 N$ square blocks, each of size $\frac{\sqrt{P}}{\log N}$ by $\frac{\sqrt{P}}{\log N}$. The block in row i and column j is denoted by B_{ij}. We use the $(\log N)$-way balancing transformation twice, independently for each dimension, to obtain two trees, T_r and T_c. The random stretch counts in the two trees are chosen independently. Every node that is in level set i of T_r and level set j of T_c is mapped to B_{ij}. Within a block the tree nodes are distributed evenly in a deterministic manner.

LEMMA 5.4. *With probability $1 - N^{-c}$, $c > 0$, the above algorithm dynamically embeds every N-node tree T in the $\sqrt{P} \times \sqrt{P}$ grid so that each block column receives $O(\frac{N}{\log N})$ tree nodes.*

Proof. The proof of this lemma results directly from Lemma 5.1. □

After knowing that each column receives $O(N/\log N)$ nodes, we show that within a column, the distribution to a particular block is the sum of many mutually independent random variables. Then by using Lemma 5.2 we can show that the algorithm distributes nodes evenly among the blocks in a column.

LEMMA 5.5. *Given that each column receives $O(N/\log N)$ tree nodes with probability $1 - N^{-c}$, $c > 0$, the above algorithm dynamically embeds every N-node tree T in the $\sqrt{P} \times \sqrt{P}$ grid so that each block receives $O(\frac{N}{\log^2 N})$ tree nodes.*

Proof. The analysis and terminology follows the analysis and terminology in [4] quite closely.

We will examine how tree nodes are distributed among the blocks in one column. Let column i be the block column with the largest number of tree nodes, let I be the set of nodes from T that are in block column i, and call any node in I an i-node. Note that all the i-nodes are in the level set i of T_c.

Recall that $n = \log N$. Tree T is divided into three zones. Zone 0 contains nodes that are in level sets 0 through $n/3-1$, zone 1 contains level sets $n/3$ through $2n/3-1$, and zone 3 contains the rest. Define the *triple* for the ith level set as the level sets i, $i + n/3$, and $i + 2n/3$.

Zone 1 of T is naturally partitioned into a set of forests $f_1, \dots, f_m$. Each forest consists of all the trees in zone 1 that have the same nearest common ancestors at level set 0 (that is the top of zone 0). Let these ancestors be $r_1, \dots, r_m$, respectively. For each forest f_j, $1 \le j \le m$, let M_j be the number of i-nodes in f_j and $x_{j,q}$ be the number of i-nodes that are mapped into the triple of level set q.

We want to show that I is evenly distributed among all the level sets of T_r. Since the number of nodes in any level set is bounded by the number of nodes in its triple, it suffices to show that with high probability any triple receives at most $O(\frac{N}{\log^2 N})$ tree nodes from I.

We show that the distribution from I to the triple of an arbitrary level set q is the sum of many mutually independent random variables. The tree nodes assigned to level set triple q have contributions from each forest. We claim that the size of these contributions, $x_{j,q}$, are mutually independent over the forests. The value of $x_{j,q}$ is defined entirely by the level of the roots of the f_j and by the stretch counts chosen there, which are independent by definition. The level of the roots of f_j depends on the level of r_j and on the stretch count chosen there. Since the stretch counts are independent, the level of the roots and thus the values of $x_{j,q}$ for any q are independent.

Now we can apply Lemma 5.2 by noting that each $x_{j,q}$ is less than $2^{\frac{2}{3}n}$ and that $E(x_{j,q}) = \frac{3M_j}{\log N}$. Let $X_q = \sum_{j=1}^{m} x_{j,q}$. Applying the lemma yields

$$\begin{aligned} Pr\left(X_q \geq \beta \frac{N}{\log^2 N}\right) &\leq \exp\left(-\frac{\beta N}{2^{\frac{2}{3}n}\log^2 N}\right) \\ &\leq \exp\left(-\frac{\beta N^{\frac{1}{3}}}{\log^2 N}\right) \\ &\leq N^{-c'}. \end{aligned}$$

A similar argument is valid for zones 0 and 2, so with probability greater than $1-3N^{-c'}$ the number of i-nodes coming from all zones to level set triple q is $O(\frac{N}{\log^2 N})$. Therefore with probability greater than $1-3nN^{-c'}$ every block in column i receives $O(\frac{N}{\log^2 N})$ nodes. And with probability greater than $1-3n^2N^{-c'} > 1-N^{-c}$ every block in the tori receives $O(\frac{N}{\log^2 N})$ nodes. □

THEOREM 5.6. *With probability* $1-N^{-c}$, $c>0$, *the above algorithm dynamically embeds every* N*-node tree* T *in the* $\sqrt{P}\times\sqrt{P}$ *grid so that each grid node receives* $O(N/P)$ *tree nodes and such that the dilation is* $O(\frac{\sqrt{P}}{\log N})$ *and the congestion is* $O(\frac{N}{\sqrt{P}\log N})$.

Proof. By Lemma 5.5 each block will receive $O(\frac{N}{\log^2 N})$ tree nodes with high probability. Since the choices of processor among one block are completely even, each processor receives $O(N/P)$ tree nodes with high probability.

The image of a tree edge can traverse at most three blocks in each dimension; therefore the dilation is bounded by $6\frac{\sqrt{P}}{\log N}$. The tree edges are mapped to the shortest path in the network with at most one turn. Denote the processor in row i and column j by $P_{i,j}$. Without loss of generality, consider a horizontal communication link ℓ between $P_{i,j}$ and $P_{i,j+1}$. From the dilation bound, at least one endpoint of every tree edge whose image traverses ℓ must lie within the interval $P_{i,j-3\sqrt{P}/\log N}$ through $P_{i,j+3\sqrt{P}/\log N}$. Since each grid node has $O(N/P)$ tree nodes and each tree node has at most degree 3, the total number of tree edges that can possibly go through ℓ is bounded by $O(\frac{N}{\sqrt{P}\log N})$. □

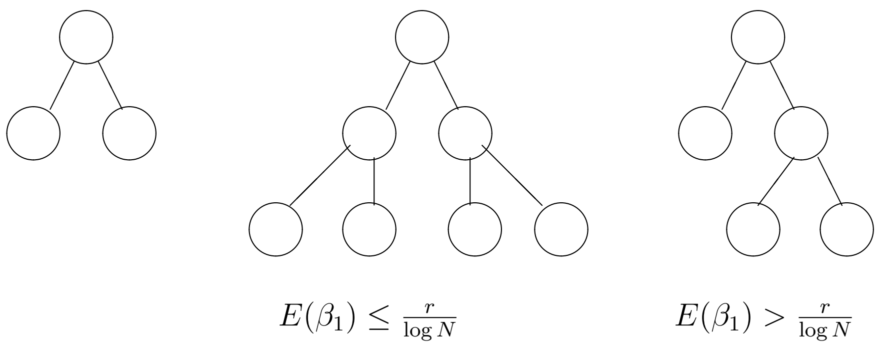
The technique for two-dimensional grids can be easily extended to grids with multiple dimensions. In particular, for P-node grids with a fixed number k of dimensions, the bounds on dilation and congestion are $O(P^{1/k}/\log N)$ and $O(\frac{N}{P^{1-1/k}\log N})$, respectively.

THEOREM 5.7. *With probability* $1-N^{-c}$, $c>0$, *the generalization of the above algorithm (which divides the grid into* $\log N$ *blocks along each dimension) dynamically embeds every* N*-node tree* T *in the* $P^{1/k}\times\cdots\times P^{1/k}$ k*-dimensional grid (constant* k*) so that each grid node receives* $O(N/P)$ *tree nodes and such that the dilation is* $O(P^{1/k}/\log N)$ *and the congestion is* $O(\frac{N}{P^{1-1/k}\log N})$.

6. Randomized lower bound. We again consider the two-processor model for our randomized lower bound. Let $\mathcal{A}$ be any probabilistic on-line algorithm which is α-balanced, $1 \leq \alpha < 2$. For an N-node tree the algorithm guarantees that there are at most $\alpha\lceil \frac{N}{2} \rceil$ nodes in either processor. In what follows we show how to construct an N-node binary tree $\mathcal{T}_{\mathcal{A}}$ such that the expected number of cut edges created by $\mathcal{A}$ for $\mathcal{T}_{\mathcal{A}}$ is at least $(1-\alpha/2)^2 N/18 \log N$. As a consequence, we can conclude that any balanced on-line tree embedding algorithm can be expected to make $\Omega(N/\log N)$ cuts on the worst-case tree.

THEOREM 6.1. *For every algorithm $\mathcal{A}$ and $\alpha > 1$, there exists a growth sequence ρ of length N such that if the on-line embedding of ρ is terminally α-balanced between two processors, then the expected number of cut edges is $\Omega(N/\log N)$.*

Proof. The worst-case tree consists of a sequence of complete binary trees that are grown as follows. We start with the depth-1 complete binary tree with three nodes. Let β_i be the random variable denoting the fraction of edges in the ith level that are cut edges and $r = \frac{1}{3}(1-\alpha/2)$. If $E(\beta_1) \leq r/\log N$, then we grow the tree one more level to form the depth-2 complete binary tree with seven nodes. On the other hand, if $E(\beta_1) > r/\log N$, then we start a new complete binary tree at the rightmost leaf of the current complete binary tree. See Figure 6.1 for an example.



$E(\beta_1) \leq \frac{r}{\log N}$
$E(\beta_1) > \frac{r}{\log N}$

FIG. 6.1. *Tree growth examples.*

In general, we continue growing $\mathcal{T}_{\mathcal{A}}$ using the same rule. If $E(\beta_i) \leq r/\log N$, then we grow $\mathcal{T}_{\mathcal{A}}$ by attaching two leaves to every level-i node. If $E(\beta_i) > r/\log N$, then we grow $\mathcal{T}_{\mathcal{A}}$ by attaching two leaves to just the rightmost level-i node. In other words, we extend the current binary subtree by one level in the former case, and we start a new binary subtree in the latter case. The procedure stops when we have grown N nodes. Figure 6.2 illustrates one possible choice for a 32-node tree. Note that every level (except possibly the last) contains 2^a nodes, where $a \geq 0$.

For the purposes of our discussion, it is useful to consider $\mathcal{T}_{\mathcal{A}}$ as a collection of complete binary subtrees $\{T_i\}$. In particular, we define T_i to be the ith maximal complete binary subtree formed during the construction of $\mathcal{T}_{\mathcal{A}}$. We denote the last subtree formed as T_m. The last level of T_m may be partially empty. We also define n_i to be the number of nodes in T_i less the rightmost leaf for $i < m$ since this node forms the root of the next tree.

Let C be the random variable denoting the number of cut edges created by $\mathcal{A}$ on $\mathcal{T}_{\mathcal{A}}$. In what follows we show that $E(C) \geq (1-\alpha/2)^2 N/18 \log N$ when $N = 2^n$. The proof is divided into two cases, depending on the value of $\sum_{i=1}^{m-1} n_i$.

Case 1. $\sum_{i=1}^{m-1} n_i \geq rN$, where $r = \frac{1}{3}(1-\alpha/2)$.

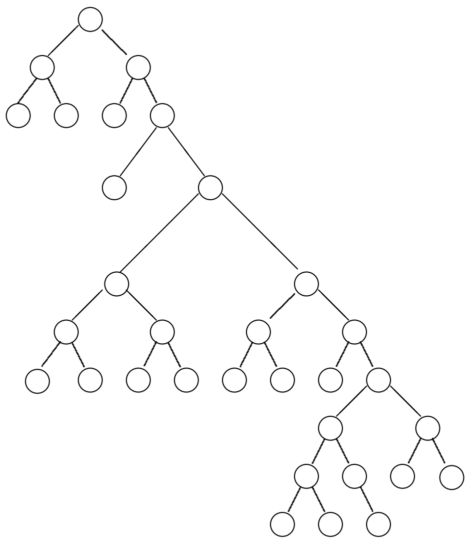


FIG. 6.2. *A 32-node example.*

Let x_i be the random variable denoting the number of cut edges in the last level of T_i, $1 \le i \le m-1$. The last level of T_i has $\frac{1}{2}n_i$ edges and expected fraction of cut edges greater than $r/\log N$, therefore $E(x_i) \ge \frac{1}{2}n_i r/\log N$. Hence,

$$\begin{aligned} E(C) &\ge \sum_{i=1}^{m-1} E(x_i) \\ &> \sum_{i=1}^{m-1} \frac{1}{2} n_i r/\log N \\ &= \frac{1}{2} rN(r/\log N) \\ &= (1-\alpha/2)^2 N/18\log N. \end{aligned}$$

Case 2. $\sum_{i=1}^{m-1} n_i < rN$.

Since $\sum_{i=1}^{m-1} n_i < (1-\alpha/2)N/3$, we know that $n_m > N - (1-\alpha/2)N/3 = (4+\alpha)N/6$ and the number of levels in T_m is $\log N - 1$. Let σ_j be the random variable denoting the fraction of cut edges at level j of T_m for $1 \le j \le \log N - 2$. By assumption, $E(\sigma_j) \le r/\log N$. Also, let s_j be the random variable denoting the number of nodes on level j that remains connected to the root of T_m if all the cut edges are cut. Then $s_0 = 1$ and $s_j \ge 2s_{j-1} - \sigma_j 2^j$ for $1 \le j \le \log N - 2$. Solving the recurrence for s_j, we find that $s_j \ge 2^j(1 - \sum_{i=1}^{j} \sigma_i)$ for $1 \le j \le \log N - 2$.

Since $r < 1/6$, T_m is a complete binary tree with at most $1/6N$ nodes not in the last level. Therefore $s_{\log N - 1} \ge 2s_{\log N-2} - Y - rN$, where Y is the random variable denoting the number of cut edges on the last level of T_m. Let R be the random variable denoting the number of nodes in T_m that are still connected to the root of T_m when all the cut edges are cut.

$$\begin{aligned}
R &\geq \sum_{j=0}^{\log N-1} s_j \\
&\geq \left(\sum_{j=0}^{\log N-2} 2^j \left(1 - \sum_{i=1}^{\log N-2} \sigma_i \right) \right) + s_{\log N-1} \\
&\geq \left(\sum_{j=0}^{\log N-2} 2^j \left(1 - \sum_{i=1}^{\log N-2} \sigma_i \right) \right) + 2s_{\log N-2} - Y - rN \\
&\geq \left(\sum_{j=0}^{\log N-1} 2^j \left(1 - \sum_{i=1}^{\log N-2} \sigma_i \right) \right) - Y - rN \\
&= (N-1) \left(1 - \sum_{i=1}^{\log N-2} \sigma_i \right) - Y - rN.
\end{aligned}$$

Since the largest component of $\mathcal{T}_\mathcal{A}$ can have size at most $\alpha N/2$ once the cut edges have been removed, we know that $R \leq \alpha N/2$. Thus we have that

$$Y \geq (N-1) \left(1 - \sum_{j=1}^{\log N-2} \sigma_j \right) - rN - \alpha N/2.$$

By definition, $C \geq Y$, and therefore

$$\begin{aligned}
E(C) &\geq E(Y) \\
&\geq (N-1)(1-(\log N - 2)r/\log N) - rN - \alpha N/2 \\
&= (1 - r + 2r/\log N)(N-1) - rN - \alpha N/2 \\
&\geq (1 - r - r - \alpha/2)N - 1 \\
&= 1/3(1-\alpha/2)N - 1.
\end{aligned}$$

This concludes the proof that $\mathcal{A}$ is expected to create at least $\frac{(1-\alpha/2)^2 N}{18 \log N}$ cut edges when embedding $\mathcal{T}_\mathcal{A}$ on-line among two processors. □

The preceding result can be generalized to show that for any on-line randomized algorithm for partitioning an N-node binary tree into components of size at most $O(N/P)$, the expected number of cuts is at least $\Omega(N/\log \frac{N}{P})$ in the worst case.

THEOREM 6.2. *For every algorithm $\mathcal{A}$ and $\alpha > 1$, there exists a growth sequence ρ of length N such that if the on-line embedding of ρ is terminally α-balanced among P processors, then the expected number of cut edges is $\Omega(N/\log \frac{N}{P})$.*

Proof. The proof is nearly identical to that above, except that we use a threshold of $\Theta(1/\log \frac{N}{P})$ instead of $\Theta(1/\log N)$ when deciding whether to start a new complete binary tree at each level of $\mathcal{T}_\mathcal{A}$. From Theorem 5.3 this bound is tight, up to constant factors, for all P, $2 \leq P < 2N$. □

7. Conclusion. The execution of divide-and-conquer type algorithms on multicomputers requires a simple strategy for distributing the subprocesses as they are created. Ideally, the distribution would give a balanced load and not require large communication overhead. We have shown that on grid and butterfly networks the worst-case dilation of any deterministic balanced algorithm is as large as the diameter of these networks.

Allowing randomization yields some improvement. Both the dilation and the congestion can be improved by a factor of $\log N$. As shown in [4] this reduces the dilation for the butterfly to a constant. We have also shown that the dilation and expected worst-case congestion for meshes cannot be improved by more than a logarithmic factor.

These large overheads for grids leads to the question of whether there are algorithms with better performance for the kinds of trees that arise in practice.

Acknowledgment. The authors thank Jin-Yi Cai for helpful discussions.

A RANDOMIZED FULLY POLYNOMIAL TIME APPROXIMATION SCHEME FOR THE ALL-TERMINAL NETWORK RELIABILITY PROBLEM*

DAVID R. KARGER†

Abstract. The classic all-terminal network reliability problem posits a graph, each of whose edges fails independently with some given probability. The goal is to determine the probability that the network becomes disconnected due to edge failures. This problem has obvious applications in the design of communication networks. Since the problem is $\sharp\mathcal{P}$-complete and thus believed hard to solve exactly, a great deal of research has been devoted to *estimating* the failure probability. In this paper, we give a *fully polynomial randomized approximation scheme* that, given any n-vertex graph with specified failure probabilities, computes in time polynomial in n and $1/\epsilon$ an estimate for the failure probability that is accurate to within a relative error of $1 \pm \epsilon$ with high probability. We also give a deterministic polynomial approximation scheme for the case of small failure probabilities. Some extensions to evaluating probabilities of k-connectivity, strong connectivity in directed Eulerian graphs and r-way disconnection, and to evaluating the Tutte polynomial are also described.

Key words. network reliability, approximation scheme, minimum cut

1. Introduction.

1.1. The problem.

We consider a classic problem in reliability theory: given a network on n vertices, each of whose m links is assumed to fail (disappear) independently with some probability, determine the probability that the surviving network is connected. The practical applications of this question to communication networks are obvious, and the problem has therefore been the subject of a great deal of study. A comprehensive survey can be found in [4].

Formally, a network is modeled as a graph G, each of whose edges e is presumed to fail (disappear) with some probability p_e and thus to survive with probability $q_e = 1 - p_e$. Network reliability problems are concerned with determining the probabilities of certain connectivity-related events in this network. The most basic question of *all-terminal network reliability* is determining the probability that the network stays connected. Others include determining the probability that two particular nodes stay connected (two-terminal reliability), and so on.

Most such problems, including the two just mentioned, are $\sharp\mathcal{P}$-complete [25, 24]. That is, they are universal for a complexity class at least as intractable as $\mathcal{NP}$ and therefore seem unlikely to have polynomial time solutions. Attention therefore turned to approximation algorithms. Provan and Ball [24] proved that it is $\sharp\mathcal{P}$-complete even to *approximate* the reliability of a network to within a relative error of ϵ. However, they posited that the approximation parameter ϵ is part of the input, and used an exponentially small ϵ (which can be represented in $O(n)$ input bits) to prove their claim. They note at the end of their article that "a seemingly more difficult unsolved

†MIT Laboratory for Computer Science, Massachusetts Institute of Technology, Room NE43-321, Cambridge, MA 02138 (karger@lcs.mit.edu). Parts of this work were done at AT&T Bell Laboratories.

problem involves the case where ϵ is constant, i.e., is not allowed to vary as part of the input list."

Their idea is formalized in the definition of a *polynomial approximation scheme (PAS)*. In this definition, the performance measure is the running time of the approximation algorithm as a function of the problem size n and the error parameter ϵ, and the goal is for a running time that is polynomial in n for each fixed ϵ (e.g., $2^{1/\epsilon}n$). If the running time is also polynomial in $1/\epsilon$, the algorithm is called a *fully polynomial approximation scheme (FPAS)*. An alternative interpretation of an FPAS is that it has a running time polynomial in the input size when ϵ is constrained to be input in unary rather than binary notation. When randomization is used in an approximation scheme, we refer to a *polynomial randomized approximation scheme (PRAS)* or *fully polynomial randomized approximation scheme (FPRAS)*. Such algorithms are required to provide an ϵ-approximation with probability at least 3/4; this probability of success can be increased significantly (e.g., to $1-1/n$ or even $1-1/2^n$) by repeating the algorithm a small number of times [23].

Deterministic FPASs for nontrivial problems seem to be quite rare. However, FPRASs have been given for several $\sharp\mathcal{P}$-complete problems such as counting maximum matchings in dense graphs [7], measuring the volume of a convex polytope [6], and *disjunctive normal form (DNF) counting*—estimating the probability that a given DNF formula evaluates to true if the variables are made true or false at random [18]. In a plenary talk, Kannan [8] raised the problem of network reliability as one of the foremost remaining open problems needing an approximation scheme.

1.2. Our results. In this paper, we provide an FPRAS for the all-terminal network reliability problem. Given a failure probability p for the edges, our algorithm, in time polynomial in n and $1/\epsilon$, returns a number P that estimates the probability FAIL(p) that the graph becomes disconnected. With high probability,[1] P is in the range $(1\pm\epsilon)$FAIL(p). The algorithm is Monte Carlo, meaning that the approximation is correct with high probability but that it is not possible to verify its correctness. It generalizes to the case where the edge failure probabilities are different, to computing the probability the graph is not k-connected (for any fixed k), and to the more general problem of approximating the Tutte polynomial for a large family of graphs. It can also estimate the probability that a Eulerian *directed* graph remains strongly connected under edge failures. Our algorithm is easy to implement and appears likely to have satisfactory time bounds in practice [3, 16].

Some care must be taken with the notion of approximation because approximations are measured by *relative* error. We therefore get different results depending on whether we discuss the failure probability FAIL(p) or the reliability (probability of remaining connected) REL(p) = 1 − FAIL(p). Consider a graph with a very low failure probability, say ϵ. In such a graph, approximating REL(p) by 1 gives a $(1+\epsilon)$-approximation to the reliability, but approximating the failure probability by 0 gives a very poor (infinite) approximation ratio for FAIL(p). Thus, the failure probability is the harder quantity to approximate well. On the other hand, in a very unreliable graph, FAIL(p) becomes easy to approximate (by 1) while REL(p) becomes the challenging quantity. Our algorithm is an FPRAS for FAIL(p). This means that in extremely unreliable graphs, it cannot approximate REL(p). However, it does solve the harder approximation problem on reliable graphs, which are clearly the ones likely to be encountered in practice.

[1]The phrase *with high probability* means that the probability that it does not happen can be made $O(n^{-d})$ for any desired constant d by suitable choice of other constants (typically hidden in the asymptotic notation).

The basic approach of our FPRAS is to consider two cases. When FAIL(p) is large, it can be estimated via direct Monte Carlo simulation of random edge failures. We thus focus on the case of small FAIL(p). Note that a graph becomes disconnected when all edges in some cut fail (a *cut* is a partition of the vertices into two groups; its edges are the ones with one endpoint in each group). The more edges cross a cut, the less likely it is that they will all fail simultaneously. We show that for small FAIL(p), only the smallest graph cuts have any significant chance of failing. We show that there is only a polynomial number of such cuts, and that they can be enumerated in polynomial time. We then use a *DNF counting* algorithm [17] to estimate the probability that one of these explicitly enumerated cuts fails, and take this estimate as an estimate of the overall graph failure probability.

After presenting our basic FPRAS for FAIL(p) in section 2, we present several extensions of it, all relying on our observation regarding the number of small cuts a graph can have. In section 3, we give FPRASs for the network failure probability when every edge has a different failure probability, for the probability that an Eulerian directed graph fails to be strongly connected under random edge failures, and for the probability that two particular "weakly connected" vertices are disconnected by random edge failures. In section 4, we give an FPRAS for the probability that a graph partitions into more than r pieces for any fixed r. In section 5, we give two deterministic algorithms for all-terminal reliability: a simple heuristic that provably gives good approximations on certain inputs and a deterministic PAS that applies to a somewhat broader class of problems. In section 6, we show that our techniques give an FPRAS for the Tutte polynomial on almost all graphs.

1.3. Related work. Previous work gave algorithms for estimating FAIL(p) in certain special cases. Karp and Luby [18] showed how to estimate FAIL(p) in n-vertex planar graphs when the expected number of edge failures is $O(\log n)$. Alon, Frieze, and Welsh [1] showed how to estimate it when the input graph is sufficiently dense (with minimum degree $\Omega(n)$). Other special case solutions are discussed in Colbourn's survey [4]. Lomonosov [21] independently derived some of the results presented here.

A crucial step in our algorithm is the enumeration of minimum and near-minimum cuts. Dinitz et al. [5] showed how to enumerate (and represent) all minimum cuts. Vazirani and Yannakakis [26] showed how to enumerate near-minimum cuts. Karger and Stein [15] gave faster cut enumeration algorithms as well as bounds on the number of cuts that we will use heavily.

A preliminary version of this work appeared in [10]. The author's thesis [9] discusses reliability estimation in the context of a general approach to random sampling in optimization problems involving cuts. In particular, this reliability work relies on some new theorems bounding the number of small cuts in graphs; these theorems have led to other results on applications of random sampling to graph optimization problems [12, 11, 2].

2. The basic FPRAS. In this section, we present an FPRAS for FAIL(p). We use two methods, depending on the value of FAIL(p).

When FAIL(p) is large, we estimate it in polynomial time by direct Monte Carlo simulation of edge failures. That is, we randomly fail edges and check whether the graph remains connected. Since FAIL(p) is large, a small number of simulations (roughly 1/FAIL(p)) gives enough data to estimate it well.

When FAIL(p) is small, we resort to *cut enumeration* to estimate it. Observe that a graph becomes disconnected precisely when all of the edges in some cut of the graph fail. By a *cut* we mean a partition of the graph vertices into two groups. The *cut edges* are those with one endpoint in each group (we also refer to these edges as the ones *crossing* the cut). The *value* of the cut is the number of edges crossing the cut.

We show that when $\mathrm{FAIL}(p)$ is small, only cuts of small value in G have any significant chance of failing. We observe that there is only a polynomial number of such cuts and that they can be found in polynomial time. We therefore estimate $\mathrm{FAIL}(p)$ by enumerating the polynomial-size set of small cuts of G and then estimating the probability that one of them fails.

If each edge fails with probability p, then the probability that a k-edge cut fails is p^k. Thus, the smaller a cut, the more likely it is to fail. It is therefore natural to focus attention on the small graph cuts. Throughout this paper, we assume that our graph has *minimum cut* value c—that is, that the smallest cut in the graph has exactly c edges. Such a graph has a probability of at least p^c of becoming disconnected—namely, if the minimum cut fails.

FACT 2.1. *If each edge of a graph with minimum cut c fails independently with probability p, then the probability that the graph becomes disconnected is at least p^c.*

Clearly, the probability that a cut fails decreases exponentially with the number of edges in the cut. This would suggest that a graph is most likely to fail at its small cuts. We formalize this intuition.

DEFINITION 2.2. *An* α-minimum cut *is a cut with value at most α times the minimum cut value.*

Below, we show how to choose between the two approaches just discussed. If $\mathrm{FAIL}(p) \geq p^c \geq n^{-4}$ then, as we show in subsection 2.1, we can estimate it via Monte Carlo simulation. This works because $\tilde{O}(1/\mathrm{FAIL}(p)) = \tilde{O}(n^4)$ experiments give us enough data to deduce a good estimate ($\tilde{O}(f)$ denotes $O(f \log n)$). On the other hand, when $p^c < n^{-4}$, we know that a given α-minimum cut fails with probability $p^{\alpha c} = n^{-4\alpha}$. We show in subsection 2.2 that there are at most $n^{2\alpha}$ α-minimum cuts. It follows that the probability that *any* α-minimum cut fails is less than $n^{-2\alpha}$—that is, exponentially decreasing with α. Thus, for a relatively small α, the probability that a greater than α-minimum cut fails is negligible. Thus (as we show in subsection 2.3) we can approximate $\mathrm{FAIL}(p)$ by approximating the probability that some less than α-minimum cut fails. Our FPRAS (in subsection 2.4) is based on enumerating these small cuts and determining the probability that one of them fails.

2.1. Monte Carlo simulation.

The most obvious way to estimate $\mathrm{FAIL}(p)$ is through Monte Carlo simulations. Given the failure probability p for each edge, we can "simulate" edge failures by flipping an appropriately biased random coin for each edge. We can then test whether the resulting network is connected. If we do this many times, then the fraction of trials in which the network becomes disconnected should intuitively provide a good estimate of $\mathrm{FAIL}(p)$. Karp and Luby [18] investigated this idea formally, and observed (a generalization of) the following.

THEOREM 2.3. *Performing $O((\log n)/(\epsilon^2 \mathrm{FAIL}(p)))$ trials will give an estimate for $\mathrm{FAIL}(p)$ accurate to within $1 \pm \epsilon$ with high probability.*

COROLLARY 2.4. *If $\mathrm{FAIL}(p) \geq p^c \geq n^{-4}$, then $\mathrm{FAIL}(p)$ can be estimated to within $(1+\epsilon)$ in $\tilde{O}(mn^4/\epsilon^2)$ time using Monte Carlo simulation.*

The criterion that $\mathrm{FAIL}(p)$ not be too small can of course be replaced by a condition that implies it. For example, Alon, Frieze, and Welsh [1] showed that for any *constant* p, there is an FPRAS for network reliability in *dense* graphs (those with minimum degree $\Omega(n)$). The reason is that as n grows and p remains constant, $\mathrm{FAIL}(p)$ is bounded below by a constant on dense graphs and can therefore be estimated in $\tilde{O}(n^2/\epsilon^2)$ time by direct Monte Carlo simulation.

The flaw of the simulation approach is that it is too slow for small values of FAIL(p), namely those less than 1 over a polynomial in n. It is upon this situation that we focus our attention for the remainder of this section. In this case, a huge number of standard simulations would have to be run before we encountered a sufficiently large number of failures to estimate FAIL(p) (note that we expect to run $1/\mathrm{FAIL}(p)$ trials before seeing *any* failures). Karp and Luby [18] tackled this situation for various problems, and showed that it could be handled in some cases by biasing the simulation such that occurrences of the event being estimated became more likely. One of their results was an FPRAS for network reliability in *planar* graphs, under the assumption that the failure probability p of edges is $O((\log n)/n)$ so that the expected number of edges failing is $O(\log n)$. Their algorithm is more intricate than straightforward simulation, and, like ours, relies on identifying a small collection of "important cuts" on which to concentrate.

Another problem where direct Monte Carlo simulation breaks down, and to which Karp and Luby [18], found a solution, is that of *DNF counting*: given a boolean formula in DNF, and given for each variable a probability that it is set to true, estimate the probability that the entire formula evaluates to true. Like estimating FAIL(p), this problem is hard when the probability being estimated is very small. Karp and Luby [18] developed an FPRAS for DNF counting using a biased Monte Carlo simulation. The running time was later improved by Karp, Luby, and Madras [17] to yield the following.

Theorem 2.5. *There is an FPRAS for the DNF counting problem that runs in* $\tilde{O}(s/\epsilon^2)$ *time on a size* s *formula.*

We will use the DNF counting algorithm as a subroutine in our FPRAS.

2.2. Counting near-minimum cuts. We now turn to the case of p^c small. We show that in this case, only the smallest graph cuts have any significant chance of failure. While it is obvious that cuts with fewer edges are more likely to fail, one might think that there are so many large cuts that overall they are more likely to fail than the small cuts. However, the following proposition lets us bound the number of large cuts and show this is not the case.

Theorem 2.6. *An undirected graph has less than* $n^{2\alpha}$ α*-minimum cuts.*

Remark. Vazirani and Yannakakis [26] gave an incomparable bound on the number of small cuts by *rank* rather than by value. $\square$

In this subsection, we sketch a proof of Theorem 2.6. A detailed proof of the theorem can be found in [15] and an alternative proof in [11]. Here, we sketch enough detail to allow for some of the extensions we will need later. We prove the theorem only for unweighted multigraphs (graphs with parallel edges between the same endpoints); the theorem follows for weighted graphs if we replace any weight w edge by a set of w unweighted parallel edges.

2.2.1. Contraction. The proof of the theorem is based on the idea of *edge contraction*. Given a graph $G = (V, W)$ and an edge (v, w), we define a contracted graph $G/(v, w)$ with vertex set $V' = V \cup \{u\} - \{v, w\}$ for some new vertex u and edge set

$$E' = E - \{(v, w)\} \cup \{(u, x) \mid (v, x) \in E \text{ or } (w, x) \in E\}.$$

In other words, in the contracted graph, vertices v and w are replaced by a single vertex u, and all edges originally incident on v or w are replaced by edges incident on u. We also remove self-loops formed by edges parallel to the contracted edge since they cross no cut in the contracted graph.

FACT 2.7. *There is a one-to-one correspondence between cuts in G/e and cuts in G that e does not cross. Corresponding cuts have the same value.*

Proof. Consider a partition (A, B) of the vertices of $G/(v, w)$. The vertex u corresponding to contracted edge (v, w) is on one side or the other. Replacing u by v and w gives a partition of the vertices of G. The same edges cross the corresponding partitions. ◻

2.2.2. The contraction algorithm. We now use repeated edge contraction in an algorithm that selects a cut from G. Consider the following *contraction algorithm.* While G has more than 2 vertices, choose an edge e uniformly at random and set $G \leftarrow G/e$. When the algorithm terminates, we are left with a two-vertex graph that has a unique cut. A transitive application of Fact 2.7 shows that this cut corresponds to a unique cut in our original graph; we will say this cut is *chosen* by the contraction algorithm. We show that any particular minimum cut is chosen with probability at least n^{-2}. Since the choices of different cuts are disjoint events whose probabilities add up to one, it will follow that there are at most n^2 minimum cuts. We then generalize this argument to α-minimum cuts.

LEMMA 2.8. *The contraction algorithm chooses any particular minimum cut with probability at least n^{-2}.*

Proof. Each time we contract an edge, we reduce the number of vertices in the graph by one. Consider the stage in which the graph has r vertices. Suppose G has minimum cut c. It must have minimum degree c, and thus at least $rc/2$ edges. Our particular minimum cut has c edges. Thus a randomly chosen edge is in the minimum cut with probability at most $c/(rc/2) = 2/r$. The probability that we never contract a minimum cut edge through all $n - 2$ contractions is thus at least

$$\begin{aligned}\left(1-\frac{2}{n}\right)\left(1-\frac{2}{n-1}\right)\cdots\left(1-\frac{2}{3}\right) &= \left(\frac{n-2}{n}\right)\left(\frac{n-3}{n-1}\right)\cdots\left(\frac{2}{4}\right)\left(\frac{1}{3}\right)\\ &= \frac{(n-2)(n-3)\cdots(3)(2)(1)}{n(n-1)(n-2)\cdots\cdots(4)(3)}\\ &= \frac{2}{n(n-1)}\\ &= \binom{n}{2}^{-1}\\ &> n^{-2}. \qquad ◻\end{aligned}$$

2.2.3. Proof of Theorem 2.6. We can extend the approach above to prove Theorem 2.6. We slightly modify the contraction algorithm and lower bound the probability so that it chooses a particular α-minimum cut. With r vertices remaining, the probability we choose an edge from our particular α-minimum cut is at most $2\alpha/r$. Let $k = \lceil 2\alpha \rceil$. Suppose we perform random contractions until we have a k-vertex graph. In this graph, choose a vertex partition uniformly at random, so that each of its cuts is chosen with probability 2^{1-k}. It follows that a particular α-minimum cut is chosen with probability

$$\begin{aligned}\left(1-\frac{2\alpha}{n}\right)\left(1-\frac{2\alpha}{(n-1)}\right)\cdots\left(1-\frac{2\alpha}{k+1}\right)2^{1-k} &= \frac{(n-2\alpha)!}{(k-2\alpha)!}\frac{k!}{n!}2^{1-k}\\ &= \frac{\binom{k}{2\alpha}}{\binom{n}{2\alpha}}2^{1-k}\\ &> n^{-2\alpha}.\end{aligned}$$

Note that for α not a half-integer, we are making use of *generalized binomial coefficients* which may have nonintegral arguments. These are discussed in [19, Sections 1.2.5–6]; cf. Exercise 1.2.6.45. There, the Gamma function is introduced to extend factorials to real numbers such that $\alpha! = \alpha(\alpha-1)!$ for all real $\alpha > 0$. Many standard binomial identities extend to generalized binomial coefficients, including the facts that $\binom{n}{2\alpha} < n^{2\alpha}/(2\alpha)!$ and $2^{2\alpha-1} \leq (2\alpha)!$ for $\alpha \geq 1$.

Remark. The contraction algorithm described above is used only to count cuts. An efficient *implementation* given in [15] can be used to *find* all α-minimum cuts in $\tilde{O}(n^{2\alpha})$ time. We use this algorithm in our FPRAS. □

2.3. Cut failure bounds. Using the cut counting theorem just given, we show that large cuts do not contribute significantly to a graph's failure probability. Consider Theorem 2.6; taking $\alpha = 1$, it follows from the union bound that the probability that some minimum cut fails is at most $n^2 p^c$. We now show that the probability that *any* cut fails is only a little bit larger.

THEOREM 2.9. *Suppose a graph has minimum cut c and that each edge of the graph fails independently with probability p, where $p^c = n^{-(2+\delta)}$ for some $\delta > 0$. Then*

1. *the probability that the given graph disconnects is at most $n^{-\delta}(1+2/\delta)$, and*
2. *the probability that a cut of value αc or greater fails in the graph is at most $n^{-\alpha\delta}(1+2/\delta)$.*

Remark. We conjecture that a probability bound of $n^{-\alpha\delta}$ can be proven (eliminating the $(1+2/\delta)$ term). □

Proof. We prove part 1 and then note the small change needed to prove part 2. For the graph to become disconnected, all the edges in some cut must fail. We therefore bound the failure probability by summing the probabilities that each cut fails. Let r be the number of cuts in the graph, and let $c_1, \ldots, c_r$ be the values of the r cuts in increasing order so that $c = c_1 \leq c_2 \leq \cdots \leq c_r$. Let $p_k = p^{c_k}$ be the probability that all edges in the kth cut fail. Then the probability that the graph disconnects is at most $\sum p_k$, which we proceed to bound from above.

We proceed in two steps. First, consider the first n^2 cuts in the ordering (they might not be minimum cuts). Each of them has $c_k \geq c$ and thus has $p_k \leq n^{-(2+\delta)}$, so that

$$\sum_{k \leq n^2} p_k \leq (n^2)(n^{-(2+\delta)}) = n^{-\delta}.$$

Next, consider the remaining larger cuts. According to Theorem 2.6, there are less than $n^{2\alpha}$ cuts of value at most αc. Since we have numbered the cuts in increasing order, this means that $c_{n^{2\alpha}} > \alpha c$. In other words, writing $k = n^{2\alpha}$,

$$c_k > \frac{\ln k}{2 \ln n} \cdot c$$

and thus

$$\begin{aligned} p_k &< (p^c)^{\frac{\ln k}{2 \ln n}} \\ &= \left(n^{-(2+\delta)}\right)^{\frac{\ln k}{2 \ln n}} \\ &= k^{-(1+\delta/2)}. \end{aligned}$$

It follows that

$$\begin{aligned}\sum_{k>n^2} p_k &< \sum_{k>n^2} k^{-(1+\delta/2)} \\ &\leq \int_{n^2}^{\infty} k^{-(1+\delta/2)}\,dk \\ &\leq 2n^{-\delta}/\delta.\end{aligned}$$

Summing the bounds for the first n^2 and for the remaining cuts gives a total of $n^{-\delta} + 2n^{-\delta}/\delta$, as claimed.

The proof of part 2 is the same, except that we sum only over those cuts of value at least αc. □

Remark. A slightly stronger version of part 1 was first proved by Lomonosov and Polesskii [22] using different techniques that identified the cycle as the most unreliable graph for a given c and n. We sketch their result, which we need for a different purpose, in subsection 4.3.2. However, part 2 is necessary for the FPRAS and was not previously known. □

2.4. An approximation algorithm. Our proof that only small cuts matter leads immediately to an FPRAS. First we outline our solution. Given that $\mathrm{FAIL}(p) < n^{-4}$, Theorem 2.9 shows that the probability that a cut of value much larger than c fails is negligible, so we need only determine the probability that a cut of value near c fails. We do this as follows. First, we enumerate the (polynomial size) set of near-minimum cuts that matter. From this set we generate a polynomial size boolean expression (with a variable for each edge, true if the edge has failed) that is true if any of our near-minimum cuts has failed. We then need to determine the probability that this boolean expression is true; this can be done using the DNF counting techniques of Karp, Luby, and Madras [18, 17]. Details are given in the following theorem.

THEOREM 2.10. *When* $\mathrm{FAIL}(p) < n^{-4}$*, there is a (Monte Carlo) FPRAS for estimating* $\mathrm{FAIL}(p)$ *running in* $\tilde{O}(mn^4/\epsilon^3)$ *time.*

Proof. Under the assumption, the probability that a particular minimum cut fails is $p^c \leq \mathrm{FAIL}(p) \leq n^{-4}$. We show there is a constant α for which the probability that any cut of value greater than αc fails is at most $\epsilon\mathrm{FAIL}(p)$. This proves that to approximate to the desired accuracy we need only determine the probability that some cut of value less than αc fails. It remains to determine α. Write $p^c = n^{-(2+\delta)}$; by hypothesis $\delta \geq 2$. Thus by Theorem 2.9, the probability that a cut larger than αc fails is at most $2n^{-\delta\alpha}$. On the other hand, we know that $n^{-(2+\delta)} = p^c \leq \mathrm{FAIL}(p)$, so it suffices to find an α for which $2n^{-\delta\alpha} \leq \epsilon n^{-(2+\delta)}$. Solving this shows that $\alpha = 1 + 2/\delta - (\ln(\epsilon/2))/\delta \ln n \leq 2 - \ln(\epsilon/2)/2\ln n$ suffices and that we therefore need only examine the smallest $n^{2\alpha} = O(n^4/\epsilon)$ cuts.

We can enumerate these cuts in $O(n^{2\alpha}\log^3 n)$ time using certain randomized algorithms [14, 11] (a somewhat slower deterministic algorithm can be found in [26]). Suppose we assign a boolean variable x_e to each edge e; x_e is true if edge e fails and false otherwise. Therefore, the x_e are independent and true with probability p. Let E_i be the set of edges in the ith small cut. Since the ith cut fails if and only if all edges in it fail, the event of the ith small cut failing can be written as $F_i = \wedge_{e\in E_i} x_e$. Then the event of some small cut failing can be written as $F = \vee_i F_i$. We wish to know the probability that F is true. Note that F is a formula in DNF. The size of the formula is equal to the number of clauses ($n^{2\alpha}$) times the number of variables per clause (at most αc), namely, $O(cn^{2\alpha})$. The FPRAS of Karp, Luby, and Madras [17] estimates the truth probability of this formula, and thus the failure probability of the small cuts, to within $(1 \pm \epsilon)$ in $\tilde{O}(cn^{2\alpha}/\epsilon^2) = \tilde{O}(cn^4/\epsilon^3) = \tilde{O}(mn^4/\epsilon^3)$ time.

We are therefore able to estimate to within $(1 \pm \epsilon)$ the value of a probability (the probability that some α-minimum cut fails) that is within $(1 \pm \epsilon)$ of the probability of the event we really care about (the probability that some cut fails). This gives us an overall estimate accurate to within $(1 \pm \epsilon)^2 \approx (1 \pm 2\epsilon)$. ∎

COROLLARY 2.11. *There is an FPRAS for* FAIL(p) *running in* $\tilde{O}(mn^4/\epsilon^3)$ *time.*

Proof. Suppose we wish to estimate the failure probability to within a $(1 \pm \epsilon)$ ratio. If FAIL$(p) > n^{-4}$, then we can estimate it in $\tilde{O}(mn^4/\epsilon^2)$ time by direct Monte Carlo simulation as in Corollary 2.4. Otherwise, we can run the $\tilde{O}(mn^4/\epsilon^3)$-time algorithm of Theorem 2.10. ∎

If the graph is sparse (with $O(n)$ edges) and the minimum cut is $\tilde{O}(1)$ (both these conditions apply to, e.g., planar graphs) then the time for a Monte Carlo trial is $O(n)$, while the size of the formula for the DNF counting step above is $\tilde{O}(n^{2\alpha})$. Thus if we use a different FAIL(p) threshold for deciding which algorithm to use, we can improve the running time bound to $\tilde{O}(n^{3.8}/\epsilon^2)$.

While this time bound is still rather poor, experiments have suggested that performance in practice is significantly better—typically $\tilde{O}(n^3)$ on sparse graphs [16].

3. Extensions.

We now discuss several extensions of our basic FPRAS. In this section, we will consider many cases in which it is sufficient to consider the probability that an α-minimum cut fails for some $\alpha = O(1 - \log\epsilon/\log n)$ (as in the previous section) that is understood in context but not worth deriving explicitly. We will refer to these α-minimum cuts as the *weak* cuts of the graph.

3.1. Varying failure probabilities.

The analysis and algorithm given above extend to the case where each edge e has its own failure probability p_e. To extend the analysis, we transform a graph with varying edge failure probabilities into one with identical failure probabilities. Given the graph G with specified edge failure probabilities, we build a new graph H all of whose edges have the same failure probability p, but that has the same failure probability as G. Choose a small parameter θ. Replace an edge e of failure probability p_e by a "bundle" of k_e parallel edges, each with the same endpoints as e but with failure probability $1 - \theta$, where

$$k_e = \lceil -(\ln p_e)/\theta \rceil .$$

This bundle of edges keeps its endpoints connected unless all the edges in the bundle fail; this happens with probability

$$(1-\theta)^{\lceil -(\ln p_e)/\theta \rceil}.$$

As $\theta \to 0$, this failure probability converges to p_e. Therefore, the reliability of H converges as $\theta \to 0$ to the reliability of G. Thus, to determine the failure probability of G, we need determine only the failure probability of H in the limit as $\theta \to 0$.

Since H has all edge failure probabilities the same, our section 2 analysis of network reliability applies to H. In particular, we know that it suffices to enumerate the weak cuts of H and then determine the probability that one of them fails. To implement this idea, note that changing the parameter θ scales the values of cuts in H without changing their relative values (modulo a negligible rounding error). We therefore build a weighted graph F by taking graph G and giving a weight $\ln 1/p_e$ to edge e. The weak cuts in F correspond to the weak cuts in H. We find these weak cuts in F using the contraction algorithm (which works for weighted graphs [15]) as before.

Given the weak cuts in H, we need to determine the limiting probability that one of them fails as $\theta \to 0$. We have already argued that as $\theta \to 0$, the probability a cut in H fails converges to the probability that the corresponding cut in G fails. Thus we actually want to determine the probability that one of a given set of cuts in G fails. We do this as before. We build a boolean formula with variables for the edges of G and with a clause for each weak cut that is true if all the edges of the cut fail. The only change is that variable x_e is set to true with probability p_e. The algorithm of [17] works with these varying truth probabilities and computes the desired quantity.

THEOREM 3.1. *There is an FPRAS for the all-terminal network reliability problem with varying edge failure probabilities.*

One might be concerned by the use of logarithms to compute edge weights. However, it is easy to see that in fact approximate logarithms suffice for the purpose of enumerating small cuts. If we approximate each logarithm to within relative error .1, then every α-minimum cut in F remains an $11\alpha/9$-minimum cut in the approximation to F. Thus we can enumerate a slightly larger set of near-minimum cuts in order to find the weak cuts. Once we find the weak cuts, we use the original p_e values in the DNF counting algorithm.

In the case of varying failure probabilities, we cannot bound the number of edges in any particular weak cut by a quantity less than m (a weak cut may have $m - n$ edges with large failure probabilities). Thus the size of the DNF formula, and thus the running time of the DNF counting algorithm, may be as large as $mn^{2\alpha} \approx mn^4/\epsilon$.

All the other extensions described in this paper can also be modified to handle varying failure probabilities. But for simplicity, we focus on the uniform case.

3.2. Multiterminal reliability. The multiterminal reliability problem is a generalization of the all-terminal reliability problem. Instead of asking whether the graph becomes disconnected, we consider a subset K of the vertices and ask if some pair of them becomes disconnected. If some pair of vertices in K is separated by a cut of value $O(c)$, then we can use the same theorem on the exponential decay of cut failure probabilities to prove that we need only to examine the small cuts in the graph to determine whether some pair of vertices in K becomes disconnected.

LEMMA 3.2. *If some pair of vertices in K is separated by a cut of value $O(c)$, then there is an FPRAS for the multiterminal reliability problem with source vertices K.*

Proof. We focus on the case of uniform failure probability p; the generalization to arbitrary failure probabilities is as before. Suppose a cut of value βc separates vertices in K. Then the probability that K gets disconnected when edges fail with probability p is at least $p^{\beta c}$. If $p^c > n^{-4}$, then $p^{\beta c} > n^{-4\beta} = n^{-O(1)}$ and we use Monte Carlo simulation as before to estimate the failure probability. If $p^c < n^{-4}$, then by Theorem 2.9, the probability that a cut of value exceeding αc fails is $O(n^{-2\alpha})$. Thus, choosing α such that $n^{-2\alpha} \leq \epsilon p^{\beta c}$, we can enumerate the weak cuts and apply DNF counting. $\square$

3.3. *k*-connectivity. Just as we estimated the probability that the graph fails to be connected, we can estimate the probability that it fails to be k-edge connected for any constant k. Note that the graph fails to be k-edge connected only if some cut has less than k of its edges survive. The probability of this event decays exponentially with the value of the cut, allowing us to prove (as with Theorem 2.9) that if the probability that fewer than k edges in a minimum cut survive is $O(n^{-(2+\delta)})$, then the probability that fewer than k edges survive in a nonweak cut is negligible. Thus, if direct Monte Carlo simulation is not applicable, we need only determine the probability that some weak cut keeps less than k of its edges. But this is another DNF counting problem. For any particular weak cut containing $C \leq m$ edges, we enumerate all $\binom{C}{C-k+1} =$

$O(C^{k-1}) = O(m^{k-1})$ sets of $C-k+1$ edges, and for each add a DNF clause that is true if all the given edges fail.

In fact, one can also adapt the algorithm of [17] to determine the probability that all but $k-1$ variables in some clause of a DNF formula become true; thus we can continue to work with the $O(mn^4/\epsilon)$-size formula we used before.

Corollary 3.3. *For any constant k, there is an FPRAS for the probability that a graph with edge failure probabilities fails to be k-edge connected.*

3.4. Eulerian directed graphs. A natural generalization of the all-terminal reliability problem to directed graphs is to ask for the probability that a directed graph with random edge failures remains strongly connected. A directed graph fails to be strongly connected precisely when all the edges in some *directed* cut fail. In general, the techniques of this paper cannot be applied to directed graphs—the main reason being that a directed graph can have exponentially many minimum directed cuts.

We can, however, handle one special case. In a *Eulerian* directed graph G on vertex set V, the number of edges crossing from any vertex set A to $V-A$ is equal to the number of edges crossing from $V-A$ to A. Thus if we construct an undirected graph H by removing the directions from the edges of G, we know that any (directed) cut in G has value equal to half that of the corresponding (undirected) cut in H. It follows that the α-minimum directed cuts of G correspond to α-minimum undirected cuts of H. Therefore, there are at most $2n^{2\alpha}$ α-minimum directed cuts in G that can be enumerated by enumerating the α-minimum cuts of H (the factor of 2 arises from considering both directions for each cut). As in the undirected case, if the directed failure probability is less than n^{-4}, an analogue of Theorem 2.9 immediately follows, showing that only weak directed cuts are likely to fail. It therefore suffices to enumerate a polynomial number of weak directed cuts to estimate the directed failure probability.

Corollary 3.4. *There is an FPRAS for the probability that a directed Eulerian graph fails to remain strongly connected under random edge failures.*

Corollary 3.5. *For any constant k there is an FPRAS for the probability that a directed Eulerian graph fails to have directed connectivity k under random edge failures.*

3.5. Random orientations. In a similar fashion, we can estimate the probability that, if we orient each edge of the graph randomly, the graph fails to be strongly connected. For each cut, we make a DNF formula with two clauses, one of which is true if all edges point "left" and the other if all edges point "right." (This observation is due to Alan Frieze.) This problem can also be phrased as estimating the number of non-strongly connected orientations of an undirected graph; in this form, it is related to the Tutte polynomial discussed in section 6. Similarly, we can estimate the probability that random orientations fail to produce a k-connected directed graph.

4. Partition into r components.

The quantity FAIL(p) is an estimate of the probability that the graph partitions into more than one connected component. We can similarly estimate the probability that the graph partitions into r or more components for any constant r. Besides its intrinsic interest, the analysis of this problem will be important in our study of some heuristics and derandomizations in section 5 and the Tutte polynomial in section 6.

We first note that a graph partitions into r or more components only if an r-*way cut*—the set of edges with endpoints in different components of an r-way vertex partition—loses all its edges. Note that some of the vertex sets of the partition might induce disconnected subgraphs, so that the r-way partition might induce more than r connected components. However, it certainly does not induce less. Our approach to r-way reliability is the same as for the 2-way case. We show that there are few small r-way cuts and that estimating the probability one fails suffices to approximate the r-way failure probability. As a corollary, we show that the probability of r-way partition is much less than that of 2-way partition.

4.1. Counting multiway cuts. We enumerate multiway cuts using the contraction algorithm as for the 2-way case. Details can be found in [15].

LEMMA 4.1. *In an m-edge unweighted graph the minimum r-way cut has value at most $2m(r-1)/n$.*

Proof. A graph's average degree is $2m/n$. Consider an r-way cut with each of the $r-1$ vertices of smallest degree as its own singleton component and all the remaining vertices as the last component. The value of this cut is at most the sum of the singleton vertex degrees, which is at most $r-1$ times the average degree. ∎

COROLLARY 4.2. *There are at most $\binom{n}{2(r-1)}$ minimum r-way cuts.*

Proof. Suppose we fix a particular r-way minimum cut and run the contraction algorithm until we have $2(r-1)$ vertices. By the previous lemma, the probability that we pick an edge of our fixed cut when k vertices remain is at most $2\frac{r-1}{k}$. Thus the probability that our fixed minimum r-way cut is chosen is

$$\prod_{k=2r-1}^{n}\left(1-\frac{2(r-1)}{k}\right),$$

which is analyzed as in the proof of Theorem 2.6, substituting $r-1$ for α. ∎

COROLLARY 4.3. *For arbitrary $\alpha \geq 1$, there are at most $(rn)^{2\alpha(r-1)}$ α-minimum r-way cuts that can be enumerated in $\tilde{O}((rn)^{2\alpha(r-1)})$ time.*

Proof. First run the contraction algorithm until the number of vertices remaining is $\lceil 2\alpha(r-1)\rceil$. At this point, choose a random r-way partition of what remains. There are at most $r^{2\alpha(r-1)}$ such partitions.

The time bound follows from the analysis of the recursive contraction algorithm [15]. ∎

Remark. We conjecture that in fact the correct bound is $O(n^{\alpha r})$ α-minimum r-way cuts. Subsection 4.3.2 shows this is true for $\alpha = 1$. Proving it for general α would slightly improve our exponents in the following sections. ∎

4.2. An approximation algorithm. Our enumeration of multiway cuts allows an analysis and reduction to DNF counting exactly analogous to the one performed for FAIL(p).

COROLLARY 4.4. *Suppose a graph has r-way minimum cut value c_r, and suppose that each edge fails with probability p, where $p^{c_r} = (rn)^{-(2+\delta)(r-1)}$ for some constant $\delta > 0$. Then the probability that an α-minimum r-way cut fails is at most $(rn)^{-\alpha\delta(r-1)}$ $(1+2/\delta)$.*

Proof. The proof is exactly as for Theorem 2.9, substituting $(rn)^{(r-1)}$ (drawn from Corollary 4.3) for n everywhere. ∎

COROLLARY 4.5. *There is an algorithm for ϵ-approximating the probability that a graph partitions into r or more components, running in $\tilde{O}(m(rn)^{4(r-1)}/\epsilon^3)$ time. The algorithm is an FPRAS with running time $\tilde{O}(mn^{4(r-1)}/\epsilon^3)$ for any fixed r.*

Proof. Exactly as for the 2-way cut case, with $(rn)^{(r-1)}$ replacing n everywhere. Let c_r be the r-way minimum cut value and let δ be defined by $p^{c_r} = (rn)^{-(2+\delta)(r-1)}$. If $p^{c_r} > (rn)^{-4(r-1)}$, estimate the partition probability via Monte Carlo simulation. Otherwise, it follows as in the 2-way cut case that for the same constant α as we chose there, the probability that a greater than α-minimum r-way cut fails is less than ϵp^{c_r}. Thus to estimate the partition probability it suffices to enumerate (in $\tilde{O}((rn)^{4(r-1)}/\epsilon)$ time) the set of α-minimum r-way cuts and perform DNF counting. □

One might wish to compute the probability that a graph partitions into *exactly* r components, but it is not clear that this can be done. In particular, computing $\mathrm{REL}(p)$ can be reduced to this problem (for any r) by adding $r-1$ isolated vertices. There is at present no known FPRAS for $\mathrm{REL}(p)$.

4.3. Comparison to 2-way cuts. For sections 5 and 6, we need to show that the probability of partition into r components is much less than that of partition into 2 components. We give two proofs, the first simpler but with a slightly weaker bound. The following subsections can use the weaker analysis at the cost of worse exponents. In this section, the term "cut" refers exclusively to 2-way cuts unless we explicitly modify it.

4.3.1. A simple argument.

LEMMA 4.6. *If $p^c = n^{-(2+\delta)}$, then the probability that an r-way cut fails is at most $n^{-\delta r/4}(1+2/\delta)$.*

Proof. We show that any r-way cut contains the edges of a (2-way) cut of value $rc/4$. Thus, if an r-way cut fails then an $(r/4)$-minimum 2-way cut fails. The probability that this happens has been upper-bounded by Theorem 2.9.

To show the claim, consider an r-way cut. Contract each component of the r-way partition to a single vertex, yielding an r-vertex graph G'. All edges in this graph correspond to edges of the r-way cut. Every cut in G' corresponds to a cut of the same value in the original graph, so it suffices to show that G' has a 2-way cut of value at least $rc/4$. To see this, note that every vertex in G' has degree at least c, so the number of edges in G' is at least $rc/2$. Consider a random cut of G', generated by assigning each vertex randomly to one side or the other. Each edge has a 1/2 chance of being cut by this partition, so the expected value of this cut is at least $rc/4$. It follows that G' has a cut of value at least $rc/4$ that corresponds to a cut of value at least $rc/4$ in the original graph. □

4.3.2. A better argument. We can get a slightly better bound on the probability that a graph partitions into r components via a small variation on an argument made by Lomonosov and Polesskii [22, 20, 4]. The better bound improves some of our exponents. Their proof uses techniques somewhat different from the remainder of the paper and can safely be skipped.

LEMMA 4.7. *Let $\mathrm{FAIL}_r(G,p)$ denote the probability that G partitions into r or more connected components when each edge fails with probability p. Let G have minimum cut c for some even c. Let C_n be a cycle with $c/2$ edges between adjacent vertices. Then for any r, $\mathrm{FAIL}_r(G,p) \le \mathrm{FAIL}_r(C_n,p)$.*

COROLLARY 4.8. *For any graph G with minimum cut c, if edges fail with probability p where $p^c = n^{-(2+\delta)}$, then the probability the failed graph has r or more connected components is less than $n^{-\delta r/2}$.*

Remark. Note that for $r=2$, the above result gives a slightly stronger bound on $\mathrm{FAIL}(p)$ than we are able to get in Theorem 2.9. Unfortunately, this argument does not appear to extend to proving the bound we need on the probability that a greater than α-minimum r-way cut fails. □

Proof of Corollary 4.8. Thanks to Lemma 4.7, it suffices to prove this claim for the case of G a cycle C_n with $(c/2)$-edge "bundles" between adjacent vertices. The number of components into which C_n is partitioned is equal to the number of bundles that fail, so we need only bound the probability that r or more bundles fail. The probability that a single bundle fails is $p^{c/2} = n^{-(1+\delta/2)}$, so the probability that r particular bundles fail is $n^{-r(1+\delta/2)}$. There are $\binom{n}{r} < n^r$ sets of exactly r bundles. It follows that the probability r or more bundles fail is less than $n^r n^{-r(1+\delta/2)} = n^{-r\delta/2}$. $\square$

Proof of Lemma 4.7. Consider the following time-evolving version of the contraction algorithm on a connected graph G. Each edge of G is given an *arrival time* chosen independently from the exponential distribution with mean 1. Each time an edge arrives, we contract its endpoints if they have not already been contracted. This gives rise to a sequence of graphs $G = G_n, G_{n-1}, \ldots, G_1$, where G_r has r vertices. Let $G[t]$ be the graph that exists at time t. Thus initially $G[0] = G_n$ and eventually $G[\infty]$ has one vertex since all edges have arrived. We draw a correspondence between this model and our edge failure model as follows: at time t, the failed edges are those which have not yet arrived. It follows that each vertex in $G[t]$ corresponds to a connected component of G when each edge has failed (to arrive) independently with probability e^{-t}.

We consider the random variable $T_r(G)$ defined as the time at which the edge that contracts G_r to G_{r-1} arrives. We show that $T_r(C_n)$ *stochastically dominates* $T_r(G)$ for every r—that is,

$$\Pr[T_r(G) \geq t] \leq \Pr[T_r(C_n) \geq t].$$

(See Motwani and Raghavan [23] for additional discussion of this definition.) Assuming this is true, we can prove our result as follows:

$$\begin{aligned}\Pr[G[t] \text{ has } r \text{ or fewer components}] &= \Pr[T_r(G) \leq t]\\ &\geq \Pr[T_r(C_n) \leq t]\\ &= \Pr[C_n[t] \text{ has } r \text{ or fewer components}].\end{aligned}$$

To prove stochastic domination, let $t_r(G) = T_{r-1}(G) - T_r(G)$ denote the length of time for which G_r exists before being contracted to G_{r-1}. Clearly, $t_r(G)$ is just the time it takes for an edge to arrive that has endpoints in different connected components of G_r. It follows that $T_r(G) = \sum_{r'=r}^{n} t_{r'}(G)$. Similarly, $T_r(C_n) = \sum_{r'=r}^{n} t_{r'}(C_n)$. Thanks to the memoryless nature of the exponential distribution, the t_r are mutually independent (this will be justified more carefully later). We will show that $t_r(C_n)$ stochastically dominates $t_r(G)$ for every r. The fact that $T_r(C_n)$ stochastically dominates $T_r(G)$ then follows from the fact that when X dominates X' and Y dominates Y' and the variables are independent, $X + Y$ dominates $X' + Y'$.

To analyze t_r, suppose there are m_r edges in G_r (note m_r is a random variable). The arrival time of each edge in G_r measured from $T_r(G)$ is exponentially distributed with mean 1. Therefore, the arrival time of the first such edge, namely $t_r(G)$, is exponentially distributed with mean $1/m_r$. Now note that G_r is c-connected, so it must have $m_r \geq cr/2$. It follows that $t_r(G)$ is exponentially distributed with mean at most $2/cr$, meaning that it is stochastically dominated by any exponentially distributed variable with mean $2/cr$. On the other hand, when C_n has been reduced to r components, it is isomorphic to C_r. By the same analysis as for G, we know $t_r(C_n)$ is exponentially distributed with mean $2/cr$, and thus stochastically dominates $t_r(G)$.

Our glib claim that the t_r are independent needs some additional justification. Technically, we condition on the values $G_n, \ldots, G_1$ of the evolving graph. We show that regardless of what values G_i we condition on, $T_r(C_n)$ stochastically dominates $T_r(G \mid G_n, \ldots, G_1)$. Since the stochastic domination applies regardless of our conditioning event, it follows even if we do not condition.

Once we have conditioned on the value G_r, t_r is just the time it takes for an edge to arrive that contracts G_r to G_{r-1} and is therefore independent of $t_{r'}$ when $r' \neq r$. But we must ask whether t_r still has the right exponential distribution—the complicating factor being that we know the first edge to arrive at G_r must contract G_r to a specific G_{r-1} and not some other graph. To see that this does not matter, let B be the event that first edge to arrive at G_r is one that creates G_{r-1}. Then

$$\begin{aligned}\Pr[t_r \geq t \mid B] &= \Pr[B \mid t_r \geq t] \Pr[t_r \geq t] / \Pr[B] \\ &= \Pr[B] \Pr[t_r \geq t] / Pr[B] \\ &= \Pr[t_r \geq t]\end{aligned}$$

since, of course, the time of arrival of the edge the contracts G_r has no impact on which of the edges of G_r is the first to arrive. □

5. Heuristics and deterministic algorithms. Until now, we have relied on the fact that the most likely way for a graph to fail is for some of its near-minimum cuts to fail. We now strengthen this argument to observe that most likely, *exactly one* of these near-minimum cuts fails. This leads to two additional results. First, we show that the sum of the individual small-cut failure probabilities is a reasonable approximation to the overall failure probability. This justifies a natural heuristic and indicates that in practice one might not want to bother with the DNF counting phase of our algorithm. In a more theoretical vein, we also give a deterministic PAS for FAIL(p) that applies whenever FAIL$(p) < n^{-(2+\delta)}$. We prove the following theorems.

THEOREM 5.1. *When $p^c < n^{-4}$ (and in particular when* FAIL$(p) < n^{-4}$*), the sum of the weak cuts' failure probabilities is a $(1+o(1))$ approximation to* FAIL(p).

THEOREM 5.2. *When $p^c < n^{-(2+\delta)}$ for any constant δ (and in particular when* FAIL$(p) < n^{-(2+\delta)}$*), there is a deterministic PAS for* FAIL(p) *running in $(n/\epsilon)^{\exp(O(-\log_n \epsilon))}$ time.*

We remark that unlike many PASs whose running times are only polynomial for constant ϵ, our PAS has polynomial running time so long as $\epsilon = n^{-O(1)}$. Its behavior when ϵ is tiny prevents it from being an FPAS, however.

To prove these theorems, we argue as follows. As shown in section 2, it is sufficient to approximate, for the given ϵ, the probability that some α-minimum cut fails, where

$$\alpha = 1 + 2/\delta - (\ln \epsilon)/\delta \ln n.$$

Let us write these α-minimum cuts as C_i, $i = 1, \ldots, n^{2\alpha}$. Let F_i denote the event that cut C_i fails. We can use inclusion-exclusion to write the failure probability as

$$\Pr[\cup F_i] = \sum_{i_1} \Pr[F_{i_1}] - \sum_{i_1<i_2} \Pr[F_{i_1} \cap F_{i_2}] + \sum_{i_1<i_2<i_3} \Pr[F_{i_1} \cap F_{i_2} \cap F_{i_3}] + \cdots .$$

Later terms in this summation measure events involving many cut failures. We show that when many cuts fail, the graph partitions into many pieces, meaning a multiway cut fails. We then argue (using Lemma 4.6 or Corollary 4.8) that this is so unlikely that later terms in the sum can be ignored. This immediately yields Theorem 5.1.

To prove Theorem 5.2, we show that for any fixed ϵ it is sufficient to consider a constant number of terms (summations) on the right-hand side in order to get a good approximation. Observe that the kth term in the summation can be computed deterministically in $O(m(n^{2\alpha})^k)$ time by evaluating the probability of each of the $(n^{2k\alpha})$ intersection events in the sum (each can be evaluated deterministically since it is just the probability that all edges in the specified cuts fail). Thus, our running time will be polynomial so long as the number of terms we need to evaluate is constant.

5.1. Inclusion-exclusion analysis. As discussed above, our analyses use a truncation of the inclusion-exclusion expression for

$$\Pr[\cup F_i] = \sum_{i_1} \Pr[F_{i_1}] - \sum_{i_1<i_2} \Pr[F_{i_1} \cap F_{i_2}] + \sum_{i_1<i_2<i_3} \Pr[F_{i_1} \cap F_{i_2} \cap F_{i_3}] + \cdots .$$

Suppose we truncate the inclusion-exclusion, leaving out the kth and later terms. If k is odd the truncated sum yields a lower bound; if k is even it yields an upper bound. We show that this bound is sufficiently tight. We do so by rewriting the inclusion-exclusion expression involving particular sets of failed cuts failing as an expression based on *how many* cuts fail.

LEMMA 5.3. *Let S_u be the event that u* or more *of the events F_i occur. If the inclusion-exclusion expansion is truncated at the kth term, the error introduced is*

$$\sum_u \binom{u-2}{k-2} \Pr[S_u].$$

Proof. Let T_u be the event that *exactly* u of the events F_i occur. Consider the first summation $\sum F_{i_1}$ in the inclusion-exclusion expansion. The event where precisely the events $F_{j_1}, \ldots, F_{j_u}$ occur (that is, the event that cuts $C_{j_1}, \ldots, C_{j_k}$ fail but no others fail) contributes to the u terms $\Pr[F_{j_1}], \ldots, \Pr[F_{j_u}]$ in the sum. It follows that each sample point contributing to T_u is counted $u = \binom{u}{1}$ times in the summation. Thus,

$$\sum \Pr[F_{i_1}] = \sum_u \binom{u}{1} \Pr[T_u].$$

By the same reasoning,

$$\sum \Pr[F_{i_1} \cap F_{i_2}] = \sum_u \binom{u}{2} \Pr[T_u],$$

and so on. It follows that the error introduced by truncation at term k is

$$\begin{aligned} \sum_{i_1<i_2<\cdots<i_k} \Pr[F_{i_1} \cap F_{i_2} \cap \cdots \cap F_{i_k}] - \sum_{i_1<i_2<\cdots<i_{k+1}} \Pr[F_{i_1} \cap F_{i_2} \cap \cdots \cap F_{i_{k+1}}] + \cdots \\ = \sum_{j \ge k} (-1)^{k-j} \sum_u \binom{u}{j} \Pr[T_u] \\ = \sum_u \sum_{j \ge k} (-1)^{k-j} \binom{u}{j} \Pr[T_u] \\ = \sum_u \binom{u-1}{k-1} \Pr[T_u]. \end{aligned}$$

Now recall that S_u is the event that u *or more* of the F_i occur, meaning that $\Pr[T_u] =$

$\Pr[S_u] - \Pr[S_{u+1}]$. Thus we can rewrite our bound above as

$$\begin{aligned}
&\sum_u \binom{u-1}{k-1}(\Pr[S_u] - \Pr[S_{u+1}]) \\
&\quad = \sum_u \binom{u-1}{k-1} \Pr[S_u] - \sum_u \binom{u-1}{k-1} \Pr[S_{u+1}] \\
&\quad = \sum_u \binom{u-1}{k-1} \Pr[S_u] - \sum_u \binom{u-2}{k-1} \Pr[S_u] \\
&\quad = \sum_u \left(\binom{u-1}{k-1} - \binom{u-2}{k-1}\right) \Pr[S_u] \\
&\quad = \sum_u \binom{u-2}{k-2} \Pr[S_u].
\end{aligned}$$

This completes the proof. $\square$

5.2. A simple approximation. Using the above error bound, we can prove Theorem 5.1. Let F_i denote the event that the ith near-minimum cut fails. Our objective is to estimate $\Pr[\cup F_i]$. Summing the individual cuts' failure probabilities corresponds to truncating our inclusion-exclusion sum at the second term, giving (by Lemma 5.3) an error of $\sum_{u \geq 2} S_u$. We now bound this error by bounding the quantities S_u.

LEMMA 5.4. *If u distinct (2-way) cuts fail then a $\lceil \log(u+1)+1 \rceil$-way cut fails.*

Proof. Consider a configuration in which u distinct cuts have failed simultaneously. Suppose this induces k connected components. Let us contract each connected component in the configuration to a single vertex. Each failed cut in the original graph corresponds to a distinct failed cut in the contracted graph. Since the contracted graph has k vertices, we know that there are at most $2^{k-1}-1$ ways to partition its vertices into two nonempty groups, and thus at most this many cuts. In other words, $u \leq 2^{k-1}-1$. Now solve for u and observe it must be integral. $\square$

COROLLARY 5.5. *If $p^c = n^{-(2+\delta)}$ then $\Pr[S_u] \leq n^{-\lceil \log(u+1)+1 \rceil \delta/2}$.*

Proof. Apply Corollary 4.8 to the previous lemma. $\square$

Thus, for example, S_2 and S_3 are upper bounded by the probability that a 3-way cut fails, which by Corollary 4.8 is at most $n^{-3\delta/2}$. More generally, all 2^k values $S_{2^k}, \ldots, S_{2^{k+1}-1}$ are at most $n^{-(k+2)\delta/2}$. It follows that the error in our approximation by the bound of Theorem 5.1 is

$$\begin{aligned}
\sum_{u \geq 2} S_u &\leq \sum_{k \geq 1} 2^k n^{-(k+2)\delta/2} \\
&= n^{-\delta} \sum_{k \geq 1} (2n^{-\delta/2})^k \\
&= 2n^{-3\delta/2}(1+o(1)),
\end{aligned}$$

whenever $\delta > 0$. This quantity is $o(p^c)$, and thus $o(\mathrm{FAIL}(p))$, whenever $n^{-3\delta/2} = o(n^{-(2+\delta)})$, i.e. $\delta > 4$. This proves Theorem 5.1.

5.3. A PAS. We now use the inclusion-exclusion analysis to give a PAS for $\mathrm{FAIL}(p)$ when $p^c = n^{-(2+\delta)}$ for some fixed $\delta > 0$, thus proving Theorem 5.2. We give an ϵ-approximation algorithm with a running time of $(n/\epsilon)^{\exp(O(-\log_n \epsilon))}$, which is clearly polynomial in n for each fixed ϵ (and in fact, for any $\epsilon = n^{-O(1)}$).

We must eliminate two uses of randomization: in the contraction algorithm for identifying the α-minimum cuts and in the DNF counting algorithm for estimating their failure probability.

The first step is to deterministically identify the near-minimum cuts of G. One approach is to use a derandomization of the contraction algorithm [13]. A more efficient approach is to use a cut enumeration scheme of Vazirani and Yannakakis [26]. This scheme enumerates cuts in increasing order of value, with a "delay" of $\tilde{O}(mn)$ per cut. From the fact that there are only $n^{2\alpha}$ weak cuts, it follows that all weak cuts (in the sense of section 3) can be found in $\tilde{O}(mn^{1+2\alpha})$ time.

We must now estimate the probability one of the near-minimum cuts fails. Let us consider truncating to the first k terms in the inclusion-exclusion expansion. From Corollary 5.5 we know that $\Pr[S_u] \leq n^{-(\log(u+1)+1)\delta/2}$. It follows from Lemma 5.3 that for any $k \leq \frac{1}{3}\delta \log n$, our error from using the k-term truncation of inclusion-exclusion is

$$\begin{aligned}
\sum_u \binom{u-2}{k-2} n^{-(\log(u+1)+1)\delta/2} &\leq n^{-\delta/2} \sum_{u \geq k} (u-2)^{k-2}(u+1)^{-\delta(\log n)/2} \\
&\leq \sum_{u \geq k} (u+1)^{k-2-\delta(\log n)/2} \\
&\leq \sum_{u \geq k} (u+1)^{\delta(\log n)/3-2-\delta(\log n)/2} \\
&\leq \sum_{u \geq k} (u+1)^{-\delta(\log n)/6-1} \\
&\leq \int_{u=k-1}^{\infty} (u+1)^{-\delta(\log n)/6-1} \, \boldsymbol{d}u \\
&= \frac{k^{-\delta(\log n)/6}}{\delta(\log n)/6} \\
&= \frac{n^{-\delta(\log k)/6}}{\delta(\log n)/6} \\
&= O(n^{-\delta(\log k)/6}).
\end{aligned}$$

This quantity is $O(\epsilon n^{-(2+\delta)}) = O(\epsilon p^c) = O(\epsilon \mathrm{FAIL}(p))$ for some $k = 2^{O(-\log_n \epsilon)}$. It follows that for an ϵ-approximation we need only evaluate the inclusion-exclusion up to the kth term. Computing the kth term requires examining every set of k of the $(n/\epsilon)^{O(1)}$ α-minimum cuts; this requires $(n/\epsilon)^{\exp(O(-\log_n \epsilon))}$ time. This concludes the proof of Theorem 5.2.

We can slightly improve our bound on $\Pr[S_u]$, which in turn gives better bounds on k.

LEMMA 5.6. *If u distinct α-minimum cuts fail, then a $u^{1/2\alpha}$-way cut fails.*

Proof. Consider a configuration in which u distinct cuts have failed simultaneously. Suppose this induces k connected components. Let us contract each connected component in the configuration to a single vertex. In this contracted graph (before edges fail), the minimum cut is at least c (since contraction never reduces the minimum cut). Furthermore, each of the u failed cuts is a cut of value at most αc, and thus an α-minimum cut, in the contracted graph. Since the contracted graph has k vertices, we know from Theorem 2.6 that $u < k^{2\alpha}$, meaning that $k > u^{1/2\alpha}$. □

However, this serves only to reduce the values of our constants (and reduce the running time from an exponential to a polynomial dependence on $1/\delta$).

6. The Tutte polynomial.

The Tutte polynomial $T(G;x,y)$ is a polynomial in two variables defined by a graph G. Evaluating it at various points x, y on the so-called Tutte plane yields various interesting quantities regarding the graph. In particular, computing the network reliability $\mathrm{REL}(p)$ is the special case of evaluating the Tutte polynomial at the point $x = 1, y = 1/(1-p)$. Another special case is counting the number of strongly connected orientations of an undirected graph, discussed in subsection 3.5. Yet another is counting the number of forests in a graph. Alon, Frieze, and Welsh [1] showed that for any *dense* graph (one with $\Omega(n^2)$ edges) and fixed x and fixed $y \geq 1$ there is an FPRAS for the Tutte polynomial.

6.1. Results.

In this section, we prove the following.

THEOREM 6.1. *For every $y \geq 1$ there is a $c = O(y \log nxy)$ (in particular, $c = O(\log n)$ for any fixed x and y) such that for all n-vertex m-edge graphs of edge-connectivity greater than c,*

$$T(G;x,y) = \frac{y^m}{(y-1)^{n-1}}(1 + O(1/n)).$$

Thus, a good approximation can be given in constant time. Note that almost all graphs fall under this theorem as the minimum cut of a random graph is tightly concentrated around $n/2 \gg c$.

THEOREM 6.2. *For every $y > 1$ there is a $c = O(y \log nxy)$ such that there is an FPRAS for $T(G;x,y)$.*

This theorem is perhaps unsurprising given the previous theorem. A slightly more challenging quantity is the "second-order term" saying how far a given graph diverges from its approximation in the first theorem.

THEOREM 6.3. *Let*

$$\Delta T(G;x,y) = \frac{y^m}{(y-1)^{n-1}} - T(G;x,y).$$

For any fixed $y > 1$ and fixed x, there is a $c = O(\log n)$ such that there is an FPRAS for $\Delta T(G;x,y)$.

This theorem is stronger than and implies the previous theorem. When ΔT is very close to 0, $\frac{y^m}{(y-1)^{n-1}}$ accurately approximates T but approximating ΔT with small relative error is harder.

6.2. Method.

Our proofs begin with a lemma of Alon, Frieze, and Welsh [1] (which we have slightly rephrased to include what is for them the special case of $x = 1$).

LEMMA 6.4 (see [1]). *When $y > 1$,*

$$T(G;x,y) = \frac{y^m}{(y-1)^{n-1}} E[Q^{\kappa-1}],$$

where $Q = (x-1)(y-1)$, and κ is a random variable equal to the number of connected components of G when each edge of G fails independently with probability $p = 1 - 1/y$. (In the case $Q = 0$ (when $x = 1$), we use the fact that $0^r = 0$ for $r \neq 0$ while $0^0 = 1$.)

In other words, when p_r is the probability that the graph with random edge failures partitions into exactly r components, the Tutte polynomial can be evaluated from

$$E[Q^{\kappa-1}] = \sum_{k=1}^{n} p_r Q^{r-1}.$$

For the remainder of this subsection, we normalize our analysis by considering the quantity $T'(G;x,y) = T(G;x,y)\frac{(y-1)^{n-1}}{y^m} = E[Q^{\kappa-1}]$. Clearly, any results on relative approximations to T' translate immediately into results on relative approximations to T.

We begin with an intuitive argument. From Theorem 2.9, when $p^c = n^{-(2+\delta)}$ (which happens for some $c = O(\log n)$ for any fixed p) we know p_r is negligible for $r \geq 1$. Intuitively, since $p_1 \approx 1$ and all other $p_r \approx 0$, we might as well approximate T' by Q. Extending this argument, we know that compared to p_2, all terms p_r for $r > 2$ are negligible. Therefore, the error in the approximation of T' by Q is almost entirely determined by $p_2 Q^2$, which we can determine by computing p_2.

To prove our results formally, we have to deal with the fact that the term Q^r in the expectation increases exponentially with r. We prove that the p_r decay fast enough to damp out the increasing values of Q^r. We also need to be careful that when $Q < 0$, the large leading terms do not cancel each other out.

6.3. Proofs. For our formal analysis, instead of the quantities p_r, it is more convenient to work with quantities s_r measuring the probability that the graph partitions into r *or more* components. Note that $s_1 = 1$ and $s_2 = \text{FAIL}(p)$. Since $p_r = s_r - s_{r+1}$, it follows that

$$\begin{aligned}
T'(G;x,y) &= \sum_{r=1}^{n} p_r Q^{r-1} \\
&= \sum_{r=1}^{n} (s_r - s_{r+1}) Q^{r-1} \\
&= \sum_{r=1}^{n} s_r Q^{r-1} - \sum_{r=2}^{n} s_r Q^{r-2} \\
&= 1 + \sum_{r=2}^{n} s_r (Q^{r-1} - Q^{r-2}) \\
&= 1 + (Q-1) \sum_{r=2}^{n} s_r Q^{r-2}.
\end{aligned}$$

Theorem 6.1 will follow directly from the last equation if we can show that the trailing term $(Q-1)\sum_{r=2}^{n} s_r Q^{r-2} = O(1/n)$. Theorem 6.3 will follow if we can give an FPRAS for $\sum_{r=2}^{n} s_r Q^{r-2}$. The fact that the value of this sum is $o(1)$ (Theorem 6.1) means that the FPRAS for it immediately yields an FPRAS for T', thus proving Theorem 6.2.

To prove these results, first consider the case $x = 1$. In this case $Q = 0$, meaning $Q^{r-2} = 1$ for $r = 2$ and 0 for $r > 2$. Thus $T'(G;x,y) = 1 - s_2 = 1 - \text{FAIL}(p) = \text{REL}(p)$. We have already seen in Theorem 2.9 that whenever $p^c = n^{-(2+\delta)}$, the probability that the graph becomes disconnected is at most $n^{-\delta}(1 + 2/\delta)$. This is certainly $O(1/n)$ if $\delta \geq 1$, meaning $\text{REL}(p) = 1 - O(1/n)$. But this in turn is true when $p^c < n^{-3}$, i.e.,

$$c > 3 \ln n / \ln(y/(y-1)) = O(y \ln n).$$

This proves Theorem 6.1 for $Q = 0$. On the other hand, Theorem 6.3 simply claims that there is an FPRAS for $1 - \text{REL}(p) = \text{FAIL}(p)$, which is what section 2 showed. Finally, Theorem 6.2 says that when $\text{FAIL}(p)$ is small, we can approximate $\text{REL}(p)$ (by approximating $\text{FAIL}(p)$).

We now generalize this argument to the case $x > 1$. To derive the appropriate lower bound on c, we state two criteria that will we need in our analysis. First, we require c to be such that $p^c = n^{-(2+\delta)}$ for some $\delta > 1$. Equivalently, we have $1 \leq \delta = -\log(n^2 p^c)/\log n$. Second, we require that $Q < \frac{1}{4}n^{\delta/4}$. Plugging in for δ, we find the equivalent requirement

$$\begin{aligned} Q &< \frac{1}{4}n^{\delta/4} \\ &= \frac{1}{4}(n^2p^c)^{-1/4}, \\ (4Q)^4 &< 1/n^2p^c, \\ n^2(4Q)^4 &< \left(\frac{y}{y-1}\right)^c, \\ \ln(256Q^4n^2)/\ln\left(1+\frac{1}{y-1}\right) &< c. \end{aligned}$$

This is true for some $c = O(y(\ln nQ)) = O(y \ln nxy)$ as claimed.

Given the above relations between Q, n, and δ, we can use Corollary 4.8. Since $p^c = n^{-(2+\delta)}$, we deduce that $s_r \leq n^{-r\delta/2}$. Since $Q < \frac{1}{4}n^{\delta/4} < \frac{1}{2}n^{\delta/2}$ we find that

$$\begin{aligned} \sum_{r=r_0}^{n} s_r Q^{r-2} &\leq Q^{-2} \sum_{r \geq r_0} (Qn^{-\delta/2})^r \\ &\leq Q^{-2}(Qn^{-\delta/2})^{r_0}/(1-(Qn^{-\delta/2})^{r_0}) \\ &\leq Q^{-2}(Qn^{-\delta/2})^{r_0}/\left(1-\frac{1}{2^{r_0}}\right) \\ &\leq 2Q^{-2}(Qn^{-\delta/2})^{r_0}. \end{aligned}$$

Our results follow from this bound. First, taking $r_0 = 2$, we find that the error in approximating $T'(G; x, y)$ by 1 is at most

$$2n^{-\delta} = o(1).$$

This proves Theorem 6.1.

To prove Theorem 6.3, note that the leading term in the summation (6.1) is $s_2 \geq n^{-(2+\delta)}$. We can therefore estimate the sum to within relative error $O(\epsilon)$ by evaluating summation terms up to summation index r_0 where $(Qn^{-\delta/2})^{r_0} \leq \epsilon n^{-(2+\delta)}$. Since the left-hand side decreases exponentially in n as a function of r_0, we can achieve this error bound by taking

$$r_0 = O(\log_n(n^{2+\delta}/\epsilon)) = O(1 + \log_n 1/\epsilon).$$

In other words, we need only to determine $O(1 - \log_n \epsilon)$ terms in the summation. This in turn reduces to determining the quantities s_r appearing in those terms.

We cannot find the s_r exactly. However, for an ϵ-approximation, it suffices to approximate each relevant s_r to within ϵ. We can do so using the algorithm of Corollary 4.5. The running time of this algorithm for estimating the r-way failure probability to within ϵ is $(n^r/\epsilon)^{O(1)}$. We have argued above that we need only to run the algorithm for $r \leq r_0 = O(1 - \log_n \epsilon)$. It follows that the running time of our algorithm is $n^{O(1-\log_n \epsilon)}/\epsilon^{O(1)} = (n/\epsilon)^{O(1)}$, as required. This proves Theorem 6.3.

Finally, we consider the case $x < 1$. Our argument is essentially unchanged from before. We need to be slightly more careful because our sum is now an alternating sum, which means that the leading terms are a good approximation only if they do not cancel each other out. To see that such cancelling does not occur, note that the first term has value $s_2 = n^{-(2+\delta)}$, while the remaining terms (by the analysis above) have total (absolute) value $O(n(Qn^{-3\delta/2}))$. If we choose n large enough that $Q < \frac{1}{4}n^{\delta/4}$, then this bound is $O(\frac{1}{4}n^{-5\delta/4}) < \frac{1}{4}s_2$ for $\delta > 4$, so the remaining terms do not cancel s_2.

7. Conclusion.

We have given an FPRAS for the all-terminal network reliability problem and several variants. In the case of large failure probability, the FPRAS uses straightforward Monte Carlo simulation. For smaller failure probabilities, the FPRAS uses an efficient reduction to DNF counting or a less efficient deterministic computation. An obvious open question is whether there is also a deterministic PAS for the case of large failure probabilities. Another is whether there is also an FPRAS for $\mathrm{REL}(p) = 1 - \mathrm{FAIL}(p)$, the question being open only for the case $\mathrm{REL}(p)$ near 0.

This work has studied probabilistic *edge* failures; a question of equal importance is that of network reliability under *vertex* failures. We are aware of no results on the structure of minimum vertex cuts that could lead to the same results as we have derived here for edge cuts. In particular, graphs can have exponentially many minimum vertex cuts. The same obstacle arises in *directed* graphs (where we wish to measure the probability of failing to be strongly connected).

Although the polynomial time bounds proven here are not extremely small, we expect much better performance in practice since most graphs will not have the large number of small cuts assumed for the analysis. Preliminary experiments [16] have suggested that this is indeed the case.

ON THE MAXIMUM SCATTER TRAVELING SALESPERSON PROBLEM[*]

ESTHER M. ARKIN[†], YI-JEN CHIANG[‡], JOSEPH S. B. MITCHELL[§], STEVEN S. SKIENA[¶], AND TAE-CHEON YANG[‖]

Abstract. We study the problem of computing a Hamiltonian tour (cycle) or path on a set of points in order to maximize the minimum edge length in the tour or path. This "maximum scatter" traveling salesperson problem (TSP) is closely related to the bottleneck TSP and is motivated by applications in manufacturing (e.g., sequencing of rivet operations) and medical imaging. In this paper, we give the first algorithmic study of these problems, including complexity results, approximation algorithms, and exact algorithms for special cases. In an attempt to model more accurately the real problems that arise in practice, we also generalize the basic problem to consider a more general measure of "scatter" in which points on a tour or path should be far not only from their immediate predecessor and successor, but also from other near-neighbors along the tour or path.

Key words. traveling salesperson problem, traveling salesman problem, maximum scatter TSP, bottleneck TSP, Hamiltonian cycle/path, approximation algorithms, matching, optimization, Posa conjecture, Dirac's theorem

1. Introduction.

In this paper we study a new class of traveling salesperson problem (TSP) variants that is based on the objective of finding, in an edge-weighted complete graph $G = (S, E)$, a tour (cycle) or a path that is most "scattered." Specifically, the goal is to *maximize* the length of a shortest edge in the tour/path; i.e., to have each point be far from the points that are visited just before or just after it in the tour/path. We refer to this problem as the *maximum scatter TSP*, or the *max-min 1-neighbor TSP*.

More generally, we consider the *max-min m-neighbor TSP* in which the goal is to maximize the minimum distance between any point and all of its "m-neighbors" along the tour/path. An *m-neighbor* of p is a point that is at most m points away

from p in the tour/path. The problem, then, is to find a tour/path, $(p_1, \ldots, p_n)$, on the n points of S in order to maximize

$$\min_{i \in \{1,\ldots,n\}} \min_{j \in \{i-m,\ldots,i-1,i+1,\ldots,i+m\}} d(p_i, p_j),$$

where $d(p_i, p_j)$ denotes the length of edge (p_i, p_j) (*not* the length along the tour/path linking p_i and p_j). The indices in the minimization should be modified appropriately to account for wrap-around effects in cycles, or endpoint effects in paths.

Motivation. This *maximum scatter TSP* problem arises in some manufacturing processes where it is important to have substantial separation (distance) between consecutive (or *nearly* consecutive) operations on a workpiece. We first encountered the problem in discussions with Boeing, where the problem was that of sequencing the riveting operations when fastening sheets of metal together [21, 22]. To prevent nonuniform deformation of the sheet metal plates that are being joined, it is important to sequence the riveting process so that the distance between one rivet and the next one is large; i.e., the riveting operations should be *scattered.* In operations that involve heating the workpiece, it may be important not just to have each point well separated from its immediate predecessor and successor, but also from its m-neighbors, in order to allow for cooling time in the vicinity of each operation.

The maximum scatter TSP also arises in some medical imaging applications, as has been recently studied by Penavic [20]. When imaging physiological functions using a dynamic spatial reconstructor (DSR), the radiation sources are placed along the top half of a circular ring, with sensors placed directly opposite, in the bottom half of the ring. The "firing sequence" determines the order in which the sources, and their partnered sensors, are activated, usually in a periodic pattern. The sensors collect intensity data of the energy that passes through the patient, who is placed in the center of the ring. When source i is activated, some amount of scattering occurs, so it is important not to activate sensors of nearby sources (e.g., $i+1, i-1, i+2, \ldots$) soon after i is activated. This motivated Penavic to study firing sequence orderings for some specific geometries of DSR hardware, and motivates our study (in section 6) of some one-dimensional versions of the maximum scatter problem.

Related Work. A closely related problem is the *bottleneck traveling salesperson problem* (BTSP), in which the goal is to *minimize* the length of a *longest* edge in a Hamiltonian cycle. (See [17].) The BTSP is known to be NP-complete, and no constant factor approximation algorithm can exist unless P=NP. Assuming the edge lengths satisfy the triangle inequality, there exists an approximation algorithm to produce a tour whose longest edge has a length that is at most twice the optimal, and this approximation factor of two is best possible [18]. By similar techniques we obtain similar hardness results for the maximum scatter TSP (in edge-weighted graphs); however, our approximation algorithm is very different from that given in [18], and neither algorithm works for the other problem.

Another variant of the TSP that is potentially related to our work is the MAX TSP, in which the goal is to find a tour whose length is as long as possible. Several approximation algorithms exist for the MAX TSP (without any assumptions on the edge lengths), including a naive algorithm that achieves a 2/3 approximation factor, and a recent algorithm of Hassin and Rubinstein [10] that achieves a 5/7 approximation factor. (See also Kosaraju [16], who claimed an earlier approximation factor of 5/7; however, Bhatia has recently shown that their algorithm gives a bound of 19/27 instead of the claimed 5/7.) However, neither of these algorithms works for our maximum scatter problem. Also, there exists a polynomial-time approximation scheme for geometric (e.g., Euclidean) versions of the MAX TSP [4]. The noncrossing version of geometric MAX TSP is considered in [2]. Very recently, since the original appearance of our own paper [3], Barvinok et al. [5] show that the MAX TSP can be solved exactly in polynomial time, for points in fixed dimension, under a (constant-complexity) polyhedral metric. Most recently, Fekete [8] shows that the Euclidean MAX TSP is NP-hard for the Euclidean metric, in three or more dimensions. His proof also shows that the Euclidean maximum scatter TSP is NP-hard in three or more dimensions. However, the complexity of the MAX TSP, as well as the maximum scatter TSP and the noncrossing MAX TSP, remains open for points in the Euclidean plane.

The most directly related previous work on the maximum scatter TSP has been done by Penavic [19], who studied the optimal firing sequences for a DSR application in which all sources are equally spaced. Our one-dimensional results generalize this previous work.

Summary of Results.

- We show that the maximum scatter TSP is, in general, NP-complete, and that no constant-factor approximation algorithm exists, unless P=NP. We do not yet know the complexity of the *geometric* maximum scatter TSP problem for points in the plane (and Euclidean distances); we conjecture that it is NP-hard. See section 2.
- In the case that distances obey the triangle inequality, we give approximation algorithms (section 3) guaranteed to get within factor 2 of optimal for the maximum scatter TSP, for both the *tour* (cycle) and *path* versions of the problem. Further, we prove that this factor is best possible.
  The methods also extend to give a factor-2 (best factor) approximation for the max-min 2-neighbor TSP, for the cycle version and some cases ($n \neq 3k+1$) of the path version of the problem, by using a very recent result on the *Pósa conjecture* (see section 3). (These extensions are not practical and are of theoretical interest only.)
- We also give (section 4) practical constant-factor approximation results on the max-min 2-neighbor TSP in the case that distances obey the triangle inequality, for both the cycle (factor 64) and path (factor 32) versions of the problem. Our approach utilizes novel methods of applying matching techniques, together with metric properties of the distance matrix, and may be of independent interest.
  These methods extend (section 5) also to yield a constant-factor ($4 \cdot 8^{\lceil m/2 \rceil}$) approximation for the path version of the max-min m-neighbor TSP, for any constant $m > 2$, when n is a multiple of $m+1$.
- We give algorithms (section 6) that find the optimal solution to the max-min 1-neighbor TSP exactly, in some special cases. In particular, we obtain linear-time (optimal) exact algorithms for the case of points on a line, or on a circle, with Euclidean distances, for both the cycle and the path versions of the problems (for the path version of points on a circle, we consider only the case in which n is an odd integer or the points are equally spaced).

Notation. We consider a complete graph, $G = (S, E)$ on a set of points S, with the full edge set E. We let $d(p,q)$ denote the distance between point p and point q, and we let $d_e = d(p,q)$ denote the length of edge $e = (p,q)$. We let $diam(R)$ denote the *diameter* of the set $R \subseteq S$; i.e., $diam(R) = \max_{p,q \in R} d(p,q)$. The (open) *disk* $\mathcal{D}_p(r)$ of radius r, centered at $p \in S$, is defined to be the set of points in S that are at distance less than r from p. The boundary of $\mathcal{D}_p(r)$ is the *circle* consisting of points of S that are at distance exactly r from p.

An algorithm is said to yield a *factor α approximation* for a maximization problem if the algorithm is guaranteed to produce a solution whose objective function value is at least $(1/\alpha)$ times the value of an optimal solution.

2. Complexity considerations: Hardness results. Our first result demonstrates the importance of restricting our problem to graphs having some structure (e.g., edge lengths obeying triangle inequality).

THEOREM 2.1. *There can exist no polynomial-time, constant-performance-bound approximation algorithm for an arbitrary instance of the maximum scatter TSP (cycle or path version), unless P=NP.*

Proof. We consider the cycle version of the problem; the same argument applies for the path version as well. Assume to the contrary that such an algorithm exists, and its performance bound is ρ. We show that this algorithm can be used to test whether a graph has a Hamiltonian cycle. Given an arbitrary graph, $G = (S, E)$, construct an instance of maximum scatter TSP (cycle version) on the complete graph on S, with edge lengths $d_e = 1$ if $e \notin E$, and $d_e = 1 + \rho$ if $e \in E$. If G has a Hamiltonian cycle, the maximum scatter TSP has an objective value of $\rho + 1$; thus, the approximation algorithm must yield a tour whose shortest edge length is greater than 1 (i.e., it produces a Hamiltonian cycle in G). If G does not have a Hamiltonian cycle, then the maximum scatter TSP has an objective value of 1, and therefore the approximation algorithm also yields a tour for which at least one edge has length 1. Thus G is Hamiltonian if and only if the alleged approximation algorithm produces a tour of minimum edge length greater than 1. $\square$

THEOREM 2.2. *There can exist no polynomial-time algorithm for the maximum scatter TSP (cycle or path version) in a graph satisfying the triangle inequality with a performance bound smaller than* 2 *unless P=NP.*

Proof. The proof follows the previous one, except that the weight $\rho+1$ is replaced by weight 2. (Note that the triangle inequality holds in the resulting graph.) $\square$

While the above two results parallel the similar facts known about the bottleneck TSP (BTSP), there is a significant difference in our current knowledge about the BTSP versus the maximum scatter TSP in the case of the geometric versions of these two problems. Specifically, it is easy to see that the BTSP is NP-hard even for points in the plane, using a reduction from Hamiltonian cycle in a grid graph (see [17]): A tour whose maximum edge length is 1 exists in the complete graph whose edge lengths are given by the Euclidean distances if and only if the grid graph is Hamiltonian. This approach does not apply, however, to show NP-hardness of the maximum scatter TSP in the plane; to date, this problem remains open. (In one dimension, the problem is solvable in linear time, as we show in section 6, while in Euclidean 3-space Fekete [8] has recently shown that the problem is NP-hard.)

Next, we show that the max-min m-neighbor TSP is at least as hard as the max-min 1-neighbor (scatter) TSP.

THEOREM 2.3. *In a graph satisfying the triangle inequality, the max-min m-neighbor TSP with $m > 1$ is at least as hard as the max-min* 1*-neighbor TSP for both the cycle and the path versions of the problems.*

Proof. We reduce the problem with $m = 1$ to that with $m > 1$. From the given node set S of the former, we construct another node set S' for the latter. Set S' consists of the original n nodes of S, plus an additional $\lceil \frac{n}{2} \rceil (m-1)$ nodes. Let D and d be the largest and smallest distances between all pairs of nodes in S. We arrange

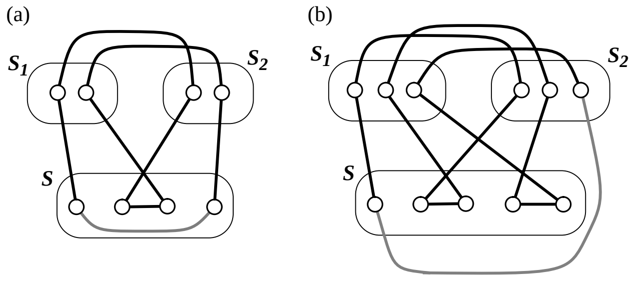

FIG. 2.1. *Examples for the construction in the proof of Theorem* 2.3 *with* $m = 3$: (a) $n = 4$ *is even*; (b) $n = 5$ *is odd. The cycles are given by connecting all* (*solid and dashed*) *edges*, *and the paths are given by removing one edge*, *e.g.*, *the dashed edge*, *from the cycles.*

the $\lceil \frac{n}{2} \rceil (m-1)$ additional nodes of S' into $m-1$ clusters $S_1, \ldots, S_{m-1}$, each with $\lceil \frac{n}{2} \rceil$ nodes. Any pair of nodes in the same cluster are within distance less than d, and any pair of nodes that are in different clusters (treating S as a cluster at this time) are separated by a distance larger than D. There must exist an optimal m-neighbor cycle on S' consisting of $\lceil \frac{n}{2} \rceil$ "rounds," where each round contains exactly two nodes of S and one node from each of $S_1, \ldots, S_{m-1}$ (see Figure 2.1). Observe that for any two nodes in the same cluster (S or S_i), only those in S can possibly be m-neighbors. An optimal 1-neighbor cycle on S can then be obtained from this cycle by skipping the nodes not in S. An optimal m-neighbor path on S' has the same structure except for cutting the cycle open by removing one edge (see Figure 2.1). Again an optimal 1-neighbor path on S can be obtained in the same way. $\square$

The following is immediate from Theorems 2.3 and 2.2.

COROLLARY 2.4. *There can exist no polynomial-time algorithm for the max-min m-neighbor TSP (cycle or path version) in a graph satisfying the triangle inequality with a performance bound smaller than* 2, *unless P=NP.*

3. Approximating the max-min 1-neighbor TSP.

In this section, we consider the maximum scatter (max-min 1-neighbor) TSP, for both the cycle and path versions, on the complete graph $\mathcal{G} = (S, E)$, whose edges are weighted with nonnegative lengths that satisfy the triangle inequality. In the riveting problem, S may be points in the plane, and edges are assigned Euclidean lengths.

We first mention that some of the natural approaches do not work in this case:

(1) The BTSP, in which we must minimize the longest edge (vs. maximizing the shortest edge), has a 2-approximation algorithm [18], which works as follows: First, find a biconnected subgraph of the given graph that minimizes the longest edge; the square of this biconnected graph is Hamiltonian; finally, we trace a Hamiltonian tour in the square of the graph. However, this approach does not yield an approximation for the maximum scatter TSP.

(2) The MAX TSP also has constant factor approximation algorithms (e.g., to get within factor 5/7 of optimal [16]), but again the methods do not yield approximations for the maximum scatter TSP. The reason for this is that the algorithms for MAX TSP generate "long" paths, and then connect them arbitrarily into a cycle, since the added edges will only add to the length of the tour. However, in the scatter problem, adding a very short edge at this stage can drastically reduce the scatter (minimum length edge) obtained, resulting in a tour that is far from optimal.

(3) A natural greedy algorithm (select the next point to be the unvisited one that is furthest away) also fails for the maximum scatter TSP, as there are simple examples showing that it can yield paths or tours that are arbitrarily bad with respect to optimum.

(4) For the geometric version of the maximum scatter TSP in the plane, we have also attempted to use our one-dimensional (exact) results, by projecting the points onto each of a small number of axes, solving the one-dimensional problems on those axes, and then lifting back to two dimensions. However, bad examples exist for this approach as well.

We now present a new approximation method that does yield provably good solutions. We concentrate for now on the cycle version of the problem. We make use of the following theorem due to Dirac [6]: *If every node of a graph having n nodes ($n \geq 3$) has degree $\geq \lceil \frac{n}{2} \rceil$, then the graph has a Hamiltonian cycle.* We devise an efficient algorithmic version of Dirac's proof in our proof of Theorem 3.5 below; we are not aware of an algorithmic proof appearing in the literature.

Our algorithm is very simple: We consider the edges E in order of increasing length. We delete edges, one by one, starting with the shortest one and stopping when the deletion of an edge, say, $e = (u, v)$ (of length $d_e = d(u, v)$), would cause a node (say, v) to have degree *less* than $\lceil \frac{n}{2} \rceil$. Let $\mathcal{G}' = (S, E')$ be the graph that remains. By definition, then, E' includes edge $e = (u, v)$, as well as all other edges of length at least d_e.

By Dirac's theorem, we know that $\mathcal{G}'$ has a Hamiltonian cycle. We can find such a cycle (call it C) in $O(n^2)$ time (see Theorem 3.5). A shortest edge of C has length at least d_e.

Let d^* be the length of a shortest edge of an optimal tour.

LEMMA 3.1. *Let $R \subset S$ be a subset of nodes with $|R| > \lfloor \frac{n}{2} \rfloor$ (resp., $|R| > \lceil \frac{n}{2} \rceil$). Then, in any Hamiltonian cycle (resp., path) on S, there must exist an edge joining two nodes of R.*

Proof. Let $k = \lfloor \frac{n}{2} \rfloor$ and $S_{out} = S \setminus R$. To avoid having any edge joining two nodes of R in a Hamiltonian cycle, all nodes in R must be connected only to nodes in S_{out}, which is impossible since the total number of edges out of R is at least $2k + 2$ but such a number for S_{out} is at most $2k$. We use the same argument to prove the case of a Hamiltonian path. Letting $k = \lceil \frac{n}{2} \rceil$, we have that the total number of edges out of R is at least $2 + 2[(k + 1) - 2] = 2k$ but such a number for S_{out} is at most $2(k - 1)$. ◻

We later also use the following immediate generalization of Lemma 3.1.

LEMMA 3.2. *For any integer $m \geq 1$, let $R \subset S$ be a subset of nodes with $|R| > \lfloor \frac{n}{m+1} \rfloor$ (resp., $|R| > \lceil \frac{n}{m+1} \rceil$). Then, in any Hamiltonian cycle (resp., path) on S, there must exist two nodes of R that are m-neighbors.*

COROLLARY 3.3. *Let $R \subset S$ be a subset of nodes with $|R| = \lfloor \frac{n}{2} \rfloor + 1$. Then, $d^* \leq diam(R)$.*

LEMMA 3.4. *$d^* \leq 2d_e$, where d_e is the length of the edge, $e = (u, v)$, which is the first edge* not *to be deleted in our algorithm, as its deletion would result in the degree of v being $< \lceil \frac{n}{2} \rceil$.*

Proof. Let $R = \{u\} \cup N_v$, where N_v denotes the set of nodes w such that $(v, w) \notin E'$. (Note that $v \in N_v$, since we do not allow self-loops, and that $u \notin N_v$.) Thus, R includes all nodes at distance at most d_e from node v, and node v itself. By specification of the algorithm, $|S \setminus N_v| \geq \lceil \frac{n}{2} \rceil$, while $|S \setminus R| < \lceil \frac{n}{2} \rceil$. Thus, $|R| = \lfloor \frac{n}{2} \rfloor + 1$, so, from Corollary 3.3, $d^* \leq diam(R)$. However, since all nodes of R are at distance

$\leq d_e$ from v, we know, from the triangle inequality, that $diam(R) \leq 2d_e$. Thus, $d^* \leq 2d_e$. ∎

THEOREM 3.5. *Given a complete graph on set S of n points satisfying triangle inequality, there exists an $O(n^2)$-time approximation algorithm for the maximum scatter TSP on S that produces a Hamiltonian tour whose shortest edge is at least $\frac{1}{2}$ times optimal. The approximation factor is the best possible unless P=NP.*

Proof. The approximation factor and its optimality follow from Lemma 3.4 and Theorem 2.2. The $O(n^2)$ running time can be accomplished as follows. First, in overall time $O(n^2)$, we find for each node the median weight (the $\lceil \frac{n}{2} \rceil$th longest) edge among those edges incident on it. By taking the minimum of these n medians, we find the length of the critical edge, e, and therefore can easily identify the edges E' of the graph $\mathcal{G}'$ by deleting all edges of E shorter than e. Our algorithm now resembles a constructive version of Dirac's proof. We start with a Hamiltonian cycle in the complete graph; this is trivially found. Then, we delete edges (u, v), one by one, which are *not* in E'. With each deletion, we modify the existing Hamiltonian cycle, $u = v_1, v_2, \ldots, v_{n-1}, v_n = v$, swapping out edges (u, v) and (v_i, v_{i+1}), and swapping in edges (u, v_{i+1}) and (v_i, v), where $i \in \mathcal{S} \cap \mathcal{T}$ is an index in the intersection of $\mathcal{S} = \{i : (u, v_{i+1}) \in E'\}$ and $\mathcal{T} = \{i : (v_i, v) \in E'\}$. As in Dirac's proof, $\mathcal{S} \cap \mathcal{T}$ must be nonempty, since $|\mathcal{S} \cup \mathcal{T}| < n$ (since $n \notin \mathcal{S}, \mathcal{T}$) and $|\mathcal{S} \cup \mathcal{T}| + |\mathcal{S} \cap \mathcal{T}| = |\mathcal{S}| + |\mathcal{T}| = deg(u) + deg(v) \geq n$. By representing the sets $\mathcal{S}$ and $\mathcal{T}$ with bit vectors of length n each, where bit j indicates if index j belongs to the set, we can find $i \in \mathcal{S} \cap \mathcal{T}$ in $O(n)$ time. Note that the new edges in the resulting Hamiltonian cycle, (u, v_{i+1}) and (v_i, v), are both in E', i.e., we never introduce new edges that need to be deleted. Therefore we need to perform the deletions at most n times, in overall time $O(n^2)$. ∎

Now we consider the path version of the problem. One simple way is to add a *fake point* Q very far away from all points of S so that it does not affect the max-min edge length at all, and then solve the cycle problem. When we get the answer that is a cycle, we simply cut the cycle open at Q to get a path, and then remove Q. Notice that using Lemma 3.1, we have a corollary for the *path version* similar to Corollary 3.3: Any subset R of S with $|R| = \lceil \frac{n}{2} \rceil + 1$ has $d^* \leq diam(R)$, where d^* is now the optimal max-min edge length of Hamiltonian paths. When we apply our cycle algorithm, the problem size is $n' = n + 1$, for which we take the size of R to be $\lfloor \frac{n'}{2} \rfloor + 1 = \lceil \frac{n}{2} \rceil + 1$, which is exactly the desired size of R for the *path* version.

COROLLARY 3.6. *Given a complete graph on set S of n points satisfying triangle inequality, there exists an $O(n^2)$-time approximation algorithm for the maximum scatter TSP on S that produces a Hamiltonian path whose shortest edge is at least $\frac{1}{2}$ times optimal. The approximation factor is the best possible unless P=NP.*

4. Approximating the max-min 2-neighbor TSP.

We turn now to the problem of approximating the max-min 2-neighbor TSP. We begin by pointing out, as observed by Khuller [12], that our method for the max-min 1-neighbor TSP can be directly extended to work for the cycle version of the max-min 2-neighbor TSP, if the following *Pósa conjecture* (which is a generalization of Dirac's theorem) is true: *If every node of an n-node graph has degree $\geq \lceil \frac{2}{3} n \rceil$, then the graph contains the square (i.e., the second power) of a Hamiltonian cycle.* Here the kth *power* of a cycle C is the graph obtained by joining every pair of nodes that are k-neighbors in C. Very recently, the Pósa conjecture has been proved for a very large n [14]. Also, the proof leads to a polynomial-time algorithm [12, 13]. Thus we have the following result.

THEOREM 4.1. *Given a complete graph on a set S of n points, with edge lengths satisfying the triangle inequality, there exists a polynomial-time approximation algorithm that constructs a Hamiltonian cycle on S whose objective value for the max-min 2-neighbor problem is at least $\frac{1}{2}$ times the optimal. The approximation factor is the best possible, unless P=NP.*

Notice that the node-degree condition in the Pósa conjecture does not work well for us in the path version unless $n = 3k$; see Lemma 3.2. For $n = 3k + 2$, we can again add a fake point Q very far away, construct a cycle, and then remove Q to obtain a desirable path. But when $n = 3k + 1$, the same trick requires us to add two fake points Q and Q'. In constructing a cycle, we also need to make sure that Q and Q' are next to each other (so that removing Q and Q' does not break the final path), which might not be easy to do. We do not explore this further here.

COROLLARY 4.2. *Given a complete graph on set S of n points satisfying triangle inequality, where $n = 3k$ or $n = 3k + 2$, there exists a polynomial-time approximation algorithm that constructs a Hamiltonian path on S whose objective value for the max-min 2-neighbor problem is at least $\frac{1}{2}$ times the optimal. The approximation factor is the best possible unless P=NP.*

Remark 1. Theorem 4.1 and Corollary 4.2 are of theoretical interest only. The current proof of the Pósa conjecture is quite complex and uses the *regularity lemma* that holds only for a very large n [14]. To turn the proof into an algorithm, it is necessary to use an algorithmic version of the regularity lemma that runs in polynomial time. Such an algorithm is given in [1]. To get an idea about how large n should be, we quote the following sentences from [1, p. 474]:

> We note that the dependence of $Q(\epsilon, t)$ on ϵ and t, as well as the running time of the algorithm on these two parameters is rather horrible; in fact, $\log^* Q$ is a polynomial (of degree about 20) in $1/\epsilon$ and in t.

As described in [1], the regularity lemma is valid for $n > Q$, where $Q = Q(\epsilon, t)$ is a function of given (fixed) parameters $\epsilon > 0$ and t (a positive integer). In typical applications, ϵ is small (and thus $1/\epsilon$ is large) and t is large. Even if we take $t = 2$ and $\epsilon = 1$, this means that n has to be larger than Q, where $\log^* Q \approx 2^{20}$!

Remark 2. An algorithmic proof of the following *Seymour conjecture* (a generalization of the Pósa conjecture) would also imply a factor-2 (optimal factor) approximation algorithm for the cycle version of the max-min m-neighbor TSP: If every node of an n-node graph has degree $\geq \lceil \frac{m}{m+1} n \rceil$, then the graph contains the mth power of a Hamiltonian cycle. Currently the conjecture is proved for the case when every node has degree $\geq (\frac{m}{m+1} + \epsilon)n$, for any $\epsilon > 0$, by using the regularity lemma [15].

We turn now to describe our own approximation method for the cycle and path versions of the max-min 2-neighbor TSP. Our method is *not* based in any way on the Pósa conjecture. Although the approximation factors are not optimal, the algorithms are simple and practical. Also, unlike Corollary 4.2, the algorithms work for all cases for the path version as well. Furthermore, the techniques can be extended to obtain an approximation for the max-min m-neighbor TSP, for *any* constant $m > 2$ (see section 5), not just $m = 2$.

Our main results are constant-factor approximation algorithms, which utilize novel methods of applying matching techniques, together with metric properties of the distance matrix, to search for "large" triangles (cycles of three nodes) that can then be concatenated to form provably good tours and paths for the 2-neighbor problem. Our overall strategy consists of the following steps:

1. Construct $\lfloor n/3 \rfloor$ vertex-disjoint *large* triangles whose vertices are the points in S. Here, by "large" we mean that all three sides of the triangles have lengths at least a constant fraction of the upper bound, $2r$ (see Lemma 4.3). (Of course, if n is not a multiple of 3, there are one or two points not part of any triangle, but this complication can be handled, as we see later.)
2. Concatenate these large triangles together in order to create a Hamiltonian path or cycle such that the distances between any 2-neighbors are large.

We elaborate these steps in the following sections.

4.1. Constructing large triangles. We describe how to construct large triangles. We assume without loss of generality that there are no two distances between points that are exactly the same. (If $d(p_i, p_j) = d(p_{i'}, p_{j'})$, where $i < j$ and $i' < j'$, then we consider edge (p_i, p_j) to be shorter than edge $(p_{i'}, p_{j'})$ if (i, j) is lexicographically less than (i', j').)

Let $\mathcal{C}$ denote a smallest circle, having a radius denoted by r, centered at one of the n points such that the corresponding (open) disk contains exactly $\lfloor n/3 \rfloor$ points of S (including the center point) interior to the circle. By definition, then, $\mathcal{C}$ passes through exactly one point of S (which is not, of course, counted as one of the $\lfloor n/3 \rfloor$ interior points).

Lemma 4.3. *The max-min distance in the cycle version of a* 2*-neighbor TSP is at most* $2r$.

Proof. The proof is immediate from Lemma 3.2. □

Computationally, r and $\mathcal{C}$ can be found as follows. For each point we find as a candidate the $\lfloor \frac{n}{3} \rfloor$th shortest edge among all edges incident on the point. The shortest edge among these n candidates defines r and the center of $\mathcal{C}$. Clearly, the computation takes $O(n^2)$ time.

For simplicity of exposition, we now assume that n is a multiple of 3. We will handle the other cases later. After computing r and $\mathcal{C}$, we use Algorithm *Big-Triangles* to construct $n/3$ vertex-disjoint large triangles, using n points of S as vertices, as follows.

Algorithm Big-Triangles**.** The algorithm takes r, $\mathcal{C}$, and S as input, and constructs $n/3$ vertex-disjoint large triangles using n points of S as vertices. It consists of the following three phases.

1. *The point-point matching phase.* Consider the bipartite graph $G = (V_1, V_2, E)$, where V_1 is the set of points inside the disk defined by $\mathcal{C}$ and V_2 is the set of points outside the disk, including the point on the boundary $\mathcal{C}$. Edge set E consists of "long" edges from V_1 to V_2, between two nodes whose distance is at least r. Refer to Figure 4.1. Note that $|V_1| = n/3$ and $|V_2| = (2n)/3$. Perform a maximum cardinality matching on G. By Lemma 4.4 (below), all nodes of V_1 are matched. For each matched pair, create a segment e by connecting the two points. Clearly, each such e is of length at least r.

Lemma 4.4. *There is a matching in G in which all nodes of V_1 are matched.*

Proof. We use Hall's theorem [9], which states that a "complete" matching of V_1 into V_2 exists if and only if for every subset A of V_1, $|A| \le |\Gamma(A)|$, where $\Gamma(A)$ is a set of those vertices of V_2 that are adjacent to at least one vertex in A.

We assume, by way of contradiction, that there exists a set $A \subseteq V_1$ for which $|A| > |\Gamma(A)|$. Consider now the nodes of $V_2 \setminus \Gamma(A)$. The cardinality of this set satisfies

$$|V_2 \setminus \Gamma(A)| = |V_2| - |\Gamma(A)| > |V_2| - |A| \ge n/3,$$

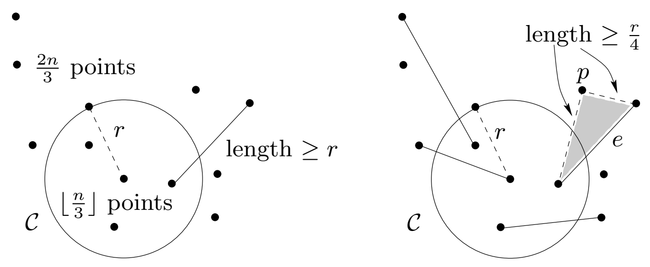

FIG. 4.1. *Left: Point-point matching phase of* Big-Triangles*. Right: Segment-point matching phase.*

since $|A| \leq |V_1| = n/3$ and $|V_2| = (2n)/3$. Furthermore, by definition, all of these points are at a distance less than r from all points of A. A disk, centered at an arbitrary point of A of radius r contains this center point as well as all of the points of $V_2 \setminus \Gamma(A)$, i.e., at least $n/3 + 2$ points in total, in its *interior*, contradicting the original choice of r. ▯

2. *The segment-point matching phase.* We now create a bipartite graph $H = (W_1, W_2, \mathcal{E})$, in which the nodes W_1 are the edges (segments) e that form the point-point matching created in phase 1, and the nodes W_2 are the points of V_2 that are *not* matched in phase 1. Note that $|W_1| = |W_2| = n/3$. The edge set $\mathcal{E}$ is specified as follows: there is an edge between node $e \in W_1$ and point $p \in W_2$ if and only if p is separated from *both* endpoints of the segment e by a distance at least $r/4$. Refer to Figure 4.1. Perform a maximum (maximal suffices) matching on H. Now, for each matched pair, e and p, create a triangle by connecting p with the two endpoints of e. If the matching is a perfect matching, stop (there are $n/3$ triangles whose edge lengths are at least $r/4$); otherwise go to the next phase.

3. *The swapping phase.* Let P be the set of "left-over" points not yet in any triangle, and E' be the set of "left-over" segments (created in phase 1) connecting points of S that are not yet in any triangle. Note that $|P| = |E'| = n/3 - T$, where T is the size of the matching in phase 2.

Let $e = (v_1, v_2) \in E'$ be an arbitrary left-over segment, and let $C_i = \mathcal{D}_{v_i}(r/2)$ and $c_i = \mathcal{D}_{v_i}(r/4)$, for $i = 1, 2$, be the (open) disks centered at v_i with radii $r/2$ and $r/4$, respectively. Since e is not matched with any point of P in phase 2, all points in P are within distances less than $r/4$ from at least one endpoint of e, i.e., $P \subset c_1 \cup c_2$. We define $P_i = c_i \cap P$, $i = 1, 2$; we refer to P_i as a *cluster*. Since e has length at least r, $c_1 \cap c_2 = \emptyset$; thus, (P_1, P_2) partition P. Now, the partition (P_1, P_2) has been defined in terms of the particular edge $e \in E'$; however, the choice of e does not matter as far as the partition is concerned.

LEMMA 4.5. *Each choice of $e \in E'$ results in the same partition of P.*

Proof. Suppose that two distinct edges, $e = (v_1, v_2) \in E'$ and $e' = (v_1', v_2') \in E'$, give rise to two distinct partitions (P_1, P_2) and (P_1', P_2'), respectively. Then, there is some pair of points, $p_1, p_2 \in P$, that is split by one partition but not by the other: without loss of generality, assume that $p_1 \in P_1$ and $p_1 \in P_1'$, while $p_2 \in P_2$ and $p_2 \in P_1'$. Then, $d(p_1, p_2) > r/2$, since $d(v_1, p_1) + d(p_1, p_2) + d(p_2, v_2) \geq d(v_1, v_2) \geq r$ implies that $d(p_1, p_2) > r - d(v_1, p_1) - d(p_2, v_2) \geq r - (r/4) - (r/4) = r/2$. On the other hand, since $p_1, p_2 \in P_1'$, we get that $d(p_1, p_2) \leq d(p_1, v_1') + d(v_1', p_2) < r/4 + r/4 = r/2$ (since $d(p_1, v_1') \neq d(v_1', p_2)$, and $d(p_1, v_1'), d(v_1', p_2) \leq r/4$), a contradiction. ▯

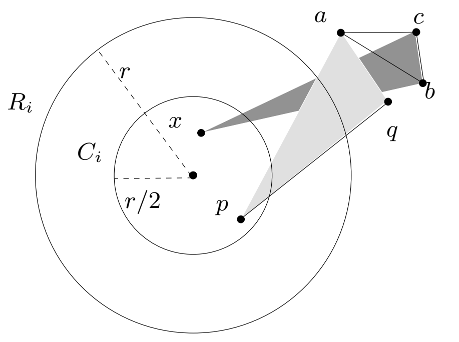

FIG. 4.2. *Swapping: $\triangle abc$ is a good triangle with respect to P_i, having edge lengths at least $r/4$. Then, triangles $\triangle pqa$ and $\triangle xbc$ have edge lengths at least $r/8$.*

LEMMA 4.6. *If $P_i \neq \emptyset$, then each segment of E' has exactly one endpoint in C_i.*

Proof. Let $p \in P_i$ and let $e' \in E'$ be any left-over segment. Since p is not matched in phase 2 with e', we know that $d(p, v') < r/4$ for an endpoint v' of e'. Then, $d(v', v_i) \leq d(v', p) + d(p, v_i) < r/2$, implying that $v' \in C_i$, so e' has at least one endpoint in C_i. Further, e' cannot have both endpoints in C_i, since e' has length greater than r, while C_i has radius $r/2$. ◻

We call (P_1, P_2) a 1-*partition* if some P_i is empty, and a 2-*partition* otherwise. For simplicity, unless otherwise stated, the following discussions assume that (P_1, P_2) is a 2-partition; the case of a 1-partition is easily handled.

For $i = 1, 2$, let $R_i = \mathcal{D}_{v_i}(r)$ be the disk of radius r that is concentric with C_i. We call a triangle $\triangle abc$ constructed from phase 2 *good* with respect to P_i if a, b, and c are all outside or on the boundary of R_i, and *bad* otherwise.

LEMMA 4.7. *Let $\triangle abc$ be a good triangle with respect to P_i whose edge lengths are at least $r/4$. Consider any segment $e = (p, q) \in E'$. Since we know (Lemma 4.6) that e has exactly one endpoint in C_i, we can assume without loss of generality that $p \in C_i$ and that $q \notin C_i$ is closer to b than to a and c. Then, for any $x \in P_i$, the triangles $\triangle pqa$ and $\triangle xbc$ have edge lengths at least $r/8$.*

Proof. Points a, b, and c are each at distance at least $r/2$ from each of x and p, since a, b, and c are each at distance at least r from the center, v_i, of R_i, while x and p are each within distance $r/2$ from v_i. Also, recall that e has length at least r. If $d(b, q) \geq r/8$, then $\triangle pqa$ and $\triangle xbc$ have edge lengths at least $r/8$. Otherwise, $d(q, a) \geq r/8$, since $d(q, a) + d(q, b) \geq d(a, b) \geq r/4$, and again $\triangle pqa$ and $\triangle xbc$ have edge lengths at least $r/8$. Refer to Figure 4.2. ◻

The operation of replacing a good triangle ($\triangle abc$), a left-over edge ($e = (p, q) \in E'$), and a left-over point ($x \in P_i$) with a pair of triangles ($\triangle pqa$ and $\triangle xbc$) is called a *swapping operation*. The above lemma assures us that the edge lengths of the new triangles are "large" (at least $r/8$), if the new triangles are as specified in the lemma.

Phase 3 proceeds by constructing C_i and R_i, $i = 1, 2$, then performing the swapping operation for all points in P_1 (*swapping stage* 1), and then performing the same operation for all points in P_2 (*swapping stage* 2). By Lemma 4.8 (given below), there are always enough good triangles to complete the swapping operations, so that all points are now vertices of $n/3$ triangles, each having edge lengths greater than $r/8$.

LEMMA 4.8. *There are always enough good triangles to complete the swapping operations on all points in P_1 and all points in P_2. Also, after completion of Algorithm* Big-Triangles, *the smallest edge length of all $n/3$ triangles is at least $r/8$.*

Proof. We first consider swapping stage 1. At the end of phase 2, suppose there are T triangles, ℓ unmatched segments (and points), $|P_1| = \ell_1$, and $|P_2| = \ell_2$; then we have $T + \ell = n/3$, and $\ell_1 + \ell_2 = \ell$. Let $T_{1,bad}$ be the number of bad triangles with respect to P_1. If t_1 is the total number of vertices of these triangles that are inside R_1, then $t_1 \geq T_{1,bad}$, since each bad triangle has at least one vertex inside R_1. Recall that R_1 is a disk of radius r; thus, by our choice of r, R_1 contains at most $n/3$ points. These points include ℓ endpoints from unmatched segments, ℓ_1 points of P_1, and t_1 vertices from bad triangles. Therefore we have $n/3 \geq \ell + \ell_1 + t_1 \geq \ell + \ell_1 + T_{1,bad}$. Let $T_{1,good}$ be the number of good triangles with respect to P_1. Then $T_{1,good} = T - T_{1,bad} = (n/3 - \ell) - T_{1,bad} \geq (n/3 - \ell) - (n/3 - \ell - \ell_1) = \ell_1$, i.e., there are enough good triangles for the points in P_1. For swapping stage 2, the situation is the same except that now $\ell = \ell_2$, meaning that we have a 1-partition, and the same counting argument applies. Finally, the smallest edge length of triangles at the end of phase 2 is at least $r/4 = \delta$. During phase 3, let $\triangle abc$ be a good triangle for P_1, and in swapping stage 1 we swap $\triangle abc$ with a segment $e = (p, q) \in E'$ and a point $x \in P_1$ to produce $\triangle pqa$ and $\triangle xbc$, as shown in the proof of Lemma 4.7. Notice that $\triangle pqa$, with edge lengths at least $\delta/2$, is now *bad* for P_2 (and also for P_1) and will not be used for swapping in swapping stage 2. Also, $\triangle xbc$ has edge lengths at least δ rather than $\delta/2$. Applying Lemma 4.7 again in swapping stage 2, the smallest edge length of the final triangles is still at least $\delta/2 = r/8$. □

Now, for n not being a multiple of 3, i.e., $n = 3k + l$, $l = 1$ or 2, we perform exactly the same operations. Note that the disk defined by $\mathcal{C}$ contains k points of S; $2k + l$ points of S lie outside the disk (including the one point on its boundary, $\mathcal{C}$). Applying Algorithm Big-Triangles then gives k large triangles, using up all k points in the interior of $\mathcal{C}$, with one or two points left over, outside, or on the boundary of $\mathcal{C}$.

To analyze the complexity, we note that phases 1 and 2 are just maximum cardinality matching and maximal matching for bipartite graphs, which can be done in time $O(n^{2.5})$ (either by the $O(n^{2.5})$-time algorithm of [11] or by the $O(\sqrt{n}m)$-time algorithm of [7], where $m = O(n^2)$ is the number of edges in the graphs). In phase 3, we consider an arbitrary edge $e \in E'$ and the disks (C_i and R_i) of radii $r/2$ and r centered at its endpoints, identify the corresponding good/bad triangles, and perform local swappings, in $O(n)$ time per swap. Finally, as analyzed before, radius r and circle $\mathcal{C}$ are determined in $O(n^2)$ time.

THEOREM 4.9. *Given a complete graph on set S of n points satisfying triangle inequality, there exists an algorithm that constructs in $O(n^{2.5})$ time $\lfloor n/3 \rfloor$ triangles from points in S such that the smallest edge length of the triangles is at least $r/8$, where r is the radius of a smallest disk centered at a point of S, containing exactly $\lfloor n/3 \rfloor$ points in its interior, and one additional point on its boundary.*

4.2. Concatenating the triangles. We first show how to concatenate the triangles into a Hamiltonian path, and then show how to make a Hamiltonian cycle.

THEOREM 4.10. *Given a list of triangles $\Delta_1, \Delta_2, \ldots, \Delta_k$, whose minimum edge length is δ, the triangles can be chained into a path such that any two nodes that are 2-neighbors in the path are at distance at least $\delta/2$ from each other.*

In fact, the order in which the triangles are placed in the path is arbitrary, so that any permutation on the triangles is possible. This will be used to complete a cycle.

To prove the theorem, we can arrange the order in which the vertices of a triangle is visited, according to the following lemma.

LEMMA 4.11. *We are given a triangle $\triangle abc$, whose nodes are visited in that order by a path, and a triangle $\triangle xyz$ to be added after $\triangle abc$, such that all six edges in both* *triangles are of length at least δ. Then the order of the nodes of triangle $\triangle xyz$ can be chosen such that, in the resulting path, if $p \in \{a, b, c, x, y, z\}$ and $q \in \{a, b, c, x, y, z\}$ are 2-neighbors, then $d(p, q) \geq \delta/2$.*

Proof. We need to satisfy the following requirements: (1) the first two nodes of triangle $\triangle xyz$ visited must each be at distance at least $\delta/2$ from c, and (2) the first node of triangle $\triangle xyz$ visited must be at distance at least $\delta/2$ from b. This task can be carried out as follows: (1) among nodes x, y, and z, the one that is closest to c (say, x) is visited last, and (2) between the remaining two nodes, the one that is closer to b (say, y) is visited second to last; this fixes the entire ordering of visiting the nodes. To verify, consider requirement (1) first. If $d(c, x) \geq \delta/2$, then the requirement is trivially satisfied. If $d(c, x) < \delta/2$, then we have $d(c, y) > \delta/2$, since $d(x, y) \geq \delta$ ((x, y) is an edge of triangle $\triangle xyz$) and $d(c, y) + d(c, x) \geq d(x, y)$. Similarly, we have $d(c, z) > \delta/2$. This completes the verification of requirement (1). Requirement (2) is satisfied by exactly the same argument. ▯

The proof of the theorem is now immediate. Start the path with any triangle, in any order of the vertices, and keep adding new triangles to the path, one at a time, according to the lemma.

Now we can directly apply Theorem 4.10 to obtain a Hamiltonian path, if n is a multiple of 3. Combining Theorem 4.10 and Theorem 4.9, the shortest distance among all 2-neighbors in the path is at least $r/16$. Recall that, from Lemma 3.2 and the definition of r given in section 4.1, the objective value of an optimal Hamiltonian path for max-min 2-neighbor problem is at most $2r$.

THEOREM 4.12. *Given a complete graph on set S of n points satisfying triangle inequality, where n is a multiple of 3, there exists an algorithm that constructs in $O(n^{2.5})$ time a Hamiltonian path on S whose objective value for the max-min 2-neighbor problem is at least $\frac{1}{32}$ times the optimal.*

Now consider the case in which n is *not* a multiple of 3. Let $k = \lfloor n/3 \rfloor$, and $n = 3k + l$, where $l = 1$ or 2. Recall from section 4.1 that at the completion of Algorithm Big-Triangles, we have k triangles and one or two left-over points outside or on the boundary ($\mathcal{C}$) of the disk of radius r. We will combine such left-over points with existing triangles, and then perform the concatenation.

For each left-over point $p \in S$ that is not a vertex of an existing triangle, we claim that we can find an existing triangle $\triangle abc$ (with edge length at least δ $(= r/8)$) such that p is at a distance at least r $(> \delta)$ from each of a, b, and c. We call $\triangle abc$ a *good* triangle for p. To prove this claim, note, from the definition of r, that there are at most k points (including p) in the open disk $\mathcal{D}_p(r)$. Thus, there are at most $k - 1$ triangles having at least one vertex in $\mathcal{D}_p(r)$, meaning that there exists some triangle $\triangle abc$ whose vertices are each outside (or on the boundary of) $\mathcal{D}_p(r)$, as claimed. We create a special "triangle," *abcp*.

If $n = 3k + 2$, let p and q denote the two left-over points. We know that each has a good triangle. If each has a distinct good triangle we obtain two special "triangles," each with four vertices. Otherwise, p and q have a common good triangle, $\triangle abc$. We claim then that $d(p, q) \geq r > \delta$; otherwise, the disk $\mathcal{D}_p(r)$ contains q, as well as at least one vertex of each of the $k - 1$ other large triangles, contradicting the choice of r. Thus we obtain one special "triangle" with five vertices, *abcpq*, with pairwise distances of at least δ.

We now treat the special "triangles" (*abcp*, *abcq*, or *abcpq*) as if they were triangles during the concatenation process. In order to concatenate it with its predecessor triangle, we treat it as triangle $\triangle abc$. The predecessor will fix a specific ordering of points a, b, and c to be visited; we then visit the remaining points of the "triangle" (p, q, or both p and q). In order to concatenate a triangle after it, we consider only the last point (p or q) and its two previously visited points as a triangle, and apply the same lemma (Lemma 4.11).

Combining Algorithm Big-Triangles with Theorem 4.10, we obtain an algorithm to construct a Hamiltonian path whose max-min 2-neighbor distance is at least $\frac{1}{32}$ times the optimal max-min 2-neighbor distance of a Hamiltonian cycle. We have proved the following lemma.

LEMMA 4.13. *Given a complete graph on set S of n points satisfying triangle inequality, there exists an algorithm that constructs in $O(n^{2.5})$ time a Hamiltonian path on S whose max-min 2-neighbor distance is at least $\frac{1}{32}$ times the optimal max-min 2-neighbor distance of a Hamiltonian cycle.*

In order to construct a Hamiltonian path whose objective function value is at least $\frac{1}{32}$ times that of an optimal *path* (as opposed to an optimal *cycle*, as in the above lemma), considerably more effort is required. The modifications to the algorithm and the analysis are given in Appendix A, where we prove the following theorem.

THEOREM 4.14. *Given a complete graph on set S of n points satisfying triangle inequality, there exists an algorithm that constructs in $O(n^{2.5})$ time a Hamiltonian path on S whose objective value for the max-min 2-neighbor problem is at least $\frac{1}{32}$ times the optimal.*

Since the Hamiltonian path on S obtained in Lemma 4.13 above has a max-min 2-neighbor distance provably close to the optimal max-min 2-neighbor distance in a *cycle*, we can use it to obtain an approximation algorithm for the cycle version of the problem, by appropriately "closing" the path into a tour.

THEOREM 4.15. *Given a complete graph on set S of n points satisfying triangle inequality, there exists an algorithm that constructs in $O(n^{2.5})$ time a Hamiltonian cycle on S whose max-min 2-neighbor distance is at least $\frac{1}{64}$ times the optimal.*

Proof. Given a list of triangles (with possibly one or two being special triangles), whose minimum edge length is at least $\delta = r/8$, we use the following process to chain the triangles into a cycle such that any two nodes that are 2-neighbors in the cycle are at distance at least $\delta/4$.

We first check if there is any pair of triangles $\triangle abc$ and $\triangle xyz$ such that two vertices of $\triangle abc$, say, a and b, are each at a distance at least $\delta/4$ from each of x, y, and z. If so, chain the triangles starting with $\triangle abc$ (visiting in that order) and end with $\triangle xyz$ (in the order required by its predecessor), by applying Lemma 4.11. The ordering of the other triangles is arbitrary.

We assume from now on that no such pair of triangles exists. We consider an arbitrary triangle $\triangle abc$, and construct disks C_a, C_b, and C_c, respectively, centered at a, b, and c, each with radius $\delta/4$. Since the search in step 1 is not successful, C_a, C_b, and C_c must together contain (in their *interiors*) at least two vertices of each of the remaining triangles (each disk contains at most one vertex of a triangle since each triangle edge has length at least δ). We say that a triangle is *covered* by a pair of disks $\{C_a, C_b\}$ if its two vertices are respectively contained in (the interiors of) C_a and C_b.

First, consider the case in which there are no special triangles.

Case (a). *One pair of disks, say, $\{C_b, C_c\}$, covers all triangles.*
Then, all triangles are of type xBC, where B and C denote the vertices, respectively, inside C_b and C_c (all such vertices form *clusters* B and C), and x denotes the third vertex (possibly $x \in A$, where cluster A is defined similarly). It is easy to see that any two points in different clusters are at a distance larger than $\delta/2$. Also, any such point

x is at a distance greater than $\delta/2$ from any point in B (resp., C). (Suppose $\triangle xb'c'$ is one such triangle with $b' \in B$. For any point $b'' \in B$, $d(b', b'') < \delta/2$, but $d(x, b') \geq \delta$, and thus $d(x, b'') \geq d(x, b') - d(b', b'') > \delta/2$.) Construct the Hamiltonian cycle by repeatedly traversing the triangles in the order of xBC, and finally going back to the starting point (denoted by $xBC \rightarrow$ starting point).

Case (b). *Two pairs of disks, say,* $\{C_b, C_c\}$ *and* $\{C_a, C_c\}$, *are necessary and sufficient to cover all triangles.*

Then there are three types of triangles: ABC, xBC, and yAC, where $x \notin A$ is at distance greater than $\delta/2$ from any point of B (resp., C) and $y \notin B$ is at distance greater than $\delta/2$ from any point of A (resp., C), by the same argument above. Construct the Hamiltonian cycle by exhausting all triangles of the same type and then going to the next type, in the order given as follows:
$ABC \rightarrow xBC \rightarrow AyC \rightarrow$ starting point.

Case (c). *All three pairs of disks are needed to cover all triangles.*

Then there are four types of triangles: ABC, xBC, yAC, and zAB, where properties analogous to those in Case (b) hold for x, y, and z. Construct the Hamiltonian cycle as follows:
$ABC \rightarrow xBC \rightarrow AyC \rightarrow ABz \rightarrow$ starting point.

Now consider the case in which there are special triangles. If there is one with five vertices, say, $uvwpq$, then at least two vertices, say, p and q, must each be "far away" from all vertices of $\triangle abc$ (since C_a, C_b, and C_c together can contain at most three vertices of $uvwpq$). Thus we can complete the chaining of triangles in step 1 by starting with $pquvw$ (in that order) and ending with $\triangle abc$ (in the order required by its predecessor). Consider therefore special triangles F with four vertices. If F has less than three vertices in the interiors of C_a, C_b, and C_c, then again F has at least two vertices each far away from all vertices of $\triangle abc$ and hence step 1 can be completed. We thus need to consider only special triangles of type $ABCt$, where t (by the same argument) is at a distance greater than $\delta/2$ from any point of A (resp., of B and of C). For Cases (a)–(c) considered above, the Hamiltonian cycle is given as follows (observe that the sequences are unchanged except for starting with the special triangles):

Case (a): $AtBC \rightarrow xBC \rightarrow$ starting point,

Case (b): $ABtC \rightarrow ABC \rightarrow xBC \rightarrow AyC \rightarrow$ starting point,

Case (c): $ABtC \rightarrow ABC \rightarrow xBC \rightarrow AyC \rightarrow ABz \rightarrow$ starting point.

The approximation factor follows by noting that $\delta/4 = \frac{r}{32}$ and that the optimal objective value is at most $2r$. □

5. Approximating the max-min m-neighbor TSP.

In this section, we show how the techniques developed in sections 4.1–4.2 can be generalized to obtain a constant-factor approximation for the max-min m-neighbor TSP, for any constant $m > 2$. For simplicity, we consider only the *path* version in which n *is a multiple of* $m+1$. The method of "closing" a path into a cycle in Theorem 4.15 and the techniques of handling the case in which n is not a multiple of $m+1$ for the path version (in Appendix A) are not easily extended to the case in which $m > 2$; we pose them as open questions.

Analogous to the techniques for 2-neighbor TSP, we use *large* $(m+1)$-*cliques* to play the role of large triangles. An $(m+1)$-clique K_{m+1} consists of $m+1$ vertices that are the points in S (thus a triangle is a 3-clique); the *clique edges* of K_{m+1} are implicitly defined by its vertices. We want K_{m+1} to be *large*, meaning that each vertex of K_{m+1} is "far away" from all the other vertices of K_{m+1} (i.e., all clique edges of K_{m+1} are "long"). Again, our overall strategy consists of the following steps:

1. Create $n/(m+1)$ vertex-disjoint *large* $(m+1)$-cliques whose vertices are the points in S.
2. Concatenate these large $(m+1)$-cliques together to create a Hamiltonian path such that the distances between any m-neighbors are large.

We elaborate these steps in the following. First, let r be the radius of a smallest circle, $\mathcal{C}$, centered at one of the n points whose corresponding disk contains exactly $n/(m+1)$ points of S (including the center point), and one additional point on its boundary. From Lemma 3.2, $2r$ is an upper bound for the max-min distance in the path version of an m-neighbor TSP (since n is a multiple of $m+1$). Again, $\mathcal{C}$ and r are easily found in $O(n^2)$ time.

After computing r and $\mathcal{C}$, we use Algorithm Big $(m+1)$-Cliques (analogous to Algorithm Big-Triangles in section 4.1), to grow the $n/(m+1)$ points in the *interior* of $\mathcal{C}$ into $n/(m+1)$ vertex-disjoint large $(m+1)$-cliques. The process consists of m phases, where in phase i we grow each i-clique into an $(i+1)$-clique.

Algorithm Big $(m+1)$-Cliques. The algorithm consists of m phases, classified into two parts.

Part 1. *Complete matching phases.* This part consists of $\lfloor m/2 \rfloor$ phases. For each phase $i = 1, 2, \ldots, \lfloor m/2 \rfloor$, perform the following.

Phase i: Construct a bipartite graph $G = (V_1, V_2, E)$, where the nodes V_1 represent the i-cliques constructed in phase $i-1$ (if $i = 1$, then the nodes V_1 are the points in the disk defined by $\mathcal{C}$) and V_2 are the left-over points. Note that $|V_1| = n/(m+1)$ and $|V_2| = n - i \cdot \frac{n}{m+1} = (m+1-i)\frac{n}{m+1}$. Edge set E consists of "long" edges from V_1 to V_2, between two nodes $K_i \in V_1$ and $p \in V_2$, where p is at distance at least r from *all* vertices of K_i. Perform a maximum cardinality matching on G. By Lemma 5.1, all nodes of V_1 are matched. For each matched pair $K_i \in V_1$ and $p \in V_2$, grow the i-clique K_i into an $(i+1)$-clique by including point p as its additional vertex. Clearly, all clique edges of all resulting $(i+1)$-cliques have lengths at least r.

Lemma 5.1. *For each phase $i = 1, 2, \ldots, \lfloor m/2 \rfloor$, there exists a matching in G in which all nodes of V_1 are matched.*

Proof. We use an argument similar to the proof of Lemma 4.4. Again, by way of contradiction, we assume that there exists a set $A \subseteq V_1$ for which $|A| > |\Gamma(A)|$, where $\Gamma(A) \subseteq V_2$ is a set of nodes that are adjacent (via edges of G) to at least one node of A. Now we have $|A| \le |V_1| = n/(m+1)$, $|V_2| = (m+1-i)\frac{n}{m+1}$, and thus $|V_2 \setminus \Gamma(A)| > |V_2| - |A| \ge (m-i)\frac{n}{m+1}$. That is, for each i-clique K_i of A, there are at least $(m-i)\frac{n}{m+1} + 1$ left-over points (in $V_2 \setminus \Gamma(A)$) that are each within distance less than r from *some* vertex of K_i. Consider i (open) disks centered at each of the i vertices of K_i, each with radius r: by the pigeonhole principle, at least one of these disks contains more than $((m-i)\frac{n}{m+1})/i$ points of $V_2 \setminus \Gamma(A)$. Since $i \le \lfloor m/2 \rfloor$, this disk contains at least $\frac{n}{m+1} + 2$ points, including the center point. This contradicts the original choice of r. ∎

Part 2. *Maximal matching and swapping phases.* This part consists of the remaining $\lceil m/2 \rceil$ phases. For each phase $i = \lfloor m/2 \rfloor + 1, \ldots, m$, perform the following.

Phase i: Let δ be the length of the shortest clique edge among all i-cliques at the end of phase $i-1$ (for $i = \lfloor m/2 \rfloor + 1$, take $\delta = r$). Construct a bipartite graph $G = (V_1, V_2, E)$ in the same way as in Part 1, except that the edge set E is specified as follows: there is an edge between two nodes $K_i \in V_1$ and $p \in V_2$ if and only if p is at a distance at least $\delta/4$ from *all* vertices of K_i. Now perform the following steps:

1. *Maximal matching step.* Perform a *maximal* matching (rather than maximum cardinality matching) on G. For each matched pair $K_i \in V_1$ and $p \in V_2$, grow

the i-clique K_i into an $(i+1)$-clique by including point p as its additional vertex. If all nodes in V_1 are matched, stop phase i here (all i-cliques in V_1 are grown into $(i+1)$-cliques); otherwise go to the next step.

2. *Swapping step.* Let $V_1' \subseteq V_1$ be the set of the left-over i-cliques of V_1 that are not matched in step 1, and $P \subseteq V_2$ the set of the left-over points that are not yet in any clique. Perform swapping operations of Lemma 5.3 on the i-cliques of V_1'. By Lemma 5.4, all of them can be grown into $(i+1)$-cliques, with the lengths of all clique edges at least $\delta/8$.

Suppose that the swapping step is performed in phase i. Let $K_i \in V_1'$ be some left-over i-clique whose vertices are $u_1, \dots, u_i$, and let $C_j = \mathcal{D}_{u_j}(\delta/2)$ be the disk centered at u_j with radius $\delta/2$, for each $j = 1, \dots, i$.

LEMMA 5.2. *Independent of the choice of the left-over i-clique K_i, the disks C_j induce a partition of the left-over points P into at most i nonempty clusters $P_1, \dots, P_h$, $h \le i$. For each $j = 1, \dots, h$, all points of P_j are enclosed in the interior of C_j (renumbering the subscripts of the vertices of K_i might be necessary), and each left-over i-clique in V_1' (including K_i) has exactly one vertex in the interior of C_j.*

Proof. This is a direct generalization of Lemmas 4.5 and 4.6. □

In phase i, let $R_j = \mathcal{D}_{u_j}(r)$ be the disk that has the same center, u_j, as C_j and has radius r, for each $j = 1, \dots, h$. We call a clique (either an i-clique or an $(i+1)$-clique) *good* for P_j if the clique has no vertex in the *interior* of R_j, and *bad* otherwise. By Lemma 5.2, each left-over i-clique in V_1' is *bad for all clusters* $P_1, \dots, P_h$.

LEMMA 5.3. *Let K_{i+1} be a good $(i+1)$-clique for cluster P_j. Then for any left-over i-clique $K_i \in V_1'$ and a left-over point $x \in P_j$, we can construct two new $(i+1)$-cliques from K_{i+1}, K_i, and x such that one new $(i+1)$-clique is bad for all $P_1, \dots, P_h$ and has clique edge lengths at least $\delta/8$, and the other has clique edge lengths at least $\delta/4$.*

Proof. Let $\delta' = \delta/4$. Note that all clique edges in K_{i+1} and in K_i have lengths at least δ'. We claim that there is always a vertex v^* of K_{i+1} that is at distance at least $\delta'/2 = \delta/8$ from all vertices of K_i. To see this, consider the vertices $u_1, \dots, u_i$ of K_i, one by one. Initially, all $i+1$ vertices of K_{i+1} are candidates for v^*. Now, u_1 can be "too close" (within distance less than $\delta'/2$) to at most one vertex of K_{i+1}: if there is a vertex v_ℓ of K_{i+1} with $d(u_1, v_\ell) < \delta'/2$, then since all clique edges in K_{i+1} have lengths at least δ', we have $d(v, v_\ell) \ge \delta'$ for each vertex $v \ne v_\ell$ of K_{i+1}, and thus $d(u_1, v) \ge d(v, v_\ell) - d(u_1, v_\ell) > \delta'/2$. Therefore u_1 can filter out at most one candidate for v^*. Now consider u_2 and the remaining i candidates. Again, u_2 can filter out at most one candidate. Repeating this process, there are i constraints (from the vertices of K_i) in total, but we have $i+1$ candidates initially. Therefore such v^* must always exist. This completes the proof of the claim.

Now we construct two new $(i+1)$-cliques from K_{i+1}, K_i, and x as follows. First, we grow K_i into an $(i+1)$-clique by including v^* as its additional vertex. Clearly, this new clique has edge lengths at least $\delta'/2 = \delta/8$. Also, since K_i is originally bad for all clusters $P_1, \dots, P_h$ by Lemma 5.2, this new $(i+1)$-clique continues to be bad for all clusters. Secondly, we construct the other $(i+1)$-clique by swapping out vertex v^* from K_{i+1} and swapping in point $x \in P_j$ as a new vertex. The fact that this clique still has edge lengths at least $\delta' = \delta/4$ follows from the observation that K_{i+1} is good for P_j (hence all vertices of K_{i+1} are at a distance at least r from the center of R_j, C_j) and that x is within distance less than $\delta/2$ from the center of C_j (by Lemma 5.2) and from the triangle inequality. □

LEMMA 5.4. *Suppose that the swapping step is performed in phase i. Then there are always enough good $(i+1)$-cliques for P_j, $j = 1, \dots, h$, such that all left-over*

i-cliques can be grown into $(i+1)$-cliques by the swapping operations of Lemma 5.3, *with final clique edge lengths at least $\delta/8$.*

Proof. This is similar to Lemma 4.8. The swapping step goes through at most h stages, where for each stage $j = 1, \ldots, h$ we perform the swapping operations of Lemma 5.3 for points in P_j, until either all points in P_j are used up (in which case we move to the next stage), or all left-over i-cliques are grown into $(i+1)$-cliques (in which case we stop the entire swapping step). Now consider any such stage j. Right before stage j, suppose there are T $(i+1)$-cliques (and hence $\frac{n}{m+1} - T$ left-over i-cliques), and ℓ left-over points that are not yet in any clique. Let $|P_j| = \ell_j$, then $\Sigma_j \ell_j = \ell$. Also, ℓ is at least $\frac{n}{m+1} - T$, the number of left-over i-cliques. We claim that all points of P_j have enough good $(i+1)$-cliques to swap with. To show this, suppose among the T $(i+1)$-cliques, $T_{j,good}$ of them are good for P_j and $T_{j,bad}$ of them are bad for P_j; $T = T_{j,good} + T_{j,bad}$. Consider all points of S in the interior of R_j: these include ℓ_j points from P_j, $\frac{n}{m+1} - T$ vertices each from a left-over i-clique (by Lemma 5.2), and t_j vertices from bad $(i+1)$-cliques, where $t_j \geq T_{j,bad}$. Since the interior of R_j contains at most $n/(m+1)$ points, we have $n/(m+1) \geq \ell_j + (\frac{n}{m+1} - T) + t_j \geq \ell_j + (\frac{n}{m+1} - T) + T_{j,bad}$. Then we have $T_{j,good} = T - T_{j,bad} \geq \ell_j$, completing the proof of the claim. Since the number of the left-over i-cliques is no more than the number of the left-over points (all of which in turn have enough good $(i+1)$-cliques to swap with), all the left-over i-cliques can eventually be grown into $(i+1)$-cliques. Also, from Lemma 5.3, after each swapping operation, the only new $(i+1)$-clique that can possibly have edge lengths less than $\delta/4$ (but at least $\delta/8$) is *bad for all* $P_1, \ldots, P_h$, and hence it will not be used for swapping hereafter in phase i. Therefore, at the end of phase i all left-over i-cliques can be grown into $(i+1)$-cliques with clique edge lengths at least $\delta/8$. ☐

From Lemma 5.4, we know that in the worst case, the length of the shortest clique edge is reduced by a factor of 8 (from δ to $\delta/8$) in each phase i of Part 2. Therefore the final $(m+1)$-cliques have edge lengths at least $r(1/8)^{\lceil m/2 \rceil}$.

THEOREM 5.5. *Given a constant $m > 2$ and a complete graph on set S of n points satisfying triangle inequality, where n is a multiple of $m+1$, there exists an algorithm that constructs in $O(n^{2.5})$ time $n/(m+1)$ vertex-disjoint $(m+1)$-cliques from points in S such that the smallest edge length of the cliques is at least $r(1/8)^{\lceil m/2 \rceil}$, where r is the radius of a smallest (open) disk centered at a point of S, containing exactly $n/(m+1)$ points of S, and one additional point on its boundary.*

Now we are ready to concatenate the $(m+1)$-cliques into a Hamiltonian path.

THEOREM 5.6. *Given a list of $(m+1)$-cliques whose minimum edge length is δ, the cliques can be chained into a path such that any two nodes that are m-neighbors in the path are at a distance at least $\delta/2$ from each other.*

Proof. This is the same as Theorem 4.10, except that we use an immediate generalization of Lemma 4.11 to chain the $(m+1)$-cliques. ☐

From Theorems 5.5 and 5.6, and the fact that $2r$ is an upper bound for the optimal objective value, we conclude with the following theorem.

THEOREM 5.7. *Given a constant $m > 2$ and a complete graph on set S of n points satisfying triangle inequality, where n is a multiple of $m+1$, there exists an algorithm that constructs in $O(n^{2.5})$ time a Hamiltonian path on S whose objective value for the max-min m-neighbor problem is at least $\frac{1}{4}(\frac{1}{8})^{\lceil m/2 \rceil}$ times the optimal.*

6. Exact algorithms for points on a line or on a circle.

We consider now the special cases in which S is a set of n points on a line or on a circle, and distances are Euclidean. In these cases, we are able to obtain linear-time (optimal) algorithms to solve exactly the maximum scatter TSP, for both the cycle and path versions. (For the path version of points on a circle, we consider only the case in which n is an odd integer or the points are equally spaced.) First, we concentrate on the cycle version of points on a line; we discuss the remaining problems and versions in Appendix B.

In the following, the n points of S lie on a line, labeled $1, 2, \dots, n$ from left to right. We distinguish between two cases, depending on whether n is odd or even. Interestingly, the latter case is more complex than the former case. In fact, when n is odd, an optimal cycle can be *specified* in $O(1)$ time, i.e., without knowing the *positions* of the nodes, a fixed specification based only on the *ordering* of the nodes is guaranteed to be an optimal cycle. Such an optimal cycle can be *constructed* and output (with the length d^* of a shortest edge of the cycle identified) in $O(n)$ time. When n is even, we show that in linear time we can identify d^*, and after that an optimal cycle can be constructed using a purely combinatorial method in $O(n)$ time.

We define the following terminology. A subset I of S containing ℓ consecutive nodes is called an *ℓ-interval*. An edge (u, v) is said to *span* the ℓ nodes in the ℓ-interval whose endpoint nodes are u and v (thus each edge spans at least two nodes). An edge is called an *ℓ-edge* if it spans ℓ nodes. We let $k = \lfloor \frac{n}{2} \rfloor$ throughout this section.

6.1. Cycle version: Points on a line (n odd). We have $n = 2k + 1$ in this case. Recall that d^* is the length of a shortest edge of an optimal cycle. By Corollary 3.3, the length of the shortest $(k + 1)$-interval is an upper bound for d^*. Now we show that this upper bound is achievable by the following specification of a Hamiltonian cycle:

> Starting from node 1, the "right" edges connect node p to node $[(k+1) + p]$, for $p = 1, 2, \dots, k$, and the "left" edges connect node $(k + q)$ to node q, for $q = 1, 2, \dots, k + 1$.

It is easy to verify that the above specification gives a Hamiltonian cycle, and that each "right" edge spans $k+2$ nodes and each "left" edge spans $k+1$ nodes. Therefore this Hamiltonian cycle is optimal.

THEOREM 6.1. *For the cycle version of the maximum scatter TSP, where the n points lie on a line, the distances are Euclidean, and n is an odd integer, there exists an algorithm that specifies an optimal Hamiltonian cycle in $O(1)$ time, and constructs such a cycle in $O(n)$ time.*

6.2. Cycle version: Points on a line (n even). We have $n = 2k$ in this case. Without loss of generality, we assume that all k-intervals on S have distinct lengths. This assumption is clearly nonrestrictive, since we can always break a tie by viewing the interval whose position is to the left of the other as having a shorter length. We say that two intervals I_1 and I_2 *overlap* if $I_1 \cap I_2 \neq \emptyset$.

LEMMA 6.2. *Let I_1 and I_2 be two overlapping k-intervals. Then in any Hamiltonian cycle on S that avoids having an edge joining two nodes of I_1, there must exist an edge joining two nodes of I_2.*

Proof. Let $S_{in} = I_1 \cap I_2$ and $|S_{in}| = \ell > 0$. Also, let $S_{out} = S \setminus (I_1 \cup I_2)$. Then since $|I_1 \cup I_2| = 2k - \ell$, we have $|S_{out}| = \ell$. Suppose on the contrary that there exists a Hamiltonian cycle C that avoids having an edge joining two nodes either both in I_1 or both in I_2. Then consider the ℓ nodes in S_{in}: they can only be connected to the ℓ nodes in S_{out}. Now there are 2ℓ edges of C going out from S_{in}, but the total degree of the nodes of S_{out} in C is 2ℓ; therefore all of the nodes of S_{out} can be connected only to the nodes of S_{in} also. This implies that the nodes in $S_{in} \cup S_{out}$ are disconnected from the other nodes of S, and thus C is not a Hamiltonian cycle, which is a contradiction. ∎

COROLLARY 6.3. *Any shortest edge in any optimal Hamiltonian cycle on S can span at most k nodes.*

Proof. By Lemma 3.1, any such edge e can span at most $k+1$ nodes. Now suppose e spans $k+1$ nodes. Let I_1 be the k-interval consisting of the leftmost k nodes spanned by e, and I_2 be the k-interval of the rightmost k nodes spanned by e. Clearly I_1 and I_2 overlap, and the optimal cycle containing e does not have any edge joining either two nodes of I_1 or two nodes of I_2, contradicting Lemma 6.2. Thus e can span at most k nodes. □

COROLLARY 6.4. *Let I_1, I_2, and I_3 be, respectively, the shortest, the second-shortest, and the third-shortest k-intervals on S, and let e_i be the edge connecting the two endpoint nodes of I_i for all $i = 1, 2, 3$. Then $d^* \leq d_{e_2}$ if I_2 overlaps with I_1, and $d^* \leq d_{e_3}$ otherwise.*

Proof. If I_1 and I_2 do not overlap, then they must be the leftmost and rightmost k-intervals on S and $I_1 \cup I_2 = S$. Thus I_3 must overlap with I_1 or I_2. The stated upper bounds follow from Lemma 6.2 and Corollary 6.3. □

Assume now that we are given the shortest k-interval, I_1, on S. We give an algorithm that specifies an optimal Hamiltonian cycle C^* by distinguishing the following two cases.

Case 1. *I_1 is the leftmost k-interval.*
Place $I_1 = \{1, 2, \ldots, k\}$ and $I_2 = \{k+1, \ldots, 2k\}$ on a *schematic cycle* as shown in Figure 6.1(a), (b). Produce edges $e_1 = (1, k+1)$ and $e_2 = (k, 2k)$.

Start visiting node 1, and then repeatedly visit the kth node in the schematic cycle counted *counterclockwise* from the current node (the current node is counted as the first node), i.e., visiting nodes $k+2, 3, k+4, \ldots$, until reaching an endpoint node of e_2. Note that this visits every other node in I_1 and in I_2 in *increasing* order (nodes $1, 3, \ldots$ in I_1 and nodes $k+2, k+4, \ldots$ in I_2). If k is an even integer (see Figure 6.1(a)), then node $2k \in I_2$ is finally reached; if k is odd (see Figure 6.1(b)), then node $k \in I_1$ is finally reached. In either case, follow e_2 to visit the other endpoint node of e_2. Now, complete the other half of C^* by a symmetric method: repeatedly visit the kth node in the schematic cycle, this time counted *clockwise* from the current node, visiting the remaining nodes in I_1 and in I_2 in *decreasing* order, until reaching node $k+1$. Finally, follow e_1 to go back to node 1 (see Figure 6.1(a), (b)).

It is easy to verify that C^* is a Hamiltonian cycle. Also, all edges in C^* other than e_1 and e_2 span k nodes on one side and $k+2$ nodes on the other side of the schematic cycle, and e_1 and e_2 span $k+1$ nodes on both sides. In addition, all edges in C^* avoid joining two nodes that are both in I_1 or both in I_2. (I_1 is the shortest k-interval, and I_2 may happen to be the second shortest k-interval.) Therefore, C^* achieves the upper bound given in Corollary 6.4 and is an optimal Hamiltonian cycle.

Case 2. *I_1 is not the leftmost k-interval.*
First, relabel the nodes of S, by labeling the nodes of I_1 from 1 to k, and continuing the labeling in a wrap-around fashion (see Figure 6.1(c)). Then, use the new labels and apply the same procedure of Case 1 to produce C^*. Since the wrap-around effect has already been taken into account in Case 1 (via the schematic cycle), it is clear that C^* is an optimal Hamiltonian cycle.

Clearly, by considering each of the $k+1$ possible k-intervals we can, in $O(n)$ time, identify the length d^*. Then, we can apply the above algorithm to construct an optimal Hamiltonian cycle in additional $O(n)$ time.

THEOREM 6.5. *For the cycle version of the maximum scatter TSP, where the n points lie on a line, the distances are Euclidean, and n is an even integer, there exists*

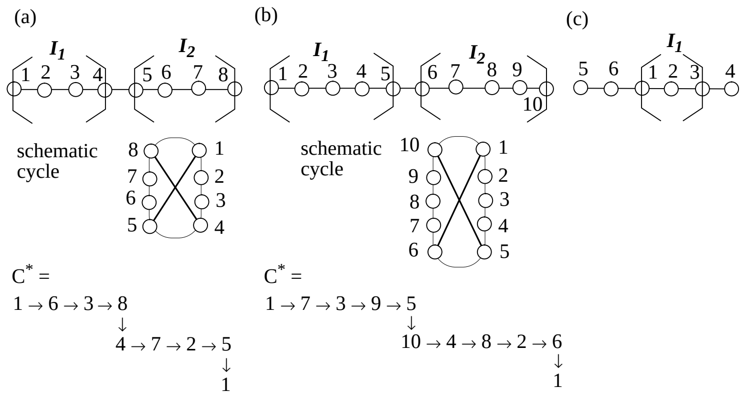

FIG. 6.1. *Examples of C^* specified by the algorithm:* (a) $n = 8$ *and* $k = 4$ *is even*; (b) $n = 10$ *and* $k = 5$ *is odd*; (c) *wrap-around relabeling when* I_1 *is not the leftmost* k*-interval.*

an algorithm that computes an optimal Hamiltonian cycle in $O(n)$ *time.*

In Appendix B we consider extensions of these results to the cycle version of points on a circle (Theorem B.2), and the path version of points on a line (Theorem B.4) or on a circle (Corollary B.5).

7. Conclusion.

We conclude with the following open problems:

- What is the complexity of the geometric maximum scatter TSP for points in the Euclidean plane? We conjecture that it is NP-hard. The recent result of Fekete [8] shows that the problem is indeed NP-hard in Euclidean spaces of dimension three or greater.
- Can better bounds for the max-min m-neighbor TSP for any $m \geq 1$ be obtained in the geometric case?
- For points on a line or on a circle, can we solve the max-min m-neighbor TSP exactly for $m > 1$? We conjecture that there exists a polynomial-time algorithm, perhaps similar to the one we presented for the case $m = 1$.
- Can we solve the maximum scatter TSP exactly for points lying on the boundary of an arbitrary convex body?

Appendix A. Max-min 2-neighbor Hamiltonian path: n not a multiple of 3. We already gave an algorithm to construct a Hamiltonian path whose objective value for the max-min 2-neighbor problem is at least $\frac{1}{32}$ times the optimal, when n is a multiple of 3 (Theorem 4.12). Now we give algorithms achieving the same factor for the remaining cases, when $n = 3k + l$, for $l = 1, 2$. Surprisingly, the case of $n = 3k + 2$ can be easily solved, but the case of $n = 3k+1$ is much more difficult, and we overcome the difficulty by refining our Algorithm Big-Triangles and utilizing metric properties of the distance matrix. Also worth noting is that in the last case of our algorithm, for $n = 3k + 1$, we actually produce an *optimal* Hamiltonian path.

One major difference between the cycle and path versions, when n is not a multiple of 3, is on the upper bounds for the optimal objective values. Let r be the radius of a smallest circle, $\mathcal{C}$, centered at one of the n points that contains exactly $\lceil n/3 \rceil = k + 1$ points in its interior (including the center point), and one additional point on its boundary.

LEMMA A.1. *The max-min distance in the path version of a* 2*-neighbor TSP is at most* $2r$*.*

Proof. The proof is immediate from Lemma 3.2. ∎

Notice that $\mathcal{C}$ now contains $k+1$ points in its *interior*, as opposed to just k points in the interior in the cycle version given in Lemma 4.3.

When $n = 3k + 2$, we add one *fake point* Q far away from all n points in S and then apply Algorithm Big-Triangles on this new set of $n' = 3k + 3$ points. The circle $\mathcal{C}$ is the smallest one containing $n'/3 = k + 1$ points in its interior and one additional point on the boundary, as desired. Suppose $\triangle Qyz$ is the (big) triangle containing Q produced by Algorithm Big-Triangles. Then in applying Theorem 4.10 to chain the $k + 1$ triangles into a Hamiltonian path, we start with $\triangle Qyz$, visiting the vertices in that order, and chain the remaining triangles in an arbitrary order. Finally, we remove Q and obtain a Hamiltonian path on S with approximation factor $\frac{1}{32}$.

When $n = 3k + 1$, we apply the same trick, adding two fake points Q and Q' far away from all n points in S as well as from each other, and apply our algorithm on this new set of $n' = 3k + 3$ points. Again circle $\mathcal{C}$ and its radius r are as desired. If we can make sure that Q and Q' are in the same triangle, say, $\triangle QQ'z$, among the $k + 1$ triangles constructed by Algorithm Big-Triangles, then we can again chain the triangles by visiting Q, Q', and z first (in that order), followed by the remaining triangles, and finally remove Q and Q' from the resulting path. This will give a desired Hamiltonian path on S.

In the rest of this section, we show how to modify Algorithm Big-Triangles so that it constructs $k + 1$ triangles whose shortest edge length is at least $r/8$, such that Q and Q' are in the same triangle. There is one case, however, in which this is not achieved, but instead we are able to produce an optimal path for this case.

Let $a \in S$ be the center point of $\mathcal{C}$. First, we want Algorithm Big-Triangles to produce $\triangle QQ'a$ at the end of phase 2. This can be done as follows: In phase 1 we match $a \in V_1$ with $Q \in V_2$ but leave $Q' \in V_2$ unmatched, and in phase 2 we match segment (Q, a) with point Q' first and then complete the matching. We have to show that there is still a complete matching in phase 1.

Lemma A.2. *In phase* 1 *of Algorithm Big-Triangles, there is a matching in* G *in which all nodes of* V_1 *are matched, with* $a \in V_1$ *and* $Q \in V_2$ *being a matched pair and* $Q' \in V_2$ *being left unmatched.*

Proof. Let $V_1' = V_1 \setminus \{a\}$ and $V_2' = V_2 \setminus \{Q, Q'\}$. We want to match all nodes in V_1' with nodes in V_2'. We use the same proof of Lemma 4.4, except that now $|A| \leq |V_1'| = n'/3 - 1$, and $|V_2'| = (2n')/3 - 2$. Thus $|V_2' \setminus \Gamma(A)| > |V_2'| - |A| \geq n'/3 - 1$, i.e., $|V_2' \setminus \Gamma(A)| \geq n'/3$. Again, any circle centered at an arbitrary point of A with radius r contains at least $n'/3 + 1 = k + 2$ points in its *interior*, contradicting the original choice of r. ∎

In phase 3, we have to make sure that Q and Q' still stay in the same triangle after swapping operations. A natural attempt to achieve this is to try to show, by modifying the argument of Lemma 4.8, that there are still enough good triangles to perform the swappings, even *without using* $\triangle QQ'a$ during the swappings. Unfortunately this method does not work, and thus we have to employ additional techniques to perform careful swappings.

Recall from Lemmas 4.5 and 4.6 that at the beginning of phase 3, the set P of left-over points is partitioned into (P_1, P_2) by the set E' of left-over segments, where (P_1, P_2) is either a 2-partition or a 1-partition. Also, the triangles constructed at the end of phase 2 have edge lengths at least $r/4$.

Lemma A.3. *If* (P_1, P_2) *is a* 2*-partition, then we can complete all swapping operations on* P_1 *and on* P_2 *in phase* 3 *of Algorithm Big-Triangles, constructing* $k+1$

triangles with edge lengths at least $r/8$, *such that* Q *and* Q' *stay in the same triangle.*

Proof. Let $e = (v_1, v_2)$ be a left-over segment in E', where v_i is within distances less than $r/4$ from all points in P_i for $i = 1, 2$ (see Lemma 4.5). Recall that e is constructed in phase 1 and that one of its endpoints, say, v_1, is inside $\mathcal{C}$, and the other endpoint, v_2, is outside or on the boundary of $\mathcal{C}$. Let R_i and C_i, $i = 1, 2$, as defined in the description of phase 3, be centered at v_i. Recall that the radiuses of R_i and C_i are r and $r/2$, respectively; also, a triangle is good for P_i if all three vertices are outside or on the boundary of R_i, and bad otherwise. Now $d(v_1, a) < r$, since v_1 is inside $\mathcal{C}$ and a is the center of $\mathcal{C}$, and thus a is inside R_1. This means that $\triangle aQQ'$ is *bad* for P_1 and is not needed for swapping the points of P_1. We first perform swappings on P_1 (swapping stage 1), with $\triangle aQQ'$ untouched. Now we perform swappings on P_2 (swapping stage 2). Observe that v_2 is outside or on the boundary of $\mathcal{C}$, so $d(a, v_2) \geq r$ and thus $\triangle aQQ'$ is *good* for P_2. Suppose in swapping stage 2 we want to swap $\triangle aQQ'$ with a point $x \in P_2$ and a left-over segment $e' = (p, q)$, where p is closer to P_1 and q is closer to P_2 (and again by Lemma 4.5 p is within distances less than $r/4$ from all points of P_1, and similarly for q and points of P_2). We claim that we can construct triangles $\triangle xQQ'$ and $\triangle apq$ so that their edge lengths are large enough. (Note that Q and Q' stay in the same triangle.) Clearly, $\triangle xQQ'$ satisfies the condition. To prove the claim, observe that q is inside C_2 and thus $d(q, v_2) < r/2$. But since $d(a, v_2) \geq r$, we have $d(a, q) \geq d(a, v_2) - d(q, v_2) > r/2$. Also, by the construction in phase 1, any left-over point $t \in P_1$ (before swapping stage 1) is *outside or on the boundary of* $\mathcal{C}$, i.e., $d(a, t) \geq r$. But as already mentioned, $d(p, t) < r/4$ by Lemma 4.5. Therefore $d(a, p) \geq d(a, t) - d(p, t) > (3r)/4$. This shows that all edge lengths in $\triangle apq$ are also large enough, which completes the proof of the claim. Now the cardinality of P_2 and the number of good triangles for P_2 are both decreased by 1, so there are enough good triangles remaining to swap with the rest of the points in P_2 (as shown in Lemma 4.8), with $\triangle xQQ'$ untouched—actually it is a bad triangle for P_2 now. This shows that the conditions of the lemma are satisfied. ☐

A nice property for (P_1, P_2) being a 2-partition is that the points of P_1 and P_2 are all outside or on the boundary of $\mathcal{C}$, and they also "confine" the endpoints of left-over segments, so that the endpoints of the left-over segments are far enough from a. When (P_1, P_2) is only a 1-partition, we do not have this nice property, and a more delicate technique is needed.

THEOREM A.4. *If* (P_1, P_2) *is a* 1*-partition with* $P_1 = P$, *then we can either complete all swapping operations on* P_1 *in phase* 3 *of Algorithm* Big-Triangles, *constructing* $k + 1$ *triangles with edge lengths at least* $r/8$, *such that* Q *and* Q' *stay in the same triangle*, *or otherwise we can construct an optimal max-min* 2*-neighbor Hamiltonian path on* S.

Proof. Let R_1 and C_1 be centered at any endpoint v_1 of a left-over segment such that v_1 is within distance less than $r/4$ from all points of P_1 (such an endpoint must exist for every segment; see Lemmas 4.5 and 4.6). If there is such v_1 inside $\mathcal{C}$, then $d(a, v_1) < r$. The conditions of the lemma are satisfied in this case, since letting R_1 and C_1 be centered at this v_1 means that a is inside R_1, i.e., $\triangle aQQ'$ is bad for P_1 and thus is not touched in the swapping operations on P_1. Therefore let us assume that all such endpoints v_1 are outside or on the boundary of $\mathcal{C}$ and thus $\triangle aQQ'$ is good for P_1. Let R_1 and C_1 be centered at any arbitrary such v_1, and call this center d. Let R_1' be a circle centered also at d with radius $(5r)/8$. Now we *redefine* a triangle to be good/bad for P_1 using R_1', namely, a triangle is *good* for P_1 if no vertex is inside R_1', and *bad* otherwise. The swapping lemma (Lemma 4.7) still works with this new definition of good/bad triangles, since any point not in the interior of R_1' is at a distance greater than $(5r)/8 - r/2 = r/8$ from each point inside C_1. Also, the two new triangles produced by a swapping operation are both *bad* for P_1, and thus there are no further shrinkings on their edge lengths. In the following, good/bad triangles are all defined by using R'_1. We consider two cases.

Case (I). There are less than $n'/3$ points inside R'_1 or some bad triangle has more than one vertex inside R'_1.

CLAIM A.1. *There are at least* $|P_1|+1$ *good triangles for* P_1, *and thus* $\triangle aQQ'$ *can be left untouched in the swapping operations on* P_1, *i.e., we can perform the desired swappings on* P_1.

Proof. The proof is a refinement of the proof of Lemma 4.8. At the end of phase 2, suppose there are T triangles, $T_{1,bad}$ bad triangles for P_1, t_1 bad triangle vertices inside R'_1, and ℓ left-over segments. Then we have $|P_1| = \ell$, $T + \ell = n'/3$, and $T_{1,bad} \leq t_1$. If R'_1 has less than $n'/3$ points in the interior, then $T_{1,bad}+\ell+\ell \leq t_1+2\ell < n'/3$; if some bad triangle has more than one vertex inside R'_1, then $T_{1,bad} < t_1$, i.e., $T_{1,bad}+\ell+\ell < t_1+2\ell \leq n'/3$. In both cases, we have $T_{1,bad} \leq n'/3-2\ell-1$. The number $T_{1,good}$ of good triangles for P_1 is then given by $T_{1,good} = T - T_{1,bad} \geq (n'/3 - \ell) - (n'/3 - 2\ell - 1) = \ell + 1 = |P_1| + 1$. ☐

Case (II). Otherwise, R'_1 has exactly $n'/3$ points in its *interior* and each bad triangle for P_1 has exactly one vertex inside R'_1. This means that there are exactly $\ell = |P_1|$ good triangles, *including* $\triangle aQQ'$. There are three subcases.

(II.1). There exists some point s inside $\mathcal{C}$, $s \neq a$, such that $d(s,a) \geq r/8$.

CLAIM A.2. *We can perform the desired swappings on* P_1.

Proof. We perform the task by considering the cases below.

Case (a). s is an endpoint of some left-over segment $e = (s,q)$. Since q is outside or on the boundary of $\mathcal{C}$, we have $d(a,q) \geq r$. Also, we already have $d(a,s) \geq r/8$. We swap $\triangle aQQ'$ with segment e and point $x \in P_1$ and produce two triangles $\triangle asq$ and $\triangle xQQ'$. Notice that $\triangle xQQ'$, with Q and Q' staying in the same triangle, is bad for P_1 and will not be touched from now on. Also, both $|P_1|$ and $T_{1,good}$, the number of good triangles for P_1, are decreased by 1 and the swapping operations can be completed as before.

Case (b). No such s exists as an endpoint of a left-over segment (i.e., each left-over segment has one endpoint within distance less than $r/8$ from a) and s is a vertex of some triangle $\triangle suv$.

Note that by the construction in phases 1 and 2, $\triangle suv$ has exactly one vertex inside $\mathcal{C}$; since s is inside $\mathcal{C}$, we have $d(a,u) \geq r$ and $d(a,v) \geq r$. We want to swap $\triangle aQQ'$ with a point $x \in P_1$ and a left-over segment (p,q), where p is inside $\mathcal{C}$ (and thus $d(p,a) < r/8$) and q is inside C_1.

1. $\triangle suv$ is good for P_1. We produce triangles $\triangle xQQ'$, $\triangle asv$, and $\triangle upq$. To verify, observe that $d(a,s) \geq r/8$ and $d(a,v) \geq r$, so $\triangle asv$ is fine. As for $\triangle upq$, we have $d(u,p) > (7r)/8$, since $d(u,a) \geq r$ and $d(p,a) < r/8$. Also, u is outside or on the boundary of R'_1 (since $\triangle suv$ is good), so $d(u,d) \geq (5r)/8$. Recall that d is the center of R'_1 and that C_1 is also centered at d with radius $r/2$. Now q is inside C_1, so $d(q,d) < r/2$. Therefore $d(u,q) \geq d(u,d) - d(q,d) > r/8$, which completes the validity of $\triangle upq$. Note that $\triangle asv$ is good, $\triangle upq$ is bad, and $\triangle xQQ'$ is bad and will not be touched from now on. Again, both $|P_1|$ and $T_{1,good}$ are decreased by 1 and the desired conditions are satisfied.

2. $\triangle suv$ is bad for P_1. Recall that each bad triangle has exactly one vertex inside R'_1. If s is inside R'_1, then both u and v are outside or on the boundary of R'_1; otherwise, one of u and v, say, v, is inside R'_1 (and s and u are outside or on the boundary of R'_1).

In both cases, we again produce triangles $\triangle xQQ', \triangle asv$, and $\triangle upq$. The validities of these triangles are established by the same arguments as before. Now $\triangle asv$ is *bad* (the other two triangles are bad as well), but originally $\triangle suv$ was bad also. Again $|P_1|$ and $T_{1,good}$ are both decreased by 1 and the desired conditions are satisfied. ∎

(II.2). All $n'/3$ points inside $\mathcal{C}$ (including a) are within distances less than $r/8$ from a, but there exists some point t inside R_1', $t \neq d$, such that $d(t, d) \geq r/8$.

Claim A.3. *The interiors of $\mathcal{C}$ and of R_1' contain two disjoint clusters, each with $n'/3$ points, and the distance between any two points in different clusters is larger than $(7r)/8$.*

Proof. Recall that $d(a, d) \geq r$ ($\triangle aQQ'$ has no vertex inside R_1 in the first place). Now any point inside R_1' is within distance less than $(5r)/8$ from d, so any point inside R_1' is at distance at greater than $r - (5r)/8 = (3r)/8$ from a. But any point inside $\mathcal{C}$ is within distance less than $r/8$ from a. Therefore all $n'/3$ points inside R_1' are outside or on the boundary of $\mathcal{C}$ (and thus at distance at least r from a). This shows the disjointness of the two clusters. Let y and z be two points inside R_1' and inside $\mathcal{C}$, respectively. Then $d(y, z) > (7r)/8$, since $d(y, a) > r$ and $d(z, a) < r/8$. ∎

Claim A.4. *We can perform the desired swappings on P_1.*

Proof. Recall that d is an endpoint of some left-over segment $e = (p, d)$, where p is inside $\mathcal{C}$ (and thus $d(p, a) < r/8$). We perform the task by considering the cases below.

Case (a). t is a point in P_1. We produce $\triangle tpd$, which is valid since $d(t, d) \geq r/8$ (the condition of Case (II.2)) and $d(t, p) > (7r)/8$ (t and p are in different clusters). Now $|P_1|$ is decreased by 1 ($|P_1| = \ell - 1$) but $T_{1,good}$ is still ℓ. Thus we can complete the swappings on P_1 *without using* $\triangle aQQ'$.

Case (b). t is an endpoint of a left-over segment $e' = (p', t)$, where p' is inside $\mathcal{C}$. Let x be any point of P_1. We produce $\triangle tpd$ and segment (p', x). Note that $\triangle tpd$ is valid as shown in Case (a), and segment (p', x) has a length larger than $(7r)/8$, since p' and x are in different clusters. Again $|P_1|$ is decreased to $\ell - 1$ but $T_{1,good}$ is still ℓ, so we can complete the desired swappings on P_1.

Case (c). t is a vertex of a (bad) triangle $\triangle tuv$ for P_1. Since each bad triangle has exactly one vertex inside R_1', u and v are outside or on the boundary of R_1', so $d(u, d) \geq (5r)/8$ and $d(v, d) \geq (5r)/8$. Let x be any point in P_1. Since x and (p, d) are the left-over point and segment, by the construction of phase 2, $d(x, d) < r/4$. Therefore $d(u, x) > (5r)/8 - r/4 = (3r)/8$; similarly, $d(v, x) > (3r)/8$. Thus we can produce triangles $\triangle uvx$ and $\triangle tpd$ (whose validity is established as before). Again $|P_1|$ is decreased to $\ell - 1$ but $T_{1,good}$ is still ℓ, so we can complete the desired swappings on P_1. ∎

(II.3). All $n'/3$ points inside $\mathcal{C}$ (including a) are within distance $< r/8$ from a and all $n'/3$ points inside R_1' (including d) are within distance $< r/8$ from d.

Claim A.5. *We can construct an optimal max-min 2-neighbor Hamiltonian path on S.*

Proof. As in Case (II.2), the interiors of $\mathcal{C}$ and of R_1' contain two *disjoint* clusters S_1 and S_2, respectively, each with $n'/3$ points (i.e., $|S_1| = |S_2| = n'/3 = k + 1$), and the distance between any two points in different clusters is larger than $(7r)/8$. Let $S' = (S \setminus S_1) \setminus S_2$; then $|S'| = k - 1$. We disregard the fake points Q and Q' from now on. Any point $p' \in S'$ is outside or on the boundary of $\mathcal{C}$, and thus p' is at a distance greater than $r - r/8 = (7r)/8$ from any point of S_1. Similarly, p' is outside or on the boundary of R_1', and thus p' is at a distance greater than $(5r)/8 - r/8 = r/2$ from any point of S_2. Note that $diam(S_1) < (r/8) \cdot 2 = r/4$, and similarly $daim(S_2) < r/4$.

Without loss of generality, assume that $diam(S_1) < diam(S_2)$. To avoid having any pair of 2-neighbors both in S_1, the Hamiltonian path starts from a point in S_1, and visits two points outside S_1 (one in S_2 and one in S'), then repeats the process. After repeating the process $(k-1)$ times, S_1 and S_2 both have two points left over, and S' is empty. The only possible way to avoid having any pair of 2-neighbors both in S_1 is to visit the kth point of S_1, then the last two points of S_2, and finally the last point of S_1. This means that there must be a pair of points both in S_2 that are 2-neighbors, i.e., $diam(S_2)$ is an upper bound for d^*, the max-min 2-neighbor distance of an optimal path. We can achieve this upper bound by constructing the path $(S_1S_2S')^{k-1}S_1S_2S_2S_1$, where each occurrence of S_1 means visiting a point in S_1, and similarly for the occurrences of S_2 and S', and the last two points in S_2 to be visited are the pair in S_2 defining $diam(S_2)$. Clearly, all other 2-neighbors in this path have distances larger than $r/2$, which is larger than $diam(S_2)$, and the minimum 2-neighbor distance is $diam(S_2)$, the upper bound of d^*. Therefore $d^* = diam(S_2)$ and the path is optimal. ∎

This completes the proof of Theorem A.4. ∎

This completes the proof of Theorem 4.14.

Appendix B. Other exact algorithms for points on a line or a circle.

B.1. Cycle version: Points on a circle. We define an *ℓ-interval* as before, and the *arc* of an ℓ-interval I to be the arc containing the ℓ nodes of I, with endpoints being the endpoint nodes of I. Also, we define the *length* of I to be the length of the longest edge among all edges joining two nodes of I. Observe that in the case of points on a line, the edge joining the two endpoints of I always gives the length of I; this is no longer true for the case of points on a circle—unless the angle subtended by the arc of I is no more than π.

LEMMA B.1. *Let S be a set of n nodes lying on a circle, and d^* be the length of the shortest edge of an optimal Hamiltonian cycle on S. If $n = 2k+1$ is odd, then for any $(k+1)$-interval $I = \{u, \ldots, v\}$ whose arc subtends an angle larger than π, the length of edge (u, v) is larger than d^*. Moreover, the shortest and the second shortest $(k+1)$-intervals are both shorter than edge (u, v) and must each subtend an angle no more than π. Similarly, if $n = 2k$ is even, then for any k-interval $I = \{u, \ldots, v\}$ whose arc subtends an angle larger than π, the length of edge (u, v) is larger than d^*. Moreover, the shortest, the second shortest, and the third shortest k-intervals are all shorter than edge (u, v) and must each subtend an angle no more than π.*

Proof. Consider the case in which n is odd (see Figure B.1(a)). Observe that $I' = \{u, s, \ldots, t\}$ is also a $(k+1)$-interval, whose arc subtends an angle no more than π. This means that edge (u, t) is the longest edge with both endpoints in I'. By Corollary 3.3, the length of (u, t) is an upper bound for d^*. But since (u, v) is longer than (u, t), the length of edge (u, v) is larger than d^*. In fact, (u, v) is longer than *both* (u, t) and (s, v) by the same argument, where (s, v) defines the length of another $(k+1)$-interval $I'' = \{s, \ldots, t, v\}$ with subtended angle no more than π.

Now consider the case in which n is even (see Figure B.1(b)). Again, $I' = \{s, p, \ldots, t\}$, $I'' = \{p, \ldots, t, v\}$, and $I''' = \{u, s, \ldots, q\}$ are three k-intervals each of whose arcs subtends an angle no more than π, and edge (u, v) is longer than all three edges joining both endpoints of I', of I'', and of I'''. This means that the length of (u, v) is larger than the length of the third shortest k-interval. The lemma then follows from Corollary 6.4. ∎

We solve the problem by the following algorithm. When $n = 2k+1$, we apply the algorithm of section 6.1 to construct a Hamiltonian cycle C^*. When $n = 2k$, we first

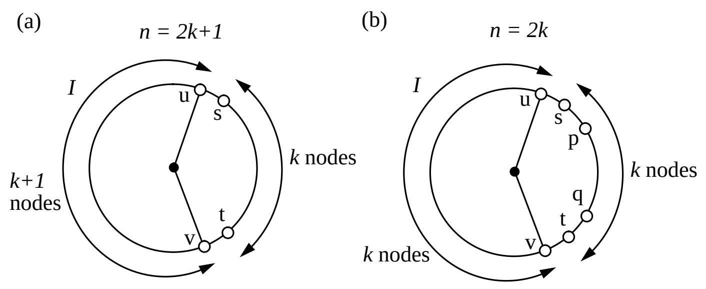

FIG. B.1. *Proof of Lemma* B.1: (a) *n is odd*; (b) *n is even.*

scan all n possible k-intervals to identify the shortest k-interval, I_1. By Lemma B.1, I_1 is found by taking the shortest edge among all edges joining the two endpoint nodes of all k-intervals. Then we label all nodes of S from 1 to $2k$ clockwise along the circle, with the nodes of I_1 labeled 1 to k. Finally, we use the new labels and apply the algorithm of Theorem 6.5 to construct a Hamiltonian cycle C^*.

We claim that the resulting C^* is optimal. First, the wrap-around effect is readily taken care of: when $n = 2k + 1$, each edge on C^* spans $k + 2$ nodes on one side and also spans $k + 1$ nodes on the other side; when $n = 2k$, each edge either spans $k + 1$ nodes on both sides (edges e_1 and e_2 given in the algorithm of section 6.2) or spans k nodes on one side and $k + 2$ nodes on the other side (the remaining edges). Secondly, let I be an $(k + 1)$-interval (resp., k-interval) when $n = 2k + 1$ (resp., $n = 2k$). The issue that an edge spanning all $k + 1$ nodes (resp., all k nodes) of I may not be the longest edge within I is resolved by Lemma B.1. Hence C^* is an optimal Hamiltonian cycle.

THEOREM B.2. *Let S be a set of n points lying on a circle and the distances are Euclidean. Then there exists an algorithm that solves the cycle version of the maximum scatter TSP on S exactly in optimal $O(n)$ time.*

B.2. Path version: Points on a line. Now, consider the path version of points on a line. As we did at the end of section 3, we add a *fake point* Q very far away from all points of S, say, at position ∞, so that it does not affect the max-min edge length, and solve the cycle problem. When we get the answer that is a cycle, we simply cut the cycle open at Q to get a path, and then remove Q. We call this method *fake-point algorithm* for future reference. We denote by C^* the intermediate cycle constructed, and P^* the final path obtained.

When $n = 2k$, adding Q makes the construction of C^* an easy case ($n' = n + 1$ is odd), for which we apply the algorithm of section 6.1. The upper bound for the path version (from Lemma 3.1: every set R of cardinality $\lceil \frac{n}{2} \rceil + 1 = k + 1$ must have an edge inside R) is easily achieved (the edges in the resulting path P^* are $(k + 1)$- or $(k + 2)$-edges), and hence P^* is optimal. When $n = 2k + 1$, adding Q makes the construction of C^* a more complicated case ($n' = 2k + 2$ is even). In this case, a tighter upper bound for an optimal path is needed. In fact, we can show the following lemma similar to Lemma 6.2.

LEMMA B.3. *Suppose $n = 2k + 1$, and let I_1 and I_2 be two* distinct $(k + 1)$-*intervals. Clearly, I_1 and I_2 must overlap. Then in any Hamiltonian path that avoids having any edge joining two nodes of I_1, there must exist an edge joining two nodes of I_2.*

Proof. Let $S_{in} = I_1 \cap I_2$ and $S_{out} = S \setminus (I_1 \cup I_2)$. If $|S_{in}| = \ell$ ($0 < \ell < k + 1$,

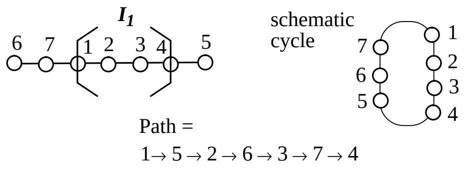

FIG. B.2. *Example of an optimal Hamiltonian path specified by the* direct algorithm *when n is odd* ($n = 7$).

since I_1 and I_2 overlap and also they are distinct), then $|I_1 \cup I_2| = 2k + 2 - \ell$, and thus $|S_{out}| = \ell - 1$. In a Hamiltonian path on S, to avoid having any edge joining two nodes both in I_1 or both in I_2, every node in S_{in} must connect only to nodes in S_{out}. Since $|S_{in}| = |S_{out}| + 1$, this means that the path must alternate between the nodes of S_{in} and the nodes of S_{out}, starting and ending at some nodes both in S_{in}, *without* visiting the nodes outside $S_{in} \cup S_{out}$ (such left-over nodes exist since $|S \setminus (S_{in} \cup S_{out})| = 2k + 1 - (\ell + \ell - 1) > 0$), a contradiction. □

This says that the length of the *second shortest* $(k + 1)$*-interval* gives an upper bound for d^*, the optimal objective value. We claim that using the fake-point algorithm, where we apply the algorithm of section 6.2 to construct cycle C^* on $n' = 2k+2$ points, achieves this upper bound. Recall from section 6.2 that each edge of C^* spans either $k' = k + 1$ and $k' + 2$ nodes on two sides of the schematic cycle (type 1 edge), or $k' + 1$ nodes on both sides (type 2 edge). When we remove Q to obtain P^*, each edge spans one less node on one side of the schematic cycle. The only possibility for an edge of P^* to span less than $k + 1$ nodes is when the k' nodes (on the schematic cycle) spanned by some type 1 edge include Q. But this means that these k' nodes are counted by wrapping around the line, and thus such an edge actually spans $k' + 2$ nodes on the line. Therefore P^* has each edge spanning at least $k + 1$ nodes (while avoiding both endpoints in the shortest $(k + 1)$-interval), and thus is optimal.

We can also use the following algorithm to solve the problem directly (we thus call the method *direct algorithm*):

When $n = 2k$**:**
Connect node p to node $(p + k)$, for all $p = 1, 2, \ldots, k$; also connect node $[(k + 1) + q]$ to node q, for all $q = 1, 2, \ldots, (k - 1)$.
When $n = 2k + 1$**:**
Identify the shortest $(k + 1)$-interval I_1. Relabel the nodes of S in a wrap-around fashion, with the nodes of I_1 labeled $1, \ldots, (k + 1)$. Put the nodes in a schematic cycle as in Figure B.2. Use the new labels to construct the following path: start visiting node 1, and repeatedly visit the $(k + 1)$-st node counted *counterclockwise* from the current node (which is counted as the first node), until reaching node $k + 1$ and stop. The resulting path is $1, (k + 2), 2, (k + 3), 3, \ldots, (k + 1)$ (see Figure B.2).

It is easy to see that when $n = 2k$, the constructed path has each edge spanning $k + 1$ or $k + 2$ nodes (in fact, the path is the same as the one constructed by the fake-point algorithm), and when $n = 2k + 1$, the constructed path has each edge spanning, respectively, $k + 1$ and $k + 2$ nodes on two sides of the schematic cycle while avoiding both endpoints in I_1. Therefore the path is optimal.

THEOREM B.4. *Let S be a set of n points lying on a line and the distances are Euclidean. Then there exists an algorithm that solves the path version of the maximum scatter TSP on S exactly in optimal $O(n)$ time.*

B.3. Path version: Points on a circle. Because of the wrap-around effect, the fake-point algorithm does not work: it is not possible to place Q so that Q is far away from *all* points of S. When $n = 2k + 1$, the above direct algorithm readily takes care of the wrap-around effect. Also, since the length of the second shortest $(k + 1)$-interval is (an upper bound for) d^*, the issue that an edge spanning all $k + 1$ nodes of a $(k + 1)$-interval I may not be the longest edge within I is resolved by Lemma B.1. Therefore we can solve the problem by scanning all n possible $(k + 1)$-intervals to identify the shortest one (whose length is given by the edge joining its two endpoints), and applying the direct algorithm. When $n = 2k$, the problem is more involved: all k edges $(1, k + 1), (2, k + 2), \ldots, (k, 2k)$ each span $k + 1$ nodes on *both* sides of the circle, and thus it is not possible to have a Hamiltonian path with each edge spanning at least $k+1$ nodes (as in the case of points on a line)—a tighter upper bound is needed. We do not explore the problem any further; however, if the points of S are *equally spaced*, then it is easy to see that the above direct algorithm gives an optimal Hamiltonian path.

COROLLARY B.5. *Let S be a set of n points lying on a circle and the distances are Euclidean. If n is an odd integer or the points are equally spaced, then there exists an algorithm that solves the path version of the maximum scatter TSP on S exactly in optimal $O(n)$ time.*

Acknowledgments. We thank Samir Khuller for stimulating discussions and comments, which led to Theorem 4.1 and an improvement on the running time of Theorem 3.5. We thank Fritz Scholz and Karel Zikan at Boeing for originally bringing the riveting problem to our attention and for discussions on the practical aspects of riveting in aircraft assembly. We thank Kresha Penavic for discussions on the applications of maximum scatter TSP in medical imaging. We also thank Vera Sacristan and Amitabh Varshney for useful discussions in the early stages of this research.

THE PARAMETRIZED COMPLEXITY OF SOME FUNDAMENTAL PROBLEMS IN CODING THEORY*

ROD G. DOWNEY†, MICHAEL R. FELLOWS‡, ALEXANDER VARDY§, AND GEOFF WHITTLE†

Abstract. The parametrized complexity of a number of fundamental problems in the theory of linear codes and integer lattices is explored. Concerning codes, the main results are that MAXIMUM-LIKELIHOOD DECODING and WEIGHT DISTRIBUTION are hard for the parametrized complexity class $W[1]$. The NP-completeness of these two problems was established by Berlekamp, McEliece, and van Tilborg in 1978 using a reduction from THREE-DIMENSIONAL MATCHING. On the other hand, our proof of hardness for $W[1]$ is based on a parametric polynomial-time transformation from PERFECT CODE in graphs. An immediate consequence of our results is that bounded-distance decoding is likely to be hard for linear codes. Concerning lattices, we address the THETA SERIES problem of determining for an integer lattice Λ and a positive integer k whether there is a vector $x \in \Lambda$ of Euclidean norm k. We prove here for the first time that THETA SERIES is NP-complete and show that it is also hard for $W[1]$. Furthermore, we prove that the NEAREST VECTOR problem for integer lattices is hard for $W[1]$. These problems are the counterparts of WEIGHT DISTRIBUTION and MAXIMUM-LIKELIHOOD DECODING for lattices. Relations between all these problems and combinatorial problems in graphs are discussed.

Key words. parametrized complexity, linear codes, decoding, codes in graphs, integer lattices

1. Introduction.

Our main objective in this paper is to explore the parametrized complexity of certain fundamental computational problems in the theories of linear codes and integer lattices. There is a natural close relationship between computational problems in these areas. We prove one main combinatorial transformation, which we then use to show hardness for problems in both domains.

There has been a substantial amount of work on the complexity of the problems considered here. Although many of these problems are naturally parametrized, all the prior work was in the framework of NP-completeness. The following three problems, considered by Berlekamp, McEliece, and van Tilborg [5] in 1978, are of importance in the theory of linear codes:

Problem: MAXIMUM-LIKELIHOOD DECODING
Instance: A binary $m \times n$ matrix H, a target vector $s \in \mathbb{F}_2^m$, and an integer $k > 0$.
Question: Is there a set of at most k columns of H that sum to s?
Parameter: k
Problem: WEIGHT DISTRIBUTION
Instance: A binary $m \times n$ matrix H and an integer $k > 0$.
Question: Is there a set of k columns of H that sum to the all-zero vector?
Parameter: k

Problem: MINIMUM DISTANCE
Instance: A binary $m \times n$ matrix H and an integer $k > 0$.
Question: Is there a nonempty set of at most k columns of H that sum to the all-zero vector?
Parameter: k

Notice that the difference between the definitions of the MINIMUM DISTANCE and WEIGHT DISTRIBUTION problems is very slight. WEIGHT DISTRIBUTION requires exactly k columns in a solution, while MINIMUM DISTANCE requires at most k columns in a solution.

Berlekamp, McEliece, and van Tilborg [5] proved that MAXIMUM-LIKELIHOOD DECODING and WEIGHT DISTRIBUTION are NP-complete by means of a reduction from THREE-DIMENSIONAL MATCHING. They conjectured that MINIMUM DISTANCE is also NP-complete, and Vardy [32] recently proved this conjecture using a nonparametric reduction from MAXIMUM-LIKELIHOOD DECODING. Since THREE-DIMENSIONAL MATCHING is fixed-parameter tractable, these earlier results do not allow us to conclude anything about the parametrized complexity of the three problems.

Over the past few years, it has been shown that many NP-complete problems are fixed-parameter tractable. For example, VERTEX COVER, a well-known NP-complete problem [22, p. 53] which asks whether a graph G on n vertices has a vertex cover of size at most k, can be solved [3] in time $O(kn + ({}^4\!/_3)^k k^2)$. Loosely speaking, the parametrized complexity hierarchy

$$\mathrm{FPT} = W[0] \;\subseteq\; W[1] \;\subseteq\; W[2] \;\subseteq\; \cdots \subseteq W[\mathrm{P}] \subseteq \cdots \subseteq XP$$

introduced by Downey and Fellows [14, 15] distinguishes between those problems that are fixed-parameter tractable and those that are not. For more details on the W hierarchy of parametrized complexity, see section 4, the Appendix, and references therein, in particular [18].

One of our main results in this paper is a proof that MAXIMUM-LIKELIHOOD DECODING and WEIGHT DISTRIBUTION are hard for the parametrized complexity class $W[1]$. We also show that both problems belong to the class $W[2]$. The proof of $W[1]$-hardness is based on a parametric polynomial-time reduction from the PERFECT CODE problem for graphs. Such a proof establishes both $W[1]$-hardness and NP-completeness at the same time. Furthermore, an immediate consequence of this result is that bounded-distance decoding is likely to be hard for binary linear codes, unless the parametrized complexity hierarchy collapses with $W[1] = \mathrm{FPT}$.

Three closely related problems in the theory of integer lattices are natural counterparts of the three problems concerning linear codes, discussed above. These problems are defined as follows:

Problem: NEAREST VECTOR
Instance: A basis $X = \{x_1, x_2, \ldots, x_n\} \subset \mathbb{Z}^n$ for a lattice Λ, a target vector $s \in \mathbb{Z}^n$, and an integer $k > 0$.
Question: Is there a vector $x \in \Lambda$ such that $\|x - s\|^2 \le k$?
Parameter: k

Problem: THETA SERIES
Instance: A basis $X = \{x_1, x_2, \ldots, x_n\} \subset \mathbb{Z}^n$ for a lattice Λ and an integer $k > 0$.
Question: Is there a vector $x \in \Lambda$ such that $\|x\|^2 = k$?
Parameter: k

Problem: Shortest Vector
Instance: A basis $X = \{x_1, x_2, \ldots, x_n\} \subset \mathbb{Z}^n$ for a lattice Λ and an integer $k > 0$.
Question: Is there a nonzero vector $x \in \Lambda$ such that $\|x\|^2 \leq k$?
Parameter: k

Here, a lattice Λ is the set of all linear combinations with integer coefficients of the elements of its basis X and $\|\cdot\|$ denotes the Euclidean norm. Again, notice that the difference between the definitions of Shortest Vector and Theta Series is very slight. Theta Series requires $\|x\|^2 = k$ in a solution, while Shortest Vector requires only the inequality $\|x\|^2 \leq k$.

Peter van Emde Boas [30] proved in 1980 that Nearest Vector is NP-complete and conjectured that Shortest Vector is also NP-complete. There has been a considerable amount of work devoted to the proof of this conjecture; see [2] and [31] for a discussion. Ajtai [1] has recently proved that the Shortest Vector problem is hard for NP under randomized reductions. Akin to the situation with linear codes, nothing is currently known regarding the parametrized complexity of the three problems discussed above.

Herein, we prove for the first time that Theta Series is NP-hard. Moreover, since our reduction is parametric, it shows that Theta Series is hard for the parametrized complexity class $W[1]$. Along similar lines, we prove that the Nearest Vector problem is also hard for $W[1]$.

Our results are based on a powerful combinatorial transformation that uses many of the ideas employed in the proofs of the main theorems in [14, 15]. We feel that one of the most interesting aspects of our work is a demonstration of the potential utility of parametric methods and perspectives in addressing issues in "classical" complexity theory. We will assume that the reader has some familiarity with the parametrized complexity framework such as can be found in [14, 15, 16, 18], for example. For the benefit of readers that do not have this background, some discussion and essential definitions are presented in section 4 and the appendix.

In the interests of readability, we defer the proof of our main combinatorial transformation to section 3. In the next section, we prove the main results using this transformation. In section 4 we present an outline of the proof of membership in $W[2]$ for several of the problems considered in this paper. We also discuss the remaining open problems and speculate on whether the techniques used herein might be adapted to provide a proof of $W[1]$-hardness for Minimum Distance or of NP-hardness for the Shortest Vector.

2. The main results through red/blue graphs.

We start with some notation and terminology. Let $G = (V, E)$ be a graph. We say that two distinct vertices $u, v \in V$ are *neighbors* if they are adjacent in G, namely, if $(u, v) \in E$. We will assume throughout that $G = (V, E)$ is loopless so that a vertex $v \in V$ is never its own neighbor. A set of vertices $V' \subseteq V$ is said to be a *perfect code* in G if every vertex of $V \setminus V'$ has a *unique* neighbor in V', while the vertices of V' itself do not have neighbors in V'. The starting point for our transformations is the parametrized problem of determining the existence of a k-element perfect code in a graph.

Problem: Perfect Code
Instance: A graph $G = (V, E)$ and an integer $k > 0$.
Question: Is there a k-element perfect code in G?
Parameter: k

This problem was shown to be hard for $W[1]$ in [15]. Kratochvíl [25, 24] was the first to prove, several years earlier, that this problem is NP-complete.

Our general approach in what follows is based on constructing and manipulating linear codes, and other sets of vectors, using bipartite graphs. Let $G = (\mathcal{R}, \mathcal{B}, E)$ be a bipartite graph with the partition of the vertices into the red set $\mathcal{R}$ and the blue set $\mathcal{B}$. We make the following definitions concerning special sets of red vertices in G.

Definition 2.1. *Suppose that $G = (\mathcal{R}, \mathcal{B}, E)$ is a red/blue bipartite graph, and let $R \subseteq \mathcal{R}$ be a nonempty set of red vertices. We say that R is*

- *a* dominating set *if every vertex in $\mathcal{B}$ has at least one neighbor in R,*
- *a* perfect code *if every vertex in $\mathcal{B}$ has a unique neighbor in R,*
- *an* odd set *if every vertex in $\mathcal{B}$ has an odd number of neighbors in R,*
- *an* even set *if every vertex in $\mathcal{B}$ has an even number of neighbors in R.*

Notice that what we define to be a perfect code is not the same for red/blue bipartite graphs and for general (uncolored) graphs. Similarly, our definition of a dominating set in a red/blue graph does not coincide with the conventional definition of dominating sets in general graphs. However, it will always be clear from the context which definition applies in each case.

We can now state the main problems concerning red/blue graphs that we consider in this paper.

Problem: Even Set
Instance: A red/blue graph $G = (\mathcal{R}, \mathcal{B}, E)$ and an integer $k > 0$.
Question: Is there a nonempty set of at most k vertices $R \subseteq \mathcal{R}$ that is an even set in G?
Parameter: k

Problem: Exact Even Set
Instance: A red/blue graph $G = (\mathcal{R}, \mathcal{B}, E)$ and an integer $k > 0$.
Question: Is there a set of k vertices $R \subseteq \mathcal{R}$ that is an even set in G?
Parameter: k

Problem: Odd Set
Instance: A red/blue graph $G = (\mathcal{R}, \mathcal{B}, E)$ and an integer $k > 0$.
Question: Is there a set of at most k vertices $R \subseteq \mathcal{R}$ that is an odd set in G?
Parameter: k

Problem: Exact Odd Set
Instance: A red/blue graph $G = (\mathcal{R}, \mathcal{B}, E)$ and an integer $k > 0$.
Question: Is there a set of k vertices $R \subseteq \mathcal{R}$ that is an odd set in G?
Parameter: k

We shall see shortly that all these problems are NP-complete. We will also prove that Exact Even Set, Odd Set, and Exact Odd Set are hard for $W[1]$. The following theorem will serve as the main combinatorial engine in our proof.

Theorem 2.2. *Let G be a graph on n vertices, and let k be a positive integer. In time polynomial in n and k we can produce a red/blue bipartite graph G' and a positive integer k' such that*

P1. *every dominating set in G' has size at least k',*
P2. *every dominating set in G' of size k' is a perfect code in G',*
P3. *there is a perfect code of size k in G if and only if there is a perfect code of size k' in G'.*

Notice that the red/blue graph G' encodes the information about the existence of a k-element perfect code in G. However, while the graph G is completely arbitrary, the red/blue graph G' has a substantial amount of useful structure, expressed by the properties P1 and P2.

The theorem itself is established in the next section by means of a somewhat complicated graph-theoretic transformation that has a general architecture similar to the one employed in proving the main theorems of [14] and [15]. In what follows, we will use Theorem 2.2 to yield significant results that illustrate the applicability of our graph-theoretic approach to parametrized problems concerning linear codes and integer lattices.

Parametrized complexity of problems concerning linear codes. First, note that we have the following merely by observing that in a red/blue bipartite graph, by definition a perfect code is an odd set and an odd set is a dominating set.

THEOREM 2.3. ODD SET *and* EXACT ODD SET *are hard for* $W[1]$ *and* NP-*complete.*

Proof. Theorem 2.2 immediately implies a polynomial-time parametrized transformation from PERFECT CODE, which is a $W[1]$-hard and NP-complete problem, to ODD SET and to EXACT ODD SET. Given an instance G and k of PERFECT CODE, we construct G' and k' as in Theorem 2.2. It follows from properties P1–P3 that G' contains an odd set of size at most k' if and only if G has a k-element perfect code and the size of this odd set is, in fact, exactly k'. □

We now observe that ODD SET is very similar to MAXIMUM-LIKELIHOOD DECODING. This immediately leads to the following.

THEOREM 2.4. MAXIMUM-LIKELIHOOD DECODING *is hard for* $W[1]$.

Proof. Given an instance $G = (\mathcal{R}, \mathcal{B}, E)$ and k of ODD SET, we construct an instance of MAXIMUM-LIKELIHOOD DECODING as follows. The binary $m \times n$ matrix $H = [h_{ij}]$ is the adjacency matrix of G, whose columns are indicators of the neighborhoods of vertices in $\mathcal{R}$. That is, without loss of generality (w.l.o.g.) we let $\mathcal{R} = \{1, 2, \dots, n\}$ and $\mathcal{B} = \{1, 2, \dots, m\}$ and then set $h_{ij} = 1$ if and only if $i \in \mathcal{B}$ is adjacent to $j \in \mathcal{R}$ in G. Thus G is a Tanner graph for the binary linear code having H as its parity-check matrix (cf. [29, 26]). We set the target vector s equal to the all-one vector $\mathbf{1}$ of length $m = |\mathcal{B}|$. It is easy to see that a set of k columns of H sums to $s = \mathbf{1}$ if and only if the corresponding k vertices of $\mathcal{R}$ constitute an odd set in G. □

We now employ Theorem 2.2 in a slightly more elaborate way to establish the following.

THEOREM 2.5. EXACT EVEN SET *is hard for* $W[1]$ *and* NP-*complete.*

Proof. We again reduce from PERFECT CODE. Given an instance G and k of PERFECT CODE, we first construct $G' = (\mathcal{R}, \mathcal{B}, E)$ and k' as in Theorem 2.2. Next, we let $G_1 = (\mathcal{R}_1, \mathcal{B}_1, E_1)$ and $G_2 = (\mathcal{R}_2, \mathcal{B}_2, E_2)$ denote two identical replicas of G'. We can combine G_1 and G_2 into a single red/blue graph H by creating a new red vertex z and connecting it to all the vertices in $\mathcal{B}_1$ and $\mathcal{B}_2$. Finally, we obtain a red/blue graph H^* by adjoining to H a set of $|\mathcal{R}|$ blue vertices $\mathcal{B}^*$, one for each vertex of $\mathcal{R}$, and connecting them as follows: every $\beta \in \mathcal{B}^*$ is adjacent to one vertex in $\mathcal{R}_1$ and one vertex in $\mathcal{R}_2$, which correspond to the same vertex of $\mathcal{R}$, and every such pair of vertices in $\mathcal{R}_1$ and $\mathcal{R}_2$ is connected through some vertex of $\mathcal{B}^*$. The construction of H^* from G' is illustrated in Figure 2.1. The instance of EXACT EVEN SET is given by H^* and $2k' + 1$.

FIG. 2.1. *Construction of H^* from G'.*

Now suppose that G has a k-element perfect code. Then by property P3 of Theorem 2.2, the red/blue graph G' has a k'-element perfect code $R \subseteq \mathcal{R}$. It is straightforward to verify that the $2k'$ vertices corresponding to R in $\mathcal{R}_1$ and $\mathcal{R}_2$, together with the vertex z, constitute an even set of size $2k' + 1$ in H^*. Indeed, by construction every blue vertex of $\mathcal{B}_1 \cup \mathcal{B}_2$ is adjacent to z and to exactly one vertex in the replica of R, either in $\mathcal{R}_1$ or in $\mathcal{R}_2$. Every blue vertex of $\mathcal{B}^*$ is either adjacent to both replicas of some vertex in R or to none at all.

In the other direction, suppose that S is an even set of size $2k' + 1$ in H^*. If S contains a vertex $\rho \in \mathcal{R}_1$, then it must also contain the corresponding vertex of $\mathcal{R}_2$, since otherwise the vertex of $\mathcal{B}^*$ adjacent to ρ will have exactly one neighbor in S. It follows that $|S \cap \mathcal{R}_1| = |S \cap \mathcal{R}_2|$ and the vertices of S are paired in this way. Since the size of S is odd, we conclude that S must contain the vertex z. This further implies that $S \cap \mathcal{R}_1$ is a dominating set in G_1, as otherwise there is a vertex $\beta \in \mathcal{B}_1$ which has the single neighbor z in S. Since $|S| = 2k' + 1$ and $|S \cap \mathcal{R}_1| = |S \cap \mathcal{R}_2|$, the size of this dominating set is exactly k'. By property P2 of Theorem 2.2, this dominating set is a perfect code in $G_1 = G'$, and property P3 implies that G has a perfect code of size k. $\square$

It is easy to see that EXACT EVEN SET and WEIGHT DISTRIBUTION are essentially different ways to formulate one and the same problem. Thus we have the following theorem.

THEOREM 2.6. WEIGHT DISTRIBUTION *is hard for* $W[1]$.

Proof. This follows directly from Theorem 2.5 by taking the matrix H in WEIGHT DISTRIBUTION to be the adjacency matrix for the graph $G = (\mathcal{R}, \mathcal{B}, E)$ in EXACT EVEN SET in the same way as it was done in the proof of Theorem 2.4. $\square$

Complexity of bounded-distance decoding. The fact that MAXIMUM-LIKELIHOOD DECODING is hard for $W[1]$, as established in Theorem 2.4, implies hardness for bounded-distance decoding of binary linear codes in a certain sense. We now explain this implication.

Maximum-likelihood decoding is a nearest neighbor search in the space $\mathbb{F}_2^n$ endowed with the Hamming distance $d(x, y)$ = number of positions where $x \in \mathbb{F}_2^n$ and

$y \in \mathbb{F}_2^n$ differ. Let H be an $m \times n$ binary matrix, and let $\mathbb{C}$ be the binary linear code defined by H; that is, $\mathbb{C} = \{x \in \mathbb{F}_2^n \;:\; Hx^t = \mathbf{0}\}$. Then for all $y \in \mathbb{F}_2^n$, a *maximum-likelihood decoder* for $\mathbb{C}$ always finds the closest codeword; that is, $x \in \mathbb{C}$ such that $d(x, y)$ is the minimum possible. If $s = Hy^t$, this is equivalent to finding the smallest set of columns of H that sums to s; hence the corresponding decision problem is precisely Maximum-Likelihood Decoding.

While the complexity of maximum-likelihood decoding has been thoroughly studied [2, 4, 5, 9, 28], almost nothing is presently known regarding the complexity of bounded-distance decoding, even though most of the decoders used in practice are bounded-distance decoders. A decoder is said to be *bounded-distance* if there exists a constant $t > 0$ such that for all $y \in \mathbb{F}_2^n$, the decoder always finds the closest codeword $x \in \mathbb{C}$, provided $d(x, y) \leq t$. Formally, for each positive integer t, we define the following problem.

Problem: BDD(t)
Instance: A binary $m \times n$ matrix H, a target vector $s \in \mathbb{F}_2^m$, and an integer $k \leq t$.
Question: Is there a set of at most k columns of H that sum to s?

Notice that BDD(t) is trivially in P for all t, since it can be solved in time $O(n^t)$ by simply computing Hx^t for every vector x in a Hamming sphere of radius t. Hence, the complexity of bounded-distance decoding has to be studied in a different framework. In particular, we would like to have an algorithm that solves BDD(t) in time $O(n^c)$, where c is a constant independent of t. That is, the multiplicative constant in $O(\cdot)$ may depend on t, but not the exponent.

The following corollary to $W[1]$-hardness of Maximum-Likelihood Decoding shows that such an algorithm does not exist unless the W complexity hierarchy collapses with $W[1] = \text{FPT}$.

Theorem 2.7. *Suppose that* $W[1] \neq \text{FPT}$. *Then for any positive constant* c, *there exists an integer* t_0 *such that* BDD(t) *is not solvable in time* $O(n^c)$ *for all* $t \geq t_0$ *even if the multiplicative constant in* $O(n^c)$ *may depend on* t.

Proof. First observe that the claim of the theorem is equivalent to the following: for any positive constant c, there exists an integer t_0 such that BDD(t_0) is not solvable in time $O(n^c)$. This is so because if $t \geq t_0$, then the set of possible instances of BDD(t_0) is a subset of the set of possible instances of BDD(t). Hence, if BDD(t_0) cannot be solved in time $O(n^c)$, then neither can BDD(t) for all $t \geq t_0$.

Now, assume to the contrary that for some c we can solve BDD(t) in time $O(n^c)$ for all t. Given an instance of Maximum-Likelihood Decoding, we set $t = k$ and query an oracle for BDD(t), which provides an answer to the question of Maximum-Likelihood Decoding in time $O(n^c)$. The constant in $O(n^c)$ may depend on $t = k$; let us denote this constant by a_k. Setting $f(k) = a_k$, we see that Maximum-Likelihood Decoding is solvable in time $f(k)n^c$. Hence, it is fixed-parameter tractable, which in view of Theorem 2.4 is possible only if $W[1] = \text{FPT}$. ☐

Parametrized complexity of problems concerning integer lattices. The combinatorial transformation in Theorem 2.2 can also be used to show both NP-completeness and $W[1]$-hardness for Nearest Vector and Theta Series. We start with the Nearest Vector problem.

Theorem 2.8. Nearest Vector *is hard for* $W[1]$.

Proof. Given an instance G and k of Perfect Code, we again construct $G' = (\mathcal{R}, \mathcal{B}, E)$ and k' as in Theorem 2.2. W.l.o.g., let $\mathcal{R} = \{1, 2, \ldots, r\}$ and

$\mathcal{B} = \{1, 2, \ldots, b\}$, and let H be the $r \times b$ blue/red adjacency matrix of G', which is the transpose of the matrix constructed in Theorem 2.4. That is, the *rows* of H are now indicators of the neighborhoods of the vertices in $\mathcal{R}$. If c is a real constant and $A = [a_{ij}]$ is an integer matrix, we let $cA = [ca_{ij}]$ denote the matrix obtained by multiplying each entry of A by c. We choose c to be a large integer, so that $c > k'$, and construct an instance of NEAREST VECTOR as follows. First, we define a $(b+r) \times (b+r)$ integer matrix

$$M = \left[\begin{array}{c|c} cH & I_r \\ \hline 2cI_b & \mathbf{0} \end{array}\right], \tag{2.1}$$

where I_r is the $r \times r$ identity matrix and $\mathbf{0}$ stands for the $b \times r$ all-zero matrix. It is easy to see that M has $n = r + b$ linearly independent rows, which constitute a basis for a sublattice Λ of $\mathbb{Z}^n$. We take the target vector as $s = (c, c, \ldots, c,\ 0, 0, \ldots, 0) \in \mathbb{Z}^n$ so that the first b entries of s are equal to c while the last r entries are equal to zero. Then Λ, s, and k' is the instance of NEAREST VECTOR to which the instance G and k of PERFECT CODE is transformed.

If there is a perfect code of size k in G, then by property P3 of Theorem 2.2 there is a perfect code $R \subseteq \mathcal{R}$ of size k' in G'. For convenience, we let M' denote the $r \times (b+r)$ matrix consisting of the first r rows of M. Thus each row of M' is naturally indexed by a unique vertex of $\mathcal{R}$. Let $x = (x_1, x_2, \ldots, x_n) \in \Lambda$ be the sum of those k' rows of M' that are indexed by the vertices of the perfect code R. Then it is easy to see that $x_i = c$ in the first b positions, and $\|x - s\|^2 = k'$.

In the other direction, suppose that there is a vector $x = (x_1, x_2, \ldots, x_n) \in \Lambda$ with $\|x - s\|^2 \le k'$, and denote $y = (y_1, y_2, \ldots, y_n) = x - s$. First observe that $y_i \equiv 0 \bmod c$ for $i = 1, 2, \ldots, b$ by the construction of M and s. Since $c > k'$ while $\|y\|^2 \le k'$, it follows that $y_i = 0$ in the first b positions. This further implies that $x_i = c$ for $i = 1, 2, \ldots, b$. Now let R be the subset of $\mathcal{R}$ consisting of all the vertices that index those rows of M' that are included in the linear combination comprising x (with a nonzero coefficient). We claim that R is a dominating set in G'. Indeed, if some vertex $i \in \mathcal{B}$ does not have a neighbor in R, then $x_i \equiv 0 \bmod 2c$ in the corresponding position, contrary to the fact that $x_i = c$, which we have already established. Hence, by property P1 of Theorem 2.2, we have that $|R| \ge k'$. Together with $\|x - s\|^2 \le k'$ this implies that $\|x - s\|^2 = |R| = k'$, and R is a perfect code in G' by property P2 of Theorem 2.2. Property P3 of Theorem 2.2 now implies that G has a perfect code of size k. $\square$

By modifying the argument of Theorem 2.8 only slightly, we can prove that THETA SERIES is also hard for $W[1]$. The idea is to incorporate the target vector s into the generator matrix M for Λ. The same argument also shows, for the first time, that THETA SERIES is NP-complete.

THEOREM 2.9. THETA SERIES *is hard for* $W[1]$ *and* NP-*complete.*

Proof. We proceed as in the proof of Theorem 2.8, except that we now choose c so that $c > 4k' + 1$ and replace the matrix in (2.1) by the slightly more elaborate $(b+r+1) \times (b+r+1)$ matrix

$$M = \left[\begin{array}{c|c|c} cH & \mathbf{0} & 2I_r \\ \hline c^2 I_b & \mathbf{0} & \mathbf{0} \\ \hline c\,c \cdots c & 1 & 0\,0 \cdots 0 \end{array}\right], \tag{2.2}$$

where $\mathbf{0}$ is used to denote both the all-zero column and the $b \times r$ all-zero matrix. We again think of the $n = r + b + 1$ rows of M as a basis for a sublattice Λ of $\mathbb{Z}^n$. Thus an instance G and k of Perfect Code is transformed by Theorem 2.2 into the red/blue graph $G' = (\mathcal{R}, \mathcal{B}, E)$ and k', which is further transformed into the instance Λ and $4k' + 1$ of Theta Series.

Suppose that G contains a k-element perfect code, and let $R \subseteq \mathcal{R}$ be the corresponding k'-element perfect code in G'. We again let M' denote the $r \times (b + r + 1)$ submatrix of M consisting of the first r rows that are naturally indexed by the vertices of $\mathcal{R}$. Let $x = (x_1, x_2, \ldots, x_n) \in \Lambda$ be the following linear combination of $k' + 1$ rows of M: k' rows of M' indexed by the k' vertices of the perfect code R with coefficient $+1$ and the last row of M with coefficient -1. Then it is easy to see that $x_i = 0$ in the first b positions and $\|x\|^2 = 4k' + 1$.

In the other direction, suppose that there exists $x = (x_1, x_2, \ldots, x_n) \in \Lambda$ with $\|x\|^2 = 4k' + 1$. Write $x = a_1 v_1 + a_2 v_2 + \cdots + a_n v_n$, where $a_1, a_2, \ldots, a_n$ are integers, not all zero, and $v_1, v_2, \ldots, v_n$ are the rows of M, listed in a top-to-bottom order. First, we again observe that $x_i \equiv 0 \bmod c$ for $i = 1, 2, \ldots, b$ by the construction of M. Since $c > 4k' + 1$, it follows that $x_i = 0$ in the first b positions. Further observe that $x_i \equiv 0 \bmod 2$ in the last r positions. Together with $\|x\|^2 \equiv 1 \bmod 4$, this implies that $x_{b+1} = a_n$ must be nonzero. Notice that

$$a_n^2 \; = \; x_{b+1}^2 \; \le \; \|x\|^2 \; = \; 4k' + 1 \; < \; c. \tag{2.3}$$

As in the proof of Theorem 2.8, let R be the subset of $\mathcal{R}$ consisting of the vertices that index those rows of M' which have a nonzero coefficient in the linear combination comprising x. We again claim that R is a dominating set in G'. Otherwise, let $i \in \mathcal{B}$ be a vertex which does not have a neighbor in R, and let $y = x - a_n v_n$. We have already shown that $x_i = 0$. Hence $y_i = -a_n c \neq 0$ and $|y_i| < c^2$ in view of (2.3). This is a contradiction, since if i does not have neighbors in R, then $y_i \equiv 0 \bmod c^2$ by the construction of M. From this point on, the proof is exactly the same as in Theorem 2.8. Referring to Theorem 2.2, we conclude that $|R| \ge k'$, which together with $\|x\|^2 = 4k' + 1$ implies that $|R| = k'$ and R is necessarily a perfect code in G'. This, in turn, further implies the existence of a k-element perfect code in G. ∎

As a final remark in this section, we observe that a theorem of Cai and Chen [11] states that if the optimization problem naturally associated to an integer-parameter problem has a fully polynomial-time approximation scheme (see [22] for an exposition of this concept), then the corresponding parametrized problem is fixed-parameter tractable. We can draw from this the following corollary.

Corollary 2.10. *There is no fully polynomial-time approximation scheme for any of the problems discussed in this section, unless* $W[1] = \mathrm{FPT}$.

In the next section, we prove our principal combinatorial transformation (Theorem 2.2), which served us so well in this section.

3. The combinatorial engine.

Our proof of Theorem 2.1 has many similarities to the proofs of the main theorems of [14] and [15], to which the reader may wish to refer. Notice that an implicit assumption in Theorem 2.2 is that the constant k' may depend on k but not on n. This assumption is essential for all the parametrized transformations in the previous section. (For more on this, see the appendix.) We now restate Theorem 2.1, while specifying a precise value for k' in terms of k.

THEOREM 2.1. *Let $G = (V, E)$ be a graph on n vertices, and let k be a positive integer. In time polynomial in n and k we can produce a red/blue bipartite graph $G' = (\mathcal{R}, \mathcal{B}, E')$ and the positive integer*

$$k' = (2k+1) + 3\left(2k(k+1) + (k+1)^2\right)$$

such that:

P1. *Every dominating set in G' has size at least k';*
P2. *Every dominating set in G' of size k' is a perfect code in G';*
P3. *There is a perfect code of size k in G if and only if there is a perfect code of size k' in G'.*

We start the proof with some notation. In describing the construction of G' from G it is convenient to identify V with the set of integers $\{1, \dots, n\}$. An *interval* of vertices is defined to be a subset of V consisting of consecutive integers, for example, $\{3, 4, 5, 6\}$, and may be empty. Let $\mathcal{J}$ denote the set of all nonempty intervals having a size of at most $n - k$; that is,

$$\mathcal{J} = \{\ J\ :\ J \text{ is an interval in } V \text{ and } 1 \le |J| \le n - k\ \}.$$

For an interval $J \in \mathcal{J}$, define the *initial boundary* $\partial(J)$ of J to be the largest nonnegative integer strictly less than the smallest element of J. For example, $\partial(\{2, 3, 4\}) = 1$, $\partial(\{6\}) = 5$, $\partial(\{1, 2\}) = 0$. Define the *terminal boundary* $\partial'(J)$ to be the smallest positive integer strictly greater than the largest element of J. Thus $\partial'(\{2, 3, 4\}) = 5$, for example.

We will also need to refer to empty intervals, but we will still need to indicate where these empty intervals begin and end. For this purpose, we introduce the special symbols $\epsilon_0, \epsilon_1, \dots, \epsilon_n$ and extend the definitions of ∂ and ∂' as follows. For $u = 0, 1, \dots, n$, we define $\partial(\epsilon_u) = u$ and $\partial'(\epsilon_u) = u + 1$. Thus ϵ_u represents the "interval" of vertices in V that is empty but "located" between u and $u + 1$. We let $\mathcal{J}^*$ denote the set of nonempty intervals $\mathcal{J}$ augmented with these empty intervals; that is, $\mathcal{J}^* = \mathcal{J} \cup \{\epsilon_u\ :\ 0 \le u \le n\}$.

If $u, v \in V$ with $u < v$, we define the interval *between* u and v as $J(u, v) = \{u + 1, \dots, v - 1\}$, provided $v - u \ge 2$. If $v = u + 1$, then $J(u, v) = \epsilon_u$. Similarly, for $u \in V$ we define the interval *preceding* u to be $J(0, u) = \{1, \dots, u - 1\}$ if $u \ge 2$, and if $u = 1$, then $J(0, u) = J(0, 1) = \epsilon_0$. The interval *succeeding* $u \in V$ is defined as $J(u, \infty) = \{u + 1, \dots, n\}$ if $u < n$, and $J(n, \infty) = \epsilon_n$.

Let $[k]$ denote the set of integers $\{1, 2, \dots, k\}$, and let $[k]^*$ denote the set of integers $\{0, 1, \dots, k\}$. Part of our construction of $G' = (\mathcal{R}, \mathcal{B}, E')$ will be quantified over the set $[k]^* \times [k]^*$ of ordered pairs of elements of $[k]^*$, while other parts of the construction will be quantified over subsets of this set, namely, $[k] \times [k]^*$ and $[k]^* \times [k]$. This distinction between $[k]$ and $[k]^*$ is basically a technicality, which is needed to account for the boundary cases in the construction.

The red foundation. Our description of G' starts with five sets of red vertices $R_1, R_2, \dots, R_5$. We will refer to the vertices of $R_1, R_2, \dots, R_5$ as *basic* red vertices. All the blue vertices, as well as some additional red vertices, will be added to G' as the construction progresses. The five sets $R_1, R_2, \dots, R_5$ are employed in our construction to represent the structure of each possible choice of a k-element subset of the set of vertices of G. Each one of the five sets is, in a sense, a gadget designed to capture a different aspect of this structure. We now describe these sets along with their roles in the construction of G' and the notation used to refer to their vertices:

- Gadgets that indicate the k chosen vertices:
  $R_1 \;=\; \{\, a(i,u) \;:\; i \in [k],\; u \in V \,\}$.
- Gadgets that indicate the intervals between chosen vertices:
  $R_2 \;=\; \{\, b(i,J) \;:\; i \in [k]^*,\; J \in \mathcal{J}^* \,\}$.
- Gadgets that indicate pairs of intervals:
  $R_3 \;=\; \{\, c(i,i',J,J') \;:\; i,i' \in [k]^*,\; J,J' \in \mathcal{J}^* \,\}$.
- Gadgets that indicate choice/interval pairs:
  $R_4 \;=\; \{\, c'(i,i',u,J) \;:\; i \in [k],\; i' \in [k]^*,\; u \in V,\; J \in \mathcal{J}^* \,\}$.
- Gadgets that indicate interval/choice pairs:
  $R_5 \;=\; \{\, c''(i,i',J,u) \;:\; i \in [k]^*,\; i' \in [k],\; J \in \mathcal{J}^*,\; u \in V \,\}$.

It will be convenient to organize the basic red vertices into *blocks*. These blocks will constitute a partition of the basic red vertices, and there will be altogether

$$k'' \;=\; 1 + 2k + 2k(k+1) + (k+1)^2 \tag{3.1}$$

blocks. Specifically, we partition R_1 into k blocks, R_2 into $k+1$ blocks, R_3 into $(k+1)^2$ blocks, and R_4, R_5 into $k(k+1)$ blocks each. These blocks are defined as follows:

$$\mathcal{A}(i) = \{a(i,u) : i \in [k],\; u \in V\} \qquad \text{for } i = 1,2,\ldots,k,$$

$$\mathcal{B}(i) = \{b(i,J) : i \in [k]^*,\; J \in \mathcal{J}^*\} \qquad \text{for } i = 0,1,\ldots,k,$$

$$\mathcal{C}(i,i') = \{c(i,i',J,J') : J,J' \in \mathcal{J}^*\} \qquad \text{for } i \in [k]^* \text{ and } i' \in [k]^*,$$

$$\mathcal{C}'(i,i') = \{c'(i,i',u,J) : u \in V,\; J \in \mathcal{J}^*\} \qquad \text{for } i \in [k] \text{ and } i' \in [k]^*,$$

$$\mathcal{C}''(i,i') = \{c''(i,i',J,u) : J \in \mathcal{J}^*,\; u \in V\} \qquad \text{for } i \in [k]^* \text{ and } i' \in [k].$$

We let $\mathfrak{R}_0$ denote the set of k'' red blocks defined above. These will be referred to as the *basic blocks*. Additional blocks of blue and red vertices will be added to G' later in the construction.

The semantics of the reduction. Our semantic intentions in the design of $G' = (\mathcal{R}, \mathcal{B}, E')$ can be summarized as follows. The k blocks of R_1 represent the choice of k vertices of V that may form a k-element perfect code in G. The $k+1$ blocks of R_2 represent the intervals between the consecutive choices of vertices of V represented in R_1. The blocks of R_3, R_4, R_5 do not carry any meaning with respect to G; these blocks are needed to impose an internal structure on G'.

Although we have only started to describe G', enough is already visible to enable us to describe, at least in part, the solution translations of the reduction. This description may serve to motivate and clarify some of the forthcoming details of the proof. There are two different solution translations, namely, translations in the

forward direction: the manner in which a k-element perfect code in G translates into a k'-element perfect code in G', and the

backward direction: the manner in which a k'-element perfect code (or dominating set) in G' translates into a k-element perfect code in G.

The forward solution translation. In the forward direction, suppose that the elements of a perfect code of size k in $G = (V,E)$ are given by $u_1, u_2, \ldots, u_k$ and w.l.o.g. assume that

$$u_1 \ < \ u_2 \ < \ \cdots \ < \ u_k.$$

Let $J_0 = J(0, u_1)$. In other words, J_0 is the interval (set) of elements of V that precede u_1. For $i = 1, 2, \ldots, k-1$, let $J_i = J(u_i, u_{i+1})$. Thus J_i is the interval of elements of V that are properly between u_i and u_{i+1}. Finally, let $J_k = J(u_k, \infty)$ be the interval of elements of V following u_k. Now consider the sets

$$S_1 = \{\, a(i, u_i) \ : \ i \in [k] \,\}, \tag{3.2}$$

$$S_2 = \{\, b(i, J_i) \ : \ i \in [k]^* \}, \tag{3.3}$$

$$S_3 = \{\, c(i, i', J_i, J_{i'}) \ : \ i \in [k]^*, i' \in [k]^* \}, \tag{3.4}$$

$$S_4 = \{\, c'(i, i', u_i, J_{i'}) \ : \ i \in [k], \ i' \in [k]^* \}, \tag{3.5}$$

$$S_5 = \{\, c''(i, i', J_i, u_{i'}) \ : \ i \in [k]^*, \ i' \in [k] \,\}, \tag{3.6}$$

and let $S = S_1 \cup S_2 \cup \cdots \cup S_5$. Notice that S contains precisely one vertex from each of the k'' basic red blocks, where k'' is given by (3.1). Our construction of $G' = (\mathcal{R}, \mathcal{B}, E')$ will ensure that the set S may be extended to a perfect code in G'. This extension is accomplished by adding two more vertices for each vertex in S_3, S_4, and S_5, as specified later in our construction.

The backward solution translation. Our construction of G' will also ensure that any k'-element dominating set S in G' must be distributed so that there is exactly one element of S in each of the k'' basic blocks of $\mathfrak{R}_0$. Furthermore, S will be forced to have the restricted form of a perfect code in G'. The construction will ensure that for such a set S, the u-indices of the k elements of $S \cap R_1$ are distinct and that these indices correspond to a k-element perfect code in G.

The construction. We will describe $G' = (\mathcal{R}, \mathcal{B}, E')$ by starting with the k'' basic red blocks of $\mathfrak{R}_0$ and applying various *operators* to these blocks. Each application of an operator results in further blocks of red and blue vertices being created, along with various edges. A high-level blueprint for $G' = (\mathcal{R}, \mathcal{B}, E')$ in terms of these operators is shown in Figure 3.1.

In constructing $G' = (\mathcal{R}, \mathcal{B}, E')$, operators are applied only to argument sets of red blocks. Thus each blue vertex $\beta \in \mathcal{B}$ is created by a single specific application of an operator, and the neighborhood of β is completely established by this application. This allows us to argue a series of claims concerning properties of G' as we continue to describe the steps of the construction.

The block guard operator $\mathbf{\Gamma_1}$. The operator Γ_1 takes a single red block $\mathcal{X}$ as an argument and adds one blue vertex connected to every red vertex in $\mathcal{X}$.

The last step of the construction of $G' = (\mathcal{R}, \mathcal{B}, E')$ will be to apply this operator to each of the red blocks of the construction. When we get to the last step, there will be k' red blocks, the collection of which will be denoted $\mathfrak{R}$.

The last step. *Apply the block guard operator* Γ_1 *to every red block.*

We cannot make this the first step of the construction because some of the k' red blocks to which Γ_1 is to be applied have yet to be created by applications of operators in earlier steps of the construction. However, Γ_1 does provide a simple initial example of an operator (the action of the block guard operator is illustrated in Figure 3.2), and we can easily prove certain important properties of $G' = (\mathcal{R}, \mathcal{B}, E')$ having only this much information about the construction.

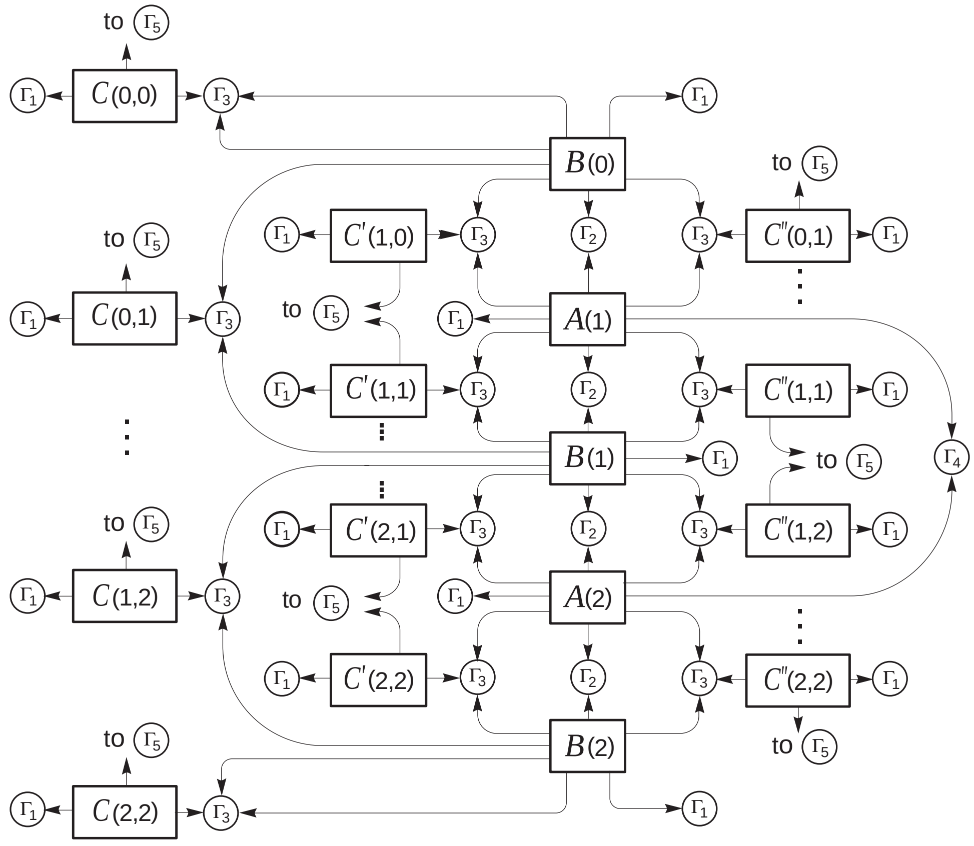

FIG. 3.1. *The blueprint for G' in terms of basic blocks and operators (example for $k = 2$).*

For example, the following lemma follows directly from the definition of Γ_1. This simple lemma already establishes property P1 of Theorem 2.2.

LEMMA 3.1. *Every dominating set in $G' = (\mathcal{R}, \mathcal{B}, E')$ has size at least k' and contains at least one vertex from each of the k' red blocks of $\mathfrak{R}$.*

Proof. Let $S \subseteq \mathcal{R}$ be a dominating set in G', and let $\mathcal{X} \in \mathfrak{R}$ be a red block. If $S \cap \mathcal{X} = \varnothing$, then the blue vertex $\beta \in \mathcal{B}$ created by the application of Γ_1 to $\mathcal{X}$ does not have a neighbor in S. ◻

Next, we need a definition. Let Γ be an operator; let A denote the union of the red blocks that either provide the arguments for the application of Γ or are created by the application of Γ; and let B denote the set of blue vertices created by the application of Γ.

DEFINITION 3.2. *We say that the operator Γ is* locally perfect *if the following condition is satisfied for every subset S of A that contains exactly one vertex from each red block contained in A: if every vertex in B has at least one neighbor in S, then every vertex in B has a unique neighbor in S. In other words, if S contains one vertex from each red block and is "locally" a dominating set, then S is necessarily a "local" perfect code.*

The above definition is motivated by the observation that if every application of an operator in the construction of $G' = (\mathcal{R}, \mathcal{B}, E')$ is locally perfect, then property P2 of Theorem 2.2 will hold. This observation is a corollary to the following lemma.

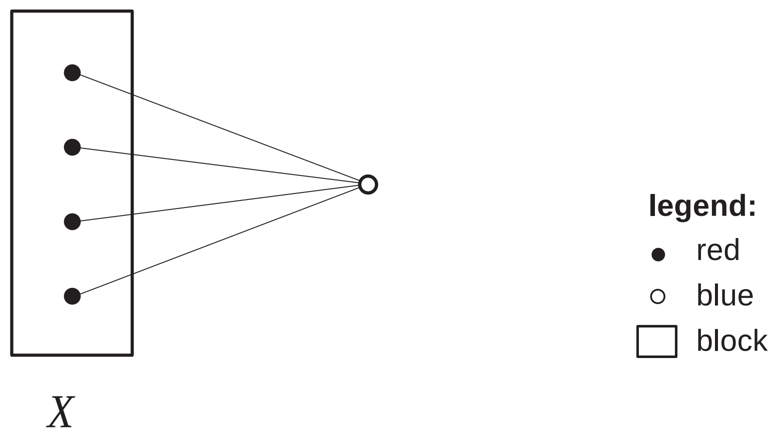

FIG. 3.2. *The block guard operator* Γ_1.

LEMMA 3.3. *Every k'-element dominating set S in G' must contain exactly one vertex from each of the k' red blocks of $\mathfrak{R}$, and the last step in the construction of G' is locally perfect.*

Proof. Since each of the k' blocks of $\mathfrak{R}$ must contain at least one element of S by Lemma 3.1, each block must contain exactly one element of S. Local perfection of Γ_1 is trivial. □

The branch operator $\mathbf{\Gamma_2}$. The arguments to the Γ_2 operator are two red blocks $\mathcal{X}$ and $\mathcal{X}'$, given together with a partition of $\mathcal{X}'$ into $|\mathcal{X}|$ or more nonempty classes, and an injective assignment to each element of $\mathcal{X}$ of a different class in the partition of $\mathcal{X}'$; that is,

$$x \in \mathcal{X} \ \mapsto \ \mathcal{S}_x \subset \mathcal{X}'$$

so that $\mathcal{S}_x \cap \mathcal{S}_y = \varnothing$ for $x \neq y$. The result of applying Γ_2 to $\mathcal{X}$ and $\mathcal{X}'$ with this assignment is

a. the creation of the set of $|\mathcal{X}|$ blue vertices

$$\{\, \beta(x) \ : \ x \in \mathcal{X} \,\},$$

b. for each blue vertex $\beta(x)$ in this set, the creation of edges connecting $\beta(x)$ to $x \in \mathcal{X}$ and to all the red vertices in $\mathcal{X}'$ that belong to $\mathcal{S}_y$ for some $y \neq x$ in $\mathcal{X}$.

LEMMA 3.4. *The branch operator Γ_2 is locally perfect. In particular, suppose that this operator is applied to the red blocks $\mathcal{X}$ and $\mathcal{X}'$, and let S be a k'-element dominating set in $G' = (\mathcal{R}, \mathcal{B}, E')$. Then $S \cap \mathcal{X} = \{x\}$ and $S \cap \mathcal{X}' = \{x'\}$ for some $x' \in \mathcal{S}_x$.*

Proof. The fact that S intersects each of the blocks $\mathcal{X}$ and $\mathcal{X}'$ at a single vertex, say, x and x', follows immediately from Lemma 3.3. The vertex $x \in \mathcal{X}$ is adjacent to the single blue vertex $\beta(x)$. If $x' \in \mathcal{X}'$ belongs to a partition class that is not assigned to a vertex of $\mathcal{X}$, then x' is not adjacent to any of the blue vertices created by Γ_2 and the set S dominates only the single vertex $\beta(x)$, a contradiction. Similarly, if $x' \in \mathcal{S}_y$ for some vertex $y \neq x$ in $\mathcal{X}$, then the blue vertex $\beta(y)$ is not adjacent to either x or x'. Hence $\beta(y)$ is not dominated by S, again a contradiction. Thus $x' \in \mathcal{S}_x$, which is the only remaining case. It now follows that every blue vertex created by Γ_2 has a

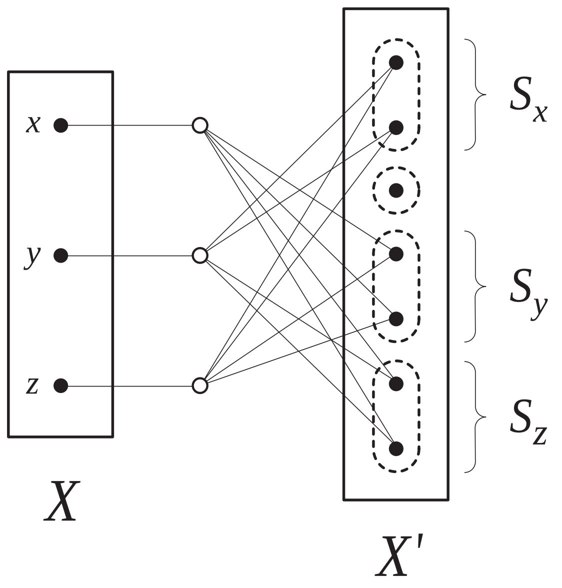

FIG. 3.3. *The branch operator* Γ_2.

unique neighbor in S. The unique neighbor of $\beta(x)$ is x and x' is the unique neighbor of every other blue vertex. Thus, the branch operator Γ_2 is locally perfect. $\square$

A useful special case of the application of Γ_2 is as "equality" enforcer. For this, we assume that the arguments to Γ_2 are isomorphic sets with the isomorphism given by the correspondence

$$x \in \mathcal{X} \quad\longleftrightarrow\quad e(x) \in \mathcal{X}',$$

and in applying the operator Γ_2, we use the natural assignment $x \mapsto \mathcal{S}_x = \{e(x)\}$. In this situation, assuming that S is a k'-element dominating set in G', we observe that $S \cap \mathcal{X} = \{x\}$ and $S \cap \mathcal{X}' = \{y\}$ necessarily imply that $y = e(x)$ in view of Lemma 3.4. With Γ_2 at hand, we are finally ready to describe the first two steps of our construction.

Step 1. *For* $i = 1, 2, \ldots, k-1$, *apply the operator* Γ_2 *to the arguments* $\mathcal{X} = \mathcal{A}(i)$ *and* $\mathcal{X}' = \mathcal{B}(i)$ *with the assignment*

$$a(i,u) \;\mapsto\; \{\, b(i,J) \;:\; J \in \mathcal{J}^*,\ \partial(J) = u \,\}. \tag{3.7}$$

Also apply Γ_2 *to the arguments* $\mathcal{X} = \mathcal{A}(k)$ *and* $\mathcal{X}' = \mathcal{B}(k)$ *with the assignment*

$$a(k,u) \;\mapsto\; \{\, b(k,J) \;:\; J \in \mathcal{J}^*,\ \partial(J) = u \ \text{ and } \ \partial'(J) = \infty \,\}. \tag{3.8}$$

Step 2. *For* $i = 2, 3, \ldots, k$, *apply the operator* Γ_2 *to the arguments* $\mathcal{X} = \mathcal{A}(i)$ *and* $\mathcal{X}' = \mathcal{B}(i-1)$ *with the assignment*

$$a(i,u) \;\mapsto\; \{\, b(i-1,J) \;:\; J \in \mathcal{J}^*,\ \partial'(J) = u \,\}. \tag{3.9}$$

Also apply Γ_2 *to the arguments* $\mathcal{X} = \mathcal{A}(1)$ *and* $\mathcal{X}' = \mathcal{B}(0)$ *with the assignment*

$$a(1,u) \;\mapsto\; \{\, b(0,J) \;:\; J \in \mathcal{J}^*,\ \partial'(J) = u \ \ \textit{and}\ \ \partial(J) = 0 \,\}. \tag{3.10}$$

The first two steps of the construction operate on the vertices in R_1 and R_2 that represent, respectively, the choice of k vertices of G and the intervals between these chosen vertices. The purpose of these two steps is reflected in the following lemma.

LEMMA 3.5. *Suppose that S is a k'-element dominating set in $G' = (\mathcal{R}, \mathcal{B}, E')$. Then the $k + (k+1)$ vertices of $S \cap R_1$ and $S \cap R_2$ consistently represent k vertices of $G = (V, E)$ and the intervals between these vertices in the following way:*

a. *If $S \cap \mathcal{A}(1) = \{a(1,u)\}$, then $S \cap \mathcal{B}(0) = \{b(0, J(0,u))\}$.*
b. *For $i = 1, 2, \ldots, k-1$, if $S \cap \mathcal{A}(i) = \{a(i,u)\}$ and $S \cap \mathcal{A}(i+1) = \{a(i+1,v)\}$, then $S \cap \mathcal{B}(i) = \{b(i, J(u,v))\}$.*
c. *If $S \cap \mathcal{A}(k) = \{a(k,u)\}$, then $S \cap \mathcal{B}(k) = \{b(k, J(u,\infty))\}$.*
d. *For all $i < i'$, if $S \cap \mathcal{A}(i) = \{a(i,u)\}$ and $S \cap \mathcal{A}(i') = \{a(i',u')\}$, then $u < u'$.*

Proof. Referring to the last application of the operator Γ_2 in Step 2, it follows from Lemma 3.4 that if $S \cap \mathcal{A}(1) = \{a(1,u)\}$, then $S \cap \mathcal{B}(0)$ consists of a vertex x' which belongs to the set assigned to $a(1,u)$ on the right-hand side of (3.10). But this set consists of the single element $b(0, J(0,u))$, which establishes part (a). Part (c) follows in a similar fashion from Lemma 3.4 and (3.8). Part (b) follows from Lemma 3.4 along with the combination of (3.7) and (3.9). Indeed, assuming the condition of part (b), it follows from Lemma 3.4 that $S \cap \mathcal{B}(i) = \{x'\}$, where x' belongs to the intersection of the set assigned to $a(i,u)$ in (3.7) with the set assigned to $a(i+1,v)$ in (3.9). Thus $x' = b(i,J)$, where $\partial(J) = u$ and $\partial'(J) = v$, that is, $J = J(u,v)$. Part (d) follows immediately from part (b). □

The product operator $\mathbf{\Gamma_3}$. The arguments for the operator are three red blocks $\mathcal{X}_1$, $\mathcal{X}_2$, and $\mathcal{Z}$, where $\mathcal{Z}$ is isomorphic to the product $\mathcal{X}_1 \times \mathcal{X}_2$, together with a one-to-one correspondence:

$$z \in \mathcal{Z} \;\longleftrightarrow\; (x_1, x_2) \in \mathcal{X}_1 \times \mathcal{X}_2. \tag{3.11}$$

We write $z = z(x_1, x_2)$ to denote the element of $\mathcal{Z}$ that corresponds to the pair $(x_1, x_2) \in \mathcal{X}_1 \times \mathcal{X}_2$ in (3.11). An application of Γ_3 augments $G' = (\mathcal{R}, \mathcal{B}, E')$ in the following ways:

a. Two auxiliary blocks of red vertices are created:

$$\mathcal{P}_1 = \{\, \rho_1(x_1,x_2) \;:\; x_1 \in \mathcal{X}_1,\ x_2 \in \mathcal{X}_2 \,\},$$
$$\mathcal{P}_2 = \{\, \rho_2(x_1,x_2) \;:\; x_1 \in \mathcal{X}_1,\ x_2 \in \mathcal{X}_2 \,\}.$$

b1. The operator Γ_2 is applied to the arguments $\mathcal{X} = \mathcal{X}_1$ and $\mathcal{X}' = \mathcal{P}_1$ with the assignment

$$x \in \mathcal{X}_1 \;\mapsto\; \{\, \rho_1(x,y) \;:\; y \in \mathcal{X}_2 \,\}. \tag{3.12}$$

b2. The operator Γ_2 is applied to the arguments $\mathcal{X} = \mathcal{X}_2$ and $\mathcal{X}' = \mathcal{P}_2$ with the assignment

$$y \in \mathcal{X}_2 \;\mapsto\; \{\, \rho_2(x,y) \;:\; x \in \mathcal{X}_1 \,\}. \tag{3.13}$$

c. The operator Γ_2 is applied as an equality enforcer to the arguments $\mathcal{X} = \mathcal{P}_1$ and $\mathcal{X}' = \mathcal{P}_2$ with the assignment

$$\rho_1(x_1,x_2) \;\mapsto\; \{\, \rho_2(x_1,x_2) \,\}. \tag{3.14}$$

d1. The operator Γ_2 is applied as an equality enforcer to the arguments $\mathcal{X} = \mathcal{P}_2$ and $\mathcal{X}' = \mathcal{Z}$ with the assignment

$$\rho_2(x_1, x_2) \mapsto \{\, z(x_1, x_2) \,\}. \tag{3.15}$$

d2. The operator Γ_2 is applied as an equality enforcer to the arguments $\mathcal{X} = \mathcal{Z}$ and $\mathcal{X}' = \mathcal{P}_1$ with the assignment

$$z(x_1, x_2) \mapsto \{\, \rho_1(x_1, x_2) \,\}. \tag{3.16}$$

Lemma 3.6. *The product operator Γ_3 is locally perfect. In particular, suppose that this operator is applied to the three red blocks $\mathcal{X}_1, \mathcal{X}_2$, and $\mathcal{Z}$, and let S be a k'-element dominating set in $G' = (\mathcal{R}, \mathcal{B}, E')$ with $S \cap \mathcal{X}_1 = \{x\}$ and $S \cap \mathcal{X}_2 = \{y\}$. Then $S \cap \mathcal{Z} = \{z(x, y)\}$.*

Proof. It follows from Lemma 3.3 that S intersects each of the red blocks $\mathcal{P}_1, \mathcal{P}_2$, and $\mathcal{Z}$ at a single vertex, say, $\rho_1(x', y') \in \mathcal{P}_1$, $\rho_2(x'', y'') \in \mathcal{P}_2$, and $z \in \mathcal{Z}$, respectively. We can now argue a series of simple observations regarding $\rho_1(x', y'), \rho_2(x'', y'')$, and z, which follow from Lemma 3.4 in conjunction with the assignments in (3.12)–(3.16). In view of (3.12), respectively, (3.13), we have that $x' = x$, respectively, $y'' = y$. By the equality enforcing assignment in (3.14), we have $x' = x''$ and $y' = y''$. Thus $x'' = x' = x$ and $y'' = y' = y$. It now follows from either (3.15) or (3.16) that $z = z(x, y)$.

Since the product operator Γ_3 is composed from five applications of the branch operator Γ_2, the local perfection of Γ_3 follows from the local perfection of Γ_2 established in Lemma 3.4. Alternatively, this can be proved directly by verifying that each of the $|\mathcal{X}_1| + |\mathcal{X}_2| + 3\,|\mathcal{X}_1||\mathcal{X}_2|$ blue vertices created by Γ_3 is adjacent to one and only one of the five red vertices $x \in \mathcal{X}_1$, $y \in \mathcal{X}_2$, $\rho_1(x, y) \in \mathcal{P}_1$, $\rho_2(x, y) \in \mathcal{P}_2$, and $z(x, y) \in \mathcal{Z}$, regardless of the choice of $x \in \mathcal{X}_1$ and $y \in \mathcal{X}_2$. ∎

With the product operator Γ_3 at hand, we can now describe the next three steps in our construction of $G' = (\mathcal{R}, \mathcal{B}, E')$. These three steps establish a relation between the blocks in R_3, R_4, R_5 and the blocks of R_1, R_2 which represent the choice of some k vertices of G according to Lemma 3.5.

Step 3. *For each pair (i, i') with $i, i' \in [k]^*$, apply the operator Γ_3 to the arguments $\mathcal{X}_1 = \mathcal{B}(i)$, $\mathcal{X}_2 = \mathcal{B}(i')$, and $\mathcal{Z} = \mathcal{C}(i, i')$ with the product correspondence*

$$c(i, i', J, J') \in \mathcal{C}(i, i') \;\longleftrightarrow\; (b(i, J), b(i', J')) \in \mathcal{B}(i) \times \mathcal{B}(i').$$

Step 4. *For each pair (i, i') with $i \in [k]$ and $i' \in [k]^*$, apply the operator Γ_3 to the arguments $\mathcal{X}_1 = \mathcal{A}(i)$, $\mathcal{X}_2 = \mathcal{B}(i')$, and $\mathcal{Z} = \mathcal{C}'(i, i')$ with the product correspondence*

$$c'(i, i', u, J) \in \mathcal{C}'(i, i') \;\longleftrightarrow\; (a(i, u), b(i', J)) \in \mathcal{A}(i) \times \mathcal{B}(i').$$

Step 5. *For each pair (i, i') with $i \in [k]^*$ and $i' \in [k]$, apply the operator Γ_3 to the arguments $\mathcal{X}_1 = \mathcal{B}(i)$, $\mathcal{X}_2 = \mathcal{A}(i')$, and $\mathcal{Z} = \mathcal{C}''(i, i')$ with the product correspondence*

$$c''(i, i', J, u) \in \mathcal{C}''(i, i') \;\longleftrightarrow\; (b(i, J), a(i', u)) \in \mathcal{B}(i) \times \mathcal{A}(i').$$

At this stage of the construction, the red/blue graph $G' = (\mathcal{R}, \mathcal{B}, E')$ is highly structured, but the adjacency structure of G' is *independent* of the adjacency structure of $G = (V, E)$. The following operator will finally establish the connection between $G = (V, E)$ and $G' = (\mathcal{R}, \mathcal{B}, E')$.

FIG. 3.4. *The product operator* Γ_3.

The G-adjacency operator Γ_4. This operator takes all the vertices of R_1 as arguments, that is, all the $\mathcal{A}$-blocks $\mathcal{A}(1), \mathcal{A}(2), \ldots, \mathcal{A}(k)$. A set of $n = |V|$ blue vertices

$$\{\, \beta(u) \ : \ u \in V \,\}$$

is created. These vertices are connected as follows. For each $i = 1, 2, \ldots, k$, the blue vertex $\beta(u)$ is connected to $a(i, u)$ and to $a(i, v)$ for all $v \in V$ that are adjacent to u in G.

It is easy to see that an application of Γ_4 essentially amounts to replicating k times the original graph $G = (V, E)$ as a red/blue bipartite graph with the set of red vertices $\mathcal{A}(i)$ and the set of blue vertices $\{\beta(u) : u \in V\}$, both isomorphic to V. This is precisely what we do next.

Step 6. *Apply the operator* Γ_4 *to all of the* $\mathcal{A}$*-blocks* $\mathcal{A}(1), \mathcal{A}(2), \ldots, \mathcal{A}(k)$.

Let S be a k'-element dominating set in $G' = (\mathcal{R}, \mathcal{B}, E')$. We know from Lemma 3.3 that S intersects each of the red blocks, in particular each of the blocks $\mathcal{A}(1), \mathcal{A}(2), \ldots, \mathcal{A}(k)$, at a single vertex. Thus for each $i = 1, 2, \ldots, k$, we can define v_i to be the unique vertex of V such that $S \cap \mathcal{A}(i) = \{a(i, v_i)\}$. With this notation, let $V(S) = \{v_1, v_2, \ldots, v_k\}$.

LEMMA 3.7. *The set* $V(S)$ *is a* k*-element dominating set in* G*. Furthermore, if* S *is a perfect code in* $G' = (\mathcal{R}, \mathcal{B}, E')$*, then* $V(S)$ *is a* k*-element perfect code in* G*.*

Proof. It follows from Lemma 3.5 that $v_1, v_2, \ldots, v_k$ are all distinct (in fact $v_1 < v_2 < \cdots < v_k$). Hence $|V(S)| = k$. The rest is immediate from the definition of Γ_4: a vertex $u \in V$ has a (unique) neighbor in $V(S)$ if and only if the vertex $\beta(u)$ created by Γ_4 has a (unique) neighbor in S. ◻

Notice that the G-adjacency operator Γ_4 is not locally perfect unless $V(S)$ is actually a perfect code in $G = (V, E)$ for every k'-element dominating set S in G'. However, the following operator ensures that the latter condition is always satisfied.

We say that two distinct vertices u and u' in $G = (V, E)$ are *close* if there is a path length of 1 or 2 between them. (Notice that a vertex u is not considered close to itself.) It is easy to see that a dominating set in G is also a perfect code if and only if it does not contain close vertices.

The perfection operator Γ_5. This operator takes as arguments all of the $\mathcal{C}, \mathcal{C}'$, and $\mathcal{C}''$ blocks. An application of the operator results in the following.

a. The creation of a set of blue vertices with one vertex for each ordered pair (u, u') of close vertices in G, that is,

$$\{\, \beta(u, u') \ :\ u \text{ is close to } u' \text{ in } G \,\}. \tag{3.17}$$

b. The creation of edges connecting each blue vertex $\beta(u, u')$ in this set to all the red vertices contained in one of the following three sets:

$$\begin{aligned}
\mathbb{C}(u, u') &= \{\, c(i, i', J, J') \ :\ i, i' \in [k]^*,\ u \in J,\ u' \in J' \,\},\\
\mathbb{C}'(u, u') &= \{\, c'(i, i', u, J) \ :\ i \in [k],\ i' \in [k]^*,\ u' \in J \,\},\\
\mathbb{C}''(u, u') &= \{\, c''(i, i', J, u') \ :\ i \in [k]^*,\ i' \in [k],\ u \in J \,\}.
\end{aligned}$$

The idea of the perfection operator Γ_5 is to ensure that if $V(S)$ contains close vertices, then S cannot be a dominating set in $G' = (\mathcal{R}, \mathcal{B}, E')$. This is accomplished in the following step.

Step 7. *Apply the perfection operator* Γ_5 *to all of the* $\mathcal{C}, \mathcal{C}'$*, and* $\mathcal{C}''$ *blocks.*

Next, we need some more notation. We again let S denote a k'-element dominating set in G' and define the sets $J_0, J_1, \ldots, J_k$ as follows:

$$J_i \quad = \quad J(u, v) \subset V \qquad \text{so that } S \cap \mathcal{B}(i) = \{b(i, J(u, v))\} \qquad \text{for } i = 0, 1, \ldots, k.$$

It follows from Lemma 3.5 that the sets $J_0, J_1, \ldots, J_k$ are well defined, and the sequence of sets $J_0, \{v_1\}, J_1, \{v_2\}, J_2, \ldots, J_{k-1}, \{v_k\}, J_k$ constitutes a partition of the vertex set V of G.

LEMMA 3.8. *The perfection operator* Γ_5 *is locally perfect, and the set* $V(S) = \{v_1, v_2, \ldots, v_k\}$ *does not contain close vertices.*

Proof. With the notation just defined, it follows from Lemma 3.6 along with Steps 3, 4, and 5 of our construction that

$$\begin{aligned}
S \cap \mathcal{C}(i, i') &= \{\, c(i, i', J_i, J_{i'}) \,\} &&\text{for all } i \in [k]^* \text{ and } i' \in [k]^*,\\
S \cap \mathcal{C}'(i, i') &= \{\, c'(i, i', v_i, J_{i'}) \,\} &&\text{for all } i \in [k] \text{ and } i' \in [k]^*,\\
S \cap \mathcal{C}''(i, i') &= \{\, c''(i, i', J_i, v_{i'}) \,\} &&\text{for all } i \in [k]^* \text{ and } i' \in [k].
\end{aligned}$$

Now consider a pair (u, u') of close vertices in G. Since $J_0, \{v_1\}, J_1, \{v_2\}, J_2, \ldots, J_{k-1}, \{v_k\}, J_k$ is a partition of the vertex set V of G, exactly one statement is true on the following list describing where u is to be found and where u' is to be found.

Case 1: $u \in J_i$ and $u' \in J_{i'}$.
In this case $\beta(u, u')$ in (3.17) is adjacent to a single red vertex in S. Specifically, $\beta(u, u')$ is connected to $c(i, i', J_i, J_{i'}) \in \mathbb{C}(u, u')$, where $\{\, c(i, i', J_i, J_{i'}) \,\} = S \cap \mathcal{C}(i, i')$.

Case 2: $u = v_i$ and $u' \in J_{i'}$.
In this case $\beta(u, u')$ in (3.17) is adjacent to a single red vertex in S. Specifically, $\beta(u, u')$ is connected to $c'(i, i', v_i, J_{i'}) \in \mathbb{C}'(u, u')$, where $\{\, c'(i, i', v_i, J_{i'}) \,\} = S \cap \mathcal{C}'(i, i')$.

Case 3: $u \in J_i$ and $u' = v_{i'}$.
In this case $\beta(u, u')$ in (3.17) is adjacent to a single red vertex in S. Specifically, $\beta(u, u')$ is connected to $c''(i, i', J_i, v_{i'}) \in \mathbb{C}''(u, u')$, where $\{\, c''(i, i', J_i, v_{i'}) \,\} = S \cap \mathcal{C}''(i, i')$.

Case 4: $u = v_i$ and $u' = v_{i'}$.
In this case $\beta(u, u')$ is *not* adjacent to any of the vertices of S.

In each case, we see that a blue vertex $\beta(u, u')$ created by Γ_5 is adjacent to at most one vertex of S, which implies that Γ_5 is locally perfect. Furthermore, since S is a dominating set by assumption, Case 4 above cannot happen. In other words, there is no pair of close vertices in the set $V(S)$ "chosen" by a k'-element dominating set S in $G' = (\mathcal{R}, \mathcal{B}, E')$. ◻

LEMMA 3.9. *The set $V(S)$ is a k-element perfect code in $G = (V, E)$.*

Proof. By Lemma 3.7, the set $V(S)$ is a k-element dominating set in G, and by Lemma 3.8 it does not contain close vertices. Hence $V(S)$ is a perfect code. ◻

We can now complete our construction and complete the proof of Theorem 2.1. Recall that the last step in the construction is as follows.

Step 8. *Apply the block guard operator Γ_1 to every red block constructed thus far.*

Theorem 2.2 now follows from a series of easy observations. Property P1 of Theorem 2.2 is established in Lemma 3.1. The fact that $V(S)$ is necessarily a perfect code in G, established in Lemma 3.9, further implies that the G-adjacency operator Γ_4 is locally perfect. Thus *all* the operators used in our construction are locally perfect, and property P2 of Theorem 2.2 holds. The "if" part of property P3 then follows directly from Lemma 3.9. The reader can now verify the few remaining details to see that the forward translation of a k-element perfect code in $G = (V, E)$ to a k'-element perfect code in $G' = (\mathcal{R}, \mathcal{B}, E')$, outlined in (3.2)–(3.6), works correctly.

4. Membership in the parametrized complexity class *W*[2].

All of the hardness results for parametrized complexity that we derive in this paper are by reduction from the PERFECT CODE problem. This particular problem has eluded exact classification in the $W[t]$ hierarchy for a number of years. What is known [15] is that PERFECT CODE is hard for $W[1]$ and belongs to $W[2]$. It may be a representative of a natural parametrized complexity degree, which is intermediate between the $W[1]$ and $W[2]$ complexity classes. This remains an interesting open problem in the structure of the parametric complexity classes, especially in view of connections to one-per-clause satisfiability problems.

In this section we indicate how some of the problems considered in this paper, namely, MAXIMUM-LIKELIHOOD DECODING, WEIGHT DISTRIBUTION, and MINIMUM DISTANCE, can be shown to belong to the parametrized complexity class $W[2]$. A wide variety of problems are known to be complete or hard for $W[2]$, including DOMINATING SET, BANDWIDTH, LENGTH-k FACTORIZATION OF MONOIDS, LONGEST COMMON SUBSEQUENCE FOR k-SEQUENCES, and k-PROCESSOR PRECEDENCE CONSTRAINED SCHEDULING (see [8, 12, 6, 7]).

To establish the necessary background for Theorem 4.4 below, we now briefly recall the definition of the classes of the $W[t]$ hierarchy based on problems about bounded-depth circuits. We will generally follow the exposition in [14]. We first define circuits in which some logic gates have bounded fan-in and some have unrestricted fan-in. It is assumed that fan-out is never restricted.

Definition 4.1. *A Boolean circuit is of* mixed type *if it consists of circuits having gates of the following kinds:*

small gates*: ¬ gates, ∧ gates, and ∨ gates with bounded fan-in; we will usually assume that the bound on fan-in is* 2 *for ∧ gates and ∨ gates and* 1 *for ¬ gates.*

large gates*: ∧ gates and ∨ gates with unrestricted fan-in.*

The *depth* of a circuit $\mathcal{C}$ is defined to be the maximum number of gates (small or large) on an input-output path in $\mathcal{C}$. The *weft* of a circuit $\mathcal{C}$ is the maximum number of large gates on an input-output path in $\mathcal{C}$. We say that a family of decision circuits F has *bounded depth* if there is a constant h such that every circuit in the family F has depth at most h. We say that F has *bounded weft* if there is constant t such that every circuit in the family F has weft at most t.

Let F be a family of mixed-type decision circuits. We allow that F may have many different circuits with a given number of inputs. To F we associate the following parametrized circuit problem $L_F = \{ (\mathcal{C}, k) : \mathcal{C} \in F$ accepts some input vector of weight $k\}$, where the (Hamming) weight of a Boolean vector x is the number of 1's in the vector.

Definition 4.2. *A parametrized language L belongs to $W[t]$ if L reduces to the parametrized circuit problem $L_{F(t,h)}$ for the family $F(t,h)$ of mixed-type decision circuits of weft at most t and depth at most h for some constant h.*

Definition 4.3. *A parametrized language L belongs to $W^*[t]$ if it belongs to $W[t]$ with the definition of a* small gate *being revised to allow fan-in bounded by a fixed arbitrary function of k and where the depth of a circuit is allowed to be a function of k as well.*

Whether $W^*[t] = W[t]$ for all t is an important open problem. The significance of this question is that for purposes of establishing membership in the $W[t]$ hierarchy, we would like to have the most generous possible characterization of $W[t]$ available to work with. It is shown that $W^*[1] = W[1]$ and $W^*[2] = W[2]$ in [21] and [18], respectively. For $t \geq 3$ the question is still open. Our argument here makes essential use of the result of [18] that $W^*[2] = W[2]$.

Theorem 4.4. Weight Distribution *belongs to* $W[2]$.

Proof. Given an instance H and k of Weight Distribution, we describe how to compute a pair (E, k'), consisting of a Boolean expression E and a positive integer k', such that the circuit corresponding to E has a form allowed by the definition of $W^*[2] = W[2]$ and such that H, k is a yes-instance of Weight Distribution if and only if E is satisfied by a weight k' truth assignment. In order for this to be a parametric reduction, we must have k' computed purely as a function of k. Our reduction is simple in this regard: we take $k' = k$.

Suppose that H is an $m \times n$ binary matrix, and let $h_1, h_2, \ldots, h_n$ denote the columns of this matrix. For $j = 1, 2, \ldots, m$, we will write $h_i[j]$ to denote the jth component of h_i. The set V of Boolean variables for E is

$$V = \{ v[b,i] : b = 1, 2, \ldots, k \text{ and } i = 1, 2, \ldots, n \}.$$

Intuition can be served by viewing V as consisting of k "choice blocks," each of size n. The expression E is constructed so that any satisfying truth assignment must make exactly one variable in each of these blocks `true`, and will in this way indicate a set of k columns of H.

Let $\mathcal{E}$ denote the set of all subsets of $\{1, 2, \ldots, k\}$ of even cardinality. For each $j \in \{1, 2, \ldots, m\}$ and $\sigma \in \mathcal{E}$, define the Boolean expressions:

$$E^+(\sigma,j) = \bigwedge_{b\in\sigma} \quad \bigwedge_{i:\, h_i[j]=0} \neg v[b,i],$$

$$E^-(\sigma,j) = \bigwedge_{b\notin\sigma} \quad \bigwedge_{i:\, h_i[j]=1} \neg v[b,i],$$

$$E(\sigma,j) = E^+(\sigma,j) \ \wedge\ E^-(\sigma,j).$$

Then the expression E has the form

$$E \ = \ E_1 \wedge E_2 \ \wedge\ E_3,$$

where

$$E_1 = \bigwedge_{1\le b<b'\le k} \ \bigwedge_{i=1}^{n} (\neg v[b,i] \ \vee\ \neg v[b',i]),$$

$$E_2 = \bigwedge_{b=1}^{k} \left(\bigvee_{i=1}^{n} v[b,i] \right),$$

$$E_3 = \bigwedge_{j=1}^{m} \ \bigvee_{\sigma\in\mathcal{E}} E(\sigma,j).$$

It is easy to see that if the definition of a small gate allows fan-in bounded by a function of k, then each of the subexpressions E_1 and E_2 has weft one, while the subexpression E_3 has weft two. The depth of E_1, E_2, and E_3 is 4, 2, and 6, respectively, so that the depth of E itself is 7. Thus E belongs to a family of weft-two circuits allowed by the definition of $W^*[2]$. We next argue the correctness of the reduction. Note the validity of the following easy claims.

CLAIM 1. *The subexpression E_2 is satisfied by a weight k truth assignment to the variables of V if and only if exactly one variable in each of the k blocks is assigned the value* `true`.

CLAIM 2. *The subexpression $E' = E_1 \wedge E_2$ is satisfied by a weight k truth assignment to the variables of V if and only if exactly one variable in each of the k blocks is assigned the value* `true` *in such a way that the second indices of the* `true` *variables are all distinct.*

Let τ be a weight k truth assignment that satisfies E'. It follows from Claim 1 that for each $b \in \{1,2,\ldots,k\}$, there is a unique $i \in \{1,2,\ldots,n\}$ such that $v[b,i]$ is assigned the value `true` by τ. Thus τ and b together specify the unique ith column of H. For $j = 1,2,\ldots,m$, we let $\alpha(b,j,\tau)$ denote the binary value to be found in the jth row of this column, that is, $\alpha(b,j,\tau) = h_i[j]$.

CLAIM 3. *The expression E_3 is satisfied by a weight k truth assignment $\tau : V \to \{$*`true`*, *`false`*$\}$ that also satisfies $E' = E_1 \wedge E_2$ if and only if for each $j \in \{1,2,\ldots,m\}$ there is some $\sigma \in \mathcal{E}$ such that the following equality holds: $\sigma = \{b : \alpha(b,j,\tau) = 1\}$.*

Now suppose that H, k is a yes-instance of WEIGHT DISTRIBUTION, and let $h_{i_1}, h_{i_2}, \ldots, h_{i_k}$ be the k columns of H that sum to the all-zero vector. Let τ be the truth assignment that assigns the variables $v[1,i_1], v[2,i_2], \ldots, v[k,i_k]$ to be `true` and assigns all the other variables in V the value `false`. Clearly, τ has weight k. It follows from Claim 2 that τ satisfies $E' = E_1 \wedge E_2$. For $j = 1, 2, \dots, m$, let σ_j be the subset of $\{1, 2, \dots, k\}$ consisting of all b such that $h_{i_b}[j] = 1$. Since

$$h_{i_1}[j] + h_{i_2}[j] + \cdots + h_{i_k}[j] \;=\; 0 \pmod 2$$

for all j, it follows that the number of such indices b must be even. Hence $\sigma_j \in \mathcal{E}$ for all j. It is not difficult to see that for the truth assignment τ specified above, σ_j is precisely the set $\{b : \alpha(b, j, \tau) = 1\}$. Hence by Claim 3, τ also satisfies E_3 and therefore E itself.

Conversely, suppose that E has a truth assignment τ of weight k. By Claim 2, there are k distinct indices $i_1, i_2, \dots, i_k$ such that τ assigns to the k variables $v[1, i_1]$, $v[2, i_2], \dots, v[k, i_k]$ the value `true` and assigns all other variables in V the value `false`. By Claim 3, the number of elements in the set $\{b : \alpha(b, j, \tau) = 1\} = \{b : h_{i_b}[j] = 1\}$ must be even for each $j = 1, 2, \dots, m$. Hence the k columns $h_{i_1}, h_{i_2}, \dots, h_{i_k}$ of H sum to the all-zero vector. $\square$

The above argument can be easily modified to show that Maximum-Likelihood Decoding and Minimum Distance also belong to $W^*[2] = W[2]$. We conjecture that all of these problems are equivalent to the Perfect Code problem.

5. Concluding discussion and open problems.

We have shown that four of six fundamental computational problems in the domains of linear codes and integer lattices are NP-complete and hard for the parametrized complexity class $W[1]$. The obvious outstanding open problems are the following.

- Is the Minimum Distance problem, recently proved to be NP-complete in [32], also hard for $W[1]$?
- Is the Shortest Vector problem hard for NP and $W[1]$?

A consequence of the proof in [32] that the Minimum Distance problem is NP-hard is that Even Set is NP-hard. This leaves us in the curious situation that the only known proof of this seemingly quite combinatorial result is by means of sophisticated algebraic techniques deeply rooted in coding theory. Is there a direct combinatorial proof? Understanding this issue may shed some light on whether the combinatorial methods used here to show NP and $W[1]$ hardness for Theta Series can be extended to the Shortest Vector problem.

6. Appendix: Short survey of parametrized complexity.

Over the past several years, it has become increasingly clear that classical complexity frameworks such as NP-completeness and PSPACE-completeness are not adequate to address intractability questions for problems that are naturally parametrized and for which the important applications are covered by parameter values of, say, $k \leq 50$.

For example, consider the Vertex Cover problem, which asks whether a graph G on n vertices has a vertex cover of size at most k. This is one of the six NP-complete problems singled out for attention by Garey and Johnson [22]. The best known result, presently, is that Vertex Cover can be solved in time $O(kn + (4/3)^k k^2)$ with a very small hidden constant [3]. This means that although the problem is NP-complete, it is well solved for input graphs of *unlimited* size, as long as k is at most 70 or so. Strong tractability results such as this seem to be not uncommon when problems are qualitatively classifiable as fixed-parameter tractable, meaning that they belong to the parametrized complexity class FPT, formally defined below. Three of the six basic NP-complete problems considered by Garey and Johnson in [22, Chapter 3] are fixed-parameter tractable.

In general, a variety of metrics can be applied to the input of a computational problem. The total length of the input is one basic measurement, but it is by no means the only important one. It is natural to try to understand how different input measurements interact in determining problem complexity. Furthermore, it is essential to understand such interactions in order to exploit the opportunities for designing algorithms that are sensitive to natural input distributions.

A generic example of a parameterization is provided by the many well-known decision problems concerning graphs that take as input a graph G and a positive integer k. The parameter k appears to contribute to the complexity of such problems in two qualitatively different ways. GRAPH GENUS, MIN-CUT LINEAR ARRANGEMENT, VERTEX COVER, and FEEDBACK VERTEX SET FOR UNDIRECTED GRAPHS (see, for example, [22] for definitions) can all be solved in time $O(f(k)n^c)$, where c is a constant independent of k and $f(\cdot)$ is some (arbitrary) function. This "good behavior" is termed *fixed-parameter tractability* in the theory introduced in [14]. As is the case with polynomial-time complexity, the exponent c is typically small. One can equivalently define fixed-parameter tractability to mean solvability in time $O(f(k) + n^c)$, that is, with only an *additive* contribution from the parameter [13]. There is a rich collection of distinctive techniques for devising FPT algorithms (see [16, 18, 23, 10, 27]).

Contrasting complexity behavior is exhibited by the naturally parametrized problems such as CLIQUE, DOMINATING SET, and BANDWIDTH for which the best known algorithms have running times $O(n^{ck})$. These problems have been shown to be complete or hard for the various levels of the W hierarchy of parametrized complexity

$$W[1] \subseteq W[2] \subseteq \cdots \subseteq W[P] \subseteq \cdots \subseteq XP,$$

which can be taken as evidence that they are unlikely to be fixed-parameter tractable [8]. With these problems, we seem to hit a natural "wall" requiring brute force effort, much as is typically the case with NP-complete problems. For example, essentially no better algorithm is known for the k-DOMINATING SET problem than checking all k-subsets.

As in the theory of NP-completeness, there are roughly two kinds of arguments that can be offered for believing that parametrized problems that are complete or hard for $W[1]$ are not likely to be fixed-parameter tractable. The first kind of argument is, roughly speaking, sociological. So many different kinds of problems stand or fall together that the combination of efforts expended unsuccessfully from the various vantages compels a belief in inherent intractability. The second kind of argument is some form of direct intuition concerning the nature of the computations that define the issue, e.g., nondeterministic as opposed to deterministic polynomial time.

For parametrized complexity, both kinds of arguments can be made. Although the amount of unsuccessful effort that has been expended in an attempt to show fixed-parameter tractability for $W[1]$-hard problems is much less than the total effort expended to date in attempting to develop polynomial-time algorithms for NP-complete problems, it is still considerable and accumulating. The parametrized complexity class $W[1]$ is particularly interesting and important for several reasons: there is a substantial list of natural and useful computational problems that are precisely $W[1]$-complete. This list includes CLIQUE, INDEPENDENT SET, VAPNIK–CHERVONENKIS DIMENSION, MONOTONE DATA COMPLEXITY FOR RELATIONAL DATABASES, SQUARE TILING, k-STEP DERIVATION FOR CONTEXT SENSITIVE GRAMMARS, m-LENGTH COMMON SUBSEQUENCE FOR k-SEQUENCES, and k-LENGTH POST CORRESPONDENCE, among other problems.

Direct intuition about $W[1]$ is also available. It is shown in [19, 12] that the k-step halting problem for nondeterministic Turing machines is $W[1]$-complete. This problem is formally defined as follows.

Problem: SHORT TURING MACHINE ACCEPTANCE
Instance: A nondeterministic Turing machine M and a positive integer k.
Question: Does M have a computation path accepting the empty string in at most k steps?
Parameter: k

This is a problem so generic and opaque that it is hard to imagine that there is any algorithm for it that radically improves on simply exploring the n-branching depth-k tree of allowed transitions exhaustively. This is essentially the same intuition as the belief that Cook's theorem provides a basis for the intractability of NP-complete problems.

For a definition of the $W[t]$ complexity classes and the fundamentals of parametrized complexity, we refer the reader to section 4 and [14, 15, 16, 18]. Here, we will briefly review the basic definitions of a parametrized problem and fixed-parameter tractability.

DEFINITION 6.1. *A* parametrized problem *is a set $L \subseteq \Sigma^* \times \Sigma^*$, where Σ is a fixed alphabet. For convenience, we can think of a parametrized problem as a subset L of $\Sigma^* \times N$, where N is the set of nonnegative integers.*

DEFINITION 6.2. *We say that parametrized problem L is (uniformly)* fixed-parameter tractable *if there is a constant α and an algorithm Φ such that Φ decides if $(x, k) \in L$ in time $f(k)|x|^\alpha$, where $f : N \to N$ is an arbitrary function.*

Let A and B be parametrized problems. We say that A is (uniformly many to 1) *reducible* to B if there is an algorithm Φ which transforms $(x, k) \in \Sigma^* \times N$ into $(x', g(k))$ in time $f(k)|x|^\alpha$, where $f, g : N \to N$ are arbitrary functions and α is a constant independent of k so that $(x, k) \in A$ if and only if $(x', g(k)) \in B$. Such an algorithm Φ may be called a parametric transformation. It is easy to see that if A reduces to B and B is fixed-parameter tractable, then so too is A.

TWO- AND HIGHER-DIMENSIONAL PATTERN MATCHING IN OPTIMAL EXPECTED TIME[*]

JUHA KÄRKKÄINEN[†] AND ESKO UKKONEN[†]

Abstract. Algorithms with optimal expected running time are presented for searching the occurrences of a two-dimensional $m \times m$ pattern P in a two-dimensional $n \times n$ text T over an alphabet of size c. The algorithms are based on placing in the text a static grid of test points, determined only by n, m, and c (not dynamically by earlier test results). Using test strings read from the test points the algorithms eliminate as many potential occurrences of P as possible. The remaining potential occurrences are separately checked for actual occurrences. A suitable choice of the test point set leads to algorithms with expected running time $O(n^2 \log_c m^2/m^2)$ using the uniform Bernoulli model of randomness. This is shown to be optimal by a generalization of a one-dimensional lower bound result by Yao. Experimental results show that the algorithms are efficient in practice, too. The method is also generalized for the k mismatches problem. The resulting algorithm has expected running time $O(kn^2 \log_c m^2/m^2)$, provided that $k \leq (m\lfloor m/\lceil \log_c m^2 \rceil \rfloor - 1)/2$. All algorithms need preprocessing of P which takes time and space $O(m^2)$. The text processing can be done on-line, using a rather small window. The algorithms easily generalize to d-dimensional matching for any d.

1. Introduction.

The classical *pattern matching problem* for strings is to find all (exact or approximate) occurrences of a *pattern* P in a *text* T. In a one-dimensional case, P and T are strings over some alphabet Σ of size c. In a d-dimensional case, P and T are d-dimensional arrays over Σ. The applications are numerous.

The exact one-dimensional pattern matching is well understood. For two- and higher-dimensional versions, several algorithms have been proposed, too, mainly aiming at a good worst-case running time; see, e.g., [7, 6, 16, 26, 11, 2, 13, 22]. Recently, the two-dimensional problem has been solved in linear worst-case time with algorithms that are alphabet-independent and work in small additional space [10].

In the applications of one-dimensional matching, the Boyer–Moore algorithm [8], whose expected running time is "sublinear," is clearly the most successful; see, e.g., [15]. Also in higher dimensions, one should look at algorithms with good expected running time, not only the worst case. The first significant step in this direction was the algorithm of Baeza–Yates and Régnier [5] that finds the occurrences of an $m \times m$ pattern in an $n \times n$ text in expected time $O(n^2/m)$.

Results. In this paper, we give better algorithms that find exact occurrences of an $m \times m$ pattern in an $n \times n$ text in expected time $O(n^2 \log_c m^2/m^2)$ under the uniform Bernoulli model of random strings over Σ. Algorithms with the same expected performance have independently appeared in [17, 12, 23].

Our algorithms are not dimensionality specific. For a d-dimensional pattern of size m^d and text of size n^d, they run in expected time $O(n^d \log_c m^d/m^d)$.

In [25], A. Yao confirmed a conjecture of Knuth [18] by proving a lower bound of $O(n \log_c m/m)$ for the expected time complexity of one-dimensional exact pattern matching. Yao's argument generalizes for d-dimensional matching and gives a lower bound $O(n^d \log_c m^d/m^d)$. Hence, our algorithms are the first algorithms for multidimensional matching with optimal expected running time. Experiments show that the algorithms are also fast in practice.

We also generalize our algorithm for approximate pattern matching. We consider the two-dimensional k *mismatches problem* (find all occurrences of P in T with $\leq k$ mismatching symbols) and give an algorithm with expected running time $O(kn^2 \log_c m^2/m^2)$. The algorithm requires that $k \leq (m\lfloor m/\lceil \log_c m^2 \rceil \rfloor - 1)/2$. Under this condition the expected running time is at most linear in $|T|$; previously Chang and Lawler [9] (see also [24]) have given an algorithm with similar properties for the k differences problem of one-dimensional approximate matching. The two-dimensional k mismatches problem has also been studied in [21, 19, 4, 3].

Overview. We next informally describe the very simple elimination idea behind our algorithms. Note first that the naive algorithm for pattern matching and its improvements such as the Knuth–Morris–Pratt algorithm [18] are based on a view of the problem that could be called *positive*: the algorithm tries to prove at each text location that there is an occurrence of P at that location.

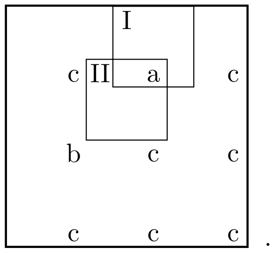
In applications, T often contains relatively few occurrences of P. Hence the *negative* view can fit the situation better than the positive one. A negative view algorithm tries to prove for each text location that there can *not* be an occurrence of P at that location. This forms the *elimination phase* of the algorithm. Whenever the elimination proof fails, the algorithm has found a potential occurrence of P that needs further consideration. A separate *checking phase* then examines whether or not a potential occurrence really matches P. This leads to fast algorithms because the elimination phase needs, on average, to examine only a small fraction of T.

The well-known Boyer–Moore algorithm [8] has this flavor. In this paper, we develop algorithms based on the negative view for two- and higher-dimensional pattern matching.

We explain the idea of our algorithms using two-dimensional P and T. Let

$$P: \boxed{\begin{array}{ccc} \mathrm{b} & \mathrm{b} & \mathrm{a} \\ \mathrm{b} & \mathrm{b} & \mathrm{b} \\ \mathrm{b} & \mathrm{a} & \mathrm{b} \end{array}} \qquad T: \boxed{\begin{array}{ccccccccc} \mathrm{a} & \mathrm{a} & \mathrm{a} & \mathrm{a} & \mathrm{b} & \mathrm{b} & \mathrm{a} & \mathrm{b} & \mathrm{b} \\ \mathrm{b} & \mathrm{b} & \mathrm{b} & \mathrm{b} & \mathrm{b} & \mathrm{b} & \mathrm{b} & \mathrm{b} & \mathrm{b} \\ \mathrm{a} & \mathrm{b} & \mathrm{c} & \mathrm{c} & \mathrm{b} & \mathrm{a} & \mathrm{b} & \mathrm{a} & \mathrm{c} \\ \mathrm{b} & \mathrm{a} & \mathrm{b} & \mathrm{a} & \mathrm{b} & \mathrm{a} & \mathrm{b} & \mathrm{a} & \mathrm{b} \\ \mathrm{a} & \mathrm{a} & \mathrm{c} & \mathrm{b} & \mathrm{b} & \mathrm{b} & \mathrm{a} & \mathrm{a} & \mathrm{a} \\ \mathrm{b} & \mathrm{c} & \mathrm{b} & \mathrm{b} & \mathrm{b} & \mathrm{c} & \mathrm{b} & \mathrm{b} & \mathrm{c} \\ \mathrm{a} & \mathrm{c} & \mathrm{c} & \mathrm{b} & \mathrm{c} & \mathrm{c} & \mathrm{a} & \mathrm{c} & \mathrm{c} \\ \mathrm{c} & \mathrm{c} & \mathrm{c} & \mathrm{b} & \mathrm{b} & \mathrm{b} & \mathrm{a} & \mathrm{a} & \mathrm{a} \\ \mathrm{c} & \mathrm{c} & \mathrm{c} & \mathrm{c} & \mathrm{a} & \mathrm{c} & \mathrm{b} & \mathrm{b} & \mathrm{c} \end{array}}\ .$$

We have to find all (I, J) such that $T[I + k - 1, J + h - 1] = P[k, h]$ for $1 \leq k, h \leq 3$. If we are lucky, we can eliminate all possible occurrences of P in T by examining only the entries $T[i, j]$ where $i = 3, 6, 9$; $j = 3, 6, 9$, because any possible occurrence of P in T must overlap at least one of these entries of T. The test entries in T are as follows:



As the first entry $T[3,3]$ equals c, and c does not occur in P at all, no occurrence of P in T can overlap $T[3,3]$. This proves that there can not be an occurrence of P inside subarray $T[1:5,1:5]$. Test entry $T[3,6]=a$ eliminates all other occurrences of P that overlap $T[3,6]$ except those that have the overlapping symbol a. The upper left-hand corners of these potential occurrences of P are $T[1,5]$ (marked I in the figure) and $T[3,4]$ (marked II), because $P[1,3]=P[3,2]=a$. The checking phase then finds that there is an occurrence of P at $T[1,5]$ but not at $T[3,4]$.

The fourth test entry $T[6,3]=b$ is least useful for elimination because b occurs 7 times in P. Hence, we are left with 7 potential occurrences of P that overlap $T[6,3]$. However, there is no reason to use only one entry of T in each elimination step. Taking $T[6,2]=c$ as an additional test entry would eliminate all possible occurrences of P that overlap $T[6,2]$ and $T[6,3]$ because substring cb does not occur in P.

Increasing the number of test entries used in each elimination step obviously leads to more extensive elimination but possibly takes more time. Therefore, we determine q such that, when each elimination step is based on q entries of T, the expected total running time of elimination and (naive) checking is minimized. It turns out that the minimum is given by $q \approx \log_{|\Sigma|}|P|$; this simply has the effect of using a superalphabet of size $\Theta(|P|)$.

The test entries will be distributed over T such that every potential occurrence of P in T covers at least q entries. We use a *static distribution* of test entries; this is a major difference to virtually all other pattern matching algorithms proposed in the literature. The grid of test entries is determined using only the size (and shape) of P, T and the underlying alphabet. The elimination phase becomes *oblivious*: the results of earlier elimination tests do not cause dynamic changes on later tests. This property helps in writing fast code for the algorithms, for both sequential and parallel environments.

The idea of using superalphabet of size $\Theta(|P|)$ in two-dimensional matching appears independently in [12, 17, 23]. All achieve the same asymptotic running time as our algorithms. Crochemore and Rytter [12, Sect. 12.7] sketch an algorithm which comes close to one of our algorithms, while the algorithms in [17, 23] differ in that they determine the test entries dynamically.

The above idea is formulated in section 2 as a generic pattern matching algorithm. The elimination of potential occurrences of P is based on reading test strings of length q from T. The strings are picked up according to a fixed sampling scheme. In section 3, we give an example scheme such that each test entry belongs to only one test string. To get the minimum total number of test entries, we use test strings whose shape has the smallest possible diameter. In section 4, we give a bit more efficient scheme in which each test entry belongs to several test strings. Section 5 reformulates the lower bound of Yao [25] for d-dimensional pattern matching. Section 6 describes the results of experiments comparing the running times of the algorithms of sections 3 and 4, the trivial algorithm, and an algorithm by Tarhio [23]. In section 7, we generalize the algorithm for the k mismatches problem. The elimination is based on $k + p$ nonoverlapping test strings; here p is a parameter used for optimizing the performance of the method.

2. General algorithm.

To keep the technical exposition simple we restrict ourselves to the two-dimensional case with square patterns and texts. The generalization of all our results to the d-dimensional pattern matching with rectangular patterns and texts is straightforward.

Let a two-dimensional $m \times m$ array $P = (p_{ij})$, $1 \le i, j \le m$, be the *pattern* and a two-dimensional $n \times n$ array $T = (t_{ij})$, $1 \le i, j \le n$, be the *text* over some alphabet Σ. Let c denote the size of the alphabet Σ.

We let integer q denote the *sample size*. Selecting a suitable q will minimize the expected running time of our algorithms. A sequence $Q = ((0,0), (i_1, j_1), (i_2, j_2), \ldots, (i_{q-1}, j_{q-1}))$ of q *disjoint* pairs of indexes is called a (two-dimensional) *template* of size q. The sequence always begins with the pair $(0,0)$ which is called the *origin* of the template. A template Q and a pair of indexes (i,j) define a *sample* $Q(i,j) = ((i,j), (i+i_1, j+j_1), \ldots, (i+i_{q-1}, j+j_{q-1}))$. Here Q gives the shape of the sample and (i,j) the location of the sample.

Pattern P is said to *contain* sample $Q(i,j)$ if all the pairs listed in $Q(i,j)$ refer to entries of P. Such sample $Q(i,j)$ determines a *test string* $s(P, Q(i,j))$ in P as $s(P, Q(i,j)) = p_{i,j} p_{i+i_1, j+j_1} \cdots p_{i+i_{q-1}, j+j_{q-1}}$.

A *sampling scheme* $\mathcal{Q}$ for a template Q, a pattern P, and a text T is a pair $(\mathcal{Q}_P, \mathcal{Q}_T)$ where *pattern sampling scheme* $\mathcal{Q}_P$ and *text sampling scheme* $\mathcal{Q}_T$ are subsets of all possible Q-shaped samples of P and T, respectively, i.e.,

$$\mathcal{Q}_P \subseteq \{Q(i,j) \mid P \text{ contains } Q(i,j)\} \text{ and}$$
$$\mathcal{Q}_T \subseteq \{Q(i,j) \mid T \text{ contains } Q(i,j)\}.$$

Let R be a potential occurrence of P in T (i.e., an $m \times m$ subarray of T) with upper left-hand corner at (i,j). A *witness* of R is a pair $(Q(i_P, j_P), Q(i_T, j_T)) \in \mathcal{Q}_P \times \mathcal{Q}_T$ such that $Q(i_T, j_T)$ is in R in the same position as $Q(i_P, j_P)$ is in P, i.e., $i_T - i + 1 = i_P$ and $j_T - j + 1 = j_P$. Witness $(Q(i_P, j_P), Q(i_T, j_T))$ is positive if $s(P, Q(i_P, j_P)) = s(T, Q(i_T, j_T))$; otherwise the witness is negative. A potential occurrence with a negative witness can not be a real occurrence of P in T.

Example 1. Let

$$Q: \begin{array}{|cc|}\hline 0 & 2 \\ \hline & \boxed{1} \end{array} \qquad P: \begin{array}{|ccc|}\hline \mathrm{b} & \mathrm{b} & \mathrm{c} \\ \mathrm{b} & \mathrm{c} & \mathrm{a} \\ \mathrm{a} & \mathrm{a} & \mathrm{a} \\ \hline \end{array} \qquad T: \begin{array}{|ccc:cc|}\hline \mathrm{c} & \mathrm{b} & \mathrm{a} & \mathrm{a} & \mathrm{b} \\ \hdashline \mathrm{b} & \mathrm{b} & \mathrm{c} & \mathrm{b} & \mathrm{c} \\ \mathrm{b} & \mathrm{c} & \mathrm{a} & \mathrm{c} & \mathrm{a} \\ \mathrm{a} & \mathrm{a} & \mathrm{b} & \mathrm{b} & \mathrm{a} \\ \hdashline \mathrm{c} & \mathrm{a} & \mathrm{b} & \mathrm{b} & \mathrm{b} \\ \hline \end{array}\ .$$

The numbers in the template $Q = ((0,0), (1,1), (0,1))$ show the order of the entries. Let R be a potential occurrence of P in T with the upper left-hand corner at $(2,1)$ (marked with dashed boundaries above). If $Q(2,2) \in \mathcal{Q}_P$ and $Q(3,2) \in \mathcal{Q}_T$, then (Q(2,2),Q(3,2)) is a negative witness of R as $s(P, Q(2,2)) = caa \ne cba = s(T, Q(3,2))$. This proves that R is not an occurrence of P. All other possible witnesses of R would be positive.

We are now ready to give a general description of our algorithms. The idea is to eliminate potential occurrences with negative witnesses and check the remaining potential occurrences using, e.g., naive checking. We select a sampling scheme $\mathcal{Q}$ such that every potential occurrence has exactly one witness in $\mathcal{Q}$. If that one witness is positive, then the potential occurrence has no negative witnesses and must be checked. In other words, the potential occurrences worth checking are determined by finding all positive witnesses. Uninteresting potential occurrences are implicitly eliminated by ignoring negative witnesses.

ALGORITHM [Generic].

1. [Selection of q, Q and $\mathcal{Q}$]. Select suitable sample size q, template Q and sampling scheme $\mathcal{Q} = (\mathcal{Q}_P, \mathcal{Q}_T)$ for a given pattern P and text T over alphabet Σ of size c. Scheme $\mathcal{Q}$ must provide exactly one witness for each potential occurrence of P in T.
2. [Preprocessing of P]. For each pattern sample $Q(i, j) \in \mathcal{Q}_P$, evaluate the test string $s(P, Q(i, j))$. Construct a suitable data structure to quickly find all pattern samples with a given test string.
3. [Elimination]. For each text sample $Q(i_T, j_T) \in \mathcal{Q}_T$, scan T to obtain the string $s(T, Q(i_T, j_T))$ and find, using the data structure constructed in the preprocessing step, all pattern samples $Q(i_P, j_P)$ such that $s(P, Q(i_P, j_P)) = s(T, Q(i_T, j_T))$. For each matching pair $(Q(i_P, j_P), Q(i_T, j_T))$, execute the checking phase for the potential occurrence R with the upper left-hand corner at $(i_R, j_R) = (i_T - i_P + 1, j_T - j_P + 1)$.
4. [Checking]. Given a potential occurrence R with the upper left-hand corner at (i_R, j_R), check whether or not there really is an occurrence, that is, test whether or not $t_{i_R+I-1, j_R+J-1} = p_{I,J}$ for $1 \leq I, J \leq m$.

Selecting different sampling schemes in the generic algorithm gives different concrete algorithms. The simplest alternative is developed in section 3 where we use templates with small diameter to maximize the number of potential occurrences each text sample is contained in. Utilizing overlaps of text samples leads to an algorithm with faster pattern preprocessing and a more sophisticated (not necessarily slower) elimination phase. Such methods are described and analyzed in section 4.

The sampling schemes of both of these algorithms are designed to minimize the number of text positions inspected during elimination as the text is typically much larger than the pattern. For the same reason, our algorithms preprocess the pattern samples. In an application, where multiple patterns are to be searched in the same static text, it might be useful to reverse the handling of text and patterns. However, we will not follow this direction further in this paper.

3. Square templates.

The requirement of one witness per potential occurrence means that the number of different witnesses in $\mathcal{Q}$, $|\mathcal{Q}_P||\mathcal{Q}_T|$, approximately equals the number of potential occurrences of P in T.[1] This implies that one can minimize the number of text samples by maximizing the number of pattern samples. This is the main idea of the algorithm presented in this section. The idea is realized by using what we call *square templates*.

DEFINITION 3.1. *Template* $Q = ((0, 0), (i_1, j_1), \ldots, (i_{q-1}, j_{q-1}))$ *of size* q *is a square template iff* $0 \leq i_k, j_k \leq \lceil \sqrt{q} \rceil - 1$ *for* $1 \leq k \leq q - 1$.

A square sample (sample whose shape is defined by a square template) of size q is contained in a $\lceil \sqrt{q} \rceil \times \lceil \sqrt{q} \rceil$ subarray whose upper left-hand corner is the origin of the sample. It is easy to see that the square shape maximizes the number of possible pattern samples.[2] Optimal sample size q will be determined in the analysis of the

[1] The nonexactness is caused by witnesses near the text boundaries.

[2] Actually, for some q, we could fit the template in a $\lceil \sqrt{q} \rceil \times \lfloor \sqrt{q} \rfloor$ subarray.

algorithm.

Given a square template Q, the pattern sampling scheme $\mathcal{Q}_P$ now contains all possible Q-shaped pattern samples, that is,

$$\mathcal{Q}_P = \{Q(i,j) \mid 1 \leq i,j \leq m - \lceil\sqrt{q}\rceil + 1\}.$$

To get one witness per potential occurrence the text samples must be placed at the intersections of every $(m - \lceil\sqrt{q}\rceil + 1)$th row and column. This gives

$$\mathcal{Q}_T = \left\{ Q\left(i(m - \lceil\sqrt{q}\rceil + 1), j(m - \lceil\sqrt{q}\rceil + 1)\right) \,\middle|\, 1 \leq i,j \leq \left\lfloor \frac{n - \lceil\sqrt{q}\rceil + 1}{m - \lceil\sqrt{q}\rceil + 1} \right\rfloor \right\}.$$

Now each text sample is a component of the witness of $|\mathcal{Q}_P| = (m - \lceil\sqrt{q}\rceil + 1)^2$ different potential occurrences. For each text sample, we need to find all matching pattern samples. To do this as quickly as possible, we preprocess the pattern to get a data structure which we call *test dictionary*.

Let w be a string of length q over alphabet Σ. Let $A(w)$ be the set of origins of pattern samples whose test string is w. That is,

$$A(w) = \{(i,j) \mid w = s(P, Q(i,j)),\ Q(i,j) \in \mathcal{Q}_P\}.$$

$A(w)$ is called the set of *addresses* of w. The test dictionary $D(P, \mathcal{Q}_P)$ for pattern P and sampling scheme $\mathcal{Q}_P$ of P is a data structure supporting queries that for a given string $w \in \Sigma^q$ yield the set of addresses of w.

There are two obvious implementations of test dictionary $D(P, \mathcal{Q}_P)$. First, one can use a trie representing the test strings, with the addresses $A(w)$ associated with the leaf that corresponds to string w. The test strings and their addresses can be constructed by scanning P for each pattern sample. There are $\leq m^2$ samples, hence the total length of the test strings is $\leq m^2 q$, and the trie representing them can be built in time $O(m^2qc)$ or $O(m^2 q \log c)$, depending on whether direct indexing or balanced search trees are used for implementing the branches of the trie. The queries for $A(w)$ can be answered in time $O(q)$ or $O(q \log c)$, respectively (plus the size of $A(w)$).

The second possibility to implement $D(P, \mathcal{Q}_P)$ is to convert the test strings into (c-ary) integers, and use these integers as indices to an array of size c^q representing the addresses $A(w)$ for each w. The optimal value of q turns out to be small enough to keep c^q acceptable. The array initialization takes $O(c^q)$ time and the trivial method of pattern processing requires $O(m^2q)$. The queries can be answered in time $O(q)$.

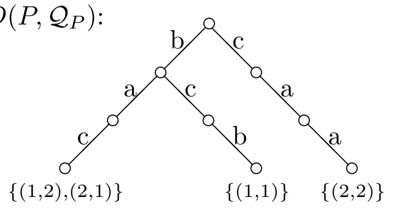
With a suitable ordering of the template entries and a little bookkeeping the pattern processing time can be reduced to $O(m^2)$. The template is ordered like text: row by row from top to bottom with each row ordered left to right. Individual rows of the samples can then be thought of as c-ary integers of $\lceil\sqrt{q}\rceil$ digits and the whole sample as a $c^{\lceil\sqrt{q}\rceil}$-ary integer of $\lceil\sqrt{q}\rceil$ digits (rows). Each sample row is a substring of a pattern row. The sample row values coming from a pattern row can be calculated with a single scan of the row in time $O(m)$ in the obvious way. Similarly, given all the sample row values the sample values can then be calculated by scanning the row values column by column. The operation is further complicated by the fact that, to have the sample size be exactly q, one of the sample rows may have to be shorter than $\lceil\sqrt{q}\rceil$. Despite the complexity of this method, it turned out to be faster, in practice, than the simpler $O(m^2q)$ method.

Example 2. Let Q, P, T and R be as in Example 1. Then Q is a square template and, using the sampling scheme of this section, we have

$$\mathcal{Q}_P = \{Q(1,1), Q(1,2), Q(2,1), Q(2,2)\},$$
$$\mathcal{Q}_T = \{Q(2,2), Q(2,4), Q(4,2), Q(4,4)\}.$$

The witness of R in $\mathcal{Q} = (\mathcal{Q}_P, \mathcal{Q}_T)$ is $(Q(1,2), Q(2,2))$. The addresses of strings $w \in \Sigma^3$ are now $A(bac) = \{(1,2),(2,1)\}$, $A(bcb) = \{(1,1)\}$, $A(caa) = \{(2,2)\}$, and $A(w) = \emptyset$ for all other w. The trie implementation of $D(P, \mathcal{Q}_P)$ would be as follows.

$D(P, \mathcal{Q}_P)$:



Analysis. We determine q such that the expected processing time of T (i.e., elimination + checking) is minimized under the assumption that T is a random text in the uniform Bernoulli model (each symbol of Σ can occur in a given position of T with probability $1/c$ independently of the content of other positions). We will next analyze the expected time for the elimination and checking of a fixed potential occurrence R of P in T.

Let $Q(i_T, j_T) \in \mathcal{Q}_T$ be the text sample contained in R. The elimination phase for R consists of evaluating string $w = s(T, Q(i_T, j_T))$ and finding $A(w)$ from $D(P, \mathcal{Q}_P)$. This takes time $O(q)$, i.e., is proportional to the number q of entries of T that have to be examined to get w. As $Q(i_T, j_T)$ is contained in $(m - \lceil\sqrt{q}\rceil + 1)^2$ potential occurrences of P, the elimination time amortized for R is proportional to $q/(m - \lceil\sqrt{q}\rceil + 1)^2$.

The analysis of the checking phase is based on the naive checking that compares the corresponding entries of P and R until the first mismatch or an entire occurrence of P is found. The expected number of comparisons is less than $\alpha = c/(c-1)$. However, the checking is activated only if the witness of R is positive. The probability of this event is $1/c^q$, and the expected number of comparisons in the checking phase is therefore less than α/c^q.

Now we choose q to minimize the total expected number of comparisons allocated for R,

$$\frac{q}{(m - \lceil\sqrt{q}\rceil + 1)^2} + \frac{\alpha}{c^q}. \tag{3.1}$$

Application of elementary calculus on (3.1) without the ceiling function gives the equation

$$q = \log_c m^2 - \log_c \frac{m^2(m+1)}{(m - \sqrt{q} + 1)^3} + \log_c \frac{c \ln c}{c-1}$$

for the optimal (real) value of q. This further implies that

$$\log_c m^2 - 1 < q < \log_c m^2 + \frac{1}{2},$$

when $m \geq 2$ and $c \geq 2$. Based on this we choose $q = \lceil \log_c m^2 \rceil$ (when $m = 1$, define $q = 1$).

Substituting this into (3.1) and noting that there are $\leq n^2$ potential occurrences gives the following bound for the expected number of symbols examined during the elimination and checking:

$$n^2 \left(\frac{\lceil \log_c m^2 \rceil}{\left(m - \left\lceil \sqrt{\lceil \log_c m^2 \rceil} \right\rceil + 1 \right)^2} + \frac{\alpha}{m^2} \right) \leq n^2 \frac{4 \lceil \log_c m^2 \rceil + \alpha}{m^2}$$
$$= O\left(\frac{n^2 \log_c m^2}{m^2} \right) = O\left(\frac{|T| \log_c |P|}{|P|} \right),$$

where we have used the fact that $m - \lceil \sqrt{\lceil \log_c m^2 \rceil} \rceil + 1 \geq m/2$ if $c \geq 2$ and $m \geq 2$.

We have shown the following result.

THEOREM 3.2. *The occurrences of an $m \times m$ pattern P in an $n \times n$ text T can be found using square templates of size $\lceil \log_c m^2 \rceil$ in expected time $O(n^2 \log_c m^2/m^2)$. The preprocessing of P takes time and space $O(m^2)$.*

When the pattern is large ($|P| = \omega(n\sqrt{\log_c n})$), the pattern preprocessing dominates the matching time. If desirable, the preprocessing time can be reduced by using only a part of the pattern in the preprocessing and elimination phases. The full pattern is used only in the checking phase. When the area of the pattern used in the preprocessing is $\Theta(n\sqrt{\log_c n})$, the expected total time becomes $O(n\sqrt{\log_c n})$.

It should be clear that the algorithm of this section generalizes to d-dimensional pattern matching for rectangular patterns P and texts T such that the expected running time is $O(|T| \log_c |P|/|P|)$ for processing T. Preprocessing P needs time $O(|P|)$.

4. Linear templates. In this section, we relax the requirement of a minimum number of text samples. Instead, we minimize the number of text entries belonging to samples by letting the samples share entries. This, together with an efficient method for reading the text samples and comparing them to pattern samples, leads to an algorithm with performance similar to the algorithm of previous section.

To make the reading of the text samples simple in the case of overlapping templates, we use *linear templates*. A linear template Q of size q defines the shape of samples to be an evenly spaced subsequence of q entries on a row of a two-dimensional array. Hence Q is of the form $Q = ((0,0), (0,h), (0,2h), \ldots, (0,(q-1)h))$ for some $h \geq 1$. Note that samples $Q(i,j)$ and $Q(i,j+h)$ share $q-1$ entries.

Text sampling scheme $\mathcal{Q}_T$ will consist of linear samples placed on every mth row, called a *test row*, such that they start from every hth entry. Hence the samples overlap each other as $Q(i,j)$ and $Q(i,j+h)$ above. This gives

$$\mathcal{Q}_T = \left\{ Q(im, jh) \,\middle|\, 1 \leq i \leq \left\lfloor \frac{n}{m} \right\rfloor, 1 \leq j \leq \left\lfloor \frac{n-m}{h} \right\rfloor + 1 \right\}.$$

The number of text entries belonging to samples in $\mathcal{Q}_T$ is now $\lfloor n/m \rfloor (\lfloor (n-m)/h \rfloor + q)$. To minimize this, we should maximize h. The upper bound for h is given by the fact that every potential occurrence must contain at least one text sample. This gives $h = \lfloor m/q \rfloor$. The pattern sampling scheme is

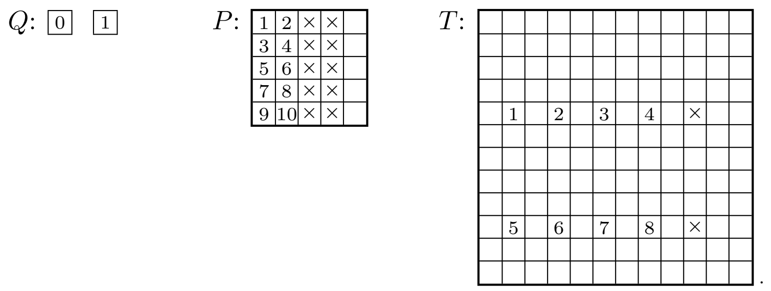
$$\mathcal{Q}_P = \{ Q(i,j) \mid 1 \leq i \leq m,\ 1 \leq j \leq h \}.$$

Note that there are no overlaps between pattern samples.

Example 3. Let P be a 5×5 pattern, T a 12×12 text and $Q = ((0,0),(0,2))$ a linear template of size 2. Using the above method, we get

$$\mathcal{Q}_P = \{Q(1,1), Q(1,2), Q(2,1), Q(2,2), Q(3,1), Q(3,2), Q(4,1), Q(4,2), Q(5,1), Q(5,2)\},$$
$$\mathcal{Q}_T = \{Q(5,2), Q(5,4), Q(5,6), Q(5,8), Q(10,2), Q(10,4), Q(10,6), Q(10,8)\}.$$

This is illustrated below:



The numbered entries in the pattern and the text are the origins of the samples. The entries marked with "×" are the other sample entries.

Utilizing the overlaps of text samples makes it possible to read each test string $s(T, Q(i,j))$, $Q(i,j) \in \mathcal{Q}_T$, in constant amortized time. For each test row, we read the sample entries from left to right and maintain a window of size q to hold the current string.

We also need to find the matching pattern samples in constant time. To achieve this we replace the trie of section 3 with an Aho–Corasick multipattern matching automaton $AC(P, \mathcal{Q}_P)$ (see [1]). The automaton can be built in the same asymptotic time as the trie; in fact $AC(P, \mathcal{Q}_P)$ is simply the trie augmented with the *failure*-transitions. The addresses of the test strings are attached to the states of $AC(P, \mathcal{Q}_P)$ that correspond to the test strings. As there are $m\lfloor m/q \rfloor$ samples of size q in $\mathcal{Q}_P$, the preprocessing time becomes $O(m^2)$; with c shown explicitly the bound becomes $O(m^2 c)$ or $O(m^2 \log c)$. This is smaller, by a factor of q, than the preprocessing time of the previous section, as there are now fewer pattern samples.

The method of treating strings as integers can be modified to work with the linear templates, too. During the scanning of T, we treat the characters as digits and maintain a window of q digits. The pattern samples can be read one at a time in $O(m^2)$ time. Otherwise, the method works as with square templates.

Analysis. As already mentioned, the number of text entries read during elimination is
