$$\left\lfloor \frac{n}{m} \right\rfloor \left(\left\lfloor \frac{n-m}{h} \right\rfloor + q \right) = \left\lfloor \frac{n}{m} \right\rfloor \left\lfloor \frac{n-m+qh}{h} \right\rfloor \le \left\lfloor \frac{n}{m} \right\rfloor \left\lfloor \frac{n}{h} \right\rfloor \le \frac{n^2}{mh} = \frac{n^2}{m\lfloor m/q \rfloor},$$

which is also the running time of the elimination phase, as each entry can be processed in constant time. The expected running time of the checking phase is, as before, at most $n^2\alpha/c^q$. Thus, the total expected text processing time is now bounded by

$$n^2 \left(\frac{1}{m \left\lfloor \frac{m}{q} \right\rfloor} + \frac{\alpha}{c^q} \right).$$

Omitting the floor function, we can again apply calculus to find that the optimal (real) value of q is

$$q = \log_c m^2 + \log_c \frac{c \ln c}{c-1},$$

where $0 < \log_c \frac{c \ln c}{c-1} < \frac{1}{2}$ for $c \geq 2$. Thus we again choose $q = \lceil \log_c m^2 \rceil$ which leads to the bound[3]

$$n^2 \left(\frac{2 \log_c m^2 + \alpha}{m^2} \right) = O\left(\frac{n^2 \log_c m^2}{m^2} \right) = O\left(\frac{|T| \log_c |P|}{|P|} \right)$$

for the total expected number of examined symbols during elimination and checking.

THEOREM 4.1. *The occurrences of an $m \times m$ pattern P in an $n \times n$ text T can be found using overlapping linear templates of size $\lceil \log_c m^2 \rceil$ in expected time $O(n^2 \log_c m^2 / m^2)$. The preprocessing of P takes time and space $O(m^2)$.*

Again, the pattern preprocessing time dominates when $|P| = \omega(n\sqrt{\log_c n})$. As with the square template algorithm, the total expected time in such a case can be limited to $O(n\sqrt{\log_c n})$ by using only an area of size $\Theta(n\sqrt{\log_c n})$ of the pattern in the preprocessing.

The algorithm again easily generalizes to d-dimensional P and T. Note that, for any d, the generalized algorithm uses linear (one-dimensional) samples scanned with the Aho–Corasick automaton. In this way, the elimination phase of d-dimensional matching reduces directly to one-dimensional techniques.

For larger d, it may happen that $q = \lceil \log_c m^d \rceil > m$ in which case the straightforward generalization does not work any more.[4] An easy correction is to use superrows, consisting of two or more adjacent one-dimensional rows. As $2^{d-1}m \geq \log_c m^d$ for $d \geq 1$, $c \geq 2$, $m \geq 2$, a superrow with diameter 2 is always sufficient. Therefore this does not change the asymptotic behavior of the algorithm.

The algorithm of this section is quite similar to the (suboptimal) algorithm by Baeza–Yates and Régnier [5], the main difference being that we use test samples with fixed size and location.

5. Lower bound.

In [25], Yao proved a lower bound of $\Omega(n \log_c m/m)$ for the expected running time of one-dimensional pattern matching. In this section, we generalize Yao's result for d-dimensional hypercubic strings.

Let P be a pattern of size m^d and T a text of size n^d over alphabet Σ of size c. There exists some minimum number of entries of T that must be examined before any algorithm can be sure that all occurrences of P in T have been found. We define $g(P, n)$ to be the minimum of such numbers for pattern P over all texts of size n^d. Thus, $g(P, n)$ gives the best case lower bound of pattern matching for pattern P.

There exists patterns that are easy to match in the best case (e.g., patterns that do not contain all characters of the alphabet). However, the following theorem shows that such patterns are rare.

DEFINITION 5.1. *For $n \geq m > 0$, let*

$$f_1(m, n) = \left\lceil \frac{1}{d} \log_c \left(\frac{(n-m)^d}{\ln(m^d + 1)} + 2 \right) \right\rceil \quad \textit{and}$$

[3]Taking the floor function into account, $q' = \lfloor m / \lfloor m/q \rfloor \rfloor$ is always at least as good a choice as q, because $q' \geq q$ and $\lfloor m/q' \rfloor = \lfloor m/q \rfloor$.

[4]For $d = 2$ there is one such case, namely $m = 3$, $c = 2$ with $\log_2 3^2 \approx 3.17$. In this special case, we can simply set $q = 3$.

$$f_2(m,n) = \left\lfloor \frac{n}{2m} \right\rfloor^d \left\lceil \frac{1}{d} \log_c(m^d + 1) \right\rceil .$$

Define

$$f(m,n) = \begin{cases} f_1(m,n) & \textit{if } m \le n \le 2m, \\ f_2(m,n) & \textit{if } n > 2m. \end{cases}$$

THEOREM 5.2. *There exists a positive number b such that, for any $|\Sigma| = c \ge 2$ and $m > 0$, there exists a set of patterns $L \subseteq \Sigma^{m^d}$ satisfying*

$$|L| \ge \left(1 - \frac{1}{m^{9d}}\right) c^{m^d},$$

and

$$\textit{for each } P \in L,\ g(P,n) \ge bf(m,n) \textit{ for all } n \ge m.$$

Proof. The proof is a simple modification of Yao's proof in [25]. As the proof is quite long we will give here only a brief guide for the modification. Almost all that is required is to remember that we are now dealing with d-dimensional strings. For example, in Yao's Lemma 5.2 the text has to be divided into hypercubes of size $(2m)^d$ instead of strings of length $2m$. Similarly, we need to replace the occurrences of m, n, $n - m$ (denoted by d in Yao's paper), $2m$ and $\lfloor n/(2m) \rfloor$ throughout the proof with m^d, n^d, $(n-m)^d$, $(2m)^d$ and $\lfloor n/(2m) \rfloor^d$, respectively. Additionally, the terms of the form $xq^4 \ldots$ and $xq^{20} \ldots$ must have an extra factor of 2^d. This is balanced by the factor $1/d$ in the definitions of f_1 and f_2. $\square$

The above theorem shows that for the majority of patterns (i.e., for the patterns in L) even the best case complexity of pattern matching is

$$\Omega\left(\frac{n^d \log_c m^d}{m^d}\right),$$

for a fixed d. This implies that for a fixed d and T and random P, the expected running time of pattern matching is $\Omega\left(n^d \log_c m^d / m^d\right)$. Thus our algorithms for fixed-dimensional strings are optimal.

It is possible to have a single version of our algorithms work for all dimensions d. In such a case, the lower bound given by Theorem 5.2, with dependency on d shown explicitly, is

$$\Omega\left(\frac{1}{d2^d} \frac{n^d \log_c m^d}{m^d}\right),$$

leaving the upper and lower bounds separated by factor $d2^d$. Our conjecture is that the lower bound can be improved to $\Omega\left(n^d \log_c m^d / m^d\right)$ in this case, too, but that remains an open question.

6. Experimental results. We have conducted some experiments to find out how these algorithms work in practice and how they compare to each other and some other algorithms. The other algorithms in the experiments are the trivial algorithm (check naively each potential occurrence of P in T) and an asymptotically optimal algorithm by Tarhio [23]. Tarhio's algorithm represents the dynamic sampling approach as opposed to the static sampling schemes of our algorithms.

Both the square template algorithm (ST) and the linear template algorithm (LT) use the method of converting strings to integers. Also Tarhio's algorithm (TDBM = two-dimensional Boyer–Moore) uses a similar method; in this sense, these algorithms are very comparable. The pattern preprocessing of ST is done using the more complicated (but faster) $O(m^2)$ method. All of these algorithms try to choose the parameters in the pattern preprocessing phase so that the running time of the text scanning phase is minimized. The algorithms were written and carefully optimized using C and were run on a Sun 4 workstation.

Table 6.1 shows the results of experiments using independently generated random texts and patterns. Text size is 1000×1000 in all of the tests, and pattern and alphabet sizes vary. The times (given in milliseconds) are averages of seven tests with different patterns.

The table gives the pattern preprocessing and text scanning times separately; the total time is the sum of these. The total time for the trivial algorithm (TRIV) is also its scanning time, as it doesn't have preprocessing. The times do not include the reading of the text and the pattern from disk.

The trivial algorithm is clearly inferior to other algorithms for all except the smallest patterns. The ST algorithm has poor preprocessing times due to the complicated preprocessing method. Otherwise the algorithms perform similarly.

The scanning times are the most interesting here as that is what the algorithms try to minimize. Figure 6.1 compares the scanning times of the algorithms. The times are shown relative to $\log_c m^2/m^2$ to bring the times with different pattern sizes to the same scale.

As the pattern size increases, the total time decreases at first but starts to increase when the pattern preprocessing starts to dominate. Both in theory and in practice, the minimum is at $m^2 \approx n\sqrt{\log_c n}$. As suggested earlier, for large patterns the total time can be reduced by using only a part of the pattern in the preprocessing phase. The algorithms LT, ST, and TDBM can all be modified in this way. Table 6.2 shows the running times for the modified LT algorithm for alphabet size 2. Figure 6.2 compares

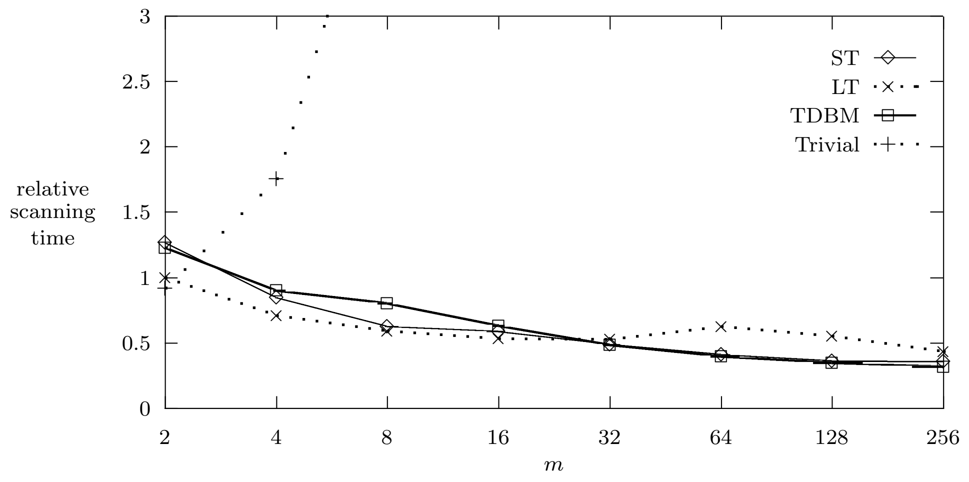

FIG. 6.1. *Scanning times relative to $\log_c m^2/m^2$ scaled so that the scanning time of LT is 1 when $m = 2$. The alphabet size c is 2.*

7. The k mismatches case.

The *k mismatches problem* asks for finding approximate occurrences of P with at most k mismatches, that is, occurrences that match with P except possibly for $\leq k$ symbols. In this section, we generalize the algorithms of sections 3 and 4 to the k mismatches problem. After the publication of an earlier version of this paper, Park [20] presented some improvements to the approximate matching algorithms and their analysis. This section includes some small changes to the earlier version inspired by Park's improvements.

One of the requirements of the algorithms in the previous sections was that every potential occurrence have exactly one witness. The k mismatches case, $k \geq 1$, can be handled by increasing the number of witnesses per potential occurrence as shown by the following lemma.

LEMMA 7.1. *Let potential occurrence R have $k+p$ disjoint witnesses. If $< p$ of them are positive, then R can not be an occurrence of P with $\leq k$ mismatches.*

Suggested by the lemma, the sampling scheme $\mathcal{Q}$ has to be such that every potential occurrence has $k+p$ nonoverlapping witnesses of size q. Parameters q and p will be determined in the analysis; note that to get optimal performance, we cannot simply choose $p = 1$.

The elimination phase now maintains a counter, initially equal to 0, for every potential occurrence R. When a positive witness of R is found, the counter of R is increased by one. When the counter achieves value p, R is transmitted to the checking phase. The checking phase naively compares R and P until $k+1$ mismatches are found or the whole pattern has been compared.

To avoid initializing all the $\Theta(n^2)$ counters, we do not create a counter until its first incrementation. The counters can be accessed in constant expected time using, e.g., hashing.

We will now show how to modify the sampling schemes of sections 3 and 4 to have $k+p$ witnesses for each potential occurrence.

Square templates. The text sampling scheme described in section 3 consists of square samples placed in the form of a regular grid such that every potential occurrence contains exactly one whole sample. If we take $k+p$ copies of such a sample grid, each translated such that there are no overlaps, we have a text sampling scheme $\mathcal{Q}_T$ where each potential occurrence contains exactly $k+p$ disjoint text samples. When we define the pattern sampling scheme $\mathcal{Q}_P$ to be the same as in section 3, we have the desired sampling scheme $\mathcal{Q} = (\mathcal{Q}_P, Q_T)$ with $k+p$ witnesses per potential occurrence.

The method works as long as we can keep the text samples disjoint. This means that we must have

$$k + p \leq \left\lfloor \frac{m - \lceil\sqrt{q}\rceil + 1}{\lceil\sqrt{q}\rceil} \right\rfloor^2 . \tag{7.1}$$

Linear templates. Using the linear templates of section 4, there are two ways to increase the number of witnesses. First, we can increase the number of test rows in $\mathcal{Q}_T$ so that every potential occurrence contains u test rows. If $k+p \leq m$, we can select $u = k+p$ and we are done. In the case $k+p > m$, every segment of length m of every test row in $\mathcal{Q}_T$ will contain more than one, say v, disjoint samples. This is achieved by selecting a step size $h = \lfloor m/vq \rfloor$. The text sampling scheme can now be defined as

$$\mathcal{Q}_T = \Big\{ Q(im-u+r, jh) \;\Big|\; 1 \le i \le \left\lfloor \frac{n-u+1}{m} \right\rfloor, \\ 1 \le j \le \left\lfloor \frac{n-m}{h} \right\rfloor + 1 + (v-1)q,\ 1 \le r \le \min\{u, n-im+u\} \Big\}.$$

The corresponding pattern sampling scheme is

$$\mathcal{Q}_P = \{ Q(i, j+rqh) \mid 0 \le r \le v-1, 1 \le i \le m,\ 1 \le j \le h \}.$$

This sampling scheme $\mathcal{Q} = (\mathcal{Q}_P, \mathcal{Q}_T)$ gives uv disjoint witnesses per potential occurrence.

For some (large) values of q and $k+p$ it may not be possible to select u and v such that the optimum value $k+p$ of uv is achieved. However, by selecting

$$v = \left\lceil \frac{k+p}{m} \right\rceil \text{ and } u = \left\lceil \frac{k+p}{v} \right\rceil,$$

we can get close, as then

$$k+p \;\le\; uv = \left\lceil \frac{k+p}{v} \right\rceil v \le k+p+v-1 = k+p+\left\lceil \frac{k+p}{m} \right\rceil - 1 < (k+p)\left(1+\frac{1}{m}\right).$$

The upper bounds for u and v are given by $u \le m$ and $vq \le m$. Thus, the above selections can be done as long as

$$k+p \le m \left\lfloor \frac{m}{q} \right\rfloor. \tag{7.2}$$

Analysis. The running time (without pattern preprocessing) is the sum of three components:
$A =$ the number of entries of T examined during the elimination,
$B =$ the number of updates of the counters for potential occurrences, and
$C =$ the number of symbols compared during the checking.
For both of the above sampling schemes we have

$$A \approx \frac{n^2(k+p)q}{m^2}. \tag{7.3}$$

The expected value $\bar{B}$ of B is

$$\bar{B} \le \frac{n^2(k+p)}{c^q} \tag{7.4}$$

because there are at most n^2 potential occurrences with $k+p$ witnesses each, and a witness is positive with probability $1/c^q$.

The third component C needs a more careful analysis. First, we denote by C' the number of character comparisons during naive checking of a randomly chosen potential occurrence R. As C' is a Pascal distributed random variable with parameters $k+1$ and $\frac{c-1}{c}$, we get

$$\bar{C'} = (k+1)\frac{c}{c-1} \le 2(k+1).$$

However, a candidate reaching the checking phase is not random: it is known to contain p positive witnesses. This increases the number of comparisons by at most pq.

Next we analyze the probability, denoted by H, that the checking is started for a fixed R. As H is the probability that at most k of the $k+p$ witnesses of R are negative, we have

$$H = \sum_{i=0}^{k} \binom{k+p}{i} \left(\frac{1}{c^q}\right)^{k+p-i} \left(1 - \frac{1}{c^q}\right)^{i}.$$

Noting that

$$\binom{k+p}{i} = \frac{\binom{k+p}{k}\binom{k}{i}}{\binom{k+p-i}{k-i}},$$

we can rewrite H as follows

$$\begin{aligned} H &= \frac{\binom{k+p}{k}}{c^{qp}} \sum_{i=0}^{k} \frac{\binom{k}{i}}{\binom{k+p-i}{k-i}} \left(\frac{1}{c^q}\right)^{k-i} \left(1 - \frac{1}{c^q}\right)^{i} \\ &\le \frac{\binom{k+p}{k}}{c^{qp}} \sum_{i=0}^{k} \binom{k}{i} \left(\frac{1}{c^q}\right)^{k-i} \left(1 - \frac{1}{c^q}\right)^{i} \\ &= \frac{\binom{k+p}{k}}{c^{qp}}. \end{aligned}$$

As there are at most n^2 potential occurrences, we now have

$$\bar{C} \le n^2 H(\bar{C}' + pq) \le \frac{n^2\binom{k+p}{k}}{c^{qp}}(2k+2+pq). \tag{7.5}$$

Select finally the parameters q and p satisfying

$$q = \lceil \log_c m^2 \rceil \quad \text{and} \tag{7.6}$$

$$p = 1 + \left\lceil \log_{c^q} \binom{k+p}{k} \right\rceil. \tag{7.7}$$

The value of p needs a little more analysis. We first note that

$$1 \le 1 + \left\lceil \log_{c^q} \binom{k+1}{k} \right\rceil \quad \text{and} \quad k+1 \ge 1 + \left\lceil \log_{c^q} \binom{2k+1}{k} \right\rceil.$$

The latter inequality holds because

$$\log_{c^q} \binom{2k+1}{k} = \log_{c^q} \left(\frac{2k+1}{k} \frac{2k}{k-1} \cdots \frac{k+1}{1} \right) \le \log_{c^q}(k+1)^k = k \log_{c^q}(k+1) \le k,$$

with the reasonable assumption that $k+1 \le m^2 \le c^q$. Given the above and the fact that the right-hand side of (7.7) is an integer valued nondecreasing function of p, we are guaranteed that there exists an integer value of p satisfying (7.7) in the range $[1, k+1]$. If there are many such values, we select the smallest of them. The value can, in practice, be found by trying with $p = 1, 2, \ldots$ until (7.7) is satisfied. Note that if $k = 0$, then $p = 1$, and the algorithm reduces to the exact matching algorithm.

Substituting (7.6), (7.7), and the fact that $p \leq k+1$ into (7.3), (7.4), and (7.5) gives

$$A, \bar{C} = O\left(\frac{n^2(k+1)\log_c m^2}{m^2}\right) \text{ and}$$
$$\bar{B} = O\left(\frac{n^2(k+1)}{m^2}\right).$$

Hence, the expected running time of the algorithm is

$$A + \bar{B} + \bar{C} = O\left(\frac{n^2(k+1)\log_c m^2}{m^2}\right).$$

As A is the most significant component in the running time, the only way to improve the selection of parameters q and p would be to decrease q. However, any asymptotically significant decrease in q would increase $\bar{B}$ past A. Thus, the above selection of the parameters is asymptotically optimal.

The maximum value of k that the algorithm can handle is limited by (7.1) with square templates and by (7.2) with linear templates. The linear template algorithm is less restrictive in most cases. Substituting $q = \lceil \log_c m^2 \rceil$ and $p \leq k+1$ into (7.2) gives the bound

$$k \leq \frac{m\left\lfloor \frac{m}{\lceil \log_c m^2 \rceil} \right\rfloor - 1}{2}$$

for the maximum value of k. For larger patterns, the actual upper bound for k in the linear template algorithm is close to $m^2/\lceil \log_c m^2 \rceil$.

If the counters are destroyed as soon as they can no longer be increased, the space taken by the counters is $O(kn/m)$ on average and $O(nm)$ in the worst case. The space requirement can be reduced with the following technique. Divide the text into slices of $2m-2$ rows that overlap each other by $m-1$ rows, and search each slice separately. All potential occurrences belong to exactly one slice, so no occurrence will be missed or found twice. The space requirement is now reduced to $O(k)$ on average and $O(m^2)$ in the worst case. The number of text samples read at most doubles, so the asymptotic time requirement remains the same. The number of samples can still be reduced by using wider slices, which increases the space requirement, and/or by optimizing the sampling scheme for the slices, which has been done by Park [20].

We have shown the following theorem.

THEOREM 7.2. *Let $k \leq (m\lfloor m/\lceil \log_c m^2 \rceil \rfloor - 1)/2$. Then the k mismatches problem for two-dimensional $m \times m$ pattern P and $n \times n$ text T can be solved in expected time $O((k+1)n^2 \log_c m^2/m^2)$ and additional space $O(m^2)$. The preprocessing of P takes time and space $O(m^2)$.*

The algorithm requires that $k = O(m^2/\log_c m^2)$. Substituting this into the bound of the above theorem shows that whenever the algorithm works, it is at most linear in $|T|$. Chang and Lawler [9] have obtained similar results for the one-dimensional k differences problem.

8. Concluding remarks. There are many possibilities for practical fine-tuning of our algorithms. For example, in the algorithm of section 3 it is possible to combine the elimination and checking phases using the spiral-shaped test strings of Gonnet [14]. The text processing in all algorithms can be performed with a window of size $O(m^2)$ into the text.

We ignored worst-case considerations in this paper. It is possible to use some linear worst-case algorithm for the checking phase of our algorithms such that the total time stays $O(n^2)$. However, it is not clear that this would be useful in practice. More important is that the obliviousness of the elimination phase makes parallel implementations of our algorithms simple.

The expected time $O(|T|\log_c |P|/|P|)$ of our exact matching algorithms was shown to be optimal for d-dimensional strings when d is considered constant, but not when d is variable. It remains an open problem to either remove the dependence on d from the lower bound or develop an algorithm that is better than ours for variable d. Another open problem is whether our approximate matching algorithms are optimal in the expected case.

Acknowledgment. We would like to thank Jorma Tarhio for his useful comments and his help in implementing the TDBM-algorithm.

KOLMOGOROV RANDOM GRAPHS AND THE INCOMPRESSIBILITY METHOD*

HARRY BUHRMAN†, MING LI‡, JOHN TROMP§, AND PAUL VITÁNYI¶

Abstract. We investigate topological, combinatorial, statistical, and enumeration properties of finite graphs with high Kolmogorov complexity (almost all graphs) using the novel incompressibility method. Example results are (i) the mean and variance of the number of (possibly overlapping) ordered labeled subgraphs of a labeled graph as a function of its randomness deficiency (how far it falls short of the maximum possible Kolmogorov complexity) and (ii) a new elementary proof for the number of unlabeled graphs.

Key words. Kolmogorov complexity, incompressibility method, random graphs, enumeration of graphs, algorithmic information theory

1. Introduction.

The incompressibility of individual random objects yields a simple but powerful proof technique. The incompressibility method [9] is a new general purpose tool and should be compared with the pigeon hole principle or the probabilistic method. Here we apply the incompressibility method to randomly generated graphs and "individually random" graphs—graphs with high Kolmogorov complexity.

In a typical proof using the incompressibility method, one first chooses an individually random object from the class under discussion. This object is effectively incompressible. The argument invariably says that if a desired property does not hold, then the object can be compressed. This yields the required contradiction. Since a randomly generated object is *with overwhelming probability* individually random and hence incompressible, one usually obtains the property with high probability.

Results. We apply the incompressibility method to obtain combinatorial properties of graphs with high Kolmogorov complexity. These properties are parametrized in terms of a "randomness deficiency" function.[1] This can be considered as a parametrized version of the incompressibility method. In section 2 we show that for every labeled graph on n nodes with high Kolmogorov complexity (also called "Kolmogorov random graph" or "high-complexity graph"), the node degree of every vertex is about $n/2$ and there are about $n/4$ node-disjoint paths of length 2 between every

[1]Randomness deficiency measures how far the object falls short of the maximum possible Kolmogorov complexity. It is formally defined in Definition 4.

pair of nodes. In section 2.2, we analyze "normality" properties of Kolmogorov random graphs. In analogy with infinite sequences one can call an infinite labeled graph normal if each finite ordered labeled subgraph of size k occurs in the appropriate sense (possibly overlapping) with limiting frequency $2^{-\binom{k}{2}}$. It follows from the Martin–Löf theory of effective tests for randomness [14] that individually random (high complexity) infinite labeled graphs are normal. Such properties cannot hold precisely for finite graphs, where randomness is necessarily a matter of degree: We determine close quantitative bounds on the normality (frequency of subgraphs) of high-complexity finite graphs in terms of their randomness deficiency.

Denote the number of unlabeled graphs on n nodes by g_n. In section 2.3 we demonstrate the use of the incompressibility method and Kolmogorov random graphs by providing a new elementary proof that $g_n \sim 2^{\binom{n}{2}}/n!$. This has previously been obtained by more advanced methods [12]. Moreover, we give a good estimate of the error term. Part of the proof involves estimating the order (number of automorphisms) $s(G)$ of graphs G as a function of the randomness deficiency of G. For example, we show that labeled graphs with randomness deficiency appropriately less than n are rigid (have but one automorphism: the identity automorphism).

Related work. Several properties (high degree nodes, diameter 2, rigidity) have also been proven by traditional methods to hold with high probability for randomly generated graphs [5, 4]. We provide new proofs for these results using the incompressibility method. They are actually proved to hold for the definite class of Kolmogorov random graphs—rather than with high probability for randomly generated graphs.

In [10] (also [9]) Li and Vitányi investigated topological properties of labeled graphs with high Kolmogorov complexity and proved them using the incompressibility method to compare ease of such proofs with the probabilistic method [7] and the entropy method.

In [8] it was shown that every labeled tree on n nodes with randomness deficiency $O(\log n)$ has maximum node degree of $O(\log n/\log\log n)$. Analysis of Kolmogorov random graphs was used to establish the total interconnect length of Euclidean (real-world) embeddings of computer network topologies [15] and the size of compact routing tables in computer networks [6]. Infinite binary sequences that asymptotically have equal numbers of 0s and 1s and, more generally, where every block of length k occurs (possibly overlapping) with frequency $1/2^k$ were called "normal" by E. Borel [2]. References [9, 11] investigate the quantitative deviation from normal as a function of the Kolmogorov complexity of a finite binary string. Here we consider an analogous question for Kolmogorov random graphs.[2] Finally, there is a close relation and genuine difference between high-probability properties and properties of incompressible objects; see [9, Section 6.2].

1.1. Kolmogorov complexity.

We use the following notation. Let A be a finite set. By $d(A)$ we denote the *cardinality* of A. In particular, $d(\emptyset) = 0$. Let x be a finite binary string. Then $l(x)$ denotes the *length* (number of bits) of x. In particular, $l(\epsilon) = 0$, where ϵ denotes the *empty word*.

Let $x, y, z \in \mathcal{N}$, where $\mathcal{N}$ denotes the natural numbers. Identify $\mathcal{N}$ and $\{0,1\}^*$

[2]There are some results along these lines related to randomly generated graphs, but as far as the authors could ascertain (consulting Alan Frieze, Svante Janson, and Andrzej Rucinski around June 1996) such properties have not been investigated in the same detail as here. See, for example, [1, pp. 125–140]. But note that pseudorandomness also is different from Kolmogorov randomness.

according to the correspondence

$$(0,\epsilon),(1,0),(2,1),(3,00),(4,01),\ldots.$$

Hence, the length $l(x)$ of x is the number of bits in the binary string or number x. Let $T_0, T_1, \ldots$ be a standard enumeration of all Turing machines. Let $\langle\cdot,\cdot\rangle$ be a standard one-to-one mapping from $\mathcal{N} \times \mathcal{N}$ to $\mathcal{N}$, for technical reasons chosen such that $l(\langle x,y\rangle) = l(y) + O(l(x))$. An example is $\langle x,y\rangle = 1^{l(x)}0xy$. This can be iterated to $\langle\langle\cdot,\cdot\rangle,\cdot\rangle$.

Informally, the Kolmogorov complexity [13] of x is the length of the *shortest* effective description of x. That is, the *Kolmogorov complexity* $C(x)$ of a finite string x is simply the length of the shortest program, say in FORTRAN (or in Turing machine codes) encoded in binary, which prints x without any input. A similar definition holds conditionally in the sense that $C(x|y)$ is the length of the shortest binary program which computes x on input y. Kolmogorov complexity is absolute in the sense of being independent of the programming language up to a fixed additional constant term which depends on the programming language but not on x. We now fix one canonical programming language once and for all as reference and thereby $C()$. For the theory and applications, see [9]. A formal definition is as follows:

Definition 1. *Let U be an appropriate universal Turing machine such that*

$$U(\langle\langle i,p\rangle,y\rangle) = T_i(\langle p,y\rangle)$$

for all i and $\langle p,y\rangle$. The conditional Kolmogorov complexity *of x given y is*

$$C(x|y) = \min_{p\in\{0,1\}^*}\{l(p) : U(\langle p,y\rangle) = x\}.$$

The unconditional Kolmogorov complexity of x is defined as $C(x) := C(x|\epsilon)$.

It is easy to see that there are strings that can be described by programs much shorter than themselves. For instance, the function defined by $f(1) = 2$ and $f(i) = 2^{f(i-1)}$ for $i > 1$ grows very fast, $f(k)$ is a "stack" of k twos. Yet for each k it is clear that $f(k)$ has complexity at most $C(k) + O(1)$. What about incompressibility?

By a simple counting argument one can show that whereas some strings can be enormously compressed, the majority of strings can hardly be compressed at all.

For each n there are 2^n binary strings of length n but only $\sum_{i=0}^{n-1} 2^i = 2^n - 1$ possible shorter descriptions. Therefore, there is at least one binary string x of length n such that $C(x) \geq n$. We call such strings *incompressible*. It also follows that for any length n and any binary string y, there is a binary string x of length n such that $C(x|y) \geq n$. Generally, for every constant c we can say a string x is *c-incompressible* if $C(x) \geq l(x) - c$. Strings that are incompressible (say, c-incompressible with small c) are patternless, since a pattern could be used to reduce the description length. Intuitively, we think of such patternless sequences as being random, and we use "random sequence" synonymously with "incompressible sequence."[3] By the same counting argument as before we find that the number of strings of length n that are c-incompressible is at least $2^n - 2^{n-c} + 1$. Hence there is at least one 0-incompressible string of length n, at least one-half of all strings of length n are 1-incompressible, at least three-fourths of all strings of length n are 2-incompressible, ..., and at least the $(1 - 1/2^c)$th part of all 2^n strings of length n are c-incompressible. This means

[3]It is possible to give a rigorous formalization of the intuitive notion of a random sequence as a sequence that passes all effective tests for randomness; see, for example, [9].

that for each constant $c \geq 1$ the majority of all strings of length n (with $n > c$) is c-incompressible. We generalize this to the following simple but extremely useful lemma.

LEMMA 1. *Let c be a positive integer. For each fixed y, every set A of cardinality m has at least $m(1-2^{-c})+1$ elements x with $C(x|y) \geq \lfloor \log m \rfloor - c$.*

Proof. The proof is by simple counting. ☐

As an example, set $A = \{x : l(x) = n\}$. Then the cardinality of A is $m = 2^n$. Since it is easy to assert that $C(x) \leq n + c$ for some fixed c and all x in A, Lemma 1 demonstrates that this trivial estimate is quite sharp. The deeper reason is that since there are few short programs, there can be only few objects of low complexity. We require another quantity: The prefix Kolmogorov complexity which is defined just as $C(\cdot|\cdot)$ but now with respect to a subset of Turing machines that have the property that the set of programs for which the machine halts is prefix-free; that is, no halting program is a prefix of any other halting program. For details see [9]. Here we require only the quantitative relation below.

DEFINITION 2. *The* prefix *Kolmogorov complexity of x conditional to y is denoted by $K(x|y)$. It satisfies the inequality*

$$C(x|y) \leq K(x|y) \leq C(x|y) + 2\log C(x|y) + O(1).$$

2. Kolmogorov random graphs. Statistical properties of strings with high Kolmogorov complexity have been studied in [11]. The interpretation of strings as more complex combinatorial objects leads to a new set of properties and problems that have no direct counterpart in the "flatter" string world. Here we derive topological, combinatorial, and statistical properties of graphs with high Kolmogorov complexity. Every such graph possesses simultaneously all properties that hold with high probability for randomly generated graphs. They constitute "almost all graphs" and the derived properties a fortiori hold with probability that goes to 1 as the number of nodes grows unboundedly.

DEFINITION 3. *Each labeled graph $G = (V, E)$ on n nodes $V = \{1, 2, \ldots, n\}$ can be represented (up to automorphism) by a binary string $E(G)$ of length $\binom{n}{2}$. We simply assume a fixed ordering of the $\binom{n}{2}$ possible edges in an n-node graph, e.g., lexicographically, and let the ith bit in the string indicate presence* (1) *or absence* (0) *of the ith edge. Conversely, each binary string of length $\binom{n}{2}$ encodes an n-node graph. Hence we can identify each such graph with its binary string representation.*

DEFINITION 4. *A labeled graph G on n nodes has* randomness deficiency *at most $\delta(n)$ and is called $\delta(n)$*-random *if it satisfies*

$$C(E(G)|n) \geq \binom{n}{2} - \delta(n). \tag{2.1}$$

2.1. Some basic properties. Using Lemma 1, with $y = n$, A the set of strings of length $\binom{n}{2}$, and $c = \delta(n)$ gives us the following lemma.

LEMMA 2. *A fraction of at least $1 - 1/2^{\delta(n)}$ of all labeled graphs G on n nodes is $\delta(n)$-random.*

As a consequence, for example, the $c \log n$-random labeled graphs constitute a fraction of at least $(1 - 1/n^c)$ of all graphs on n nodes, where $c > 0$ is an arbitrary constant.

Labeled graphs with high complexity have many specific topological properties, which seem to contradict their randomness. However, these are simply the likely properties, whose absence would be rather unlikely. Thus, randomness enforces strict statistical regularities—for example, to have diameter exactly 2.

We will use the following lemma (Theorem 2.6.1 in [9]).

LEMMA 3. *Let $x = x_1 \dots x_n$ be a binary string of length n, and y a much smaller string of length l. Let $p = 2^{-l}$ and $\#y(x)$ be the number of (possibly overlapping) distinct occurrences of y in x. For convenience, we assume that x "wraps around" so that an occurrence of y starting at the end of x and continuing at the start also counts. Assume that $l \leq \log n$. There is a constant c such that for all n and $x \in \{0,1\}^n$ if $C(x) \geq n - \delta(n)$, then*

$$|\#y(x) - pn| \leq \sqrt{\alpha pn}$$

with $\alpha = [K(y|n) + \log l + \delta(n) + c]3l/\log e$.

LEMMA 4. *All $o(n)$-random labeled graphs have $n/4 + o(n)$ disjoint paths of length 2 between each pair of nodes i, j. In particular, all $o(n)$-random labeled graphs have diameter 2.*

Proof. The only graphs with diameter 1 are the complete graphs that can be described in $O(1)$ bits, given n, and hence are not random. It remains to consider an $o(n)$-random graph $G = (V, E)$ with diameter greater than or equal to 2. Let i, j be a pair of nodes connected by r disjoint paths of length 2. Then we can describe G by modifying the old code for G as follows:

- a program to reconstruct the object from the various parts of the encoding in $O(1)$ bits;
- the identities of $i < j$ in $2 \log n$ bits;
- the old code $E(G)$ of G with the $2(n-2)$ bits representing presence or absence of edges (j, k) and (i, k) for each $k \neq i, j$ deleted;
- a short program for the string $e_{i,j}$ consisting of the (reordered) $n - 2$ pairs of bits deleted above.

From this description we can reconstruct G in

$$O(\log n) + \binom{n}{2} - 2(n-2) + C(e_{i,j}|n)$$

bits, from which we may conclude that $C(e_{i,j}|n) \geq l(e_{i,j}) - o(n)$. As shown in [11] or [9] (here Lemma 3) this implies that the frequency of occurrence in $e_{i,j}$ of the aligned 2-bit block "11"—which by construction equals the number of disjoint paths of length 2 between i and j—is $n/4 + o(n)$. ☐

A graph is *k-connected* if there are at least k node-disjoint paths between every pair of nodes.

COROLLARY 1. *All $o(n)$-random labeled graphs are $(\frac{n}{4} + o(n))$-connected.*

LEMMA 5. *Let $G = (V, E)$ be a graph on n nodes with randomness deficiency $O(\log n)$. Then the largest clique in G has at most $\lfloor 2 \log n \rfloor + O(1)$ nodes.*

Proof. The proof is the same as the largest size transitive subtournament in a high-complexity tournament as in [9]. ☐

With respect to the related property of random graphs, in [1, pp. 86–87], it is shown that a random graph with edge probability 1/2 contains a clique on asymptotically $2 \log n$ nodes with probability at least $1 - e^{-n^2}$.

2.2. Statistics of subgraphs. We start by defining the notion of labeled subgraph of a labeled graph.

DEFINITION 5. *Let $G = (V, E)$ be a labeled graph on n nodes. Consider a labeled graph H on k nodes $\{1, 2, \ldots, k\}$. Each subset of k nodes of G induces a subgraph G_k of G. The subgraph G_k is an ordered labeled* occurrence *of H when we obtain H by relabeling the nodes $i_1 < i_2 < \cdots < i_k$ of G_k as $1, 2, \ldots, k$.*

It is easy to conclude from the statistics of high-complexity strings in Lemma 3 that the frequency of each of the two labeled two-node subgraphs (there are only two different ones: the graph consisting of two isolated nodes and the graph consisting of two connected nodes) in a $\delta(n)$-random graph G is

$$\frac{n(n-1)}{4} \pm \sqrt{\frac{3}{4}(\delta(n) + O(1))n(n-1)/\log e}.$$

This case is easy since the frequency of such subgraphs corresponds to the frequency of 1s or 0s in the $\binom{n}{2}$-length standard encoding $E(G)$ of G. However, to determine the frequencies of labeled subgraphs on k nodes (up to isomorphism) for $k > 2$ is a matter more complicated than the frequencies of substrings of length k. Clearly, there are $\binom{n}{k}$ subsets of k nodes out of n and hence that many occurrences of subgraphs. Such subgraphs may overlap in more complex ways than substrings of a string. Let $\#H(G)$ be *the number of times H occurs* as an ordered labeled subgraph of G (possibly overlapping). Let p be the probability that we obtain H by flipping a fair coin to decide for each pair of nodes whether it is connected by an edge or not:

$$p = 2^{-k(k-1)/2}. \tag{2.2}$$

THEOREM 1. *Assume the terminology above with $G = (V, E)$ a labeled graph on n nodes, k is a positive integer dividing n, and H is a labeled graph on $k \le \sqrt{2 \log n}$ nodes. Let $C(E(G)|n) \ge \binom{n}{2} - \delta(n)$. Then*

$$\left| \#H(G) - \binom{n}{k} p \right| \le \binom{n}{k} \sqrt{\alpha(k/n)p}$$

with $\alpha := (K(H|n) + \delta(n) + \log \binom{n}{k}/(n/k) + O(1))3/\log e$.

Proof. A *cover* of G is a set $C = \{S_1, \ldots, S_N\}$ with $N = n/k$, where the S_i's are pairwise disjoint subsets of V and $\bigcup_{i=1}^{N} S_i = V$. According to [3], we have the following claim.

Claim 1. There is a partition of the $\binom{n}{k}$ different k-node subsets into $h = \binom{n}{k}/N$ distinct covers of G, each cover consisting of $N = n/k$ disjoint subsets. That is, each subset of k nodes of V belongs to precisely one cover.

Enumerate the covers as $C_0, C_2, \ldots, C_{h-1}$. For each $i \in \{0, 1, \ldots, h-1\}$ and k-node labeled graph H, let $\#H(G, i)$ be the number of (now nonoverlapping) occurrences of subgraph H in G occurring in cover C_i.

Now consider an experiment of N trials, each trial with the same set of $2^{k(k-1)/2}$ outcomes. Intuitively, each trial corresponds to an element of a cover, and each outcome corresponds to a k-node subgraph. For every i we can form a string s_i consisting of the N blocks of $\binom{k}{2}$ bits that represent presence or absence of edges within the induced subgraphs of each of the N subsets of C_i. Since G can be reconstructed from n, i, s_i, and the remaining $\binom{n}{2} - N\binom{k}{2}$ bits of $E(G)$, we find that $C(s_i|n) \ge l(s_i) - \delta(n) - \log h$. Again, according to Lemma 3 this implies that the frequency of occurrence of the aligned $\binom{k}{2}$-block $E(H)$, which is $\#H(G, i)$, equals

$$Np \pm \sqrt{Np\alpha}$$

with α as in the statement of Theorem 1. One can do this for each i independently, notwithstanding the dependence between the frequencies of subgraphs in different covers. Namely, the argument depends on the incompressibility of G alone. If the number of occurrences of a certain subgraph in *any* of the covers is too large or too small then we can compress G. Now,

$$\begin{aligned}\left|\#H(G) - p\binom{n}{k}\right| &= \sum_{i=0}^{h-1} |\#H(G,i) - Np| \\ &\leq \binom{n}{k}\sqrt{\alpha(k/n)p}. \qquad \square\end{aligned}$$

In [9, 11] we investigated up to which length l all blocks of length l occurred at least once in each $\delta(n)$-random string of length n.

Theorem 2. *Let $\delta(n) < 2^{\sqrt{\frac{1}{2}\log n}}/4\log n$ and G be a $\delta(n)$-random graph on n nodes. Then for sufficiently large n, the graph G contains all subgraphs on $\sqrt{2\log n}$ nodes.*

Proof. We are sure that H on k nodes occurs at least once in G if $\binom{n}{k}\sqrt{\alpha(k/n)p}$ in Theorem 1 is less than $\binom{n}{k}p$. This is the case if $\alpha < (n/k)p$. This inequality is satisfied for an overestimate of $K(H|n)$ by $\binom{k}{2}+2\log\binom{k}{2}+O(1)$ (since $K(H|n) \leq K(H)+O(1)$), and $p = 2^{-k(k-1)/2}$, with k set at $k = \sqrt{2\log n}$. This proves the theorem. $\square$

2.3. Unlabeled graph counting. An unlabeled graph is a graph with no labels. For convenience we can define this as follows: Call two labeled graphs *equivalent* (up to relabeling) if there is a relabeling that makes them equal. An *unlabeled graph* is an equivalence class of labeled graphs. An *automorphism* of $G = (V, E)$ is a permutation π of V such that $(\pi(u), \pi(v)) \in E$ iff $(u, v) \in E$. Clearly, the set of automorphisms of a graph forms a group with group operation of function composition and the identity permutation as unity. It is easy to verify that π is an automorphism of G iff $\pi(G)$ and G have the *same binary string standard encoding*, that is, $E(G) = E(\pi(G))$. This contrasts with the more general case of permutation relabeling, where the standard encodings may be different. A graph is *rigid* if its only automorphism is the identity automorphism. It turns out that Kolmogorov random graphs are rigid graphs. To obtain an expression for the number of unlabeled graphs we have to estimate the number of automorphisms of a graph in terms of its randomness deficiency.

In [12] an asymptotic expression for the number of unlabeled graphs is derived using sophisticated methods. We give a new elementary proof by incompressibility. Denote by g_n the number of unlabeled graphs on n nodes—that is, the number of isomorphism classes in the set $\mathcal{G}_n$ of undirected graphs on nodes $\{0, 1, \ldots, n-1\}$.

Theorem 3. $g_n \sim \frac{2^{\binom{n}{2}}}{n!}$.

Proof. Clearly,

$$g_n = \sum_{G \in \mathcal{G}_n} \frac{1}{d(\bar{G})},$$

where $\bar{G}$ is the isomorphism class of graph G. By elementary group theory,

$$d(\bar{G}) = \frac{d(S_n)}{d(Aut(G))} = \frac{n!}{d(Aut(G))},$$

where S_n is the group of permutations on n elements and $Aut(G)$ is the automorphism group of G. Let us partition $\mathcal{G}_n$ into $\mathcal{G}_n = \mathcal{G}_n^0 \cup \cdots \cup \mathcal{G}_n^n$, where $\mathcal{G}_n^m$ is the set of graphs for which m is the number of nodes moved (mapped to another node) by any of its automorphisms.

Claim 2. *For $G \in \mathcal{G}_n^m$, $d(Aut(G)) \leq n^m = 2^{m \log n}$.*

Proof. $d(Aut(G)) \leq \binom{n}{m} m! \leq n^m$. □

Consider each graph $G \in \mathcal{G}_n$ having a probability $\text{Prob}(G) = 2^{-\binom{n}{2}}$.

Claim 3. $\text{Prob}(G \in \mathcal{G}_n^m) \leq 2^{-m(\frac{n}{2} - \frac{3m}{8} - \log n)}$.

Proof. By Lemma 2 it suffices to show that if $G \in \mathcal{G}_n^m$ and

$$C(E(G)|n, m) \geq \binom{n}{2} - \delta(n, m)$$

then $\delta(n, m)$ satisfies

$$\delta(n, m) \geq m \left(\frac{n}{2} - \frac{3m}{8} - \log n \right). \tag{2.3}$$

Let $\pi \in Aut(G)$ move m nodes. Suppose π is the product of k disjoint cycles of sizes $c_1, \ldots, c_k$. Spend at most $m \log n$ bits describing π: For example, if the nodes $i_1 < \cdots < i_m$ are moved then list the sequence $\pi(i_1), \ldots, \pi(i_m)$. Writing the nodes of the latter sequence in increasing order we obtain $i_1, \ldots, i_m$ again; that is, we execute permutation π^{-1} and hence we obtain π.

Select one node from each cycle—say, the lowest numbered one. Then for every unselected node on a cycle, we can delete the $n-m$ bits corresponding to the presence or absence of edges to stable nodes, and $m-k$ half-bits corresponding to presence or absence of edges to the other, unselected cycle nodes. In total we delete

$$\sum_{i=1}^{k} (c_i - 1) \left(n - m + \frac{m-k}{2} \right) = (m-k) \left(n - \frac{m+k}{2} \right)$$

bits. Observing that $k = m/2$ is the largest possible value for k, we arrive at the claimed $\delta(n, m)$ of G (difference between savings and spendings is $\frac{m}{2}(n - \frac{3m}{4}) - m \log n$) of (2.3). □

We continue the proof of Theorem 3:

$$g_n = \sum_{G \in \mathcal{G}_n} \frac{1}{d(\bar{G})} = \sum_{G \in \mathcal{G}_n} \frac{d(Aut(g))}{n!} = \frac{2^{\binom{n}{2}}}{n!} E_n,$$

where $E_n := \sum_{G \in \mathcal{G}_n} \text{Prob}(G) d(Aut(G))$ is the expected size of the automorphism group of a graph on n nodes. Clearly, $E_n \geq 1$, yielding the lower bound on g_n. For the upper bound on g_n, noting that $\mathcal{G}_n^1 = \emptyset$ and using the above claims, we find

$$\begin{aligned} E_n &= \sum_{m=0}^{n} \text{Prob}(G \in \mathcal{G}_n^m) Avg_{G \in \mathcal{G}_n^m} d(Aut(G)) \\ &\leq 1 + \sum_{m=2}^{n} 2^{-m(\frac{n}{2} - \frac{3m}{8} - 2 \log n)} \\ &\leq 1 + 2^{-(n - 4 \log n - 2)}, \end{aligned}$$

which proves the theorem. □

The proof of the theorem shows that the error in the asymptotic expression is very small.

COROLLARY 2. $\frac{2^{\binom{n}{2}}}{n!} \leq g_n \leq \frac{2^{\binom{n}{2}}}{n!}(1 + \frac{4n^4}{2^n})$.

The next corollary follows from (2.3) (since $m = 1$ is impossible).

COROLLARY 3. *If a graph G has randomness deficiency slightly less than n (more precisely, $C(E(G)|n) \geq \binom{n}{2} - n - \log n - 2$) then G is rigid.*

The expression for g_n can be used to determine the maximal complexity of an unlabeled graph on n nodes. Namely, we can effectively enumerate all unlabeled graphs as follows:

- Effectively enumerate all labeled graphs on n nodes by enumerating all binary strings of length n and for each labeled graph G do the following:
  If G cannot be obtained by relabeling from any previously enumerated labeled graph then G is added to the set of unlabeled graphs.

This way we obtain each unlabeled graph by precisely one labeled graph representing it. Since we can describe each unlabeled graph by its index in this enumeration, we find by Theorem 3 and Stirling's formula that if G is an unlabeled graph then

$$C(E(G)|n) \leq \binom{n}{2} - n \log n + O(n).$$

THEOREM 4. *Let G be a labeled graph on n nodes and let G_0 be the unlabeled version of G. There exists a graph G' and a label permutation π such that $G' = \pi(G)$ and up to additional constant terms $C(E(G')) = C(E(G_0))$ and $C(E(G)|n) = C(E(G_0), \pi|n)$.*

By Theorem 4, for *every* graph G on n nodes with maximum complexity there is a relabeling (permutation) that causes the complexity to drop by as much as $n \log n$. Our proofs of topological properties by the incompressibility method required the graph G to be Kolmogorov random in the sense of $C(E(G)|n) \geq \binom{n}{2} - O(\log n)$ or for some results $C(E(G)|n) \geq \binom{n}{2} - o(n)$. Hence by relabeling such a graph we can always obtain a labeled graph that has a complexity too low to use our incompressibility proof. Nonetheless, topological properties do not change under relabeling.

SELF-STABILIZING ALGORITHMS FOR FINDING CENTERS AND MEDIANS OF TREES[*]

STEVEN C. BRUELL[†], SUKUMAR GHOSH[†], MEHMET HAKAN KARAATA[‡], AND SRIRAM V. PEMMARAJU[§]

Abstract. Locating a center or a median in a graph is a fundamental graph-theoretic problem. Centers and medians are especially important in distributed systems because they are ideal locations for placing resources that need to be shared among different processes in a network. This paper presents simple self-stabilizing algorithms for locating centers and medians of trees. Since these algorithms are self-stabilizing, they can tolerate transient failures. In addition, they can automatically adjust to a dynamically changing tree topology. After the algorithms are presented, their correctness is proven and upper bounds on their time complexity are established. Finally, extensions of our algorithms to trees with arbitrary, positive edge costs are sketched.

1. Introduction.

Let $G = (V, E)$ be a simple, connected graph with vertex set V and edge set E. The *eccentricity* of a vertex $i \in V$ is the largest distance from i to any vertex in V. A vertex with minimum eccentricity is called a *center* of G. The *weight* of a vertex $i \in V$ is the sum of the distances from i to all vertices in V. A vertex with minimum weight is called a *median* of G.

Locating centers and medians of graphs has a wide variety of important applications because placing a common resource at a center or a median of a graph minimizes the costs of sharing the resource with other locations. This is especially important in distributed systems in which information is disseminated from or gathered at a single node (or a small number of nodes). As a result, distributed algorithms for locating centers and medians of graphs are extremely useful. There are several known algorithms [10, 11, 15, 18, 24, 25, 29, 31] for finding centers and medians of graphs, including distributed algorithms by Korach, Rotem, and Santoro [27]. In this paper, we propose two simple, self-stabilizing, distributed algorithms for finding centers and medians of trees. We then prove the correctness of these algorithms and establish upper bounds on their time complexity. We finally show that the algorithms can be slightly modified to locate centers and medians in trees with arbitrary positive edge costs.

Self-stabilization in distributed systems was first introduced by Dijkstra [8] in 1974. Since then the power and simplicity of self-stabilizing algorithms has been amply demonstrated. For example, self-stabilizing mutual exclusion algorithms for various classes of networks have been presented in [5, 8, 19, 22, 28]; self-stabilizing algorithms

for electing a leader appear in [9, 21, 30]; self-stabilizing algorithms for constructing spanning trees have been presented in [1, 6, 7]; self-stabilizing algorithms for problems related to maximum flow and maximum matching appear in [13, 16, 20]; self-stabilizing algorithms for coloring graphs appear in [14, 34]; general techniques for constructing self-stabilizing algorithms are presented in [2, 26]. Not only are self-stabilizing algorithms tolerant to transient failures, but many of them are also capable of handling the addition and deletion of vertices or edges in a transparent manner. These attractive properties give self-stabilizing algorithms a distinct advantage over the more classical distributed algorithms.

By using the general techniques of Katz and Perry [26] and Awerbuch and Varghese [2], it is possible to construct self-stabilizing center-finding or median-finding algorithms. However, the general technique proposed by Katz and Perry [26] requires global state collection at a leader followed by distributed reset (if necessary) and this makes their method unacceptably inefficient. Therefore, we view Katz and Perry more as a demonstration of the feasibility of self-stabilization than as a practical alternative. A similar claim can be made about the compiler of Awerbuch and Varghese [2] that takes any deterministic, synchronous, distributed protocol in a message passing system and produces an equivalent asynchronous, self-stabilizing, distributed protocol. The technique of Awerbuch and Varghese for constructing self-stabilizing protocols is powerful and general. However, it is because of the generality of their technique that often, hand-crafted protocols for a particular problem are simpler and more efficient than the self-stabilizing protocols generated by their compiler. This is certainly true for the center- and median-finding problems for which our solutions are not only extremely simple, but also time and space optimal.

The balance of this paper is organized as follows. In section 2 we discuss the notion of self-stabilization in distributed systems. In section 3 we present two self-stabilizing algorithms—one for finding centers of trees and the other for finding medians of trees. Section 4 contains proofs that establish the partial correctness of the proposed algorithms. In section 5 we present proofs to show that the proposed algorithms terminate. In section 6 we establish upper bounds on the time complexity of the algorithms. Section 7 extends our algorithms so as to locate centers and medians in trees that have arbitrary, positive edge costs. Section 8 contains concluding remarks and a glimpse of possible future work.

2. Self-stabilization in distributed systems.

Following Schneider [32], we view a distributed system S as consisting of two types of components: *processes* and *interconnections* between processes representing communication through local shared memory or through message channels. Each component in the system has a *local state* and the *global state* of the system is simply the union of the local states of all components. Let P be a predicate defined over the set of global states of the system. An algorithm A running on S is said to be *self-stabilizing* with respect to P if it satisfies the following:

Closure: If a global state q satisfies P, then any global state that is reachable from q using algorithm A, also satisfies P.

Convergence: Starting from an arbitrary global state, the distributed system S is guaranteed to reach a global state satisfying P in a finite number of steps of A.

Global states satisfying P are said to be *stable*. To show that an algorithm is self-stabilizing with respect to P we need to show both closure and convergence. In addition, to show that an algorithm solves a certain problem, we need to show *partial*

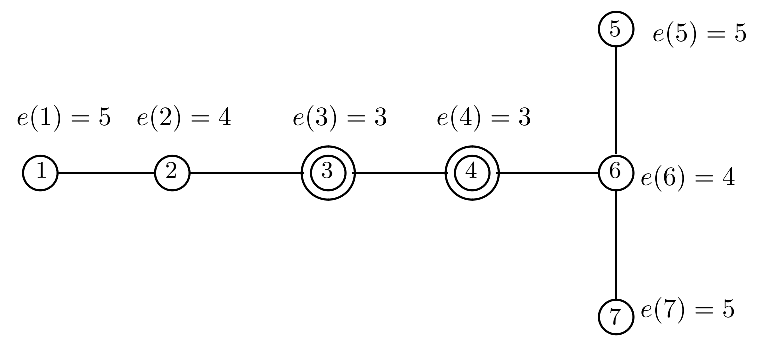

FIG. 1. *Eccentricities of vertices in a tree. The two centers in the tree are marked by double circles.*

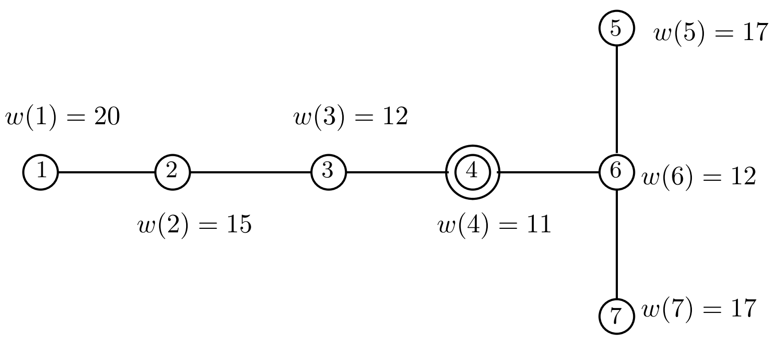

FIG. 2. *Weights of vertices in a tree. The unique median in the tree is marked by a double circle.*

correctness, that is, every stable state of S constitutes a solution to the problem.

3. Center and median-finding algorithms.

3.1. Notation. We begin this section with some notation and terminology.

- $d(i, j)$ denotes the *distance*, the length of a shortest path in G, between vertices i and j.
- $e(i) = \max\{d(i, j) \mid j \in V\}$ denotes the *eccentricity* of a vertex i, the distance between i and a farthest vertex from i in G.
- $\mathit{center}(G) = \{i \in V \mid e(i) \leq e(j) \text{ for all } j \in V\}$ denotes the set of *centers* of G, the set of vertices in V with minimum eccentricity.
- $w(i) = \sum_{j \in V} d(i, j)$ denotes the *weight* of a vertex i, the sum of the distances between i and all vertices in V.
- $\mathit{median}(G) = \{i \in V \mid w(i) \leq w(j) \text{ for all } j \in V\}$ denotes the set of *medians* of G, the set of vertices in V with minimum weight.

Figure 1 shows a tree along with the eccentricity of each vertex. Vertices 3 and 4 have the minimum eccentricity, and are therefore centers of the tree. Figure 2 shows the same tree along with the weight of each vertex. Vertex 4 has the minimum weight, and is therefore the unique median.

For the remainder of the paper we restrict our attention to trees. We demonstrate that for this class of graphs, simple and elegant self-stabilizing algorithms for locating centers and medians exist. Our algorithms have been used as the basis of other self-stabilizing algorithms on trees [12, 33]. We hope that our algorithms can be extended to solve the corresponding problems for arbitrary graphs. Let $T = (V, E)$ be a tree with vertex set V and edge set E. Without loss of generality we assume that $V = \{1, 2, \ldots, n\}$. The following proposition states well-known properties of centers and medians of trees [3, 4, 17].

PROPOSITION 3.1. *A tree has a single center (median) or two adjacent centers (medians).*

3.2. The model of computation. Before presenting our self-stabilizing algorithms, we briefly describe the underlying model of computation. We assume that each vertex in T is a process. Each process i maintains a single local variable whose value can be read by the neighboring processes, but can be written into only by i. The program executed by each process is expressed in the language of guarded commands. We assume that each process repeatedly evaluates its guards and checks if any guard is true. If so, the process executes the corresponding action in a *single atomic step*. Such an atomic step by a process is called a *move*. A guard that evaluates to true in a certain global state is said to be *enabled* in that global state. In this model of computation, the execution of our algorithms can be viewed as a sequence of moves, in which moves by different processes are interleaved. In particular, an *execution sequence* of an algorithm A running on a distributed system S is a sequence: $q_0, m_1, q_1, m_2, q_2, \ldots$ such that

(i) q_i, for each $i \geq 0$, is a global state of the system S,
(ii) m_i, for each $i \geq 1$, is a move by some process executing algorithm A,
(iii) move m_i is a move whose guard is enabled in state q_{i-1}; move m_i takes the system from state q_{i-1} into state q_i,
(iv) the sequence is either infinite or is finite and, if finite, ends in a global state in which no guard is enabled.

Since our algorithms are self-stabilizing, no initialization of the variables is assumed. Furthermore, the underlying network topology is permitted to change under the condition that the topology remain connected and acyclic.

3.3. The algorithms. To facilitate the description of the algorithms, we introduce two functions. Let $h : V \to \mathcal{N}$ be a function from vertex set V to the set of natural numbers $\mathcal{N}$. Similarly, let $s : V \to \mathcal{N} - \{0\}$ be a function from V to the set of positive natural numbers. We will refer to $h(i)$ and $s(i)$ as the h-value and the s-value, respectively, of vertex i. In addition, we will use the following notation:

$N(i) = \{j \mid (i, j) \in E\}$ denotes the set of neighbors of vertex i.

$N_h(i) = \{h(j) \mid (i, j) \in E\}$ denotes the *multiset* of h-values of the neighbors of i.

$N_h^-(i) = N_h(i) - \{\max(N_h(i))\}$ denotes all of $N_h(i)$ with *one* maximum h-value removed. For example, if $N_h(i) = \{2, 3, 3\}$, then $N_h^-(i) = \{2, 3\}$.

$N_s(i) = \{s(j) \mid (i, j) \in E\}$ denotes the *multiset* of s-values of the neighbors of i.

$N_s^-(i) = N_s(i) - \{\max(N_s(i))\}$ denotes all of $N_s(i)$ with *one* maximum s-value removed.

To motivate our algorithms, we first make a few observations. The following condition on the h-value of vertex i is called the *height condition*:

$$h(i) = \begin{cases} 0 & \text{if } i \text{ is a leaf,} \\ 1 + \max(N_h^-(i)) & \text{otherwise.} \end{cases}$$

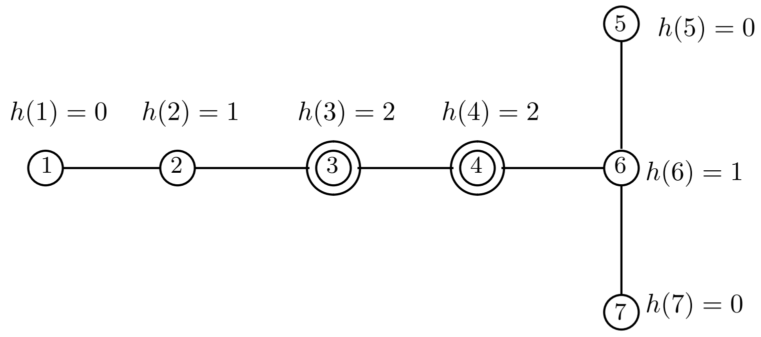

FIG. 3. *h-values of vertices satisfying the height condition in a tree.*

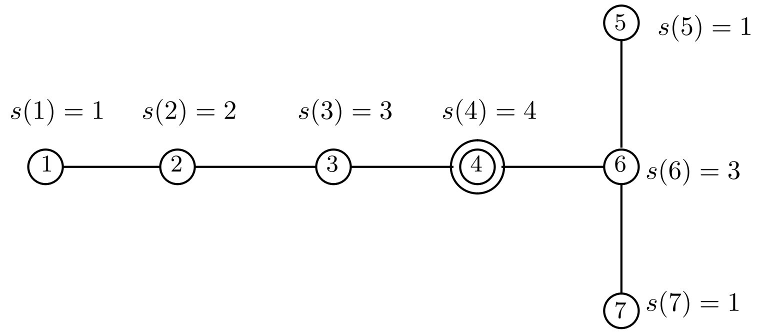

FIG. 4. *s-values of vertices satisfying the size condition in a tree.*

Here we use the notation $\max(N_h^-(i))$ to stand for the maximum value in the multiset $N_h^-(i)$.

The following condition on the s-value of a vertex i is called the *size condition*:

$$s(i) = \begin{cases} 1 & \text{if } i \text{ is a leaf,} \\ 1 + \Sigma(N_s^-(i)) & \text{otherwise.} \end{cases}$$

Here we use the notation $\Sigma(N_s^-(i))$ to represent the sum of all the elements in the multiset $N_s^-(i)$.

We will show that if the h-values (s-values) of all the vertices in T satisfy the height (size) condition, then the centers (medians) of T are the *only* vertices whose h-values (s-values) are greater than or equal to the h-values (s-values) of all neighboring vertices. Figure 3 shows a tree with the h-values of all its vertices satisfying the height condition. The two centers, 3 and 4, are the only vertices whose h-values are greater than or equal to the h-values of all neighbors. Figure 4 shows a tree with the s-values of all its vertices satisfying the size condition. The median, 4, is the only vertex whose s-value is greater than or equal to the s-values of all neighbors. Our center-finding and the median-finding algorithms are shown in Figure 5. It is easy to observe that each of the two statements in the center-finding (median-finding) algorithm is an attempt to ensure that the height (size) condition is satisfied by vertex i.

4. Partial correctness. The stable states of the center-finding algorithm are defined as those that satisfy the height condition. Similarly, the stable states of the

```

$\Box\ (i \text{ is not a leaf}) \wedge (s(i) \neq 1 + \Sigma(N_s^-(i)))$   $\longrightarrow$   $s(i) := 1 + \Sigma(N_s^-(i))]$
```

FIG. 5. *The center-finding and the median-finding algorithms.*

median-finding algorithm are those that satisfy the size condition. We prove the partial correctness of the center-finding and median-finding algorithms by showing that the stable states of these algorithms indeed constitute a solution to the center-finding and median-finding problem, respectively.

To prove the partial correctness of the proposed algorithms, we introduce the notion of an ordering function. A function $f : V \to \mathcal{N}$, that associates natural numbers to all vertices in T, is an *ordering function* if for all $i \in V$, there exists at most one neighbor j of i such that $f(i) \leq f(j)$. We shall refer to $f(i)$ as the f-value of vertex i. The following is easily verified (see Figures 3 and 4 for examples).

PROPOSITION 4.1. *If the h-values (s-values) of all the vertices in T satisfy the height condition (size condition), then h (s) is an ordering function.*

Given an ordering function $f : V \to \mathcal{N}$, define a directed graph (digraph) $G(f) = (N(f), A(f))$ whose node[1] set is $N(f) = V$ and whose arc set $A(f)$ is defined as

$$A(f) = \{(i,j) \mid j \in N(i) \text{ and } (f(j), j) \text{ is lexicographically the largest}\}.$$

Thus, from each node $i \in N(f)$ there is an outgoing arc to a neighbor with largest f-value. If there are several neighbors with largest f-value, then the tie is broken by choosing a neighbor with the largest f-value *and* the largest label.

The following lemma states an important property of the digraph $G(f)$.

LEMMA 4.2. *The underlying undirected graph of the digraph $G(f)$ is connected. $G(f)$ contains exactly one cycle and this cycle is of length two.*

Proof. Since T is connected, by definition of the arc set $A(f)$, for all $i \in N(f)$, there exists exactly one neighbor of i, say j, such that $(i,j) \in A(f)$. By definition of an ordering function, for any other neighbor of i, say k, $k \neq j$, we have $f(k) < f(i)$. Since $f(k) < f(i)$, from the definition of an ordering function, we conclude that for all neighbors k' of k, where $k' \neq i$, $f(k') < f(k)$. Therefore $(k,i) \in A(f)$. This implies that for every edge in T there is at least one corresponding arc in $G(f)$ and hence $G(f)$ is connected. Furthermore, every node in $G(f)$ has exactly one outgoing arc implying that $G(f)$ has $|N(f)|$ arcs. Since $G(f)$ is a connected graph with $|N(f)|$ arcs, it contains exactly one cycle. Suppose that $(i_1, i_2, \ldots, i_l)$ for $l \geq 3$ is a cycle in $G(f)$. We know that if (i,j) is an arc in $A(f)$, then (i,j) is an edge in E. This implies that $(i_1, i_2, \ldots, i_l)$ is a cycle in T also. But, T is acyclic. Hence, the single cycle that $G(f)$ contains has to be a 2-cycle (a cycle of length two). $\Box$

Let i and j be the two nodes in $G(f)$ that belong to its unique cycle. Without loss of generality assume that $f(i) \geq f(j)$. On deleting the arcs (i,j) and (j,i) from

[1]We employ the convention of using "vertex" and "edge" for undirected graphs and "node" and "arc" for directed graphs.

$G(f)$ we obtain two connected components, each of which is a directed tree, with arcs directed towards i and j, respectively. Denote the directed tree containing node i by $T_i(f) = (N_i(f), A_i(f))$ and the directed tree containing node j by $T_j(f) = (N_j(f), A_j(f))$. Designate i as the root of $T_i(f)$ and j as the root of $T_j(f)$. Since $T_i(f)$ and $T_j(f)$ are now rooted trees, we can use the standard notion of a parent-child relationship between pairs of adjacent nodes in these trees. The following property of the trees $T_i(f)$ and $T_j(f)$ is easy to verify.

PROPOSITION 4.3. *Each arc in $T_i(f)$ and in $T_j(f)$ is directed from a node to its parent and if k is a nonleaf node in $T_i(f)$ or in $T_j(f)$, then $f(k) > f(\ell)$ for each child ℓ of k.*

We now use Proposition 4.1, Lemma 4.2, and Proposition 4.3 to prove the following theorem that provides a way of identifying the centers in T using the h-values associated with the vertices.

THEOREM 4.4. *Let the h-values of all vertices in T satisfy the height condition. Then*

$$center(T) = \{k \mid h(k) \geq h(\ell) \text{ for all } \ell \in N(k)\}.$$

Proof. Since the h-values satisfy the height condition, by Proposition 4.1, h is an ordering function. Hence by Lemma 4.2, $G(h) = (N(h), A(h))$ is a connected digraph, with a unique cycle that is of length two. Let i and j be the two nodes in the unique cycle in $G(h)$ such that $h(i) \geq h(j)$. Consider the rooted, directed trees $T_i(h) = (N_i(h), A_i(h))$ and $T_j(h) = (N_j(h), A_j(h))$. It is easy to see that for all $k \in N_i(h)$ $(N_j(h))$, $h(k)$ is the height of the subtree of $T_i(h)$ $(T_j(h))$ rooted at k.

The rest of the proof is organized into the following two subcases that are based on the relationship between $h(i)$ and $h(j)$.

Case 1. $h(i) > h(j)$. In this case, it follows from Proposition 4.3 that i is the only vertex in T whose h-value is greater than or equal to the h-values of all of its neighbors. We will now show that $center(T) = \{i\}$. Since h is an ordering function and $(i, j) \in A(h)$ we know that j has the largest h-value among all the neighbors of i. Let ℓ be a child of i in $T_i(h)$ with the largest h-value. Then, $h(j) \geq h(\ell)$. Furthermore, we know that $h(i) > h(j)$ and $h(i) = h(\ell)+1$. This implies that $h(\ell) = h(j)$ and hence $h(i) = h(j) + 1$. Since the height of $T_i(h)$ is equal to the distance between the root i and the farthest node from i in $T_i(h)$, we have that $e(i) = \max\{h(i), h(j)+1\} = h(i)$. Similarly, $e(j) = \max(h(i) + 1, h(j)) = h(i) + 1$. Any node in $N_i(h) - \{i\}$ is at least a distance of $h(j) + 2 = h(i) + 1$ from the farthest node in $T_j(h)$ and any node in $N_j(h) - \{j\}$ is at least a distance of $h(i) + 2$ from the farthest node in $T_i(h)$. This implies that i is the vertex in T with the smallest eccentricity. Hence, $center(T) = \{i\}$ and the claim in the theorem is true for the case when $h(i) > h(j)$.

Case 2. $h(i) = h(j)$. In this case, Proposition 4.3 implies that i and j are the only two vertices in T whose h-values are greater than or equal to the h-values of all of their neighbors. We will now show that $center(T) = \{i, j\}$. Furthermore, it is easy to see that $e(i) = e(j) = h(i) + 1 = h(j) + 1$. As in Case 1, any node in $N_i(h) - \{i\}$ is at least a distance of $h(j)+2$ from the farthest node in $T_j(h)$ and any node in $N_j(h)-\{j\}$ is at least a distance of $h(i) + 2$ from the farthest node in $T_i(h)$. Hence, i and j are the two vertices in T with minimum eccentricity. Therefore, $center(T) = \{i, j\}$. The claim in the theorem is true even in the case when $h(i) = h(j)$. ∎

Theorem 4.4 implies that if all h-values satisfy the height-condition, then each process can determine if it is a center of T, by simply checking if its h-value is greater than or equal to the h-values of all its neighbors. Thus a stable state of the system running our center-finding algorithm constitutes a solution to the center-finding problem.

The following theorem is similar to Theorem 4.4 and provides a way of identifying the medians in T using the s-values of the vertices in T. We omit the proof since it is similar to the proof of Theorem 4.4.

THEOREM 4.5. *Let the s-values of all the vertices in T satisfy the size condition. Then*

$$\mathit{median}(T) = \{k \mid s(k) \geq s(\ell) \text{ for all } \ell \in N(k)\}.$$

Theorem 4.5 implies that if all s-values satisfy the size condition, then each process can determine if it is a median of T or not, by simply checking if its s-value is greater than or equal to the s-values of all its neighbors.

5. Convergence.

Our algorithms trivially satisfy the closure property. This is because in a stable state all guards are false and no moves are possible. This implies that once the system reaches a stable state, it remains in a stable state. So we turn our attention to convergence.

To establish convergence of an algorithm, we need to show that any execution sequence of the algorithm is finite in length. In this section we show that any execution sequence of the center-finding algorithm is finite in length, thereby showing that the center-finding algorithm satisfies the convergence property. A similar proof (omitted, see [23]) suffices to show that any execution sequence of the median-finding algorithm is also finite. We call a move by process i a *decreasing move* if it decreases the h-value of process i; otherwise we call the move an *increasing move*. The convergence proof of the center-finding algorithm is organized in two sections. Section 5.1 shows the total number of decreasing moves that all processes can make is at most n^2. Section 5.2 shows that the total number of increasing moves is also finite. The precise upper bound on the number of increasing moves is established in section 6.

5.1. Decreasing moves.

We start with an arbitrary execution sequence by the center-finding algorithm. Let $M(i, p)$ denote a move by process i that is the pth move in this execution sequence. Occasionally, when the identity of the process making a move is irrelevant to our discussion, we will simply use $M(\_, p)$ to denote the move. In what follows, we show that the processes in T can make at most n^2 decreasing moves during the execution of the center-finding algorithm. Our proof is presented in two sections. In section 5.1.1 we define the notion of the cause of a decreasing move and prove two properties related to the cause of a decreasing move. Section 5.1.2 extends the notion of the cause of a decreasing move to define the source of a decreasing move and then shows that distinct decreasing moves by a process have distinct sources. We then show an upper bound on n on the number of distinct sources and this leads to the upper bound of n on the number of decreasing moves each process can make. The upper bound of n^2 on the total number of decreasing moves by all processes follows.

5.1.1. The cause of a decreasing move.

Let $h(i, p)$ denote the value of the variable $h(i)$ after move $M(\_, p)$ and before move $M(\_, p + 1)$. Accordingly, we use $N_h^-(i, p)$ to denote the multi-set $N_h^-(i)$ after move $M(\_, p)$ and before move $M(\_, p+1)$.

Consider a decreasing move $M(i, p)$ by process i. Let us suppose that $M(i, p)$ is not the initial (first) move by process i. Intuitively, our goal is to identify a unique neighbor of process i, say j, and a unique decreasing move, say $M(j, q)$, by process j to be the "cause" of move $M(i, p)$. Since $M(i, p)$ is not the initial move by process i, we can identify a $p' < p$ such that $M(i,p')$ is the move made by process i just before move $M(i,p)$. Note that $M(i,p')$ may or may not be a decreasing move. Focusing on the situation just after move $M(i,p')$, we notice that since process i has just made a move,

$$h(i,p') = \max(N_h^-(i,p')) + 1. \tag{5.1}$$

Since move $M(i,p)$ is decreasing, we have that

$$h(i,p-1) > \max(N_h^-(i,p-1)) + 1. \tag{5.2}$$

Since $M(i,p')$ and $M(i,p)$ are consecutive moves by process i, the value of the variable $h(i)$ does not change after move $M(i,p')$ and before move $M(i,p)$. Hence, $h(i,p') = h(i,p-1)$. This fact, along with (1) and (2), implies that

$$\max(N_h^-(i,p-1)) < \max(N_h^-(i,p')). \tag{5.3}$$

It is then easy to see that there exists a neighbor j, of i, such that

$$h(j,p-1) \le \max(N_h^-(i,p-1)) \tag{5.4}$$

and j makes at least one decreasing move between moves $M(i,p')$ and $M(i,p)$. Furthermore, j itself may have made several decreasing moves between $M(i,p')$ and $M(i,p)$. Let $M(j,q)$ be the *last* decreasing move by process j such that $p' < q < p$. Define *cause*$(M(i,p)) = M(j,q)$. Note that so far *cause*() has been defined only for those decreasing moves that are not initial moves. We extend the definition to include decreasing moves that are initial, by setting *cause*$(M(i,p)) = M(i,p)$ if $M(i,p)$ is decreasing and is the initial move by process i. Hence, the cause of a decreasing move by a process is always a decreasing move made by that process or made by a neighbor.

We now state and prove two useful properties related to the function *cause*(). The first property is that distinct decreasing moves by a process have distinct causes.

LEMMA 5.1. *Suppose that $M(i,p')$ and $M(i,p)$ are distinct decreasing moves by a process i. Then cause$(M(i,p')) \neq$ cause$(M(i,p))$.*

Proof. Without loss of generality assume that $p' < p$. Then *cause*$(M(i,p')) = M(\_,a')$ for some $a' \le p'$ and *cause*$(M(i,p)) = M(\_,a)$ for some a, $p' < a < p$. Thus $a' < a$ and the lemma follows. ☐

The next property that we establish is that the cause relationship is "acyclic."

LEMMA 5.2. *Let $M(i,p)$ be a decreasing move by process i. If $M(i,p)$ is not the initial move by process i, then the move cause(cause$(M(i,p))$) is not made by process i.*

Proof. Suppose that $M(i,p)$ is not the initial move of process i. Then there is a neighbor of i, say j, such that *cause*$(M(i,p)) = M(j,q)$. If $M(j,q)$ is the initial move by process j, then *cause*$(M(j,q)) = M(j,q)$ and the lemma holds. So we assume that $M(j,q)$ is not the initial move by process j. We combine inequalities (2) and (4) to obtain

$$h(j,p-1) \le \max(N_h^-(i,p-1)) < h(i,p-1) - 1. \tag{5.5}$$

After the decreasing move $M(i,p)$ we have $h(j,p) \le \max(N_h^-(i,p)) = h(i,p) - 1$, implying that $h(j,p) < h(i,p)$. By the same token, if *cause*$(M(j,q)) = M(i,r)$ for some $r < q$, then we should have

$$h(i,q) < h(j,q). \tag{5.6}$$

But, we know that $h(j,q) \leq h(j,p-1)$ because $M(j,q)$ is the last decreasing move by process j before move $M(i,p)$. In addition, it follows from (5) that $h(j,p-1) < h(i,p-1)$. We also know that $h(i,p-1) = h(i,q)$ because the h-value of process i remains unchanged between moves $M(j,q)$ and $M(i,p)$. Thus we have

$$h(j,q) \leq h(j,p-1) < h(i,p-1) = h(i,q),$$

which contradicts inequality (6). Hence, *cause*$(M(j,q))$ cannot be a move by process i. $\square$

5.1.2. The source of a decreasing move. Based on the definition of the cause of a decreasing move, we define the notion of the source of a decreasing move.

For each decreasing move $M(i,p)$ define *source*$(M(i,p))$ as follows:

$$\mathit{source}(M(i,p)) = \begin{cases} M(i,p) & \text{if } M(i,p) \text{ is decreasing and is} \\ & \text{the first move of process } i, \\ \mathit{source}(\mathit{cause}(M(i,p))) & \text{if } M(i,p) \text{ is decreasing, but is} \\ & \text{not the first move by process } i. \end{cases}$$

Intuitively, *source*$(M(i,p))$ can be thought of as the initial move that is decreasing and causes $M(i,p)$ through a chain of decreasing moves.

Now suppose that

$$M(i_0,p_0), M(i_1,p_1), \ldots, M(i_a,p_a)$$

is a sequence of decreasing moves where

(a) $M(i_0,p_0) = M(i,p)$,

(b) $M(i_a,p_a) = \mathit{source}(M(i,p))$, and

(c) for all b, $0 \leq b \leq a-1$, we have that $M(i_{b+1},p_{b+1}) = \mathit{cause}(M(i_b,p_b))$, and $M(i_{b+1},p_{b+1}) \neq M(i_b,p_b)$.

Using Lemma 5.2 and the fact that our algorithm is running on an acyclic network, we conclude that the sequence $i_0, i_1, \ldots, i_a$ is a path. Thus, we can associate with each decreasing move $M(i,p)$ a path $i_0, i_1, \ldots, i_a$, called the *path to the source* of move $M(i,p)$. By inductively applying Lemma 5.1 to paths to the sources of moves $M(i,p)$ and $M(i,p')$, we easily obtain the following lemma (see [23] for a proof).

LEMMA 5.3. *Suppose that $M(i,p')$ and $M(i,p)$ are distinct decreasing moves by process i. Then source$(M(i,p')) \neq$ source$(M(i,p))$.*

Since the source of a decreasing move is the first move by some process, Lemma 5.3 has the following immediate consequence.

COROLLARY 5.4. *Each process in T can make at most n decreasing moves.*

As an immediate consequence we have the following lemma.

LEMMA 5.5 (decreasing moves lemma). *The processes in T can make a total of at most n^2 decreasing moves.*

5.2. Increasing moves. In this section we show that the number of increasing moves by the center-finding algorithm is finite. Consider an arbitrary execution sequence of the center-finding algorithm. Since the algorithm can make at most n^2 decreasing moves, there exists a finite prefix of the execution sequence that contains all the decreasing moves made by the algorithm. Let the length of the smallest such prefix be t. Hence the execution sequence $X = M(\_,t+1), M(\_,t+2), M(\_,t+3), \ldots$ contains only increasing moves. Our goal is to show that X is a finite sequence.

LEMMA 5.6 (increasing moves lemma). *X is a finite sequence.*

Proof (by contradiction). To obtain a contradiction, suppose that X is infinite. Clearly, there exists at least one process, say j_0, such that infinitely many moves in X are made by j_0. Recall that a leafprocess can make at most one move (and that move is decreasing) and hence j_0 is not a leaf-process and has at least two neighbors. Clearly, j_0 has at least one nonleaf neighbor, say j_1, that makes infinitely many moves in X. We will now show that j_0 has at least two neighbors that make infinitely many moves in X. Again we show this by contradiction.

Suppose that j_1 is the only neighbor of j_0 that makes infinitely many moves in X. Then there exists $t' > t$ such that no neighbor of j_0, except j_1, makes moves in the execution sequence

$$X' = M(\_, t'), M(\_, t'+1), M(\_, t'+2), \ldots .$$

Note that j_0 and j_1 make infinitely many moves in X'. Clearly, after finitely many moves in X', $h(j_1)$ will be strictly greater than the h-value of any other neighbor of j_0. This means that after finitely many moves in X', $N_h^-(j_0)$ will no longer contain $h(j_1)$ and will therefore subsequently remain unchanged. But if $N_h^-(j_0)$ remains unchanged, j_0 has no reason to make any more moves. The implication is that j_0 makes only finitely many moves in X' and as a result j_0 makes finitely many moves in X. This contradicts our original supposition that j_0 makes infinitely many moves in X.

Thus j_0 has at least two nonleaf neighbors that make infinitely many moves in X. The same is true of j_1 and hence we claim that j_1 has a nonleaf neighbor j_2, distinct from j_0, that makes infinitely many moves in X. This argument can be carried on further to claim the existence of an infinite sequence of distinct nonleaf processes that make infinitely many moves in X. But this is a contradiction because T has a finite number of processes. Hence, our original assumption that X is an infinite execution sequence is false. $\square$

The increasing moves lemma along with the decreasing moves lemma (Lemma 5.5) leads to the following theorem.

THEOREM 5.7. *Any execution sequence of the center-finding algorithm is finite.*

This establishes the total correctness of the center-finding algorithm.

6. Time complexity.

In this section we establish upper bounds on the time complexity of the center-finding and median-finding algorithms. In section 6.1 we show that the center-finding algorithm makes $O(n^3 + n^2 \cdot c_h)$ moves in the worst case, where c_h is the maximum initial h-value of any process. A similar proof shows that the median-finding algorithm makes $O(n^3 \cdot c_s)$ moves in the worst case, where c_s is the maximum initial s-value of any process. This proof is omitted (see [23] for the proof). By worst case, we mean a case in which an adversary is allowed not only to maliciously select an initial global state, but is also allowed to choose an execution sequence out of many possible execution sequences. In [12] we show that, when measured in rounds, the time complexity of our center-finding algorithms is $\Theta(r)$, where r is the radius of the tree (eccentricity of the centers). A similar proof suffices to show that when measured in rounds, the time complexity of our median-finding algorithm is $\Theta(d)$ where d is the maximum distance from a median to a leaf.

6.1. Complexity of the center-finding algorithm.

To be specific, define the global state of the distributed system running the center-finding algorithm to be the n-dimensional vector of natural numbers

$$\Big(h(1), h(2), \ldots, h(n)\Big).$$

Let $\mathbf{q}$ be an arbitrary state of the system. We denote the h-value of process i in state $\mathbf{q}$ by $h(i, \mathbf{q})$. Accordingly, we use $N_h^-(i, \mathbf{q})$ to denote the multiset $N_h^-(i)$ in state $\mathbf{q}$. Given two n-dimensional vectors of natural numbers, $\mathbf{q_0}$ and $\mathbf{q}$, we write $\mathbf{q_0} \rightarrow \mathbf{q}$ if there is a move of the center-finding algorithm by some process in T that takes the system from state $\mathbf{q_0}$ to state $\mathbf{q}$. As is usual, we use $\overset{*}{\rightarrow}$ to denote the reflexive, transitive closure of $\rightarrow$. We use $\mathbf{q_0} \overset{p}{\rightarrow} \mathbf{q}$ to denote that there exists a sequence of p moves of the center-finding algorithm that takes the system from state $\mathbf{q_0}$ to state $\mathbf{q}$.

Consider two n-dimensional vectors of natural numbers $\mathbf{q_0} = (h_1, \dots, h_n)$ and $\mathbf{q_0'} = (h_1', \dots, h_n')$. We say that $\mathbf{q_0'}$ *dominates* $\mathbf{q_0}$ (or $\mathbf{q_0}$ is *dominated* by $\mathbf{q_0'}$) if $h_i \leq h_i'$ for all i, $1 \leq i \leq n$. The next three lemmas are used in Theorem 6.5 to establish an upper bound on the number of moves made by the center-finding algorithm in the worst case. The following lemma can be easily shown by induction on the number of moves required to take the system from state $\mathbf{q_0}$ to state $\mathbf{q}$ (see [23] for the proof).

LEMMA 6.1. *Suppose that $\mathbf{q_0}$ and $\mathbf{q_0'}$ are states of the center-finding algorithm such that $\mathbf{q_0}$ is dominated by $\mathbf{q_0'}$. Let $\mathbf{q}$ be a state such that $\mathbf{q_0} \overset{*}{\rightarrow} \mathbf{q}$. Then there exists a state $\mathbf{q}'$, with $\mathbf{q_0'} \overset{*}{\rightarrow} \mathbf{q}'$, that dominates $\mathbf{q}$.*

In any state $\mathbf{q}$ of the system denote the maximum h-value of any process in T, by $h_m(\mathbf{q})$. Let $h_M(\mathbf{q_0})$ be the maximum h-value of any process in any state that is reachable from $\mathbf{q_0}$. In other words,

$$h_M(\mathbf{q_0}) = \max\{h_m(\mathbf{q}) \mid \mathbf{q_0} \overset{*}{\rightarrow} \mathbf{q}\}.$$

We know that $h_M(\mathbf{q_0})$ exists because we have shown that the center-finding algorithm converges to a state in which all guards are false in a finite number of moves. This implies that every execution sequence starting at $\mathbf{q_0}$ is finite in length and hence the number of states reachable from $\mathbf{q_0}$ is also finite. Thus $h_M(\mathbf{q_0})$ is the maximum h-value that any process can achieve when the center-finding algorithm is executed starting in state $\mathbf{q_0}$. The following corollary immediately follows from the above lemma.

COROLLARY 6.2. *Let $\mathbf{q_0}$ and $\mathbf{q_0'}$ be states of the center-finding algorithm such that $\mathbf{q_0}$ is dominated by $\mathbf{q_0'}$. Then $h_M(\mathbf{q_0}) \leq h_M(\mathbf{q_0'})$.*

The following lemma uses Corollary 6.2 to establish an upper bound on the maximum h-value reachable from a state $\mathbf{q_0} = (c_h, c_h, \dots, c_h)$, in terms of the maximum h-value reachable from the state $\mathbf{q_0'} = (0, 0, \dots, 0)$. Since the proof of this lemma is similar to the proof of Lemma 6.1, it is omitted.

LEMMA 6.3. *Suppose that $\mathbf{q_0} = (c_h, c_h, \dots, c_h)$ for some $c_h \in \mathcal{N}$ and $\mathbf{q_0'} = (0, 0, \dots, 0)$. Then $h_M(\mathbf{q_0}) \leq h_M(\mathbf{q_0'}) + c_h$.*

The following lemma establishes a relationship between $h_m(\mathbf{q_0})$ and $h_M(\mathbf{q_0})$.

LEMMA 6.4. *Let $\mathbf{q_0}$ be a state of T. Then, $h_M(\mathbf{q_0}) \leq h_m(\mathbf{q_0}) + \lfloor n/2 \rfloor$.*

Proof. Let $\mathbf{q_0'} = (h_m(\mathbf{q_0}), h_m(\mathbf{q_0}), \dots, h_m(\mathbf{q_0}))$. Since $\mathbf{q_0}$ is dominated by $\mathbf{q_0'}$, by Corollary 6.2, $h_M(\mathbf{q_0}) \leq h_M(\mathbf{q_0'})$. Now let $\mathbf{q_0''} = (0, 0, \dots, 0)$. By Lemma 6.3, $h_M(\mathbf{q_0'}) \leq h_M(\mathbf{q_0''}) + h_m(\mathbf{q_0})$. This leads to the inequality $h_M(\mathbf{q_0}) \leq h_M(\mathbf{q_0''}) + h_m(\mathbf{q_0})$. It is easy to see that an upper bound on $h_M(\mathbf{q_0''})$ is $\lfloor n/2 \rfloor$. □

THEOREM 6.5. *The center-finding algorithm can make at most $O(n^3 + n^2 \cdot h_m(\mathbf{q_0}))$ moves starting from state $\mathbf{q_0}$.*

Proof. Let $\mathbf{q}$ be a state such that $\mathbf{q_0} \overset{*}{\rightarrow} \mathbf{q}$. Let $H(\mathbf{q})$ be the sum of the h-values of all the processes in state $\mathbf{q}$. Thus $H(\mathbf{q}) = \Sigma_{i \in V} h(i, \mathbf{q})$. Clearly, $0 \leq H(\mathbf{q}) \leq n h_M(\mathbf{q_0})$, for all $\mathbf{q}$, with $\mathbf{q_0} \overset{*}{\rightarrow} \mathbf{q}$. If the center-finding algorithm makes no decreasing moves, then an upper bound on the total number of increasing moves is $n h_M(\mathbf{q_0})$. But the algorithm may make up to n^2 decreasing moves and each decreasing move may reduce the value of $H()$ by at most $h_M(\mathbf{q_0})$. Hence, the total amount of reduction that the

$\square$ $(i$ is not a leaf$) \wedge (h(i) \neq \max(NC_h^-(i)))$   $\longrightarrow$   $h(i) := \max(NC_h^-(i))]$
```

FIG. 6. *The center-finding algorithm for a tree with nonunit edge costs.*

decreasing moves can cause is at most $n^2 h_M(\mathbf{q_0})$. Thus an upper bound on the total number of increasing moves is $nh_M(\mathbf{q_0}) + n^2 h_M(\mathbf{q_0})$. Using Lemma 6.4 this bound can be translated into $(h_m(\mathbf{q_0}) + \lfloor n/2 \rfloor)(n + n^2)$. Thus, including decreasing moves, the center-finding algorithm can make at most $O(n^3 + n^2 \cdot h_m(\mathbf{q_0}))$ moves. $\square$

7. Extensions. It is easy to extend the center-finding and median-finding algorithms to trees with arbitrary, positive edge costs. In particular, suppose that $c(i,j) \in \Re^+$ (the set of positive reals) is the cost associated with edge $(i,j) \in E$. Based on this, we can define the *distance* $d(i,j)$ between any pair of vertices $i, j \in V$ as follows. Let P be an arbitrary path between vertices i and j. The distance between i and j *along path* P is the sum of the costs of all the edges in P. The distance $d(i,j)$ is the smallest distance between i and j along any path between i and j. Having defined the distance $d(i,j)$ between any pair of vertices i and j, we can define the notions of eccentricity, weight, centers, and medians as in section 3.1.

We first focus on the task of modifying our original center-finding algorithm to work correctly for trees with possibly nonunit edge costs. Before we present the modified algorithm, we introduce some additional notation.

- $NC_h(i) = \{h(j) + c(i,j) \mid (i,j) \in E\}$ denotes the multiset that contains, for each neighbor j of i, the sum of the h-value of j and the cost of the edge (i,j).
- $NC_h^-(i) = NC_h(i) - \{\max(NC_h(i))\}$ denotes all of $NC_h(i)$ with one maximum element removed.

The modified version of the center-finding algorithm is presented in Figure 6. This algorithm is a generalization of our original center-finding algorithm (shown in Figure 5). This is because if $c(i,j) = 1$ for all edges $(i,j) \in E$, then $\max(NC_h^-(i)) = \max(N_h^-(i)) + 1$. The proof of total correctness of this algorithm is almost identical to the proof of total correctness of our original center-finding algorithm and is therefore omitted.

We now examine the task of generalizing the median-finding algorithm to work correctly for trees with possibly nonunit edge costs. For any edge (i,j) in T, on deleting (i,j) from T we obtain two trees, one containing i and the other containing j. Denote these trees by $T_{i,j}$ and $T_{j,i}$, respectively. Let $N_{i,j}$ and $N_{j,i}$ denote the number of vertices in $T_{i,j}$ and $T_{j,i}$, respectively. Korach, Rotem, and Santoro [27] characterize a median of a tree as follows.

LEMMA 7.1. *A vertex $i \in V$ is a median of T if and only if for all $j \in N(i)$ $N_{i,j} \geq N_{j,i}$.*

It is easy to see that even if edges have associated arbitrary, positive edge costs, the above lemma holds. Therefore, we have the following.

LEMMA 7.2. *The medians of a tree remain unchanged independent of any change in the costs of the edges.*

Thus, our median-finding algorithm, without any modification, works correctly for a tree with arbitrary, positive costs associated with its edges.

8. Conclusion. The proofs of correctness of our algorithms rely on the assumption that when a guard evaluates to true, then the corresponding action is executed in one *atomic step* by the process. However, it is possible to show that our algorithms are correct even when this assumption is relaxed in the following sense. Suppose that each action by a process i is a sequence of atomic reads of i's neighbors' local variables followed by an atomic write into process i's local variable. Now the execution of our algorithms can be viewed as a sequence in which atomic reads and writes by different processes are interleaved. The proofs of correctness of our algorithms under these weaker assumptions are essentially similar, but more tedious than those we have presented here. A sketch of the proof of the correctness of the center-finding algorithm can be found in [12].

Our time complexity analysis (section 6) reveals that the number of moves made by the center-finding algorithm depends not only on n, the number of processes in T, but also on the initial h-values of the processes. This is somewhat unfortunate because we can construct small trees with large initial h-values that could cause the center-finding algorithm to be rather slow. The median-finding algorithm has a similar problem. One possible way to overcome this problem is to assume that each process knows an upper bound on the total number of processes in T. Using this information, processes could refuse to make moves that would make their local variable unreasonably large. We also suspect that the problem could be overcome by the use of randomization.

Buckley and Harary [4] have defined various other types of "central" vertices in a graph. Some examples are *centroids*, *cores*, *pits*, *path-centers*, *p-centers*, and *p-medians*. Part of our future work will focus on extending the techniques presented in this paper for designing self-stabilizing algorithms to locate p-centers and p-medians of trees. Another aspect of this work that we wish to pursue further is applying the techniques presented in this paper to locating centers and medians in arbitrary graphs.

Acknowledgments. We gratefully acknowledge the comments of the referees that have improved the paper in many ways.

AUTOMATIC METHODS FOR HIDING LATENCY IN PARALLEL AND DISTRIBUTED COMPUTATION*

MATTHEW ANDREWS†, TOM LEIGHTON‡, P. TAKIS METAXAS§, AND LISA ZHANG†

Abstract. In this paper we describe methods for mitigating the degradation in performance caused by high latencies in parallel and distributed networks. For example, given any "dataflow" type of algorithm that runs in T steps on an n-node ring with unit link delays, we show how to run the algorithm in $O(T)$ steps on any n-node bounded-degree connected network with *average* link delay $O(1)$. This is a significant improvement over prior approaches to latency hiding, which require slowdowns proportional to the *maximum* link delay. In the case when the network has average link delay d_{ave}, our simulation runs in $O(\sqrt{d_{\text{ave}}}T)$ steps using $n/\sqrt{d_{\text{ave}}}$ processors, thereby preserving efficiency. We also show how to efficiently simulate an $n \times n$ array with unit link delays using slowdown $\tilde{O}(d_{\text{ave}}^{2/3})$ on a two-dimensional array with average link delay d_{ave}. Last, we present results for the case in which large local databases are involved in the computation.

Key words. hiding latency, parallel and distributed computation, linear and two-dimensional arrays, complementary slackness

1. Introduction.

Most papers describing algorithms for parallel or distributed computation assume a model of computation in which all the links have unit delay. Such a model is nice to work with and it is realistic for some parallel machines, but not for most. In reality, there are often substantial delays associated with some or all of the links. These delays can be caused by long wires, links that are realized by paths that go through one or more intermediate switches, wires that are required to go off-chip or off-board, communication overheads, and/or by the method which is used to prepare a packet for entry into the network. Link delays are an even greater concern for distributed machines and networks of workstations (NOWs). This is because some latencies can be very high (due to the fact that some processors can be far apart physically) and also because the variation among latencies can be high (since some processors may be very close or even part of the same tightly coupled parallel machine).

1.1. Traditional approaches.

Since communication latency is an important factor in the performance of a parallel or distributed algorithm, several methods have been devised in an attempt to compensate for latency. The simplest of these methods is to slow down the computation to the point where the latency is accommodated. This approach is most commonly used at the circuit level, where the clock speed

is set to be slow enough so that all of the data has time to reach its destination before the next step begins. This means that the circuit needs to be slowed down to accommodate the highest latency. Such an approach is clearly less than desirable in the context of a NOW with high-latency links.

An alternative approach is to organize the network in a hierarchical fashion so that the latencies are consistent with the hierarchy. For example, the CM-5 [1, 14] is organized into a fat tree and the KSR consists of two levels of nested rings. In both cases, the highest latency links are segregated into the top levels of the network hierarchy. This type of architecture works well for applications in which most of the computation is local since local computation can proceed using the low-level low-latency links. Only rarely, it is hoped, would the high-latency links be needed. Thus, only certain steps of the computation would be slow. Unfortunately, this approach is not suitable for scenarios where the network is unstructured (which is often the case for a NOW) or when the underlying application requires frequent communications through the high-level links.

Redundant computation is another approach that has been used in the past [6, 11, 13] to hide the effects of latency. Here the idea is to avoid latency by recomputing data locally instead of waiting to receive it through a high-latency link.

Probably the most generally applicable method of hiding latency is the approach known as *complementary slackness*. The idea behind this approach is to load each processor with enough work so that it stays productive while waiting for data to be supplied by the network. There are many implementations and incarnations of this method. For example, each processor in the CRAY YMP C-90 keeps busy by operating on a pipeline of 128 64-bit words. Processors on the HEP machine [21] swapped between unrelated threads while waiting for the data. The CM-1 and CM-2 were designed to simulate much larger virtual machines so that a single processor would perform the computation of many virtual processors [4, 22]. The technique also forms a critical component of Valiant's bulk synchronous model of parallel computing [23, 24] and it has been employed in several papers [3, 10, 11, 15, 20].

Unfortunately, in all of the preceding examples, it is incumbent on the programmer to provide the slackness or pipelining needed or to determine what part of the computation must be redundantly duplicated and by which processors to overcome the latencies in the network. Even in the scenario where a large virtual network is being simulated on a small parallel machine, it is incumbent on the programmer to find the parallelism necessary to efficiently implement the algorithm on a (potentially very large) virtual network.

The goal of our research is to devise *automatic* methods for hiding latency. Our approach falls within the broad class of methods based on complementary slackness, but it does not require the programmer to provide slackness, pipelines, or greater parallelism in order to hide the latency. Rather, our methods attempt to find the slackness automatically. By automatically finding the slackness, we hope to allow the programmer to assume that there are uniform delays on each link of the network, thereby easing the task of writing code. Moreover, our methods will enable us to automatically convert a program that was written for a well-structured unit-delay machine into a program that will run with minimal degradation in performance on a network with potentially large and variable latencies, at least for certain classes of networks.

1.2. Model and problem. We consider the problem of simulating a network G with unit-delay links on a network H with arbitrary delays on its links. We refer to G

as the *guest* and H as the *host.* Let $g_1, g_2, \ldots$ be the processors of G and $p_1, p_2, \ldots$ be the processors of H. We shall use *pebbles* to record the computations performed by the guest processors. In particular, pebble (i,t) represents the tth step of computation by processor g_i. In a *simulation* of G, H carries out the same step-by-step computation as G. In other words, H simulates G by computing every pebble created by G in an order that preserves the "dependency" of the pebbles. Our goal is to provide methods that would allow H to simulate G with a minimum amount of *slowdown* when G is used in a general-purpose way. Formally, slowdown is the ratio of T_H to T_G, where T_G is the time taken by G to compute all the pebbles and T_H is the time taken by H to simulate this computation. Two computation models are studied here: the *dataflow model* and the *database model.*

Dataflow model. In the dataflow model, each computation solely depends on the computation of the previous step. Creating a pebble (i,t) involves two time units. The first time unit is for communication, where g_i obtains pebbles of the form $(j,t-1)$ from all its neighbors g_j. The second time unit is for computation, where g_i performs computation based on pebbles $(j,t-1)$ and records the result in pebble (i,t). Take an example of an n-node guest linear array. In $2T$ time steps, G creates $n \times T$ pebbles, where pebble (i,t), for $1 < i < n$ and $1 < t \leq T$, depends on pebbles $(i-1,t-1)$, $(i,t-1)$, and $(i+1,t-1)$. (See Figure 1.) Any host processor p can compute pebble (i,t) as long as p has the information in pebbles $(i-1,t-1)$, $(i,t-1)$, and $(i+1,t-1)$, either by directly computing these pebbles or by receiving them from neighboring processors.

The dataflow model is applicable to many computations such as matrix operations, Fourier transform, sorting, algorithms for computational geometry, etc. A large number of examples can be found in [12].

Database model. In the database model each guest processor g_i has a potentially large local memory that may be accessed and updated by g_i during each step. We refer to the local memory of g_i as the *database*, b_i. Each computation not only depends on the computation of the immediate past but also the state of the database. For example, let G be a linear array. To create pebble (i,t), g_i first communicates with its neighbors, then performs computations based on pebbles $(i-1, t-1)$, $(i, t-1)$, and $(i+1, t-1)$ and the current state of database b_i. Last, g_i updates database b_i. Hence, creating a pebble involves two time units as in the dataflow model: one for communication and one for computation and recording.

In the database model, a pebble not only records the result of a computation but also the *changes* to the database incurred by this computation. To emphasize, a pebble does not contain a snapshot of the whole database but rather the changes incurred by one computation. Therefore, a pebble has small size and can be passed along links.

In order to simulate G on H, we assume that the initial contents of each database can be copied *before* the computation begins (thereby allowing redundant computations), but that the large size of a database makes it impractical to transmit a copy of a database through the network *during* the computation. Suppose processor p of H copies databases b_i and b_j; then p only has access to b_i and b_j and hence can only compute pebbles of the form (i, t) and (j, t) for $t \geq 1$. Moreover, if both processors p and q decide to copy b_i, then p and q each maintains a copy of b_i, and each looks up and updates its own copy. If p is to compute pebble (i, t), then p needs an updated copy of the database that includes all the changes incurred by the computations (i, t') for all $t' < t$. Hence, p must either have directly computed all the pebbles (i, t') or else have received the information from its neighbors.

Unlike the dataflow model, the database model captures a scenario where the computation performed by a processor depends on the state of a local memory or where part of the computation performed by a processor is to update its local memory. These situations could be critical in some applications involving a network of workstations.

Bandwidth. The guest network G has unit bandwidth on each link. This allows each pebble to be passed along a unit-delay link of G in one time step. In our simulation we assume that the link bandwidth of the host network H is w. That is, P pebbles can be passed along a d-delay link of H in $d + \lceil \frac{P}{w} \rceil - 1$ steps by pipelining. In many cases of our study, it is sufficient to assume that the host and the guest have comparable link bandwidth; i.e., w is a constant. However, in certain situations the bandwidth needs to be $\tilde{O}(\log n)$. Otherwise, we pay an extra factor of $\tilde{O}(\log n)$ in the slowdown. The details are discussed in sections 3.2.4 and 4.2.4.

1.3. Results. Table 1 summarizes our results. In the table, n is the size of the guest, d_{ave} is the average delay of the host and "Bd-deg" stands for bounded-degree. The ratio of n and the slowdown is the size of the host, since all the simulations are *work efficient*; i.e., it takes the guest and the host the same amount of work to compute the same result, where *work* is the product of the number of processors used and the running time.

The first two results in Table 1 are proved in terms of linear arrays. An n-node unit-delay ring is essentially the same as an n-node unit-delay linear array, since the latter can simulate the former with a slowdown of 2 [12]. Result 1 is asymptotically optimal in some cases. In addition, we also have a constant-approximation algorithm for simulating rings and linear arrays in the dataflow model. Results 2 and 3 are optimal up to a polylogarithmic factor in some cases. Result 3 is for a worst-case model. When the delays on the host are randomly arranged, the bound can be improved to $O(d_{\text{ave}}^{2/3})$. Results 4 and 5 are easy generalizations of results 1 and 2, respectively. Sections 2 and 3 present latency hiding methods for the dataflow model.

Section 4 concentrates on the database model.

The methods for latency hiding in the two computation models are substantially different. For example, we make heavy use of redundant computation in the database model, whereas redundancy is apparently not useful for the dataflow model.

Our bounds indicate that hiding latency in the database model is more difficult than in the dataflow model. Intuitively, this is because computation in the dataflow model is processor independent and hence can be done by any processor with the information of the previous computation. In the database model, computation can only be done by the processors with the right databases. One cannot afford to pass large databases across the links with limited bandwidth, because this will cause high slowdown. One also cannot afford to keep many copies of the databases, because memory is expensive and keeping every copy of the databases updated is difficult.

In section 4, we also establish limits on the degree to which the high latency can be mitigated when each database is allowed a small number of copies. For example, if each database has only one copy, we show that the slowdown can be as much as $d_{\max}$ even if d_{ave} is a constant and the best simulation is used. When each database has at most two copies and each host processor copies a constant number of databases, we give an example of a host whose average delay is a constant, but for which the slowdown has a lower bound of $\Omega(\log n)$. These results demonstrate that it is easier to overcome latencies in dataflow types of computations than in computations that require access to large local databases.

1.4. A related scheduling problem. The problem of latency hiding in the dataflow model can be viewed as the following scheduling problem. The pebbles created by the guest network together with their dependencies form a directed acyclic graph (dag), whose nodes represent computational tasks of equal execution time, and whose arcs represent precedence. All these tasks are to be computed by the processors in a given host network. If the same host processor computes two tasks of direct dependence, no communication cost is incurred. Otherwise, there is a communication cost between the two host processors that compute these two tasks, and this cost is equal to the total delay between the processors in the host network. The goal here is to schedule the dag (with possible repetitions of the nodes) using the given host processors so as to minimize the *makespan*, i.e., the total time taken to execute all the tasks.

A variation of the above scheduling problem has been studied. Here, we are given any task dag (not necessarily created by a guest network in the dataflow model). All the arcs in the dag are associated with a fixed quantity that indicates the communica-

TABLE 1
Result summary.

	Guest	Host	Model	Order of slowdown
1	Ring/linear array	Bd-deg network	Dataflow	$\sqrt{d_{\text{ave}}}$
2	Ring/linear array	Bd-deg network	Database	$\sqrt{d_{\text{ave}}}\log^3 n$
3	2-D array	2-D array	Dataflow	$d_{\text{ave}}^{2/3}\log^{5/3} n$
4	2-D array	Bd-deg network	Dataflow	$n^{1/4}(\sqrt{d_{\text{ave}}}+n^{1/4})$
5	2-D array	Bd-deg network	Database	$n^{1/4}\log^3 n(\sqrt{d_{\text{ave}}}+n^{1/4})$

tion cost. Note that, unlike our problem, the communication cost here is the same for any processor pair. In [18] Papadimitriou and Ullman studied an $n \times n$ grid dag (which they called a diamond dag). They showed a nontrivial time-communication tradeoff and gave an asymptotically optimal schedule. Their result was similar to the special case of our Result 1 stated in section 1.3, where all the link delays in our host network are the same. In [19] Papadimitriou and Yannakakis presented a 2-approximation algorithm for general dags where an unlimited number of processors could be used. For well-known families of dags such as the full binary tree, the diamond dag, and the fast Fourier transform, only a finite number of processors were needed and their approximation algorithms were optimal (or near optimal). Redundant computation was used in [19].

Dag scheduling has been studied in other papers, including [2, 5, 7, 8, 9, 16, 17]. Some variations of the problem are the cases in which the dags are limited to certain topologies, the task nodes require different execution times, arcs require different communication time, and processors have different processing powers.

2. Dataflow model—Linear arrays.

We begin our presentation with the methods for hiding latency in linear arrays. Our basic approach is to transfer a process that involves a two-way communication to a process that involves one-way communication only. (This idea is also essential for simulating two-dimensional arrays in section 3.) We present an asymptotically tight bound on the slowdown for linear arrays. All the results for linear arrays are applicable to rings.

2.1. Average delay—An upper bound.

Let the network G be an n-processor guest linear array with unit delay on all the edges. Let the network H be an n-processor host linear array with arbitrary delays, where d_i is the delay on the ith edge of H. As discussed in section 1.2, in $2T$ time steps G creates $n \times T$ pebbles, where pebble (i, t), for $1 < i < n$ and $1 < t \leq T$, depends on pebbles $(i-1, t-1)$, $(i, t-1)$, and $(i+1, t-1)$. We first present algorithm Stripe in which H simulates G with a slowdown of $O(d_{\text{ave}})$, where $d_{\text{ave}} = \sum_{k=1}^{n-1} d_k/(n-1)$ is the average delay of H.

Consider the first $n/2$ rows of pebbles created by G. Let L be the triangle formed by pebbles (i, t), where $i + t \leq n + 1$. Let R be the triangle formed by pebbles (i, t), where $i \leq t$. (See Figure 2.) In Stripe, H first simulates the bottom half of L and then the bottom half of R. At this point every pebble in the first $n/2$ rows is simulated. If the entire computation of G is partitioned into groups each of which consists of $n/2$ rows of pebbles, then H can repeat the process and simulate every group in a similar manner.

To simulate the bottom half of L, the computation pebbles of G are divided into n slanted stripes, and each processor of H simulates one stripe. (See Figure 2.) In particular, processor p_i of H simulates a stripe consisting of pebbles $(i - t + 1, t)$ for $1 \leq t \leq i$ and $t \leq n/2$. Note that in the original computation by G, processor g_i depends on both g_{i-1} and g_{i+1}. However, in the simulation by H p_i depends on p_{i-1} and p_{i-2}. Hence, Stripe transforms a process that involves two-way communication into a process that involves only one-way communication.

Lemma 2.1. *Processor p_i $(1 \leq i \leq n)$ is able to compute pebble $(i - t + 1, t)$ at step $t + \sum_{k=1}^{i-1} d_k$.*

Proof. We use induction on i. The base case for p_1 is obvious. Pebble $(i-t+1, t)$ depends on pebbles $(i-t, t-1)$, $(i-t+1, t-1)$, and $(i-t+2, t-1)$, which are computed by processors p_{i-2}, p_{i-1}, and p_i, respectively. By induction these three pebbles are computed at step $(t-1) + \sum_{k=1}^{i-3} d_k$, $(t-1) + \sum_{k=1}^{i-2} d_k$, and $(t-1) + \sum_{k=1}^{i-1} d_k$,

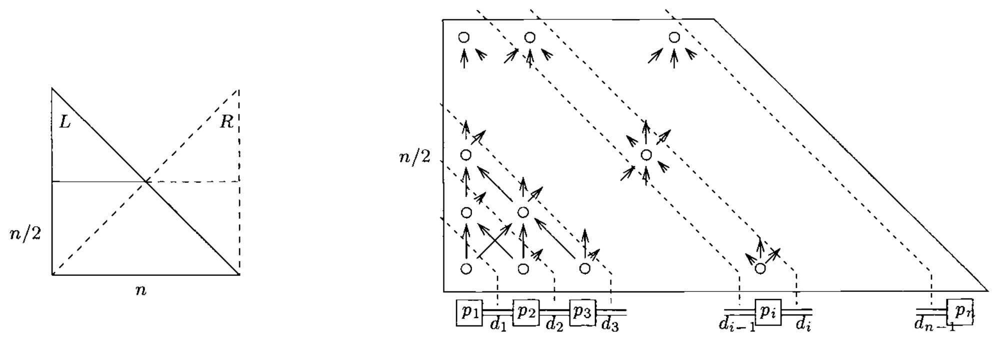

FIG. 2. *(Left) Triangles L and R. (Right) Algorithm* STRIPE. *Each slanted stripe is simulated by one processor of H. Arrows correspond to communications. Dashed lines correspond to the delays d_i encountered by communications.*

respectively. It follows that $(i-t+1,t)$ can be computed at step $t+\sum_{k=1}^{i-1} d_k$. □

Hence, pebbles $(i+1,n/2)$, for $0 \le i \le n/2$, are computed at steps $n/2+\sum_{k=1}^{i+n/2-1} d_k$, and so the bottom half of L is simulated in $n/2+\sum_{k=1}^{n-1} d_k$ steps by H. The bottom half of R is simulated in a similar manner. (Note that the intersection of R and L only needs to be computed once.) Thus, H has completed simulating the first $n/2$ rows of pebbles created by G. To continue the simulation, each pebble $(i,n/2)$ is passed to processor p_i. With pipelining, this can be done in $\sum_{k=1}^{n-1} d_k$ steps. The next $n/2$ and every subsequent $n/2$ rows of pebbles can be simulated in a similar manner. Therefore, the slowdown is upper bounded by

$$s = \frac{2\cdot(n/2+\sum_{k=1}^{n-1} d_k)+\sum_{k=1}^{n-1} d_k}{n/2} = O(d_{\text{ave}}).$$

2.2. A better upper bound. To get a better upper bound on the best achievable slowdown, we use the idea of "complementary slackness" in our new algorithm called FATSTRIPE. Each host processor is loaded with enough work to balance out the communication time. Suppose FATSTRIPE uses an interval of m processors to carry out the simulation. For simplicity, assume that this interval consists of processors $p_1,\dots,p_m$. The bottom half of L is divided into m slanted stripes, each of which has width $\ell = n/m$. Again, p_i computes every pebble in stripe i. (See Figure 3.) Within each stripe i, p_i first computes all the pebbles in the bottom row and then moves up.

LEMMA 2.2. *Processor p_i finishes simulating stripe i by step $\ell n/2+\sum_{k=1}^{i-1} d_k$.*

Proof. We inductively show that p_i can compute the pebbles in the xth row of stripe i by time step $\ell x+\sum_{k=1}^{i-1} d_k$. The base of the induction holds trivially for $i=1$ and $x=1$, since processor p_1 does not depend on other processors and pebbles in the first row do not depend on other pebbles. Let us consider the pebbles on the $(x+1)$st row of stripes $i+1$ for $x \ge 1$ and $i \ge 1$. These pebbles could only depend on pebbles on the xth row of stripe $i-1$, i, and $i+1$, which can be computed by processors p_{i-2}, p_{i-1}, and p_i by steps $\ell x+\sum_{k=1}^{i-3} d_k$, $\ell x+\sum_{k=1}^{i-2} d_k$, and $\ell x+\sum_{k=1}^{i-1} d_k$, respectively, by induction. Hence, p_i is able to receive all the information necessary to compute its $(x+1)$st row by step $\ell x+\sum_{k=1}^{i-1} d_k$ and therefore finish computing the $(x+1)$st row by step $\ell(x+1)+\sum_{k=1}^{i-1} d_k$. Since each stripe contains at most $n/2$ rows, p_i finishes simulating stripe i by step $\ell n/2+\sum_{k=1}^{i-1} d_k$. □

Hence, the slowdown is $O(n/m+\sum_{k=1}^{m-1} d_k/n)$ in simulating the first $n/2$ rows of pebbles. All the subsequent $n/2$ rows can be simulated in a similar manner. To

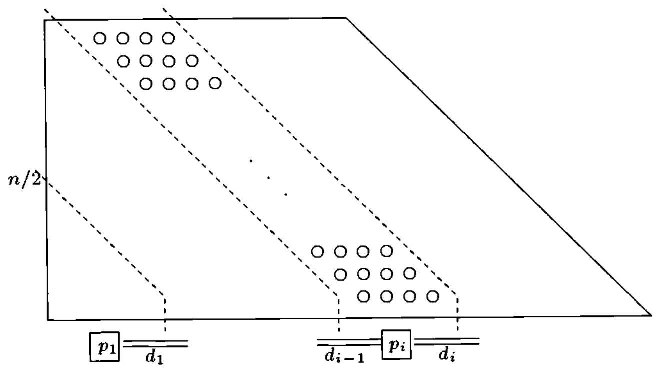

FIG. 3. *Algorithm* FATSTRIPE. *Processor p_i simulates stripe i, which has width $\ell = n/m$. (In the figure, $\ell = 4$.) All the pebbles in stripe i are computed by time step $\ell n/2 + \sum_{k=1}^{i-1} d_k$.*

minimize the slowdown, FATSTRIPE uses the interval I (with m_I processors and d_I average delay) that minimizes the quantity $n/m_I + d_I m_I/n$. Therefore, Theorem 2.3 follows.

THEOREM 2.3. FATSTRIPE *achieves slowdown of* $\min_{intervals\ I} O(n/m_I + d_I m_I/n)$.

In the case when $\sqrt{d_{\text{ave}}} \le n$, there exists an interval I with $M_I = n/\sqrt{d_{\text{ave}}}$ processors and average delay $d_I \le d_{\text{ave}}$ by the pigeon-hole principle. Theorem 2.3 implies that the slowdown is $O(\sqrt{d_{\text{ave}}})$ when M_I simulates G. In the case when $\sqrt{d_{\text{ave}}} > n$ a single host processor is used to carry out the simulation, which incurs a slowdown of $n = O(\sqrt{d_{\text{ave}}})$. The simulation is work efficient in both cases. Therefore, Corollary 2.4 holds.

COROLLARY 2.4. FATSTRIPE *efficiently simulates G on H and achieves a slowdown of $O(\sqrt{d_{ave}})$, where d_{ave} is the average delay of H.*

Let us consider the effect of bandwidth on the slowdown. In FATSTRIPE as long as the stripe width is at least 2, then pebbles cross the edges one at a time by using pipelining. In STRIPE (i.e., FATSTRIPE with stripe width 1) at most two pebbles may cross an edge at the same time. Therefore, it is sufficient for the host bandwidth to be twice as large as that of the guest bandwidth. Otherwise, we pay another factor of 2 in the slowdown.

2.3. A matching lower bound. We proceed to show that the upper bound, $\min_I O(n/m_I + d_I m_I/n)$, in Theorem 2.3 is asymptotically tight by showing that $\min_I \max\{n/2m_I, d_I m_I/2n\}$ is a lower bound on the best achievable slowdown even if we allow *redundant computation.* Note that with redundant computation, a pebble may be computed by several host processors. This technique makes it more likely for the host to simulate the guest efficiently. However, we show below that redundancy does not help in this case.

LEMMA 2.5. *The top pebble,* $(1, n)$ *of triangle L, cannot be computed at a time step earlier than*

$$\tau = \min_{intervals\ I} \max\{n^2/2m_I, d_I m_I/2\}.$$

Proof. We consider how the pebbles in L are computed in some simulation of G by H. In particular, we build a ternary tree T to keep track of the processors that have "effectively" computed the pebbles in L. The top pebble $(1, n)$ has to be computed by some processor of H. Call this processor q. (If more than one processor of H has computed $(1, n)$, then we pick any one of them to be q.) We label the root of tree T with $q^{(1,n)}$. Let u be a processor that has computed $(1, n-1)$ *and* has passed this information to q, and let v be a processor that has computed $(2, n-1)$ *and* has passed this information to q. (Note that other processors may compute $(1, n-1)$ and $(2, n-1)$. We are only concerned with processors that pass information to q.) Now label the children of $q^{(1,n)}$ with $u^{(1,n-1)}$ and $v^{(2,n-1)}$. We proceed to construct the children of $u^{(1,n-1)}$ and $v^{(2,n-1)}$. In general, node $a^{(i,t)}$ in T has children $b^{(i-1,t-1)}$, $c^{(i,t-1)}$, and $d^{(i+1,t-1)}$ if the following holds. Processors a, b, c, and d compute pebbles (i, t), $(i-1, t-1)$, $(i, t-1)$, and $(i+1, t-1)$, respectively, *and* a receives the values of $(i-1, t-1)$, $(i, t-1)$, and $(i+1, t-1)$ from b, c, and d before a is able to compute (i, t). The leaves of T are nodes of the form $p^{(i,1)}$. The important observation is the following. If $p^{(i,t)}$ is a node in T, then information has to be passed from processor p to q in H. The total delay from p to q lower bounds the number of steps in the simulation.

Let J be the smallest interval that contains all the processors appearing in tree T. If processors x and y are at the two ends of J, then there exist two nodes of the form $x^{(i_x,t_x)}$ and $y^{(i_y,t_y)}$ in T. Hence, information has to be passed from x and y to q in H. This takes at least $d_J m_J/2$ steps, and pebble $(1, n)$ therefore cannot be computed at a step earlier than $d_J m_J/2$. Since m_J processors are computing $n^2/2$ pebbles, a work argument shows that $(1, n)$ cannot be computed before step $n^2/2m_J$. Hence, $(1, n)$ cannot be computed at a step earlier than $\tau = \min_I \max\{n^2/2m_I,\ d_I m_I/2\}$. ∎

It follows that the slowdown in simulating triangle L is lower bounded by τ/n. By a similar argument to Lemma 2.5 none of the pebbles (i, n), for $1 \le i \le n$, can be computed at a time step earlier than τ. By repeating this argument the first kn rows of G cannot be simulated in time less than $k\tau$. Therefore, we obtain Theorem 2.6.

THEOREM 2.6. *The slowdown of any simulation of an n-node guest linear array G by a host linear array H is lower bounded by* $\min_I \Theta(n/m_I + d_I m_I/n)$*, where I is a subarray of H and has m_I processors and average delay d_I. Hence,* FATSTRIPE *is optimal up to a constant factor.*

2.4. Simulating linear arrays on general networks. We now consider simulating a linear array G on a general n-node network H with average delay d_{ave}. We first embed a linear array $\mathcal{H}$ in H and then use $\mathcal{H}$ to carry out the simulation of G.

LEMMA 2.7. *Let H be a connected n-node network with arbitrary topology. Then an n-node linear array $\mathcal{H}$ can be one-to-one embedded in H such that every edge of H is used at most twice in $\mathcal{H}$.*

Proof. Our proof follows the approach of Theorem 3.15 in [12, page 470]. We include the proof here for completeness. It is sufficient to embed a linear array $\mathcal{H}$ in a spanning tree of H. The proof proceeds by induction on the height of the tree with the following inductive hypothesis. For any child u of the root v, there is a one-to-one embedding of a linear array in the tree such that v and u form two endpoints of the array, the edge uv is used at most once, and all other edges of the tree are used at most twice. (Note that we treat all the edges as undirected.)

Let T be any spanning tree of H. The base of the induction in which T is a single node, i.e., the height is 0, is trivial. Otherwise, let v be the root of T and u be any child of v. We label the children of v as $u_1, \ldots, u_d$ and assume $u = u_d$ without loss of generality. We place the first node of the linear array at v, and we place the second node of the array at any child w of u_1 (if any) using edges vu_1 and u_1w. Next, we inductively place the nodes of the array in each node of the subtree of T rooted at u_1, making sure that the last node is placed at u_1, the edge u_1w is used at most once, and that all other edges in the subtree are used twice. Therefore, edge u_1w is used at

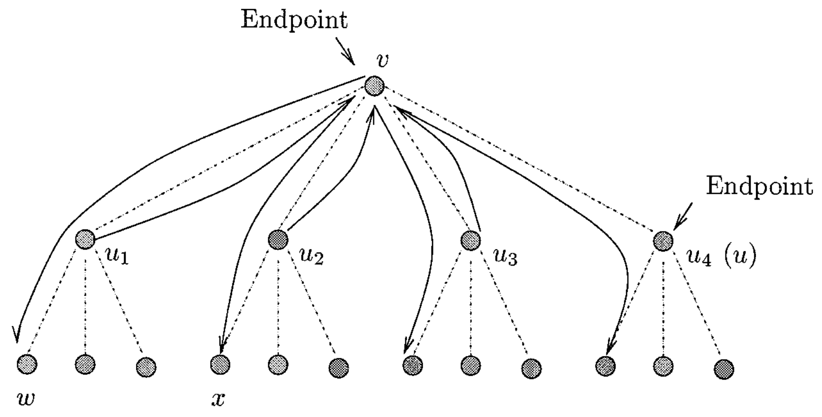

FIG. 4. *Embed a linear array one to one in a tree such that each tree edge is used at most twice. The dotted lines indicate tree edges and the solid lines indicate array edges.*

most twice in total.

We place the next node of the linear array at any child x of u_2 (if any), using edges u_1v, vu_2 and u_2x. Again, we inductively place nodes of the linear array in the subtree rooted at u_2 such that u_2 and x are endpoints. We continue in this fashion. At the last subtree rooted at u, we enter this subtree at a child of u (if any) and exit at u. This completes the embedding of the linear array. Our lemma follows from the observation that the linear array has endpoints v and u, edges vu_1, …, vu_{d-1} are used twice, and vu_d is used once. (See Figure 4.) □

Since H has n nodes and degree δ, H has at most $\delta n/2$ edges, and therefore the total delays on all edges of H are at most $\delta d_{\text{ave}} n/2$. By Lemma 2.7, $\mathcal{H}$ uses each edge of H at most twice. Hence, the total delays on all edges of $\mathcal{H}$ is at most $\delta d_{\text{ave}} n$, and the average delay of $\mathcal{H}$ is at most δd_{ave}. By Corollary 2.4, $\mathcal{H}$ can simulate G with a slowdown of $O(\sqrt{\delta d_{\text{ave}}})$. When H has bounded degree, i.e., $\delta = O(1)$, we have Theorem 2.8.

THEOREM 2.8. *A bounded-degree host network with average delay d_{ave} can efficiently simulate an n-processor guest linear array with a slowdown of $O(\sqrt{d_{ave}})$.*

Theorem 2.8 does not hold when H has unbounded degree. Consider the following example. Let H be a linear array of $\sqrt{n}$ cliques, in which each clique contains $\sqrt{n}$ nodes. If a clique edge has delay 1 and an edge connecting two adjacent cliques has delay n, then H has $d_{\text{ave}} < 4$. Suppose m connected cliques are used to simulate n steps of G. Lemma 2.5 implies a slowdown of $\min_m \max\{\sqrt{n}/2m, m/2\}$ in simulating every n steps of computation by the guest. The first term follows from a work argument, since $m\sqrt{n}$ processors are in m cliques. The second term comes from the communication delay, since a linear array embedded in these m connected cliques has a total delay of at least mn. Hence, the slowdown is at least $\min_m \max\{\sqrt{n}/2m, m/2\}$, which is $\Omega(n^{1/4})$, whereas the average delay is a constant.

3. Dataflow model—Two-dimensional arrays.

In this section we present methods for hiding latency in two-dimensional arrays. The analysis here is substantially more complex than that for the one-dimensional case. We focus on simulating a two-dimensional array on a two-dimensional array. Section 3.1 generalizes the approach for the linear arrays. Section 3.2 introduces some new mechanism to improve the bound. Section 3.3 discusses the case when the delays are randomly arranged.

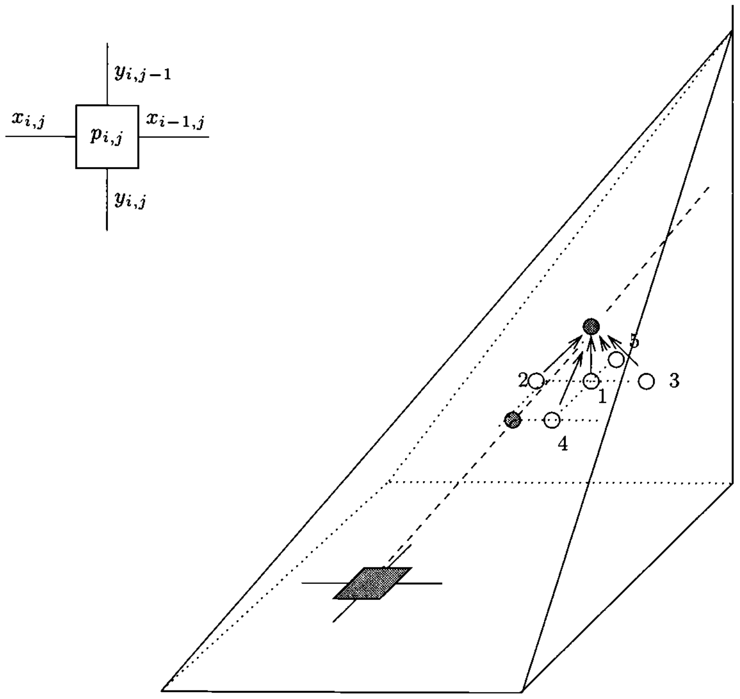

FIG. 5. *Algorithm* 2D-RAY. *In pyramid P_1 the dashed line represents the ray of pebbles computed by processor $p_{i,j}$ (which is shown in the upper left corner). Two of those pebbles, computed at times t and $t-1$, are shown shaded. The five numbered pebbles are those upon which $(i-t+1, j-t+1, t)$ depends.*

3.1. An analogue of the one-dimensional case. Let the guest network G be an $n \times n$ two-dimensional array with unit delay on all the edges. Let the host network H be an $n \times n$ two-dimensional array with arbitrary delays. Let $x_{i,j}$ be the delay between processors $p_{i,j}$ and $p_{i+1,j}$ of H for $1 \le i \le n-1$ and $1 \le j \le n$, and let $y_{i,j}$ be the delay between $p_{i,j}$ and $p_{i,j+1}$ of H for $1 \le i \le n$ and $1 \le j \le n-1$. The tth step of computation by processor $g_{i,j}$ of G is recorded in pebble (i,j,t). In $2T$ steps, G creates $n \times n \times T$ pebbles, where pebble (i,j,t), for $1 < i,j < n$ and $1 < t \le T$, depends on $(i-t+1, j-t+1, t-1)$, $(i-t, j-t+1, t-1)$, $(i-t+2, j-t+1, t-1)$, $(i-t+1, j-t, t-1)$, and $(i-t+1, j-t+2, t-1)$.

Consider the first $n/2$ steps of computation by G. We define four pyramids P_1, P_2, P_3, and P_4 analogous to the left and right triangles in the linear array case. All four pyramids have the square, defined by vertices $(1,1,1)$, $(1,n,1)$, $(n,1,1)$, and $(n,n,1)$, as their bases. The top vertices of P_1, P_2, P_3, and P_4 are $(1,1,n)$, $(1,n,n)$, $(n,1,n)$, and (n,n,n), respectively. Note that the bottom half of the four pyramids contains all the pebbles created by G for the first $n/2$ steps of computation.

Algorithm 2D-RAY is a two-dimensional analogue of STRIPE. To simulate the first $n/2$ steps of computation of G, 2D-RAY simulates P_1, P_2, P_3, and P_4 one by one. Pyramid P_1 is divided into n^2 rays, each of which is simulated by one processor of H. In particular, processor $p_{i,j}$ of H simulates ray $R_{i,j}$, consisting of pebbles $(i-t+1, j-t+1, t)$ for $1 \le t \le \min\{i, j, n/2\}$. (See Figure 5.) When every pebble for the first $n/2$ steps of computation of G is simulated, 2D-RAY repeats the process and simulates the next $n/2$ steps of computation. In the following we bound the slowdown in terms of the total delay on *monotone paths*, where a monotone path travels in two directions, up and right. Let the length of a path be the total delay on the path, and let $D_{i,j}$ be the length of the longest monotone path from processor $p_{1,1}$ to $p_{i,j}$ in H. We have Lemma 3.1.

LEMMA 3.1. *Processor $p_{i,j}$ of H is able to compute pebble $(i-t+1, j-t+1, t)$ at step $D_{i,j}+t$.*

Proof. We use induction on the indices (i,j) of the processors. The base of the induction for $p_{1,1}$ is obvious. Pebble $(i-t+1, j-t+1, t)$ depends on pebbles $(i-t+1, j-t+1, t-1)$, $(i-t, j-t+1, t-1)$, $(i-t+2, j-t+1, t-1)$, $(i-t+1, j-t, t-1)$, and $(i-t+1, j-t+2, t-1)$, which are computed by processors $p_{i-1,j-1}$, $p_{i-2,j-1}$, $p_{i,j-1}$, $p_{i-1,j-2}$, and $p_{i-1,j}$, respectively. (See Figure 5.) By induction, these five pebbles are computed at steps $D_{i-1,j-1}+(t-1)$, $D_{i-2,j-1}+(t-1)$, $D_{i,j-1}+(t-1)$, $D_{i-1,j-2}+(t-1)$, and $D_{i-1,j}+(t-1)$, respectively. It follows that pebble $(i-t+1, j-t+1, t)$ can be computed at step $\max\{D_{i-1,j}+x_{i-1,j}, D_{i,j-1}+y_{i,j-1}\}+t = D_{i,j}+t$. ∎

Hence, 2D-RAY simulates pyramid P_1 in $D_{n,n}+n$ steps. Since P_2, P_3, and P_4 can be simulated similarly, 2D-RAY simulates the first $n/2$ steps of computation of G in $O(D_{n,n}+n)$ steps. The simulation is repeated for every $n/2$ steps of computation of G. Therefore, Lemma 3.2 holds.

LEMMA 3.2. *Algorithm* 2D-RAY *achieves a slowdown of $O(D_{n,n}/n)$, where $D_{n,n}$ is the length of the longest monotone path in H.* ∎

Unfortunately, $D_{n,n}$ can be large compared with d_{ave}, the average delay of H. In the worst case $D_{n,n}$ can be $\Theta(n^2 d_{\text{ave}})$, implying a slowdown of $\Theta(n d_{\text{ave}})$. We introduce algorithm FATRAY, a two-dimensional analogue of FATSTRIPE, to achieve a slowdown that is often better than $O(D_{n,n}/n)$. Pyramid P_1 is divided into m^2 rays, each of which has size $\ell \times \ell = \frac{n}{m} \times \frac{n}{m}$. FATRAY uses an $m \times m$ contiguous subarray of processors in H to carry out the simulation. For simplicity, assume FATRAY uses processors $p_{i,j}$ $(1 \le i,j \le m)$. Again, $p_{i,j}$ computes every pebble in ray $R_{i,j}$, and $p_{i,j}$ first computes all the pebbles on the bottom plane and then moves up. The following lemma is analogous to Lemma 2.2.

LEMMA 3.3. *Processor $p_{i,j}$ finishes simulating ray $R_{i,j}$ by using step $\ell^2 n/2 + D_{i,j}$.*

Proof. As in Lemma 2.2 we can inductively show that $p_{i,j}$ can compute all the pebbles in the xth plane in ray $R_{i,j}$ by using time step $\ell^2 x + D_{i,j}$. Since each ray contains at most $n/2$ planes of pebbles, $p_{i,j}$ finishes simulating ray $R_{i,j}$ by using step $\ell^2 n/2 + D_{i,j}$. ∎

This implies a slowdown of $O(n^2/m^2 + D_{m,m}/n)$. To minimize the slowdown, FATRAY uses the contiguous subarray S that minimizes $n^2/m_S^2 + D_S/n$, where $m_S \times m_S$ is the size of S and D_S is the length of the longest monotone path in S.

THEOREM 3.4. FATRAY *achieves a slowdown of* $\min_{subarrays\ S} O(n^2/m_S^2 + D_S/n)$.

Unfortunately, the slowdown can still be big compared with d_{ave}. For example, suppose that H is partitioned into n squares of size $\sqrt{n} \times \sqrt{n}$ with one edge of delay n in the center of each square and unit delay on all other edges. The slowdown is $\min_S \Theta(n^2/m_S^2 + D_S/n) = \Theta(n^{1/3})$, whereas d_{ave} is a constant. Matters are better, however, when all the delays are the same, as we show in the following theorem.

THEOREM 3.5. *In the case where all the delays in H are d,* FATRAY *efficiently simulates G on H and achieves a slowdown of $\Theta\left(\min\{d^{2/3}, n^2\}\right)$. The slowdown is optimal up to a constant factor.*

Proof. When $d \le n^3$ FATRAY uses a subarray of size $\frac{n}{d^{1/3}} \times \frac{n}{d^{1/3}}$. Theorem 3.4 implies a slowdown of $O(d^{2/3})$. We show that the slowdown is asymptotically tight as follows. Consider pebble $(i, j, d^{1/3})$, and suppose processor q computes it in a simulation.

Let A be the set of pebbles of the form (i', j', t), for $1 \leq t < d^{1/3}$, on which $(i, j, d^{1/3})$ depends; i.e., $(i, j, d^{1/3})$ cannot be computed until after (i', j', t) is computed. If every pebble in A is computed q, then it takes at least $|A| = \Omega\left((d^{1/3})^3\right) = \Omega(d)$ time steps to simulate A. Otherwise, a processor $p \neq q$ computes some pebble in A and passes this information to q. The delay from p to q is at least d. Hence, the slowdown on simulating the first $d^{1/3}$ steps is $d^{2/3}$. The same argument applies for the slowdown in the next $d^{1/3}$ steps.

When $d > n^3$ FatRay uses a single host processor for the simulation and achieves a slowdown of $O(n^2)$. This slowdown is asymptotically tight for the same reason as in the previous case. We consider pebbles (i, j, n) instead of $(i, j, d^{1/3})$. In both cases the simulation is work efficient. □

Theorem 3.5 can be generalized to any k-dimensional array for $k \geq 1$.

Theorem 3.6. *Suppose G is an $n \times \cdots \times n$ k-dimensional array with unit-delay edges, and H is an $n \times \cdots \times n$ k-dimensional array with delay-d edges; then H can efficiently simulate G with a slowdown of* $\Theta(\min\{d^{k/k+1}, n^k\})$. *The slowdown is optimal up to a constant factor.*

3.2. Improved bounds for worst-case delays. In order to improve the slowdown, we observe that not all the host processors are useful. If a host processor is surrounded by high delays, then the benefit to be gained by using its computing power is nullified by the communication cost. We first describe criteria of removing such host processors. We then embed guest processors to the unremoved host processors. Suppose that guest processor $g_{i,j}$ is mapped to host processor p; then p computes the pebbles in ray $R_{i,j}$ in the 2D-Ray algorithm. For any arrangement of the delays in H, we show how to embed G on H such that, for any monotone path in G, its image in H has length of $O(d_{\text{ave}} n \log^{5/2} n)$. As a result, Lemma 3.2 implies a slowdown of $O(d_{\text{ave}} \log^{5/2} n)$ as long as only $O(1)$ guest processors are mapped to each host processor. By applying the idea used in FatRay, we improve the slowdown to $O(d_{\text{ave}}^{2/3} \log^{5/3} n)$ and achieve work efficiency at the same time.

3.2.1. Removing useless processors. We first recursively represent H using a quadtree, in which each node corresponds to a subarray of H. The root represents the entire $n \times n$ array. The four children of the root represent the four $\frac{n}{2} \times \frac{n}{2}$ subarrays, etc. In general, a node at depth k of the quad tree corresponds to an $\frac{n}{2^k} \times \frac{n}{2^k}$ subarray of H. We refer to this subarray as a *depth-k* array. The leaves represent the individual processors of H. (See Figure 6.)

We describe a two-stage procedure to remove "useless" processors of H. A processor is removed if it is surrounded by high delays (Stage 1) or few unremoved processors (Stage 2). (When a processor is removed, its incident edges remain in the network.) For each depth k, we define two quantities D_k for "delay threshold" and m_k for "survival threshold." Note that D_k is larger than the average delay on a row/column in a depth-k array by a factor of $\Theta(\log n)$, and m_k is smaller than the number of processors in a depth-k array by a factor of $\Theta(\log n)$:

$$D_k = (c \log n)\left(\frac{n}{2^k} d_{\text{ave}}\right), \tag{1}$$

$$m_k = \left(\frac{1}{c \log n}\right)\left(\frac{n^2}{4^k}\right). \tag{2}$$

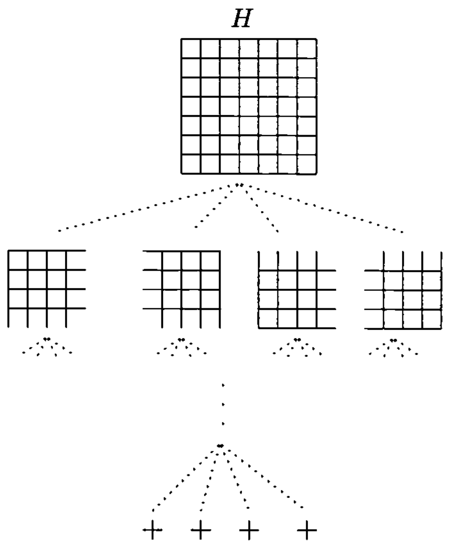

FIG. 6. *The quad tree that represents H.*

A constant c is specified later. We also define a maximum depth $k_{\max}$ such that when $k = k_{\max}$ the survival threshold m_k becomes 1.

$$k_{\max} = \log n - \frac{1}{2}\log c - \frac{1}{2}\log\log n. \tag{3}$$

- **Stage 1.** From depth $k = k_{\max}$ down to depth 0, if the total delay on a row/column of a depth-k array exceeds the threshold D_k, then all the $\frac{n}{2^k}$ processors on that row/column are removed.
- **Stage 2.** From depth $k = k_{\max}$ down to depth 0, if the number of unremoved processors in a depth-k array is smaller than the threshold m_k, then all the processors in that array are removed. Moreover, we also remove processors so that the number of remaining processors in any depth-k array is an integer multiple of m_k.

LEMMA 3.7. *At most $2n^2/c$ processors are removed in Stage* 1.

Proof. The total delay of H is $2n^2 d_{\text{ave}}$. At most $\frac{2n2^k}{c\log n}$ depth-k rows and columns can have delay more than D_k. Since each depth-k row/column contains $\frac{n}{2^k}$ processors, at most $\frac{2n^2}{c\log n}$ processors are removed at depth k. There are $\log n$ depths, and so the lemma follows. □

LEMMA 3.8. *At most n^2/c processors are removed at Stage* 2.

Proof. Since there are 4^k depth-k arrays, at most $\frac{n^2}{c\log n}$ processors are removed at depth k. □

We label each array with the number of unremoved processors contained in it. By Lemmas 3.7 and 3.8, at most $3n^2/c$ processors of H are removed. Therefore, H is labeled with $c_1 n^2$, where $c_1 \geq 1 - (3/c)$. Any constant $c > 3$ works for our argument.

3.2.2. The embedding. For clarity of presentation, we create an intermediate two-dimensional array $\mathcal{G}$ that has size $\sqrt{c_1}n \times \sqrt{c_1}n$ and unit-delay edges only. We describe an algorithm EMBED that maps the processors of $\mathcal{G}$ one to one to the

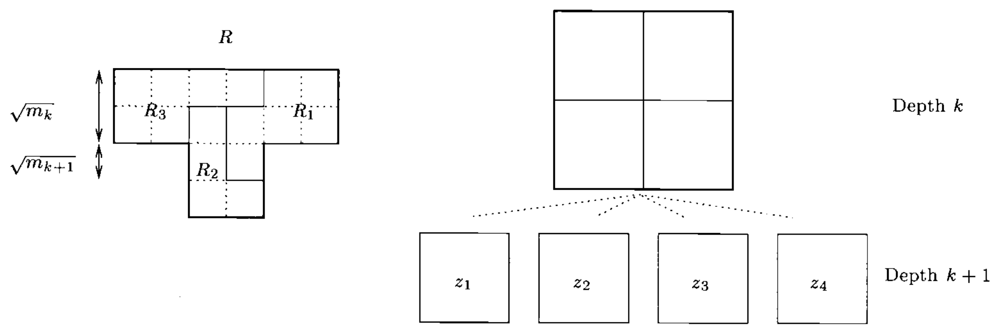

FIG. 7. *(Left) Depth-k region R and depth $k+1$ regions R_1, R_2, and R_3 of $\mathcal{G}$. (Right) Depth-k and $k+1$ arrays of H. Depth $k+1$ region R_i has size z_i, where z_i is the number of unremoved processors in the corresponding array of H. In this figure, $z_4 = 0$, and R_4 is therefore empty.*

unremoved processors of H. The goal is to show that for any monotone path in $\mathcal{G}$ its image in H under EMBED has length $O(d_{\text{ave}} n \log^{5/2} n)$. As a result, H can simulate $\mathcal{G}$ with a slowdown of $O(d_{\text{ave}} \log^{5/2} n)$. Obviously $\mathcal{G}$ can simulate G with constant slowdown.

EMBED partitions $\mathcal{G}$ into *regions* recursively, and each depth-k region of $\mathcal{G}$ corresponds to a depth-k array of H. The depth-0 region is the entire network $\mathcal{G}$. By the construction of Stage 2, $c_1 n^2$ (the number of processors in $\mathcal{G}$) is a multiple of m_0. Hence, $\mathcal{G}$ can be viewed as a collection of contiguous squares of size $\sqrt{m_0} \times \sqrt{m_0}$. We inductively assume that each depth-k region consists of contiguous squares of size $\sqrt{m_k} \times \sqrt{m_k}$, where m_k is defined in equation (2). Each depth-k region R is partitioned into four depth $k+1$ regions R_1, R_2, R_3, and R_4 as follows. First, each $\sqrt{m_k} \times \sqrt{m_k}$ square of R is divided into four squares of size $\sqrt{m_{k+1}} \times \sqrt{m_{k+1}}$, where $\sqrt{m_{k+1}} = \sqrt{m_k}/2$. Suppose that R_i corresponds to a depth $k+1$ square of H that has z_i unremoved processors; then R_i has size z_i. By the construction of Stage 2, z_i is a multiple of m_{k+1}. Hence, R_i can be formed as a collection of contiguous squares of size $\sqrt{m_{k+1}} \times \sqrt{m_{k+1}}$. Note that if z_i is 0, then the corresponding R_i is empty. (See Figure 7.)

At depth $k_{\max}$, each depth-$k_{\max}$ region consists of contiguous squares of size 1×1. EMBED maps the processors in a depth-$k_{\max}$ region of $\mathcal{G}$ to the unremoved processors in the corresponding depth-$k_{\max}$ array of H in an arbitrary one-to-one manner. Thus, we have a one-to-one mapping from the processors of $\mathcal{G}$ to the unremoved processors of H.

We also define the *depth-k boundaries* in $\mathcal{G}$ to be the borders of depth-k regions of $\mathcal{G}$. Note that the depth-k boundaries are at least $\sqrt{m_k}$ apart in both horizontal and vertical directions.

3.2.3. Bounding monotone path length. In this section we bound the total delay on the image of P in H, where P is any monotone path in $\mathcal{G}$. Suppose a and b are two neighboring processors in $\mathcal{G}$; then their images a_H and b_H in H are connected by a 1-*bend* route as follows. First, a_H is routed along its row to b_H's column and then routed to b_H along the column. We define a and b (resp., a_H and b_H) to be *k-related* if k is the largest integer such that a and b (resp., a_H and b_H) are in a same depth-k region (resp., depth-k array). We also define a_H and b_H to be *peers* of each other. Note that each unremoved host processor can have four peers.

LEMMA 3.9. *Let P be any monotone path in $\mathcal{G}$. The image of P in H has a total delay of $O(d_{ave} n \log^{5/2} n)$ under* EMBED.

Proof. Let a and b be two neighboring processors on P and let a_H and b_H be their images. Suppose a and b (resp., a_H and b_H) are k-related. We first bound the length of the 1-bend route from a_H to b_H. By the construction of Stage 1, the total delay on a depth-k row/column that contains a_H or b_H is at most D_k. Hence, the distance from a_H to b_H is at most $2D_k$.

We now bound the number of neighboring a's and b's that can be k-related. If $k < k_{\max}$, P must cross some depth $k+1$ boundary of $\mathcal{G}$ in traveling from a to b. Since P is monotone and the depth-k boundaries are $\sqrt{m_k}$ apart in both horizontal and vertical directions, P can cross the depth-k boundaries at most $\frac{2n}{\sqrt{m_k}}$ times. Hence, at most $\frac{2n}{\sqrt{m_{k+1}}}$ neighboring a's and b's on P can be k-related. This implies that the total delay incurred by k-related peers on the image of P is at most $2D_k \frac{2n}{\sqrt{m_{k+1}}}$ for $k < k_{\max}$. Obviously, at most $2n$ neighboring a's and b's can be $k_{\max}$-related. Summing over all depths, we conclude that the total delay on the image of P is at most $2D_{k_{\max}} \cdot 2n + \sum_{k<k_{\max}} 2D_k \frac{2n}{\sqrt{m_{k+1}}}$, which is $O(d_{\text{ave}} n \log^{5/2} n)$ by the definitions of D_k, m_k and $k_{\max}$. ◻

Hence, we can embed G on H such that $O(1)$ guest processors are mapped to each host processor and that the image in H of any monotone path in G has length $O(d_{\text{ave}} n \log^{5/2} n)$. Lemma 3.2 implies that H can simulate G with a slowdown of $O(d_{\text{ave}} \log^{5/2} n)$. To improve the slowdown and achieve efficiency, we apply the idea of complementary slackness and use an $m \times m$ contiguous subarray of H for simulation as in FATRAY. Theorem 3.4 and Lemma 3.9 imply a slowdown of $O((d_{\text{ave}} m \log^{5/2} m)/n + n^2/m^2)$. By choosing m to be $\max\{n d_{\text{ave}}^{-1/3} \log^{-5/6} n, 1\}$, we have Theorem 3.10.

THEOREM 3.10. *Network H with average delay d_{ave} can efficiently simulate G with a slowdown of $O(d_{ave}^{2/3} \log^{5/3} n)$.*

3.2.4. Bandwidth. The preceding analysis focuses entirely on the issue of latency and ignores bandwidth constraints. This does not present any problems if the link bandwidth available on the host array is $\Omega(\log^{3/2} n)$ times larger than that on the guest array. If the bandwidth of the host and guest arrays are comparable, however, and if the guest array is fully utilizing the bandwidth on its links, then *congestion* becomes an issue. Formally, the congestion on an edge equals the number of pebbles that wish to cross this edge simultaneously. In this case, we may need to slow down the simulation by an additional factor of $O(\log^{3/2} n)$.

In section 3.2.3, peers a_H and b_H are connected by a 1-bend route in H. To address the congestion issue, we present a more sophisticated method of connecting a_H and b_H such that each edge in H has $O(\log^{3/2} n)$ routes going through it and that the distance between a_H and b_H remains unchanged asymptotically.

We begin with some definitions. Recall that EMBED maps each depth-k region R_k of $\mathcal{G}$ to a depth-k array S_k of H. A depth-k row/column of S_k is *live* if it contains some unremoved host processors. A boundary point of S_k is live if it belongs to some live row or column of S_k. We first bound the number of connections from inside of S_k to outside of S_k in terms of the number of live rows and columns of S_k.

LEMMA 3.11. *Consider any depth-k array, S_k, of H. The number of processors in S_k that have peers outside S_k is $O(x\sqrt{\log n})$, where x is the number of live rows and columns in S_k.*

Proof. Let z be the number of unremoved processors in S_k; then the number of live rows and columns is at least $\frac{z}{n/2^k}$. The number of host processors in S_k that have peers outside S_k is proportional to the perimeter of R_k, the depth-k region that corresponds to S_k. By the construction of EMBED, R_k consists of squares of size $\sqrt{m_k} \times \sqrt{m_k}$. Hence, R_k has perimeter of $O(z/\sqrt{m_k})$, which is $O(\frac{z}{n/2^k}\sqrt{\log n})$ by the definition of m_k in (2). Our lemma follows. $\square$

We now describe a recursive procedure that connects the peers. The following facts are used in our routing.

FACT 3.12. *Consider a routing problem on a square array of size $x \times x$.*

1. *If each node has $O(y)$ requests, then the routing can be done in one bend and $O(xy)$ congestion.*
2. *Let the nodes on the* cross *divide the square array into four $\frac{x}{2} \times \frac{x}{2}$ quadrants. If each boundary node and cross node have $O(y)$ requests and all other nodes have no requests, then the routing can be done in $O(1)$ bends and $O(y)$ congestion.*

Our recursive routing starts at depth $k = k_{\max}$. Consider all the depth-k arrays S_k. For all the peers that are k-related, we connect them through a 1-bend routing within S_k. Since S_k has size $\sqrt{\log n} \times \sqrt{\log n}$ and each host processor has at most 4 peers, the congestion caused by this 1-bend routing within S_k is $O(\sqrt{\log n})$ by item 1 of Fact 3.12. For all the processors that have peers outside S_k, we route them to live boundary points such that the following two conditions hold. First, each live boundary point of S_k receives $O(\sqrt{\log n})$ requests. This is possible because of Lemma 3.11. Second, the routing uses 1 bend and causes a congestion of $O(\log n)$ by item 1 of Fact 3.12.

We proceed recursively to depths $k < k_{\max}$. Consider all the depth-k arrays S_k. From the previous stage the host processors that are not connected to their peers are routed to some live boundary points of depth $k+1$ arrays. Hence, they are either on the boundary or on the cross of S_k, and $O(\sqrt{\log n})$ host processors are routed to the same location. For all the peers that are k-related, we connect them within S_k. Otherwise, we route them to the live boundary points of S_k such that each live point receives $O(\sqrt{\log n})$ requests (including those from all previous stages but have not yet connected to their peers). This is possible by Lemma 3.11. In both cases, item 2 of Fact 3.12 implies that the routing can be done in $O(1)$ bends and that the congestion incurred is $O(\sqrt{\log n})$.

The congestion incurred at depth k, for $1 \le k < k_{\max}$, is $O(\sqrt{\log n})$ and at depth $k_{\max}$ is $O(\log n)$. Since each of the depths uses the same underlying edges, the overall congestion is $O(\log^{3/2} n)$. The host processors are routed to live boundary points in $O(1)$ bends at each depth, and therefore the length incurred at depth k is $O\left(\frac{n}{2^k} d_{\text{ave}} \log n\right)$. Suppose that a_H and b_H are k-related; then the distance between them is $\sum_{k' \ge k} O(\frac{n}{2^{k'}} d_{\text{ave}} \log n)$, which remains $O(\frac{n}{2^k} d_{\text{ave}} \log n)$ as in Lemma 3.9. In summary, we have Lemma 3.13.

LEMMA 3.13. *In the above routing scheme the congestion is $O(\log^{3/2} n)$ on all edges of H. Furthermore, for any monotone path P in $\mathcal{G}$, the image of P in H has length $O(d_{ave} n \log^{5/2} n)$.*

3.3. Improved bounds for randomly arranged delays. In this section, we show that the length of the longest monotone path in H is often short when the delays are randomly arranged. If M is the number of edges in an $n \times n$ array H, then for a given set of M delays with average d_{ave} the longest monotone path in H has length $O(nd_{\text{ave}})$ for most of the $M!$ permutations of the delays. That is, in the uniform distribution of the $M!$ permutations, the longest monotone path has length $O(nd_{\text{ave}})$ with high probability, and therefore the slowdown is $O(d_{\text{ave}})$ with high probability.

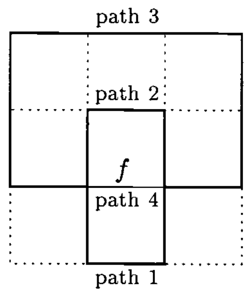

FIG. 8. *The bounding box and four edge-disjoint alternate paths for edge f.*

Without loss of generality we assume that d_{ave} is a constant. (For a nonconstant d_{ave}, each delay d is normalized to $\max\{d/d_{\text{ave}}, 1\}$. The normalized delays have average $O(1)$, and the total original delay on any monotone path is at most d_{ave} times the total normalized delay.) We divide the delays in H into $O(\log n)$ levels. Level ℓ contains the delays that are in the range of $[2^\ell, 2^{\ell+1})$, and level ℓ^+ contains the delays that are at least 2^ℓ.

3.3.1. Shortcuts and edge coloring. If an edge with a large delay is surrounded by edges with small delays, we can route around this large delay. The intuition is that in a random permutation most long delays can be shortcut. For each edge f, we consider four edge-disjoint *alternate* paths that connect the two endpoints of f. (See Figure 8.) The 3×3 box that contains these four paths is called the *bounding box* of f. After the *shortcut*, the total delay on f equals the shortest alternate path length. For clarity, we shall refer to the delay before the shortcut as the *original delay* and the delay after the shortcut as the *shortcut delay.*

For a given set of delays with a constant average, the number of level-ℓ^+ original delays is $O(n^2 2^{-\ell})$. Therefore, the probability for an edge f to have a level-ℓ^+ original delay is $O(2^{-\ell})$. However, shortcutting dramatically decreases this probability as the following lemma shows.

LEMMA 3.14. *The probability for an edge f to have a level-ℓ^+ shortcut delay is $O(2^{-4\ell})$.*

Proof. If edge f has a shortcut delay from level ℓ^+, then the four alternate paths must each have an edge whose original delay is from level $(\ell-4)^+$. For a particular set of four edges to have level $(\ell-4)^+$ original delays, the probability is $\binom{B}{4}/\binom{M}{4}$, where B is the number of level $(\ell-4)^+$ original delays, and M is the number of edges in H. Since there are $3 \cdot 3 \cdot 9 \cdot 1 = 81$ ways to choose four edges from four alternate paths, we derive the following from a union bound:

$$\Pr[\text{ Shortcut delay on } f \text{ is from level } \ell^+ \;] \le 81 \cdot \binom{B}{4} \bigg/ \binom{M}{4}.$$

Our lemma follows from the observation that $B = O(n^2 2^{-\ell})$ since $d_{\text{ave}} = O(1)$, and that $M = \Theta(n^2)$. □

Unfortunately, these probabilities are *not* independent from edge to edge for two reasons. First, the arrangement of delays is a permutation of a given set of delays. This does not cause a problem, however, as the analysis in Lemmas 3.15 and 3.17 will show. Intuitively, in a permutation if one edge has a large delay, then other edges are less likely to have large delays. Second, the bounding boxes are not necessarily disjoint. To resolve this problem we introduce an *edge coloring*, so that any two distinct edges with the same color have edge-disjoint bounding boxes. Clearly, only a constant number of colors are needed.

We show in the following that, for *any* monotone path in H, the total delay incurred from the edges in one particular color group is $O(n)$ with high probability. Since there are $O(1)$ color groups, our results follows from a union bound. For each color group we consider two cases, edges with large shortcut delays and edges with small shortcut delays.

3.3.2. Large delays. In this section we show that, with high probability, the total delay in H due to shortcut delays from large levels is $O(n)$. Therefore, any monotone path can only pick up $O(n)$ delays from these levels.

LEMMA 3.15. *With probability* $1 - O(n^{-1})$, any *monotone paths pick up a total delay of* $O(n)$ *from levels* $\ell \geq L$, *where* $L = \frac{1}{2}\log n - \frac{1}{2}\log\log n$.

Proof. By Lemma 3.14, the probability that one particular edge has a shortcut delay from level $(\frac{3}{4}\log n)^+$ is $O(n^{-3})$. Since H has $\Theta(n^2)$ edges, with probability $1 - O(n^{-1})$ no edge in H has shortcut delay from level $(\frac{3}{4}\log n)^+$.

We show below that, with high probability, H has $O(\log^3 n)$ shortcut delays from level L^+. Let $A = an^2$ be an upper bound on the number of edges in one particular color group, where a is a constant. Since $d_{\text{ave}} = O(1)$, at most $B = bn^{3/2}\log^{1/2} n$ original delays can be from levels $(L-4)^+$, where b is a constant. We show that, with a small probability, more than $C = c\log^3 n$ edge delays are from level L^+ for a sufficiently large constant c.

For a particular set of C edges to have level-L^+ shortcut delays, at least four edges in each of these C bounding boxes have level $(L-4)^+$ original delays. For a particular set of four edges in each bounding box to have level $(L-4)^+$ original delays, the probability is at most $\binom{B}{4C}/\binom{M}{4C}$. This is true since all the C bounding boxes are edge disjoint. There are at most $\binom{A}{C}$ ways to choose C edges whose shortcut delays are from L^+ and 81^C ways to choose four edges from each of the C boxes. We therefore derive the following from a union bound:

$$\begin{aligned} p &= \Pr[\text{ At least } C \text{ edges have level-}L^+ \text{ shortcut delays }] \\ &\leq 81^C \binom{A}{C}\binom{B}{4C} \Big/ \binom{M}{4C}. \end{aligned} \tag{4}$$

We bound probability p with the inequalities

$$\left(\frac{y}{x}\right)^x \leq \binom{y}{x} \leq \left(\frac{ye}{x}\right)^x, \tag{5}$$

where $e = 2.718$ is the base of the natural logarithm. By the definitions of A, B, and C and the fact that $M \approx 2n^2$, we have

$$p \leq \left(\frac{81 \cdot Ae}{C}\right)^C \left(\frac{Be}{M}\right)^{4C} = \left(\frac{81 \cdot a \cdot b^4 \cdot e^5}{2^4 \cdot c \cdot \log n}\right)^{c\log^3 n}.$$

Let c be a sufficiently large constant; then the above probability is bounded by $O(n^{-1})$. Summing over all the $O(1)$ color groups, we conclude that with probability $1-O(n^{-1})$ H has no shortcut delays from level $(\frac{3}{4}\log n)^+$ and $O(\log^3 n)$ shortcut delays from level L^+. Hence, any monotone path picks up a total delay of $O(n^{3/4}\log^3 n) = O(n)$ from levels $\ell \geq L$. $\square$

3.3.3. Small delays. In this section we show that the shortcut delay from small levels do not accumulate too much on any monotone path with high probability. In particular, with probability $1 - O(n^{-2})$, each monotone path picks up an $O(n2^{-\ell})$ delay from each "small" level ℓ. Summing over all $O(\log n)$ "small" levels, we can conclude that each monotone path picks up a total of $O(n)$ small delays with probability $1 - O(n^{-1})$.

Consider a particular level $\ell < L$, where $L = \frac{1}{2}\log n - \frac{1}{2}\log\log n$. We divide H into m^2 squares of size $2^{2\ell} \times 2^{2\ell}$, where $m = n2^{-2\ell}$. There are $\binom{2m-1}{m}$ sequences of $2m-1$ squares that some monotone path could possibly go through. We call these sequences of $2m-1$ squares *monotone sequences.* If the total number of level-ℓ shortcut delays in each of these sequences is bounded, then the total level-ℓ shortcut delay that any monotone path picks up is also bounded.

LEMMA 3.16. *With probability* $1 - O(n^{-2})$, *any monotone path picks up a total of a* $O(n2^{-\ell})$ *delay from level-*ℓ *shortcut delays, where* $\ell < L$ *is one particular level and* $L = \frac{1}{2}\log n - \frac{1}{2}\log\log n$.

Proof. Consider one particular monotone sequence of $2m-1$ squares of size $2^{2\ell} \times 2^{2\ell}$, where $m = n2^{-2\ell}$. Let random variable X be the number of level-ℓ shortcut delays in this sequence of squares, and let random variable X_i be the number of level-ℓ shortcut delays from the ith square in the sequence. We use a moment generating function argument to upper bound $X = X_1 + \cdots + X_{2m-1}$. We first bound the probability $\Pr[\, X_1 = k_1, \ldots, X_{2m-1} = k_{2m-1} \,]$. Let $A = a2^{4\ell}$ be an upper bound on the number of edges from one particular color group in each $2^{2\ell} \times 2^{2\ell}$ square, where a is a constant. Since $d_{\text{ave}} = O(1)$, at most $B = bn^2 2^{-\ell}$ original delays can be from level $(\ell-4)^+$, where b is a constant. Let $k = \sum_{i=1}^{2m-1} k_i$. By applying the same logic as for inequality (4), we have

$$\begin{aligned} P &= \Pr[\, X_1 = k_1, \ldots, X_{2m-1} = k_{2m-1} \,] \\ &\le 81^k \cdot \binom{A}{k_1} \cdots \binom{A}{k_{2m-1}} \cdot \binom{B}{4k} \Big/ \binom{M}{4k}. \end{aligned}$$

By inequality (5), the probability is bounded by

$$\begin{aligned} P &\le 81^k \cdot \left(\frac{Ae}{k_1}\right)^{k_1} \cdots \left(\frac{Ae}{k_{2m-1}}\right)^{k_{2m-1}} \cdot \left(\frac{Be}{M}\right)^{4k} \\ &= \prod_{i=1}^{2m-1} \left(\frac{81 \cdot a \cdot b^4 \cdot e^5}{2^4 \cdot k_i}\right)^{k_i}. \end{aligned} \tag{6}$$

We proceed to bound the expectation of e^X:

$$\begin{aligned} E[e^X] &= E[e^{X_1 + \cdots + X_m}] \\ &= \sum_{k \ge 0} e^k \sum_{\sum k_i = k} \Pr[\, X_1 = k_1, \ldots, X_{2m-1} = k_{2m-1} \,] \\ &\le \sum_{k \ge 0} \sum_{\sum k_i = k} \prod_{i=1}^{2m-1} \left(\frac{y}{k_i}\right)^{k_i}, \qquad \text{where } y = 81 \cdot a \cdot b^4 \cdot e^6 \cdot 2^{-4} \\ &\le \sum_{k \ge 0} \sum_{\sum k_i = k} \prod_{i=1}^{2m-1} \frac{y^{k_i}}{k_i!} \\ &= e^{y(2m-1)}. \end{aligned}$$

The first inequality follows from inequality (6), and the last equality follows from $e^{y(2m-1)} = (\sum_{j\geq 0} \frac{y^j}{j!})^{2m-1}$. We use Markov's inequality to bound the probability that the total number of level-ℓ shortcut delays exceeds $\beta(2m-1)$ in this particular monotone sequence:

$$\Pr\left[\, X \geq \beta(2m-1)\right] = \Pr\left[\, e^X \geq e^{\beta(2m-1)}\right] \leq \frac{E[e^X]}{e^{\beta(2m-1)}} \leq e^{(y-\beta)(2m-1)}.$$

There are $\binom{2m-1}{m} < 2^{2m-1}$ monotone sequences. By a union bound, the probability that every sequence has fewer than $\beta(2m-1)$ level-ℓ shortcut delays is at least $1 - 2^{2m-1}e^{(y-\beta)(2m-1)}$. Let β be the constant $y+2$; then this probability is bounded by $1 - O(n^{-2})$, since $m = n/2^{2\ell} \geq \log n$. Therefore, every monotone path picks up a total of $O(n2^{-\ell})$ shortcut delays from level ℓ with probability $1 - O(n^{-2})$. $\square$

Summing over all levels $\ell < L$ results in a total delay that is linear in n as desired.

LEMMA 3.17. *With probability $1-O(n^{-1})$, all the monotone paths pick up a total delay of $O(n)$ from levels $\ell < L$ for $L = \frac{1}{2}\log n - \frac{1}{2}\log\log n$.*

For the case in which $d_{\text{ave}} = O(1)$, Lemmas 3.15 and 3.17 show that any monotone path has a total delay of $O(n)$ with high probability. For the case in which d_{ave} is nonconstant, the discussion at the beginning of the section implies that Theorem 3.18 holds.

THEOREM 3.18. *Suppose H is a network with average delay d_{ave}; then with high probability every monotone path in H has delay $O(nd_{ave})$.*

To make the algorithm work efficient, we use an $m \times m$ subarray of H of average delay at most d_{ave} to simulate G. Theorems 3.4 and 3.18 imply that the slowdown is $O(n^2/m^2 + d_{\text{ave}}m/n)$ with high probability. By choosing m to be $\max\{nd_{\text{ave}}^{-1/3}, 1\}$, we have Theorem 3.19.

THEOREM 3.19. *Suppose the delays on network H are from a random permutation of a set of delays whose average is d_{ave}; then with high probability H can simulate G with slowdown $O(d_{ave}^{2/3})$.*

Congestion problems are not an issue here, since each edge of H is used $O(1)$ times by alternate paths in the shortcut process.

4. Database model. We switch our attention to the database model. As discussed in section 1, simulation in the database model is more difficult than in the dataflow model. For algorithms such as STRIPE in section 2 to work for the database model a host processor needs $\Theta(n)$ copies of the databases on average. This is unrealistic because of the memory requirement as well as the difficulty in updating the databases. We therefore develop new machinery for the database model. Contrary to the dataflow model, we make substantial use of redundant computation. Apart from the slowdown, another important parameter for the database model is *load*, which is the number of databases that a host processor copies.

The main contribution of this section is an algorithm called OVERLAP that simulates linear arrays in the database model with a small load and a small slowdown. Since OVERLAP is technically involved, we begin with a special case in section 4.1, where the host linear array has delay d on all edges. The simulation in this special case is much simpler, and it conveys some intuition for using redundant computation in the general case. Section 4.2 presents OVERLAP in detail. The techniques are generalized to simulate linear and two-dimensional arrays on general networks in sections 4.3 and 4.4. Last, in section 4.5 we discuss the lower bounds on slowdown when each database is allowed a small number of copies.

4.1. A special case. In this section we consider a special case. Let G be a guest linear array with n processors and unit-delay edges, and let H be a host linear array with n processors and delay d on all edges. We use redundant computation to achieve an optimal slowdown of $O(\sqrt{d})$. Recall that in the dataflow model, the optimal slowdown is achieved for linear arrays without using redundancy.

THEOREM 4.1. *In the database model, H can efficiently simulate G with a slowdown and a load of $O(\sqrt{d})$. This slowdown is optimal up to a constant factor.*

Proof. We consider two cases. If $n \le \sqrt{d}$, then one host processor copies all the databases and carries out the entire computation by itself. Hence the load and the slowdown are n, which is $O(\sqrt{d})$. Otherwise, the first $\frac{n}{\sqrt{d}}$ host processors are used for the simulation. For $1 \le j \le \frac{n}{\sqrt{d}}$, processor p_j copies $3\sqrt{d}$ databases b_i and computes $3\sqrt{d}$ columns of pebbles (i,t), where $(j-2)\sqrt{d}+1 \le i \le (j+1)\sqrt{d}$ and $1 \le t$. In this way each processor shares $\sqrt{d}$ databases with its right and left neighbors and each pebble is redundantly computed by three neighboring processors.

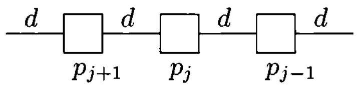
We show how to simulate the first $\sqrt{d}$ rows of pebbles created by G in $O(d)$ steps by H. Every subsequent $\sqrt{d}$ rows of pebbles are simulated in the same manner. The algorithm is demonstrated in Figure 9. For $1 \le j \le \frac{n}{\sqrt{d}}$, let

$$\begin{array}{rcll}
P_j &=& \{\text{Pebbles } (i,t): & 1 \le t \le \sqrt{d}, \quad -2\sqrt{d}+1 \le i - j\sqrt{d} \le \sqrt{d}\},\\
L_j &=& \{\text{Pebbles } (i,t): & 1 \le t \le \sqrt{d}, \quad 1 \le i-(j-2)\sqrt{d} \le t\},\\
R_j &=& \{\text{Pebbles } (i,t): & 1 \le t \le \sqrt{d}, \quad -t+1 \le i-(j+1)\sqrt{d} \le 0\},\\
T_j &=& P_j - (L_j \cup R_j), & \\
A_j &=& \{\text{Pebbles } ((j-2)\sqrt{d},t): & 1 \le t \le \sqrt{d}\},\\
B_j &=& \{\text{Pebbles } ((j-1)\sqrt{d}+1,t): & 1 \le t \le \sqrt{d}\},\\
C_j &=& \{\text{Pebbles } ((j\sqrt{d},t): & 1 \le t \le \sqrt{d}\},\\
D_j &=& \{\text{Pebbles } ((j+1)\sqrt{d}+1,t): & 1 \le t \le \sqrt{d}\}.
\end{array}$$

Processor p_j of H computes all the pebbles in P_j. First, p_j computes the pebbles in the trapezium T_j without communicating with its neighbors. There are $2d$ pebbles in T_j, and so this takes $2d$ steps. Next, p_j passes column B_j to processor p_{j-1} and receives column A_j from p_{j-1}. It also passes column C_j to processor p_{j+1} and receives column D_j from p_{j+1}. This communication takes $d+\sqrt{d} < 2d$ steps using pipelining. Processor p_j can now compute the pebbles in triangles L_j and R_j in d steps. It is important for p_j to compute the pebbles in L_j and R_j in order to continue the simulation of the next $\sqrt{d}$ rows of pebbles, since databases need to be updated. This presents a major difference between the dataflow and database models.

Hence, it takes at most $5d$ steps in total for processor p_j to compute every pebble in P_j. The next $\sqrt{d}$ steps of computation can be simulated in a similar fashion. The slowdown is therefore $O(\sqrt{d})$. The lower bound proof in Theorem 3.5 implies that the slowdown of $\Omega(\sqrt{d})$ is necessary.

Note that during the computation of T_j, the pebbles in columns B_j and C_j can start to travel to the neighboring processors of p_j as soon as they are ready. Processor p_j can also start to compute triangles L_j and R_j before the entire columns of A_j and D_j are transferred. In this way, the communication time can be saved. Although it does not make a difference asymptotically in this case we take advantage of this observation in OVERLAP. $\square$



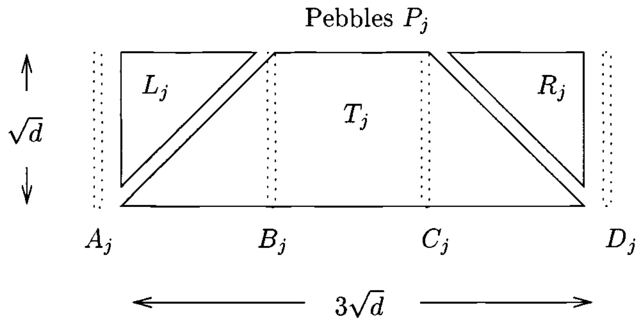


FIG. 9. *Simulating $\sqrt{d}$ steps of computation of G on H.*

4.2. Algorithm OVERLAP. To simulate a guest linear array on a host linear array with arbitrary delays we use an algorithm called OVERLAP. In OVERLAP, we remove host processors that are surrounded by high delays. The motivation of this step is similar to that of section 3.2. For the remaining processors, we decide how much redundancy is needed for neighboring processors and how much computation each processor is able to carry out. During the simulation, some pebbles are redundantly computed to ensure that the communication is not too costly. We first obtain a slowdown of $O(d_{\text{ave}} \log^3 n)$, where d_{ave} is the average delay of H and n is the size of G and H, and later improve the slowdown to $O(\sqrt{d_{\text{ave}}} \log^3 n)$ while achieving work efficiency.

4.2.1. Removing useless processors. We recursively represent H using a binary tree, in which each node corresponds to a subarray of H. The root represents the entire array. The left and right children of the root represent the left and right halves of the array, respectively. In general, a node at depth k of the binary tree corresponds to a subarray of H that contains $\frac{n}{2^k}$ processors. We refer to this subarray as a *depth-k interval*. The leaves represent the individual processors of H. (See Figure 10.)

We describe a two-stage process that removes the processors that are surrounded by high delays (Stage 1) and the processors that are surrounded by few unremoved processors (Stage 2). During Stage 2, we also label each *live* subarray, where a live subarray contains some unremoved processor. These labels indicate how many columns of pebbles the live subarrays are able to compute.

For every depth k, we define D_k to be the "delay threshold" and m_k to be the "overlap size" as follows. Note that D_k is larger than the average delay in a depth-k interval by a factor of $\Theta(\log n)$, and m_k is smaller than the number of processors in a depth-k interval by a factor of $\Theta(\log n)$. We shall use m_k to indicate the size of overlap between neighboring depth-k intervals, i.e., the number of columns of pebbles redundantly computed by both intervals:

$$D_k = (c \log n) \left(\frac{n}{2^k} d_{\text{ave}} \right), \tag{7}$$

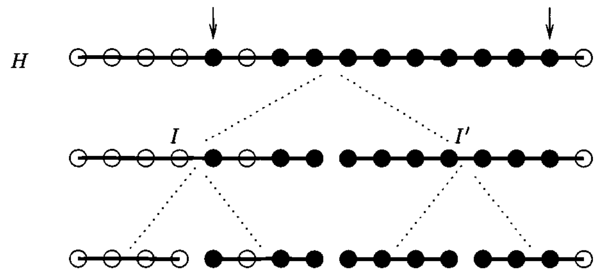

FIG. 10. *The binary tree that represents H. In this figure, unremoved processors of H are represented by black circles; removed processors are represented by white circles. Arrows indicate the endpoints of the root interval. Interval I has one live child and I' has two live children.*

$$m_k = \left(\frac{1}{c\log n}\right)\left(\frac{n}{2^k}\right). \tag{8}$$

As we shall see, any constant $c > 5/2$ works for our argument. We also define a maximum depth $k_{\max}$ such that when $k = k_{\max}$ the overlap size m_k becomes 1:

$$k_{\max} = \log n - \log\log n - \log c. \tag{9}$$

- **Stage 1.** From depth $k = k_{\max}$ down to depth 0, if the total delay in a depth-k interval exceeds D_k, then all the processors in that interval are removed.
- **Stage 2.** At depth $k = k_{\max}$, let I be a live depth-k interval and let x be the number of unremoved processors in I. If x is smaller than $2m_k$, then we remove all the remaining processors in I and I is no longer live. Otherwise, we label I with x.
  Suppose all the live depth-$(k+1)$ intervals are labeled. Now consider each live depth-k interval I. If I has two live children I_1 and I_2 that are labeled with x_1 and x_2, then let $x = x_1 + x_2 - m_{k+1}$. If I has one live child I_1 that is labeled with x_1, then let $x = x_1$. If $x < 2m_k$, we remove all the remaining processors in I and I is no longer live. Otherwise, we label I with x. We proceed to depth $k-1$ until reaching depth 0.

LEMMA 4.2. *At most n/c processors are removed at Stage* 1.

Proof. The total delay in the array H is nd_{ave}. At most $\frac{2^k}{c\log n}$ depth-k intervals can have delay more than D_k. Each depth-k interval contains $\frac{n}{2^k}$ processors and so at most $\frac{n}{c\log n}$ processors are removed at depth k. Since there are $\log n$ depths, at most n/c processors are removed at Stage 1. ☐

LEMMA 4.3. *The label on the root interval is at least $\left(1 - \frac{5}{2c}\right) n$ at Stage* 2.

Proof. Before Stage 2, the number of remaining processors in H is at least $(1 - 1/c)n$ by Lemma 4.2. At depth $k = k_{\max}$ of Stage 2, the sum of the labels on the live depth-k intervals is at least $(1-1/c)n - 2m_k2^k$, which is $(1-1/c)n - \frac{2n}{c\log n}$. At each depth $k < k_{\max}$, the sum of the labels on the live depth-k intervals decreases by at most $(2m_k + m_{k+1})2^k$, which is $\frac{5n}{2c\log n}$. Summing over all depths, we conclude that the label at the root interval is at least $\left(1 - \frac{5}{2c}\right) n$. ☐

4.2.2. Assigning databases. For clarity of presentation, we first assume that G has n' processors, where n' is the label on the root interval of G and n' is a constant fraction of n by Lemma 4.3. We also assume the existence of pebbles $(0, t)$ and $(n'+1, t)$, for all $t \geq 1$, which are known to H at time step 0. This ensures that each pebble computed by G is dependent on three pebbles.

Algorithm Overlap assigns one database to each remaining processor of H so that H has load one. In particular, a depth-k interval with label x is assigned x databases. The depth-0 interval, i.e., H, has all the databases $b_1, \ldots, b_{n'}$. We assume inductively that a depth-k interval I labeled x is assigned databases $b_{i+1}, \ldots, b_{i+x}$. If I has only one child I_1, then Overlap assigns $b_{i+1}, \ldots, b_{i+x}$ to I_1. If I has two children I_1 and I_2 that are labeled x_1 and x_2, respectively, then $x = x_1 + x_2 - m_{k+1}$ by the construction of Stage 2. Overlap assigns $b_{i+1}, \ldots, b_{i+x_1}$ to interval I_1 and $b_{i+x-x_2+1}, \ldots, b_{i+x}$ to I_2. Note that m_{k+1} databases, namely, $b_{i+x-x_2+1}, \ldots, b_{i+x_1}$, are assigned to both I_1 and I_2. These m_{k+1} columns of pebbles will be redundantly computed by both I_1 and I_2. At depth $k_{\max}$ each remaining processor of H is assigned one database.

4.2.3. The simulation. In Overlap, H recursively simulates every $m_0 = \frac{n}{c \log n}$ rows of pebbles created by G as follows. If H (the depth-0 interval) has two live depth-1 intervals I_1 and I_2 as children, then I_1 and I_2 recursively compute the first $m_1 = m_0/2$ rows of pebbles and then repeat for the next m_1 rows. In particular, I_1 (resp., I_2) computes all the pebbles of the form (i, t), where I_1 (resp., I_2) owns database b_i and $1 \le t \le m_1$. Intervals I_1 and I_2 share m_1 databases and therefore redundantly compute these m_1 columns of pebbles. If H has one live child I_1, then I_1 recursively computes the first m_1 rows and then repeats for the second m_1 rows. At depth $k = k_{\max}$, each depth-k interval computes $m_k = 1$ row of pebbles. Theorem 4.4 explains the simulation in detail.

Let us define a set of values $s_t^{(k)}$ for $0 \le k \le k_{\max}$ and $1 \le t \le m_k$, where the superscript k represents the depth of the recursion, and the subscript t represents the row number. Roughly speaking, $s_t^{(k)}$ corresponds to the time by which a depth-k interval computes its pebbles in the tth row. We are interested in the slowdown $s_{m_0}^{(0)}/m_0$, where $s_{m_0}^{(0)}$ corresponds to the time that H takes to simulate the first m_0 steps of computation by G. Recall that the delay threshold D_k defined in (7) is an upper bound on the total delay in any live depth-k interval. The recurrences are as follows.

$$s_t^{(k)} = s_t^{(k+1)} + D_k \qquad \text{for} \qquad 1 \le t \le m_{k+1}, \tag{10}$$

$$s_t^{(k)} = s_{t-m_{k+1}}^{(k)} + s_{m_{k+1}}^{(k)} \qquad \text{for} \quad m_{k+1} + 1 \le t \le m_k. \tag{11}$$

The base of the recurrence is defined to be

$$s_{m_k}^{(k)} = s_1^{(k)} = 1 \qquad \text{for } k = k_{\max}. \tag{12}$$

Let the *left endpoint* of interval I be the leftmost unremoved processor in I, and let the *right endpoint* be the rightmost unremoved processor in I. (See Figure 10.) For notational simplicity, we assume that I is the leftmost live depth-k interval and is assigned databases $b_1, \ldots, b_x$. Let $B_k = \{(i, t) : 1 \le i \le x, 1 \le t \le m_k\}$. The proof of the following theorem describes how algorithm Overlap performs the simulation.

Theorem 4.4. *For $1 \le t \le m_k$, if pebbles $(0, t)$ and $(x + 1, t)$ are known by time step $s_t^{(k)}$ by the left and right endpoints of interval I, respectively, then by time step $s_t^{(k)}$ every pebble (i, t) in B_k is computed by all the processors in interval I that have a copy of database b_i.*

Proof. We proceed by a backward induction on k. At level $k = k_{\max}$, we have $m_k = 1$ and box B_k has size $x \times 1$. Since the remaining processors of I have load one,

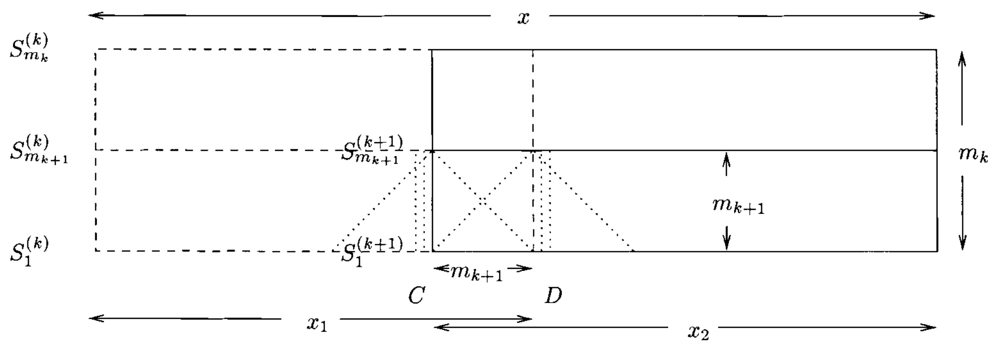

FIG. 11. *The box of pebbles B_{k+1} has size $x_1 \times m_{k+1}$ and is represented by the lower left box with a dashed boundary. B'_{k+1} has size $x_2 \times m_{k+1}$ and is represented by the lower right box with a solid boundary. B_k is the union of all four boxes. For interval I to compute every pebble in B_k, I_1 and I_2 (the live children of I) recursively compute B_{k+1} and B'_{k+1}. Once the bottom half of B_k is computed the top half is computed in a similar manner.*

each processor computes one pebble in B_k. By definition, $s_1^{(k)} = 1$. Hence, the base of the induction holds.

Suppose that the inductive hypothesis is true for $k+1$. Note that the hypothesis can be applied to any depth $k+1$ interval. Let us concentrate on I, the leftmost live depth-k interval. Suppose I is labeled with x. There are two cases to consider.

Case 1. Suppose I has two live children I_1 and I_2 that are labeled with x_1 and x_2, respectively. By construction $x = x_1 + x_2 - m_{k+1}$. Let $B_{k+1} = \{(i,t) : 1 \le i \le x_1, 1 \le t \le m_{k+1}\}$. Let $y = x_1 - m_{k+1}$ and $B'_{k+1} = \{(i,t) : y+1 \le i \le x, 1 \le t \le m_{k+1}\}$. Let column C consist of pebbles (y,t) and column D consist of pebbles (x_1+1,t), where $1 \le t \le m_{k+1}$. Note that boxes B_{k+1} and B'_{k+1} have an overlap of width m_{k+1}; i.e., the m_{k+1} columns between C and D are common to both B_{k+1} and B'_{k+1}. (See Figure 11.) Two observations can be made from the inductive hypothesis.

- **Observation 1.** For $1 \le t \le m_{k+1}$, every pebble (y,t) in column C can be computed by I_1 by time step $s_t^{(k+1)}$ *without any conditions on pebbles* $(0,t)$ *and* (x_1+1,t). Since C and D are m_{k+1} columns apart and $x_1 \ge 2m_{k+1}$ by the construction of Stage 2, the pebbles in column C therefore do not depend on the pebbles $(0,t)$ and (x_1+1,t). (The dotted diagonal lines in Figure 11 show the dependencies of columns C and D.)
- **Observation 2.** Let $z \ge 0$ be some constant. For $1 \le t \le m_{k+1}$, if the value of pebbles $(0,t)$ and (x_1+1,t) are known at time step $s_t^{(k+1)} + z$ by the left and right endpoints of interval I_1, respectively, then by time step $s_t^{(k+1)} + z$, every pebble (i,t) in B_{k+1} is computed. This is true because there is no difference between starting the simulation at time step z and at time step 0.

Similar statements can be made about the box B'_{k+1} and column D. Now suppose that the value of pebbles $(0,t)$ and $(x+1,t)$ are known at time step $s_t^{(k)}$ by the left and right endpoints of interval I, respectively. Observation 1 and the inductive hypothesis imply that any pebble (y,t) in column C can be computed by I_1 by time $s_t^{(k+1)}$. Since the total delay in interval I is at most D_k, then the left endpoint of interval I_2 can receive the pebble (y,t) (together with any relevant database changes) by time $s_t^{(k+1)} + D_k$, which equals $s_t^{(k)}$ (10). Similarly, all of the pebbles in column D can be sent to the right endpoint of interval I_1 by time $s_t^{(k)}$. Since $s_t^{(k)}$ is greater than

$s_t^{(k+1)}$ by a constant amount, namely, D_k, for $1 \leq t \leq m_{k+1}$, Observation 2 and the inductive hypothesis imply that pebbles (i, t) in box B_{k+1} (resp., B'_{k+1}) are computed by I_1 (resp., I_2) by time $s_t^{(k)}$. Therefore, pebbles (i, t) in the bottom half of B_k are computed by time $s_t^{(k)}$.

Once the bottom half of B_k is simulated I simulates the top half in a similar manner. Thus, pebbles (i, t) in the top half of B_k are computed by time $s_{m_{k+1}}^{(k)} + s_{t-m_{k+1}}^{(k)}$, which equals $s_t^{(k)}$ (11).

Case 2. The case in which I has one live child is simpler. Let I_1 be the child of I. By construction, I_1 has label $x_1 = x$. By Observation 2 and the induction hypothesis, if the values of the pebbles $(0, t)$ and $(x_1 + 1, t)$, for $1 \leq t \leq m_{k+1}$, are known at time steps $s_t^{(k)}$ by the left and right endpoints of interval I_1, respectively, then every pebble (i, t) in B_{k+1} (i.e., the bottom half of B_k) is computed by I_1 by time step $s_t^{(k)}$. Since intervals I and I_1 have the same remaining processors (and hence the same endpoints), the above statement holds for I. Interval I then computes the top half in the same manner. Thus, pebbles (i, t) in the top half of B_k are computed by time $s_{m_{k+1}}^{(k)} + s_{t-m_{k+1}}^{(k)}$, which equals $s_t^{(k)}$ (11).

The inductive step is complete. Hence, given that the value of pebbles $(0, t)$ and $(x + 1, t)$ are known at time step $s_t^{(k)}$ by the left and right endpoints of interval I, all pebbles (i, t) in box B_k are computed by time step $s_t^{(k)}$. ∎

Recall that n' is the label of the tree root and n' is a constant fraction of n by Lemma 4.3. We have the following theorem.

THEOREM 4.5. *Suppose that guest linear array G has n' processors and the host linear array H has n processors and an average delay of d_{ave}. Algorithm* OVERLAP *simulates G with H such that the load on H is one and the slowdown is $O(d_{ave} \log^3 n)$.*

Proof. The load on H follows directly from the database assignment. The box B_0 contains all of the pebbles for the first m_0 steps of computations by G, where $m_0 = \frac{n}{c \log n}$. The root interval I_0 contains all the remaining processors of H. Since pebbles $(0, t)$ and $(n' + 1, t)$ are available at time step 0 by assumption, Theorem 4.4 implies that I_0, i.e., H, computes the pebbles in box B_0 by time $s_{m_0}^{(0)}$. We derive $s_{m_0}^{(0)}$ from the recurrence of $s_t^{(k)}$ in (10) and (11) and the definition of D_k in (7).

$$s_{m_0}^{(0)} = 2^k s_{m_k}^{(k)} + 2kD_0 \text{ for } k = k_{\max}. \tag{13}$$

Therefore, $s_{m_0}^{(0)} \leq \frac{n}{c \log n} + 2cd_{\text{ave}} n \log^2 n = O(d_{\text{ave}} n \log^2 n)$. Since $m_0 = \frac{n}{c \log n}$, the slowdown is $O(d_{\text{ave}} \log^3 n)$. ∎

4.2.4. Bandwidth. It is clear that the bandwidth required for the communication between depth-k intervals is at most the bandwidth of G. Therefore, congestion is not an issue if the bandwidth on H is at least $\log n$ times the bandwidth on G. If, however, the bandwidth on G and H are comparable, then we need to pay an extra factor of $\log n$ in the slowdown.

4.2.5. Improvements. In this section we first modify OVERLAP to achieve work efficiency. So far each host processor is assigned at most one database, and the base of the recurrence is therefore $s_{m_k}^{(k)} = 1$ for $k = k_{\max}$ as defined in (12). Observe that in (13) the second term of $s_{m_0}^{(0)}$ dominates the first term. We can balance the two terms by increasing the value of $s_{m_k}^{(k)}$ for the base case, i.e., increasing the load on the host processors.

In particular, we use an m-processor subarray of the host linear array H to simulate an n-processor guest linear array, where $m = \max\{1, \frac{n}{d_{\text{ave}}} \log^{-3} n\}$ and the subarray has average delay at most d_{ave}. If $m = 1$, the slowdown and the load are both n. Otherwise, we carry out the two-stage process to remove the useless processors of the m-processor subarray as as described in section 4.2.1. The only difference is that the network size is m instead of n, and the variables such as D_k, m_k, and $k_{\max}$ are also defined in terms of m. Each unremoved host processor is assigned $\Theta\left(\frac{n}{m}\right)$ databases, and hence the base case is $s^{(k)}_{m_k} = \Theta\left(\frac{n}{m}\right)$ for $k = k_{\max}$. We obtain

$$s^{(0)}_{m_0} = \Theta\left(\frac{m}{c \log m} \cdot \frac{n}{m} + 2cd_{\text{ave}} m \log^2 m\right)$$

from (13). Since $m = \frac{n}{d_{\text{ave}}} \log^{-3} n$, we have $s^{(0)}_{m_0} = O(n \log^{-1} \frac{n}{d_{\text{ave}}})$. Since $m_0 = \frac{m}{c \log m}$, the slowdown $s^{(0)}_{m_0}/m_0$ is $O(d_{\text{ave}} \log^3 n)$. This implies that the simulation is work preserving.

THEOREM 4.6. *In the database model, an n-processor guest linear array can be efficiently simulated by an n-processor host linear array with a slowdown and a load of $O\left(d_{ave} \log^3 n\right)$, where the host has average delay d_{ave}.*

Combining Theorems 4.1 and 4.6 we can improve the slowdown by a factor of $O(\sqrt{d_{\text{ave}}})$ while preserving efficiency. Suppose that G is an n-processor guest linear array, and H is an n-processor host linear array with average delay d_{ave}. We make use of an intermediate linear array H_0 that has a delay of d_{ave} on every edge. Theorem 4.1 implies that network H_0 can efficiently simulate G with a slowdown of $O(\sqrt{d_{\text{ave}}})$, where $\max\{\frac{n}{\sqrt{d_{\text{ave}}}}, 1\}$ processors of H_0 are used. In the simulation by H_0, every $O(d_{\text{ave}})$ steps of computation interleave with every $O(d_{\text{ave}})$ steps of communication. If we treat every $O(d_{\text{ave}})$ steps as one time unit, then H_0 acts like a guest linear array with unit-delay edges and H has a normalized average delay of $O(1)$. Theorem 4.6 implies that H can simulate H_0 with a slowdown of $O(\log^3 n)$. The combined slowdown is therefore $O(\sqrt{d_{\text{ave}}} \log^3 n)$. It is obvious that the combined load is $O(\sqrt{d_{\text{ave}}} \log^3 n)$. Theorem 4.6 is improved to the following.

THEOREM 4.7. *In the database model, an n-processor guest linear array can be efficiently simulated by an n-processor host linear array with a slowdown and a load of $O(\sqrt{d_{ave}} \log^3 n)$, where the host has average delay d_{ave}.*

4.3. Simulating linear arrays on general networks. We generalize algorithm OVERLAP to simulate a guest linear array on an arbitrary bounded-degree connected host network. Given a connected bounded-degree n-processor network H with average delay d_{ave}, we first find a linear array $\mathcal{H}$ that can be embedded one to one to H and has average delay d_{ave}. As discussed in section 2.4 such $\mathcal{H}$ can be found, and $\mathcal{H}$ is used to carry out the simulation. Combined with Theorem 4.7, we obtain Theorem 4.8.

THEOREM 4.8. *An n-processor guest linear array can be efficiently simulated by a connected bounded-degree n-processor host with a slowdown of $O(\sqrt{d_{ave}} \log^3 n)$, where the host has average delay d_{ave}.*

For the same reason as in section 2.4, Theorem 4.8 does not hold when H has unbounded degree.

4.4. Simulating two-dimensional arrays on general networks. Our techniques can also be generalized to simulate a two-dimensional array on any connected bounded-degree network.

THEOREM 4.9. *In the database model, an $n \times n$ guest can be efficiently simulated by a bounded-degree host network with a slowdown of $O(n \log^3 n + \sqrt{nd_{ave}} \log^3 n)$, where the host has average delay d_{ave}.*

Proof. As discussed in section 2.4 there exists a linear array $\mathcal{H}$ such that $\mathcal{H}$ is embedded one to one in H and that $\mathcal{H}$ has average delay $O(d_{\text{ave}})$. The simulation of G on H will be performed by simulating G on $\mathcal{H}$. We first show how to simulate G on an intermediate linear array $\mathcal{H}_0$, where $\mathcal{H}_0$ has delay d_{ave} on all the edges. The size of $\mathcal{H}_0$ depends on the relative sizes of d_{ave} and n.

Case 1. If $d_{\text{ave}} < n$, then $\mathcal{H}_0$ has n processors, each of which simulates one column of processors of G. To simulate one step of G, a processor of $\mathcal{H}_0$ computes n pebbles and then communicates with both of its neighbors. The communication takes at most $n + d_{\text{ave}}$ steps, which is $O(n)$ steps. Hence the slowdown of $\mathcal{H}_0$ simulating G is $O(n)$. Also, in this simulation every $O(n)$ steps of computation interleave with every $O(n)$ steps of communication.

Since $d_{\text{ave}} < n$, if every $O(n)$ step is treated as one time unit, then $\mathcal{H}$ has a normalized average delay $O(1)$ and $\mathcal{H}_0$ acts like a guest linear array with unit-delay edges. Therefore, Theorem 4.7 implies that $\mathcal{H}$ can efficiently simulate $\mathcal{H}_0$ with a slowdown of $O(\log^3 n)$. The combined slowdown is therefore $O(n \log^3 n)$.

Case 2. If $d_{\text{ave}} \geq n$, then $\mathcal{H}_0$ has n/x processors, where $x = \sqrt{d_{\text{ave}}/n}$. Each processor of $\mathcal{H}_0$ simulates $3x$ columns of G, overlapping x columns with each neighbor. (The redundant computation used here is similar to that in Theorem 4.1.) To simulate x steps of G, each processor of $\mathcal{H}_0$ computes at most $3x^2 n$ pebbles and then communicates with both of its neighbors. The communication takes at most $3x^2 n + d_{\text{ave}}$ steps, which is $O(d_{\text{ave}})$ steps. Hence the slowdown of simulating every x steps is d_{ave}/x, which is $O(\sqrt{nd_{\text{ave}}})$. Also, in this simulation every $O(d_{\text{ave}})$ steps of computation interleave with every $O(d_{\text{ave}})$ steps of communication.

If every $O(d_{\text{ave}})$ step is treated as one time unit, $\mathcal{H}$ has normalized average delay $O(1)$ and $\mathcal{H}_0$ acts like a linear array with unit-delay edges. If n/x processors of $\mathcal{H}$ are used to simulate $\mathcal{H}_0$, Theorem 4.7 implies a slowdown of $O(\log^3 \frac{n}{x})$, which is $O(\log^3 n)$. The combined slowdown is therefore $O(\sqrt{nd_{\text{ave}}} \log^3 n)$. □

The above technique can be applied to the dataflow model, where $\mathcal{H}_0$ simulates G in the same manner and $\mathcal{H}$ simulates $\mathcal{H}_0$ with a slowdown of $O(1)$ in both cases.

THEOREM 4.10. *In the dataflow model, an $n \times n$ guest can be efficiently simulated by a bounded-degree host network with a slowdown of $O(n + \sqrt{nd_{ave}})$, where the host has average delay d_{ave}.*

4.5. Lower bounds. In this section we discuss the impact on the slowdown of the simulation when the number of copies of each database is bounded and the load is a constant. We consider the case in which each database can have one copy and the case in which each database can have at most two copies. Notice that although we are restricting the number of copies of each database to either one or two, a particular processor in the host can have a copy of many databases.

For the case in which each database is allowed one copy we give an example to show that the slowdown can be $d_{\max}$. Let G and H_1 be n-processor guest and host linear arrays. Every $\sqrt{n}$th edge of H_1 has a delay of $\sqrt{n}$, and all other edges have unit delay. Therefore, H_1 has an average delay of $O(1)$. If at most $\sqrt{n}$ processors of H_1 have copies of databases, then by a work argument the slowdown when H_1 simulates G is at least $\sqrt{n}$. Otherwise, there exist databases b_i and b_{i+1} such that they are assigned to processors p and q of H_1, respectively, and that the delay between p and q is at least $\sqrt{n}$. Hence, for all time steps t, processor p cannot compute pebble (i, t)

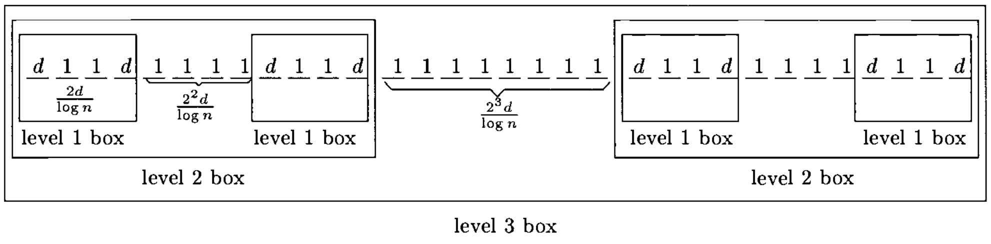

FIG. 12. *A level-3 box. Host network H_2 is a level-k box, where $k = \log \frac{n}{d}$.*

until $\sqrt{n}$ steps after q computes $(i+1, t-1)$, and q cannot compute $(i+1, t)$ until $\sqrt{n}$ steps after p computes $(i, t-1)$. This implies a slowdown of $d_{\max} = \sqrt{n}$, whereas d_{ave} is a constant. Note that the above argument makes no assumption on the load.

THEOREM 4.11. *If each database can have at most one copy, then there exists a host with $d_{ave} = O(1)$ such that the slowdown is $\Omega(\sqrt{n})$.*

For the case in which each database is allowed at most two copies we construct a host network H_2 whose average delay is $O(1)$, but for which the simulation slowdown is $\Omega(\log n)$. Network H_2 is made up of $\Theta(n)$ processors and the edge delays are either 1 or d. The following is a recursive construction of H_2 in which we define a series of boxes. (See Figure 12.) We regard H_2 as a level-k box, where $k = \log \frac{n}{d}$. Network H_2 consists of two level $k-1$ boxes that are connected by $\frac{2^k d}{\log n}$ edges of delay 1. In general, a level-ℓ box, for $1 \le \ell \le k$, consists of two level $\ell - 1$ boxes that are connected by $\frac{2^\ell d}{\log n}$ edges of delay 1. We say that these $\frac{2^\ell d}{\log n}$ processors are in a *segment.* A level-0 box consists of a single edge of delay d.

Let $d = \log n$. Since a level-ℓ box contains 2^ℓ edges of delay d and $\frac{2^\ell d \ell}{\log n}$ edges of delay 1, H_2 has $\Theta(n)$ processors and constant average delay d_{ave}. Furthermore, Lemma 4.12 holds.

LEMMA 4.12. *If processors p and q are in two different segments I and J, then the delay between p and q is at least* $\min\left\{\frac{u}{2}\log n, \frac{v}{2}\log n\right\}$*, where u and v are the numbers of processors in segments I and J, respectively. In particular, the delay between p and q is at least $d = \log n$.*

THEOREM 4.13. *If each database is allowed at most two copies and the load is a constant c, then there exists a host with $d_{ave} = O(1)$ such that the slowdown is $\Omega(\log n)$.*

Proof. We consider the following two cases when H_2 simulates G.

Case 1. There exists some "overlap" in the database assignment. In particular, suppose databases b_i, $b_{i+1}, \ldots,$ b_{i+j} are assigned to processors in segment I and $b_{i+1}, \ldots,$ b_{i+j}, b_{i+j+1} are assigned to segment $J \ne I$ for some $j \ge 1$. Suppose also that the other copy of b_{i+j+1} is assigned to $J' \ne I$ and the other copy of b_i is assigned to $I' \ne J$. Notice that pebbles of the form $(i+k, t)$, for $1 \le k \le j$, can only be computed by processors in segment I or J. Since the load is c, the number of processors in segment I is at least j/c. The same is true for segment J. We shall find a path of $4j$ pebbles such that either a delay of $O(j \log n)$ occurs, or a delay of $\log n$ occurs $O(j)$ times during the simulation. For simplicity we assume that j is even. The case in which j is odd is similar.

We use a triple (i, t, p) to say that processor p computes pebble (i, t), and we use expressions of the form $(i, t, p) \leftarrow (i-1, t-1, q)$ to indicate dependency. That is, processor p receives pebble $(i-1, t-1)$ from processor q before p computes (i, t).

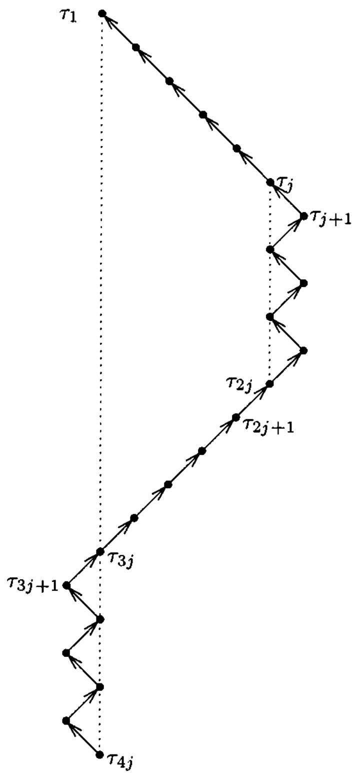

FIG. 13. *A path of* $4j$ *pebbles, where* j *is even.*

(Note that p may be the same as q.) Consider the computation of the following path of $4j$ pebbles, $\tau_1 \leftarrow \cdots \leftarrow \tau_{4j}$, where τ_k is a triple of the form

$$\tau_k = \begin{cases} (i+k, t-k, p_k) & \text{for } k \in A, \text{ where } \quad A = \{k : 1 \le k \le j\}, \\ (i+j+1, t-k, p_k) & \text{for } k \in B, \text{ where } \quad B = \{k \text{ odd} : j < k \le 2j\}, \\ (i+j, t-k, p_k) & \text{for } k \in C, \text{ where } \quad C = \{k \text{ even} : j < k \le 2j\}, \\ (i-k+3j, t-k, p_k) & \text{for } k \in D, \text{ where } \quad D = \{k : 2j < k \le 3j\}, \\ (i+1, t-k, p_k) & \text{for } k \in E, \text{ where } \quad E = \{k \text{ even} : 3j < k \le 4j\}, \\ (i, t-k, p_k) & \text{for } k \in F, \text{ where } \quad F = \{k \text{ odd} : 3j < k \le 4j\}. \end{cases}$$

This path goes backward in time and zigzags during time steps k for $k \in B \cup C \cup E \cup F$. (See Figure 13.)

By assumption, processors p_k, for $k \in C \cup E$, can only belong to segment I or J. If processors p_k, for $k \in C \cup E$, do not belong to the same segment, then Lemma 4.12 implies a delay of $\frac{j}{2c} \log n$ for the communication between segments I and J. Hence, it takes more than $\frac{j}{2c} \log n$ steps to compute this path of $4j$ pebbles. Otherwise, processors p_k, for $k \in C \cup E$, all belong to segment I. Lemma 4.12 implies a delay of $\log n$ in computing every τ_k for $j < k \le 2j$. This is because processors p_k, for $k \in B$, cannot be in segment I by assumption. Similarly, if processors p_k, for $k \in C \cup E$, all belong to segment J, then there is a delay of $\log n$ in computing every τ_k for $3j < k \le 4j$. Hence, it takes more than $j \log n$ steps to compute this path of $4j$ pebbles.

We can repeat this argument for every $4j$ steps. Hence the slowdown is $\Omega(\log n)$.

Case 2. There exists no "overlapping" of the databases as in Case 1. Let $b_i, \ldots, b_j$, for $j \geq i$, be the longest sequence of consecutive databases assigned to one segment. Call this segment I and the sequence of databases S_I. Notice that processors in I do not have a copy of b_{i-1}. Let J be a segment that is assigned a copy of b_{i-1}. Let S_J be the sequence of consecutive databases such that b_{i-1} is a member of S_J and that each member of S_J has a copy in J. If b_i were a member of S_J, then either the database sequences S_J and S_I would produce the "overlapping" pattern sufficient for Case 1 or S_J would be longer than S_I. This latter case contradicts the definition of S_I. Hence, any segment that has a copy of b_{i-1} cannot have a copy of b_i. This implies that the processors computing the pebbles in the $(i-1)$st and ith column are at least $\log n$ delay apart by Lemma 4.12. Therefore, the slowdown is $\Omega(\log n)$. □

5. Conclusions.

In this paper we presented methods for latency hiding in simple networks such as linear arrays and two-dimensional arrays. Ultimately, we are interested in the efficient implementation of algorithms designed for networks that appear often in the architectures of parallel computers, such as trees, arrays, butterflies, and hypercubes, on a network with arbitrary topology and arbitrary link delays, such as NOWs. The special case in which two networks have identical topology but different link delays is a starting point where we can study the effect of latencies in isolation. Indeed, the general case of simulating a unit-delay guest on a host with arbitrary delays and arbitrary topology so as to minimize slowdown seems to be a very challenging problem.

IMPROVED APPROXIMATION GUARANTEES FOR PACKING AND COVERING INTEGER PROGRAMS[*]

ARAVIND SRINIVASAN[†]

Abstract. Several important NP-hard combinatorial optimization problems can be posed as *packing/covering integer programs*; the *randomized rounding* technique of Raghavan and Thompson is a powerful tool with which to approximate them well. We present one elementary unifying property of all these integer linear programs and use the FKG correlation inequality to derive an improved analysis of randomized rounding on them. This yields a *pessimistic estimator*, thus presenting deterministic polynomial-time algorithms for them with approximation guarantees that are significantly better than those known.

1. Introduction.

Several important NP-hard combinatorial optimization problems, such as basic problems on graphs and hypergraphs, can be posed as *packing/covering integer programs*; the *randomized rounding* technique of Raghavan and Thompson is a powerful tool with which to approximate them well [30]. We present an elementary property (*positive correlation*) of all these integer linear programs (ILPs); we then use the FKG inequality (Fortuin, Kasteleyn, and Ginibre [14], Sarkar [31]) to derive an improved analysis of randomized rounding on the problems. Interestingly, this yields a *pessimistic estimator*, thus presenting deterministic polynomial algorithms with approximation guarantees that are significantly better than those known, in a unified way.

1.1. Previous work.

Let Z_+ and $\Re_+$ denote the nonnegative integers and the nonnegative reals, respectively. For a (column) vector v, let v^T denote its transpose and let v_i stand for the ith component of v. We first define the packing and covering integer programs.

DEFINITION 1.1. *Given $A \in [0,1]^{n\times m}$, $b \in [1,\infty)^n$, and $c \in [0,1]^m$ with $\max_j c_j = 1$, a packing (respectively, covering) integer program (PIP) (respectively, CIP) seeks to maximize (respectively, minimize) $c^T \cdot x$ subject to $x \in Z_+^m$ and $Ax \leq b$*

(respectively, $Ax \geq b$). Furthermore if $A \in \{0,1\}^{n \times m}$, we assume that each entry of b is integral. We also define $B = \min_i \ b_i$; we assume without loss of generality (w.l.o.g.) that $B \geq 1$.

Although there usually are no restrictions on the entries of A, b, and c beyond nonnegativity, it is easily seen that the above restrictions are w.l.o.g. because of the following. First, we may assume that $\forall i,j$, A_{ij} is at most b_i. If this is not true for a PIP, then we may as well set $x_j := 0$; if this is not true for a CIP, we can reset $A_{ij} := b_i$. Next, by scaling each row of A such that $\max_j \ A_{i,j} = 1$ for each row i and by scaling c so that $\max_j \ c_j = 1$, we get the above form for A, b, and c. (In particular, we get $B \geq 1$ since $A_{i,j} \leq b_i \ \forall i,j$.) Finally, if $A \in \{0,1\}^{n \times m}$, then for a PIP we can always reset $b_i := \lfloor b_i \rfloor$ for each i, and for a CIP we can reset $b_i := \lceil b_i \rceil$, hence the assumption on the integrality of each b_i in this case.

Remark. The reader is requested to take note of the parameter B; it will occur frequently in the rest of the paper. Whenever we use the symbol B as a parameter for any given problem, B will play the same role in the "natural" PIP/CIP formulation of the problem, as it does in Definition 1.1.

As mentioned above, PIPs and CIPs model some basic problems in combinatorial optimization, but most of these problems are NP-hard; hence we are interested in efficient approximation algorithms for PIPs and CIPs with a good performance guarantee. We now turn to an important technique for approximating integer linear programs—"relaxing" their integrality constraints and considering the resulting linear program.

DEFINITION 1.2. *The standard linear programming (LP) relaxation of PIPs/CIPs lets $x \in \Re_+^m$; given a PIP/CIP, x^* and y^* denote, respectively, an optimal solution to, and the optimum value of, this relaxation. (For packing, we also allow constraints of the form $x_i \in \{0,1,\ldots,d_i\}$, where d_i is some positive integer; the LP relaxation sets $x_i \in [0,d_i]$ here.)*

Given a PIP or a CIP, we can solve its LP relaxation efficiently. However, how do we handle the possibility of possibly fractional entries in x^*? We need some mechanism to "round" fractional entries in x^* to integers, suitably. One possibility is to round every fractional value x_i^* to the closest integer, with some tie-breaking rule if x_i^* is half of an integer. However, it is known that such "thresholding" methods are of limited applicability.

A key technique with which to approximate a class of integer programming problems via a new rounding method—*randomized rounding*—was proposed in [30]. Given a positive real v, the idea is to look at its fractional part as a probability: round v to $\lfloor v \rfloor + 1$ with probability $v - \lfloor v \rfloor$, and round v to $\lfloor v \rfloor$ with probability $1 - v + \lfloor v \rfloor$. This has the nice property that the expected value of the result is v. How can we use this for packing and covering problems? Consider a PIP, for instance. Solve its LP relaxation and set $x_i' := x_i^*/\alpha$ for some parameter $\alpha > 1$ to be fixed later; this scaling down by α is done to boost the chance that the constraints in the PIP are all satisfied; recall that they are all $\leq$-constraints. Now define a random $z \in Z_+^m$, the outcome of randomized rounding, as follows. Independently for each i, set z_i to be $\lfloor x_i' \rfloor + 1$ with probability $x_i' - \lfloor x_i' \rfloor$ and $\lfloor x_i' \rfloor$ with probability $1 - (x_i' - \lfloor x_i' \rfloor)$.

We now need to show that all the constraints in the PIP are satisfied *and* that $c^T \cdot z$ is not "much below" y^*, with reasonable probability; we also need to choose α suitably. This is formalized in [30] as follows. In what follows, let $\Pr(\mathcal{E})$ denote the probability of an event $\mathcal{E}$ and $\mathbf{E}[X]$ denote the expected value of random variable X.

As seen above, an important observation is that $\mathbf{E}[z_i] = x'_i$. Hence,

$$\mathbf{E}[(Az)_i] = (Ax')_i \leq b_i/\alpha,\ 1 \leq i \leq n; \quad \mathbf{E}[c^T \cdot z] = y^*/\alpha.$$

For some $\beta > 1$ to be fixed later, define $(n+1)$ "bad" events

$$E_i \equiv ((Az)_i > b_i),\ 1 \leq i \leq n; \quad E_{n+1} \equiv (c^T \cdot z < y^*/(\alpha\beta)). \tag{1.1}$$

Now, z is an $(\alpha\beta)$-approximate solution to the PIP if

$$\bigwedge_{i=1}^{n+1} \overline{E_i} \neq \phi \tag{1.2}$$

holds. How small a value for $(\alpha\beta)$ can we achieve while still guaranteeing (1.2)? Bounding

$$\Pr\left(\bigvee_{i=1}^{n+1} E_i\right) \leq \sum_{i=1}^{n+1} \Pr(E_i), \tag{1.3}$$

we can pick $\alpha, \beta > 1$ such that $\sum_{i=1}^{n+1} \Pr(E_i) < 1$ holds, using the Chernoff–Hoeffding (CH) bounds. This gives us an $(\alpha\beta)$-aproximation z with nonzero probability, which is also made deterministic by Raghavan, using pessimistic estimators [28]. Similar ideas hold for CIPs—the fractions $\{x_i^*\}$ are scaled *up* by some $\alpha > 1$ here. Similar approximation bounds are derived through different methods by Plotkin, Shmoys, and Tardos [27]. See Raghavan [29] for a survey of randomized rounding and Crescenzi and Kann [9] for a comprehensive collection of approximation results on NP-optimization problems.

Although randomized rounding is a unifying idea with which to derive good approximation algorithms, there are better approximation bounds for specific key problems such as set cover (Johnson [21], Lovász [23], Chvátal [8]), hypergraph matching (Aharoni, Erdős, and Linial [1]), and file-sharing in distributed networks (Naor and Roth [26]), each derived through different means. (For instance, for the set cover problem, which will be defined soon, let n denote the number of vertices of a given hypergraph H and $d \leq n$ be the maximum number of vertices in any edge of H. The analysis of randomized rounding via (1.3) for appropriately defined events E_i yields an approximation of $\mathrm{O}(\ln n)$. However, an $\mathrm{O}(\log d)$ approximation is provided in [21], [23], [8].) One reason for this slack stems from bounding $\Pr(\bigvee_{i=1}^{n+1} E_i)$ by $\sum_{i=1}^{n+1} \Pr(E_i)$: to quote Raghavan [28],

> Throughout, we naively (?) sum the probabilities of all bad events—although these bad events are surely correlated. Can we prove a stronger result using algebraic properties (e.g., the rank) of the coefficient matrix? A tighter bound for the probabilistic existence proofs should lead to tighter approximation algorithms.

1.2. Proposed method. We make progress in the above-suggested direction by exploiting an elementary property—positive correlation—of CIPs and PIPs. To motivate this idea, let us take two constraints of a PIP and let E_1 and E_2 be the corresponding bad events, as defined before. For instance, suppose E_1 is the event that $0.1z_1 + z_3 + 0.5z_4 + 0.9z_6 > 1.1$ and E_2 stands for the event that $0.4z_1 + 0.3z_2 + z_5 + 0.1z_6 > 1.2$, where the z_i are all *independent* 0-1 random variables. Now suppose we are given that $\overline{E_1}$ holds. Very roughly speaking, this seems to suggest that "many" among z_1, z_3, z_4, and z_6 were "small" (i.e., zero), which seems to boost the chance that $\overline{E_2}$ holds, too. Formally, the claim is that $\Pr(\overline{E_2}|\overline{E_1}) \geq \Pr(\overline{E_2})$, i.e., that $\Pr(\overline{E_1} \bigwedge \overline{E_2}) \geq \Pr(\overline{E_1}) \cdot \Pr(\overline{E_2})$. This "intuitively clear" fact then can be easily generalized to

$$\forall k\ \forall 1 \leq i_1 < i_2 < \cdots < i_k \leq n, \ \Pr\left(\bigwedge_{j=1}^{k} \overline{E_{i_j}}\right) \geq \prod_{j=1}^{k} \Pr(\overline{E_{i_j}}). \tag{1.4}$$

In other words, (1.4) claims that the constraints are positively correlated—given that all of any given subset of them are satisfied, the conditional probability that any other constraint is also satisfied cannot go below its unconditional probability.

We prove (1.4), which seems plausible, using the FKG inequality. Thus,

$$\Pr\left(\bigvee_{i=1}^{n+1} E_i\right) \leq \Pr\left(\bigvee_{i=1}^{n} E_i\right) + \Pr(E_{n+1}) \leq 1 - \left(\prod_{i=1}^{n} (1 - \Pr(E_i))\right) + \Pr(E_{n+1}), \tag{1.5}$$

which is always as good as, and most often much better than, (1.3). (For a detailed study of the FKG inequality, see, e.g., Graham [15] and Chapter 6 of Alon, Spencer, and Erdős [3].)

It is not hard to verify such a property for CIPs also. Why have we been so lucky as to have positive correlation among the constraints of PIPs and CIPs? The features of PIPs and CIPs which guarantee this are

- all the entries of the matrix A are nonnegative, and
- all the constraints "point" in the same direction.

Of course, given that all of any given subset of the constraints are *violated*, the conditional probability that any other constraint is also violated cannot go below its unconditional probability; however, we will not have to deal with this situation! Also, (1.4) may not hold if the z_i's are not independent.

This approach usually only guarantees that z is a "good" approximation with very low (albeit positive) probability; it does not seem to provide a randomized algorithm with any good success probability. However, the structure of PIPs and CIPs implies a subadditivity property that yields a *pessimistic estimator* (a notion to be recalled in section 2); we thus get deterministic polynomial-time algorithms achieving these improved approximation bounds. The problem in arriving at a good pessimistic estimator is that while the previous estimator $\sum_{i=1}^{n+1} \Pr(E_i)$ (i.e., the one used in [28] and in related papers) is upper-bounded by $\mathbf{E}[Z]$ (for some random variable Z) on applying the CH bounds, such a fact does not seem to hold here. Nevertheless, the structure of CIPs/PIPs—in particular, the two simple properties itemized above—help to provide a good pessimistic estimator. This is a point that we would like to stress.

Thus we get, in a unified way, improved bounds on the *integrality gap*

$$\max\{(c^T \cdot z)/y^*, y^*/(c^T \cdot z)\}$$

and hence improved approximation algorithms for all PIPs and CIPs. In particular, we improve on the above-mentioned results of [21], [23], [1], [26]; our bound is incomparable with that of [8].

Positive correlation has been used in the context of network reliability by Esary and Proschan [11]; see, e.g., Chapter 4.1 in [32]. It has also been used for the set cover problem, an important covering problem, to be defined below, by Bertsimas and Vohra [5].

1.3. Approximation bounds achieved. Our best improvements are for PIPs. For PIPs, the standard analysis of randomized rounding, i.e., the usage of (1.3), guarantees integral solutions of value $t_1 = \Omega(y^*/n^{1/B})$ and $t_2 = \Omega(y^*/n^{1/(B+1)})$, respectively, if $A \in [0,1]^{n\times m}$ and $A \in \{0,1\}^{n\times m}$. (For completeness, we prove this in the appendix.) Our method provides $\Omega(\min\{y^*, (K_0 t_1)^{B/(B-1)}\})$ and $\Omega(\min\{y^*, t_2^{(B+1)/B}\})$ bounds, respectively, where $0 < K_0 < 1$ is an absolute constant, thus improving on the previous solutions. For instance, if $A \in \{0,1\}^{n\times m}$, $y^* = \Theta(n)$, and $B = 1$, we get an integral solution of value $\Theta(n)$, as opposed to the previous $\Omega(\sqrt{n})$ bound. This method also gives Turán's classical theorem on independent sets in graphs [39] to within a constant factor.

An important packing problem where $A \in \{0,1\}^{n\times m}$ is *simple B-matching in hypergraphs* [23]: given a hypergraph with nonnegative edge weights, find a maximum weight collection of edges such that no vertex occurs in more than B of them. Usual hypergraph matching has $B = 1$ and is a well-known NP-hard problem. To our knowledge, the only known good bound for this problem, apart from the standard analysis of randomized rounding, was provided by the work of [1], which focused on the special case of *unweighted* edges. The methods of [1] can be used to show that if f is the minimum size of an edge in the hypergraph, then there exists an integral matching of value at least

$$\frac{(y^*)^2}{B^2 n - (f-1)(y^*)^2/\min\{m,n\}} \geq \frac{(y^*)^2}{B^2 n}.$$

This matches our result to within a constant factor for $B = 1$. However, this bound *worsens* as B increases, while the standard analysis, as well as our present analysis, of randomized rounding show that the integrality gap decreases as B increases. (An interesting point is that approximation algorithms for packing and covering often have an approximation ratio that is independent of y^*. The work of [1], and our work here, are exceptions.)

For covering, we prove an

$$1 + \mathrm{O}(\max\{\ln(nB/y^*)/B, \sqrt{\ln(2\lceil nB/y^*\rceil)/B}\}) \tag{1.6}$$

integrality gap and derive the corresponding deterministic polynomial-time approximation algorithm. (To parse the "$\ln(2\lceil t\rceil)$" term for $t > 0$, first take "t large" (say, $t \geq 2$) to be the typical case, wherein the term equals $\ln t + \Theta(1)$. If t is "small," say, $t < 2$, then the term is $\Theta(1)$.) This improves on the

$$1 + \mathrm{O}(\max\{(\ln n)/B, \sqrt{(\ln n)/B}\})$$

bound given by the standard analysis of randomized rounding. Also, Dobson [10] and Fisher and Wolsey [13] bound the performance of a natural greedy algorithm for CIPs; their results are as follows. For a given CIP, let $\gamma_1 = \min_i \max_j A_{i,j}/c_j$, and let $\gamma_2 = \max_j(\sum_{i=1}^n A_{i,j}/c_j)$. Then the work of [13] shows that the greedy algorithm produces a solution of value at most $y^*(1 + \ln(\gamma_2/\gamma_1))$. Alternatively, if each row of the linear system $Ax \geq b$ is scaled so that the minimum nonzero entry in the row is at least 1, then if OPT denotes the value of the optimal *integral* solution to the CIP, it is shown in [10] that the greedy algorithm produces a solution of value at most $OPT(1 + \ln(\max_j \sum_{i=1}^n A_{i,j}))$. However, more general covering problems that have constraints of the form $x_j \leq u_j$ are also considered in [10]. Our bound is incomparable with these previous bounds, but for any given (A, b, c), our bound is always better for CIP instances parametrized by $(A, \lambda b, c)$ if the scalar λ is more than a certain threshold thresh(A, b, c). See [5] for a detailed study of approximating CIPs; our work improves on all of their randomized rounding bounds except for their *weighted* CIPs (wherein it is not the case that $c_i = 1$ for all i), for which our bounds are incomparable with theirs.

An important subclass of the CIPs models the *unweighted set cover problem*: $\forall i, j$, $A_{i,j} \in \{0, 1\}$, $b_i = 1$, and $c_j = 1$, here. The combinatorial interpretation is that we have a hypergraph $H = (V, E)$ and wish to pick a minimum cardinality collection of the edges so that every vertex is covered. (When viewed as an LP, this is the "dual" of the hypergraph matching problem.) The rows correspond to V and the columns to E. Clearly, this problem requires that $x \in \{0, 1\}^m$, which is not guaranteed by Definition 1.1; however, for this problem, any $x \in Z_+^m$ with $Ax \geq b$ trivially yields a $y \in \{0, 1\}^m$ with $Ay \geq b$ and $c^T \cdot y \leq c^T \cdot x$ (set $y_i = \min\{1, x_i\}$).

For set cover, we tighten the constants in (1.6) to derive a $\ln(n/y^*) + \ln\ln(n/y^*) + \mathrm{O}(1)$ approximation bound. Recent work of Feige [12], improving earlier results of [24], [4], shows that for any fixed $\epsilon > 0$, approximating this problem to within $(1 - \epsilon) \ln n$ is likely to take superpolynomial time. However, this problem is important enough to study approximations parametrized by other parameters of A, b, and c that are at least as good as and often much better than $\Theta(\log n)$; for instance, the work of [21], [23], [8] shows a $\ln d + \mathrm{O}(1)$ approximation bound, where d is the maximum column sum in A; note that $d \leq n$. Also, since there is a trivial solution of size n for any set cover instance, n/y^* is a simple upper bound on the approximation ratio. Our bound is a further improvement—it is easily seen that $n/y^* \leq d$ always and that there is a constant $\ell > 0$ such that for every nondecreasing function $f(n)$ with $1 \leq f(n) \leq \ell \ln n / \ln\ln n$, there exist families of (A, b, c) such that

$$\ln(n/y^*) \leq \min\{n/y^*, \ln d\}/f(n).$$

Thus our bound is never more than a multiplicative $(1 + o(1))$ factor above the classical bound and is usually much better; in the best case, our improvement is by $\Theta(\log n / \log\log n)$. (We can construct, e.g., instances with $d = n^{\Theta(1)}$ and $y^* = n/\log^{\Theta(1)} n$, giving a $\Theta(\log n/\log\log n)$ improvement.)

Another noteworthy class of CIPs is related to the B-domination problem: given a (directed) graph G with n vertices, we want to place a minimum number of facilities on the nodes such that every node has at least B facilities in its out-neighborhood. This is also a key subproblem in sharing files in a distributed system [26]; under the assumption that G is undirected and letting Δ be its maximum degree, an

$$1 + \mathrm{O}(\max\{\ln(\Delta)/B, \sqrt{\ln(\Delta)/B}\})$$

approximation bound is presented in [26], improving on the standard analysis of randomized rounding. Bound (1.6) improves further on this; in particular, even if G is directed with maximum in-degree Δ, (1.6) shows that the Naor–Roth bound holds. Furthermore, the comments regarding the $\Theta(\log n/\log\log n)$ improvement for set cover hold even in the undirected case. All of this, in turn, provides better bounds for the file-sharing problem.

Thus, the two main contributions of this work are as follows. First, we identify a very desirable "correlation" property of all packing and covering integer programs, which enables one to prove, quite easily, improved bounds on the integrality gap for the linear relaxations of these problems. However, as shown in section 4, this is often not constructive, since the probability of randomized rounding resulting in such good approximations can be (and usually is) negligibly small; section 4 shows a simple family of instances where this "success probability" is as small as $\exp(-\Omega(n+m))$. The second contribution is in showing that the structure of PIPs and CIPs presents a suitable pessimistic estimator (see section 2 for the definition), which allows one to obtain such approximations efficiently.

In section 2, we present some basic notions such as large-deviation inequalities, the FKG inequality, and the idea of pessimistic estimators. Section 3 covers PIPs. We devote section 4 to the important problem of finding a maximum independent set problem on graphs by looking at it in the usual way as a PIP. Its analysis shows the strengths and weaknesses of both our approach and related approaches. Section 5 deals with CIPs; a good understanding of section 3 is essential for this section. Section 6 concludes.

2. Preliminaries.

Let r.v. abbreviate "random variable" and for any positive integer k, let $[k]$ denote the set $\{1, 2, \ldots, k\}$. If a universe $N = \{a_1, a_2, \ldots, a_\ell\}$ is understood, then for any $S \subseteq N$, $\chi(S)$ denotes its characteristic vector: $\chi(S) \in \{0,1\}^\ell$ with $\chi(S)_j = 1$ iff $a_j \in S$. For a sequence $s_1, s_2, \ldots$ and any integer $i \geq 1$, $s^{(i)}$ denotes the vector $(s_1, s_2, \ldots, s_i)$. In our usage, $s_1, s_2, \ldots$ could be a sequence of reals or of random variables. For any i, any vector $w \in \{0,1\}^i$, and for $j \in \{0,1\}$, we define $wj \in \{0,1\}^{i+1}$ as $(w_1, w_2, \ldots, w_i, j)$. As usual, e denotes the base of the natural logarithm. We let $\exp(x)$ denote e^x.

Remark. The following is filled with formulae and calculations, many of them routine. The real ideas of this work are contained in Lemmas 3.1, 3.5, and 3.6. The reader might consider skipping the proofs of most of the rest of the lemmas, for the first reading.

We first recall the CH bounds for the tail probabilities of sums of bounded independent random variables (r.v.'s) [7], [19]. Theorem 2.1 presents these tail bounds; see, e.g., Motwani and Raghavan [25] for the proofs.

THEOREM 2.1. *Let $X_1, X_2, \ldots, X_\ell$ be* independent *r.v.'s, each taking values in* $[0,1]$*, with $R = \sum_{i=1}^{\ell} X_i$ and $\mathbf{E}[R] = \mu$. For any $\delta \geq 0$,*

$$\Pr(R \geq \mu(1+\delta)) < \mathbf{E}[(1+\delta)^{R-\mu(1+\delta)}] \leq G(\mu,\delta) \doteq (\exp(\delta)/(1+\delta)^{(1+\delta)})^\mu,$$

and if $0 \leq \delta < 1$*,*

$$\Pr(R \leq \mu(1-\delta)) < \mathbf{E}[(1-\delta)^{R-\mu(1-\delta)}] \leq H(\mu,\delta) \doteq \exp(-\mu\delta^2/2). \qquad \square$$

The following fact is easily seen.

FACT 1.

(a) $G(\mu,\delta) \leq (e/(1+\delta))^{(1+\delta)\mu}$.

(b) $G(\mu,\delta) \leq \exp(-\delta^2\mu/3)$ *if* $\delta \leq 1$.

(c) $G(\mu,\delta) \leq \exp(-(1+\delta)\ln(1+\delta)\mu/4)$ *if* $\delta \geq 1$.

(d) *If* $0 < \mu_1 \leq \mu_2$*, then* $G(\mu_1,\delta) \geq G(\mu_2,\delta)$.

Call a family $\mathcal{F}$ of subsets of a set N *monotone increasing* (respectively, *monotone decreasing*) if $\forall S \subseteq T \subseteq N$, $S \in \mathcal{F}$ implies that $T \in \mathcal{F}$ (respectively, $T \in \mathcal{F}$ implies that $S \in \mathcal{F}$). We next present Theorem 2.2, a special case of the powerful FKG inequality [14], [31]; for a proof, see, e.g., Chapter 6 of [3].

THEOREM 2.2. *Given a set $N = \{a_1, a_2, \ldots, a_\ell\}$ and some $p = (p_1, p_2, \ldots, p_\ell) \in [0,1]^\ell$, suppose we pick a random $Y \subseteq N$ by placing each a_i in Y* independently*, with probability p_i. For any $\mathcal{F} \subseteq 2^N$, let $Pr_p(\mathcal{F}) \doteq \Pr(Y \in \mathcal{F})$. Let $F_1, F_2, \ldots, F_s \subseteq 2^N$*

be any sequence of monotone increasing families, and let $G_1, G_2, \ldots, G_s \subseteq 2^N$ be any sequence of monotone decreasing families. Then,

$$Pr_p\left(\bigwedge_{i=1}^{s} F_i\right) \geq \prod_{i=1}^{s} Pr_p(F_i) \quad \textit{and} \quad Pr_p\left(\bigwedge_{i=1}^{s} G_i\right) \geq \prod_{i=1}^{s} Pr_p(G_i).$$

Finally, we recall the notion of *pessimistic estimators* [28]. For our purposes, we focus on the case of independent binary r.v.'s. Let $X_1, X_2, \ldots, X_\ell \in \{0,1\}$ be independent r.v.'s with $\Pr(X_i = 1) = p_i$, for some $p \in [0,1]^\ell$. Suppose, for some implicitly defined $L \subseteq \{0,1\}^\ell$, that $\Pr(X^{(\ell)} \in L) < 1$. Our goal is to find some $v \in \{0,1\}^\ell - L$ efficiently. Theorem 2.4 presents the idea of pessimistic estimators applied to the method of conditional probabilities as a means to achieve this goal. See [28] for a detailed discussion and proof. We define as follows.

Definition 2.3. *A function $U : [0,1]^\ell \to \Re^+$ is a pessimistic estimator with respect to $(X_1, \ldots, X_\ell)$ and L if*

(1) *$U(p_1, p_2, \ldots, p_\ell) < 1$, and*

(2) *$\forall i \in (\{0\} \cup [\ell])\ \forall w \in \{0,1\}^i$,*

  (a) *$U(w_1, \ldots, w_i, p_{i+1}, \ldots, p_\ell) \geq \Pr(X^{(\ell)} \in L | X^{(i)} = w)$, and*

  (b) *if $i \leq \ell - 1$, then $U(w_1, \ldots, w_i, p_{i+1}, \ldots, p_\ell)$ is at least as large as*

$$\min\{U(w_1, \ldots, w_i, 0, p_{i+2}, \ldots, p_\ell), U(w_1, \ldots, w_i, 1, p_{i+2}, \ldots, p_\ell)\}.$$

Theorem 2.4 (see [28]). *Let U be a pessimistic estimator with respect to $(X_1, \ldots, X_\ell)$ and L. The following algorithm produces a vector $v \notin L$:*

```
For $i := 0$ to $\ell - 1$ do
  if $U(v_1, \ldots, v_i, 0, p_{i+2}, \ldots, p_\ell) \leq U(v_1, \ldots, v_i, 1, p_{i+2}, \ldots, p_\ell)$, then $v_{i+1} := 0$, else $v_{i+1} := 1$.
```

Proof. It is not hard to see by induction on i that $\forall i \in \{0\} \cup [\ell]$, $\Pr(X^{(\ell)} \in L | X^{(i)} = v^{(i)}) < 1$. Using this for $i = \ell$ in conjunction with property 2(a) of Definition 2.3 completes the proof. ◻

The efficiency of the algorithm depends on how efficiently we can compute U. Also note that for the proof of Theorem 2.4, it suffices if property 2(a) of Definition 2.3 holds just for $i = \ell$.

3. Approximating PIPs.

Let a PIP be given, conforming to Definition 1.1. We assume that $x \in Z_+^m$ is the constraint on x. (Clearly, even if we have constraints such as $x_i \in \{0, 1, \ldots, d_i\}$, we will get identical bounds since scaling down by $\alpha > 1$ and then performing a randomized rounding cannot make $x_i \notin \{0, 1, \ldots, d_i\}$.) Lemmas 3.1 and 3.6 are crucial, wherein the structure of PIPs is exploited. It is essential to read this section before reading section 5—some proofs are omitted in section 5 since they are very similar to the ones in this section.

We solve the LP relaxation and let the scaling by α, events $E_1, E_2, \ldots, E_{n+1}$, and vectors z, x', etc., be as in section 1.1; α and β will be determined later. The main point of this section is to show that good integral solutions exist and to present a candidate for a pessimistic estimator (see (3.3)). We show that this estimator satisfies the conditions of Definition 2.3, and we invoke Theorem 2.4 to show that we can constructivize the existence proof for the improved integrality gap. The work of this section culminates in Theorem 3.7.

We first set up some notation to formulate our "failure probability." For every $j \in [m]$, let $s_j = \lfloor x'_j \rfloor$ and $p_j = x'_j - s_j \in [0,1)$. Let A_i denote the ith row of A. Let

$X_1, X_2, \ldots, X_m \in \{0,1\}$ be *independent* r.v.'s with $\Pr(X_j = 1) = p_j \; \forall j \in [m]$, and let $X \doteq X^{(m)}$. It is clear that

$$E_i \equiv \text{“}A_i \cdot X > \mu_i(1+\delta_i)\text{”} \;\forall i \in [n] \quad \text{and that} \quad E_{n+1} \equiv \text{“}c^T \cdot X < \mu_{n+1}(1-\delta_{n+1})\text{”},$$

where $\mu_i = \mathbf{E}[A_i \cdot X]$ and

$$\delta_i = (b_i - A_i \cdot s)/\mu_i - 1$$

for $i \in [n]$, $\mu_{n+1} = \mathbf{E}[c^T \cdot X]$, and

$$\delta_{n+1} = 1 - (y^*/(\alpha\beta) - \; c^T \cdot s)/\mu_{n+1}.$$

It is readily verified that $\delta_i \geq 0 \; \forall i \in [n]$ and that $\delta_{n+1} \geq 0$. Also, since $c^T \cdot X \geq 0$ with probability 1, we may assume that β is not so large that $\delta_{n+1} \geq 1$: if $\delta_{n+1} \geq 1$, then $\Pr(E_{n+1}) = \Pr(c^T \cdot X < \mu_{n+1}(1-\delta_{n+1})) = 0$, and the bad event E_{n+1} will never happen. Thus, we may assume that $0 \leq \delta_{n+1} < 1$.

Our first objective is to prove (1.4) and hence (1.5) using Theorem 2.2; this will also suggest a choice for a pessimistic estimator. In the notation of Theorem 2.2, $N = [m]$ and $Y = \{i \in N : X_i = 1\}$. For each $i \in [n]$, define $F_i \subseteq 2^N$ as

$$\{S \subseteq N : (A_i \cdot \chi(S)) \leq \mu_i(1+\delta_i)\}.$$

It is easy to see that *each* F_i *is monotone decreasing.* Since $\overline{E_i} \equiv (Y \in F_i)$ for each i, we deduce (1.4) from Theorem 2.2. In fact, a similar proof shows that since the components of X are picked *independently*, we have the following lemma.

LEMMA 3.1. *For any* $j \in \{0\} \cup [m]$ *and any* $w \in \{0,1\}^j$,

$$\Pr\left(\bigvee_{i=1}^{n+1} E_i | X^{(j)} = w\right) \leq 1 - \left(\prod_{i=1}^{n}(1 - \Pr(E_i|X^{(j)} = w))\right) + \Pr(E_{n+1}|X^{(j)} = w). \qquad \square$$

Let

$$F_{n+1} = \{S \subseteq [m] : c^T \cdot \chi(S) \geq \mu_{n+1}(1-\delta_{n+1})\}.$$

In the notation of Definition 2.3, the set to be avoided, L, is

$$\{x \in \{0,1\}^m : \exists i \in [n+1] \;\; \chi^{-1}(x) \notin F_i\}.$$

We next upper-bound $\Pr(E_i)$ for each i. Recall, by Theorem 2.1, that for each $i \in [n]$, $\Pr(E_i) \leq G(\mu_i, \delta_i)$; also, $\Pr(E_{n+1}) \leq H(\mu_{n+1}, \delta_{n+1})$. Lemma 3.2 upper-bounds these quantities.

LEMMA 3.2. (a) *For every* $i \in [n]$, $G(\mu_i, \delta_i) \leq G(b_i/\alpha, \alpha - 1) \leq G(B/\alpha, \alpha - 1)$.
(b) $H(\mu_{n+1}, \delta_{n+1}) \leq H(y^*/\alpha, 1 - 1/\beta)$.

Proof. (a) Note that $\mu_i + A_i \cdot s \leq b_i/\alpha$, with $\mu_i, A_i \cdot s \geq 0$. Subject to these constraints and that $\alpha > 1$, we will show that $G(\mu_i, \delta_i)$ is maximized when $\mu_i = b_i/\alpha$ and $A_i \cdot s = 0$; this will prove (a). Now,

$$G(\mu_i, \delta_i) = \mu_i^{b_i - A_i \cdot s} \exp(-\mu_i)(e/(b_i - A_i \cdot s))^{b_i - A_i \cdot s}. \tag{3.1}$$

If $A_i \cdot s$ is held fixed at some $\gamma \geq 0$, (3.1) is maximized at $\mu_i = \Delta \doteq b_i/\alpha - \gamma$, under the constraint that $\mu_i \in [0, \Delta]$. Thus,

$$G(\mu_i, \delta_i) \leq \exp(b_i - b_i/\alpha)((b_i/\alpha - A_i \cdot s)/(b_i - A_i \cdot s))^{b_i - A_i \cdot s},$$

which is readily shown to be maximized when $A_i \cdot s = 0$. A similar proof holds for (b). ∎

Now that we have good tail bounds, we set $\alpha, \beta > 1$ such that $(\alpha\beta)$ is small and such that for the PIP, $1 - (\prod_{i=1}^{n}(1 - \Pr(E_i))) + \Pr(E_{n+1}) < 1$ holds. This, combined with setting $j = 0$ in Lemma 3.1, will show that there exists a feasible integral solution with objective function value at least $y^*/(\alpha\beta)$. Observe that the bound of Lemma 3.3 makes sense only if $B > 1$. Lemma 3.4 handles the common case where $A_{i,j} \in \{0, 1\}$ $\forall i, j$, to get improved bounds which, in particular, work even if $B = 1$. We have not attempted to optimize the constants.

LEMMA 3.3. *There exist constants $K_1 \geq 3$ and $K_2 \geq 1$ such that for any PIP, if α is taken as $K_1 \cdot \max\{1, (K_2 n/y^*)^{1/(B-1)}\}$ and $\beta = 2$, then $1 - (\prod_{i=1}^{n}(1 - \Pr(E_i))) + \Pr(E_{n+1}) < 1$.*

Proof. Suppose we agree to guarantee

$$\alpha \geq 3 \tag{3.2}$$

and $\beta = 2$. By Lemma 3.2, it suffices to show that $H(y^*/\alpha, 1/2) < (1 - G(B/\alpha, \alpha - 1))^n$. Furthermore, Fact 1(a) shows that

$$\exp(-y^*/(8\alpha)) < (1 - \exp(-B(\ln \alpha - 1)))^n$$

suffices. Since $B \geq 1$ and $\ln \alpha - 1 \geq \ln 3 - 1 > 0$, there exists a fixed $d > 0$ such that

$$1 - \exp(-B(\ln \alpha - 1)) \geq \exp(-d \exp(-B(\ln \alpha - 1)))$$

and hence, it suffices if $y^*/(8\alpha) > nd \exp(-B(\ln \alpha - 1))$. Simplifying, we see that

$$\alpha \geq K_1 (K_2 n/y^*)^{1/(B-1)}$$

suffices for certain positive absolute constants $K_1 \geq 3$ and $K_2 \geq 1$. Thus, to satisfy the requirement (3.2), it will suffice to take $\alpha = K_1 \cdot \max\{1, (K_2 n/y^*)^{1/(B-1)}\}$. ∎

LEMMA 3.4. *There exists a constant $K_1 \geq 3$ for PIP instances with $A_{i,j} \in \{0, 1\}$ $\forall i, j$, such that if $\alpha = K_1 \cdot \max\{1, (n/y^*)^{1/B}\}$ and $\beta = 2$, then $1 - (\prod_{i=1}^{n}(1 - \Pr(E_i))) + \Pr(E_{n+1}) < 1$.*

Proof. Since $A_{i,j} \in \{0, 1\}$, we may assume w.l.o.g. that each b_i is an integer, as mentioned in Definition 1.1. Again, since $A_{i,j} \in \{0, 1\}$, we have, for any $i \in [n]$, $((Az)_i > b_i) \rightarrow (Az)_i \geq b_i + 1$. Hence, B essentially gets replaced by $B + 1$ in Lemma 3.3, leading to the strengthened bounds. (We have eliminated the constant K_2 here, since $K_2^{1/B} \leq K_2$; hence, this term can be absorbed into the constant K_1.) ∎

As remarked in the introduction, it can be seen that the bounds (on the integrality gap $(\alpha\beta)$) of Lemmas 3.3 and 3.4 significantly strengthen the corresponding bounds achievable by the standard analysis of randomized rounding. However, as will be seen in section 4, the probability of outputting such an integral solution through randomized rounding can be as small as $\exp(-\Omega(n + m))$; hence, showing a good bound on the integrality gap alone is not satisfactory from the algorithmic viewpoint. We now show that there is indeed a suitable pessimistic estimator; we first introduce some notation to avoid lengthy formulae.

NOTATION 1. *$\forall i \in [n]$, $j \in \{0\} \cup [m]$, and $w \in \{0, 1\}^j$, let*

$$h_i(j, w) \doteq \mathbf{E}[(1 + \delta_i)^{A_i \cdot X - \mu_i(1+\delta_i)} | X^{(j)} = w],$$

$$f_i(j,w) \doteq \mathbf{E}[(1+\delta_i)^{A_i \cdot X - \mu_i(1+\delta_i)} | X^{(j+1)} = w0], \text{ and}$$

$$g_i(j,w) \doteq \mathbf{E}[(1+\delta_i)^{A_i \cdot X - \mu_i(1+\delta_i)} | X^{(j+1)} = w1].$$

When j and w are clear from the context, we may refer to these as h_i, f_i, and g_i.

From Theorem 2.1 and Lemma 3.1, a natural guess for a pessimistic estimator, $U(w_1, \ldots, w_j, p_{j+1}, \ldots, p_m)$ $\forall j \in \{0\} \cup [m]$ $\forall w \in \{0,1\}^j$, might be

$$1 - \left(\prod_{i=1}^{n} (1 - h_i(j,w))\right) + \mathbf{E}[(1-\delta_{n+1})^{c^T \cdot X - \mu_{n+1}(1-\delta_{n+1})} | X^{(j)} = w].$$

This might complicate matters if $h_i(j,w) > 1$, however, so we first define $h'_i(j,w) = \min\{h_i(j,w), 1\}$, $f'_i(j,w) = \min\{f_i(j,w), 1\}$, and $g'_i(j,w) = \min\{g_i(j,w), 1\}$. We now let $U(w_1, \ldots, w_j, p_{j+1}, \ldots, p_m)$ $\forall j \in \{0\} \cup [m]$ $\forall w \in \{0,1\}^j$ be

$$1 - \left(\prod_{i=1}^{n} (1 - h'_i(j,w))\right) + \mathbf{E}[(1-\delta_{n+1})^{c^T \cdot X - \mu_{n+1}(1-\delta_{n+1})} | X^{(j)} = w]. \tag{3.3}$$

At this point, we have exhibited suitable α and β such that our function U satisfies properties (1) and 2(a) of Definition 2.3. We now turn to proving property 2(b), the proof of which is more interesting. Before showing Lemma 3.6, which proves this, we first establish a simple lemma which facilitates the proof of Lemma 3.6.

Lemma 3.5. *$\forall i \in [n]$, $j \in \{0\} \cup [m]$, and $w \in \{0,1\}^j$,*

(i) $0 \le f'_i(j,w) \le g'_i(j,w) \le 1$, *and*

(ii) $h'_i(j,w) \ge (1-p_{j+1}) f'_i(j,w) + p_{j+1} g'_i(j,w)$.

Proof. We drop the parameters j and w for the rest of the proof. Part (i) is easily seen. For part (ii), we first note that

$$0 \le f_i \le g_i \quad \text{and} \quad h_i = (1-p_{j+1}) f_i + p_{j+1} g_i \tag{3.4}$$

by the definition of these quantities. If $h_i < 1$ and $g_i \le 1$, then $f_i < 1$ by (3.4) and hence part (ii) above follows from (3.4), with equality. If $h_i < 1$ and $g_i > 1$, note again that $f_i < 1$ and furthermore that $g_i > g'_i = 1$; thus, part (ii) follows from (3.4). Finally if $h_i \ge 1$, note that $h'_i = 1$, $g'_i = 1$ and that $f'_i \le 1$, implying (ii) again. □

Remark. In many constructions of pessimistic estimators for various analyses, equality holds in part (ii) of Lemma 3.5 (as opposed to our "$\ge$"). This makes it easy to prove that the function on hand is a valid pessimistic estimator. Our task is made more challenging because of this change in our case.

Lemma 3.6. *$\forall j \in \{0\} \cup [m-1]$ $\forall w \in \{0,1\}^j$, $U(w_1, \ldots, w_j, p_{j+1}, p_{j+2}, \ldots, p_m) \ge (1-p_{j+1}) U(w_1, \ldots, w_j, 0, p_{j+2}, \ldots, p_m) + p_{j+1} U(w_1, \ldots, w_j, 1, p_{j+2}, \ldots, p_m)$. Thus, in particular, $U(w_1, \ldots, w_j, p_{j+1}, p_{j+2}, \ldots, p_m)$ is at least as high as*

$$\min\{U(w_1, \ldots, w_j, 0, p_{j+2}, \ldots, p_m), U(w_1, \ldots, w_j, 1, p_{j+2}, \ldots, p_m)\}.$$

Proof. Let $r \doteq p_{j+1}$, for convenience. Note that

$$\mathbf{E}[(1-\delta_{n+1})^{c^T \cdot X - \mu_{n+1}(1-\delta_{n+1})} | X^{(j)} = w]$$

equals the sum of two terms:

$$(1-r)\mathbf{E}[(1-\delta_{n+1})^{c^T \cdot X - \mu_{n+1}(1-\delta_{n+1})} | X^{(j+1)} = w0]$$

and

$$r\mathbf{E}[(1-\delta_{n+1})^{c^T\cdot X-\mu_{n+1}(1-\delta_{n+1})}|X^{(j+1)}=w1].$$

Omitting the parameters j and w in f_i, g_i, etc., it is thus sufficient to show that

$$\prod_{i=1}^{n}(1-h_i') \leq (1-r)\prod_{i=1}^{n}(1-f_i') + r\prod_{i=1}^{n}(1-g_i').$$

Thus from Lemma 3.5(ii) and since $h_i' \leq 1$, it suffices to show that

$$\prod_{i=1}^{n}(1-(1-r)f_i'-rg_i') \leq (1-r)\prod_{i=1}^{n}(1-f_i') + r\prod_{i=1}^{n}(1-g_i'), \tag{3.5}$$

which we now prove by induction on n.

Equality holds in (3.5) for the base case $n=1$. We now prove (3.5) by assuming its analogue for $n-1$, i.e., we show that

$$\left((1-r)\prod_{i=1}^{n-1}(1-f_i') + r\prod_{i=1}^{n-1}(1-g_i')\right)(1-(1-r)f_n'-rg_n') \leq (1-r)\prod_{i=1}^{n}(1-f_i')+r\prod_{i=1}^{n}(1-g_i').$$

Simplifying, we need to show that

$$r(1-r)(g_n'-f_n')\left(\prod_{i=1}^{n-1}(1-f_i') - \prod_{i=1}^{n-1}(1-g_i')\right) \geq 0, \tag{3.6}$$

which holds in view of Lemma 3.5(i). □

Since all the requirements of Definition 2.3 are satisfied, we have the following theorem.

THEOREM 3.7. *There exist constants $K_3, K_4 > 0$ such that given any PIP conforming to the notation of Definition* 1.1, *we can produce, in deterministic polynomial time, a feasible solution to it, of value at least*

$$K_3 \cdot \min\{y^*, (K_4 y^*/n^{1/B})^{B/(B-1)}\}.$$

If $A \in \{0,1\}^{n\times m}$, the guarantee on the solution value is at least

$$K_3 \cdot \min\{y^*, (y^*/n^{1/(B+1)})^{(B+1)/B}\}.$$

Proof. Lemmas 3.3 and 3.4 show property (1) of Definition 2.3. Properties 2(a) and 2(b) of Definition 2.3 are shown by Lemmas 3.1 and 3.6, respectively. Theorem 2.4 now completes the proof. □

4. The maximum independent set problem on graphs.

We consider the classical NP-hard problem of finding a maximum independent set (MIS) in a given undirected graph $G=(V,E)$ and formulate it as a packing problem. Although we do not get improved approximation algorithms for this problem, a few observations on this important problem are relevant, as we shall see shortly.

Turán's classical theorem [39] shows that G always has an independent set of size at least $|V|^2/(2|E|+|V|)$; such a set can also be found in polynomial time. The standard packing formulation described below, combined with our approach, shows the existence of an independent set of size $\Omega(|V|^2/|E|)$. The constant factor hidden in the $\Omega(\cdot)$ is weaker than that of Turán's theorem, however—we present this result to show that our approach proves a few other known results, too, in a unified way. We remark that we do not use the standard notation of graphs having n vertices and m edges, as it will go against our notation for PIPs and CIPs; the packing formulation has $|E|$ constraints and $|V|$ variables.

Define an indicator variable $x_i \in \{0,1\}$ for each vertex i, for the presence of vertex i in the independent set (IS). Subject to the constraint that $x_i + x_j \leq 1$ for every edge (i,j), we want to maximize $\sum_i x_i$. For specific problems like this, we can get better bounds than does the analysis for Theorem 3.7, which uses the general CH bounds. The fractional solution $x_i^* = 1/2$ for each i is optimal to within a factor of 2. Suppose we scale x^* down by some $\alpha > 1$ and do the randomized rounding as before. Then for any given edge (i,j), $\Pr(z_i + z_j > 1) \leq 1/(4\alpha^2)$, a bound much better than the CH bound. Analysis as above then shows that $\alpha = \Theta(|E|/|V|)$ and $\beta = \Theta(1)$ suffice, thus producing an IS of size $\Omega(y^*/(\alpha\beta)) = \Omega(|V|^2/|E|)$.

One reason for considering the MIS problem is to show that the failure probability given by (1.5) can be extremely close to (although strictly smaller than) 1. This would underscore the importance of the fact that a pessimistic estimator can be constructed for PIPs and CIPs. Suppose the graph $G = (V,E)$ is a line on the N vertices $1, 2, \ldots, N$ and that each vertex independently picks a random bit for itself with the bit being one with probability q, for some $q \in [0,1]$. Let p_N be the probability that no two adjacent vertices choose the bit 1. Setting $q = 1/(2\alpha) = \Theta(|V|/|E|) = \Theta(1)$ above, it is then clear that the probability that randomized rounding (with the above values for α and β) picks a valid IS in G equals p_N. We now proceed to show that p_N is exponentially small in N, validating our point.

Computing p_N by induction on N is standard. Let a_N (respectively, b_N) denote the probability that not only do no pair of adjacent vertices both choose 1 but also that vertex N chooses the bit 1 (respectively, 0). Note that $p_N = a_N + b_N$. The recurrences

$$\begin{aligned} a_{N+1} &= q b_N, \\ b_{N+1} &= (1-q)(a_N + b_N) \end{aligned}$$

are immediate. Letting $\nu \doteq \sqrt{(1-q)(1+3q)}$, it can then be seen that

$$a_N = \frac{q}{\nu}\left(\left(\frac{1-q+\nu}{2}\right)^N - \left(\frac{1-q-\nu}{2}\right)^N\right).$$

Using the facts $b_N = a_{N+1}/q$ and $p_N = a_N + b_N$, we then see that $p_N = \exp(-\Omega(N))$, i.e., extremely small. Thus, the success probability of randomized rounding with our chosen values for α and β can be (and usually is) extremely small, motivating the need for a good pessimistic estimator.

The MIS problem also illustrates the well-known fact that linear relaxations are not always tight. As seen above, this problem always has a fractional solution lying between $|V|/2$ and $|V|$. However, the graph G can have its independence number to be any integer in $[|V|]$ and hence, the integrality gap of this LP formulation can be quite bad. Furthermore, recent work of Håstad, building on earlier research, has shown that the MIS cannot be approximated in polynomial time to within any factor better than $|V|^{1-\epsilon}$ for any fixed $\epsilon > 0$, unless some unexpected containment results hold in computational complexity theory [17]. This shows that we cannot expect even reasonably good approximation algorithms for *all* PIPs.

5. Approximating CIPs. Given a CIP conforming to Definition 1.1, we show how to get a good approximation algorithm for it. Since the ideas here are very similar to those of section 3, we borrow a lot of notation from there, skim over most details, and present only the essential differences.

The idea here is to solve the LP relaxation and, for an $\alpha > 1$ to be fixed later, to set $x'_j = \alpha x^*_j$ for each $j \in [m]$. We then construct a random integral solution z by setting, *independently* for each $j \in [m]$, $z_j = \lfloor x'_j \rfloor + 1$ with probability $x'_j - \lfloor x'_j \rfloor$ and $z_j = \lfloor x'_j \rfloor$ with probability $1 - (x'_j - \lfloor x'_j \rfloor)$. Let A_i, s_i, and $X_1, X_2, \ldots, X_m$ be as in section 3. The bad events now are

$$E_i \equiv \text{“}A_i \cdot X < \mu_i(1-\delta_i)\text{”} \ \forall i \in [n] \text{ and}$$

$$E_{n+1} \equiv \text{“}c^T \cdot X > \mu_{n+1}(1+\delta_{n+1})\text{”},$$

where $\mu_i = \mathbf{E}[A_i \cdot X]$ and

$$\delta_i = 1 - (b_i - A_i \cdot s)/\mu_i$$

for $i \in [n]$, $\mu_{n+1} = \mathbf{E}[c^T \cdot X]$, and

$$\delta_{n+1} = (y^* \alpha\beta - \ c^T \cdot s)/\mu_{n+1} - 1.$$

Analogously to PIPs, $0 \le \delta_i < 1 \ \forall i \in [n]$ and $\delta_{n+1} \ge 0$.

For any $i \in [n]$, let

$$F_i = \{S \subseteq [m] : A_i \cdot \chi(S) \ge \mu_i(1-\delta_i)\}.$$

Each of these families is *monotone increasing* now, and thus Theorem 2.2 again guarantees Lemma 3.1, for the present definition of $E_1, E_2, \ldots, E_{n+1}$ also.

Suppose given some $j \in \{0\} \cup [m-1]$ and some $w \in \{0,1\}^j$ we define $h'_i(j,w)$, $f'_i(j,w)$, and $g'_i(j,w)$ for every $i \in [n]$ analogously as in Notation 1:

$$h'_i(j,w) \doteq \min\{1, \mathbf{E}[(1-\delta_i)^{A_i \cdot X - \mu_i(1-\delta_i)} | X^{(j)} = w]\},$$

$$f'_i(j,w) \doteq \min\{1, \mathbf{E}[(1-\delta_i)^{A_i \cdot X - \mu_i(1-\delta_i)} | X^{(j+1)} = w0]\}, \text{ and}$$

$$g'_i(j,w) \doteq \min\{1, \mathbf{E}[(1-\delta_i)^{A_i \cdot X - \mu_i(1-\delta_i)} | X^{(j+1)} = w1]\}.$$

As can be expected, the pessimistic estimator $U(w_1, \ldots, w_j, p_{j+1}, \ldots, p_m) \ \forall j \in \{0\} \cup [m] \ \forall w \in \{0,1\}^j$ is now

$$1 - \left(\prod_{i=1}^{n}(1 - h'_i(j,w))\right) + \mathbf{E}[(1+\delta_{n+1})^{c^T \cdot X - \mu_{n+1}(1+\delta_{n+1})} | X^{(j)} = w]. \tag{5.1}$$

Now we address the analogue of the important Lemma 3.6. It is easily checked that Lemma 3.5(ii) holds again and that instead of part (i) of Lemma 3.5, we have

$$0 \le g'_i \le f'_i \le 1. \tag{5.2}$$

Thus, (5.2) guarantees (3.6) even now! This shows that Lemma 3.6 holds for the current definition of U also.

Thus to establish that U is a pessimistic estimator, we only have to exhibit, as do Lemmas 3.3 and 3.4, $\alpha, \beta > 1$, which ensure that $U(p_1, \ldots, p_m) < 1$. We first present a lemma similar to Lemma 3.2, whose simple proof is omitted.

LEMMA 5.1. *For all $i \in [n]$, $\Pr(E_i) \leq H(B\alpha, 1 - 1/\alpha)$. Also, $\Pr(E_{n+1}) \leq G(y^*\alpha, \beta - 1)$.*

We now present the main theorem on covering problems. Since unweighted set cover is an important problem, we present the precise approximation bound for this problem as a distinct part of the theorem. For this problem, the term "$\ln\ln(n/y^*)$" appears in our approximation bound with the understanding that we are working in the nontrivial range where $y^* \leq n/e$, say. Since there is always a trivial integral solution of value at most n for this problem, the case $y^* > n/e$ admits an e-approximation.

THEOREM 5.2. (a) *Given a CIP conforming to the notation of Definition 1.1, we can produce, in deterministic polynomial time, a feasible solution to it with value at most*

$$y^*(1 + \mathrm{O}(\max\{\ln(nB/y^*)/B, \sqrt{\ln(2\lceil nB/y^*\rceil)/B}\})).$$

(b) *For unweighted set cover, we can improve this to $y^*(\ln(n/y^*) + \ln\ln(n/y^*) + \mathrm{O}(1))$.*

Proof. We start with the simple claim that for $t \in (0, 1/e)$, $1-t > \exp(-1.25t)$. To see this, let $u = e(1-\ln(e-1)) = 1.246\cdots$. Consider the function $t \mapsto 1-t-\exp(-ut)$; we now show that for $t \in (0, 1/e)$, this function is positive. The function vanishes at $t = 0$, and its derivative is $u\exp(-ut) - 1$. So as t increases from 0, the function increases initially and then decreases. Thus since the function vanishes at $t = 1/e$, it is positive for $t \in (0, 1/e)$.

Recall from the above discussion that $(1 - \max_{i\in[n]} \Pr(E_i))^n > G(y^*\alpha, \beta - 1)$ suffices. In all cases here, we will ensure that

$$\max_{i\in[n]} \Pr(E_i) < 1/e \text{ and } 1 < \beta \leq 2. \tag{5.3}$$

Thus, by the above claim and from Fact 1(b), it will suffice to show that

$$1.25n \max_{i\in[n]} \Pr(E_i) \leq y^*\alpha(\beta - 1)^2/3. \tag{5.4}$$

We now choose α and β appropriately for each of our cases.

(a) For general CIPs, we will use the bound $\max_{i\in[n]} \Pr(E_i) \leq H(B\alpha, 1 - 1/\alpha)$ of Lemma 5.1. So, assuming $H(B\alpha, 1 - 1/\alpha) < 1/e$ and $1 < \beta \leq 2$ hold, (5.4) shows that it will be enough to show

$$1.25n \exp(-B\alpha(1 - 1/\alpha)^2/2) \leq y^*\alpha(\beta - 1)^2/3. \tag{5.5}$$

For general CIPs, we will consider three cases: $\ln(nB/y^*) > B$, $3 \leq \ln(nB/y^*) \leq B$, and $\ln(nB/y^*) < 3$. (The first and third cases are not necessarily mutually exclusive.)

Suppose $\ln(nB/y^*) > B$. Since $B \geq 1$, this shows that $nB/y^* \geq e$. We take $\alpha = 4\ln(nB/y^*)/B$ and $\beta = 2$. Since $\alpha \geq 4$, $(1 - 1/\alpha) \geq 3/4$; thus it is easy to check that $H(B\alpha, 1 - 1/\alpha) < 1/e$. Therefore to prove (5.5), it is enough to show

$$1.25n(y^*/(nB))^{9/8} \leq 4y^*\ln(nB/y^*)/(3B), \quad \text{i.e.,} \quad 1.25(y^*/(nB))^{1/8} \leq 4\ln(nB/y^*)/3,$$

which is true since $nB/y^* \geq e$. Thus, the approximation bound $\alpha\beta$ in this case is $\mathrm{O}(\ln(nB/y^*)/B)$.

Next, suppose $3 \leq \ln(nB/y^*) \leq B$. Thus $nB/y^* \geq e^3$. We choose $\alpha = 1 + 3\sqrt{\ln(nB/y^*)/B}$ and $\beta = 1 + \sqrt{\ln(nB/y^*)/B} \leq 2$. We have

$$\begin{aligned}\exp(-B\alpha(1-1/\alpha)^2/2) &= \exp(-B(\alpha-1)^2/(2\alpha)) \\ &= \exp(-9\ln(nB/y^*)/(2\alpha)) \\ &\leq \exp(-9\ln(nB/y^*)/8),\end{aligned}$$

since $\alpha \leq 4$. We see that $\exp(-B\alpha(1-1/\alpha)^2/2) < 1/e$. Hence by (5.5), it is enough to show

$$1.25n(y^*/(nB))^{9/8} \leq y^*\alpha\ln(nB/y^*)/(3B),$$

which follows from the facts that $\alpha \geq 1$ and $nB/y^* \geq e^3$. The approximation bound $\alpha\beta$ is $1 + \mathrm{O}(\sqrt{\ln(nB/y^*)/B})$ here.

Now consider the third case $\ln(nB/y^*) < 3$. Choose $\alpha = 1 + 10/\sqrt{B}$ and $\beta = 1 + 1/\sqrt{B} \leq 2$. Now,

$$\exp(-B\alpha(1-1/\alpha)^2/2) = \exp(-50/\alpha) \leq \exp(-50/11),$$

since $\alpha \leq 11$. So $\exp(-B\alpha(1-1/\alpha)^2/2) < 1/e$. Hence, again by (5.5), it suffices to show that

$$1.25n\exp(-50/11) \leq y^*\alpha/(3B),$$

which follows from the facts that (i) $\alpha \geq 1$ and (ii) $nB/y^* \leq \exp(3) \leq \exp(50/11)/3.75$. Therefore $\alpha\beta = 1 + \mathrm{O}(1/\sqrt{B})$ in this case.

(b) Thus we have proved the theorem for general CIPs. For the important unweighted set cover problem (see section 1.3 for the definition), we observe that for any $i \in [n]$, E_i holds iff $A_i \cdot s = A_i \cdot X = 0$; this makes the calculations easier. If A_i has j nonzeroes (ones) in it, say in columns $\ell_1, \ell_2, \ldots, \ell_j$, then it is not hard to see that $\Pr(A_i \cdot X = 0)$ is maximized when $x'_{\ell_k} = \alpha/j \ \forall k \in [j]$. Thus, $\Pr(E_i) \leq (1-\alpha/j)^j < \exp(-\alpha)$ and hence, by (5.4), it suffices to pick $\alpha > 1$ and $1 < \beta \leq 2$ such that

$$1.25n\exp(-\alpha) \leq y^*\alpha(\beta-1)^2/3. \tag{5.6}$$

It can now be verified that by choosing

$$\alpha = \ln(n/y^*) + \ln\ln(n/y^*) + \mathrm{O}(1) \text{ and } \beta = 1 + (\ln(n/y^*))^{-1},$$

we will satisfy (5.6). Hence, the approximation guarantee $\alpha\beta$ can be made as small as $\ln(n/y^*) + \ln\ln(n/y^*) + \mathrm{O}(1)$. $\square$

It is also worth looking at some concrete improvements over existing algorithms brought about by Theorem 5.2. In the case of unweighted set cover, suppose $d \leq n$ is the maximum column sum—the maximum cardinality of any edge in the given hypergraph. Then, by summing up all the constraints, we can see that

$$y^*d \geq n. \tag{5.7}$$

Thus, our approximation bound for the set cover problem (see the second statement of Theorem 5.2) is never more by a multiplicative $(1 + o(1))$ factor above the classical bound of $\min\{n/y^*, \ln d + \mathrm{O}(1)\}$. On the other hand, $n/y^* \ll d$ is quite likely, and it is easy to construct set cover instances with

$$\min\{n/y^*, \ln d\} = \Theta(\log n/\log\log n)\ln(n/y^*).$$

For instance, we can arrange for just a few edges to have the maximum edge size of $n^{\Theta(1)}$, while keeping y^* as high as $n/\log^{\Theta(1)} n$. Thus in the best case, we get a $\Theta(\log n/\log\log n)$ factor improvement in the approximation ratio.

An important case of the unweighted set cover problem is the *dominating set* problem: given a (directed) graph G, the problem is to pick a minimum number of vertices such that for every one vertex v, at least one vertex in $v \cup \mathrm{Out}(v)$ is picked, where $\mathrm{Out}(v)$ denotes the out-neighborhood of v.

We next consider a more general domination-type problem on graphs, modeling a class of location problems. Given a (directed) graph G with n nodes and some integral parameter $B \geq 1$, we have to place the smallest possible number of facilities on the nodes of G, so that every node u has at least B facilities in $u \cup \mathrm{Out}(u)$; multiple facilities at the same node are allowed. Let us call this the B-domination problem on G.

For the case where G is *undirected* with maximum degree Δ, an approximation bound of $1 + \mathrm{O}(\max\{\ln(\Delta)/B, \sqrt{\ln(\Delta)/B}\})$ is presented in [26], improving on the $1+\mathrm{O}(\max\{\ln(n)/B, \sqrt{\ln(n)/B}\})$ bound given by the standard analysis of randomized rounding. Our Theorem 5.2 gives a bound of

$$1 + \mathrm{O}(\max\{\ln(nB/y^*)/B, \sqrt{\ln(2\lceil nB/y^*\rceil)/B}\}).$$

Even if G is directed, this new bound is as good as or better than

$$1 + \mathrm{O}(\max\{\ln(\Delta_{in})/B, \sqrt{\ln(\Delta_{in})/B}\}),$$

where Δ_{in} denotes the maximum in-degree of G; this is easily seen from the fact that $y^* \geq nB/\Delta_{in}$, which follows from the same reasoning as for (5.7). We thus get a generalization of the Naor–Roth result. In the case of undirected graphs, it is not hard to show families of graphs for which the present bound is better than that of Naor and Roth's by a factor of up to $\Theta(\log n/\log\log n)$.

In addition to its independent interest, the above B-domination problem is a crucial subproblem in the following file-sharing problem in distributed networks [26]. Given an undirected graph $G = (V, E)$ with n vertices and maximum degree Δ and a file F of k bits, F must be stored in some way at the nodes of G, such that every node can recover F by examining the contents of its and its neighbor's memories; the aim is to minimize the total amount of memory used. (Note that solving the above domination problem is not sufficient for this task.) Letting y^* be the optimum of the (obvious) linear relaxation of the k-domination problem on G, a memory allocation that uses a total of

$$1 + \mathrm{O}(\max\{\ln(\Delta)/k, \sqrt{\ln(\Delta)/k}\}) \tag{5.8}$$

bits is presented in [26]. (Note that y^* is a lower bound on the total amount of memory needed.) Briefly, the approach of [26] works as follows. Let $B = k + 3\lceil\log_2 \Delta\rceil + 1$. Given a feasible integral solution (vector) $x = [x_v]_{v \in V}$ to the B-domination problem on G, the work of [26] shows how to come up with a feasible memory allocation for

F, using a total of $t = \sum_{v \in V} x_v$ bits. Recall that our bound for CIPs shows a way of achieving

$$t = y^*(B/k)(1 + \mathrm{O}(\max\{\ln(nB/y^*)/B, \sqrt{\ln(2\lceil nB/y^* \rceil)/B}\})),$$

which equals

$$y^*(1 + \mathrm{O}(\max\{\ln(\Delta)/k, \sqrt{\ln(2\lceil nk/y^* \rceil)/k}\})).$$

This is always as good as (5.8) and better if $k \gg \ln(\Delta)$.

5.1. Applications to a facility location problem. We now consider another type of canonical facility location problem: *uncapacitated facility location*. Given a directed graph $G = (V, E)$ with nonnegative vertex-costs $\{d(j)\}$ and nonnegative edge-lengths $\{c(i,j)\}$, let $\mathrm{Out}(v)$ denote the out-neighborhood of vertex v. Suppose it costs $d(j)$ units to locate a facility at vertex j. The problem is to place facilities on the nodes of G such that for every vertex v, at least one vertex in $\mathrm{Out}(v)$ houses a facility; the aim is to minimize the sum of the total weight of the sites of the facilities and the total distance (in terms of edge-lengths) traveled by all the vertices to their closest facilities. By scaling, we assume w.l.o.g. that all the $d(j)$ and $c(i,j)$ lie in $[0,1]$. $\mathrm{O}(\log n)$ approximation bounds are known for this problem (Hochbaum [18], [5]). There is a known LP relaxation for the problem to be described below. Letting $n = |V|$ and y^* be the optimal value of this relaxation, we now show how to obtain an integral solution of value $\mathrm{O}(y^*(1 + \log(\lceil n/y^* \rceil)))$.

We start with a known ILP formulation of the problem (Kolen and Tamir [22]). Let $\Delta(i) \doteq |\mathrm{Out}(i)|$. For each $i \in V$, sort the set $\{c(i,j) : j \in \mathrm{Out}(i)\}$ in nondecreasing order to obtain a sequence $c'(i,1), c'(i,2), \ldots, c'(i,\Delta(i))$. Following [22], consider the following variables. For all $i \in V$ and all $j \leq \Delta(i) - 1$, let

- $x_i \in \{0,1\}$ be the indicator variable for a facility being placed at i, and
- $z_{i,j} \in \{0,1\}$ be the indicator variable for no facility being at a distance of at most $c'(i,j)$ from i.

Then it is not hard to see that the following ILP formulation of [22] is valid:

$$\text{minimize } \sum_{j \in V} d_j x_j + \sum_{i \in V} \left(c'(i,1) + \sum_{j=1}^{\Delta(i)-1} (c'(i,j+1) - c'(i,j)) z_{i,j} \right) \text{ subject to}$$

$$\forall i \in V\ \forall k \leq \Delta(i) - 1, \quad z_{i,k} + \sum_{j:\ (i,j) \in E,\ c(i,j) \leq c'(i,k)} x_j \geq 1; \tag{5.9}$$

$$\forall i \in V, \quad \sum_{j:\ (i,j) \in E} x_j \geq 1; \tag{5.10}$$

$$\forall i \in V\ \forall k \leq \Delta(i) - 1, \quad x_i \in \{0,1\}, \qquad z_{i,k} \in \{0,1\}. \tag{5.11}$$

Relaxing each x_i and $z_{i,j}$ to be a real in $[0,1]$, we get an LP relaxation. Let y^* denote the optimum value of this relaxation and $\{x^*, z^*\}$ be an optimal solution to the relaxation. We now show how to round this to a feasible solution for the above ILP. Let $m = |E|$. Note that a direct application of our covering results will lead to an integral solution of value $\mathrm{O}(y^*(1 + \log(\lceil m/y^* \rceil)))$, since there are $\mathrm{O}(m)$ constraints above. We now improve this to $\mathrm{O}(y^*(1 + \log(\lceil n/y^* \rceil)))$.

For each (i,j), set $z'_{i,j} := 0$ if $z^*_{i,j} < 1/2$ and $z'_{i,j} := 1$ if $z^*_{i,j} \geq 1/2$. For each i, set $x'_i = \min\{2x^*_i, 1\}$. It is not hard to check that this is a feasible fractional solution to the LP with objective function value at most $2y^*$; crucially, we have rounded all the $z_{i,j}$ to 0 and 1. Let us see how to round the vector x' to a $\{0,1\}$-vector. Fix $i \in V$. It is easily seen that $z^*_{i,1} \geq z^*_{i,2} \geq \cdots$. Let $k(i)$ be the maximum k for which $z^*_{i,k} \geq 1/2$ (if no such k exists, $k(i) = 0$); for all $k \leq k(i)$, (5.9) will be satisfied irrespective of our rounding of x', since $z'_{i,k} = 1$. It is not hard to check that to satisfy (5.9) and (5.10), it suffices to have

$$\sum_{j:\ (i,j)\in E,\ c(i,j)\leq c'(i,k(i)+1)} x_j \geq 1.$$

Thus, we are left with at most one constraint per vertex i. Moreover, the fractional vector x' satisfies these constraints as seen above. Thus, we can invoke our approach for CIPs to efficiently construct a feasible integral solution of value $\mathrm{O}(y^*(1 + \log(\lceil n/y^* \rceil)))$.

The reader is referred to [18], [5] for other interesting approaches to the problem. We also mention that for the important special case where the distances $c(i,j)$ are symmetric (i.e., $c(i,j) = c(j,i)$) and satisfy the triangle inequality, work of Shmoys, Tardos, and Aardal [33] and Guha and Khuller [16] has led to good *constant-factor* approximations for this problem.

6. Concluding remarks.

We have presented a simple but very useful property of all packing and covering integer programs—positive correlation. This naturally suggests a better way of analyzing the performance of randomized rounding on PIPs and CIPs. However, the provable probability of success—of satisfying all the constraints *and* delivering a very good approximation—can be extremely low; therefore, in itself, this approach may just prove an existential result. Fortunately, the structure of PIPs and CIPs in fact suggests a pessimistic estimator, thus converting this existence proof into a (deterministic) polynomial-time algorithm. In our view, this is very interesting and gives evidence of the utility of derandomization techniques. A common objection to derandomization is that often it converts a fast randomized algorithm that has a good probability of success to a somewhat slower deterministic algorithm. In our case, the opposite is true! The randomized algorithm suggested by the existence proof has an extremely low probability of success; second, solving the LP relaxation heavily dominates the running time, and the time for running the derandomization is comparatively negligible. (This observation about running the LP relaxation also suggests that, in practice, it would be better to get quickly an approximately optimal solution to the LP relaxation, since we are dealing with approximate solutions anyway.)

The basic idea here has been that by using the correlations, we could improve on the Boole–Bonferroni inequality for our applications. There is much interesting work on approximating the probability of a union using the structure of the underlying events: see, e.g., Hunter [20] and Aldous [2]. In the case of PIPs and CIPs, we have benefited from the fact that the constraints "help each other," by being positively correlated. The precise reasons for such a correlation are spelled out in section 1.2. It is a challenging open question to use the structure of correlations in more complicated scenarios; one such problem is the *set discrepancy problem* [35], [3]. Given a system of n subsets $S_1, S_2, \ldots, S_n$ of a ground set A with n elements, the problem is to come up with a function $\psi : A \rightarrow \{-1, 1\}$, such that the *discrepancy* $\mathrm{disc}(\psi) \doteq \max_{i\in[n]} |\psi(S_i)|$ is small, where $\psi(S_i) = \sum_{j\in S_i} \psi(j)$. While randomized rounding and the method of conditional probabilities can be used to produce a ψ with discrepancy $\mathrm{O}(\sqrt{n \log n})$ [35], [3], a classical *nonconstructive* result of Spencer shows the existence of a ψ with $\mathrm{disc}(\psi) = \mathrm{O}(\sqrt{n})$ [36]. This is best possible, and it is an important open problem to make this constructive. If we write down the natural integer programming formulation for this problem, we can see that each constraint is positively correlated with some subsets of the constraints and negatively correlated with others. (There is the associated observation that in several IPs with both $\leq$ and $\geq$ constraints, the $\leq$ constraints are often positively correlated amongst each other; this is similar for the $\geq$ constraints. This idea potentially could bring improvements in some cases.) It would be very interesting if such more complicated forms of correlation can be used to get a constructive result here.

The set discrepancy problem, an undirected multicommodity flow problem presented in [28], and certain other NP-hard problems in very large scale integration routing, are all modeled by a class of integer programs that are referred to as *minimax integer programs* (MIPs) in recent work of this author [37]. These are different from PIPs and CIPs; an improved integrality gap for sparse instances of such problems is proved in [37].

Yet another potential room for improvement lies in lower-bounding, in the context of (1.4), the ratio

$$\Pr\left(\bigwedge_{i=1}^{n} \overline{E_i}\right) / \prod_{i=1}^{n} \Pr(\overline{E_i}),$$

at least for some particular classes of PIPs/CIPs. We know this ratio to be at least one, by (1.4); a better lower bound (at least for particular problems) will lead to better bounds on the integrality gap. Roughly speaking, such better lower bounds seem plausible especially for PIPs/CIPs wherein several columns have several nonzero entries, i.e., in situations where there is heavy (positive) correlation among the constraints of the IP. This could be a difficult problem, however.

How far can such ideas be pushed? In the general setting of all PIPs and CIPs, not much progress seems to be possible along these lines, as shown in section 4. Also, for some important covering problems such as various "cut" problems on graphs and some network design problems, the number of constraints is *exponential* in the number of variables. Our approach will not give good approximation algorithms for such problems, although some of these problems do admit good approximations via other methods [5]. It would be interesting to apply our approach to get improved approximations for some specific important packing and covering problems; one such recent result is for edge-disjoint paths and related problems [38]. Furthermore, it will be interesting to study the correlations involved in other relaxation approaches such as semidefinite programming relaxations.

For the unweighted set cover problem, recent work of Slavík improves upon our result, showing that a natural greedy algorithm outputs a solution of value at most $(y^* - 1/2)\ln(n/y^*) + y^*$ [34]. Furthermore, improved approximation algorithms for the unweighted set cover problem in many geometric settings have been obtained in [6]. If the dual set-system of a given set cover instance has Vapnik–Chervonenkis (VC) dimension d and if c is the size of the optimal set cover, then the work of [6] presents an algorithm that delivers a solution of value at most $\mathrm{O}(c\log(cd))$. Please refer to [6] for the definitions of dual set systems and VC dimension. We just mention here that $d = \mathrm{O}(1)$ in many geometric settings; thus, the work of [6] leads to an approximation guarantee of $\mathrm{O}(\log c)$ in such cases.

As we had seen before, our bounds are incomparable with known results for some *weighted* CIPs, e.g., those considered in [8], [5]. For instance, our approximation ratio of $O(\ln(n/y^*))$ for the weighted set cover problem is incomparable with the ratio of $O(\ln d)$ obtained in [8], where d denotes the maximum column sum in A; this is because unlike the unweighted case, n/y^* is not necessarily at most d, in the weighted case. Recent work of the author improves on many current results, including some of the results on weighted PIPs and CIPs from the present paper [37]. The work of [37] presents improved approximation guarantees for PIPs, CIPs, and MIPs, if the coefficient matrix A does not have many nonzero entries in any column; in particular, it generalizes the result of [8] shown above.

Appendix. Standard analysis of randomized rounding for PIPs. Choose $\alpha = e(5n)^{1/B}$. We first handle an easy case. If $y^* \leq 3\alpha$, we just choose any j such that $c_j = 1$ and set $x_j = 1$ and $x_k = 0\ \forall k \neq j$. This is clearly an $O(n^{1/B})$-approximation algorithm if $y^* \leq 3\alpha$.

Suppose $y^* > 3\alpha$. Let the bad events $E_1, E_2, \ldots, E_{n+1}$ be as in (1.1) with $\beta = 3$. If we avoid all these $(n+1)$ events, we would have a feasible solution with objective function value at least $y^*/(3\alpha)$. The goal now is to show

$$\sum_{i\in[n+1]} \Pr(E_i) \leq K_4 \tag{A.1}$$

for say some constant $K_4 < 1$.

For the purpose of analysis, view each z_j as a sum of $\lceil x'_j \rceil$ independent $\{0,1\}$ r.v.'s, where the first $\lceil x'_j \rceil - 1$ are 1 with probability 1 and the last is 1 with probability $1 - (\lceil x'_j \rceil - x'_j)$. Recalling that $A_{i,j} \in [0,1]\ \forall i,j$, we see, for each $i \in [n]$, that $(Az)_i$ is a sum of independent r.v.'s, each of which takes on values in $[0,1]$. Also, $\mathbf{E}[(Az)_i] = (Ax')_i/\alpha \leq b_i/\alpha$.

Thus, for $i \in [n]$, $\Pr(E_i)$ can be upper-bounded using part (a) of Fact 1,

$$\Pr((Az)_i > b_i) \leq (e/\alpha)^{b_i} = (5n)^{-b_i/B} \leq 1/(5n), \tag{A.2}$$

since $b_i \geq B$. To upper-bound $\Pr(E_{n+1})$, even Chebyshev's inequality will suffice here. If Y is a sum of independent r.v.'s, each taking values in $[0,1]$, it is easy to check that the variance of Y is at most $\mathbf{E}[Y]$. Thus, Chebyshev's inequality shows that for such a Y and any $a > 0$, $\Pr(|Y - \mathbf{E}[Y]| \geq a) \leq \mathbf{E}[Y]/a^2$. Since $y^* > 3\alpha$ now by assumption, we have $\mu \doteq \mathbf{E}[c^T \cdot z] = y^*/\alpha \geq 3$. Thus by Chebyshev's inequality

$$\Pr(c^T \cdot z < \mu/3) \leq \Pr(|c^T \cdot z - \mu| > 2\mu/3] \leq 9/(4\mu) \leq 3/4. \tag{A.3}$$

Bounds (A.2) and (A.3) show that

$$\sum_{i\in[n+1]} \Pr[E_i] \leq 1/5 + 3/4 = 0.95;$$

by repeating this algorithm an appropriate constant number of times, the probability of failure can be reduced to any desired positive constant.

Next suppose $A \in \{0,1\}^{n\times m}$. Recall from Definition 1.1 that we take each b_i to be an integer here. Thus, $E_i \equiv ((Az)_i > b_i)$ is equivalent to $((Az)_i \geq b_i + 1)$ now; thus B essentially gets replaced by $B+1$ in (A.2). We may thus take $\alpha = \Theta(n^{1/(B+1)})$ and get an $O(\alpha)$ approximation as above.

Acknowledgments. We thank Moni Naor, Babu Narayanan, and David Shmoys for their valuable comments. Thanks in particular to Prabhakar Raghavan for his insightful suggestions and pointers to the literature. We acknowledge the valuable feedback of the STOC 1995 program committee and referees. We also thank the journal referees for their very helpful comments and suggestions, which have substantially improved the quality of this paper.

AN EFFICIENT ALGORITHM FOR GENERATING NECKLACES WITH FIXED DENSITY[*]

FRANK RUSKEY[†] AND JOE SAWADA[†]

Abstract. A k-ary necklace is an equivalence class of k-ary strings under rotation. A necklace of fixed density is a necklace where the number of zeros is fixed. We present a fast, simple, recursive algorithm for generating (i.e., listing) fixed-density k-ary necklaces or aperiodic necklaces. The algorithm is optimal in the sense that it runs in time proportional to the number of necklaces produced.

Key words. necklaces, Lyndon words, fixed density, CAT algorithm, generate, difference covers

1. Introduction.

There are many reasons to develop algorithms for producing lists of basic combinatorial objects. First, the algorithms are truly useful and find many applications in diverse areas such as hardware and software testing, nonparametric statistics, and combinatorial chemistry. Second, the development of these algorithms can lead to mathematical discoveries about the objects themselves, either experimentally or through insights gained in the development of the algorithms.

The primary performance goal in an algorithm for listing a combinatorial family is an algorithm whose running time is proportional to the number of objects produced. In this paper an *efficient* algorithm is one that uses only a constant amount of computation per object, in an amortized sense. Such algorithms are also said to be constant amortized time (CAT) algorithms.

Necklaces are a fundamental type of combinatorial object, arising naturally, for example, in the construction of single-track Gray codes, in the enumeration of irreducible polynomials over finite fields, and in the theory of free Lie algebras. Efficient algorithms for exhaustively generating necklaces were first developed by Fredricksen and Kessler [4] and Fredricksen and Maiorana [5], although they did not prove that they were efficient. They were proven to be efficient by Ruskey, Savage, and Wang [8]. Closely related algorithms for generating Lyndon words (aperiodic necklaces) were developed by Duval [3] and shown to be efficient by Berstel and Pocchiola [1]. Subsequently, a recursive algorithm was developed that was more flexible and easier to analyze than the earlier algorithms, which were all iterative [2]. In many applications not all necklaces are required, but rather only those of fixed density (the number of zeros is fixed). Previous to this paper, no efficient generation algorithm for fixed-density necklaces was known.

Previous fixed-density necklace algorithms had running times of $O(n \cdot N(n,d))$ (Wang and Savage [9]) and $O(N(n))$ (Fredricksen and Kessler [4]), where $N(n,d)$ denotes the number of necklaces with length n and density d and $N(n)$ denotes the number of necklaces with length n. Wang and Savage base their algorithm on finding a Hamilton cycle in a graph related to a tree of necklaces. The main feature

of their algorithm is that it also generates the strings in Gray code order. The basis of Fredricksen and Kessler's algorithm is a mapping of lexicographically ordered compositions to necklaces. Both algorithms consider only binary necklaces, but our results apply over a general alphabet. We take a new approach by first modifying Ruskey's recursive algorithm for generating necklaces [2] and then optimizing it for the fixed-density case. Recursive algorithms have several advantages over their iterative counterparts. They are generally simpler and easier to analyze. They are more suitable to conversion to backtracking algorithms, since subtrees are easily pruned from the computation tree. In fact, we have used just such a backtracking to discover new minimal difference covers (sets of numbers achieving all possible differences, mod n).

In the following section we will give some definitions related to necklaces. In section 3 we will introduce a fast algorithm for generating fixed-density k-ary necklaces. In section 4 we analyze the algorithm, proving the algorithm is CAT for any density. In section 5 we conclude by outlining an application and some future work.

2. Background and definitions. A k-ary *necklace* is an equivalence class of k-ary strings under rotation. We identify each necklace with the lexicographically least representative in its equivalence class. The set of all k-ary necklaces with length n is denoted $\mathbf{N}_k(n)$. For example, $\mathbf{N}_2(4) = \{0000, 0001, 0011, 0101, 0111, 1111\}$. The cardinality of $\mathbf{N}_k(n)$ is denoted $N_k(n)$.

An important class of necklaces are those that are aperiodic. An aperiodic necklace is called a *Lyndon word*. Let $\mathbf{L}_k(n)$ denote the set of all k-ary Lyndon words with length n. For example, $\mathbf{L}_2(4) = \{0001, 0011, 0111\}$. The cardinality of $\mathbf{L}_k(n)$ is denoted $L_k(n)$.

A string α is a *prenecklace* if it is a prefix of some necklace. The set of all k-ary prenecklaces with length n is denoted $\mathbf{P}_k(n)$. For example, $\mathbf{P}_2(4) = \mathbf{N}_2(4) \cup \{0010, 0110\}$. The cardinality of $\mathbf{P}_k(n)$ is $P_k(n)$.

We denote fixed-density necklaces, Lyndon words, and prenecklaces in a similar manner by adding the additional parameter d to represent the number of nonzero characters in the strings. We refer to the number d as the density of the string. Thus the set of k-ary necklaces with density d is represented by $\mathbf{N}_k(n,d)$ and has cardinality $N_k(n,d)$. For example, $\mathbf{N}_3(4,2) = \{0011, 0012, 0021, 0022, 0101, 0102, 0202\}$. Similarly, the set of fixed-density Lyndon words is represented by $\mathbf{L}_k(n,d)$ with cardinality $L_k(n,d)$. The set of fixed-density prenecklaces is denoted by $\mathbf{P}_k(n,d)$ and has cardinality $P_k(n,d)$. In addition to these familiar terms we introduce the set $\mathbf{P}'_k(n,d)$, which is the elements of $\mathbf{P}_k(n,d)$ whose last character is nonzero. Its cardinality is denoted $P'_k(n,d)$.

To count fixed-density necklaces we let $N(n_0, n_1, \ldots, n_{k-1})$ denote the number of necklaces composed of n_i occurrences of the symbol i for $i = 0, 1, \ldots, k-1$. Let the density of the necklace $d = n_1 + \cdots + n_{k-1}$ and $n_0 = n - d$. It is known from Gilbert and Riordan [6] that

$$N(n_0, n_1, \ldots, n_{k-1}) = \frac{1}{n} \sum_{j \backslash gcd(n_0, \ldots, n_{k-1})} \phi(j) \frac{(n/j)!}{(n_0/j)! \cdots (n_{k-1}/j)!}. \tag{2.1}$$

To get the number of fixed-density necklaces with length n and density d, we sum over all possible values of $n_1, n_2, \ldots, n_{k-1}$:

$$N_k(n,d) = \sum_{n_1 + \cdots + n_{k-1} = d} N(n-d, n_1, \ldots, n_{k-1}).$$

The number of fixed-density Lyndon words is defined similarly:

$$L(n_0, n_1, \ldots, n_{k-1}) = \frac{1}{n} \sum_{j \backslash gcd(n_0, n_1, \ldots, n_{k-1})} \mu(j) \frac{(n/j)!}{(n_0/j)!(n_1/j)! \cdots (n_{k-1}/j)!},$$

$$L_k(n,d) = \sum_{n_1 + \cdots + n_{k-1} = d} L(n-d, n_1, \ldots, n_{k-1}).$$

In the binary case these expressions simplify as follows:

$$N_2(n,d) = \frac{1}{n} \sum_{j \backslash gcd(n,d)} \phi(j) \binom{n/j}{d/j},$$

$$L_2(n,d) = \frac{1}{n} \sum_{j \backslash gcd(n,d)} \mu(j) \binom{n/j}{d/j}.$$

Currently, it is not known how to count fixed-density prenecklaces.

In the following section we will introduce a CAT algorithm to generate fixed-density necklaces. When analyzing the performance of our algorithm we make use of the following lemmas about prenecklaces and Lyndon words.

Cattell et al. [2] give a lemma that characterizes prenecklaces by making use of a function lyn on strings, which is the length of the longest Lyndon prefix of the string:

$$lyn(a_1 a_2 \cdots a_n) = \max\{1 \le p \le n | a_1 a_2 \cdots a_p \in \mathbf{L}_k(p)\}.$$

LEMMA 2.1. *Let k-ary string $\alpha = a_1 \cdots a_n$ and $p = lyn(\alpha)$. Then $\alpha \in \mathbf{P}_k(n)$ if and only if $a_{j-p} = a_j$ for $j = p+1, \ldots, n$.*

Reutenauer [7] gives a useful lemma about Lyndon words. Inequalities between words are always with respect to lexicographic order.

LEMMA 2.2. *If α and β are Lyndon words with $\alpha < \beta$, then $\alpha\beta$ is a Lyndon word.*

3. Generating fixed-density necklaces. We use a two-step approach to develop a fast algorithm for generating fixed-density necklaces. First we create a new necklace algorithm based on the recursive necklace-generation algorithm $\mathsf{Gen}(t,p)$ (Figure 3.1) [2]. We then optimize this new necklace algorithm for the fixed-density case by making a few key observations about fixed-density necklaces.

To begin we give a brief overview of $\mathsf{Gen}(t,p)$. The general approach of this algorithm is to generate all length n prenecklaces. The prenecklace being generated is stored in the array a with one position for each character. We assume that $a_0 = 0$. The initial call is $\mathsf{Gen}(1,1)$ and each recursive call appends a character to the prenecklace to get a new prenecklace. At the beginning of each recursive call to $\mathsf{Gen}(t,p)$, the length of the prenecklace being generated is $t-1$ and the length of the longest Lyndon prefix is p. As long as the length of the current prenecklace is less than n, each call to $\mathsf{Gen}(t,p)$ makes one recursive call for each valid value for the next character in the string, updating the values of both t and p in the process. This algorithm can generate necklaces, Lyndon words, or prenecklaces of length n in lexicographic order by specifying which object we want to generate. The function $\mathsf{PrintIt}(p)$ allows us to differentiate between these various objects as shown in Figure 3.2.

The computation tree for $\mathsf{Gen}(t,p)$ consists of all prenecklaces of length less than or equal to n. As an example, we show a computation tree for $N_2(4)$ in Figure 3.3. By comparing the number of nodes in the computation tree to the number of objects generated it was shown that this algorithm is CAT [2].

```
procedure Gen ( $t$, $p$ : integer );
local $j$ : integer;
begin
    if $t > n$ then PrintIt( $p$ )
    else begin
        $a_t := a_{t-p}$;    Gen( $t+1$, $p$ );
        for $j \in \{a_{t-p}+1, \ldots, k-2, k-1\}$ do begin
            $a_t := j$;    Gen( $t+1$, $t$ );
        end;
    end;
end {of Gen};
```

FIG. 3.1. *The recursive necklace algorithm.*

FIG. 3.2. *Different objects output by different versions of* PrintIt(p).

3.1. Modified necklace algorithm. For every necklace of positive density, the last character of the string must be nonzero. Thus, if we are concerned only with generating necklaces or Lyndon words we can reduce the size of the computation tree by compressing all the prenecklaces whose last character is 0. Looking at Figure 3.3, we want to generate only the nodes in bold. This results in the modified computation tree shown in Figure 3.4. Notice that at each successive level in this tree we are incrementing the density of the prenecklace rather than the length. To generate this modified tree we create a recursive routine based on the original necklace algorithm in Figure 3.1; however, rather than determining the valid values for the next position in the string, we need to determine both the valid positions and the values for the next nonzero character.

To make this change we use the array a to hold the positions of the nonzero characters and maintain another array b to indicate the values of the nonzero characters. The ith element of the array a represents the position of the ith nonzero character, and the ith element of the array b represents the value of the ith nonzero character. Thus if we generate a necklace with length 7 with $a = [3, 4, 5, 7]$ and $b = [1, 3, 2, 1]$, the corresponding necklace is 0013201. (We can also maintain the original necklace structure by performing some extra constant-time operations.) Note that in the binary case, the second array b is not necessary since all nonzero characters must be 1. We use the parameter t to indicate the current density of the string. The length of the current string is a_t. Since all Lyndon prefixes end in a nonzero character, we let a_p indicate the length of the longest Lyndon prefix. Using these two parameters, we can compute all valid positions and values for the next nonzero character.

To determine the valid positions and values for the next nonzero character and to maintain the lexicographic ordering we compute the maximum position and the minimum value for that position so that the new string still has the prenecklace property. We compute this maximal position for the next character using the following

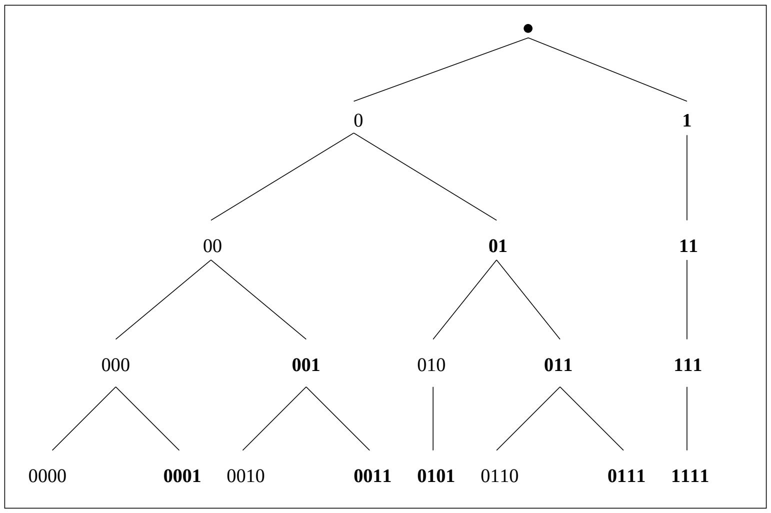

FIG. 3.3. *Computation tree for $N_2(4)$ from* $\mathsf{Gen}(t,p)$.

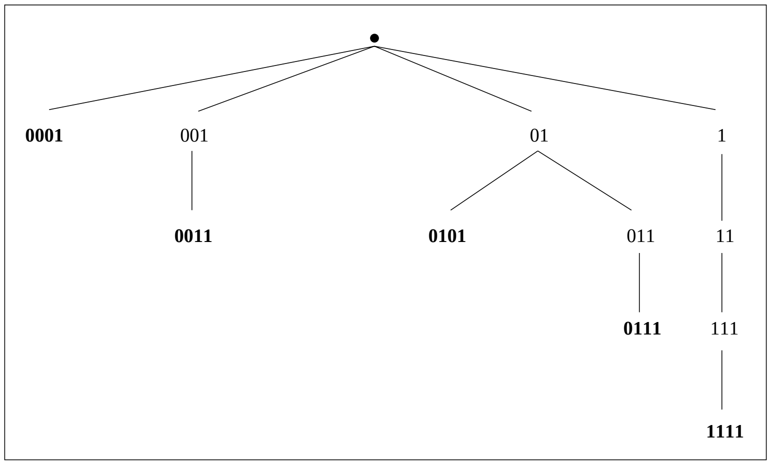

FIG. 3.4. *Computation tree for $N_2(4)$ from* $\mathsf{Gen2}(t,p)$.

expression:

$$\lfloor (t+1)/p \rfloor a_p + a_{(t+1) \bmod p}.$$

The minimal value for this position is b_{t+1-p}. By the properties of prenecklaces all larger values at the maximal position are also valid [8]. Also, all positions before the maximum position and greater than the position of the last assigned nonzero character (a_t) can hold all values ranging from 1 to $k-1$. (Note that since we want to generate all necklaces with length n, we restrict the position to be less than or equal to n.) For each of these valid combinations of position and value, we lexicographically assign the position to a_{t+1} and the value to b_{t+1}, followed by a recursive call updating both t and p. Finally, if the position of the last nonzero element is greater than or equal to n, we call the $\mathsf{PrintIt}(p)$ function to print out either the Lyndon words or necklaces in a similar manner to the original algorithm $\mathsf{Gen}(t,p)$.

```
procedure Gen2 ( $t$, $p$ : integer );
local $i, j, max$ : integer;
begin
    if $a_t \geq n$ then PrintIt( $p$ )
    else begin
        $max = a_{t+1-p} + a_p$;
        if $max \leq n$ then begin
            $a_{t+1} := max$;
            $b_{t+1} := b_{t+1-p}$;
            Gen2 ( $t+1$, $p$ );
        end else begin
            $max := n$;    $a_{t+1} := n$;    $b_{t+1} := 1$;
            Gen2 ( $t+1$, $t+1$ );
        end;
        for $i \in \{b_{t+1}+1, \ldots, k-2, k-1\}$ do begin
            $b_{t+1} := i$;
            Gen2 ( $t+1$, $t+1$ );
        end;
        for $j \in \{max-1, max-2, \ldots, a_t+1\}$ do begin
            $a_{t+1} := j$;
            for $i \in \{1, \ldots, k-2, k-1\}$ do begin
                $b_{t+1} := i$;
                Gen2 ( $t+1$, $t+1$ );
    end; end; end;
end {of Gen2};
```

FIG. 3.5. *Modified recursive necklace algorithm.*

This modified algorithm, Gen2(t, p), for generating necklaces is given in Figure 3.5. Each initial branch of the computation tree is a result of a separate call to Gen2(t, p), each call specifying a different combination for the position and value of the first nonzero character. Note that the zero string is not generated by Gen2(t,p) and must be generated separately. The nodes of the resulting computation tree for Gen2(t, p) are all prenecklaces with length less than or equal to n whose last character is nonzero.

A complete C program for this modified necklace algorithm is available from the authors. A simplified program for the binary case is also available. Observe that we are not restricted to generating the necklaces in lexicographic order. Many orders are possible by reordering the recursive calls.

3.2. Fixed-density necklace algorithm. We now optimize our modified algorithm for the fixed-density case by making several observations. First, we restrict the position of the first nonzero character depending on the density. In particular, there are no necklaces with density d that can have the first nonzero character in a position after $n - d + 1$ or before $\lfloor (n-1)/d + 1 \rfloor$. Also, if we are generating a string with length n and density d and have just placed the ith nonzero character, then the $(i+1)$st nonzero character must come before the position $n - (d - i) + 2$. If we place the next character at or after this position, then any resulting string with length n will have density less than d. Also, because the last nonzero character must be in the nth position, we stop the string generation after placing the $(d-1)$st nonzero character.

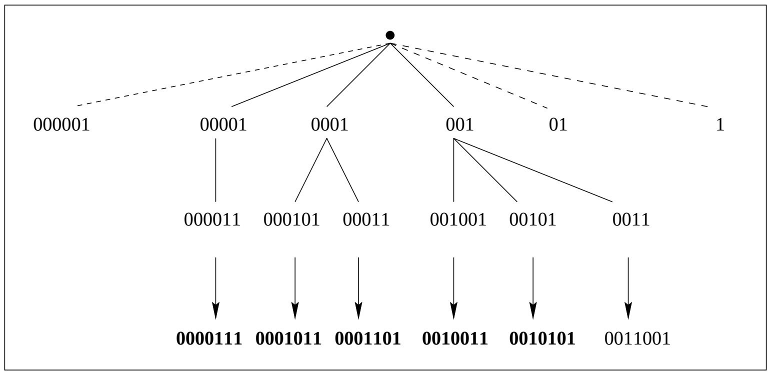

FIG. 3.6. *Computation tree (solid edges only) for $N_2(7,3)$ from* GenFix(t,p).

Thus, the strings generated by following this last restriction are strings with length less than n and density $d-1$. By following this approach, we may generate up to $k-1$ strings for each call to PrintIt(p), since we can place up to $k-1$ characters in the nth position. However, it is not always the case that we will generate all $k-1$ strings or even any strings with each call to PrintIt(p). Thus we add an additional constant-time test to see which values can be placed in the nth position. This test is similar to the test for finding the maximal valid position and minimum value for the next nonzero character as outlined in the previous subsection. Once a minimum value is determined (if there is one at all), we perform the usual tests to determine if the string is a necklace or a Lyndon word. All larger values for the nth position will result in a string that is a Lyndon word [8]. Thus the overall work done in the PrintIt(p) function to determine the valid strings remains constant for each string generated.

In summary, we use our modified necklace algorithm outlined in Figure 3.5 with the following optimizations:

1. The first nonzero character must be between $n-d+1$ and $(n-1)/d+1$ inclusive.
2. The ith nonzero character must be placed at or before the $(n-d+i)$th position.
3. Stop generating when we have assigned $d-1$ nonzero characters.
4. Determine valid values for the nth position in the PrintIt(p) function.

The computation tree for generating $N_2(7,3)$ is given in Figure 3.6. The dotted lines indicate the initial branches we do not need to follow by modification 1. The arrows indicate the strings produced by adding the final character to the nth position. The bold strings indicate the actual necklaces produced by the PrintIt(p) function. The remaining string (0011001) is rejected since it is not a necklace.

The algorithm for generating fixed-density necklaces and Lyndon words in lexicographic order is given in Figure 3.7. To generate fixed-density prenecklaces, we generate $N(n+1,d+1)$ and print out only the first n characters, making sure we do not print the same string twice. A complete C program for this fixed-density necklace algorithm is available from the authors. A simplified program for the binary case is also available. In the latter program we make use of the fact that we can generate binary necklaces with density $d > n/2$ by complementing the output from generating necklaces with density $n-d$. In this case, however, the strings generated are not in lexicographic order and are not necessarily the lexicographic representatives for their respective equivalence classes.

```
procedure GenFix ( $t$, $p$ : integer );
local $i, j, max, tail$ : integer;
begin
    if $t \geq d-1$ then PrintIt($p$);
    else begin
        $tail := n - (d-t) + 1$;
        $max := a_{t+1-p} + a_p$;
        if $max \leq tail$ then begin
            $a_{t+1} := max$;
            $b_{t+1} := b_{t+1-p}$;
            GenFix( $t+1$, $p$ );
            for $i \in \{b_{t+1}+1, \ldots, k-2, k-1\}$ do begin
                $b_{t+1} := i$;
                GenFix( $t+1$, $t+1$ );
            end;
            $tail := max - 1$;
        end;
        for $j \in \{tail, tail-1, \ldots, a_t+1\}$ do begin
            $a_{t+1} := j$;
            for $i \in \{1, \ldots, k-2, k-1\}$ do begin
                $b_{t+1} := i$;
                GenFix( $t+1$, $t+1$ );
    end; end; end;
end {of GenFix};
```

FIG. 3.7. *Fixed-density necklace algorithm.*

4. Analysis of algorithm. In this section we show that GenFix(t,p) is CAT. We start the analysis by analyzing several trivial cases. When the desired density of the string is n the computation tree and strings produced are equivalent to the generation of $N_{k-1}(n)$, which we already know is CAT. When the density is zero we simply generate the zero string, and when $d=1$ we generate the $k-1$ strings where the last bit ranges from 1 to $k-1$ and the rest of the string is all zeros. In each case where the density is greater than zero the resulting strings are generated in CAT.

For the nontrivial cases we examine the number of nodes in the computation tree, noting that the amount of work to generate each node is constant. When $1 < d < n$, the nodes in the computation tree consist only of prenecklaces that end in a nonzero bit with density i ranging from 1 to $d-1$ and length ranging from $(n-1)/d+i$ to $n-d+i$. Recall that $\mathbf{P}'_k(n,d)$ is the set of prenecklaces with length n and density d, where the last bit is nonzero. Thus, the size of the computation tree for our fixed-density algorithm $(1 < d < n)$ is bounded by the expression

$$CompTree_k(n,d) \leq \sum_{i=1}^{d-1} \sum_{j=\frac{n-1}{d}+i}^{n-d+i} P'_k(j,i).$$

Recall that we generate binary fixed-density necklaces with density greater than $n/2$ by generating $N(n, n-d)$ and complementing the output. Therefore, in the case where $k=2$ (and only in this case), we have the restriction that d is less than or equal to $n/2$.

To prove that our algorithm is efficient we will show that the ratio between the size of the computation tree and the number of strings produced is bounded by a constant. Since there does not appear to be a simple explicit formula for $P'_k(n,d)$, our approach will be to derive an upper bound in terms of $N_k(n,d)$ and $L_k(n,d)$.

LEMMA 4.1. $P'_k(n,d) \le N_k(n,d) + L_k(n,d)$.

Proof. We partition $\mathbf{P}'_k(n,d)$ into two categories: necklaces and nonnecklaces. Let the elements of $\mathbf{P}'_k(n,d)$ that are not necklaces be $\mathbf{Q}'_k(n,d)$.

We show that $Q'_k(n,d) \le L_k(n,d)$ by providing an injective mapping of $\mathbf{Q}'_k(n,d)$ to $\mathbf{L}_k(n,d)$. By Lemma 2.1 each element of the set $\mathbf{Q}'_k(n,d)$ must have the form $\alpha = (a_1 \cdots a_p)^j a_1 \cdots a_m$, where $p = lyn(\alpha)$, $j \ge 1$, and $0 < m < p$. Let n_i be the number of occurrences of the symbol i in $a_1 \cdots a_m$ and define the string $\gamma = 0^{n_0}1^{n_1} \cdots (k-1)^{n_{k-1}}$. We define a function f on the set $\mathbf{Q}'_k(n,d)$ as follows:

$$f(\alpha) = \gamma(a_1 \cdots a_p)^j.$$

For example, $f((002101303)^7 0021013) = 0001123(002101303)^7$. This mapping preserves both length and density. Since γ and $a_1 \cdots a_p$ are both Lyndon words and $\gamma < a_1 \cdots a_p$, it follows from repeated use of Lemma 2.2 that $f(\alpha) \in \mathbf{L}_k(n,d)$.

To show that f is injective consider two unique elements of $\mathbf{Q}'_k(n,d)$: $\alpha = (a_1 \cdots a_p)^s a_1 \cdots a_i$ and $\beta = (b_1 \cdots b_q)^t b_1 \cdots b_j$. If $i = j$, then $f(\alpha) \ne f(\beta)$, since $a_1 \cdots a_p$ and $b_1 \cdots b_q$ are both Lyndon words and $a_1 \cdots a_p \ne b_1 \cdots b_q$. Otherwise assume that $i < j$. Since a_i and b_j are both nonzero, the ith element of $f(\alpha)$ is nonzero and the jth element of $f(\beta)$ is nonzero. Now if the ith element of $f(\beta)$ is nonzero then the $(i+1)$st element must also be nonzero if $f(\alpha) = f(\beta)$. However the $(i+1)$st element of $f(\alpha) = a_1$, which is 0. Thus $f(\alpha) \ne f(\beta)$ for unique $\alpha, \beta \in \mathbf{Q}'_k(n,d)$. Thus f is an injection from $\mathbf{Q}'_k(n,d)$ to $\mathbf{L}_k(n,d)$.

Now since there exists an injective mapping from $\mathbf{Q}'_k(n,d)$ to $\mathbf{L}_k(n,d)$ we have $Q'_k(n,d) \le L_k(n,d)$. From earlier discussion we know that $P'_k(n,d) = N_k(n,d) + Q'_k(n,d)$ and thus $P'_k(n,d) \le N_k(n,d) + L_k(n,d)$. ◻

We observe in the binary case that by taking each element from $\mathbf{P}_2(n,d)$ and adding a 1 to the end of the string we get the set $\mathbf{P}'_2(n+1,d+1)$. Thus from the previous lemma we also get an upper bound on $P_2(n,d)$.

COROLLARY 4.2. $P_2(n,d) \le N_2(n+1,d+1) + L_2(n+1,d+1)$.

We can now bound our computation tree as the sum of fixed-density necklaces and fixed-density Lyndon words:

$$CompTree_k(n,d) \le \sum_{i=1}^{d-1} \sum_{j=\frac{n-1}{d}+i}^{n-d+i} N_k(j,i) + L_k(j,i).$$

However, by plugging the formulas for fixed-density necklaces and Lyndon words into the above expression we end up with a complicated quadruple sum. Therefore we will prove two lemmas, which give simple bounds for fixed-density Lyndon words and necklaces.

LEMMA 4.3. *The following inequality is valid for all* $0 \le d \le n$*:*

$$L_k(n,d) \le \frac{1}{n}\binom{n}{d}(k-1)^d.$$

Proof. Each element of $\mathbf{L}_k(n,d)$ is a representative of an equivalence class of k-ary strings, each with n elements. If we add up the elements from each equivalence class we will get $nL_k(n,d)$ unique strings each of length n and density d. The expression

$\binom{n}{d}(k-1)^d$ counts the total number of k-ary strings with length n and density d. Therefore $L_k(n,d) \leq \frac{1}{n}\binom{n}{d}(k-1)^d$. ☐

A similar bound for $N_k(n,d)$ is more difficult to obtain. Here we bound $N_k(n,d)$ by $L_k(n,d)$.

LEMMA 4.4. *The following inequality is valid for all* $0 < d < n$*:*

$$\frac{1}{n}\binom{n}{d}(k-1)^d \leq N_k(n,d) \leq 2L_k(n,d).$$

Proof. By considering the case when $j = 1$ in (2.1) and noting that the remaining terms are all nonnegative, we have

$$\begin{aligned} N_k(n,d) &\geq \frac{1}{n}\sum_{n_1+\cdots+n_{k-1}=d} \frac{n!}{(n_0!)(n_1!)\cdots(n_{k-1}!)} \\ &= \frac{1}{n}\binom{n}{d}\sum_{n_1+\cdots+n_{k-1}=d} \frac{d!}{(n_1!)\cdots(n_{k-1}!)} \\ &= \frac{1}{n}\binom{n}{d}(k-1)^d. \end{aligned}$$

The final equality is a result of the basic multinomial expansion.

To show that $N_k(n,d) \leq 2L_k(n,d)$, we provide an injective mapping of the periodic necklaces to Lyndon words. If α is a periodic necklace, then $\alpha = (a_1 \cdots a_p)^j$, where $p = lyn(\alpha)$ and $j > 1$. Since $d < n$ we know that $a_1 = 0$. We define a function g on all periodic necklaces with length n and density d as follows:

$$g(\alpha) = 0(a_1 \cdots a_p)^{j-1} a_2 \cdots a_p.$$

This function simply moves the bit $a_{p(j-1)+1} = a_1 = 0$ to the front of the string. This operation preserves both length and density. Since $(a_1 \cdots a_p)^{j-1} a_2 \cdots a_p$ is a Lyndon word, by Lemma 2.2 $g(\alpha)$ is a Lyndon word.

To show that g is an injection we consider two unique periodic necklaces: $\alpha = (a_1 \cdots a_p)^i$ and $\beta = (b_1 \cdots b_q)^j$. If $p = q$ and $g(\alpha) = g(\beta)$, then $a_1 \cdots a_p = b_1 \cdots b_q$, contradicting the fact that $\alpha \neq \beta$. If $p \neq q$, then assume that $p < q$. This implies that $i > j > 1$. Now comparing the characters in positions $2, 3, \ldots, q+1$ of $g(\alpha)$ and $g(\beta)$ we observe that if $g(\alpha) = g(\beta)$ then $b_1 \cdots b_q = (a_1 \cdots a_p)^t a_1 \cdots a_s$ for some $t \geq 1$ and $1 \leq s \leq p$. However, since $a_1 \cdots a_p$ is a Lyndon word, then $(a_1 \cdots a_p)^t a_1 \cdots a_s$ is periodic if $s = p$ and is not a necklace if $s < p$. This contradicts the fact that $b_1 \cdots b_q$ is a Lyndon word. Thus $g(\alpha) \neq g(\beta)$ for unique periodic necklaces α and β. Therefore g is an injective mapping from the periodic necklaces to Lyndon words.

Since there exists an injective mapping from the periodic strings of $\mathbf{N}_k(n,d)$ to $\mathbf{L}_k(n,d)$ we get the result $N_k(n,d) \leq 2L_k(n,d)$. ☐

Using the previous lemmas we can simplify our upper bound on the size of the computation tree:

$$\begin{aligned} CompTree_k(n,d) &= \sum_{i=1}^{d-1} \sum_{j=\frac{n-1}{d}+i}^{n-d+i} P'_k(j,i) \\ &\leq \sum_{i=1}^{d-1} \sum_{j=\frac{n-1}{d}+i}^{n-d+i} N_k(j,i) + L_k(j,i) \end{aligned}$$

$$
\begin{aligned}
&\le 3\sum_{i=1}^{d-1}\sum_{j=1}^{n-d+i} L_k(j,i)\\
&\le 3\sum_{i=1}^{d-1}\sum_{j=1}^{n-d+i} \frac{1}{j}\binom{j}{i}(k-1)^i\\
&= 3\sum_{i=1}^{d-1}\frac{1}{i}(k-1)^i\sum_{j=1}^{n-d+i}\binom{j-1}{i-1}\\
&= 3\sum_{i=1}^{d-1}\frac{1}{i}\binom{n-d+i}{i}(k-1)^i. \qquad (4.1)
\end{aligned}
$$

To get the last two equalities we use some basic binomial coefficient identities.

To simplify this bound for the computation tree even more, we inductively prove yet another upper bound for the remaining sum in (4.1). We first prove an upper bound for the case when $k > 2$ and $1 < d < n$. We then provide a similar proof for the case when $k = 2$. In the latter case we take advantage of the fact that we can generate binary necklaces with $d > n/2$ by generating necklaces with density $n-d$ and then complementing the output of each generated necklace to get all necklaces with density d. Once again, this is the only situation where the strings are not generated in lexicographic order. Thus when $k = 2$, we only consider the case when $1 < d \le n/2$.

LEMMA 4.5. *For $2 \le d < n$ and $k > 2$,*

$$\sum_{i=1}^{d-2}\frac{1}{i}\binom{n-d+i}{i}(k-1)^i \;<\; \frac{2}{d-1}\binom{n-1}{d-1}(k-1)^{d-1}.$$

Proof. We prove the lemma by induction on d. Let

$$S_k(n,d) = \sum_{i=1}^{d-2}\frac{1}{i}\binom{n-d+i}{i}(k-1)^i.$$

Basis: $d = 2$ or 3, $n \ge 3$. Observe that this covers all cases for $n = 3, 4$:

$$
\begin{aligned}
&d = 2\colon S_k(n,2) = 0 < 2(n-1)(k-1),\\
&d = 3\colon S_k(n,3) = (n-2)(k-1) < \binom{n-1}{2}(k-1)^2.
\end{aligned}
$$

Assume: $S_k(n,d) < \frac{2}{d-1}\binom{n-1}{d-1}(k-1)^{d-1}$ for $1 < d < n-1$, $k > 2$, and $n \ge 5$. Consider $S_k(n,d+1)$:

$$
\begin{aligned}
S_k(n,d+1) &= \sum_{i=1}^{d-1}\frac{1}{i}\binom{n-d-1+i}{i}(k-1)^i\\
&= \sum_{i=1}^{d-2}\frac{1}{i}\binom{(n-1)-d+i}{i}(k-1)^i + \frac{1}{d-1}\binom{n-2}{d-1}(k-1)^{d-1}\\
&< \frac{2}{d-1}\binom{(n-1)-1}{d-1}(k-1)^{d-1} + \frac{1}{d-1}\binom{n-2}{d-1}(k-1)^{d-1}\\
&= \frac{3}{d-1}\binom{n-2}{d-1}(k-1)^{d-1}
\end{aligned}
$$

$$= \frac{3d}{(d-1)(n-1)}\binom{n-1}{d}(k-1)^{d-1}$$
$$\leq \frac{2}{d}\binom{n-1}{d}(k-1)^{d}.$$

To show that the last inequality is correct we prove that $\frac{3d}{(d-1)(n-1)} \leq \frac{2}{d}(k-1)$ for $n \geq 5$. By multiplying both sides by $\frac{d}{k-1}$ we get $\frac{3d^2}{(d-1)(n-1)(k-1)} \leq 2$. The LHS of this inequality is maximized when we maximize $d = n-2$ and minimize $k = 3$. By substituting these values and rearranging we get

$$\begin{aligned} 3(n-2)(n-2) &\leq 4(n-1)(n-3), \\ 0 &\leq 4(n^2-4n+3) - 3(n^2-4n+4), \\ 0 &\leq n(n-4). \end{aligned}$$

This equality is true for $n \geq 4$. ☐

LEMMA 4.6. *For $2 \leq d \leq n/2$ and $k = 2$,*

$$\sum_{i=1}^{d-2} \frac{1}{i}\binom{n-d+i}{i}(k-1)^i \; < \; \frac{2}{d-1}\binom{n-1}{d-1}(k-1)^{d-1}.$$

Proof. We prove the lemma by induction on d. Let

$$S_k(n,d) = \sum_{i=1}^{d-2} \frac{1}{i}\binom{n-d+i}{i}(k-1)^i.$$

Basis: $d = 2$ or 3, $n \geq 3$. Observe that this covers all cases for $n = 3,4,5,6,7$:

$$\begin{aligned} &d = 2\colon S_k(n,2) = 0 < 2(n-1)(k-1), \\ &d = 3\colon S_k(n,3) = (n-2)(k-1) < \binom{n-1}{2}(k-1)^2. \end{aligned}$$

Assume: $S_k(n,d) < \frac{2}{d-1}\binom{n-1}{d-1}(k-1)^{d-1}$ for $1 < d < n/2$ and $n \geq 5$. From the proof of the previous lemma we know

$$\begin{aligned} S_k(n,d+1) &< \frac{3d}{(d-1)(n-1)}\binom{n-1}{d}(k-1)^{d-1} \\ &\leq \frac{2}{d}\binom{n-1}{d}(k-1)^{d}. \end{aligned}$$

To show that the last inequality is correct we prove that $\frac{3d}{(d-1)(n-1)} \leq \frac{2}{d}(k-1)$ for $n \geq 8$. By substituting the value 2 for k and multiplying both sides by d we get $\frac{3d^2}{(d-1)(n-1)} \leq 2$. The LHS of this inequality is maximized when we maximize $d = \frac{n}{2} - 1$. By substituting this value for d and rearranging the terms we get

$$\begin{aligned} 3\left(\frac{n}{2}-1\right)^2 &\leq 2\left(\frac{n}{2}-2\right)(n-1), \\ 0 &\leq 2\left(\frac{n}{2}-2\right)(n-1) - 3\left(\frac{n}{2}-1\right)^2, \\ 0 &\leq 2\left(\frac{n^2}{2} - \frac{5n}{2} + 2\right) - 3\left(\frac{n^2}{4} - n + 1\right), \\ 0 &\leq \frac{n^2}{4} - 2n + 1. \end{aligned}$$

By solving this quadratic we see that the inequality holds for $n \geq 8$. ◻

We now use the previous lemmas to get a simple upper bound on the size of the computation tree:

$$\begin{aligned} CompTree_k(n,d) &\leq 3\sum_{i=1}^{d-1} \frac{1}{i}\binom{n-d+i}{i}(k-1)^i \\ &= 3\sum_{i=1}^{d-2} \frac{1}{i}\binom{n-d+i}{i}(k-1)^i + \frac{3}{d-1}\binom{n-1}{d-1}(k-1)^{d-1} \\ &< \frac{6}{d-1}\binom{n-1}{d-1}(k-1)^{d-1} + \frac{3}{d-1}\binom{n-1}{d-1}(k-1)^{d-1} \\ &= \frac{9}{d-1}\binom{n-1}{d-1}(k-1)^{d-1}. \end{aligned}$$

Recall that our goal is to prove that the ratio of nodes in the computation tree to the number of strings produced is bounded by a constant. From Lemma 4.4 we have a lower bound on the number of strings produced:

$$N_k(n,d) > \frac{1}{n}\binom{n}{d}(k-1)^d = \frac{1}{d}\binom{n-1}{d-1}(k-1)^d.$$

Thus the ratio of our computation tree to necklaces produced is

$$\frac{CompTree_k(n,d)}{N_k(n,d)} < 9\frac{d}{(d-1)(k-1)} \leq 18.$$

Experimentally, this constant is less than 3.

THEOREM 4.7. *Algorithm* GenFix *for generating fixed-density k-ary necklaces is CAT.*

5. Future work and an application. In this paper we have presented a CAT algorithm for generating fixed-density k-ary necklaces. This algorithm is used when we want to generate necklaces where the number of zeros is fixed; however, if we want all necklaces where the number of occurrences for every character is fixed, then our algorithm works only for the binary case. An efficient algorithm for the k-ary case would be very interesting, but currently does not exist. Another open problem is to count the number of fixed-density prenecklaces; the number of fixed-density necklaces and Lyndon words is known and was given in this paper.

5.1. Generating difference covers. As an application, we embed our fixed-density necklace algorithm into a program that generates difference covers. A set $D = \{a_1, \ldots, a_k\}$, $1 < a_i < n$, is called an (n,k) difference cover if for every $d \neq 0 \bmod n$ there exists an ordered pair (a_i, a_j) in D such that $a_i - a_j = d \bmod n$. For example, the set $\{1, 2, 3, 6\}$ is a $(10,4)$ difference cover. An (n,k) difference cover is minimal if an $(n,k-1)$ difference cover does not exist.

To generate all difference covers (n,k) we generate all fixed-density necklaces $\mathbf{N}_2(n,k)$ where the position of each one in the necklace represents a number in the set D. To determine whether the necklace represents a difference cover, we keep track of information about each ordered pair. This additional work takes at worst case $O(k)$ time for every node in the computation tree. Thus the overall running time for generating all the (n,k) difference covers is $O(kN_2(n,k))$.

In practice, it is useful to know whether or not an (n, k) difference cover exists. When n gets large the search space may become infeasible to work with; however, if we have some intuition about what the first few numbers may be in the set D, we can customize our algorithm to drastically reduce the search space. Using this strategy we were able to prove the existence of a (131, 13) difference cover, namely

$$\{1, 8, 27, 33, 34, 44, 57, 71, 73, 79, 88, 91\}.$$

A complete C program for generating difference covers with equivalence under rotation is available from the authors.

FINDING AN EVEN SIMPLE PATH IN A DIRECTED PLANAR GRAPH[*]

ZHIVKO PRODANOV NEDEV[†]

Abstract. In this paper we show that the following problem, the *even simple path* (ESP) *problem for directed planar graphs*, is solvable in polynomial time:

Given: a directed planar graph $G = (V, E)$ and two nodes $s\,(startingnode)$, $t\,(targetnode) \in V$;

Find: a simple path (i.e., without repeated nodes) from s to t of even length. (The length of the path is the number of edges it contains.)

Key words. labeled directed graphs, NP-completeness, polynomial-time algorithms, regular expressions, simple paths, planar graphs

1. Introduction.

A linear-time algorithm solving this problem for general undirected graphs is given in [5]; it is also shown there that the same problem (ESP) is NP-complete [3] for directed graphs. This is achieved by polynomially reducing the *path via node problem for directed graphs* to the ESP problem. The former problem is one of the many subgraph homeomorphism problems for *directed graphs* that have been shown to be NP-complete in [2].

In [6], the regular simple path (RSP) problem is investigated:

Given: a finite alphabet $\sum$,
a database in the form of a edge-labeled directed graph G, with labels taken from $\sum$,
a query R in the form of a regular expression over the same alphabet $\sum$,
and a pair of vertices (x, y) from G;

Find: a simple path p in G from x to y such that the concatenation of labels along p satisfies R.

In [6], it is also shown that RSP is NP-hard in general. One of the cases used to prove this statement is the query $R = (\_\ \_)*$. (Here the symbol "_" stands for any letter of the alphabet.) This is just the ESP problem stated in another way—in this case the labels play no role. As has already been pointed out [5], this problem is NP-complete for a general digraph. But in [6] several algorithms are presented which run in polynomial time in the size of the graph for certain classes of graphs and queries.

As a result of our paper we can state that the same query, $R = (\_\ \_)*$, is polynomially solvable if G is a planar graph. Thus, our paper broadens the knowledge of the RSP problem—expanding the number of situations where this NP-complete problem can be polynomially solved.

In our paper we show that the ESP problem is solvable in polynomial time by polynomially reducing it to the following *k disjoint paths problem for directed planar graphs*:

[†]Department of Computer Science, University of Cape Town, Rondebosch 7700, South Africa (nedev@cs.uct.ac.za).

Given: a directed planar graph $G = (V, A)$ and k pairs $(r_1, s_1), \ldots, (r_k, s_k)$ of vertices of G;

Find: k pairwise vertex-disjoint paths $P_1, \ldots, P_k$ in G, where P_i runs from r_i to s_i $(i = 1, \ldots, k)$.

for the simplest case $k = 2$. Recently it was shown that this problem is polynomially solvable for any fixed k [7].

In our solution we introduce two new data structures: The first one is a plane region with oriented boundaries, called "list," which has theoretical value only, as the number of list structures in a planar graph might be exponential (we present such an example in section 5). The second data structure is a special case of the first structure; we call it "simple list." We prove that the number of simple lists in any planar graph is polynomial and we give a polynomial algorithm to generate all of them. In this algorithm we also invent a special modification of depth-first search (DFS) [8] for the case of planar graphs.

The rest of the paper is organized as follows. Section 2 gives preliminary definitions. Section 3 gives the general idea of the main algorithm. Section 4 contains the basic lemmas about list superfaces. Section 5 introduces the new modification of the DFS algorithm for planar digraphs and gives polynomial algorithm for finding all its simple lists. Section 6 presents the final algorithm for the ESP problem and section 7 gives possible future extensions.

2. Preliminaries.

The following "basics for planar graphs" have been taken almost directly from [4].

Consider a directed graph $G = (V, E)$ with edge set E and vertex set V. Let $n = |V|$ and $m = |E|$. We can draw a picture G' of G in the plane as follows: For each vertex $v \in V$, we draw a distinct point v'; for each edge $(u, v) \in E$, we draw a simple arc connecting the two points u' and v'. We call this arc an *embedding* of the edge (u, v). For brevity, we will sometimes identify graphs with their pictures thus drawn in the plane. If no arcs of G' cross each other, we call G' a *planar embedding* or *embedding* of G. If G has a planar embedding, then we say that G is *planar*.

Let G be a connected embedded planar digraph. If the edges and vertices of G are deleted from the plane in which G is embedded, the plane is divided into disconnected regions. Exactly one of the regions is infinite; all others are finite. Each region is called a *face* of G—in this paper we will call it an *elementary face* to distinguish it from a superface (defined below). The infinite region is also called the *external* face; the finite regions are called *internal* faces. The *boundary* of a face f is the sequence of edges and vertices surrounding f. Any face boundary is a simple cycle.

DEFINITION 1. *If we have a digraph G, then we will call any set of edges that forms a simple cycle (possibly disregarding the directions of the edges), together with its interior or exterior, a* superface. *We will call that simple cycle the* boundary *of the superface. This interior or exterior part of the plane that is associated with the boundary is the* inside *part of the superface; further, if a vertex or edge lies there, we will say that it is inside even if it is from the exterior part of the plane.*

Please note that for any given simple cycle, we have exactly two superfaces with boundary this cycle: one with finite and one with infinite face.

DEFINITION 2. *A superface is called a* list superface *LS or* list *if its boundary contains two special nodes b and e, the first called the beginning and the second called the end, such that all the edges from the boundary moving clockwise from the beginning b to the end e are in one direction—from the beginning to the end—and all the edges from the boundary moving counterclockwise from the beginning b to the end e are in*

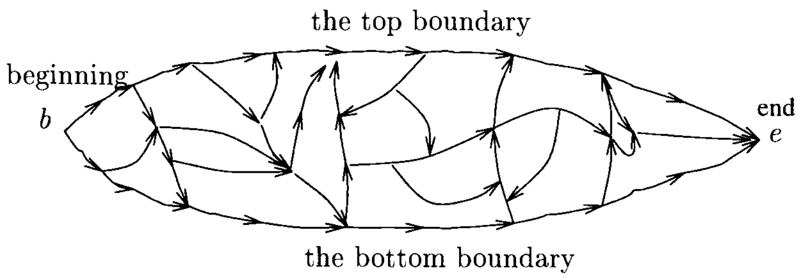

FIG. 1. *An example of a list superface.*

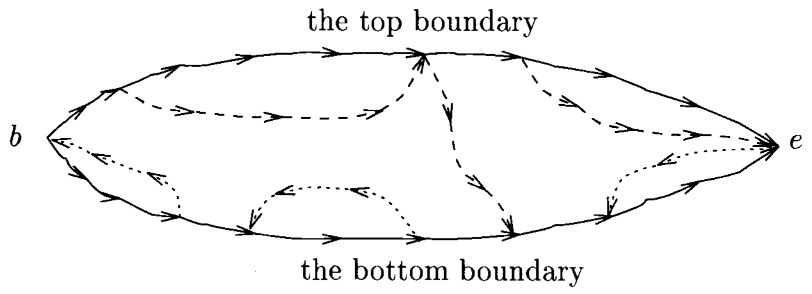

FIG. 2. *An example of forbidden (dashed) and permitted (dotted) paths in a simple list superface.*

one direction—from the beginning to the end (see Figure 1*).*

DEFINITION 3. *A list superface LS is called a* simple *list superface if for all directed paths $P = p_0, p_1, \dots, p_n$ where p_0 and p_n lie on the boundary, $p_1, \dots, p_{n-1}$ are strictly from the inside, and p_n is a predecessor of p_0 (meaning that from p_n we can reach p_0 using only the directed edges from the boundary of the LS; see Figure* 2*).*

From now on we will assume that our graph at hand has been preprocessed so that the following will hold:

- All vertices in the graph are reachable from s (the starting node), and t (the target node) can be reached from any vertex. In doing this we discard all the nodes that are irrelevant to the ESP problem between the nodes s and t. This can be done if we run BFS(s), reverse the direction of each edge, run BFS(t) and delete each node that hasn't been marked by both runs of breadth-first search algorithms.
- The graph has been tested for planarity and embedded if found planar.

3. Outline of the main algorithm. First we find one simple path from s to t. If it has even length, we stop and print it as a final solution. From now on we will assume that we are working on the nontrivial case—as a result of the first step, we have a path of odd length.

We prove that if there is at least one solution—an even path between s and t—in addition to the odd path found previously, then there exists a list superface LS with one even and one odd border and two simple node-disjoint paths P_1 and P_2, the first from s to the beginning of the list b, and the second from the end of the list e to t, such that P_1 and P_2 are also node-disjoint from the boundary of LS less $\{b,e\}$.

Next we prove that if there exists a list superface LS and two simple node-disjoint paths P_1 and P_2 as above, then there exists a *simple* list superface LS' and P_1' and P_2' with the same property. We need this because a planar graph can have an exponential number of list superfaces, but the number of simple list superfaces is polynomial in the size of the graph.

Based on these facts, we employ a modified DFS to construct all simple list superfaces in G. For each found simple list superface F we check if it has one odd and one even border; if this is the case, first we delete all the nodes on the boundary of F (except b and e) with their associated edges. Then we employ the algorithm from [7] to find node-disjoint paths between s and the beginning b of the simple list superface and between the end e of the simple list superface and t. If we find at least one such complete construct, then one solution—an even path—can be constructed as a concatenation of these two paths and one of the two borders of the simple list at hand. If in searching through all simple lists we fail to find such a construct, then it will mean that we have proved that a solution doesn't exist.

4. Basic theorem.

LEMMA 1. *Let F be a nonsimple list superface with one odd and one even boundary. Also let there be two simple node-disjoint paths, P_1 and P_2, the first from s to b (the beginning of F) and the second from e (the end of F) to t, such that P_1 and P_2 are also node-disjoint from the boundary of F less $\{b,e\}$. Then using a path P which makes F nonsimple, we can find a list superface $F' \subsetneqq F$, with one odd and one even boundary and two simple node-disjoint paths P_1' and P_2', such that P_1' and P_2' are also node-disjoint from the boundary of F' less $\{b',e'\}$, one from s to the beginning of F' and one from the end of F' to t.*

Proof. There are two general cases for the paths P_1 and P_2:

1. The two paths are from the same side with respect to the boundary of F, either outside or inside. If they are inside we can map all the nodes and edges from the outside of F inside, and vice versa. Therefore we can treat these two subcases as one—we will assume that the two paths are from the outside of F.
2. The two paths are from different sides with respect to the boundary of F, one is outside and the other inside. Again using remapping of all the nodes and edges from the outside of F inside and vice versa, we can treat these two subcases as one—we will assume that the two paths are P_1 outside and P_2 inside F.

A. Let us consider the first case for P_1 and P_2: the two paths are from the outside of F. Let the path P make F nonsimple. There are two cases for this path P with beginning p_0 and end p_n. In the first case, suppose p_0 lies on one boundary and p_n lies on the other (see Figure 3 (a)). Here there are two possible sublist superfaces of F. The two boundaries are divided into four pieces, of which one is even and three are odd, or three even and one odd. In either case there will be one sublist with subboundaries of equal parity and one with subboundaries of different parities. If P is even, we take as F' the sublist with subboundaries of different parities; if P is odd, we take the sublist with subboundaries of equal parity. One of the two paths from s to the beginning of F' and from the end of F' to t will stay the same; the other will be a continuation of the path for F with one piece of the boundary (see Figure 3). The second case where p_0 and p_n lie on the same boundary of F is similar (see Figure 3 (b)).

B. Let us consider the second case for P_1 and P_2: P_1 outside and P_2 inside F. Let path P with beginning p_0 and end p_n make F nonsimple. In this case, P and P_2

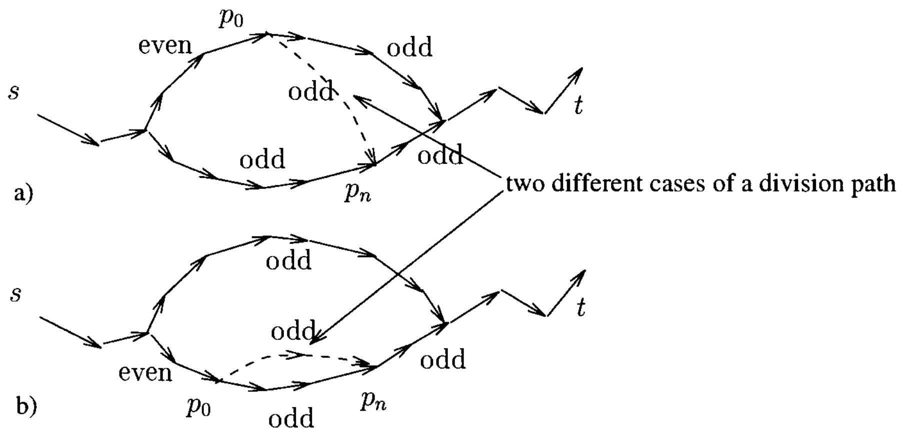

FIG. 3. *Nonsimple list and the division path.*

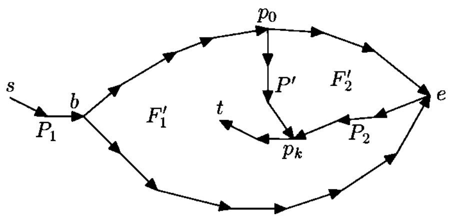

FIG. 4. *Nonsimple list with P_2 inside; a division path intersects P_2.*

are inside F. If P is node-disjoint with P_2, we repeat the logic from case A to derive P'_1, F', and P'_2. Let us assume, then, that P intersect P_2 and let us denote by P' this part of P that starts from its beginning p_0 until the first common node with P_2, p_k (see Figure 4).

Let a = *length* (the path of the upper boundary from b up to p_0). Let b = *length* (the path of the upper boundary from p_0 up to e). Let c = *length* (the lower boundary). Let x = *length* (the subpath P'). And let y = *length* (the subpath of P_2 from e to p_k). There are two possible sublists: F'_1 and F'_2 of the list F, which possibly can lead to the solution of our lemma. Let us presume for the moment that their boundaries are of equal parity. Then the following equations are correct:

$$\begin{aligned} a + b + c &= 2k_1 + 1, \\ x + b + y &= 2k_2, \\ a + x + c + y &= 2k_3. \end{aligned}$$

Adding the above three equations we get the following:

$$2(a + b + c + x + y) = 2(k_1 + k_2 + k3) + 1.$$

But as a, b, c, x, and y are whole numbers, this is impossible. It means that one of the two possible subfaces of F has boundaries with different parities. If it is F'_1, taking $P'_1 = P_1$ and $P'_2 = \{$the subpath of P_2 from p_k to $t\}$, we have a solution of the lemma. If F'_2 has boundaries with different parities, taking $P'_1 = \{P_1$ concatenated with the subpath of the upper boundary from b to $p_0\}$ and $P'_2 = \{$the subpath of P_2 from p_k to $t\}$, we have a correct solution of the lemma. $\square$

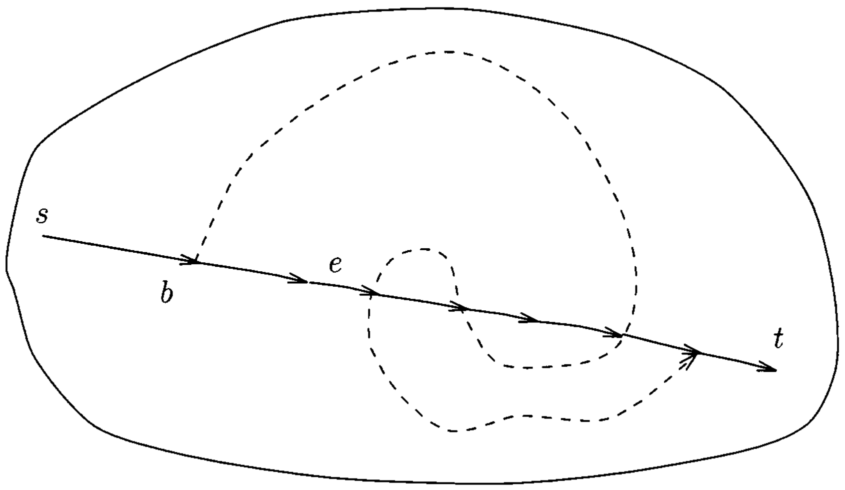

FIG. 5. *Two simple paths, one even and one odd, between s and t.*

COROLLARY. *If we have the situation of Lemma 1, we can derive $F' \subsetneq F$ with the same property as F. We can repeat this only a finite number of times, so we must eventually reach a simple list superface with the same property as F.*

LEMMA 2. *Suppose G is planar graph embedded in the plane, and s and t are two vertices from G. If there are two simple paths from s to t, one of which is even and the other odd, then there exists a simple list superface F with one odd and one even boundary, and two simple paths P_1 and P_2, one from s to the beginning of F and one from the end of F to t, such that F, P_1, and P_2 are mutually node disjoint.*

Proof. Let the even path be $s, v_1, v_2, \dots, v_k, t$ and the odd path be $s, u_1, u_2, \dots, u_l, t$. Let b be the first point lying on both paths, such that P_1 and P_2 coincide from s up to b and separate at b. Let e be the first vertex of P_1 after b which is also on P_2 (see Figure 5 ($P_1 \equiv$ solid line, $P_2 \equiv$ dashed line)).

Let us consider the length of the subpaths of P_1 and P_2 between b and e. Suppose they are of equal parity; then, because P_2 does not have any point in common with the subpath of P_1 between b and e, we can replace the subpath of P_2 between b and e with the subpath of P_1 between b and e. In other words, we can make the two paths P_1 and P_2 coincide from s to e and still have different parities.

We cannot repeat the previous step indefinitely or we will reach two paths of equal parity. Eventually we will reach a point where b and e are as above, but the subpaths of P_1 and P_2 between b and e have different parity.

Now consider the list which starts at b and ends at e, with boundaries the subpaths of P_1 and P_2 between b and e. We also have two node-disjoint paths, the coinciding part of P_1 and P_2 from s to b, and the subpath of P_2 from e to t. Now we have the situation of Lemma 1. It follows that we must have a simple list superface F with one odd and one even boundary, and two simple node-disjoint paths P_1' and P_2', one from s to b', the beginning of that simple list superface, and one from e', the end of the list, to t. It is also true that these two paths are node-disjoint from $F - b' - e'$. □

5. Finding all simple lists. The DFS algorithm [8], [1] does not specify the order in which the neighbors of a given vertex are to be visited. For a planar em-

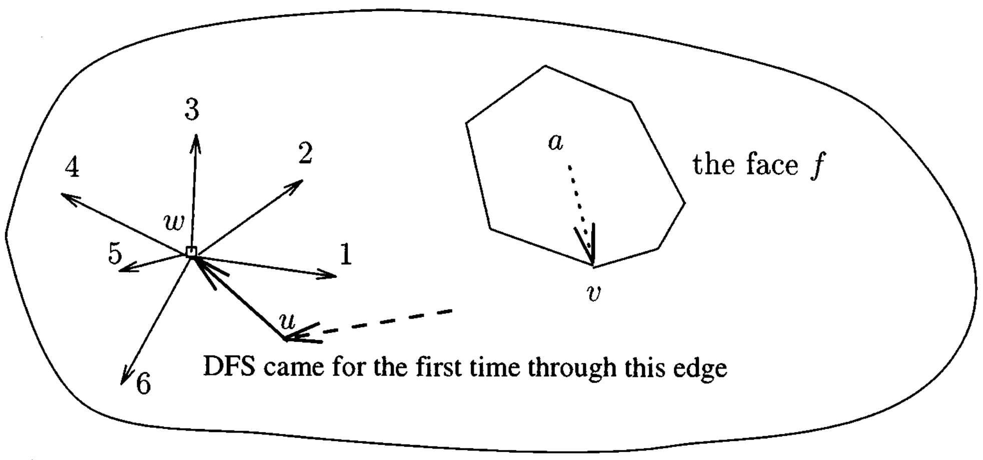

FIG. 6. *A dynamically introduced order during the DFS of all outgoing edges.*

bedding of a planar graph G, we introduce a *right depth-first search* (RDFS) and *left depth-first search* (LDFS), depending initially on a starting vertex v and an elementary face f which must have v on its boundary.

DEFINITION 4. *First we pick any point a from the interior of f and connect it to v through a new edge $a \mapsto v$. Since a planar embedding means that the edges incident with every vertex can be sorted clockwise or counterclockwise, we reorder all outgoing edges from v in counterclockwise manner starting with the first outgoing edge counterclockwise from $a \mapsto v$. Now we start a DFS of G from v using the new order from above. Whenever the DFS visits a new vertex w for the first time through the edge $u \mapsto w$, we reorder all outgoing edges from w counterclockwise from this edge (see Figure 6). After this reordering is done, we continue the DFS in a normal way using this new order. This modification of DFS we will call LDFS (v,f).*

RDFS (v, f) is defined similarly, using the clockwise order.

It is easy to see that the price paid for the dynamic reordering of the outgoing edges in each vertex is not significant. Let $m_1, m_2, \ldots, m_n$ (note that $\sum_{i=1}^{n} m_i = m$, the number of all edges in G) be the number of edges incident with every node of G. Then if we perform only a binary search and the "reordering" is done by showing only the position of the first clockwise outgoing edge in the old double-linked adjacency list at each vertex of G, the running time of the modified DFS is

$$T \le T_{DFS} + \log_2 m_1 + \log_2 m_2 + \cdots + \log_2 m_n \le T_{DFS} + \log_2 \left(\prod_{i=1}^{n} m_i \right)$$

$$\le T_{DFS} + \log_2 \left(\left(\sum_{i=1}^{n} m_i \right) / n \right)^n \le T_{DFS} + n \log_2((3n-6)/n) \le O(n).$$

Here we used the inequality $\prod_{i=1}^{n} m_i \le (\sum_{i=1}^{n} m_i)/n)^n$ and the fact that the sum of all edges in a planar graph is less than or equal to $3n - 6$.

We now apply the modified DFS in the following algorithm.

```
1.    ALGORITHM A: Finding_all_simple_list_superfaces (G); /*G is planar digraph*/
2.    begin  for each edge $v \mapsto u$ in the graph $G$ do
```

```
                /* There are two elementary faces having $v \mapsto u$ on their
                        boundaries.*/
                /* We use the face $f$ to guarantee the uniqueness of the simple face
                        output in line 12*/
3.              choose the face $f$ that contains the edge $v \mapsto u$ in the clockwise
                        direction;
4.              build $LDFSTree(v, f)$ with the condition that $v \mapsto u$ is the only
                        outgoing edge from $v$;
                  /* all other outgoing edges are temporarily deleted until the end
                        of this line */
5.              build $RDFSTree(v, f)$;
6.              for each vertex $w \in G$, $w \neq v$ do
7.                  if $w \in$ both of the above trees then
8.                      find the path $P_1$ from $v$ to $w$ made up of vertices in the first
                              tree;
9.                      find the path $P_2$ from $v$ to $w$ made up of vertices in the
                              second tree;
10.                     if $P_1 \cap P_2 = \{v, w\}$ && the face $f \in$ the finite region between
                                    $P_1$ and $P_2$ then
11.                         print $P_1 \cup P_2$ as a simple list superface;
                        end if ;
                    end if ;
                end for ;
            end for ;
      end;
```

LEMMA 3. *Algorithm* A *gives us all simple list superfaces in G, and the number of simple list superfaces is polynomial in the number of vertices of G.*

Proof. First we will prove that the output of Algorithm A is a simple list superface. Consider the output of line 12. From line 11 we have $P_1 \cap P_2 = \{v, w\}$ and face $f \in$ the finite region between P_1 and P_2. Let us assume that this list superface is not simple. But then there must be a directed path $P = p_0, p_1, \ldots, p_n$ where p_0 and p_n lie on the boundary and $p_1, \ldots, p_{n-1}$ lie inside, such that p_n is not a predecessor of p_0. There are two possible cases (see Figure 7):

a. p_0 and end p_n lie on opposite boundaries of F;

b. p_0 is a predecessor of p_n on the same boundary.

Without loss of generality, we suppose that p_0 lies on P_1. Let the first vertex after p_0 be p_1 on P and p' on P_1. In Algorithm A, the path P_1 consists of tree arcs formed during $LDFS(v, f)$, so the arc $p_0 \mapsto p_1$ will be traversed before the arc $p_0 \mapsto p'$ because of the counterclockwise order induced on the outgoing arcs from p_0. There is now a path from p_1 to w in the first case and from p_1 to p_n in the second case. But then the DFS must have visited w or p_n already when it finished with p_1 and before it returned to p_0 (see [1]). Therefore, when the arc $p_0 \mapsto p'$ was traversed later, the algorithm would not have repeated its visit to w (in the first case) or p_n (in the second case).

This contradiction means that the output of line 12 of Algorithm A is a simple list superface.

Second, let's take any simple list superface F in G and prove that it will be found by Algorithm A.

Let F begin at b and end at e, and let b_1 and b_2 be the neighbors of b on each

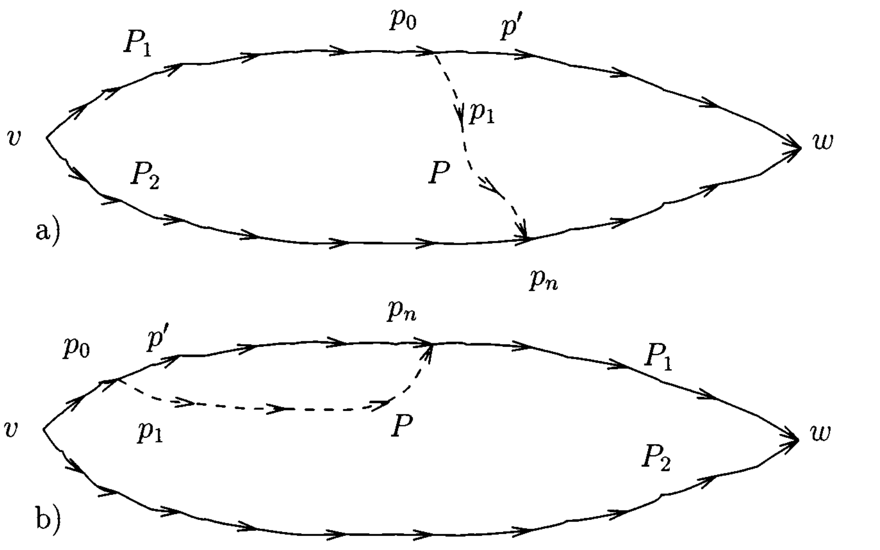

FIG. 7. *If we assume that F is not simple, there are two possible paths which split F.*

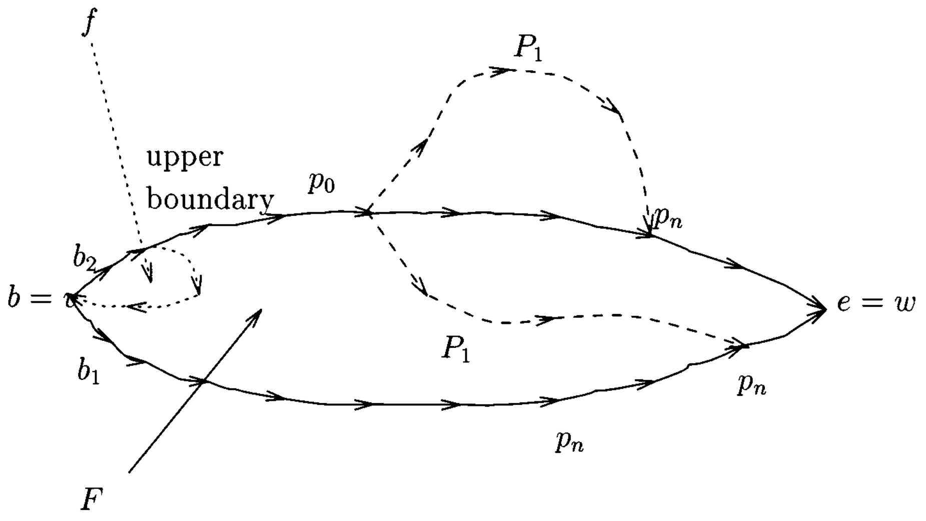

FIG. 8. *We assume that the simple list superface F is not generated by Algorithm* A.

of the two boundaries of F, ordered counterclockwise. Let f be the elementary face inside F which has $b \mapsto b_2$ on its boundary (see Figure 8).

Suppose that Algorithm A reaches b in line 2, $b \mapsto b_2$ in line 3, and e in line 7 and that the paths found in lines 9 and 10 are such that P_1 is not the upper boundary of F (the boundary which contains b_2) or P_2 is not the lower boundary of F.

Let p_0 be the first vertex where the upper boundary separates from the path from $LDFSTree(b, f)$ from b to e. There are two possibilities for P_1:

1. to go counterclockwise from the upper boundary,
2. to go clockwise from the upper boundary.

In the first case let p_n be the vertex where P_1 and the upper boundary meet again.

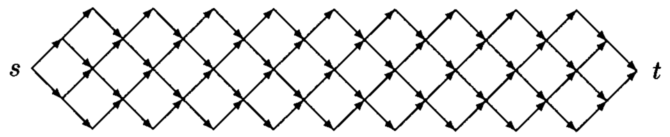

FIG. 9. *An example of exponential number of list superfaces ($l = 11$).*

As in the first part of the proof, p_n will be traversed by LDFS before considering the subpath of P_1 after p_0—which is a contradiction. In the second case, p_n can't be a predecessor of p_0 because P_1 is a path from a tree and therefore simple. Thus p_n might be an ancestor of p_0 on the same boundary or lie on the opposite boundary, but both of these cases violate the fact that F is simple.

We have proved that the upper boundary and P_1 must be identical. The proof that the lower boundary of F is P_2, the path found by $RDFSTree(b, f)$ between b and e, is similar. ∎

LEMMA 4. *The number of simple list superfaces is polynomial.*

Proof. The number of iterations of the outmost loop (line 2) will not be more that the number of arcs in G. The innermost loop (line 6) will not execute more than n times on each round of the outmost loop, where n is the number of vertices. Inside the innermost loop each line will take at most $O(n)$ time. So Algorithm A will be $O(m * n * n)$, which is $O(n^3)$ for planar graphs. ∎

Example. It is not easy to find a case where there is an exponential number of list superfaces with start vertex s and end vertex t. In Figure 9 the graph has the number of vertices $\geq 5l - 6$, where l is a parameter. In a list superface from s to t, either the top or the bottom square or both (3 variant) from each vertical pair (one top and one bottom square form one vertical pair) must be present. Thus there are at least 3^{l-2} list superfaces, none of which is simple, starting at s and ending at t. If Algorithm A is run with this example, all these superfaces will be discarded because of the violation of the first condition in line 10 of Algorithm A.

6. Final algorithm.

We are ready to formulate and prove an algorithm to find an even simple path between vertices s and t in a planar digraph G.

```
1.  ALGORITHM B: Find_even_simple_path_in_planar_digraph(G);
2.  Find one simple directed path from s to t; if there is none, go to line 12;
3.  If the path found at the previous step is even, then print the solution and exit;
4.  Use Algorithm A(G) to generate all simple list superfaces and feed them one
        by one to the next line;
5.  for each simple list superface F with start b and end e in G do
6.      if F has one even and one odd boundary then
7.          delete temporarily until end if all the nodes from the boundary of F,
                except b and e;
8.          run the polynomial algorithm from [7] to find two node-disjoint paths:
                one from s to b, and one from e to t;
9.          if there is a solution for the latest task then
10.             there is final solution—concatenation of these three pieces:
                    a) the path, found in line 8, from s to b
                    b) the subboundary of F, that is, of the same parity as
                       the sum of the two paths from line 8
                    c) the path from e to t, found in line 8
11.             print this solution and exit;
```

```
            end if ;
        end if ;
    end for ;
12. print THERE IS NO SOLUTION!;
    end;
```

LEMMA 5. *Algorithm* B *is correct and is polynomial in the size of the graph G.*

Proof. Step 2 is no more than an algorithm for the shortest distance between s and t. For step 4, we use the result from Lemma 3 that Algorithm A is polynomial and that the number of all simple list superfaces in a planar graph is polynomial. This means that the **for** cycle starting in line 5 executes a polynomial number of times. Since all steps in the body of the **for** loop are polynomial (for line 8, see [7]), and there is a polynomial number of iterations, the whole of Algorithm B is polynomial. □

We haven't tried to calculate any estimation for the running time of Algorithm B because it refers to the algorithm from [7], which has had only theoretical value up to now.

7. Conclusion.

As a result of Lemma 5 we can state that the query $R = (\_ \, \_)*$ from RSP problem (described in the introduction) is polynomially solvable for planar graphs. It is an open problem to find which other queries or classes of queries allow a polynomial solution to the RSP problem in planar digraphs and digraphs embedded onto orientable surfaces. Also there is a need for efficient polynomial algorithms for them. It would also be interesting to investigate which classes of queries remain NP-complete for planar graphs. Furthermore, it would be interesting if there exists a more efficient algorithm than that presented here for finding all simple list superfaces in a directed planar graph.

THE ANGULAR-METRIC TRAVELING SALESMAN PROBLEM*

ALOK AGGARWAL†, DON COPPERSMITH†, SANJEEV KHANNA‡,
RAJEEV MOTWANI§, AND BARUCH SCHIEBER†

Abstract. Motivated by applications in robotics, we formulate the problem of minimizing the total angle cost of a TSP tour for a set of points in Euclidean space, where the angle cost of a tour is the sum of the direction changes at the points. We establish the NP-hardness of both this problem and its relaxation to the cycle cover problem. We then consider the issue of designing approximation algorithms for these problems and show that both problems can be approximated to within a ratio of $O(\log n)$ in polynomial time. We also consider the problem of simultaneously approximating both the angle and the length measure for a TSP tour. In studying the resulting tradeoff, we choose to focus on the sum of the two performance ratios and provide tight bounds on the sum. Finally, we consider the extremal value of the angle measure and obtain essentially tight bounds for it. In this paper we restrict our attention to the *planar* setting, but all our results are easily extended to higher dimensions.

1. Introduction.

The traveling salesman problem (TSP) is one of the most widely studied combinatorial optimization problem, to the extent that there is an entire book [16] devoted to it. The importance of this problem is in large part due to the richness of its structure, which has led to the development of a variety of general paradigms and techniques for dealing with optimization problems. We further explore this structure by formulating a natural version of the TSP problem that does not seem to have been studied earlier in the literature [16]. The new problem, called the Angle-TSP problem, seeks to minimize the total angle of a TSP tour for a set of points in Euclidean space, where the angle of a tour is the sum of the direction changes at the points. We establish the NP-hardness of this problem and the related cycle-cover problem, provide approximation algorithms for both problems, study their extremal properties, and give tight bounds on the trade-off between the angular and the length performance ratio achievable by a TSP tour.

Formally, we define the optimization problem *angle-TSP* as follows: given a collection $P = \{p_1, \ldots, p_n\}$ of n points in Euclidean space, find a tour of the points in

P with minimum total angle. For two edges (u, v) and (v, w) incident on a vertex v, we define the angle subtended by them as the angle between the vectors $\vec{uv}$ and $\vec{vw}$. Equivalently, this angle is the absolute value of the change in the direction of motion when traveling from u to w via v, along these edges. Note that the angle always lies in the interval $[0, \pi]$. For a path or a cycle on a subset of P, the total angle subtended is defined as the sum over all pairs of adjacent edges of the angle subtended by the pair. We also define an angular-metric version of the cycle cover problem (CCP) called **Angle-CCP:** given a collection $P = \{p_1, \ldots, p_n\}$ of n points in the Euclidean plane, find a cycle cover of the points in P subtending the minimum possible total angle. As will become clear shortly, unlike the length-metric cycle cover problem that is relatively easy, the Angle-CCP problem is as hard as the angle-TSP problem itself.

Our main results are as follows. We show that the Angle-TSP and the Angle-CCP problem are both NP-hard. Given this, we turn our attention to designing approximation algorithms for these problems and show that both problems can be approximated to within a ratio of $O(\log n)$ in polynomial time. It should be noted that the Angle-TSP appears easier than Angle-CCP since an approximation algorithm for Angle-CCP would imply a similar approximation for Angle-TSP but the reverse is not clear. We also consider the problem of simultaneously approximating both the angle and the length measure for a TSP tour. In studying the tradeoff between the angle and the length metric, we choose to focus on the sum of the two performance ratios and provide tight bounds on the sum. Finally, we consider the extremal value of the angle measure and obtain essentially tight bounds for this too. While we state our results in context of *planar* angle-TSP, all our results are easily extended to higher dimensions.

Our original motivation was a problem posed by Guibas, namely, to find a "smooth" tour that visits a set of prescribed viewpoints of an object [12]. The smoothness criteria arises naturally in the context of nonholonomic robots [2, 3, 14]. Of late, there has been considerable interest in motion planning with "curvature constraints" (for example, see Agarwal, Raghavan, and Tamaki [1]). This is motivated by nonholonomic motion planning for steering-constrained robots that have stops on the steering mechanisms limiting the rate of change of direction [4, 5, 10, 13, 15]. Our problem involves a different notion of smoothness, but it could be used as a preprocessing step for planning curvature-constrained paths as suggested by Fraichard [10]. Our notion is of direct relevance in situations where a rotation by a robot is significantly more expensive than a translation. For instance, this would be the case for robots with high inertia, or where relatively large mechanical errors during rotation would necessitate error-detection and correction process via localization [14]. Also, there are applications in planning the trajectories of high-speed aircraft [8].

The angle-TSP is a special case of TSP problems where the cost of an edge depends on the edges traversed earlier in the tour. Several applications can be modeled by such TSP problems. For example, the problem of scheduling orders in a production line can be modeled as a TSP problem where the vertices represent orders that have to be scheduled and edges represent set-up costs in moving from one order to another. In applications such as VLSI fabrication, steel mills and chemical plants scheduling, the set-up cost of chemical cleansing and temperature control depend not only on the previous order, but on several previous orders. This translates to a TSP problem where the cost of an edge depends on previous edges.

Our work suggests many interesting and challenging directions for future work.

Can our approximation ratio of $O(\log n)$ be improved to a constant, or be matched by a complementary hardness result? What can be said about other forms of trade-off such as the product of the angle and the length measures? It is also interesting to consider other natural variants of the basic angle-TSP problem; for example, the variant where the maximum angle change at a vertex is bounded and the goal is to minimize the length measure.

The rest of this paper is organized as follows. We begin in Section 2 by showing that there are polynomial time $O(\log n)$-approximation algorithms for both angle-TSP and Angle-CCP. In Section 3, we establish essentially tight bounds on the extremal cost of Angle-TSP. Building on the latter result, in Section 4, we establish tight bounds on the ability of a polynomial time algorithm to simultaneously approximate both the optimal angle-TSP and the optimal Length-TSP. Finally, in Section 5, we present the proof of NP-hardness of angle-TSP and Angle-CCP.

2. Approximation algorithms for angle-TSP and angle-CCP.

In this section, we describe an $O(\log n)$-approximation algorithm for the angle-TSP problem on an instance P containing n points, with a running time polynomial in n. But first we need the following lemmas.

LEMMA 2.1. *Suppose there is a cycle C on a set of points P in the plane that subtends a total angle of α. Then, for any subset $P' \subset P$, there exists a cycle C' subtending a total angle at most α.*

The proof of Lemma 2.1 is straightforward: using short-cuts to eliminate the points of $P \setminus P'$ from C, we obtain a cycle C' of no larger total angle by the triangle inequality for angles.

LEMMA 2.2. *There is a polynomial-time algorithm that finds a maximum cardinality path on the points in P that subtends a total angle at most π.*

Proof. We use dynamic programming similar to Boyce *et al.* [6]. Fix some directed edge s in P and define the array A_s as follows: for each directed edge e in P and for $1 \leq k \leq n$, the array entry $A_s[e, k]$ contains the minimum angle subtended by a path of cardinality k starting with the edge s and ending at edge e; by convention, the entry is ∞ if there is no such path of cost at most π. We claim that the array entries for paths of cardinality k can be computed from the array entries for paths of cardinality $k-1$ in polynomial time, as follows: for any directed edge e and any edge f directed into the source point of e, let $\theta_{f,e}$ be the angle between f and e; then, $A_s[e,k] \leftarrow \min_f \{A_s[f,k-1] + \theta_{f,e}\}$, and $A_s[e,k]$ is set to ∞ if it exceeds π. To verify the correctness of this computation, observe that in a path with total angle at most π, neither vertices nor edges can repeat.

It is fairly easy to modify the preceding construction to store actual paths, rather than the angle subtended by them. The maximum cardinality path starting from the edge s with total subtended angle at most π can be determined by finding the largest k for which there exists an edge e such that $A_s[e,k]$ is finite. Repeating this for all choices of the starting edge s gives the desired result. It is easy to verify that this computation can be performed in polynomial time. □

We now establish the desired result.

THEOREM 2.3. *There is a polynomial-time algorithm which gives $O(\log n)$-approximation for angle-TSP.*

Proof. Suppose that we are given an instance P consisting of n points $\{p_1, \ldots, p_n\}$ in the plane. Let τ^* be the minimum angle tour for P, where $\theta = \theta_{opt}(P)$ is the total angle change in the optimal cycle. Define $K = \lceil \theta/\pi \rceil$, clearly $K \geq 2$. It follows that the tour τ^* contains a subpath of cardinality at least n/K which subtends a net angle change at most π.

We now claim that for any instance P with n points with $\theta_{opt}(P) \leq K\pi$, it is possible to compute in polynomial time, a cycle cover $\mathcal{C} = \{C_1, \ldots, C_r\}$ for P with the following properties: $r = K \log n$; and, each cycle C_i subtends a total angle at most 3π. It can be verified that patching together any two cycles C and C' subtending total angles α and α' gives a single cycle C'' subtending an angle $\alpha'' \leq \alpha + \alpha' + 2\pi$. From this, it follows that repeatedly patching together the cycles in $\mathcal{C}$ gives a tour τ with $\theta(\tau, P) = O(\pi K \log n)$. Since $\theta_{opt}(P) = \Omega(\pi K)$, it follows that $R_\theta(\tau, P) = O(\log n)$, giving the desired result.

It remains to validate the polynomial-time construction of the claimed cycle cover. We do so by induction on n. The base case is trivial and is omitted. For the induction step, first observe that by Lemma 2.2, we can find a path of cardinality at least n/K in P with total angle at most π. Joining together the two endpoints of this path gives a cycle C_1 subtending a total angle at most 3π. Consider the instance P' with n' points obtained by deleting the points in C_1 from P. From Lemma 2.1, it follows that $\theta_{opt}(P') \leq \theta_{opt}(P) \leq K\pi$. Since $n' \leq n(1 - 1/K)$ and $K \log n' \leq K \log n - 1$, we obtain from the induction hypothesis that it is possible to recursively compute in polynomial time a suitable cycle cover for P' consisting at most $K \log n - 1$ cycles. Adding C_1 to this collection of cycles gives the desired cycle cover for P. $\square$

We note that the same proof applies also to the Angle-CCP problem.

COROLLARY 2.4. *There is a polynomial-time algorithm which gives $O(\log n)$-approximation for* Angle-CCP.

3. The extremal cost of angle-TSP.

In this section, we address the question: What is the extremal cost of an optimal angle-TSP as a function of n? While this question is of intrinsic interest in its own right, we will see in Section 4 that it also enables us to analyze the trade-off between the performance ratio for the angle and the length metrics.

Note that for any n points in the plane there is a solution for the angle-TSP of cost $O(n)$. We improve this upper bound and show that for any n points in the plane there is a solution for the angle-TSP of cost $O(n/\log n)$. On the other hand, we are able to match this bound by showing the existence of an instance for which the optimal cost is $\Omega(n/\log n)$.

THEOREM 3.1. *Given a set of n points in the plane, there exists a solution for the angle-TSP problem of cost $O(n/\log n)$.*

Proof. Our proof relies on the following classic result of Erdős and Szekeres [9]: Given a set of n points in general position, there exists a subset of size $\Omega(\log n)$ which induces a convex polygon. This means that the entire point set can be covered by $O(n/\log n)$ convex polygons. Since traversing each polygon has a cost of 2π and linking two polygons costs at most another 2π, we can construct a tour that visits all the n points at a total cost of $O(n/\log n)$. This establishes the claimed result. As an aside, one may note that the claimed $\Omega(\log n)$ size convex polygon can be found in polynomial time by a simple dynamic programming. $\square$

We now establish a matching lower bound on the extremal cost.

THEOREM 3.2. *There exists an instance P of angle-TSP with n points in the plane such that the optimal cost for this instance is $\Omega(n/\log n)$.*

Proof. We describe a recursive construction that achieves this lower bound. Assume that $n = 2^k$, for some integer k. In the construction, we have $k = \log n$ levels of recursion. Define an instance of level i to be the instance constructed after i levels of recursion, and note that the final instance is the instance of level k. The instance of level 0 simply contains one point. The instance of level $i+1$ consists of two instances of level i at distance 4^i from each other such that the line connecting the centroids[1] of these two instances makes an angle of $i\pi/k$ with the X axis. We say that these two instances are *aligned* at angle $i\pi/k$. Note that the instance of level k has $2^k = n$ instances of level 0, and in general 2^{k-i} instances of level i.

Consider any solution to angle-TSP on this instance. To prove the lower bound we show that the cost of traversing any three consecutive points in this solution is $\Omega(\pi/k)$. This readily implies the desired bound.

Fix any three consecutive points, and let i be the maximum level such that these three points do not belong to the same instance of level i. Clearly, such an i exists since the instance of level one consists of only two points. Note that these three points belong to the same single instance of level $i+1$.

It is not difficult to verify that the cost of traversing points in the two instances is $\Omega(\pi/k)$, since: (i) the two instances of level i are aligned at angle $i\pi/k$; (ii) all the instances of lower levels are aligned at an angle that is at most $(i-1)\pi/k$; and, (iii) the distance between points in different instances of level i is at least twice the distance between points in the same instance of level i. □

4. Simultaneously approximating length and angle. In this section we discuss the possibility of *simultaneously* obtaining a good approximation to both the angle measure and the length measure for planar TSP. Fix an instance P and consider any tour τ for it. Denote by $\theta(\tau, P)$ the total angle subtended by τ, and by $\ell(\tau, P)$ the total length of τ. Further, let $\theta_{opt}(P)$ be the angle subtended by the optimal angle-TSP solution for P, and $\ell_{opt}(P)$ be the total length of the optimal Length-TSP solution for P. Note that the optimal angle-TSP and the optimal Length-TSP solutions for P need not be the same. We define the performance ratio of τ with respect to the two measures as:

$$R_\theta(\tau, P) = \frac{\theta(\tau, P)}{\theta_{opt}(P)} \qquad \text{and} \qquad R_\ell(\tau, P) = \frac{\ell(\tau, P)}{\ell_{opt}(P)}.$$

Our goal is to study the tradeoff between the two ratios $R_\theta(\tau, P)$ and $R_\ell(\tau, P)$ over all possible TSP solutions τ.

THEOREM 4.1. *There exists an instance P consisting of n points in the plane, such that for any tour τ on P,*

$$R_\theta(\tau, P) + R_\ell(\tau, P) = \Omega\left(\sqrt{n/\log n}\right).$$

Proof. Consider the following scenario in the plane. Fix $t = \sqrt{n \log n}$ and let $P_1, \ldots, P_t$ be a collection of identical instances described in the proof of Theorem 3.2 each with $\sqrt{n/\log n}$ points. Scale these instances so that the length of the path connecting the points in each instance is of unit length. We arrange these instances in a vertical stack so that they are perfectly aligned, and two successive instances in the vertical sequence are at a unit distance from each other. We refer to this entire set of points as the instance P.

We claim that: (a) $\ell_{opt}(P) = O(\sqrt{n \log n})$; and, (b) $\theta_{opt}(P) = O(\sqrt{n/\log n})$. To see (a), observe that by our scaling, there exists a Hamiltonian path of unit length in each of the instances P_i; also, since the optimal Length-TSP tour can visit the

[1] The centroid of a finite set of points is their arithmetic mean.

instances in the vertical order, the total cost of traveling between the series of $\sqrt{n \log n}$ instances is $O(\sqrt{n \log n})$. To see (b), observe that a set of $\sqrt{n/\log n}$ straight lines cover all points in P and these can be stitched together into a tour using $O(\sqrt{n/\log n})$ changes in the direction of travel.

Fix any tour τ for P. Consider any three consecutive points in τ. If these points are in the same instance P_i then, by the proof of Theorem 3.2, the *angular* cost of traversing them is $\Omega(1/\log n)$. If these points belong to at least two different instances then, because of the spacing between instances, the *length* cost of traversing them is $\Omega(1)$. Consider the $\lfloor n/2 \rfloor$ consecutive triples. We either incur the angular cost for at least half of them ($\geq \lfloor n/4 \rfloor$), or we incur the length cost for at least half of them. We conclude that $\theta(\tau, P) = \Omega(n/\log n)$ or $\ell(\tau, P) = \Omega(n)$. Combining this with the upper bounds on $\ell_{opt}(P)$ and $\theta_{opt}(P)$, we conclude that $R_\theta(\tau, P) + R_\ell(\tau, P) = \Omega(\sqrt{n/\log n})$. $\square$

We can show that there is a polynomial-time algorithm that matches the lower bound to within a factor of $\sqrt{\log n}$. We first show a marginally weaker upper bound that is considerably easier to obtain.

THEOREM 4.2. *Given a set P of n points in the plane, there is a polynomial-time algorithm for constructing a tour τ on P such that: $R_\theta(\tau, P) + R_\ell(\tau, P) = O(\sqrt{n \log n})$.*

Proof. To find the desired tour we first compute an $O(\log n)$-approximation to the optimal angle-TSP tour by using the approximation algorithm described in Section 2. Denote the resulting tour by τ. We distinguish between two cases.

Case 1. $\theta(\tau, P) = \Omega(\sqrt{n \log n})$. In this case compute a constant approximation to the Length-TSP using, e.g., Christofides' approximation [7] for TSP. Denote the resulting tour by τ'. We claim that $R_\theta(\tau', P) + R_\ell(\tau', P) = O(\sqrt{n \log n})$. Clearly, $R_\ell(\tau', P) = O(1)$. Since $\theta(\tau, P) = \Omega(\sqrt{n \log n})$, we know that $\theta_{opt}(P) = \Omega(\sqrt{n/\log n})$. Also $\theta(\tau', P) = O(n)$. Hence $R_\theta(\tau', P) = O(\sqrt{n \log n})$.

Case 2. $\theta(\tau, P) = O(\sqrt{n \log n})$. In this case $R_\theta(\tau, P) = O(\log n)$. We claim that in $R_\ell(\tau, P) = O(\sqrt{n \log n})$. To see this we re-examine the approximation algorithm for the angle-TSP problem. Recall that in this algorithm we find K' paths each of which subtends an angle of at most π that cover all the n points. Note that in our case $K' = O(\sqrt{n \log n})$. Below, we show that the length of each such path is a lower bound on $\ell_{opt}(P)$. Since there are $O(\sqrt{n \log n})$ such paths this implies that $R_\ell(\tau, P) = O(\sqrt{n \log n})$. (Note that the stitching of these paths costs $O(\sqrt{n \log n}\ell_{opt}(P))$.) Consider such a path Q with endpoints u and v. Clearly, the distance between u and v is a lower bound on $\ell_{opt}(P)$. We show that the length of Q is at most $4\sqrt{2}$ times this length. Partition Q into four segments, such that each segment subtends an angle of at most $\pi/4$. We claim that the length of each such segment is $\sqrt{2}$ times the distance from u to v. Consider such a segment. The length of it is just the sum of the lengths of its edges. Consider the projections of all these edges on the straight line connecting u and v. The sum of the lengths of these projections is the distance between u and v. Since each edge has an angle of at most $\pi/4$ with this straight line, the projection of each edge is at least $\sqrt{2}/2$ of its length. $\square$

The proof of the following tighter upper bounds is much more involved.

THEOREM 4.3. *Given a set P of n points in the plane, there is a polynomial-time algorithm for constructing a tour τ on P for which $R_\theta(\tau, P) + R_\ell(\tau, P)$ is bounded as follows:*

(1) *if* $\theta_{opt}(P) \leq \frac{\sqrt{n}}{\log n}$, *then*

$$R_\theta(\tau, P) + R_\ell(\tau, P) = O\left(\theta_{opt}(P) \log\left(\frac{n}{\theta_{opt}(P)}\right)\right)$$

(2) *if* $\frac{\sqrt{n}}{\log n} \leq \theta_{opt}(P) \leq \sqrt{n \log n}$, *then*

$$R_\theta(\tau, P) + R_\ell(\tau, P) = O\left(\sqrt{\frac{n}{\log n}}\right)$$

(3) *if* $\theta_{opt}(P) \geq \sqrt{n \log n}$, *then*

$$R_\theta(\tau, P) + R_\ell(\tau, P) = O\left(\frac{n}{\theta_{opt}(P)}\right).$$

Thus the worst cast sum of the ratios is $O(\sqrt{n})$.

Proof. To find the desired tour, τ, we use two approximation algorithms: (a) the approximation algorithm for the angle-TSP problem given in Section 2; and, (b) a constant-factor approximation to the Length-TSP in the plane, e.g., Christofides' approximation [7] for TSP.

We begin by finding a constant-factor approximation to the Length-TSP. Let L be the resulting tour. Fix a parameter k; the value of k will be determined later.

The next stage consists of $m = c \max\{\lceil \log(k/\theta_{opt}(P)) \rceil, 0\}$ iterations, for some constant $c > 1$. Note that since we can approximate $\theta_{opt}(P)$ up to a logarithmic factor, we can compute the number of iterations.

In each iteration, we find sub-paths that cover at least 3/4 of the points that still need to be covered and concatenate them in to the desired tour τ. Let P_i be the set of uncovered points at the beginning of iteration i, for $i = 0, ..., m-1$. Let L_i be the sub-tour of L induced by P_i. In iteration i we break L_i into a minimal number of sub-paths each containing at most $k/2^i$ points. Note that the number of such sub-paths is at most $n/(k2^i)$ (since the $|P_i| \leq n/4^i$). Denote these sub-paths by $L_{i,j}$, and the points on $L_{i,j}$ by $P_{i,j}$, for $1 \leq j \leq n/(k2^i)$. In each subset $P_{i,j}$ we use the approximation algorithm of Section 2 to find a maximal path which subtends an angle of at most π. We stitch all these paths in the order of their appearance in L, and concatenate the resulting path to the desired path τ. We repeat this step until at least 3/4 of the points of P_i are covered.

After terminating the iterations, we concatenate the sub-tour of L induced by the points that are still uncovered to τ.

We now bound $\theta(\tau, P)$ and $\ell(\tau, P)$; we begin with $\theta(\tau, P)$. The desired path τ is the concatenation of the paths computed in the iterations and the final path. The final path consists $O(n/4^m) = O(n/(k2^m)\theta_{opt}(P))$ points and hence its angular cost is $O(n/(k2^m)\theta_{opt}(P))$. Consider a path concatenated to τ in iteration i. Recall that this path is given by stitching the maximal paths computed in each of $P_{i,j}$. Since the angular cost of each maximal path is at most π, the angular cost of the path concatenated to τ is $O(n/(k2^i))$. Similar to the proof given in Section 2 it can be shown that the number of maximal paths which subtends an angle of at most π required to cover at least 3/4 of the points in the set $P_{i,j}$ is $O(\theta_{opt}(P_{i,j}))$. Hence the number of paths (which are given by stitching the maximal paths computed in each of $P_{i,j}$) required to cover at least 3/4 of the points in the set P_i is $O(\max_j\{\theta_{opt}(P_{i,j})\}) = O(\theta_{opt}(P))$. Summing over the m iterations and adding the angular cost of the final path, we conclude that $R_\theta(\tau, P) = O(\sum_{i=0}^{m} n/(k2^i)) = O(n/k)$. Since $\theta(\tau, P) = O(n)$, we have $R_\theta(\tau, P) = O(\min\{n/k, n/\theta_{opt}(P)\})$.

Next, we bound $\ell(\tau, P)$. The desired path τ is the concatenation of the paths computed in the iterations and the final path. We claim that the length of each such path is $O(\ell_{opt}(P))$. This is clearly true for the last path concatenated to τ since this path is a sub-tour of L and L is a constant-factor approximation to the Length-TSP. Consider a path concatenated to τ in iteration i. Recall that this path is given by stitching the maximal paths computed in each subset $P_{i,j}$. To show that the length of this path is $O(\ell_{opt}(P))$, it suffices to show that: (1) the cost of the stitching is $O(\ell_{opt}(P))$, and (2) the total length of the sub-paths is $O(\ell_{opt}(P))$. Statement (1) follows since the subpaths are stitched in the order of their appearance on L. To prove (2) consider such a sub-path Q with endpoints u and v computed in $P_{i,j}$. Similar to the proof of Theorem 4.2 it can be shown that the length of Q is at most $4\sqrt{2}$ times the distance between u and v. This clearly implies that the length of Q is proportional to the length of $L_{i,j}$. Since each sub-path is computed in a different $L_{i,j}$, the total length of the sub-paths is proportional to the length of L, and hence, is $O(\ell_{opt}(P))$.

It follows that $R_\ell(\tau, P)$ is proportional to the *number* of subpaths concatenated to τ. Consider an iteration i. As above it can be shown that the number of paths required to cover at least $3/4$ of the points is $O(\max_j\{\theta_{opt}(P_{i,j})\})$. There are two ways to bound this maximum. First, $\theta_{opt}(P_{i,j}) \le \theta_{opt}(P)$. Second, since the cardinality of each $P_{i,j}$ is at most $k/2^i$, by Theorem 3.1, we get that $\max_j\{\theta_{opt}(P_{i,j})\} = O((k/2^i)/\log k)$. Summing over the m iterations, we conclude that

$$R_\ell(\tau, P) = O\left(\min\left\{\frac{k}{\log k}, \theta_{opt}(P) \cdot \log\frac{k}{\theta_{opt}(P)}\right\}\right).$$

We distinguish between three possible ranges of θ_{opt}.

1. In the range $\theta_{opt}(P) \le \frac{\sqrt{n}}{\log n}$, we set
$$k = \frac{n}{\theta_{opt}(P) \cdot \log(\frac{n}{\theta_{opt}(P)})},$$
and thus get
$$R_\theta(\tau, P) + R_\ell(\tau, P) = O\left(\frac{n}{k} + \theta_{opt}(P)\log(\frac{k}{\theta_{opt}(P)})\right)$$
$$= O\left(\theta_{opt}(P)\log(\frac{n}{\theta_{opt}(P)})\right).$$
2. In the range $\frac{\sqrt{n}}{\log n} \le \theta_{opt}(P) \le \sqrt{n \log n}$, we set $k = \sqrt{n \log n}$, and get that
$$R_\theta(\tau, P) + R_\ell(\tau, P) = O(\frac{n}{k} + \frac{k}{\log k}) = O(\sqrt{\frac{n}{\log n}})$$
3. In the range $\theta_{opt}(P) \ge \sqrt{n \log n}$, we set $m = 0$, and thus τ is set to be L. We get that
$$R_\theta(\tau, P) + R_\ell(\tau, P) = O\left(\frac{n}{\theta_{opt}(P)}\right).$$

$\square$

5. The intractability of angle-TSP and angle-CCP. In this section we prove that finding an optimal Angle-CCP is NP-hard. A similar reduction shows that the Angle-TSP problem is also NP-hard. We give the proof for the Angle-CCP problem, and then describe briefly how this proof can be modified to show the NP-hardness of the Angle-TSP problem.

THEOREM 5.1. *The* Angle-CCP *and* Angle-TSP *problems are NP-hard.*

We provide a reduction to Angle-CCP from the one-in-three 3SAT problem that is known to be NP-hard (Problem LO4 of Garey and Johnson [11]). The input to one-in-three 3SAT is a set of m clauses $C_1, \dots, C_m$, with each clause consisting of three literals from the set $\{u_1, \dots, u_n, \overline{u}_1, \dots, \overline{u}_n\}$, where $\{u_1, \dots, u_n\}$ are boolean variables and $\{\overline{u}_1, \dots, \overline{u}_n\}$ are their negations. The problem is to decide whether there exists a truth assignment to the variables such that each clause contains exactly one true literal. From now on we use the notation N to denote $n + m$.

For an instance ϕ of the one-in-three 3SAT problem, we construct a corresponding instance P of the Angle-CCP problem such that there exists a one-in-three 3SAT solution to ϕ if and only if the corresponding instance P has a cycle cover of total angle at most T, for a value T to be specified later. We index the points in P by their coordinates along the X and Y axes.

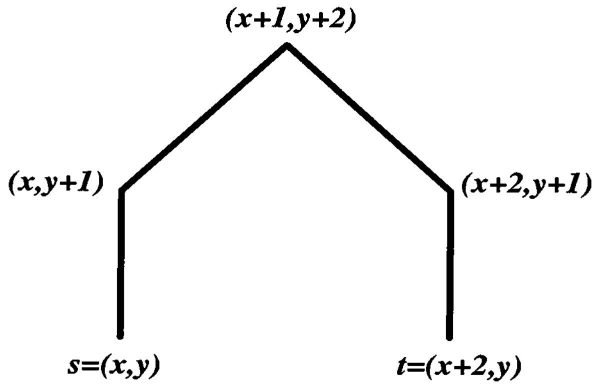

FIG. 5.1. *A U-turn gadget in direction* $+Y$.

For the reduction we need a gadget that we call a "U-turn gadget," although "V-turn gadget" would perhaps be a more appropriate name for it. This consists of points on two straight lines and on two diagonals connecting those lines as shown in Figure 5.1. Each such gadget is characterized by its *endpoints* and its *direction.* Intuitively, a gadget pointing in the direction $+Y$ with endpoints $s = (x, y)$ and $t = (x + 2, y)$ consists of a set of points in the plane such that in order to cover them efficiently we have to make a U-turn after entering at s (t) in the direction $+Y$ and exiting at t (respectively, s) in the direction $-Y$. To achieve this goal, the gadget contains $12N^5$ points where $N = n + m$. Of these, $10N^5$ points are spread uniformly on the two unit-length intervals from (x, y) to $(x, y+1)$, and from $(x+2, y)$ to $(x + 2, y + 1)$. The remaining $2N^5$ points are spread uniformly along the two diagonals from $(x, y + 1)$ to $(x + 1, y + 2)$ and from $(x + 2, y + 1)$ to $(x + 1, y + 2)$.

We are now ready to define the instance P of Angle-CCP. In P, we have nine points corresponding to each clause C_i. Suppose that clause C_i consists of the literals

u_a,$\overline{u}_b$, and u_c. The points corresponding to this clause are: (N^2i, N^2a), (N^2i, N^2b), (N^2i, N^2c+1), (N^2i+1, N^2a+1), (N^2i+1, N^2b+1), (N^2i+1, N^2c+1), (N^2i+2, N^2a+1), (N^2i+2, N^2b), and (N^2i+2, N^2c); see Figure 5.2.

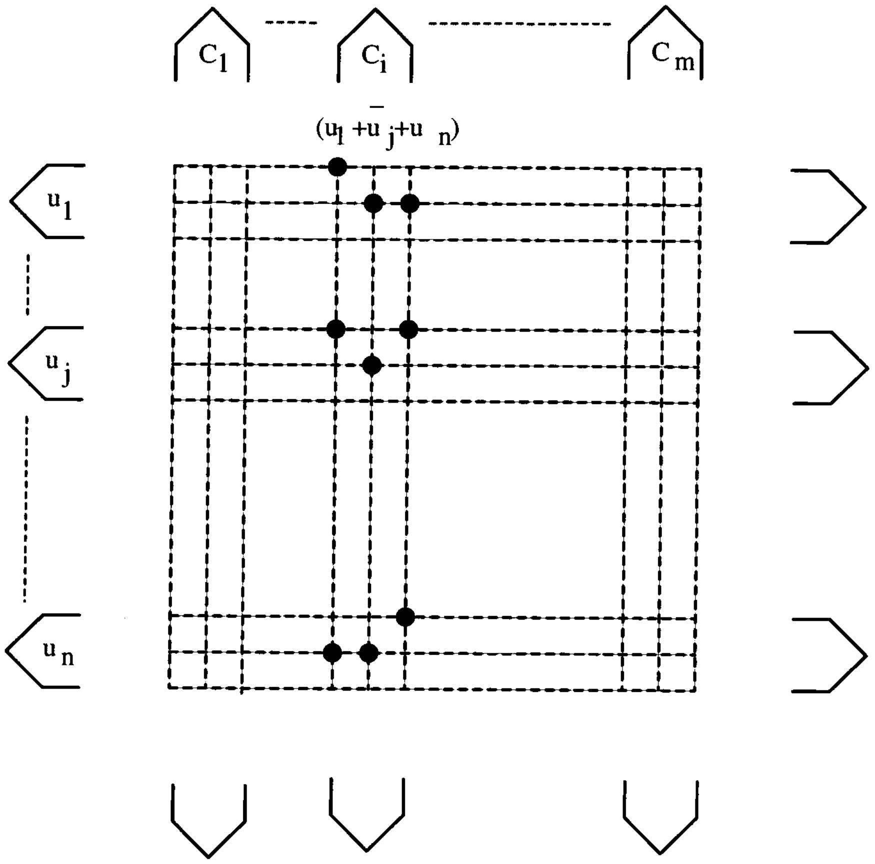

FIG. 5.2. *Illustrating the reduction.*

Let us understand the reasoning behind this assignment of points. We allocate three "columns" to each clause, where the clause C_i is associated with the columns with X-coordinates N^2i, N^2i+1, and N^2i+2. Similarly, we allocate three "rows" to each variable, where the variable u_j is associated with the rows with Y-coordinates N^2j, N^2j+1, and N^2j+2. In addition, we allocate the row N^2j to the literal u_j, and the row N^2j+1 to the literal $\overline{u}_j$. (We assume that $N = (n+m)$ is large enough, so that $N^2i + 3 < N^2(i+1)$.)

Let us fix our attention on a clause C_i and the three columns associated with it. For $j \in \{1, 2, 3\}$, in the jth column associated with this clause, we have the points in its intersection with the rows corresponding to the jth literal in the clause and the complements of the other two literals. In addition, we have the points (N^2i+3, N^2j+2), for $j = 1, \ldots, n$, and $i = 1, \ldots, m$. We call all the points defined so far *grid points.*

Finally, we add $2N$ U-turn gadgets. For each variable u_j, $1 \le j \le n$, we have two U-turn gadgets – one with endpoints $(-N^5, N^2j)$ and $(-N^5, N^2j+2)$ pointing in the direction $-X$ (the "left" gadget), and another with endpoints (N^5+N^2m, N^2j) and (N^5+N^2m, N^2j+2) pointing in the direction $+X$ (the "right" gadget). Similarly, for each clause C_i, $1 \leq i \leq m$, we have two U-turn gadgets – one with endpoints $(N^2i, -N^5)$ and $(N^2i+2, -N^5)$ pointing in the direction $-Y$ (the "bottom" gadget), and another with endpoints (N^2i, N^5+N^2n) and (N^2i+2, N^5+N^2n) pointing in the direction $+Y$ (the "top" gadget).

Our goal now is to show that the instance of the one-in-three 3SAT has a satisfying assignment if and only if the corresponding instance of Angle-CCP has a cycle cover of total angle at most $T = 2\pi N + 4N^{-4}$.

LEMMA 5.2. *If there exists a one-in-three truth assignment satisfying ϕ, then there is a cycle cover for P of total angle at most T.*

Proof. We will construct a cycle cover that has N cycles, one per clause and one per variable. Consider a clause C_i and suppose that the literal that satisfies C_i is the first literal; the other cases are similar. The cycle corresponding to C_i covers the points on the two U-turn gadgets of C_i and also the points in two of the columns assigned to C_i. These are the columns that do not contain the point intersecting the row assigned to the literal satisfying C_i, i.e., the cycle covers the columns with X-coordinates N^2i+1 and N^2i+2.

We bound the angle of the cycle starting from point $(N^2i, -N^5)$, going counterclockwise. The angle cost of covering the points of the bottom gadget exiting at $(N^2i+2, -N^5)$ is π. From here, we can cover all the points in column N^2i+2 without incurring any angle cost. Then, the angle cost of covering the top U-turn gadget entering at (N^2i+2, N^5+N^2n) and exiting at (N^2i, N^5+N^2n) is again π. From this point we traverse to point (N^2i+1, N^2n) at an angle cost of (approximately) $2N^{-5}$ and then, without incurring any further angle cost, cover all the points in column N^2i+1. Finally, we traverse from $(N^2i+1, 0)$ to $(N^2i, -N^5)$ at an angle cost of (approximately) $2N^{-5}$. Overall, the angle of the cycle is $2\pi + 4N^{-5}$.

The remaining points are covered by the cycles corresponding to the variables. Consider a variable u_j, and suppose that the assignment of u_j is TRUE; the other case is similar. The cycle corresponding to u_j covers the points on the two U-turn gadgets of u_j. It also covers the points in two of the rows assigned to u_j, viz., the row N^2j corresponding to the literal u_j and row N^2j+2.

We now bound the angle of the cycle starting from point $(-N^5, N^2j+2)$, going counterclockwise. The angle cost of covering the points of the left gadget exiting at $(-N^5, N^2j)$ is π. From here, we cover all the points in row N^2j at no additional angle cost. Then, the angle cost of covering the right U-turn gadget entering at (N^5+N^2m, N^2j) and exiting at (N^5+N^2m, N^2j+2) is again π. From this point, we cover all the points in row N^2j+2 at no additional angle cost. Overall, the angle cost is 2π. Note that in case u_j is assigned FALSE, the total angle is $2\pi + 4N^{-5}$.

Summing over all the $N = (n+m)$ cycles, we obtain that total angle is bounded by $T = 2\pi N + 4N^{-4}$. ◻

The following lemmas help us to establish the reverse direction.

LEMMA 5.3. *The angle cost of covering only the U-turn gadgets in P is $2\pi N$. The cover that achieves this has N cycles, each of angle 2π and each of which covers a pair of gadgets corresponding to either a clause or a variable. Moreover, any other cover that traverses the points in a different order has an angle cost at least $2\pi N + \Omega(N^{-3})$.*

Proof. It can be verified that the cover with N cycles in which each pair of gadgets corresponding to either a clause or a variable is covered by one cycle indeed achieves an angle cost of $2\pi N$. We now prove that this is the only cover of angle cost $2\pi N + o(N^{-3})$. Clearly, any cycle cover of this angle cost has at most N cycles. Consider such a cover $\mathcal{C}$.

Recall that each gadget contains two straight line intervals. We call these lines the *spokes* of the gadget. We have horizontal and vertical spokes. Each spoke has two endpoints: *internal* and *external*. The internal endpoint is the one closer to the grid points. For simplicity, consider first only cycle covers that cover all the points in each such spoke consecutively; i.e., when we follow a cycle in $\mathcal{C}$, the first point of a spoke that we encounter is an endpoint, and starting from it we cover all the spoke points ending at the other endpoint.

We now prove that any cycle cover $\mathcal{C}$ with the above property that covers only the spoke points must have an angle cost of at least $2\pi N$. Clearly, the cover described in the lemma achieves this angle cost. To show this we prove that the "average" angle cost of covering each spoke is at least $\pi/2$, since there are $4N$ spokes this implies the bound. Consider a cycle $C \in \mathcal{C}$. Note that by our assumption, whenever C covers a horizontal (vertical) spoke it subtends an angle 0 or π (respectively, $\pi/2$ or $3\pi/2$) with the $+X$ direction. There are two cases: either C covers only spokes of the same orientation (horizontal or vertical), or C covers both horizontal and vertical spokes. In the first case it is easy to see that the angle cost of covering k spokes of the same orientation is at least $\lceil k/2 \rceil \pi$. Thus the average angle cost is at least $\pi/2$.

Consider a cycle C that covers alternate runs of horizontal and vertical spokes. For each such run we distinguish whether if starts (ends) in an internal or external endpoint. The following properties are easy to verify.

1. The angular cost subtended when moving from an external endpoint of a vertical (horizontal) spoke to an external endpoint of a horizontal (respectively, vertical) spoke is at least $3\pi/2 - o(N^{-2})$.
2. The angular cost subtended when moving from an internal endpoint of a vertical (horizontal) spoke to an internal endpoint of a horizontal (respectively, vertical) spoke is at least $\pi/2 - o(N^{-2})$.
3. The angular cost subtended when moving from an internal endpoint of a vertical (horizontal) spoke to an external endpoint of a horizontal (respectively, vertical) spoke, or vice versa, is at least $\pi - o(N^{-2})$.
4. The angular cost subtended while covering k spokes of the same orientation by a *path* that starts and ends in external endpoints is at least $\lceil (k-2)/2 \rceil \pi$. (Note that this is only the angle cost of the path without including the angle cost of reaching the first endpoint and leaving the last.)
5. The angular cost subtended while covering k spokes of the same orientation by a *path* that starts and ends in internal endpoints is at least $\lceil k/2 \rceil \pi$.
6. The angular cost subtended while covering k spokes of the same orientation by a *path* that starts in an internal endpoint, and ends in an external endpoint, or vice versa, is at least $\lceil (k-1)/2 \rceil \pi$.

These observations imply that the average angular cost of a spoke in such a cover is more than $\pi/2$. We conclude that to achieve a cover $\mathcal{C}$ of angle cost at most $2\pi N$ all the cycles must cover only spokes of the same orientation and in this case the cost of the cover is at least $2\pi N$.

We now show that the same holds even if we remove the assumption that spokes are traversed consecutively. For each spoke ℓ consider the interval of length N^{-3} starting at its external endpoint. This interval consists of $5N^2$ points. Hence, there is a cycle $C \in \mathcal{C}$ that covers at least $5N$ of these points; we say that this C is the *main cycle* for the spoke ℓ. We claim that C must traverse at least two points of the interval one after the other. This is because each time a point not in the interval is traversed between two points in the interval, the cycle C subtends an angle cost of $\pi - o(N^{-2})$. Note that in case ℓ is horizontal (vertical), C subtends an angle 0 or π (respectively, $\pi/2$ or $3\pi/2$) with the $+X$ direction. Among the points traversed consecutively, let the external point be the one closest to the external endpoint of ℓ, and the internal point be the one closest to the internal endpoint. It is not difficult to verify that the same arguments we used above would hold if we let the main cycle of ℓ play the role of the cycle that traverses ℓ (consecutively), and the internal and external points of the interval play the role of the internal and external endpoints.

Recall that each gadget contains also two diagonal lines. To achieve the desired angle cost, it must be the case that all points on a diagonal are covered by the main cycle of the spoke touching it, and that these points are traversed either just before or just after the points of the touching spoke are traversed. To see this, recall that every cycle covers at least two spokes and that all its covered spokes are of the same orientation. Consider a such a cycle, and assume that it covers some points on a diagonal line, between the traversal of two spokes not touching it. It is easy to see that in this case the additional angular cost subtended is at least $\pi/2$. This would make the average angular cost of a spoke $\pi/2 + O(N^{-1})$; a contradiction. Now, consider the leftmost gadget on the top. The cycle that covers the points on the right diagonal of this gadget must be the main cycle of its left spoke, otherwise its angle cost would be too large, following from arguments similar to the ones given above. Hence, we have that both spokes of this gadget have the same main cycle, which covers also the points on its two diagonals. Similarly, both spokes of the bottom leftmost gadget have the same main cycle, which covers also the points on its two diagonals. Moreover, it must be the case that the same cycle covers both gadgets. Otherwise, the cost of the cycle would be $k\pi + \Omega(N^{-3})$.

In the same way we can show that both gadgets corresponding to the second clause are covered by the same cycle, and so on. It follows that in order to achieve the desired angle cost, no cycle covers gadgets corresponding to more than one clause. In a similar fashion, it can be shown that the gadgets corresponding to a variable must be covered by the same cycle, and that no cycle covers the gadgets corresponding to more than one variable. We conclude that the only cycle cover that achieves the desired cost is the one with N cycles, each of which covers a pair of gadgets corresponding to either a clause or a variable. $\square$

LEMMA 5.4. *If there exists a cycle cover P of total angle at most T, then there is a one-in-three truth assignment satisfying ϕ.*

Proof. Suppose that there exists a cover of the Angle-CCP instance of angle cost at most $T = 2\pi N + 4N^{-4}$. Since it covers all the U-turn gadgets and its cost is bounded by $2\pi N + o(N^{-3})$, it must be that this cover consists of N cycles each of which covers the two gadgets corresponding to either a clause or a variable. Consider the cycle that covers the U-turn gadgets of a clause C_i. In addition to the points of the two gadgets, this cycle can cover at most two of the columns corresponding to C_i. Otherwise, the cost of the cycle would be $2\pi + \Omega(N^{-3})$. (Note that covering more than one column in a path connecting the two gadgets would incur a cost of $\Omega(N^{-3})$.) Similarly, the cycle that covers the U-turn gadgets of a variable u_j can additionally cover at most two of the rows corresponding to u_j. One of these rows must be row $N^2 j + 2$, since none of the other cycles can cover the points on this row within the angle bounds.

It follows that for each clause C_i, all the grid points in one of its columns are covered by cycles corresponding to variables. Recall that such a column consists of points in the rows corresponding to one literal $l_j \in \{u_j, \overline{u}_j\}$ in the clause, and to the complements of the other two. Assign a TRUE value to l_j, and assign a FALSE value to the other two literals in C_i. Repeating this for all clauses implies that in the resulting truth assignment, for each clause we have exactly one literal that is TRUE. We claim that this assignment is consistent, i.e., no variable is assigned both TRUE and FALSE. This is because a literal is assigned the value TRUE only if its corresponding row is covered by the cycle corresponding to its originating variable. However, a cycle corresponding to a variable u_j can cover either the row corresponding to the literal u_j or the row corresponding to the literal $\overline{u}_j$, but not both. This implies that ϕ has a one-in-three truth assignment. □

We briefly sketch the modifications required to prove the NP-hardness of the Angle-TSP problem. Again, the reduction is quite similar and is from the one-in-three 3SAT problem. Given an instance ϕ of the one-in-three 3SAT problem, the corresponding instance of the Angle-TSP problem would include the same grid points and the left/top U-turn gadgets as before. In addition, in the "right" and the "bottom" we add U-turn gadgets of a different size that are used to "stitch" the rows (columns) corresponding to adjacent variables (respectively, clauses). Finally, we add two other gadgets: one to connect the bottom end of the rightmost column with the right end of the bottom row, and another to connect the bottom end of the leftmost column with the right end of the top row. It can be shown that there exists a tour of total angle cost at most T if and only if there is a one-in-three truth assignment satisfying ϕ.

Acknowledgments. We would like to thank Leonidas Guibas for suggesting the problem. We would like to thank the anonymous referees for helpful comments and especially for pointing out reference [9] that enabled us to improve Theorems 3.1 and 4.3.

ON LEARNING FUNCTIONS FROM NOISE-FREE AND NOISY SAMPLES VIA OCCAM'S RAZOR[*]

B. NATARAJAN[†]

Abstract. An Occam approximation is an algorithm that takes as input a set of samples of a function and a tolerance ϵ and produces as output a compact representation of a function that is within ϵ of the given samples. We show that the existence of an Occam approximation is sufficient to guarantee the probably approximate learnability of classes of functions on the reals even in the presence of arbitrarily large but random additive noise. One consequence of our results is a general technique for the design and analysis of nonlinear filters in digital signal processing.

1. Introduction.

We begin with an overview of our main result. Suppose we are allowed to randomly sample a function f on the reals, with the sample values of f being corrupted by additive random noise ν of strength b. Let g be a sparse but approximate interpolant of the random samples of f—sparse in the sense that it can be compactly represented, and approximate in the sense that the interpolation error in g with respect to the samples is at most b. Intuitively, we would expect that the noise and the interpolation error add in their contribution to the error in g with respect to f, i.e., $||g - f|| \approx 2b$. However, our results show that the noise and the interpolation error tend to cancel, i.e., $||g-f|| \approx 0$, with the extent of the cancellation depending on the sparseness of g and how often f is sampled.

We consider the paradigm of probably approximately correct learning of Valiant, as reviewed in Natarajan [21] and Anthony and Biggs [3]. Broadly speaking, the paradigm requires an algorithm to identify an approximation to an unknown target set or function, given random samples of the set or function. Of central interest in the paradigm is the relationship between the complexity of the algorithm, the a priori information available about the target set or function, and the goodness of the approximation. When learning sets, if the target set is known to belong to a specific target class, Blumer et al. [9] establish that the above quantities are related via the Vapnik–Chervonenkis dimension of the target class, and if this dimension is finite, then learning is possible. They also show that even if the Vapnik–Chervonenkis dimension is infinite, learning may still be possible in a generalized sense, via the use of Occam's Razor. Specifically, if it is possible to compress collections of examples for the target set, then a learning algorithm exists. For instance, the class of sets composed of finitely many intervals on the reals satisfies this condition and hence can be learned. Kearns and Schapire [18] extend the above results to the case of probabilistic concepts and offer an Occam's Razor result in that setting. For the case of functions, Natarajan [20] examines conditions under which learning is possible and shows that it is sufficient if the "graph" dimension of the target class is finite. Haussler [13] generalizes this result to a "robust" model of

[†]Hewlett Packard Laboratories, 1501 Page Mill Road, Palo Alto, CA 94304 (natarajan@hpl.hp.com).

learning and shows that it is sufficient if the metric dimension of the class is finite. Alon et al. [1] generalize these results further via the "scale-sensitive" dimension. Anthony et al. [4] give sufficient conditions linking approximate interpolation and learning. Learning sets in the presence of noise was studied by Angluin and Laird [2], Kearns and Li [17], and Sloan [27], amongst others. Kearns and Li show that the principle of Occam's Razor can be used to learn in the presence of a limited amount of noise. Bartlett, Long, and Williamson [6] link the learnability of functions in the presence of observation noise to the "fat-shattering" function of the class.

We consider the learning of functions, both with and without random sampling noise. In the latter case, we mean that the function value obtained in the sampling process is corrupted by additive random noise. In this setting, we show that if it is possible to construct sparse but approximate interpolants to collections of examples, then a learning algorithm exists. For instance, it is possible to construct optimally sparse but approximate piecewise linear interpolants to collections of examples of univariate functions. As a consequence, we find that the class of all univariate Baire functions [10] can be learned in terms of the piecewise linear functions, with the number of examples required to learn a particular Baire function depending on the number of pieces required to approximate it as a piecewise linear function. In the absence of noise, our results hold for all L_p metrics over the space of functions. In the presence of noise, the results are for the L_2 and L_∞ metrics. There are two points of significance in regard to these results: (1) the noise need not be of zero mean for the L_∞ metric; (2) for both metrics, the magnitude of the noise can be made arbitrarily large and learning is still possible, although at increased cost.

Our results are closely related to the work in signal processing [24], [25], [16], and [19] on the reconstruction and filtering of discretely sampled functions. However, much of that literature is on linear systems and filters, with the results expressed in terms of the Fourier decomposition, while relatively little is known about nonlinear systems or filters. Our results allow a unified approach to both linear and nonlinear systems and filters, and in that sense, we offer a new and general technique for signal reconstruction and filtering. This is explored in [23], where we analyze a broad class of filters that separate functions with respect to their encoding complexity—since random noise has high complexity in any deterministic encoding and is hard to compress, it can be separated from a function of low complexity.

Of related interest is the literature on sparse polynomial interpolation [8], [7], [12], and [5]. These papers study the identification of an unknown polynomial that can be evaluated at selected points.

The results of this paper appeared in preliminary form in [22].

2. Preliminaries.

We consider functions $f : [0, 1] \to [-K, K]$, where $[0, 1]$ and $[-K, K]$ are intervals on the reals $\mathbf{R}$. A class of functions F is a set of such functions and is said to be of envelope K. Unless we state otherwise, we assume that a class has unit envelope. A complexity measure l is a mapping from F to the natural numbers $\mathbf{N}$. An example for a function f is a pair $(x, f(x))$. Our discussion will involve metrics on several spaces. For the sake of concreteness, we will deal only with the L_p metrics, $p \in \mathbf{N}, p \geq 1$, and will define these exhaustively. For two functions f and g and probability distribution P on $[0, 1]$,

$$L_p(f, g, P) = \left(\int_x |f(x) - g(x)|^p dP \right)^{1/p}. \tag{2.1}$$

For function f and collection of examples $S = \{(x_1, y_1), (x_2, y_2), \ldots, (x_m, y_m)\}$,

$$L_p(f, S) = \left(\frac{1}{m}\sum |f(x_i) - y_i|^p\right)^{1/p}. \tag{2.2}$$

Let l be a complexity measure on a class G, f a function not necessarily in G, L a metric, and P a distribution on $[0, 1]$. For $\epsilon > 0$, $l_{\min}(f, \epsilon, P, L)$ is defined by

$$l_{\min}(f, \epsilon, P, L) = \min\ \{l(g) | g \in G, L(f, g, P) \leq \epsilon\}. \tag{2.3}$$

If $\{l(g)|g \in G, L(f, g, P) \leq \epsilon\}$ is empty, then $l_{\min}(f, \epsilon, P, L) = \infty$.
Analogously, for a collection of examples S and metric L,

$$l_{\min}(S, \epsilon, L) = \min\ \{l(g)|g \in G, L(g, S) \leq \epsilon\}. \tag{2.4}$$

If $\{l(g)|g \in G, L(g, S) \leq \epsilon\}$ is empty, then $l_{\min}(S, \epsilon, L) = \infty$.
Using Jensen's inequality [10], it is easy to show that

$$L_1(f, g, P) \leq L_p(f, g, P) \leq (L_1(f, g, P))^{1/p}. \tag{2.5}$$

A learning algorithm A for target class F has at its disposal a subroutine EXAMPLE, that at each call returns an example for an unknown target function $f \in F$. The example is chosen at random according to an arbitrary and unknown probability distribution P on $[0, 1]$. After seeing some number of such examples, the learning algorithm identifies a function g in the hypothesis class G such that g is a good approximation to f. Formally, we have the following. Algorithm A is a learning algorithm for F in terms of G, with respect to metric L, if (a) A takes as input ϵ and δ; (b) A may call EXAMPLE; (c) for all probability distributions P and all functions f in F, A identifies a function $g \in G$, such that with probability at least $(1 - \delta)$, $L(f, g, P) \leq \epsilon$.

The sample complexity of a learning algorithm for F in terms of G, with respect to the complexity measure l, is the number of examples sought by the algorithm as a function of the parameters of interest. In noise-free learning, these parameters are ϵ, δ, and $l_{\min}(f, \epsilon, P, L)$, where f is the target function. In the presence of random sampling noise, the properties of the noise distribution would be additional parameters. Since we permit our learning algorithms to be probabilistic, we will consider the expected sample complexity of a learning algorithm, which is the expectation of the number of examples sought by the algorithm as a function of the parameters of interest.

In light of the relationship between the various L_p metrics established in (2.5), we focus on the L_1 metric and, unless we explicitly state otherwise, we use the term *learning algorithm* to signify a learning algorithm with respect to the L_1 metric. We denote the probability of an event A occurring by $Pr\{A\}$ and the expected value of a random variable x by $\mathbf{E}\{x\}$.

With respect to a class of functions F of envelope K, $\epsilon > 0$ and $m \in \mathbf{N}$, and metric L: The size of the minimum ϵ-cover of a set $X = \{x_1, x_2, \ldots, x_m\}$ is the cardinality of the smallest set of functions G from X to $\mathbf{R}$ such that for each $f \in F$, there exists $g \in G$ satisfying $L(f, g, P_X) \leq \epsilon$, where P_X is the distribution placing equal mass $1/m$ on each of the x_i in X. The covering number $N(F, \epsilon, m, L)$ is the maximum of the size of the minimum ϵ-cover over all $\{x_1, x_2, \ldots, x_m\}$.

The following convergence theorem will be of considerable use to us. The theorem is predicated on mild measurability assumptions as discussed in [26].

THEOREM 2.1 (see [26, pp. 25–27]). *For a class of functions F with envelope K, the probability that the observed mean over $m \geq 8/\epsilon^2$ random samples of any function in F will deviate from its true mean by more than ϵ is at most*

$$8N(F, \epsilon/8, m, L_1)e^{-(m/128)(\epsilon/K)^2}. \tag{2.6}$$

3. Occam approximations. An approximation algorithm Q for hypothesis class G and metric L is an algorithm that takes as input a collection S of examples and a tolerance $\epsilon > 0$ and identifies in its output a function $g \in G$ such that $L(g, S) \leq \epsilon$, if such exists.

For particular values of $m, t \in \mathbf{N}$ and $\epsilon > 0$, let $\hat{G}$ be the class of all functions identified in the output of Q when its input ranges over all collections S of m examples such that $l_{\min}(S, \epsilon, L) \leq t$. Q is said to be an Occam approximation if there exists a polynomial $q(a, b) : \mathbf{N} \times \mathbf{R} \to \mathbf{N}$ and $r : \mathbf{N} \to \mathbf{N}$ such that $r(m)$ is $O(m^\alpha)$, for fixed $0 \leq \alpha < 1$, and for all m, t, ϵ, and $\zeta > 0$, $\log(N(\hat{G}, \zeta, m, L)) \leq q(t, 1/\zeta)r(m)$. We say that (q, r) is the characteristic of Q.

The above notion of an Occam approximation is a generalization to functions of the more established notion of an Occam algorithm for concepts [9] and its extension to probabilistic concepts in [18].

Example 1. We consider univariate polynomials with coefficients of Euclidean norm at most unity, i.e., polynomials of the form $\sum a_i x^i$, where $\sum a_i^2 \leq 1$. Let G be the class of such polynomials over the unit interval. As a complexity measure on G, we choose the degree of the polynomial. Consider the following approximation algorithm Q with respect to the L_2 metric. Given is a collection of samples

$$S = \{(x_1, y_1),\ (x_2, y_2), \ldots,\ (x_m, y_m)\}, \tag{3.1}$$

and tolerance ϵ. We shall fit the data with a polynomial of the form $a_0 + a_1 x + \cdots + a_i x^i + \cdots + a_d x^d$. For $d = 0, 1, 2, \ldots$ construct a linear system $Xa = y$, where X is the matrix of m rows and d columns, with row vectors of the form $(1, x_i, x_i^2 \ldots, x_i^d)$, y is the column vector $(y_1, y_2, \ldots, y_m)$, and a is the column vector $(a_0, a_1, \ldots, a_d)$. Find the smallest value of d for which the minimum Euclidean norm least squares solution a of the linear system has residue at most ϵ in the L_2 norm, and the Euclidean norm of a is at most unity. If such a solution vector a exists, it determines the polynomial g. This computation can be carried out efficiently [11].

Claim 1. Algorithm Q is Occam.

Proof. Fix the number of samples m, the degree d of the polynomial, and the tolerance ϵ. For collection of samples S, $l_{\min}(S, \epsilon, L_2)$ is the degree of the lowest-degree polynomial that fits the samples in S with error at most ϵ in the L_2 metric. By construction, Q outputs only polynomials of degree d on such inputs. Thus, $\hat{G}$ is a subset of the class of polynomials of degree d. By Claim 2,

$$\log(N(\hat{G}, \zeta, m, L_2) \leq (d+1)\log(2m/\zeta), \tag{3.2}$$

which implies that Q is Occam.

Claim 2. If F is the class of polynomials of degree d with coefficients of Euclidean norm at most unity,

$$N(F, \zeta, m, L_2) \leq (2(d+1)/\zeta)^{d+1}. \tag{3.3}$$

Proof. Let $f(x)$ be a polynomial in F. Since f is of Euclidean norm at most unity, each of the $d+1$ coefficients of f lie in $[-1, +1]$. Truncate each of the coefficients to the nearest multiple of $\zeta/(d+1)$ to obtain a polynomial g. The resulting function g is clearly everywhere within ζ of f on $[0,1]$. It follows that for every polynomial $f \in F$ there exists a polynomial $g \in F$ within ζ of f in the L_2 metric, where each coefficient of g is one of $(2(d+1)/\zeta)$ values. Thus, g is one of at most $(2(d+1)/\zeta)^{d+1}$ functions. Hence the claim.

Example 2. Another class with an Occam approximation algorithm with respect to the L_2 metric is the class of trigonometric interpolants with coefficients having bounded Euclidean norm, and complexity measure the highest frequency, i.e., functions of the form

$$f(x) = \sum_{i=0}^{\infty} A_i \cos(2\pi i x) + \sum_{i=0}^{\infty} B_i \sin(2\pi i x), \tag{3.4}$$

where $\sum a_i^2 \leq 1$. For the class of such functions, the least squares technique described in the context of the polynomials in Example 1 can be used to construct an Occam approximation.

4. Noise-free learning. In this section we show that the existence of an Occam approximation is sufficient to guarantee the efficient learnability of a class of functions in the absence of noise. The theorem is stated for Occam approximations with respect to the L_1 metric and subsequently is extended to other metrics.

THEOREM 4.1. *Let F be the target class and G the hypothesis class with complexity measure l, both of envelope* 1. *Let Q be an Occam approximation for G, with respect to metric L_1, with characteristic (q,r). Then, there exists a learning algorithm for F with expected sample complexity polynomial in $1/\epsilon$, $1/\delta$, and $l_{\min}(f, \epsilon/8, P, L_1)$.*

Proof. We claim that Algorithm A_1 below is a learning algorithm for F. Let f be the target function. In words, the algorithm makes increasingly larger guesses for $l_{\min}(f)$, and based on its guesses it constructs approximations for f, halting if and when a constructed approximation appears to be good.

```
ALGORITHM $A_1$.
input $\epsilon, \delta$
begin
    $t = 2$;
    repeat forever
        let $m$ be the least integer satisfying
        $m \geq (9216/\epsilon^2)q(t, 32/\epsilon)r(m)$;
        make $m$ calls of EXAMPLE to get collection $S$;
        let $g = Q(S, \epsilon/4)$;
        let $m_1 = (16t^2)/(\epsilon^2\delta)$;
        make $m_1$ calls of EXAMPLE to get collection $S_1$;
        if $L_1(g, S_1) \leq (3/4)\epsilon$ then output $g$ and halt;
        else $t = t + 1$;
    end
end
```

We first show that the probability of the algorithm halting with a function g as output such that $L_1(f, g, P) > \epsilon$ is at most δ. At each iteration, by Chebyshev's inequality,

$$Pr\left\{|L_1(g, S_1) - L_1(g, f, P)| \geq \epsilon/4\right\} \leq \frac{16}{\epsilon^2 m_1}. \tag{4.1}$$

Since $m_1 = 16t^2/(\epsilon^2\delta)$,

$$Pr\left\{|L_1(g, S_1) - L_1(g, f, P)| \geq \epsilon/4\right\} \leq \frac{\delta}{t^2}. \tag{4.2}$$

If the algorithm halts, then $L_1(g, S_1) \leq (3/4)\epsilon$ and hence

$$Pr\left\{L_1(g, f, P) > \epsilon\right\} \leq \frac{\delta}{t^2}. \tag{4.3}$$

Hence, the combined probability that the algorithm halts at any iteration with $L_1(g, f, P) > \epsilon$ is at most $\sum_{t=2}^{\infty} \frac{\delta}{t^2} < \delta$.

Let $t_0 = l_{\min}(f, \epsilon/8, P, L_1)$. We now show that when $t \geq t_0$, the algorithm halts on iteration t with probability at least 1/4. Let $h \in G$ be such that $L_1(h, f, P) \leq \epsilon/8$ and $l(h) = t_0$. Fix $t \geq t_0$. By Chebyshev's inequality,

$$Pr\left\{|L_1(h, S) - L_1(h, f, P)| \geq \epsilon/8\right\} \leq \frac{64}{\epsilon^2 m}. \tag{4.4}$$

Hence, if $m \geq 256/\epsilon^2$ with probability at least $(1 - 1/4) = 3/4$,

$$|L_1(h, S) - L_1(h, f, P)| \leq \epsilon/8. \tag{4.5}$$

Since $L_1(h, f, P) \leq \epsilon/8$, it follows that with probability 3/4, $L_1(h, S) \leq \epsilon/4$. In other words, with probability 3/4, $l_{\min}(S, \epsilon/4, L_1) \leq l(h) = t_0 \leq t$.

At each iteration of A_1, let $\hat{G}$ be the class of all functions that Q could output if $l_{\min}(S, \epsilon/4, L_1) \leq t$ holds. Since Q is Occam, $\log(N(\hat{G}, \epsilon/32, m)) \leq q(t, 32/\epsilon)r(m)$. Let H be the class of functions $H = \{h : h(x) = |f(x) - g(x)|,\ g \in \hat{G}\}$, and let h_1 and h_2 be any two functions in H. Now,

$$|h_1(x) - h_2(x)| = ||f(x) - g_1(x)| - |f(x) - g_2(x)|| \tag{4.6}$$
$$\leq |g_1(x) - g_2(x)|. \tag{4.7}$$

Hence,

$$N(H, \epsilon/32, m, L_1) \leq N(\hat{G}, \epsilon/32, m, L_1) \leq q(t, 32/\epsilon)r(m). \tag{4.8}$$

If

$$m \geq (9216/\epsilon^2)q(t, 32/\epsilon)r(m), \tag{4.9}$$

m satisfies

$$8e^{q(t,32/\epsilon)r(m)}e^{-(m/128)(\epsilon/4)^2} \leq 1/4, \tag{4.10}$$

and then by Theorem 2.1, with probability at least $(1-1/4) = 3/4$, the observed mean of each function $h \in H$ will be within $\epsilon/4$ of its true mean. That is, with probability at least 3/4, for each $g \in \hat{G}$,

$$|L_1(g, S) - L_1(f, g, P)| \leq \epsilon/4. \tag{4.11}$$

If g is the function that is returned by $Q(S, \epsilon/4)$, then $L_1(g, S) \leq \epsilon/4$. Therefore, if $l_{\min}(S, \epsilon/4, L_1) \leq t$, with probability at least 3/4, $L_1(f, g, P) \leq \epsilon/2$. Since we showed earlier that with probability at least 3/4, $l_{\min}(S, \epsilon/4, L) \leq t$, we get that with probability at least 1/2 the function g returned by Q will be such that $L_1(f, g, P) \leq \epsilon/2$.

We now estimate the probability that the algorithm halts when Q returns a function g such that $L_1(f, g, P) \leq \epsilon/2$. Once again by Chebyshev's inequality,

$$Pr\{|L_1(g, S_1) - L_1(g, f, P)| \geq \epsilon/4\} \leq \frac{16}{\epsilon^2 m_1}. \tag{4.12}$$

Given that $L_1(f, g, P) \leq \epsilon/2$ and that $m_1 = 16t^2/(\epsilon^2\delta)$, we have

$$Pr\{L_1(g, S_1) \geq (3/4)\epsilon\} \leq \frac{\delta}{t^2} \leq 1/2. \tag{4.13}$$

Hence, we have $Pr\{L_1(g, S_1) < (3/4)\epsilon\} \geq 1/2$. That is, if the function g returned by Q is such that $L_1(f, g, P) \leq \epsilon/2$, then A_1 will halt with probability at least 1/2.

We have therefore shown that when $t \geq t_0$, the algorithm halts with probability at least 1/4. Hence, the probability that the algorithm does not halt within some $t > t_0$ iterations is at most $(3/4)^{t-t_0}$. Noting that the function $q()$ is a polynomial in its arguments, it follows that the expected sample complexity of the algorithm is polynomial in $1/\epsilon$, $1/\delta$ and t_0.

We now discuss the extension of Theorem 4.1 to other metrics. The one ingredient in the proof of Theorem 4.1 that does not directly generalize to the other L_p metrics is the reliance on Theorem 2.1, which is in terms of the L_1 metric. This obstacle can be overcome by using the relationship between the various L_p metrics as given by inequality 2.5.

5. Learning in the presence of noise. We assume that the examples for the target function are corrupted by additive random noise in that EXAMPLE returns $(x, f(x) + \nu)$, where ν is a random variable. The noise variable ν is distributed in an arbitrary and unknown fashion and is independent of the target function and the sampling distribution.

We can show that the existence of an Occam approximation suffices to guarantee learnability in the presence of such noise, under some special conditions. Specifically we assume that the strength of the noise in the metric of interest is known a priori to the learning algorithm. Then a learning algorithm would work as follows. Obtain a sufficiently large number of examples, large enough that the observed strength of the noise is close to the true strength. Pass the observed samples through an Occam approximation, with tolerance equal to the noise strength. The function output by the Occam approximation is a candidate for a good approximation to the target function. Test this function against additional samples to check whether it is indeed close. Since these additional samples are also noisy, take enough samples to ensure that the observed noise strength in these samples is close to the true strength. The candidate function is good if it checks to be roughly the noise strength away from these samples.

The essence of the above procedure is that the error allowed of the Occam approximation is equal to the noise strength, and the noise and the error subtract rather than add. In order for us to prove that this indeed is the case, we must restrict ourselves to linear metrics; metrics L such that in the limit as the sample size goes to infinity, the observed distance between a function g in the hypothesis class and the noisy target function is the sum of the strength of the noise and the distance between g and the noise-free target function. Two such metrics are the L_∞ metric and the square of the L_2 metric when the noise is of zero mean.

5.1. Noise of known L_2 measure. We assume that the noise is of bounded magnitude, zero mean, and known L_2 measure. Specifically, (1) we are given $b \geq 0$ such the noise ν is a random variable in $[-b, +b]$; (2) the noise ν has zero mean; (3) we are given the variance c of the noise. It is easy to see that statistical access to the noise variable ν is sufficient to obtain accurate estimates of the variance c.

THEOREM 5.1. *Let F be the target class and G the hypothesis class with complexity measure l, where F and G are of envelope 1 and $b+1$, respectively. Assume a noise source of known L_2 measure per our assumptions. Let Q be an Occam approximation for G with respect to the L_2 metric, with characteristic (q, r). Then, there exists a learning algorithm for F with expected sample complexity polynomial in $1/\epsilon$, $1/\delta$, $l_{\min}(f, \epsilon/8, P, L_2^2)$, and the noise bound b.*

Proof. Let f be the target function. Algorithm A_2 below is a learning algorithm for F in the L_2^2 metric; i.e., on input ϵ and δ, with probability at least $1-\delta$, the algorithm will identify a function g such that $L_2^2(f, g, P) \leq \epsilon$.

ALGORITHM A_2.

```
input $\epsilon, \delta$, noise bound $b$, noise variance $c$;
begin
    $t = 2$;
    repeat forever
        let $m$ be the least integer satisfying
        $m \geq \frac{32768 \log(8)(b+1)^4}{\epsilon^2} q\,(t, (128(b+2)/\epsilon))\, r(m) + \frac{4096(b+1)^4}{\epsilon^2}$;
        make $m$ calls of EXAMPLE to get collection $S$;
        let $g = Q(S, \sqrt{c+\epsilon/4})$;
        let $m_1 = \frac{256(b+1)^4 t^2}{\delta\epsilon^2}$;
        make $m_1$ calls of EXAMPLE to get collection $S_1$;
        if $L_2^2(g, S_1) \leq c + (3/4)\epsilon$ then output $g$ and halt;
        else $t = t + 1$;
    end
end
```

We first show that the probability of the algorithm halting with a function g as output such that $L_2^2(f, g, P) > \epsilon$ is less than δ. Now,

$$L_2^2(g, S_1) = \frac{1}{m_1} \sum_{S_1} (g - (f + \nu))^2 \tag{5.1}$$

$$= \frac{1}{m_1} \sum_{S_1} (g-f)^2 + \frac{2}{m_1} \sum_{S_1} \nu(g-f) + \frac{1}{m_1} \sum_{S_1} \nu^2. \tag{5.2}$$

Since $\mathbf{E}\{\nu(g-f)\} = 0$, $\mathbf{E}\{\nu^2\} = c$, and $\mathbf{E}\{(g-f)^2\} = L_2^2(g, f, P)$, it follows that $\mathbf{E}\{L_2^2(g, S_1)\} = L_2^2(g, f, P) + c$. Noting that $(g-(f+\nu))^2 \leq (2(b+1))^2$, we can invoke Chebyshev's inequality to write

$$Pr\left\{\left|L_2^2(g, S_1) - (L_2^2(g, f, P) - c)\right| \geq \epsilon/4\right\} \leq \frac{256(b+1)^4}{m_1 \epsilon^2}. \tag{5.3}$$

If $L_2^2(g, f, P) > \epsilon$, (5.3) implies that

$$Pr\{L_2^2(g, S_1) \leq c + (3/4)\epsilon\} \leq \frac{256(b+1)^4}{m_1 \epsilon^2}. \tag{5.4}$$

If

$$m_1 = \frac{256(b+1)^4 t^2}{\delta \epsilon^2}, \tag{5.5}$$

then

$$Pr\{L_2^2(g, S_1) \leq c + (3/4)\epsilon\} \leq \frac{\delta}{t^2}. \tag{5.6}$$

Summing over all $t \geq 2$, we get that the probability that the algorithm halts with $L_2^2(g, f, P) > \epsilon$ is at most δ.

Let $h \in G$ be such that $L_2^2(h, f, P) \leq \epsilon/8$ and $l_{\min}(f, \epsilon/8, P, L_2^2) = l(h) = t_0$. As in (5.3) and (5.6), with Chebyshev's inequality we can show that

$$Pr\{L_2^2(h, S) > c + \epsilon/4\} \leq \frac{1024(b+1)^4}{m\epsilon^2}. \tag{5.7}$$

If $m \geq 4096(b+1)^4/\epsilon^2$, then $Pr\{L_2^2(h, S) > c + \epsilon/4\} \leq 1/4$ and as a consequence

$$Pr\{l_{\min}(S, c + \epsilon/4, L_2^2) \leq l(h) \leq t_0\} \geq 3/4. \tag{5.8}$$

Let $\hat{G}$ be the class of functions that Q could output on inputs S and $\sqrt{c + \epsilon/4}$, when S satisfies $l_{\min}(S, c+\epsilon/4, L_2^2) \leq t_0$. Let H be the class of functions $\{(f-g)^2 | g \in \hat{G}\}$. Then, for every pair h_1 and h_2 in H, there exists g_1 and g_2 in $\hat{G}$ such that

$$|h_1 - h_2| = |(f - g_1)^2 - (f - g_2)^2| \tag{5.9}$$
$$= |f^2 + g_1^2 - 2fg_1 - f^2 - g_2^2 + 2fg_2| \tag{5.10}$$
$$= |g_1^2 - g_2^2 - 2f(g_1 - g_2)| \tag{5.11}$$
$$= |(g_1 - g_2)(g_1 + g_2 - 2f)|. \tag{5.12}$$

Since g_1 and g_2 have envelope $b + 1$ and f has envelope 1, we can write

$$|(g_1 - g_2)(g_1 + g_2 - 2f)| \leq 2(b+2)|g_1 - g_2|. \tag{5.13}$$

Hence,

$$|h_1 - h_2| \leq 2(b+2)|g_1 - g_2|, \tag{5.14}$$

and $L_1(h_1, h_2, P) \leq 2(b+2)L_1(g_1, g_2, P)$. Invoking (2.5), we get

$$L_1(h_1, h_2, P) \leq 2(b+2)L_1(g_1, g_2, P) \leq 2(b+2)L_2(g_1, g_2, P). \tag{5.15}$$

Combining the above with the assumption that Q is Occam, it follows that

$$N(H, \epsilon/64, m, L_1) \leq N\left(\hat{G}, \left(\frac{\epsilon}{128(b+2)}\right), m, L_2\right) \tag{5.16}$$
$$\leq e^q\left(t_0, (128(b+2)/\epsilon)\right) r(m). \tag{5.17}$$

Noting that H has envelope $(b+1)^4$ and invoking Theorem 2.1, we have that if $t \geq t_0$, $l_{\min}(S, c + \epsilon/4, L_2) \leq t_0$, and

$$m \geq \frac{32768 \log(8)(b+1)^4}{\epsilon^2} q\left(t, (128(b+2)/\epsilon)\right) r(m), \tag{5.18}$$

then with probability at least 3/4 the observed mean over the m samples of S of each $h \in H$ will be within $\epsilon/8$ of its true mean. That is,

$$Pr\left\{\left|\frac{1}{m}\sum_S (g-f)^2 - L_2^2(g, f, P)\right| \leq \epsilon/8\right\} \geq 3/4. \tag{5.19}$$

Noting that the probability estimate in the above inequality is conditional on (5.8), we can remove the conditionality by combining it with (5.8) to get

$$Pr\left\{\left|\frac{1}{m}\sum_S (g-f)^2 - L_2^2(g,f,P)\right| \le \epsilon/8\right\} \ge 1/2, \tag{5.20}$$

when

$$m \ge \frac{32768\log(8)(b+1)^4}{\epsilon^2} q\left(t,(128(b+2)/\epsilon)\right) r(m) + \frac{4096(b+1)^4}{\epsilon^2}. \tag{5.21}$$

Now,

$$L_2^2(g,S) = (1/m)\sum_S (g-f)^2 + (2/m)\sum_S \nu(g-f) + (1/m)\sum_S \nu^2. \tag{5.22}$$

Once again by Chebyshev's inequality, we can write

$$Pr\left\{\left|(2/m)\sum_S \nu(g-f) + (1/m)\sum_S \nu^2 - c\right| \ge \epsilon/8\right\} \le \frac{256(b+2)^4}{\epsilon^2 m}. \tag{5.23}$$

If

$$m \ge \frac{512(b+2)^4}{\epsilon^2}, \tag{5.24}$$

then

$$Pr\left\{\left|(2/m)\sum_S \nu(g-f) + (1/m)\sum_S \nu^2 - c\right| \ge \epsilon/8\right\} \le 1/2. \tag{5.25}$$

Combining (5.20), (5.22), and (5.25), we have

$$Pr\left\{\left|L_2^2(g,S) - L_2^2(g,f,P) - c\right| \le \epsilon/4\right\} \ge 1/4, \tag{5.26}$$

when

$$m \ge \frac{32768\log(8)(b+1)^4}{\epsilon^2} q\left(t,(128(b+2)/\epsilon)\right) r(m) + \frac{4096(b+1)^4}{\epsilon^2}. \tag{5.27}$$

If g is the function output by $Q(S, \sqrt{c+\epsilon/4})$, then $L_2^2(g,S) \le c+\epsilon/4$ and (5.26) can be written as

$$Pr\{L_2^2(g,f,P) \le \epsilon/2\} \ge 1/4. \tag{5.28}$$

If $L_2^2(g,f,P) \le \epsilon/2$, then by (5.3) we get

$$Pr\{L_2^2(g,S_1) \le c + (3/4)\epsilon\} \ge 1 - \frac{256(b+1)^4}{m_1\epsilon^2}. \tag{5.29}$$

If m_1 is chosen as in the algorithm, then we can rewrite the above as

$$Pr\{L_2^2(g,S_1) \le c + (3/4)\epsilon\} \ge 1 - \delta/t^2 \ge 3/4. \tag{5.30}$$

Combining (5.28) and (5.30), we get that when $t \geq t_0$, with probability at least 3/16, the function g output by $Q(S, \sqrt{c+\epsilon/4})$ will be such that $L_2^2(g, S_1) \leq c+(3/4)\epsilon$ and the algorithm will halt. Hence, the probability that the algorithm does not halt within some $t > t_0$ iterations is at most $(13/16)^{t-t_0}$. Noting that the function $q()$ is a polynomial in its arguments, it follows that the expected sample complexity of the algorithm is polynomial in $1/\epsilon$, $1/\delta$, t_0, and b.

Our assumption that the noise lies in a bounded range $[-b, +b]$ excludes natural distributions over infinite spans such as the normal distribution. However, we can include such distributions by a slight modification to our source of examples. Specifically, assume that we are given a value of b such that the second moment of the noise variable outside the range $[-b, +b]$ is small compared to ϵ. Noting that the target function f has range $[-1, 1]$ by assumption, we can screen the output of EXAMPLE, rejecting the examples with values outside $[-(b+1), +(b+1)]$ and otherwise passing them on to the learning algorithm. Thus, the noise distribution effectively seen by the learning algorithm is of bounded range $[-b, +b]$. We leave it to the reader to calculate the necessary adjustments to the sampling rates of the algorithm.

5.2. Noise of known L_∞ measure. We assume that we know the L_∞ measure of the noise in that we are given the following:

(1) $b \geq 0$ such that the noise ν is a random variable in $[-b, +b]$, not necessarily of zero mean. Also, the symmetry is not essential; it suffices if $b_1 \leq b_2$ are given, with $\nu \in [b_1, b_2]$.

(2) A function $\gamma(\epsilon)$ polynomial in ϵ such that $Pr\{\nu \in [b-\epsilon, b]\} \geq \gamma(\epsilon)$, and $Pr\{\nu \in [-b, -b+\epsilon]\} \geq \gamma(\epsilon)$. Also, b is a meaningful L_∞ estimate in that for all $\epsilon > 0$, $\gamma(\epsilon) > 0$.

It is easy to see that statistical access to the noise variable ν is sufficient to obtain an accurate estimate of the value of γ for a particular value of ϵ. We now revisit our definition of an Occam approximation to define the notion of a strongly Occam approximation.

For a function f, let $band(f, \epsilon)$ denote the set of points within ϵ of f, i.e., $band(f, \epsilon) = \{(x, y) : |y - f(x)| \leq \epsilon\}$. For a class F, $band(F, \epsilon)$ is the class of all band sets for the functions in F, i.e., $band(F, \epsilon) = \{band(f, \epsilon) | f \in F\}$. A class of sets F is said to shatter a set S if the set $\{f \cap S : f \in F\}$ is the power set of S. $D_{VC}(F)$ denotes the Vapnik–Chervonenkis dimension of F and is the cardinality of the largest set shattered by F. The Vapnik–Chervonenkis dimension is a combinatorial measure that is useful in establishing the learnability of sets [9], [21].

Let Q be an approximation algorithm with respect to the L_∞ metric. Fix $m, t \in \mathbf{N}$, and $\epsilon > 0$. Let $\hat{G}$ be the class of all functions identified in the output of Q when its input ranges over all collections S of m examples such that $l_{\min}(S, \epsilon, L) \leq t$. Q is said to be strongly Occam if there exists a function $q(a, b)$ that is polynomial in a and $1/b$ and $r : \mathbf{N} \to \mathbf{N}$ such that $r(m)$ is $O(m^\alpha)$, for fixed $0 \leq \alpha < 1$ and for all m, t, ϵ, and $\zeta > 0$, $D_{VC}(band(\hat{G}, \zeta)) \leq q(t, 1/\zeta)r(m)$.

Example 3. Let F be the Baire functions and G the class of piecewise linear functions with complexity measure the number of pieces.

Consider the following approximation algorithm Q with respect to the L_∞ metric. Given is a collection of samples $S = \{(x_1, y_1),\ (x_2, y_2), \ldots,\ (x_m, y_m)\}$ and tolerance ϵ. Using the linear time algorithm of [15], [28], construct a piecewise linear function g such that $|g(x_i) - y_i| \leq \epsilon$ for each of the samples in S and g consists of the fewest number of pieces over all such functions.

Claim 3. Algorithm Q is strongly Occam.

Proof. Fix the number of samples m, tolerance ϵ, and complexity bound t. For the set of examples S, $l_{\min}(S, \epsilon, L_2)$ is the fewest number of pieces in any piecewise linear function g such that $L_\infty(g, S) \leq \epsilon$. By construction, Q outputs such a function. Thus $\hat{G}$ is a subset of the class of all piecewise linear functions of t pieces. By Claim 4, for all ζ, $D_{VC}(band(\hat{G}, \zeta)) \leq 7t$, and the claim follows.

Claim 4. If F is the class of piecewise linear functions of at most t pieces, for all ζ, $D_{VC}(band(F, \zeta)) \leq 7t$.

Proof. Assume that we are given a set S of more than $7t$ points that is shattered by $band(F, \zeta)$. Let $S = \{(x_1, y_1),\ (x_2, y_2), \ldots,\ (x_m, y_m)\}$, where the x_i are in increasing order. We shall construct a subset S_1 of S that is not induced by any set in $band(F, \zeta)$, thereby contradicting the assumption that $band(F, \zeta)$ shatters S. Start with $S_1 = \{(x_1, y_1),\ (x_7, y_7)\}$. Now some three of (x_i, y_i) for $i = 2, 3, \ldots, 6$ must lie on the same side of the line joining (x_1, y_1) and (x_7, y_7). Call these points a, b, and c, in order of their x coordinate. If b is within the quadrilateral formed by (x_1, y_1), (x_7, y_7), a, and c, add a and c to S_1, else add b to S_1. Repeat this procedure with the rest of the points in S. The resulting set S_1 is such that no function g of fewer than $m/7$ pieces is such that $band(g, \zeta)$ picks out S_1. This is a contradiction and hence the claim.

We leave it to the reader to show that the following classes also possess efficient strongly Occam approximation algorithms:

(1) The polynomials with complexity measure the highest degree (we can construct a strongly Occam approximation via linear programming).

(2) The trigonometric interpolants with complexity measure the highest frequency (we can construct a strongly Occam approximation via linear programming).

(3) The piecewise constant functions with complexity measure the number of pieces (we can construct a greedy approximation algorithm that is strongly Occam).

In Claim 5 we will show that every strongly Occam approximation is an Occam approximation as well, confirming that the strong notion is indeed stronger. In order to prove the claim, we need the following lemma.

LEMMA 5.2 (see [29]). *Let X be a finite set and let F be a set of subsets of X, with $|X| > d = D_{VC}(F)$. Then,*

$$|F| \leq |X|^d. \tag{5.31}$$

Claim 5. If Q is a strongly Occam approximation for a class F, then it is also an Occam approximation with respect to the L_∞ metric.

Proof. Let Q be a strongly Occam approximation for a class G of unit envelope. Fix $m, t \in \mathbf{N}$, $\epsilon > 0$, and $\zeta > 0$. Let $\hat{G}$ be the class of all functions identified in the output of Q when its input ranges over all collections S of m examples such that $l_{\min}(S, \epsilon, L_\infty) \leq t$. Let $X = \{x_1,\ x_2, \ldots, x_m\}$ be a set of m points. We will construct a ζ-cover C of $\hat{G}$ on X for L_∞. The functions in C will be pairwise ζ apart in the L_∞ sense.

```
ALGORITHM.
Pick any $f \in \hat{G}$ and initialize $C = \{f\}$
while there exists $f \in \hat{G}$ such that for all $g \in C$, $L_\infty(f, g, X) > \zeta$
        $C = C \cup \{f\}$.
end
```

When the algorithm halts, for every $f \in \hat{G}$ there exists some $g \in C$ such that $L_\infty(f, g, X) \leq \zeta$. Hence C is indeed a ζ-cover of $\hat{G}$. Furthermore, for every pair of functions f and g in C,

$$L_\infty(f, g, X) > \zeta. \tag{5.32}$$

Since C is a ζ-cover,

$$\log(N(\hat{G}, \zeta, m, L_\infty)) \leq |C|. \tag{5.33}$$

Let Y be the set $\{-n\zeta, -(n-1)\zeta, \ldots, 0, \zeta, 2\zeta, \ldots, n\zeta\}$, where $n = \lfloor 1/\zeta \rfloor$. We construct a class of sets D from C as follows:

$$D = \{band(f, \zeta/2) \cap X \times Y : f \in C\}. \tag{5.34}$$

By virtue of (5.32), the sets in D are all distinct and in one-to-one correspondence with the functions of C. Also, every set of points shattered by D will also be shattered by $band(\hat{G}, \zeta/2)$, and hence $D_{VC}(D) \leq D_{VC}(band(\hat{G}, \zeta/2))$. Let $d = D_{VC}(band(\hat{G}, \zeta/2))$. By Lemma 1,

$$|D| \leq |X \times Y|^d = (2mn)^d \leq (2m/\zeta)^d. \tag{5.35}$$

Combining (5.33) and (5.35), we get

$$\log(N(\hat{G}, \zeta, m, L_\infty)) \leq \log(|C|) = \log(|D|) \leq d \log(2m/\zeta). \tag{5.36}$$

Since Q is strongly Occam, d is bounded as in the definition of strongly Occam. Combining this with (5.36), it follows that Q is an Occam approximation as well.

THEOREM 5.3. *Let F be the target class and G the hypothesis class with complexity measure l, where F and G are of envelope 1 and $b+1$, respectively. Assume a noise source of known L_∞ measure per our assumptions. Let Q be a strongly Occam approximation for G, with characteristic (q, r). Then, there exists a learning algorithm for F with expected sample complexity polynomial in $1/\epsilon$, $1/\delta$, b, and $l_{\min}(f, \epsilon/4, P_u, L_1)$, where P_u is the uniform distribution on $[0, 1]$.*

Proof. Let f be the target function, and let (q, r) be the characteristic of the Occam approximation Q. We claim that Algorithm A_3 is a learning algorithm for F with respect to the L_1 metric.

```
ALGORITHM $A_3$.
input $\epsilon, \delta, b$;
begin
    $t = 2$;
    $\eta = \frac{\gamma(\epsilon/4)\epsilon}{2(b+2)}$;
    repeat forever
        let $m$ be the least integer satisfying
        $m \geq (16/\eta)q(t, 1/(b+\epsilon/4))r(m)\log(m)$;
        make $m$ calls of EXAMPLE to get collection $S$;
        let $g = Q(S, b+\epsilon/4)$;
        let $m_1 = \frac{16t^2}{\eta^2\delta}$;
        make $m_1$ calls of EXAMPLE to get collection $S_1$;
        if no more than a fraction $(3/4)\eta$ of $S_1$
        is outside $band(g, b+\epsilon/4)$then output $g$ and halt;
        else $t = t+1$;
    end
end
```

For a particular function g, let $\mu(g, \beta)$ be the probability that a call of EXAMPLE will result in an example outside $band(g, b+\beta)$. We now estimate $\mu(g, \epsilon/4)$ when g

is such that $L_1(f, g, P) > \epsilon$. For such g, since F is of envelope 1 and G is of envelope $b+1$, $|f - g| \leq b + 2$ and

$$\int_{|f-g|>\epsilon/2} dP \quad > \epsilon/(2(b+2)). \tag{5.37}$$

It follows that

$$\mu(g, \epsilon/4) = Pr\{f(x) + \nu \notin band(g, b + \epsilon/4)\} \tag{5.38}$$
$$> Pr\{f(x) - g(x) > \epsilon/2 \;\&\; \nu \in [b, b - \epsilon/4]\} \tag{5.39}$$
$$+ Pr\{g(x) - f(x) > \epsilon/2 \;\&\; \nu \in [-b, -b + \epsilon/4]\} \tag{5.40}$$
$$\geq \min\left(Pr\{\nu \in [b - \epsilon/4, b]\},\ Pr\{\nu \in [-b, -b + \epsilon/4]\}\right) \tag{5.41}$$
$$\times Pr\{|f - g| > \epsilon/2\} \tag{5.42}$$
$$\geq \gamma(\epsilon/4)\epsilon/(2(b+2)) = \eta. \tag{5.43}$$

Let $\mu_1(g, \beta)$ denote the fraction of S_1 that is outside $band(g, b + \beta)$. By Chebyshev's inequality,

$$Pr\{|\mu_1(g, \epsilon/4) - \mu(g, \epsilon/4)| > \eta/4\} \leq \frac{16}{\eta^2 m_1}. \tag{5.44}$$

Since $m_1 = 16t^2/(\eta^2\delta)$ and the algorithm halts only when $\mu_1(g, \epsilon/4) \leq (3/4)\eta$, when the algorithm halts

$$Pr\{\mu(g, \epsilon/4) > \eta\} \leq \frac{\delta}{t^2}. \tag{5.45}$$

Summing over all $t \geq 2$, we get that the probability that the algorithm halts with $\mu(g, \epsilon/4) > \eta$ is at most δ. It follows that the probability that the algorithm halts with $L_1(g, f, P) > \epsilon$ is at most δ. Let P_u be the uniform distribution on $[0, 1]$. We now show that when $t \geq t_0 = l_{\min}(f, \epsilon/4, P_u, L_\infty)$ the algorithm halts with probability at least 1/4.

Let $t \geq t_0$ at a particular iteration, and let $\hat{G}$ be the class of all functions that Q could output during that iteration. Since $\nu \in [-b, +b]$, it is clear that $l_{\min}(S, b + \epsilon/4, L_\infty) \leq t_0 \leq t$. Since Q is strongly Occam, $D_{VC}(band(\hat{G}, b + \epsilon/4)) \leq q(t, 1/(b + \epsilon/4))r(m)$. By Theorem 4.3 of [21], for $m \geq 8/\eta$, the probability that m random samples will all fall in $band(g, b + \epsilon/4)$ for any $g \in \hat{G}$ such that $\mu(g, \epsilon/4) > \eta/2$ is at most

$$2 \sum_{i=0}^{d} \binom{2m}{i} 2^{-\eta m/4}. \tag{5.46}$$

Hence, if m is chosen so that the above probability is less than 1/2, then with probability at least 1/2, $Q(S, b+\epsilon/4)$ will return a function g such that $\mu(g, \epsilon/4) \leq \eta/2$. Indeed

$$m \geq \frac{16}{\eta} q(t, 1/(b + \epsilon/4))r(m)\log(m) \tag{5.47}$$

suffices. By assumption, $r(m)$ is $O(m^\alpha)$, for some $0 \leq \alpha < 1$. It follows that $r(m)\log(m)$ is $O(m^\beta)$, for some $0 \leq \beta < 1$, and there exists m satisfying (5.47).

We now estimate the probability the algorithm halts when Q returns a function g satisfying $\mu(g, \epsilon/4) \leq \eta/2$. Once again by Chebyshev's inequality,

$$Pr\{|\mu_1(g, \epsilon/4) - \mu(g, \epsilon/4)| > \eta/4\} \leq \frac{16}{\eta^2 m_1}. \tag{5.48}$$

Given that $\mu(g, \epsilon/4) \leq \eta/2$ and that $m_1 = 16t^2/(\eta^2\delta)$, we have

$$Pr\{\mu_1(g, \epsilon/4) > (3/4)\eta\} \leq \frac{\delta}{t^2} \leq 1/2. \tag{5.49}$$

Hence, we have $Pr\{\mu_1(g, \epsilon/4) \leq (3/4)\eta\} \geq 1/2$. That is, if the function g returned by Q is such that $\mu(g, \epsilon/4) \leq \eta/2$, then A_1 will halt with probability at least $1/2$. We have therefore shown that when $t \geq t_0$, the algorithm halts with probability at least $1/4$. Hence, the probability that the algorithm does not halt within some $t > t_0$ iterations is at most $(3/4)^{t-t_0}$, which goes to zero with increasing t.

5.3. Application to filtering. An important problem in signal processing is that of filtering random noise from a discretely sampled signal [24]. The classical approach to this problem involves manipulating the spectrum of the noisy signal to eliminate noise. This works well when the noise-free signal has compact spectral support, but is not effective otherwise. However, the noise-free signal may have compact support in some other representation, where the filtering may be carried out effectively.

When we examine Algorithm A_2, we see that the sampling rate m varies roughly as $q()r(m)/\epsilon^2$, or $\epsilon^2 \approx q()r(m)/m$. In a sense, $q()r(m)$ is the support of the noise-free target function in the hypothesis class G. While spectral filters choose G to be the trigonometric interpolants, we are free to choose any representation, aiming to minimize $q()r(m)$. Furthermore, the Occam approximation Q need not manipulate its input samples in a linear fashion, as is the case with spectral filters. In this sense, our results offer the first general technique for the construction of nonlinear filters.

In the practical situation, our results can be interpreted thus: Pass the samples of the noisy signal through a data compression algorithm, allowing the algorithm an approximation error equal to the noise strength. The decompressed samples compose the filtered signal and are closer to the noise-free signal than the noisy signal. Implementations of this are pursued in [23].

6. Conclusion. We showed that the principle of Occam's Razor is useful in the context of probably approximate learning functions on the reals, even in the presence of arbitrarily large additive random noise. The latter has important consequences in signal processing in that it offers the first general technique for the design and construction of nonlinear filters.

Acknowledgments. Thanks to A. Lempel for discussions. Particular thanks to the referees for their extraordinary patience in carefully reading the manuscript and offering numerous suggestions for improvement.

Abstract. One of the main unsolved problems confronting Hypertext is the navigation problem, namely, the problem of having to know where you are in the database graph representing the structure of a Hypertext database, and knowing how to get to some other place you are searching for in the database graph. In order to tackle this problem we introduce a formal model for Hypertext. In this model a Hypertext database consists of an information repository, which stores the contents of the database in the form of pages, and a reachability relation, which is a directed graph describing the structure of the database. The notion of a trail, which is a path in the database graph describing some logical association amongst the pages in the trail, is central to our model.

We define a Hypertext query language for our model based on a subset of propositional linear temporal logic, which we claim to be a natural formalism as a basis for establishing navigation semantics for Hypertext. The output of a trail query in this language is the set (which may be infinite) of all trails that satisfy the query. We show that there is a strong connection between the output of a trail query and finite automata in the sense that, given a Hypertext database and a trail query, we can construct a finite automaton representing the output of the query, which accepts a star-free regular language. We show that the construction of the finite automaton can be done in time exponential in the number of conjunctions, between the subformulas of the trail query, plus one.

Given a Hypertext database and a trail query, the problem of deciding whether there exists a trail in the database that satisfies the trail query is referred to as the model checking problem. We show that, although this problem is NP-complete for different subsets of our query language, it can be solved in polynomial time for some significant special cases. Thus the navigation problem can only be efficiently solved in some special cases, and therefore in practice Hypertext systems could include algorithms which return randomized and/or fuzzy solutions.

Key words. Hypertext, navigation, trail query, temporal logic, finite automata, computational complexity

1. Introduction.

Traditional text, for example in book form, has a single linear sequence defining the order in which the text is to be scanned. In contrast Hypertext [CONK87] (or more generally Hypermedia; see [HALA88]) is text (which may contain multimedia) that can be read nonsequentially. Hypertext presents several different options to readers, and the individual reader chooses a particular sequence at the time of reading.

The inspiration for Hypertext comes from the *memex* machine proposed by Bush [BUSH45] (see also [NYCE89]). The memex is a "sort of mechanized private file and library" which supports "associative indexing" and allows navigation whereby "any item may be caused at will to select immediately and automatically another." Bush emphasizes that "the process of tying two items together is an important thing." In addition, by repeating this process of creating links we can form a *trail* which can be traversed by the user, in Bush's words, "when numerous items have been thus joined together to form a trail they can be reviewed in turn." Hypertext can be viewed as the formalization and realization of Bush's original ideas.

A *Hypertext database* [STOT89, TOMP89, FRIS92] is formalized as a directed graph [BUCK90] (called the *database graph*) whose nodes represent textual units of information (called *pages*) and whose arcs (also called *links*) allow the reader to navigate from an anchor node to a destination node. The structure of a Hypertext database changes over time and thus differs from traditional databases, such as relational databases [ULLM88], which have a regular structure defined by a relational database schema. It is evident that a Hypertext database can be implemented on top of a relational database provided it has the facilities to store and retrieve textual objects. A comparison of the functional characteristics of several Hypertext systems can be found in [SCHN88].

The process of traversing links and following a *trail* of information in a Hypertext database is called *navigation* (or alternatively *link following*). In graph-theoretic terms a trail in a Hypertext database is a *path* in the database graph (we allow a node to occur more than once in a path; paths are called *walks* in [BUCK90]).

Navigating through a Hypertext database leads to the problem of getting "lost in hyperspace" [CONK87, VAND88], which is the problem of having to know where you are in the database graph and knowing how to get to some other place that you are searching for in the database graph. From now on we will refer to this fundamental problem as the *navigation problem.*

In order to solve the navigation problem we can augment link following with a *query*-based access mechanism [HALA88]. Such a mechanism allows users to specify the characteristics of the information they are searching for and then to obtain the output of their query from the Hypertext system. Two types of querying mechanism are the following:

- *Content-based search*, which typically uses index-based information retrieval technology. When searching by content, pages are searched independently of their association with other pages in the database.
- *Structure-based search*, which extends content-based search by additionally specifying a description of a subgraph [BUCK90] of the database graph. When searching by structure, contents of pages are searched in association with their linkage with other pages in the database according to the said specified subgraph.

We will refer to the formal semantics of the query mechanism used in a Hypertext system as its *navigation semantics.*

In a more general context of a Hypertext system the process of finding and examining the text pages associated with destination nodes is called *browsing* [CONK87]. The *browser* is the component of a Hypertext system that helps users search for the information they are interested in by graphically displaying the relevant parts of the database and providing contextual and spatial cues with the use of *navigational aids* such as *maps* and *guides* [FRIS92]. A set of tools that aid navigation by performing a structural analysis of the database graph is described in [RIVL94].

Herein, we are only interested in the navigation semantics of structure-based search as a means of attempting to solve the navigation problem and thus assume that navigational aids are available within the browser and are independent of the navigation semantics.

Example 1. *The database graph of a Hypertext database, which models a simple* Teletext *system storing pages of information according to the following topics: news, sports, travel, and weather, is shown in Figure* 1.1. *In a more comprehensive example the nodes in this database graph can be expanded into subgraphs; for instance, the*

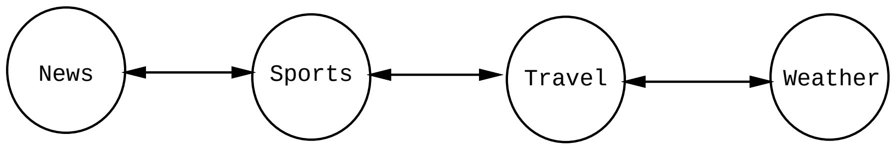

FIG. 1.1. *A simple database graph.*

node labeled news *can be expanded into several pages, one for regional news, one for countrywide news, one for European news, and one for worldwide news.*

In our Hypertext model we separate the contents of nodes (i.e., the pages) from the database graph. We define a Hypertext database to be an ordered pair $\langle I, R\rangle$, where I is an *array* [TREN73] of pages, called the *information repository*, and R is a binary relation in the indices of I, called the *reachability relation*; the indices of I are referred to as the *page numbers* of I. Thus arrays are used to provide an indexing mechanism for pages. This leads us to define a *trail* as an array of page numbers corresponding to a path in the directed graph representing R.

In the navigation semantics that we propose, the notion of a trail is central. The output of a query is the set of trails in the Hypertext database satisfying the query specification; each trail in the output of a query is called an *answer* of the query. Therefore, a query consists of two orthogonal parts:

(i) logical formulas composed of predicates to be satisfied by the contents of pages in the information repository, and

(ii) the order in which the pages, satisfying the logical formulas, are to be found in the reachability relation.

An important requirement of the query language is that users should have as much flexibility as possible when posing a query according to their knowledge of the contents and structure of the Hypertext database.

This suggests that a logic of *positions* [RESC71] would be well suited as a query language for Hypertext due to the spatial interpretation of the database graph. As pointed out by Rescher and Urquhart [RESC71] there is a close connection between *positional* and *temporal* logic. Therefore, we choose to utilize *propositional linear temporal logic* (PLTL) [EMER90] as the underlying semantics for navigation, where in our context *time* actually means *position.* (We mention that temporal logic is widely employed in the very active research area of specification and verification of concurrent programs [EMER90, MANN92].)

In our context we view a Hypertext database as a *temporal structure* [EMER90], where the page numbers of I are associated with the states of the structure and the binary relation R is associated with the transition relation of the structure.

We define a query language, called *Hypertext query language* (HQL), based on a subset of PLTL and call HQL formulas *trail queries* (or HQL queries). In particular, HQL includes the temporal operators "nexttime" (denoted by $\bigcirc$) and "sometimes" (denoted by $\diamond$). A fundamental difference between the semantics of PLTL and HQL is that models of PLTL formulas are *timelines*, which are infinite paths describing computation sequences [EMER90, THOM90], while models of HQL formulas are *trails*, which are finite paths describing sequences of pages that can be traversed by users. Thus, in addition to the temporal operators $\bigcirc$ and $\diamond$, HQL supports a novel temporal operator "finaltime" (denoted by $\triangle$), which refers to the final page number in a trail. (We will show that $\triangle$ adds expressive power to the query language.)

HQL provides a natural vehicle for combining content-based querying with structure-based search via the above temporal operators. The "nexttime" operator allows the user to navigate through the pages one step at a time, the "sometimes" operator allows the user to skip as many pages as necessary in order to arrive at the next page he wishes to browse through, and the "finaltime" operator allows the user to specify the final page in a navigation session.

The output of a trail query is defined to be the set of all trails that satisfy the query, and the problem of whether there exists an answer to a trail query with respect to a Hypertext database is the problem of deciding whether the database is a model of the trail query; this problem is known as the *model checking* problem (see [EMER90]).

In order to construct the output of a query we take advantage of the strong connection between finite automata [HOPC79, PERR90] and PLTL [VARD86a, VARD86b, EMER90, THOM90] as follows.

First, we show that a Hypertext database, say, H, can be represented by a finite automaton $\mathcal{M}_H$ and that the language accepted by $\mathcal{M}_H$ is a *star-free* regular language [MCNA71, PERR90]. Second, we show that a finite automaton $\mathcal{M}_f$ can be constructed for a trail query, say, f, with respect to the Hypertext database H, and that the language accepted by $\mathcal{M}_f$ is also a star-free regular language. Finally, we show that the output of a trail query corresponds to the intersection of $\mathcal{M}_H$ and $\mathcal{M}_f$, which also accepts a star-free regular language, since star-free regular languages are closed under intersection. Thus the navigation semantics of HQL are given in terms of star-free regular languages.

In addition, we show that constructing $\mathcal{M}_H \cap \mathcal{M}_f$ can be done in time exponential in the number of conjunctions, between the subformulas of f, plus one, and in the case when the number of conjunctions between the subformulas of f is one, then the construction can be done in time polynomial in the size of H and the length of f. Thus, we give an exponential time upper bound for query evaluation in HQL, which is tractable as long as the number of conjunctions in the subformulas of trail queries is bounded by some constant.

In order to measure the difficulty of navigation in Hypertext we investigate the computational complexity of the model checking problem for HQL queries. We prove that in the general case the model checking problem is NP-complete, which is to be expected by inspecting the results in [SIST85] (see also [EMER90]). We also show that in two special cases, when trail queries do not contain any occurrences of $\diamond$, the model checking problem can be solved in polynomial time in the length of the information repository I and the length of the trail query f.

The rest of the paper is organized as follows. In section 2 we briefly survey related work. In section 3 we formalize the notion of a Hypertext database. In section 4 we present our query language, HQL. In section 5 we investigate a strong connection between the output of a trail query and finite automata that accept star-free regular languages. In section 6 we investigate the computational complexity of navigation in a Hypertext database. Finally, in section 7 we give our concluding remarks.

2. A brief survey of related work. Several researchers [STOT89, STOT92, MEND95] have recognized that the semantics of navigation in a Hypertext database can be formalized in terms of finite automata [HOPC79, PERR90].

In [MEND95] a query language, called G^+, is described in which the database graph is defined as a finite automaton, a query is defined as a regular expression, and the output of a query is computed from the intersection of the database graph and a finite automaton representing the query. In particular, the output of a query is the set of ordered pairs, (x, y), such that x and y are nodes in the database graph and there is a *simple path* from x to y (i.e., a path in which no node occurs more than once) labeled by a word which is accepted by the query. (See [CONS89] for a description of a later language, called GraphLog, which is an extension of G^+, and for examples of how GraphLog supports structure-based searching.)

It is shown that query evaluation is, in general, exponential time in the size of the input database graph and that the problem of deciding whether an ordered pair of nodes is in an answer to a given query is NP-complete. Some special cases are exhibited when query answering can be done in polynomial time; in particular, query answering is polynomial time when either the database graph is acyclic or the query is a *restricted regular expression* [MEND95]. The contents of nodes are not discussed in [CONS89, MEND95].

In contrast to HQL, the query language G^+ [MEND95] does not utilize temporal logic, which syntactically restricts trail queries to be equivalent to *star-free* regular languages. In addition, the navigation semantics of G^+ [MEND95] process only simple paths in the database graph, while the navigation semantics of HQL process trails which may not be simple paths. Finally, we claim that HQL is a more natural formalism for expressing queries in Hypertext than the language of regular expressions, since it is closer in nature to the navigational requirements of Hypertext.

In [STOT89] *Petri nets* [PETE81] are suggested as an underlying formalism for the specification of navigation semantics. Since Petri nets are inherently a concurrency model, they provide natural semantics for concurrent navigation paths. Furthermore, finite automata are a special case of Petri nets [PETE81] and thus as a special case simplified navigation semantics based on finite automata can be supported.

An important feature of the model presented in [STOT89] is the separation of content from structure, in the sense that the contents of the database are described via a mapping from the nodes of the Petri net (called *places* in Petri net terminology [PETE81]) to the actual pages of information.

Although Petri nets are amenable to formal analysis and constructing the reachability tree for a Petri net is decidable, in general, the complexity of the reachability problem is intractable; in fact, it has been shown that the reachability problem for Petri nets is EXPSPACE-hard [PETE81]; for special cases of Petri nets when the reachability problem is easier see [ESPA94]. Thus there is a trade-off between expressiveness and complexity, which implies that in practice only special cases of the reachability problem can be incorporated into the navigation semantics of the said model.

In [STOT92] a Hypertext database (called a *hyperdocument*) is viewed as a finite automaton, called the *link automaton*. A *branching temporal logic* [EMER90] language, called HTL*, is proposed for the specification of properties that should be exhibited when navigating through a Hypertext database. HTL* is based on *full branching-time logic* (CTL*) and a subset of HTL*, called HTL, is based on a subset of CTL*, called *computational tree logic* (CTL) [CLAR86, EMER90]. HTL* adds direction to CTL* formulas in order to allow both forward and backward navigation paths to be specified. The propositions of HTL* are atomic predicates, which are conditions to be satisfied at specific states of the link automaton. Correspondingly, the formulas of HTL* are viewed as assertions about the navigation paths of the link automaton. Model checking of an HTL* formula is then used in order to verify that the assertions specified by the formula are satisfied in the link automaton.

Although model checking for a CTL formula can be done in linear time in the length of the formula and the temporal structure being verified, model checking for a CTL* formula was shown to be PSPACE-complete [CLAR86]. In practice, it would be useful to investigate a language whose model checking complexity is in between HTL and HTL*, since HTL may turn out to be too restrictive.

There are several differences between the model presented in [STOT92] and our model. First, we are interested in querying a Hypertext database while Stotts, Furata, and Ruiz [STOT92] are interested in verifying that the Hypertext database satisfies a set of specifications. In fact, a query can also be viewed as a specification that is satisfied if and only if the set of trails that satisfy the query is not empty. Second, branching temporal logic is used in [STOT92] while we use linear time temporal logic. This difference is more fundamental, since in querying a Hypertext database we are only interested in the set of trails that satisfies a trail query independently of other trails in the database graph. Third, in [STOT92] results from the area of specification and verification of concurrent programs are directly used, while as mentioned in section 1 there is a fundamental difference between the semantics of PLTL and HQL, in that models of HQL queries are trails which are finite paths, while models of PLTL formulas (and also of path formulas of CTL and CTL* [CLAR86, EMER90]) are infinite paths. Lastly, Stotts, Furata, and Ruiz [STOT92] do not investigate any specific expressiveness or complexity results relating to their model and concentrate mainly on the definition of their model and showing how it can be applied to other models of Hypertext such as Trellis [STOT92] and Hyperties [RIVL94]. On the other hand, the main aim of our work is actually to investigate the expressiveness and complexity of HQL.

Recently Beeri and Kornatzky [BEER94] have proposed a query language for Hypertext databases which is based on branching temporal logic, with the provision for generalized path quantifiers (which capture natural language assertions) over the trails that satisfy a query. Query answering in their language can be computed in polynomial time in the size of the database graph, since only trails of some fixed bounded length are considered. In HQL no quantifiers are allowed, since its semantics are based on linear-time temporal logic. Moreover, we do not bound the lengths of trails under consideration, and thus as we show herein, query answering in our model cannot always be computed in time polynomial in the size of the database graph. Indeed one conclusion of our results may be that for practical purposes the lengths of trails must be bounded, but this comes at the cost of limiting the notion of a trail and thus forcing the user to tune the bounds of the lengths of trails for specific queries.

3. A formal model for Hypertext based on temporal logic. In this section we formalize our model for Hypertext which was motivated in the introduction. We begin by introducing the notation.

We denote the cardinality of a set, S, by $|S|$ and the length of a string, w, by $||w||$. In addition, we denote the maximum of two natural numbers m and n by $\max(m, n)$. We will use the O-notation for measuring the computational complexity of algorithms [GARE79]. Finally, we abbreviate "if and only if" to iff.

In the following we will be using the following disjoint primitive domains of countably infinite sets:

1. The set of all natural numbers, denoted by ω.
2. The set of all finite length strings, Σ^*, over a finite nonempty alphabet Σ; the empty string is denoted by ϵ, concatenation of two strings w and z will be denoted by wz and a string y is a substring of a string w iff there exist strings x and z such that $w = xyz$.

3. A set of attribute names (or simply attributes), denoted by $\mathcal{U}$.
4. A set of variables, denoted by $\mathcal{V}$.

DEFINITION 3.1 (projection). *We define the two* projection *operators* α *and* β, *such that* $\alpha((x, y)) = x$ *and* $\beta((x, y)) = y$, *where* (x, y) *is an ordered pair of values.*

DEFINITION 3.2 (page). *A* page *is an attribute-value pair of the form* $(A,\ w)$, *where* $A \in \mathcal{U}$ *and* $w \in \Sigma^*$.

We now give the basic definitions pertaining to arrays [TREN73].

DEFINITION 3.3 (array). *Let* $N = \{1,\ldots,n\}$ *be a finite index set, where* $n \in \omega$.

An array *is a family* $\{t_i\}$ *of* items $(i \in N)$; *each* $i \in N$ *is called an* index. (*At this stage the definition of the type of items in an array is left unspecified.*)

We will use the usual convention whereby $A[i]$ *denotes the ith item,* $A(i)$, *of an array,* A, *when* $1 \leq i \leq n$; *otherwise* $A[i]$ *is taken to be undefined. If* $A[i] = t$, *then we say that* $t \in A$.

In the special case when $n = 0$, *the array* A *is* empty *and* $\forall i \in \omega$, $A[i]$ *is taken to be undefined; we denote the empty array by* [ ].

The count *of an array* A, *denoted as* $\#A$, *is the number of items in* A, *i.e.,* $\#A = n$.

Two arrays, A_1 *and* A_2, *are* equal, *denoted as* $A_1 = A_2$, *if* $\#A_1 = \#A_2$ *and* $\forall i \in \{1, \ldots, \#A_1\}, A_1[i] = A_2[i]$.

An array A_1 *is a* suffix *of an array* A_2, *if* $\#A_1 \leq \#A_2$ *and* $\forall i \in \{1, \ldots, \#A_1\}$, $A_1[i] = A_2[(\#A_2 - \#A_1) + i]$. *We let* A^i *denote the suffix of an array,* A, *satisfying* $\#A^i = \#A - i$, *where* $i \in \{0, \ldots, \#A\}$.

An array A_1 *is a* prefix *of an array* A_2, *if* $\#A_1 \leq \#A_2$ *and* $\forall i \in \{1, \ldots, \#A_1\}$, $A_1[i] = A_2[i]$. *We let* A_i *denote the prefix of an array,* A, *satisfying* $\#A_i = i$, *where* $i \in \{0, \ldots, \#A\}$.

The concatenation *of two arrays,* A_1 *and* A_2, *denoted by* A_1A_2, *is an array* A_3 *such that* $\#A_3 = \#A_1 + \#A_2$, $A_{3_{\#A_1}} = A_1$, *and* ${A_3}^{\#A_1} = A_2$.

An array, A, *is said to be* simple *whenever* $\forall i \in \{1, \ldots, \#A\}$, *if* $i \neq j$, *then* $A[i] \neq A[j]$.

An *information repository* is a simple array of pages; i.e., it satisfies the constraint that pages are unique within the repository. The formal definition follows.

DEFINITION 3.4 (information repository). *An* information repository (*or simply a repository*) *is a simple array,* I, *whose items are pages. The indices of* I *are called the* page numbers *of* I. *We let* $\|I\|$ *denote the length of the string* $I[1]I[2]\ldots I[\#I]$.

The constraint that a repository be a simple array is similar to entity integrity [CODD79] and thus avoids duplication of information. Furthermore, the assumption that a repository is an array, which is *not* nested, is similar to the *first normal form assumption* of tuples in relational databases [LEVE99a].

A reachability relation R over a repository, I, is a set of ordered pairs of page numbers of I. The formal definition follows.

DEFINITION 3.5 (reachability relation). *A* reachability relation, R, *over a repository* I (*or simply a reachability relation if* I *is understood from context*) *is a binary relation in* $\{1, \ldots, \#I\}$.

When R *corresponds to an acyclic directed graph* [BUCK90], *we say that* R *is* acyclic; *otherwise* R *is* cyclic (*unless explicitly stated otherwise, we assume that* R *is cyclic*).

It follows that a reachability relation corresponds to a directed graph. A *trail* in a reachability relation, R, is an array of page numbers corresponding to a path in R. The full definition follows.

Definition 3.6 (trail). *A* trail*, T, in a reachability relation, R, over a repository, I (or simply a trail in R if I is understood from context), is an array of page numbers of I such that $\forall i \in \{1, \ldots, \#T-1\}, (T[i], T[i+1]) \in R$. The indices of T are called the* markers *of T.*

A trail *which is a simple array is called a* loop-free *trail. A* subtrail *of a trail, T in R, is a trail in R that is a suffix of a prefix of T (or, equivalently, a prefix of a suffix of T).*

The string induced by a trail T in R, denoted by $\rho(T)$, is defined by $\rho(T) = T[1]T[2]\ldots T[\#T]$.

In general, a trail in a reachability relation, R, corresponds to a path in the directed graph representing R. There are two special cases worth mentioning: a trail of count zero, which corresponds to the empty array and a trail of count one which corresponds to a single page number in I.

The following proposition states that the set of trails in R is *suffix closed* and *prefix closed* (cf. [EMER90]).

Proposition 3.7. *The following statements are true:*

1. *A trail T is in a reachability relation, R, iff $\forall i \in \{0, \ldots, \#T\}$, T^i is in R.*
2. *A trail T is in a reachability relation, R, iff $\forall i \in \{0, \ldots, \#T\}$, T_i is in R.*

We next define Hypertext databases.

Definition 3.8 (Hypertext database). *A* Hypertext database *(or simply a database)* H *is an ordered pair $\langle I, R\rangle$, where I is a repository and R is a reachability relation over I.*

We note that there are no constraints on the reachability relation, R . A Hypertext database $\langle I, R\rangle$ can be viewed as a *temporal structure* [EMER90], where the page numbers of I are associated with the states of the structure and the binary relation R is associated with the transition relation of the structure (we do not assume that R is total as is the case in [EMER90]).

From now on we will assume that $H = \langle I, R\rangle$ is a Hypertext database.

4. A query language for navigating in Hypertext.

In this section we define the syntax and semantics of HQL.

We will assume that strings in Σ^* are distinguished by strings beginning with lowercase letters; attribute names in $\mathcal{U}$ are distinguished by strings beginning with uppercase letters excluding X, Y, and Z; and variables are distinguished by strings beginning with the uppercase letters X, Y, or Z.

Definition 4.1 (normal and unique variables). *We assume that $\mathcal{V}$ is partitioned into two countably infinite sets of variables called* normal variables *and* unique variables.

Normal variables are distinguished by strings beginning with the uppercase letter X, and unique variables are distinguished by strings beginning with the uppercase letter Y. Variables which may be either normal or unique are distinguished by strings beginning with the uppercase letter Z.

In an interpretation, defined below, both normal and unique variables map to page numbers. However, unique variables restrict the mapping such that no two unique variables can map to the same page number.

Informally, a condition is a propositional logic formula such that its atomic formulas are binary predicates.

Definition 4.2 (condition). *Assume a countably infinite set of binary predicate letters. A* numeric term *is either a natural number or a variable and a* symbolic term *is either an attribute or a string. An* atomic formula *is an expression of the* *form $P(t_1, t_2)$, where P is a binary predicate letter, t_1 is a numeric term, and t_2 is a symbolic term. An atomic formula, $P(t_1, t_2)$, is said to be* ground *if t_1 is a natural number; otherwise if t_1 is a variable, then $P(t_1, t_2)$ is said to be* nonground.

We recursively define the class of conditions *using the following rules:*

C1. *A nonground atomic formula $P(t_1, t_2)$ is a condition.*

C2. *If C is a condition, then $\neg(C)$ is a condition.*

C3. *If C_1 and C_2 are conditions, then $(C_1 \wedge C_2)$ is a condition.*

C4. *If C is a condition, then $|\mathbf{V}| = 1$, where $\mathbf{V}$ is the set of variables appearing in C; the single variable appearing in C is called* the variable *of C.*

We note that ground atomic formulas are excluded from conditions, since pages are identified by their content and not by their page number. As usual $C_1 \vee C_2$ stands for $\neg(\neg(C_1) \wedge \neg(C_2))$. Also, when no ambiguity arises we omit parentheses in conditions. In addition, the *length* of a condition, C, is the number of symbols in C assuming that no parentheses are omitted.

An interpretation gives meaning to the predicate letters and variables in conditions such that predicate letters are mapped to polynomial-time algorithms and variables are mapped to page numbers.

Definition 4.3 (an interpretation). *An* interpretation *σ over a Hypertext database $H = \langle I, R\rangle$ (or simply an interpretation σ if H is understood from context) assigns an appropriate meaning to binary predicate letters and terms as follows:*

- *If P is a binary predicate letter, then $\sigma(P)$ is a mapping from $\omega \times (\mathcal{U} \cup \Sigma^*)$ to* {true, false} *such that $\sigma(P)$ is a polynomial-time algorithm* [GARE79] *in $||I||$.*
- *If t is a natural number, an attribute, or a string, then $\sigma(t) = t$.*
- *If Z is a variable, then $\sigma(Z) \in \{1, \ldots, \#I\}$, with the constraint that the restriction* [HALM74] *of σ to unique variables is a one-to-one mapping.*

Restricting σ to be a one-to-one mapping, when its domain is the set of unique variables, implies that two distinct unique variables are mapped by σ to distinct page numbers and this allows us to assert the inequality of page numbers.

Definition 4.4 (satisfaction in an interpretation). *Let σ be an interpretation and let C be a condition. Then we say that σ* satisfies *C, written $\sigma \models C$, provided C is true under the interpretation σ in the usual sense. Specifically,*

C1. $\sigma \models P(t_1, t_2)$ *iff* $\sigma(P)(\sigma(t_1), \sigma(t_2)) =$ true.

C2. $\sigma \models \neg(C)$ *iff* $\sigma \not\models C$.

C3. $\sigma \models (C_1 \wedge C_2)$ *iff* $\sigma \models C_1$ *and* $\sigma \models C_2$.

The following proposition follows by a straightforward induction on the length of a condition.

Proposition 4.5. *Let σ be an interpretation over a Hypertext database $H = \langle I, R\rangle$ and let C be a condition. Then $\sigma \models C$ can be evaluated in polynomial time in $||I||$ and the length of C.*

Hereafter the binary predicate letters *substr* and *att* will be utilized. For all interpretations σ over $\langle I, R\rangle$ their meaning is fixed as follows:

1. $\sigma(\mathit{substr})$ is the substring pattern matching algorithm; that is, $\sigma \models \mathit{substr}(t_1, t_2)$ iff $\sigma(t_2)$ is a substring of $\beta(\mathrm{I}[\sigma(t_1)])$.
2. $\sigma(\mathit{att})$ is the attribute equality algorithm; that is, $\sigma \models \mathit{att}(t_1, t_2)$ iff $\alpha(I[\sigma(t_1)]) = \sigma(t_2)$.

Both $\sigma(\mathit{substr})$ and $\sigma(\mathit{att})$ can be evaluated in polynomial time in $||\mathrm{I}||$ (see [SEDG90] for efficient substring pattern matching).

We next define the notion of a trail formula and its satisfaction utilizing a *tem-*

poral logic framework [EMER90]. In particular, we will employ propositional linear temporal logic (PLTL) with discrete time.

The temporal operators that will be utilized in the context of a Hypertext database are as follows: $\bigcirc$ means "nexttime" (one step at a time navigation) and $\diamond$ means "sometimes" (several steps at a time navigation). We also define an additional temporal operator, denoted by $\triangle$, which means "finaltime" (reaching the last step of navigation). For simplicity, in this paper, we do not consider the "until" temporal operator, which would add expressive power to our query language [GABB80, EMER90]. From now on, we will refer to these temporal operators as *trail operators.*

Strictly speaking, when we refer to *time* we are actually referring to a *position* in a trail. As pointed out by [RESC71] there is a close connection between *positional* and temporal logic which motivates our use of a subset of PLTL as a query language for Hypertext.

We next define trail formulas, which are similar to PLTL formulas [EMER90]. For simplicity, at this stage, we do not consider negation or disjunction in formulas.

Definition 4.6 (trail formulas). *We recursively define the class of* trail formulas (*or simply formulas*) *using the following rules:*

T1. *A condition C is a trail formula.*

T2. *If f_1 and f_2 are trail formulas, then $(f_1 \wedge f_2)$ is also a trail formula.*

T3. *If f is a trail formula, then $\diamond(f)$ is also a trail formula.*

T4. *If f is a trail formula, then $\bigcirc(f)$ is also a trail formula.*

T5. *If f is a trail formula, then $\triangle(f)$ is also a trail formula.*

When no ambiguity arises we omit parentheses in formulas.

Example 2. *We now demonstrate the usefulness of* HQL *with several example formulas and their intuitive semantics, where we assume that the substring pattern matching algorithm is case insensitive.*

1. *The formula*

$$\diamond(substr(X_1, local\ news)) \wedge \diamond(substr(X_2, world\ news)) \wedge \\ \diamond(substr(X_3, sports)) \wedge \diamond(substr(X_4, weather))$$

specifies the trails that have a page of local news, a page of world news, a page of sports news and a page with the weather information.

2. *The formula*

$$substr(X_1, UK\ news) \wedge \bigcirc(substr(X_2, South\ East\ news)) \wedge \\ \bigcirc\bigcirc(substr(X_3, London\ news)) \wedge \triangle(substr(X_4, North\ London\ news))$$

specifies the trails whose first page contains UK news, followed by a page containing South East news, followed by a page containing London news, and a final page containing North London news.

3. *The formula*

$$\diamond(substr(X_1, five\ star\ hotels) \wedge substr(X_1, Austin\ Texas)) \wedge \\ \bigcirc(substr(X_2, five\ star\ hotels) \wedge substr(X_1, Dallas\ Texas))$$

specifies the trails that have a page of five star hotels in Austin, Texas, followed by a page of five star hotels in Dallas, Texas.

4. *The formula*

$$substr(X_1, underground) \wedge \neg(substr(X_1, delayed)) \wedge \\ \triangle((substr(X_2, buses)) \wedge \neg(substr(X_2, delayed)))$$

specifies the trails whose first page gives us the information about the underground lines that are running normally and whose last page gives us the information about the bus lines that are running normally.

DEFINITION 4.7 (subformulas). *The set of subformulas of a formula, f, is defined recursively as follows:*

1. *f is a subformula of f.*
2. *If f is of the form $f_1 \wedge f_2$, then f_1 and f_2 are subformulas of f.*
3. *If f is any of the forms $\Diamond(f')$, $\bigcirc(f')$, or $\triangle(f')$, then f' is a subformula of f.*

We denote the set of all subformulas of a trail formula, f, by $Sub(f)$. The length *of a formula, f, is the number of symbols in f assuming that all conditions have the same length of one and that no parentheses are omitted. We denote the length of f by $|f|$. It therefore follows that $|Sub(f)| \leq |f|$.*

The reason we have assumed that all conditions *have the same length of one* is that, from a database point of view, the purpose of conditions is to retrieve the set of pages satisfying the condition. Herein we are not interested in the internal structure of conditions, since by Proposition 4.5 we can test whether a page satisfies a condition in polynomial time.

DEFINITION 4.8 (satisfaction of a trail formula). *Let $H = \langle I, R \rangle$ be a Hypertext database, σ be an interpretation over H, and T be a trail in R . Then we say that T* satisfies *a formula, f, with respect to H and σ (or simply T satisfies f if H and σ are understood from context), written $T \models f$, provided f is true under T . Specifically,*

T1. *$T \models C$ iff $\#T > 0, \sigma \models C$, and $\sigma(Z) = T[1]$, where Z is the variable of C.*
T2. *$T \models f_1 \wedge f_2$ iff $T \models f_1$ and $T \models f_2$.*
T3. *$T \models \Diamond(f)$ iff $\exists i \in \{0, \ldots, \#T - 1\}$ such that $T^i \models f$.*
T4. *$T \models \bigcirc(f)$ iff $\#T > 1$ and $T^1 \models f$.*
T5. *$T \models \triangle(f)$ iff $\#T > 0$ and $T^i \models f$, where $i = \#T - 1$.*

From Definition 4.8 it follows that for all trail formulas, $f, [\,] \not\models f$.

DEFINITION 4.9 (a model of a trail formula). *A Hypertext database $H = \langle I, R \rangle$ is a* model *of a trail formula, f, if $\exists T$ in R such that $T \models f$ with respect to H and some interpretation σ. Whenever H is understood from context we also say that T is a model of f.*

DEFINITION 4.10 (trail equivalence). *A formula f_1* trail implies *(or simply implies) a formula f_2, written $f_1 \Rightarrow f_2$, if*

for all Hypertext databases $\langle I, R \rangle$, for all trails T in R, if $T \models f_1$ then $T \models f_2$.

A formula f_1 is trail equivalent *(or simply equivalent) to a formula f_2, written $f_1 \equiv f_2$, if $f_1 \Rightarrow f_2$ and $f_2 \Rightarrow f_1$.*

The following proposition gives the significant equivalences and implications between HQL formulas. We note that the implications given in the proposition cannot be strengthened to equivalences.

PROPOSITION 4.11. *The following equivalences and implications are satisfied:*

1. $\Diamond(f) \equiv \Diamond\Diamond(f)$.
2. $\triangle(f) \equiv \triangle\triangle(f)$.
3. $\Diamond \bigcirc (f) \equiv \bigcirc\Diamond(f)$.
4. $\triangle(f) \equiv \triangle\Diamond(f) \equiv \Diamond\triangle(f)$.
5. $\bigcirc(f_1 \wedge f_2) \equiv \bigcirc(f_1) \wedge \bigcirc(f_2)$.
6. $\triangle(f_1 \wedge f_2) \equiv \triangle(f_1) \wedge \triangle(f_2)$.
7. $\Diamond(f_1 \wedge f_2) \Rightarrow \Diamond(f_1) \wedge \Diamond(f_2)$.

8. $f \Rightarrow \Diamond(f)$.
9. $\bigcirc(f) \Rightarrow \Diamond(f)$.
10. $\triangle(f) \Rightarrow \Diamond(f)$.
11. $\bigcirc\triangle(f) \Rightarrow \triangle(f)$.

The following definition will be useful when we consider subclasses of HQL.

DEFINITION 4.12 (op-free trail formulas). *A trail formula is* op-free *if it does not contain any occurrences of* op, *where* op $\in \{\Diamond, \bigcirc, \triangle\}$.

The $\Diamond$ operator is declarative since it does not specify the precise navigation sequence, while the $\bigcirc$ operator is procedural since it progresses navigation one step at a time. Thus $\bigcirc$-free trail queries can be viewed as declarative queries and $\Diamond$-free trail queries can be viewed as procedural queries. On the other hand, $\triangle$-free trail queries are queries which do not specify any condition on the final item of a trail which satisfies the query.

The next proposition shows that the general class of trail formulas is more expressive than the class of $\triangle$-free trail formulas. That is, if we remove $\triangle$ from HQL we lose expressive power.

PROPOSITION 4.13. *It is not the case that for all $\triangle$-free trail formulas, g, there exists a $\triangle$-free trail formula, f, such that $f \Rightarrow \triangle(g)$.*

Proof. The result follows by a straightforward induction on the length of f.

(*Basis*): If $|f| = 1$, then f is a condition, say, C. Without loss of generality, let $H = \langle I, R\rangle$ be a Hypertext database having a trail T in R with $\#T = 2$ and such that $T \models C$ but $T^1 \not\models g$. The result that $T \not\models \triangle(g)$ follows by Definition 4.8 part (T5).

(*Induction*): Assume that the result holds when $|f| = k$, where $k \geq 1$; we then need to prove that the result holds when $|f| > k$.

We now consider in turn the different cases pertaining to the structure of f:

1. If f is the trail formula $f_1 \wedge f_2$, then by the inductive hypothesis there exists a Hypertext database $H = \langle I, R\rangle$ and a trail T in R such that $T \models f_1$ and $T \models f_2$ but $T \not\models \triangle(g)$. The result follows by Definition 4.8 part (T2), since $T \models f$.
2. If f is the trail formula $\Diamond(f')$, then by the inductive hypothesis there exists a Hypertext database $H = \langle I, R\rangle$ and a trail T in R such that $T^i \models f'$ but $T^i \not\models \triangle(g)$, where $i \in \{0, \ldots, \#T - 1\}$. The result that $T \models f$ but $T \not\models \triangle(g)$ follows by Definition 4.8 part (T3) and part (T5), respectively.
3. If f is the trail formula $\bigcirc(f')$, then by the inductive hypothesis there exists a Hypertext database $H = \langle I, R\rangle$ and a trail T in R such that $\#\, T > 1$ and $T^1 \models f'$ but $T^1 \not\models \triangle(g)$. The result that $T \models f$ but $T \not\models \triangle(g)$ follows by Definition 4.8 part (T4) and part (T5), respectively. $\square$

A *trail query* is a trail formula viewed as a mapping from Hypertext databases to sets of trails, where a trail is in the output of the trail query iff it satisfies the trail formula with respect to the input Hypertext database and some interpretation. The formal definition follows.

DEFINITION 4.14 (trail query). *A* trail query (*or simply an HQL query or a query*) *is a trail formula, f, viewed as a mapping from Hypertext databases to sets of trails such that, given an input Hypertext database $H = \langle I, R\rangle$, the output $f(H)$ is defined by*

$$\{T \mid T \textit{ is a trail in } R \textit{ and } T \models f\}.$$

A trail T in R satisfying $T \models f$ is called an answer *of $f(H)$.*

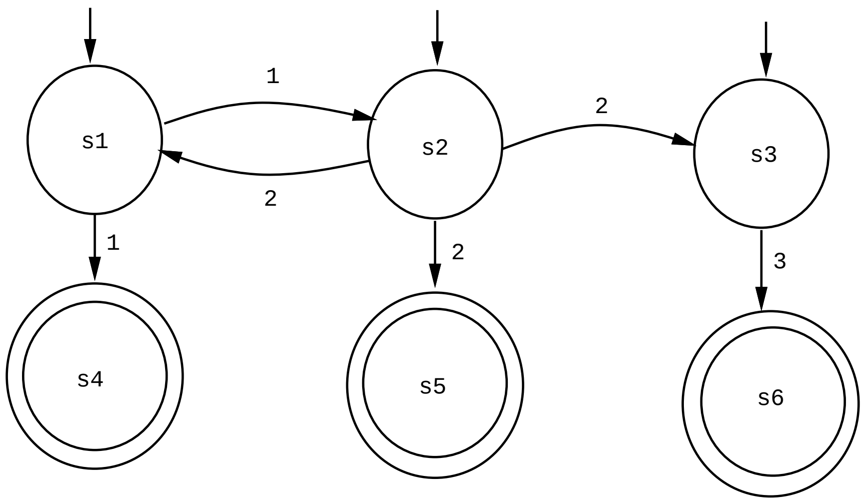

FIG. 5.1. *A finite automaton for a Hypertext database.*

5. Finite automata and trail queries. In this section we utilize the theory of finite automata [HOPC79, PERR90] in order to construct the output of a query, which in the general case may consist of a countably infinite set of trails. In particular, we exploit the strong connection between finite automata accepting star-free regular languages and PLTL [VARD86a, VARD86b, EMER90, THOM90].

DEFINITION 5.1 (Hypertext automaton). *The* Hypertext automaton *representing a Hypertext database, $H = \langle I, R\rangle$ (or simply the Hypertext automaton whenever H is understood from context), is a finite automaton defined by a quintuple of the form $\mathcal{M}_H = (\mathcal{A}, Q, \Delta, S, F)$ (or simply $\mathcal{M}$ whenever H is understood from context), where*

- $\mathcal{A} = \{1, \dots, m\}$ *is a finite alphabet with $m = \#I$.*
- $Q = \{s_1, \dots, s_m, s_{m+1}, \dots, s_{2m}\}$ *is a set of $2m$ states.*
- $\Delta \subseteq Q \times \mathcal{A} \times Q$ *is a transition relation, where $(s_j, \delta(s_j), s_k) \in \Delta$ iff $j \in \{1, \dots, m\}$ and either $k \in \{1, \dots, m\}$, with $(\delta(s_j), \delta(s_k)) \in R$, or $k = m + j$, where δ is a one-to-one and onto mapping from $\{s_1, \dots, s_m\}$ to $\mathcal{A}$ such that $\delta(s_i) = i$, $1 \le i \le m$.*
- $S = \{s_1, \dots, s_m\}$ *is the set of initial states.*
- $F = \{s_{m+1}, \dots, s_{2m}\}$ *is the set of terminal states.*

If $S = \emptyset$ and thus $F = \emptyset$, then $\mathcal{M}$ is called the empty Hypertext automaton.

We observe that the construction of $\mathcal{M}_H$ is independent of the actual contents of the pages in the repository I of H. It only depends on the cardinality, $\#I$ of I, and the reachability relation R of H. In other words, a finite automaton representing a Hypertext database is independent of the actual data stored in the repository and thus induces an equivalence class of Hypertext databases having repositories of the same cardinality and having the same reachability relation.

EXAMPLE 3. *The finite automaton $\mathcal{M}_H$ is shown in Figure 5.1, where $H = \langle I, R\rangle$, $\#I = 3$ and $R = \{(1, 2), (2, 1), (2, 3)\}$.*

DEFINITION 5.2 (the language accepted by a finite automaton). *A* path *in the finite automaton, $\mathcal{M} = (\mathcal{A}, Q, \Delta, S, F)$ (or simply a path if $\mathcal{M}$ is understood from context), is a nonempty sequence $\{(s_i, \delta(s_i), s_{i+1})\}$ $(i \in N)$ of transitions in Δ, with $N = \{1, \dots, n\}$ and $n \in \omega$. (We also say that there exists a path from*

$(s_1, \delta(s_1), s_2)$ *to* $(s_n, \delta(s_n), s_{n+1})$.) *If* $s_1 = s_{n+1}$, *then the path is a* cycle. *The string* $w = \delta(s_1)\delta(s_2)\ldots\delta(s_n)$ *is called the* label *of the path,* s_1 *is called its* origin, *and* s_{n+1} *is called its* end. *The* length *of the path is* n.

A path is successful *if its origin is in* S *and its end is in* F. *A string* $w \in \mathcal{A}^*$ *is said to be* accepted *by* $\mathcal{M}$ *if it is the label of some successful path. The language accepted by* $\mathcal{M}$, *denoted by* $\mathcal{L}(\mathcal{M})$, *is the set of all strings accepted by* $\mathcal{M}$.

When $\mathcal{M}$ is the empty Hypertext automaton, $\mathcal{L}(\mathcal{M}) = \emptyset$, that is, the empty language is accepted. Furthermore, there does not exist a Hypertext database H such that $\mathcal{L}(\mathcal{M}_H) = \{\epsilon\}$; i.e., no finite automaton representing a Hypertext database accepts the empty string. Thus only subsets of $\mathcal{A}^+ = \mathcal{A}^* - \{\epsilon\}$ are accepted by finite automata representing Hypertext databases.

We proceed to show that $\mathcal{L}(\mathcal{M}_H)$ is a *star-free* regular language [MCNA71, PERR90] (or simply a star-free language).

DEFINITION 5.3 (star-free languages). *A regular language is* star-free *if it can be generated from a finite set of strings by repeated applications of the Boolean operations, union, intersection and complementation* (*with respect to* $\mathcal{A}^*$), *together with concatenation.*

The following definition is needed in order to state an alternative characterization of star-free languages.

DEFINITION 5.4 (aperiodic regular languages). *A regular language* $\mathcal{L} \subseteq \mathcal{A}^*$ *is* aperiodic *if* $\exists n \in \omega (n > 0)$ *such that* $\forall x, y, z \in \mathcal{A}^*$,

$$xy^n z \in \mathcal{L} \textit{ iff } xy^{n+1} z \in \mathcal{L}, \tag{5.1}$$

where y^n *is the concatenation of* y *with itself* n *times.*

The following theorem states the equivalence of star-free and aperiodic regular languages [PERR90, Theorem 6.1].

THEOREM 5.5. *A regular language is* star-free *iff it is aperiodic.*

THEOREM 5.6. $\mathcal{L}(\mathcal{M}_H)$ *is a star-free language.*

Proof. Let $\mathcal{L} = \mathcal{L}(\mathcal{M}_H)$. In order to prove the result we use Theorem 5.5 to show that (5.1) is satisfied, with $n = 2$. If $y = \epsilon$, then the result holds trivially, so we assume that this is not the case. Next assume that $xy^2z \in \mathcal{L}$ and let $y = a_1 \ldots a_k = \delta(s_1)\ldots\delta(s_k)$ be the label of the path $\{(s_i, \delta(s_i), s_{i+1})\}(i \in \{1, \ldots, k\})$ in $\mathcal{M}_H$.

It follows that $s_i (i \in \{1, \ldots, k\})$ is one of the initial $\#I$ states in Q, i.e., $1 \leq i \leq \#I$, since by Definition 5.1 terminal states in $\mathcal{M}_H$ cannot be the first component of any transition. Furthermore, $s_{k+1} = s_1$, since $a_1 \ldots a_k a_1$ is a substring of y^2 and by Definition 5.1 δ is a one-to-one and onto mapping from the initial $\#I$ states in Q to $\mathcal{A}$.

Thus, the substring $a_1 \ldots a_k$ corresponds to a *cycle* [BUCK90] in the directed graph corresponding to R (where we allow a node to appear more than once in a cycle). The result follows, since it is implied that $xy^2z \in \mathcal{L}$ iff $xy^nz \in \mathcal{L}$, with $n \geq 2$. □

It is easy to demonstrate that the converse of Theorem 5.6 does not hold. For example, let $\mathcal{A} = \{a\}$ and $\mathcal{L} = \{aa\}$. $\mathcal{L}$ is obviously star-free, since it is a finite regular language, but there does not exist a Hypertext database H such that $\mathcal{L} = \mathcal{L}(\mathcal{M}_H)$. Thus, the class of languages accepted by finite automata representing Hypertext databases is a proper subclass of the class of star-free languages.

DEFINITION 5.7 (the language induced by a trail query). *The language induced by a set* $\mathbf{T}$ (*possibly countably infinite*) *of trails in* R, *denoted by* $\mathcal{L}(\mathbf{T})$, *is defined by*

$\mathcal{L}(\mathbf{T}) = \{\rho(T) | T \in \mathbf{T}\}$. *The language induced by the output* $f(H)$ *of a trail query* f *is defined to be* $\mathcal{L}(f(H))$.

It follows that, if a string $w = \delta(s_1)\delta(s_2)\ldots\delta(s_n)$ is accepted by $\mathcal{M}$, then there exists a trail, T, in R such that $\rho(T) = w$.

The following lemma states that the language induced by the output of a trail query over a Hypertext database H is a subset of the language accepted by the finite automaton representing H.

LEMMA 5.8. $\mathcal{L}(f(H)) \subseteq \mathcal{L}(\mathcal{M}_H)$, *where* f *is a trail query and* H *is a Hypertext database.*

Proof. The result follows immediately from Definitions 5.1 and 5.7 on using Definition 4.14. $\square$

The following proposition shows that the finite automaton representing a Hypertext database can be viewed as the output of a certain trail query.

PROPOSITION 5.9. *For all Hypertext databases,* $H = \langle I, R\rangle$, *there exists a trail query* f *such that* $\mathcal{L}(f(H)) = \mathcal{L}(\mathcal{M}_H)$.

Proof. Let $S = \{s_1, \ldots, s_m\}$ be the set of initial states of $\mathcal{M}_H$, and let $F = \{s_{m+1}, \ldots, s_{2m}\}$ be the set of terminal states of $\mathcal{M}_H$. Furthermore, let pages(S) = pages$(F) = \{I[i] | s_i \in S\}$ be the set of pages in I corresponding to S and F, respectively. Hereafter we assume that pages(S) = pages$(F) = \{(A_1, w_1), \ldots, (A_m, w_m)\}$.

Let f^S be the trail formula

$$(att(X_1, A_1) \wedge substr(X_1, w_1)) \vee \ldots \vee (att(X_1, A_m) \wedge substr(X_1, w_m))$$

and let f^F be the trail formula

$$\triangle((att(X_2, A_1) \wedge substr(X_2, w_1)) \vee \ldots \vee (att(X_2, A_m) \wedge substr(X_2, w_m))),$$

where X_1 and X_2 are distinct normal variables.

Finally, let T be a trail in R and let f be the trail formula $f^S \wedge f^F$. By Definition 4.8 it follows that $T \models f$ iff $T \models f^S$ and $T \models f^F$. Furthermore, $T \models f^S$ iff $T[1] \in$ pages(S) and $T \models f^F$ iff $T[\#T] \in$ pages(F). Thus T is an answer of $f(H)$ iff $T[1] \in$ pages(S) and $T[\#T] \in$ pages(F). Therefore, we have that $\mathcal{L}(f(H)) = \mathcal{L}(\mathcal{M}_H)$ holds as required. $\square$

We proceed to investigate the correspondence between finite automata and trail queries.

Recall that star-free regular languages are closed under union, intersection, and concatenation [HOPC79, PERR90]. We will assume that when taking the union, intersection, or concatenation of two finite automata *their sets of states are disjoint.* Furthermore, for convenience we will also assume that the concatenation of any finite automaton with the empty Hypertext automaton yields the empty Hypertext automaton.

We next define a useful finite automaton with respect to a repository, I, which accepts the star-free regular language $\mathcal{A}^+$; we call this finite automaton the *complete automaton.*

DEFINITION 5.10 (the complete automaton of a repository). *The complete automaton with respect to a repository,* I, *is a quintuple of the form* $\mathcal{M}_{(\gamma,I)} = (\mathcal{A}, Q_\gamma, \Delta_\gamma, S_\gamma, F_\gamma)$ (*or simply* $\mathcal{M}_\gamma$ *whenever* I *is understood from context*), *where*

- $\mathcal{A} = \{1, \ldots, m\}$ *is a finite alphabet with* $m = \#I$.
- $Q_\gamma = \{s\}$ *is the singleton set of states.*
- $\Delta_\gamma = Q_\gamma \times \mathcal{A} \times Q_\gamma$ *is the transition relation.*
- $S_\gamma = \{s\}$ *is the initial state.*

- $F_\gamma = \{s\}$ *is the terminal state.*

The finite automaton representing a trail query f, with respect to a repository I (or simply the finite automaton representing f if I is understood from context), is a quintuple of the form $\mathcal{M}_{(f,I)} = (\mathcal{A}, Q_f, \Delta_f, S_f, F_f)$ (or simply $\mathcal{M}_f$ whenever I is understood from context), whereas before $\mathcal{A} = \{1, \ldots, m\}$ with $m = \#I$.

Prior to constructing $\mathcal{M}_f$ we present an algorithm, which recursively constructs an intermediate finite automaton, $\mathcal{M}_{f'}$, in accordance with the subformulas of f.

We will assume that with each transition, (s_i, p, s_j), in the transition relation of a finite automaton, say, $\mathcal{M}$, we maintain an auxiliary set, denoted by cond($\mathcal{M}$, (s_i, p, s_j)) (or simply cond(s_i, p, s_j) if $\mathcal{M}$ is understood from context), which is initialized to the empty set. The set cond(s_i, p, s_j) will store the conditions associated with the said transition.

Definition 5.11 (the intermediate finite automaton representing a trail query). *As an intermediate step we present an algorithm, which recursively constructs a finite automaton $\mathcal{M}_{f'} = (\mathcal{A}, Q_{f'}, \Delta_{f'}, S_{f'}, F_{f'})$ with f and I given as its inputs; the algorithm is designated by τ^I when I is its input repository (or simply τ when I is understood from context). For the purpose of the algorithm we will assume that τ has an additional implicit Boolean parameter, designated by $\triangle$flag, which is initialized to* false.

The algorithm considers all of the subformulas $g \in Sub(f)$ in decreasing order of $|g|$ in accordance with the structure of g (recall that we have assumed that all conditions have the same length of one):

1. *If g is just the condition C, with variable Z, then let $\{i_1, \ldots, i_k\}$ be the largest subset of $\{1, \ldots, \#I\}$ such that there exists an interpretation σ satisfying $\sigma(Z) = i_j$, $1 \leq j \leq k$, and $\sigma \models C$.*
   If $k \geq 1$, then $\mathcal{M}_C = (\mathcal{A}, Q_C, \Delta_C, S_C, F_C)$, where
   - $Q_C = \{s_{C_1}, s_{C_2}\}$.
   - $\Delta_C = \{(s_{C_1}, i_1, s_{C_2}), \ldots, (s_{C_1}, i_k, s_{C_2})\}$ *and* $\forall j \in \{1, \ldots, k\}$, *set* cond$(s_{C_1}, i_j, s_{C_2})$ *to* C.
   - $S_C = \{s_{C_1}\}$ *is the initial state.*
   - $F_C = \{s_{C_2}\}$ *is the terminal state.*

   If $\triangle$flag is true, *then $\tau(g)$ returns $\mathcal{M}_C$; otherwise (when $\triangle$flag is* false) *$\tau(g)$ returns the concatenation of $\mathcal{M}_C$ and $\mathcal{M}_\gamma$. Finally, if the aforesaid subset is empty, i.e., $k = 0$, then $\tau(g)$ returns the empty Hypertext automaton.*
2. *If g is the formula $g_1 \wedge g_2$, such that $\tau(g_1)$ returns $\mathcal{M}_{g_1}$ and $\tau(g_2)$ returns $\mathcal{M}_{g_2}$, then $\tau(g)$ returns the intersection of $\mathcal{M}_{g_1}$ and $\mathcal{M}_{g_2}$. In addition, if* cond$((s_{i_1}, s_{i_2}), p, (s_{j_1}, s_{j_2}))$ *is in the transition relation of the intersection of $\mathcal{M}_{g_1}$ and $\mathcal{M}_{g_2}$, then* cond$((s_{i_1}, s_{i_2}), p, (s_{j_1}, s_{j_2}))$ *is set to* cond$(\mathcal{M}_{g_1}, (s_{i_1}, p, s_{j_1}))$ $\cup$ cond$(\mathcal{M}_{g_2}, (s_{i_2}, p, s_{j_2}))$.
3. *If g is the formula $\diamond(g')$ and $\tau(g')$ returns $\mathcal{M}_{g'}$, then $\tau(g)$ returns $\mathcal{M}_{g'}$ if $\triangle$flag is* true*; otherwise (when $\triangle$flag is* false) *$\tau(g)$ returns the concatenation of $\mathcal{M}_\gamma$ and $\mathcal{M}_{g'}$.*
4. *If g is the formula $\bigcirc(g')$ and $\tau(g')$ returns $\mathcal{M}_{g'}$, then $\tau(g)$ returns the empty Hypertext automaton if $\triangle$flag is* true, *otherwise (when $\triangle$flag is* false) *$\tau(g)$ returns the concatenation of $\mathcal{M}_\bigcirc$ and $\mathcal{M}_{g'}$, where $\mathcal{M}_\bigcirc = (\mathcal{A}, Q_\bigcirc, \Delta_\bigcirc, S_\bigcirc, F_\bigcirc)$ is defined as follows:*
   - $Q_\bigcirc = \{s_{\bigcirc_1}, s_{\bigcirc_2}\}$.
   - $\Delta_\bigcirc = \{(s_{\bigcirc_1}, 1, s_{\bigcirc_2}), \ldots, (s_{\bigcirc_1}, m, s_{\bigcirc_2})\}$, *where* $m = \#I$.
   - $S_\bigcirc = \{s_{\bigcirc_1}\}$ *is the initial state.*

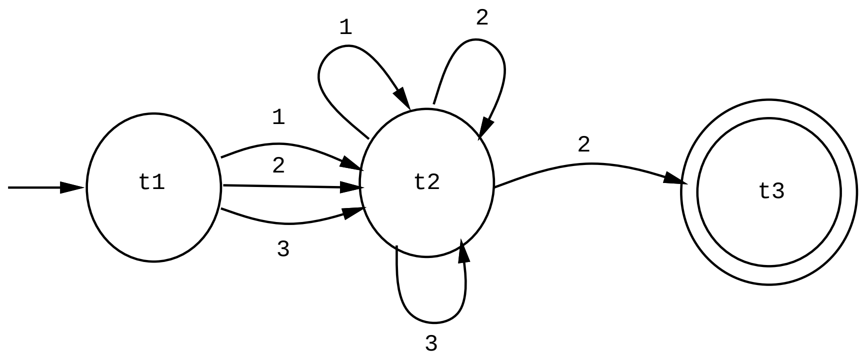

FIG. 5.2. *A finite automaton for a trail query.*

- $F_{\bigcirc} = \{s_{\bigcirc_2}\}$ *is the terminal state.*

5. *If g is the formula $\triangle(g')$, $\triangle$flag is set to* true*, and if $\tau(g')$ returns $\mathcal{M}_{g'}$, then $\tau(g)$ returns $\mathcal{M}_{g'}$ provided $\triangle$flag was* true *prior to invoking $\tau(g')$; otherwise (when $\triangle$flag was* false *prior to invoking $\tau(g')$) $\tau(g)$ returns the concatenation of $\mathcal{M}_\gamma$ and $\mathcal{M}_{g'}$.*

EXAMPLE 4. *Let f be the trail query $\bigcirc\triangle(C)$, with C being a condition such that the only interpretation σ over H, with $\sigma \models C$, satisfies $\sigma(Z) = 2$, where Z is the variable of C and 2 is a page number of I. In addition, let I be the information repository of the Hypertext database H of Example* 3*. The finite automaton for $\mathcal{M}_{f'}$ is shown in Figure* 5.2*.*

It can be verified that the regular language accepted by the finite automaton shown in Figure 5.2 *would remain the same were f to be the trail formula $\bigcirc\diamond\triangle(C)$. This can also be deduced from Proposition* 4.11 *part* (4)*.*

We next prove that the language accepted by $\tau(f)$ is a star-free regular language.

LEMMA 5.12. *$\mathcal{L}(\tau(f))$ is a star-free regular language.*

Proof. The result follows by a straightforward induction on the length of f, observing that $\mathcal{L}(\mathcal{M}_\gamma) = \mathcal{A}^+$ is star-free and by the fact that, due to the construction of $\mathcal{M}_g$ via τ, $\mathcal{L}(\mathcal{M}_g)$ is also star-free for all subformulas g of f. (Recall that a finite regular language is star-free and that a finite automaton having no cycles accepts a finite regular language.) □

The following lemma gives an upper bound on the cardinality of the set of states of the finite automaton $\tau(f)$ constructed by the algorithm given in Definition 5.11. Note that this upper bound is independent of the repository, I, and is exponential only in the number of conjunctions, between subformulas of f, plus one.

LEMMA 5.13. *$|Q_{f'}| \leq O(|f|)^{\wedge(f)}$, where f is a trail formula, $\tau(f) = \mathcal{M}_{f'} = (\mathcal{A}, Q_{f'}, \Delta_{f'}, S_{f'}, F_{f'})$ and $\wedge(f)$ is the number of conjunctions, between subformulas of f, plus one.*

Proof. We prove the result by induction on $\wedge(f)$. We observe that given two finite automata, whose state sets are Q_1 and Q_2, when we concatenate, or correspondingly, intersect the two finite automata, then the cardinality of the state set of the resulting finite automaton is $|Q_1| + |Q_2|$, or correspondingly, $|Q_1| \cdot |Q_2|$ [HOPC79, PERR90].

Recall that we have assumed that all conditions in f have the same length of one.

(*Basis*): If $\wedge(f) = 1$, then f has no conjunctions. The result that $|Q_{f'}| \leq O(|f|)$ follows by a straightforward induction on the length of f by inspecting Definition 5.11

in accordance with the structure of f.

(*Induction*): Assume that the result holds when $\wedge(f) = k$, where $k \geq 1$; we then need to prove that the result holds when $\wedge(f) = k + 1$.

It follows that f must be of the form $op_1(\dots op_q(g)\dots)$, where $op = op_1 \dots op_q$ is a sequence of trail operators, with $q \geq 0$, and g is a subformula of f of the form $g_1 \wedge g_2$, satisfying $\wedge(g_1) \leq k$ and $\wedge(g_2) \leq k$.

By part (2) of the description of τ in Definition 5.11 $|Q_g| \leq |Q_{g_1}| \cdot |Q_{g_2}|$, where Q_{g_1} and Q_{g_1} are the state sets of the finite automata $\mathcal{M}_{g_1}$ and $\mathcal{M}_{g_2}$, respectively. Furthermore, by the inductive hypothesis $|Q_{g_1}| \leq O(|g_1|)^{\wedge(g_1)}$ and $|Q_{g_2}| \leq O(|g_2|)^{\wedge(g_2)}$. It therefore follows that $|Q_g| \leq O(|f|)^{\wedge(f)}$, since $|g_1| + |g_2| < |f|$ and $\wedge(g_1) + \wedge(g_2) = \wedge(f)$.

The result now follows by a straightforward induction on the number, q, of trail operators in op by inspecting Definition 5.11 according to the three different cases where the first operator, op_1, is $\Diamond, \bigcirc$, or $\triangle$. $\square$

In order to conclude the construction of $\mathcal{M}_f$ we need to take into account the semantics of normal and unique variables. To accomplish this we use the auxiliary sets $\text{cond}(s_i, p, s_j)$ and modify the output of $\tau(f)$ so that it satisfies the constraints enumerated below.

First, we define some convenient terminology. A *time unit* of a trail formula f (or simply a time unit whenever f is understood from context) is defined to be a transition, (s_i, p, s_j), in the transition relation of the finite automaton $\tau(f)$, where p is a page number of I and s_i, s_j are states. The variable of a condition, $C \in \text{cond}(s_i, p, s_j)$, is said to be *appearing* at the time unit (s_i, p, s_j).

The following two constraints must be enforced on variables appearing at time units:

1. No two unique variables, which are distinct, can appear at two (not necessarily distinct) time units having the same page number (recall Definition 4.1 and the comment that follows).
2. If the same variable appears at two distinct time units, then its corresponding interpretations must be the same.

In order to formalize the above constraints, let $\varphi(\text{cond}(s_i, p, s_j))$ denote the set of variables of the conditions contained in $\text{cond}(s_i, p, s_j)$, where (s_i, p, s_j) is a time unit of a trail formula f. Thus the following conditions, corresponding to the above two constraints, must be enforced in the finite automaton $\tau(f)$.

V1. For all (not necessarily distinct) time units (s_{i_1}, p, s_{j_1}) and (s_{i_2}, p, s_{j_2}), if there exists a path from (s_{i_1}, p, s_{j_1}) to (s_{i_2}, p, s_{j_2}), then there do not exist two unique variables, which are distinct, included in $\varphi(\text{cond}(s_{i_1}, p, s_{j_1})) \cup \varphi(\text{cond}(s_{i_2}, p, s_{j_2}))$.

V2. For all distinct time units, (s_{i_1}, p_1, s_{j_1}) and (s_{i_2}, p_2, s_{j_2}), if there exists a path from (s_{i_1}, p_1, s_{j_1}) to (s_{i_2}, p_2, s_{j_2}) and $\varphi(\text{cond}(s_{i_1}, p_1, s_{j_1})) \cap \varphi(\text{cond}(s_{i_2}, p_2, s_{j_2})) \neq \emptyset$, then $p_1 = p_2$.

We now present a further algorithm, designated by π, that takes as its input the finite automaton $\tau(f)$ and transforms it into the desired finite automaton $\mathcal{M}_f$.

ALGORITHM 1 ($\pi(f)$).

```
1. begin
2.   $\mathcal{M}_f = (\mathcal{A}, Q_f, \Delta_f, S_f, F_f) := \tau(f)$;
3.   while $\exists (s_{i_1}, p_1, s_{j_1}), (s_{i_2}, p_2, s_{j_2}) \in \Delta_f$ that violate either (V1) or (V2) do
4.     $\Delta_1 := \Delta_f - \{(s_{i_1}, p_1, s_{j_1})\}$;
```

```
5.        $\mathcal{M}_1 := (\mathcal{A}, Q_f, \Delta_1, S_f, F_f)$;
6.        $\Delta_2 := \Delta_f - \{(s_{i_2}, p_2, s_{j_2})\}$;
7.        $\mathcal{M}_2 := (\mathcal{A}, Q_f, \Delta_2, S_f, F_f)$;
8.        $\mathcal{M}_f :=$ the union of $\mathcal{M}_1$ and $\mathcal{M}_2$;
9.    end while
10.   return $\mathcal{M}_f$;
11. end.
```

EXAMPLE 5. *It can be verified that for the trail query f of Example* 4 $\mathcal{M}_{f'} = \mathcal{M}_f$, *since both the constraints* (V1) *and* (V2) *are satisfied.*

In order to prove that the regular language, accepted by the finite automaton, $\mathcal{M}_f = \pi(f)$, output from Algorithm 1, is a star-free regular language we first prove the following lemma.

LEMMA 5.14. *If $\mathcal{L}(\mathcal{M})$ is a star-free regular language, then $\mathcal{L}(\mathcal{M}')$ is also a star-free regular language, where $\mathcal{M} = (\mathcal{A}, Q, \Delta, S, F)$ and $\mathcal{M}' = (\mathcal{A}, Q, \Delta - \{(s_i, p, s_j)\}, S, F)$ are finite automata.*

Proof. Let $\mathcal{L} = \mathcal{L}(\mathcal{M})$ and $\mathcal{L}' = \mathcal{L}(\mathcal{M}')$. Also, assume that $(s_i, p, s_j) \in \Delta$; otherwise the result follows trivially. We note that by the construction of $\mathcal{M}'$ we have $\mathcal{L}' \subseteq \mathcal{L}$.

We say that an occurrence of an alphabet symbol p in a substring y of $w \in \mathcal{A}^*$ is *necessary* with respect to (s_i, p, s_j) (or simply $p \in y$ is necessary if w and (s_i, p, s_j) are understood from context) whenever the following statement is satisfied: If w is accepted by $\mathcal{M}$ and p is the ith symbol in w, then (s_i, p, s_j) is the ith transition of *all* successful paths whose label is w.

Since $\mathcal{L}$ is a star-free regular language, then from Theorem 5.5 $\exists n \in \omega(n > 0)$ such that $\forall x, y, z \in \mathcal{A}^*$, (5.1) is satisfied; let us fix n to be such a natural number.

In order to conclude the proof we show that $\exists m(m \geq n)$ such that $\forall x, y, z \in \mathcal{A}^*$,

$$xy^m z \in \mathcal{L}' \text{ iff } xy^{m+1} z \in \mathcal{L}'.$$

Let us fix $m = n + 1$ and $x, y, z \in \mathcal{A}^*$ to be arbitrary strings.

By Theorem 5.5 $xy^m z \in \mathcal{L}$ iff $xy^{m+1} z \in \mathcal{L}$. Furthermore, if $xy^m z \in \mathcal{L}$, then it is also the case that $xy^{m-1} z \in \mathcal{L}$, since $n = m - 1$, and thus the mth occurrence of y in y^m must be the label of a cycle that causes the string $xy^m z$ to be in $\mathcal{L}$.

We have that the following two statements are equivalent:

1. $xy^m z \in \mathcal{L}'$ iff $xy^{m+1} z \in \mathcal{L}'$.
2. The number of necessary occurrences of p in the mth occurrence of the substring y of $xy^m z \in \mathcal{L}$ is zero iff the number of necessary occurrences of p in the $(m+1)$th occurrence of the substring y of $xy^{m+1} z \in \mathcal{L}$ is also zero.

It remains to show that statement (2) above is true.

The *if part* of statement (2) implies that there exists a cycle, say, θ, whose label is y, that causes $xy^{m+1} z$ to be in $\mathcal{L}$ and does not include (s_i, p, s_j). Therefore, θ also causes $xy^m z$ to be in $\mathcal{L}$, since $n = m - 1$, implying that there exists a cycle, whose label is y, that causes $xy^m z$ to be in $\mathcal{L}$. It follows that the number of necessary occurrences of p in the mth occurrence of the substring y of $xy^m z \in \mathcal{L}$ is zero, as required.

Similarly, the *only if part* of statement (2) implies that there exists a cycle, whose label is y, that causes $xy^m z$ to be in $\mathcal{L}$ and does not include (s_i, p, s_j). Therefore, the number of necessary occurrences of p in the $(m+1)$th occurrence of the substring y of $xy^{m+1} z \in \mathcal{L}$ is also zero, as required. $\square$

We proceed to show that $\mathcal{L}(\mathcal{M}_f)$ is a star-free regular language. In particular, the class of languages accepted by finite automata representing trail queries is a proper subclass of the class of star-free regular languages. (Recall that trail formulas do not include the until temporal operator and that negation and disjunction are included only in conditions; see [EMER90, Theorem 6.4].)

THEOREM 5.15. *$\mathcal{L}(\mathcal{M}_f)$ is a star-free regular language.*

Proof. By Lemma 5.12 the regular language $\mathcal{L}(\mathcal{M}_{f'})$, where $\mathcal{M}_{f'} = \tau(f)$, is star-free. In addition, by Lemma 5.14 the regular languages accepted by the finite automata, $\mathcal{M}_1$ and $\mathcal{M}_2$, of Algorithm 1 are both star-free. Furthermore, the regular language accepted by $\mathcal{M}_f$, the finite automaton assigned a value at line 8 of the said algorithm, is also star-free, since star-free regular languages are closed under union. Thus, the transformation carried out via the while loop of Algorithm 1, beginning at line 3 and ending at line 9, preserves star-freeness of the regular language accepted by $\mathcal{M}_f$. The result now follows. □

The next theorem follows by a straightforward inspection of Algorithm 1 noting that given the auxiliary set, cond(s_i, p, s_j), $\sum_q |C_q| \leq |f|$, where $C_q \in$ cond(s_i, p, s_j). (See Algorithm 2 in section 6, whose polynomial-time complexity is $O(|Q_f| \cdot |\Delta_f|)$, which can be used to decide whether there exists a path from (s_{i_1}, p_1, s_{j_1}) to (s_{i_2}, p_2, s_{j_2}), where $\pi(f) = \mathcal{M}_f = (\mathcal{A}, Q_f, \Delta_f, S_f, F_f)$.)

THEOREM 5.16. *The finite automaton, $\mathcal{M}_f = \pi(f)$, returned by Algorithm 1, can be constructed in polynomial time in $\#I, |f|$, and $|Q_{f'}|$, where $\tau(f) = (\mathcal{A}, Q_{f'}, \Delta_{f'}, S_{f'}, F_{f'})$.*

The following theorem shows that the language induced by the output of a trail query f is equal to the regular language accepted by the intersection of the finite automaton representing f and the finite automaton representing the Hypertext database H, which constitutes the input to f.

THEOREM 5.17. *$\mathcal{L}(f(H)) = \mathcal{L}(\mathcal{M}_H \cap \mathcal{M}_f)$, where H is a Hypertext database and f is a trail query.*

Proof. ($\mathcal{L}(f(H)) \subseteq \mathcal{L}(\mathcal{M}_H \cap \mathcal{M}_f)$): By Lemma 5.8 $\mathcal{L}(f(H)) \subseteq \mathcal{L}(\mathcal{M}_H)$. Thus, we need to show that it is also the case that $\mathcal{L}(f(H)) \subseteq \mathcal{L}(\mathcal{M}_f)$.

Let $\rho(T) \in \mathcal{L}(f(H))$ implying by Definition 4.14 that $T \models f$. We note that the constraint corresponding to (V1), i.e., that no two unique variables, which are distinct, can be mapped by an interpretation to the same $T[i]$, and the constraint corresponding to (V2), i.e., that an interpretation maps the same variable to the same $i \in \{1, \ldots, \#I\}$ are both satisfied by Definition 4.3 of an interpretation σ.

We show that $\rho(T) \in \mathcal{L}(\mathcal{M}_f)$ by induction on the length of f. Recall that we have assumed that all conditions in f have the same length of one.

(*Basis*): If $|f| = 1$, then f is a condition, say, C. The result follows by Definition 4.8 part (T1) and the description of τ in Definition 5.11 part (1), since there is a transition in $\mathcal{M}_f$ for each page number i_j with $\sigma(Z) = i_j$.

(*Induction*): Assume that the result holds when $|f| = k$, where $k \geq 1$; we then need to prove that the result holds when $|f| > k$.

We consider the four cases according to the structure of f as follows:

1. If f is the query $g_1 \wedge g_2$, then by Definition 4.8 part (T2) $T \models f$ iff $T \models g_1$ and $T \models g_2$. Furthermore, by the inductive hypothesis, $\rho(T) \in \mathcal{L}(\mathcal{M}_{g_1})$ and $\rho(T) \in \mathcal{L}(\mathcal{M}_{g_2})$. Therefore, by the description of τ in Definition 5.11 part (2), $\rho(T) \in \mathcal{L}(\mathcal{M}_{f'})$, where $\mathcal{M}_{f'}$ is the intersection of the intermediate automata $\mathcal{M}_{g'_1}$ and $\mathcal{M}_{g'_2}$. The result follows from Algorithm 1, which implies that $\mathcal{M}_f$ is equal to the intersection of $\mathcal{M}_{g_1}$ and $\mathcal{M}_{g_2}$.

2. If f is the query $\Diamond(g)$, then by Definition 4.8 part (T3) $T \models f$ iff $\exists i \in \{0, \ldots, \#T - 1\}$ such that $T^i \models g$. Furthermore, by the inductive hypothesis, $\rho(T^i) \in \mathcal{L}(\mathcal{M}_g)$. Therefore, by the description of τ in Definition 5.11 part (3), $\rho(T) \in \mathcal{L}(\mathcal{M}_{f'})$, where $\mathcal{M}_{f'}$ is the concatenation of $\mathcal{M}_\gamma$ and the intermediate automaton $\mathcal{M}_{g'}$. The result follows from Algorithm 1, which implies that $\mathcal{M}_f$ is equal to the concatenation of $\mathcal{M}_\gamma$ and $\mathcal{M}_g$.
3. If f is the query $\bigcirc(g)$, then by Definition 4.8 part (T4) $T \models f$ iff $\# T > 1$ and $T^1 \models g$. Furthermore, by the inductive hypothesis, $\rho(T^1) \in \mathcal{L}(\mathcal{M}_g)$. Therefore, by the description of τ in Definition 5.11 part (4), $\rho(T) \in \mathcal{L}(\mathcal{M}_{f'})$, where $\mathcal{M}_{f'}$ is the concatenation of $\mathcal{M}_\bigcirc$ and the intermediate automaton $\mathcal{M}_{g'}$. The result follows from Algorithm 1, which implies that $\mathcal{M}_f$ is equal to the concatenation of $\mathcal{M}_\bigcirc$ and $\mathcal{M}_g$.
4. If f is the query $\triangle(g)$, then by Definition 4.8 part (T5) $T \models f$ iff $\# T > 0$ and $T^i \models g$, where $i = \#T - 1$. Furthermore, by the inductive hypothesis, $\rho(T^i) \in \mathcal{L}(\mathcal{M}_g)$. Therefore, by the description of τ in Definition 5.11 part (5), $\rho(T) \in \mathcal{L}(\mathcal{M}_{f'})$, where $\mathcal{M}_{f'}$ is the concatenation of $\mathcal{M}_\gamma$ and the intermediate automaton $\mathcal{M}_{g'}$. Moreover, when contructing $\mathcal{M}_{g'}$ $\triangle$flag will have been set to *true* implying that $\rho(T^i) \in \mathcal{L}(\mathcal{M}_{g'})$, where $i = \#T - 1$. The result follows from Algorithm 1, which implies that $\mathcal{M}_f$ is equal to the concatenation of $\mathcal{M}_\gamma$ and $\mathcal{M}_g$.

($\mathcal{L}(\mathcal{M}_H \cap \mathcal{M}_f) \subseteq \mathcal{L}(f(H))$): Let $w \in \mathcal{L}(\mathcal{M}_H \cap \mathcal{M}_f)$, where $w = \delta(s_1)\delta(s_2)\ldots\delta(s_n)$ (see Definition 5.2). Thus $w = \rho(T)$ for some trail T in R, with $\#T = n$, since $w \in \mathcal{L}(\mathcal{M}_H)$. Furthermore, there exists an interpretation σ over H such that $\forall i \in \{1, \ldots, n\}$ $\forall Z \in \varphi(\text{cond}(s_i, \delta(s_i), s_{i+1})), \sigma(Z) = \delta(s_i)$, since by Algorithm 1 both conditions, (V1) and (V2), are satisfied by the path whose label is w.

We now show that $T \models f$ with respect to H and σ, implying that $w \in \mathcal{L}(f(H))$ as required, by induction on the length of f. As before, recall that we have assumed that all conditions have the same length of one.

(*Basis*): If $|f| = 1$, then f is a condition, say, C. The result follows as in the previous basis step.

(*Induction*): Assume that the result holds when $|f| = k$, where $k \geq 1$; we then need to prove that the result holds when $|f| > k$.

We consider the four cases according to the structure of f as follows:

1. If f is the query $g_1 \wedge g_2$, then by the description of τ in Definition 5.11 part (2) $\rho(T) \in \mathcal{L}(\mathcal{M}_{g_1'})$ and $\rho(T) \in \mathcal{L}(\mathcal{M}_{g_2'})$. Moreover, by Algorithm 1, $\rho(T) \in \mathcal{L}(\mathcal{M}_{g_1})$ and $\rho(T) \in \mathcal{L}(\mathcal{M}_{g_2})$. Furthermore, by the inductive hypothesis, $T \models g_1$ and $T \models g_2$. The result then follows by Definition 4.8 part (T2).
2. If f is the query $\Diamond(g)$, then by the description of τ in Definition 5.11 part (3) $\rho(T) \in \mathcal{L}(\mathcal{M}_{f'})$, where $\mathcal{M}_{f'}$ is the concatenation of $\mathcal{M}_\gamma$ and $\mathcal{M}_{g'}$. Moreover, by Algorithm 1, $\exists i \in \{0, \ldots, \#T - 1\}$ such that $\rho(T^i) \in \mathcal{L}(\mathcal{M}_g)$. Furthermore, by the inductive hypothesis, $T^i \models f$. The result then follows by Definition 4.8 part (T3).
3. If f is the query $\bigcirc(g)$, then by the description of τ in Definition 5.11 part (4) $\rho(T) \in \mathcal{L}(\mathcal{M}_{f'})$, where $\mathcal{M}_{f'}$ is the concatenation of $\mathcal{M}_\bigcirc$ and $\mathcal{M}_{g'}$. Moreover, by Algorithm 1, $\#T > 1$ and $\rho(T^1) \in \mathcal{L}(\mathcal{M}_g)$. Furthermore, by the inductive hypothesis, $T^1 \models f$. The result then follows by Definition 4.8 part (T4).
4. If f is the query $\triangle(g)$, then by the description of τ in Definition 5.11 part (5) $\rho(T) \in \mathcal{L}(\mathcal{M}_{f'})$, where $\mathcal{M}_{f'}$ is the concatenation of $\mathcal{M}_\gamma$ and $\mathcal{M}_{g'}$. Moreover, when contructing $\mathcal{M}_{g'}$ $\triangle$flag will have been set to *true* implying that $\rho(T^i) \in$

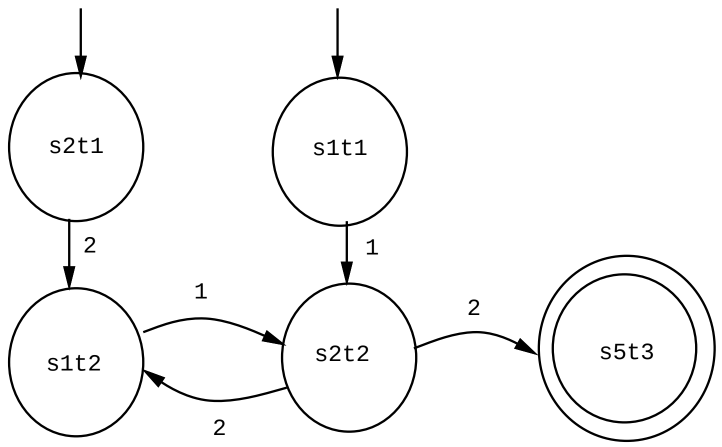

FIG. 5.3. *A finite automaton for the output of a trail query.*

$\mathcal{L}(\mathcal{M}_{g'})$, where $i = \#T - 1$. By Algorithm 1 $\# \ T > 0$ and $\rho(T^i) \in \mathcal{L}(\mathcal{M}_g)$, where $i = \#T - 1$. Furthermore, by the inductive hypothesis, $T^i \models f$. The result then follows by Definition 4.8 part (T5). □

EXAMPLE 6. *The finite automaton $\mathcal{M}_H \cap \mathcal{M}_f$, where $\mathcal{M}_H$ is shown in Figure* 5.1 *and $\mathcal{M}_f$ is shown in Figure* 5.2*, which accepts the same language that is induced by $f(H)$, is shown in Figure* 5.3*.*

In order to test whether *f(H)* is nonempty, by Theorem 5.17 we can check whether $\mathcal{L}(\mathcal{M}_H \cap \mathcal{M}_f)$ is nonempty, which can be done in nondeterministic logspace [JONE75] and thus in polynomial time in the size of $\mathcal{M}_H \cap \mathcal{M}_f$.

The following corollary is an immediate consequence of Theorems 5.6, 5.15, and 5.17, since the class of regular star-free languages is closed under intersection.

COROLLARY 5.18. *$\mathcal{L}(f(H))$ is a star-free regular language.*

We note that by Theorem 6.4 in [EMER90] PLTL is exactly as expressive as the class of star-free languages which do not include ϵ. Corollary 5.18, in view of Theorem 5.17, implies that $\mathcal{L}(f(H))$ is actually a member of a proper subclass of the class of star-free regular languages corresponding to the intersection of the star-free regular languages accepted by the finite automata representing trail queries and Hypertext databases, respectively.

The following corollary concerning the complexity of constructing $\mathcal{M}_H$, $\mathcal{M}_f$ and the intersection thereof is an immediate consequence of Definition 5.1, Lemma 5.13, and Theorem 5.16.

COROLLARY 5.19. *The following statements are true:*

1. *$\mathcal{M}_H$ can be constructed in linear time in $\#I$ and $|R|$.*
2. *$\mathcal{M}_f$ can be constructed in time exponential in the number of conjunctions, between subformulas of f, plus one; if there are no conjunctions in f, then $\mathcal{M}_f$ can be constructed in polynomial time in $\#I$ and $|f|$.*
3. *$\mathcal{M}_H \cap \mathcal{M}_f$ can be constructed in polynomial time in $|Q_H|$ and $|Q_f|$, where Q_H and Q_f are the state sets of $\mathcal{M}_H$ and $\mathcal{M}_f$, respectively.*

It is interesting to compare Corollary 5.19 with a result of [LICH84] showing that although model checking of PLTL formulas (see Definition 6.2) is exponential time in the length of the formulas it is linear time in the size of the temporal structure being checked.

A special case worth considering is when R is acyclic. In this case the number of trails in R is finite and thus the regular language defined by the output of a query is a finite regular language and therefore trivially star-free. As we will see in the next section, the fact that R is acyclic does not necessarily reduce the complexity of computing the star-free regular language induced by $f(H)$, namely, $\mathcal{L}(f(H))$.

Finally, it would be useful to extend HQL to enable the specification of second-order notions such as specifying that only the shortest trails (i.e., the trails with the least count) would be included in $f(H)$. Obviously for such an extension further analysis of $\mathcal{M}_H \cap \mathcal{M}_f$ would have to be carried out.

6. The complexity of navigation in Hypertext.

In this section we investigate the complexity of deciding whether a Hypertext database is a model of a trail formula. Our results show that, in general, this problem cannot be solved efficiently (assuming P $\neq$ NP). On the positive side we exhibit two significant subclasses of $\Diamond$-free trail formulas for which this decision problem can be solved in polynomial time.

Our results imply that the navigation problem is not easily solved in the general case. In practice Hypertext systems could include algorithms which return randomized and/or fuzzy solutions.

The following lemma shows that if a Hypertext database is a model of a given trail formula f, then we can find a trail, which satisfies f, and whose count is no greater than $\#I$ multiplied by $|Sub(f)|$.

LEMMA 6.1. *Let a Hypertext database, $H = \langle I, R\rangle$, be a model of the trail formula, f. Then $\exists T$ in R such that $T \models f$ and $\#T \leq \#I \cdot |Sub(f)|$.*

Proof. Let L in R be a trail such that $L \models f$ holds; such a trail exists in R, since H is a model of f. We prove the result by showing that there exists a subtrail (see Definition 3.6), T of L, such that $T \models f$ and $\#T \leq \#I \cdot |Sub(f)|$; the proof is by induction on $|Sub(f)|$.

(*Basis*): If $|Sub(f)| = 1$, then the result follows from Definition 4.8 part (T1), since $\#L > 0$ and the prefix L_1 satisfies $L_1 \models f$ and $\#L_1 = 1$.

(*Induction*): Assume that the result holds when $|Sub(f)| = k$, where $k \geq 1$; we then need to prove that the result holds when $|Sub(f)| = k + 1$.

We conclude the result by considering the form of f according to the four cases, T2 to T5, of Definition 4.8 as follows (recalling the definition of the concatenation of two arrays given in Definition 3.3):

1. If f is of the form $f_1 \wedge f_2$, then $L \models f_1$ and $L \models f_2$. Furthermore, by the inductive hypothesis $T \models f_1$ and $T \models f_2$, where T is a subtrail of L, and $\# T \leq \#I \cdot \max(|Sub(f_1)|, |Sub(f_2)|)$. The result follows, since $\max(|Sub(f_1)|, |Sub(f_2)|) \leq |Sub(f)|$.
2. If f is of the form $\Diamond(f')$, then $\exists i \in \{0, \ldots, \#L - 1\}$ such that $L^i \models f'$. Furthermore, by the inductive hypothesis there exists a subtrail T of L^i, with $\#T \leq \#I \cdot |Sub(f')|$, such that $T \models f'$. The result follows by Proposition 4.11 part (8) which implies that $T \models \Diamond(f')$, since $|Sub(f')| \leq |Sub(f)|$.
3. If f is of the form $\bigcirc(f')$, then $\#L > 1$ and $L^1 \models f'$. Furthermore, by the inductive hypothesis there exists a subtrail T of L^1 such that $T \models f'$, with $\#T \leq \#I \cdot |Sub(f')|$. Let L_j be the prefix of L such that $L_j T$ is also a prefix of L. It follows that there exists a subtrail T' of L in R such that $\#T' = 1$ and $T'[1] = L[j]$, since $\#L_j \geq 1$. The result follows, since by Definition 4.8 part (T4) $T'T \models f$ and $\#(T'T) = \#T + 1$.

4. If f is of the form $\triangle(f')$, then $\#L > 0$ and $L^i \models f'$, where $i = \#L - 1$. The result follows, since by Definition 4.8 part (T5) $L^i \models \triangle(f')$ and $\#L^i = 1$. $\square$

DEFINITION 6.2 (model checking). *The* model checking *problem is the problem of deciding whether a Hypertext database is a model of a trail formula.*

We proceed to investigate the complexity of the model checking problem.

LEMMA 6.3. *The model checking problem is in NP.*

Proof. In order to show that the model checking problem is in NP we present a nondeterministic polynomial-time algorithm that decides the problem (cf. [SIST85, Theorem 3.5]).

Let $H = \langle I, R\rangle$ be a Hypertext database and f be a trail formula. We first guess a trail T in R and an interpretation σ over H. It can easily be checked in polynomial time in $|f|$ that the restriction of σ to the unique variables in the subformulas of f is a one-to-one mapping. Furthermore, by Lemma 6.1 we can assume without loss of generality that $\#\, T \leq \#I \cdot |Sub(f)|$.

We now present an algorithm, which verifies whether $T \models f$ or not. The algorithm maintains a set, called *label*(i), for each marker i of T, which is initialized to the empty set. It then considers all of the subformulas $g \in Sub(f)$ in increasing order of $|g|$, assuming as before that all conditions in g have the same length of one, as follows:

1. If g is the condition C, with variable Z, then add g to label(i) iff $\sigma \models C$ and $T[i] = \sigma(Z)$.
2. If g is the formula $g_1 \wedge g_2$, then add g to label(i) iff $g_1, g_2 \in$ label(i).
3. If g is the formula $\diamond(g')$, then add g to label(i) iff $\exists j \in \{i, \ldots, \#T\}$ such that $g' \in$ label(j).
4. If g is the formula $\bigcirc(g')$, then add g to label(i) iff $g' \in$ label$(i+1)$.
5. If g is the formula $\triangle(g')$, then add g to label (i) iff $g' \in$ *label*$(\#T)$.

At the end of the above algorithm, whose time complexity is a polynomial in $\#I$ and $|f|$, it can be verified that $T \models f$ iff $f \in$ label(1). $\square$

THEOREM 6.4. *The model checking problem is NP-complete.*

Proof. By Lemma 6.3 model checking is in NP. It remains to show that the problem is NP-hard.

In order to show NP-hardness we reduce, in polynomial time, 3SAT [GARE79] to the model checking problem using a reduction similar to that used in [SIST85, Theorem 3.5].

Let $J = J_1 \wedge \ldots \wedge J_m$ be a conjunction of m clauses on a finite set of variables $\{x_1, \ldots, x_n\}$ such that $\forall i \in \{1, \ldots, m\}$, $J_i = L_{i1} \vee L_{i2} \vee L_{i3}$ is a clause of three literals, where each literal L_{ij} is either x_q or $\neg x_q$, with $q \in \{1, \ldots, n\}$.

We define an operator, denoted by ϕ, which returns the clauses that contain a literal x_i or $\neg x_i$ as follows:

- $\phi(x_i) = \{J_j | x_i \text{ is a literal in } J_j\}$ and
- $\phi(\neg x_i) = \{J_j | \neg x_i \text{ is a literal in } J_j\}$.

Let $H(J) = \langle I(J), R(J)\rangle$ be the Hypertext database defined by the following:

1. The set of strings $\{a_1, \ldots, a_n, b_1, \ldots, b_n, c_1, \ldots, c_m, y_0, y_1, \ldots, y_n\} \subseteq \Sigma^*$, where the a_i's, b_i's, c_i's, and y_i's are distinct, and $A \in \mathcal{U}$.
2. $\#I(J) = 3n + 1$.
3. $\forall i \in \{1, \ldots, n\}, I(J)[i] = (A, w_i)$, with $w_i = a_i c_1 \ldots c_k, k \leq m$, and where $\phi(x_i) = \{J_1, \ldots, J_k\}$.
4. $\forall i \in \{n+1, \ldots, 2n\}, I(J)[i] = (A, w_i)$, with $w_i = b_{i-n} c_1 \ldots c_k, k \leq m$, and where $\phi(\neg x_{i-n}) = \{J_1, \ldots, J_k\}$.
5. $\forall i \in \{2n+1, \ldots, 3n+1\}, I(J)[i] = (A, y_{i-(2n+1)})$.

6. $R(J) = \{(\psi(y_{i-1}), \psi(w_i)), (\psi(w_i), \psi(y_i)), (\psi(y_{i-1}), \psi(w_{i+n})), (\psi(w_{i+n}), \psi(y_i)) \mid i \in \{1, \ldots, n\}\}$, where $\forall j \in \{1, \ldots, \#I(J)\}, \psi(I(J)[j])$ denotes the page number j of $I(J), \psi(w_i)$ stands for $\psi((A, w_i))$, and $\psi(y_i)$ stands for $\psi((A, y_i))$.

The structure of $R(J)$ is shown in Figure 6.1, where for notational convenience the page numbers $\psi((A, a_i c_1 \ldots c_k))$, $\psi((A, b_{i-n} c_1 \ldots c_k))$, and $\psi((A, y_{i-(2n+1)}))$ are abbreviated to a_i, b_i, and y_i, respectively.

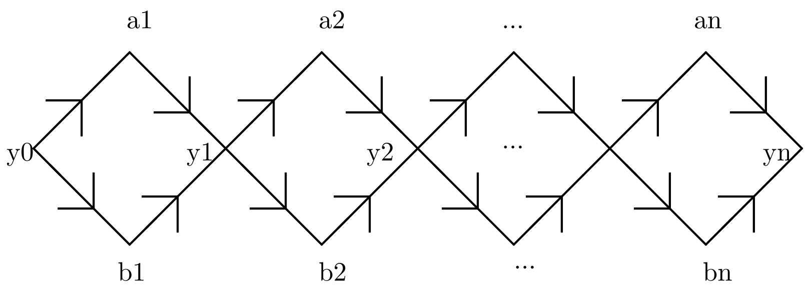

FIG. 6.1. *The reachability relation R(J).*

It can now be verified that J is satisfiable iff $H(J)$ is a model of the trail formula,

$$substr(X_0, y_0) \wedge \Diamond(substr(X_1, c_1)) \wedge \ldots \wedge \Diamond(substr(X_m, c_m)) \wedge \triangle(substr(X_{m+1}, y_n)),$$

where $X_0, X_1, \ldots, X_m, X_{m+1}$ are $m + 2$ distinct normal variables. □

The following result is an immediate consequence of the reduction in the proof of Theorem 6.4.

COROLLARY 6.5. *The model checking problem is NP-complete for the class of Hypertext databases having acyclic reachability relations and the class of* $\bigcirc$*-free trail formulas whose conditions do not contain any unique variables.*

The next result shows that the model checking problem does not become tractable by allowing unique variables in conditions and disallowing normal variables.

THEOREM 6.6. *The model checking problem is NP-complete for the class of Hypertext databases having acyclic reachability relations and the class of* $\bigcirc$*-free trail formulas whose conditions do not contain any normal variables.*

Proof. As in Theorem 6.4, by Lemma 6.3 the model checking problem is in NP. It remains to show that the problem is NP-hard. In order to conclude the result we modify the reduction of 3SAT given in the proof of Theorem 6.4. First, we modify parts 3 and 4 of the construction of $H(J)$ as follows:

3. $\forall i \in \{1, \ldots, n\}, I(J)[i] = (A, w_i)$, with $w_i = a_i$; these pages represent the literals x_i.

4. $\forall i \in \{n + 1, \ldots, 2n\}, I(J)[i] = (A, w_i)$, with $w_i = b_{i-n}$; these pages represent the literals $\neg x_i$.

Second, for each $x_q, q \in \{1, \ldots, n\}$, such that $\phi(x_q) = \{J_1, \ldots, J_k\}$ we add k additional pages to $I(J)$. Each such additional page $I(J)[i]$ is of the form $(A, a_i c_j), j \in \{1, \ldots, k\}$, where c_j corresponds to the clause J_j. Similarly, for each $\neg x_q, q \in \{1, \ldots, n\}$, such that $\phi(\neg x_q) = \{J_1, \ldots, J_k\}$ we add another k additional pages to $I(J)$. As in the preceding case each such additional page $I(J)[i]$ is of the form $(A, b_{i-n} c_j), j \in \{1, \ldots, k\}$, where c_j corresponds to the clause J_j.

As in the previous theorem the page numbers $\psi((A, a_i)), \psi((A, b_{i-n}))$, and $\psi((A, y_{i-(2n+1)}))$ are abbreviated for notational convenience to a_i, b_i, and y_i, respectively, with $i \in \{1, \ldots, n\}$. In addition, both the page numbers $\psi((A, a_i c_j))$ and

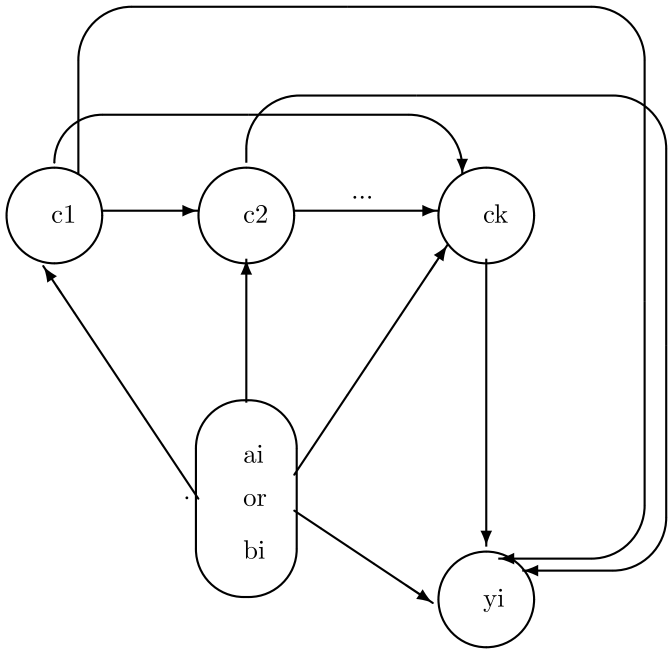

FIG. 6.2. *The subgraph added to R(J).*

$\psi((A, b_{i-n}c_j))$ are abbreviated to c_j, with $j \in \{1, \ldots, k\}$, where the distinction between a_ic_j and $b_{i-n}c_j$ is understood from context.

Moreover, for each page number i of $I(J)$ representing x_i, we add a subgraph to the reachability relation $R(J)$ of Theorem 6.4 (see Figure 6.1) as follows. First, we add an arc from the page number i of $I(J)$ to each of the page numbers c_j. Second, we add an arc from each of the page numbers c_j, $j \in \{1, \ldots, k\}$, to each of the page numbers c_p, with $j < p$ and $p \in \{1, \ldots, k\}$. Finally, we add an arc from each of the page numbers c_j to the page number y_i. We repeat this process for each page number i of $I(J)$ representing $\neg x_i$.

The subgraph added to the reachability relation $R(J)$ of Theorem 6.4 is shown in Figure 6.2.

It can now be verified that J is satisfiable iff $H(J)$ is a model of the trail formula,

$$\begin{aligned} &substr(Y_0, y_0) \wedge \Diamond(substr(Y_1, c_1)) \wedge \ldots \\ &\ldots \wedge \Diamond(substr(Y_m, c_m)) \wedge \triangle(substr(Y_{m+1}, y_n)), \end{aligned} \tag{6.1}$$

where $Y_0, Y_1, \ldots, Y_m, Y_{m+1}$ are $m+2$ distinct unique variables.

Specifically, if $H(J)$ is a model of (6.1), then for some trail $T \in R(J), T$ satisfies (6.1) with respect to some interpretation σ over H. Now, for each $\sigma(Y_i), i \in \{1, \ldots, m\}$, let a_i or b_i be the page number such that either $(a_i, \sigma(Y_i))$ or $(b_i, \sigma(Y_i))$ is in $R(J)$. It follows therefore that J is satisfiable under an assignment where each literal corresponding to a_i or b_i is made true.

Correspondingly, if J is satisfiable then we need to exhibit a trail T that satisfies (6.1) with respect to some interpretation σ over H. Now, since J is satisfiable there is an assignment that makes each J_j in J, $j \in \{1, \ldots, m\}$, true. Furthermore, J_j is true due to a literal, say, L_i, being true in J_j. Let either a_i or b_i be the page number corresponding to L_i and let c_j be the page number corresponding to J_j such that either (a_i, c_j) or (b_i, c_j) is in $R(J)$. Let σ be such that $\sigma(Y_0) = y_0$, $\sigma_{m+1}(Y_{m+1}) = y_n$ and for $j \in \{1, \ldots, m\}$ $\sigma(Y_j) = c_j$. The result now follows, since there is a trail passing through all the c_j's satisfying the desired trail formula. $\square$

We next show that the model checking problem is also NP-complete for the subclass of $\diamond$-free trail formulas.

THEOREM 6.7. *The model checking problem is NP-complete for the class of $\diamond$-free trail formulas.*

Proof. By Lemma 6.3 the model checking problem is in NP. It remains to show that the problem is NP-hard. In order to show NP-hardness we reduce, in polynomial time, the longest path problem, which is known to be NP-complete [GARE79], to the model checking problem for the class of $\diamond$-free trail formulas.

Let $G = (V, E)$ be a directed graph with $V = \{v_1, \ldots, v_m\}$ and $s, t \in V$. We need to solve the problem: does there exist a *simple path* (that is, a path in which no node occurs more than once) from s to t in G of length k or more?

We first let ϕ be a one-to-one mapping from V to $\{A\} \times \Sigma^*$, where $A \in \mathcal{U}$.

Next let $H(G) = \langle I(G), R(G) \rangle$ be a Hypertext database defined by

1. $\#I(G) = |V| = m$.
2. $\forall i \in \{1, \ldots, m\}, \phi(v_i) = I(G)[i]$.
3. $\psi(G) = R(G)$, where ψ is an isomorphism from G to $R(G)$ such that $\psi((v_i, v_j)) = (i, j)$, where i is the page number satisfying $\phi(v_i) = I(G)[i]$ and j is the page number satisfying $\phi(v_j) = I(G)[j]$.

It can now be verified that there exists a simple path from s to t in G of length k or more iff $H(G)$ is a model of the trail formula

$$\begin{aligned} &substr(Y_0, \beta(\phi(s))) \wedge \bigcirc(att(Y_1, A)) \wedge \bigcirc^2(att(Y_2, A)) \wedge \\ &\bigcirc^{k-1}(att(Y_{k-1}, A)) \wedge \triangle(substr(Y_k, \beta(\phi(t)))), \end{aligned} \tag{6.2}$$

where $Y_0, Y_1, \ldots, Y_k$ are distinct unique variables and $\bigcirc^p$ denotes the composition, $\bigcirc \ldots \bigcirc, p$ times, with $p \in \omega$. $\square$

The following two results follow from the reduction in the proof of Theorem 6.7.

COROLLARY 6.8. *The model checking problem is NP-complete for the class of $\diamond$-free trail formulas whose conditions do not contain any normal variables.*

The next corollary is easily shown by replacing all occurrences of $\bigcirc$ in (6.2) by $\diamond$; it also follows from Theorem 6.6.

COROLLARY 6.9. *The model checking problem is NP-complete for the class of $\bigcirc$-free trail formulas whose conditions do not contain any normal variables.*

We now show that model checking can be done in polynomial time for $\diamond$-free trail formulas when the reachability relation of the Hypertext database is acyclic. In order to prove the result we first solve the following graph-theoretic problem: Given a directed acyclic graph (V, E) and a family $\{V_i\}$ $(i \in \{0, \ldots, k\})$ of subsets of V, does there exist a path, $\langle v_0, \ldots, v_k \rangle$, of length k in G such that $v_i \in V_i$?

Let us call this the *path of length k* problem. We note that when we consider directed acyclic graphs every path is actually a simple path.

We next show that a solution to the path of length k problem can be obtained in $O(k \cdot |E|)$ time; when (V, E) is acyclic then $k \leq |V|$.

LEMMA 6.10. *Given a directed graph (V, E) and a family $\{V_i\}$ $(i \in \{0, \ldots, k\})$ of subsets of V, then the path of length k problem can be solved in $O(k \cdot |E|)$ time.*

Proof. In order to solve the problem we give the pseudocode of an algorithm designated PATH$((V, E), \{V_i\})$, which takes as input a directed graph and a family of $k + 1$ subsets of V and returns YES if there is a solution to the path of length k problem; otherwise it returns NO.

For each subset $V_i \subseteq V$ we maintain an auxiliary set, called P_i, which stores all the nodes that can be reached from a node in V_0 via a path of length i. We also assume that adjacent(v) denotes the set of nodes: $\{u|(v, u) \in E\}$.

Algorithm 2 (PATH((V, E), $\{V_i\}$)).

```
1.  begin
2.    $P_0 := V_0$;
3.    for $i = 1$ to $k$ do
4.      $P_i := \emptyset$;
5.      for all $v \in P_{i-1}$ do
6.        for all $u \in adjacent(v)$ do
7.          if $u \in V_i$ then
8.            $P_i := P_i \cup \{u\}$;
9.          end if
10.       end for
11.     end for
12.   end for
13.   if $P_k \neq \emptyset$ then
14.     return YES;
15.   else
16.     return NO;
17.   end if
18. end.
```

It can be verified that the algorithm is correct and solves the path of length k problem in $O(k \cdot |E|)$ time. $\square$

We next present a special case when model checking can be done in polynomial time.

Theorem 6.11. *The model checking problem can be solved in polynomial time in the length of the repository and the length of the trail formula for the class of Hypertext databases having acyclic reachability relations and for the class of $\diamond$-free trail formulas.*

Proof. Let $H = \langle I, R\rangle$ be a Hypertext database with R being acyclic and let f be a $\diamond$-free trail formula. Since f is $\diamond$-free it follows that we can use Proposition 4.11 in order to obtain a trail formula which is equivalent to f and is in the following *normal form*:

$$C_{1_1} \wedge \ldots \wedge C_{n_1} \wedge \triangle(C_{1_2}) \wedge \ldots \wedge \triangle(C_{n_2}) \wedge \bigcirc \ldots \bigcirc (C_{1_3}) \wedge \ldots \wedge \\ \bigcirc \ldots \bigcirc (C_{n_3}) \wedge \bigcirc \ldots \bigcirc \triangle(C_{1_4}) \wedge \ldots \wedge \bigcirc \ldots \bigcirc \triangle(C_{n_4}),$$

where each C_i is a condition which is also a subformula of f, noting that for any trail T in R it cannot be the case that $T \models \triangle \bigcirc (f)$.

On using Proposition 4.11 it can be verified that if a trail formula, f, is $\diamond$-free, then f can be converted into a normal form $\diamond$-free trail formula in time polynomial in $|f|$. For the rest of the proof we assume that f is in normal form.

Let $\bigcirc^k[f]$ denote the set of conditions in the conjuncts of f having no instance of $\triangle$ and exactly k instances of $\bigcirc$, where $k \geq 0$, and let max$\bigcirc(f)$ denote the maximum number of instances of $\bigcirc$ in any conjunct of f. In addition, let $\triangle[f]$ denote the set of conditions, $\{C_{1_2}, \ldots, C_{n_2}, C_{1_4}, \ldots, C_{n_4}\}$, in conjuncts of f having an instance of $\triangle$.

Finally, let F be an array of sets of page numbers such that $\#F = \max\bigcirc(f) + 2$ and such that initially $\forall i \in \{1, \ldots, \#F\}, F[i] = \emptyset$.

The first step in our model checking algorithm is syntactic. If one of the following constraints is violated, then H is not a model of f, since a contradiction arises:

1. There do not exist two unique variables, which are distinct, contained in the set of conditions $\bigcirc^k[f]$ for any $k \geq 0$; i.e., no two unique variables, which are distinct, can appear at the *same time*.
2. There do not exist two unique variables, which are distinct, contained in the set of conditions $\triangle[f]$; i.e., no two unique variables, which are distinct, can appear at the *final time*.
3. There do not exist natural numbers, k_1, k_2, with $k_1 \neq k_2$ and $0 \leq k_1, k_2 \leq \max\bigcirc(f)$, such that the intersection of the set of variables contained in $\bigcirc^{k_1}[f]$ with the set of variables contained in $\bigcirc^{k_2}[f]$ is nonempty; i.e., no variable can appear in two distinct *times*.
4. $\forall k, 0 \leq k < \max\bigcirc(f)$, the intersection of the set of variables contained in $\bigcirc^k[f]$ with the set of variables contained in $\triangle[f]$ is empty; i.e., no variable can appear before and at the *final time*.

It can be verified that all of the above constraints can be checked in polynomial time in $|f|$. Assuming that the above constraints are satisfied, then the following statements are true:

1. $\forall k, 0 \leq k \leq \max\bigcirc(f)$, if $\bigcirc^k[f]$ is nonempty, then we can assume that there exists only one variable in its conjuncts such that this variable does not appear in any other set $\bigcirc^q[f]$, where $0 \leq k \neq q \leq \max\bigcirc(f)$; i.e., there is only one variable per *time unit*.
2. If $\triangle[f]$ is nonempty, then we can assume that there is only one variable in its conjuncts, such that this variable does not appear in any other set $\bigcirc^k[f]$, where $0 \leq k < \max\bigcirc(f)$; i.e., there is only one variable for the *final time unit*.
3. If the intersection of the set of variables contained in $\triangle[f]$ and the set of variables contained in $\bigcirc^k[f]$ is nonempty, where $k = \max\bigcirc(f)$, then the single variable assumed to be in their conjuncts must be the same variable; i.e., in this case the *final time* coincides with the time implied by $\max\bigcirc(f)$. Otherwise, we assume that their single respective variables are distinct.

We note that statements (1) and (2) above are valid, since if H is a model of f and T is a trail in R such that $T \models f$ with respect to some interpretation σ over H, then for the variables X_i in the conjunctions of $\bigcirc^k[f]$ or $\triangle[f]$, σ must map X_i to the same page number.

From now on we assume that the above statements are enforced in normal form trail formulas by a straightforward renaming of variables. We are not concerned whether the single variable per time unit is normal or unique due to the fact that R is acyclic and thus all the paths in the directed acyclic graph corresponding to R are simple.

For each page number, *pn* of I, we maintain an auxiliary set, called cond(*pn*), which is initialized to the empty set. We then consider all the conditions C, of all the conjuncts of f, in turn and add C to cond(*pn*) according to the following constraint:

- Add C to cond(*pn*) iff $\sigma \models C$, assuming that σ is an interpretation over H and $\sigma(Z) = pn$, where Z is the variable of C.

Constructing the sets cond(*pn*) can be done in polynomial time in $\#I$ and $|f|$.

Next, for each page number *pn* of I add *pn* to F according to the following two rules:

1. If $(\bigcirc^k[f] \neq \emptyset) \subseteq \text{cond}(pn)$, where $0 \leq k \leq \max\bigcirc(f)$, then add pn to $F[k+1]$.
2. If $(\triangle[f] \neq \emptyset) \subseteq \text{cond}(pn)$, then add pn to $F[\#F]$.

In the next step of our model checking algorithm we check if one of the ensuing constraints is violated in which case H is not a model of *f*.

1. For any $k, 0 \leq k \leq \max\bigcirc(f)$, if $\bigcirc^k[f] \neq \emptyset$, then $F[k+1] \neq \emptyset$.
2. If $\triangle[f] \neq \emptyset$, then $F[\#F] \neq \emptyset$.

The above constraints can be tested in polynomial time in $\#I$ and $|f|$. We therefore assume that the above two constraints are satisfied.

In order to utilize Lemma 6.10, we modify F by setting $F[i]$ to $\{1, \ldots, \#I\} \forall i \in \{1, \ldots, \#F\}$ whenever $F[i] = \emptyset$. The result now follows, on viewing R as a directed acyclic graph, and viewing the prefix F_{k+1} of F, where $k+1 = \#F - 1$, as a family of $k+1$ subsets of I. The model checking problem thus reduces to the path of length k problem, with the following final test: $P_k^* \cap F[\#F] \neq \emptyset$, where ${P_k}^*$ denotes the set of nodes, $P_k \cup \{u | v \in P_k$ and (v, u) is an arc in the transitive closure of $R\}$. □

The following corollary, which is an immediate consequence of Theorem 6.11, demonstrates a special case when model checking can be solved in polynomial time even when the reachability relation is cyclic.

Corollary 6.12. *The model checking problem can be solved in polynomial time in the length of the repository and the length of the trail formula for the class of $\diamond$-free trail formulas whose conditions do not contain any unique variables and such that the normal variables appearing in conditions at distinct times are distinct.*

Proof. The result follows, since in this special case constraints (1) to (4) in the proof of Theorem 6.11 do not have to be satisfied. Furthermore, in this special case, Algorithm 2 will return YES iff there exists a trail in R, which is not necessarily loop-free; i.e., a node may appear more than once in the path corresponding to the trail. □

The following corollary, which is given for completeness, follows immediately from Theorem 6.11 on using Algorithm 2, since we need only inspect $O(\#I^2)$ pages.

Corollary 6.13. *The model checking problem can be solved in polynomial time in the length of the repository and the length of the trail formula for the classes of $\diamond$-free and $\bigcirc$-free trail formulas.*

The next theorem shows that if we relax the condition stated in Corollary 6.12, namely, that normal variables appearing in conditions at distinct times be distinct, then the model checking problem is again NP-complete.

Theorem 6.14. *The model checking problem is NP-complete for the class of $\diamond$-free trail formulas whose conditions do not contain any unique variables.*

Proof. By Lemma 6.3 the model checking problem is in NP. It remains to show that the problem is NP-hard. In order to show NP-hardness we reduce, in polynomial time, the clique [BUCK90] of size k problem, which is known to be NP-complete [GARE79], to the model checking problem for the class of $\diamond$-free trail formulas, whose conditions do not contain any unique variables.

Let $G = (V, E)$ be a graph with $V = \{v_1, \ldots, v_m\}$. We need to solve the problem: does G contain a clique of size k or more, where $k \leq |V|$?

We first let ϕ be a one-to-one mapping from V to $\{A\} \times \Sigma^*$, where $A \in \mathcal{U}$. Next, let $H(G) = \langle I(G), R(G) \rangle$ be a Hypertext database defined by

1. $\#I(G) = |V| = m$.
2. $\forall i \in \{1, \ldots, m\}, \phi(v_i) = I(G)[i]$.
3. $\psi(G) = R(G)$, where ψ is an isomorphism from G to R (G) such that

$\psi(\{v_i, v_j\}) = \{(i,j),(j,i)\}$, where i and j are the page numbers satisfying $\phi(v_i) = I(G)[i]$ and $\phi(v_j) = I(G)[j]$, respectively.

Let $K = \{1,\dots,k\}$ and $\text{lex}(K) = \langle (1,2),(1,3),\dots,(1,k),(2,3),\dots,(2,k), \dots,(k-1,k)\rangle$ be the lexicographically ordered sequence [HALM74] of $(k^2-k)/2$ pairs in K^2 such that (i,j) is in $\text{lex}(K)$ iff $i < j$. Furthermore, let $\text{path}(K) = \langle 1,2,1,3, \dots,1,k,2,3,\dots,2,k,\dots,k-1,k,1\rangle$ be the sequence of the $(k^2-k)+1$ numbers in K resulting from transforming each pair (i,j) in $\text{lex}(K)$ into the subsequence i, j and then adding 1 at the end of the resulting sequence.

It can be verified that G contains a clique of size k or more iff we can find k nodes in the directed graph corresponding to $R(G)$ numbered from 1 to k such that $\text{path}(K)$ is a path in this directed graph.

We next transform $\text{path}(K)$ into the following $\Diamond$-free trail formula, denoted by $f(\text{path}(K))$, whose conditions do not contain any unique variables, namely,

$$\begin{aligned}
&att(X_1,A) \wedge \bigcirc(att(X_2,A)) \wedge \bigcirc^2(att(X_1,A)) \wedge \bigcirc^3(att(X_3,A)) \wedge \dots \wedge\\
&\bigcirc^{2(k-1)-2}(att(X_1,A)) \wedge \bigcirc^{2(k-1)-1}(att(X_k,A)) \wedge \bigcirc^{2(k-1)}(att(X_2,A)) \wedge\\
&\bigcirc^{2(k-1)+1}(att(X_3,A)) \wedge \dots \wedge \bigcirc^{4(k-2)}(att(X_2,A)) \wedge \bigcirc^{4(k-2)+1}(att(X_k,A)) \wedge \dots \wedge\\
&\bigcirc^{(k^2-k)-1}(att(X_{k-1},A)) \wedge \bigcirc^{k^2-k}(att(X_k,A)) \wedge \bigcirc^{(k^2-k)+1}(att(X_1,A)),
\end{aligned}$$

where $X_1,\dots,X_k$ are distinct normal variables and $\bigcirc^k$ denotes the composition, $\bigcirc\dots\bigcirc$, k times, with $k \in \omega$.

It can be verified that G contains a clique of size k or more iff $H(G)$ is a model of the trail formula $f(\text{path}(K))$. $\square$

Table 6.1, shown below, summarizes the complexity results obtained in this section; the reader can verify that all possible cases have been considered. "Yes" in the acyclic column indicates that the reachability relation of the Hypertext database is acyclic, "Yes" in the no-normal column indicates that trail formulas do not contain normal variables, "Yes" in the no-unique column indicates that trail formulas do not contain unique variables, "Yes" in the $\Diamond$-free column indicates that trail formulas are $\Diamond$-free, "Yes" in the $\bigcirc$-free column indicates that trail formulas are $\bigcirc$-free, "NPC" stands for NP-complete, "P" stands for polynomial time; finally, "No†" in the no-normal column indicates that normal variables appearing in conditions at distinct times are distinct.

TABLE 6.1
Summary of the complexity results.

Acyclic	No-normal	No-unique	$\Diamond$-free	$\bigcirc$-free	Complexity
Yes	No	Yes	No	Yes	NPC
Yes	Yes	No	No	Yes	NPC
No	Yes	No	Yes	No	NPC
No	No	Yes	Yes	No	NPC
Yes	No	No	Yes	No	P
No	No†	Yes	Yes	No	P
No	No	No	Yes	Yes	P

7. Concluding remarks.

An attempt has been made to tackle the navigation problem for Hypertext, namely, the problem of getting "lost in hyperspace." In order to solve this problem we utilized temporal logic and defined the navigation semantics of Hypertext in terms of the query language HQL, which is based on a subset of PLTL. In the navigation semantics of HQL the notion of a trail is central. The output to a trail query with respect to a Hypertext database is the set of all trails in the Hypertext database which satisfy the trail query.

We investigated the evaluation of HQL queries, showing that by using the automata-theoretic approach we can construct a finite automaton representing the output $f(H)$ of a trail query f with respect to a Hypertext database H. We have shown in Corollary 5.18 that the language $\mathcal{L}(f(H))$ induced by $f(H)$ is a star-free regular language. Furthermore, in Corollary 5.19 we obtained an upper bound on the time complexity of the construction of $\mathcal{M}_H \cap \mathcal{M}_f$, which is exponential in the number of conjunctions, between subformulas of f, plus one.

We also investigated the complexity of the model checking problem for HQL queries and summarized our results in Table 6.1. We have shown that, in general, this problem is NP-complete but that there are important special cases when the problem can be solved in polynomial time.

Our conclusion is that the navigation problem in Hypertext cannot be solved efficiently unless users have some a priori knowledge about the order in which the pages of information are structured in the database graph. Having this knowledge users can utilize the $\diamond$-free polynomial-time subset of HQL to pursue a one-step-at-a-time navigation session through the database graph. Experimental research has to be carried out in order to ascertain whether expensive queries will often be posed. In practice, it may also be useful to seek randomized and/or fuzzy solutions to this problem [LEVE99b].

Acknowledgments. The authors would like to thank Trevor Fenner for helping us solve some of the complexity problems posed in section 6. We would also like to thank the referee for his many incisive comments which helped us to improve an earlier version of the paper.

A POLYNOMIAL-TIME APPROXIMATION SCHEME FOR MINIMUM ROUTING COST SPANNING TREES[*]

BANG YE WU[†], GIUSEPPE LANCIA[‡], VINEET BAFNA[§], KUN-MAO CHAO[¶], R. RAVI[‖], AND CHUAN YI TANG[**]

Abstract. Given an undirected graph with nonnegative costs on the edges, the routing cost of any of its spanning trees is the sum over all pairs of vertices of the cost of the path between the pair in the tree. Finding a spanning tree of minimum routing cost is NP-hard, even when the costs obey the triangle inequality. We show that the general case is in fact reducible to the metric case and present a polynomial-time approximation scheme valid for both versions of the problem. In particular, we show how to build a spanning tree of an n-vertex weighted graph with routing cost at most $(1+\epsilon)$ of the minimum in time $O(n^{O(\frac{1}{\epsilon})})$. Besides the obvious connection to network design, trees with small routing cost also find application in the construction of good multiple sequence alignments in computational biology.

The communication cost spanning tree problem is a generalization of the minimum routing cost tree problem where the routing costs of different pairs are weighted by different requirement amounts. We observe that a randomized $O(\log n \log\log n)$-approximation for this problem follows directly from a recent result of Bartal, where n is the number of nodes in a metric graph. This also yields the same approximation for the generalized sum-of-pairs alignment problem in computational biology.

1. Introduction.

Consider the following problem in network design: given an undirected graph with nonnegative delays on the edges, the goal is to find a spanning tree such that the average delay of communicating between any pair using the tree is minimized. The delay between a pair of vertices is the sum of the delays of the edges in the path between them in the tree. Minimizing the average delay is equivalent to minimizing the total delay between all pairs of vertices in the tree.

In general, when the cost on an edge represents a price for routing messages between its endpoints (such as the delay), we define the *routing cost* for a pair of vertices in a given spanning tree as the sum of the costs of the edges in the unique tree path between them. The routing cost of the tree itself is the sum over all pairs of vertices of the routing cost for the pair in this tree.

Finding a spanning tree of minimum routing cost in a general weighted undirected graph is known to be NP-hard [11]. In this paper we show that finding a minimum routing cost tree in a general weighted graph G is equivalent to solving the same problem on a complete graph in which the edge weights are the shortest path lengths in G. This result implies that the minimum routing tree problem with metric inputs is also NP-hard.

Wong [22] studied the minimum routing cost tree problem and presented a 2-approximation algorithm even without the metric requirement. We give a better result for the metric case, which, by the above remark, applies to the general case as well.

THEOREM 1.1. *There is a polynomial-time approximation scheme (PTAS) for finding the minimum routing cost tree of a weighted undirected graph. In particular, on an n-vertex graph, we can find a $(1+\epsilon)$-approximate solution in time $O(n^{2\lceil \frac{2}{\epsilon} \rceil - 2})$.*

Our result is derived by approximating a minimum routing cost tree by a restricted class of trees that we call *k-stars.* For any fixed size k, a k-star is a tree in which at most k vertices have degree greater than one. For a given accuracy parameter ϵ, we consider all $\lceil \frac{2}{\epsilon} - 1 \rceil$-stars and output the one with the minimum routing cost. To argue the performance guarantee, we show how a minimum routing cost tree can be converted into a k-star without much degradation in its routing cost (no more than a factor of $1 + \frac{2}{k+1}$). We also prove that for any fixed k, the minimum k-star can be determined in polynomial time. Hence, by finding the $\lceil \frac{2}{\epsilon} - 1 \rceil$-star with the minimum routing cost, we get a $(1+\epsilon)$-approximate solution.

There is an important difference between our PTAS for the routing cost tree problem and Wong's 2-approximation: While we show an approximation bound to the best tree's routing cost, Wong's proof shows that his trees have routing cost at most twice the value of the sum of pairwise distances between nodes in the input graph. This stronger connection is exploited by Gusfield [9] in an application to multiple alignments in computational biology (described later).

1.1. Optimum communication spanning trees. Hu [10] formulated a general version of the routing cost spanning tree problem that he called optimum communication spanning trees. In this problem, in addition to the costs on edges, a requirement value r_{ij} is specified for every pair of vertices i, j. The communication cost between a pair in a given spanning tree is the cost of the path between them in the tree multiplied by their requirement r_{ij}. The communication cost of the tree is the sum of all the pairwise communication costs. Thus the routing cost is a special case of the communication cost when all the requirement values are one.[1] In [10], Hu derives weak conditions under which the optimum routing cost tree is a star. In this paper, we demonstrate that simple generalizations of stars are indeed sufficient to guarantee any desirable accuracy in approximating optimal routing trees.

By using a recent result of Bartal [3] on approximating metrics probabilistically by tree metrics, we notice the following result.

THEOREM 1.2. *There is an $O(\log^2 n)$-approximation algorithm for the communication spanning tree problem on an n-node metric.*

Recent improvements to Bartal's original result in [4, 6] also lead to an improvement of the performance guarantee in Theorem 1.2 to $O(\log n \log\log n)$.

The result in Theorem 1.2 is actually stronger in the same sense as Wong [22].

[1]Hu uses the term "optimum distance spanning trees" to denote trees with minimum routing cost.

Given (symmetric) requirement values r_{ij} and metric distances d_{ij} between node pairs i, j, our approximate solution has communication cost at most $O(\log^2 n)$ times $\sum_{i,j} r_{ij} d_{ij}$. As in [9], we exploit this connection in the application to computational biology.

An overview of the remainder of the paper is as follows. In section 2 we describe the application of minimum routing cost trees to alignment problems in computational biology. In section 3 we give some basic definitions. In section 4, we show how the general case of the problem can be reduced to the metric one. Section 5 describes how k-stars provide good approximations to the optimum routing cost trees in metrics. In section 6, we discuss a polynomial algorithm for finding minimum cost k-stars in a graph. Finally, in section 7 we describe an algorithm for approximating optimum communication spanning trees.

2. An application to computational biology.

2.1. Multiple sequence alignments. Multiple sequence alignments are important tools for highlighting patterns common to a set of genetic sequences in computational biology. A multiple alignment of a set of n strings involves inserting gaps in the strings and arranging their characters into columns with n rows, one from each string. The order of characters along a row corresponding to string s_i is the same as that in s_i, with possibly some blanks inserted. The following is an example of an alignment of three strings `ATTCGAC`, `TTCCGTC`, and `ATCGTC`.

```
A T T - C G A - C
- T T C C G - T C
A - T - C G - T C
```

The intent of identifying common patterns is represented by attempting as much as possible to place the same character in every column.

The multiple sequence alignment problem has typically been formalized as an optimization problem in which some explicit objective function is minimized or maximized. One of the most popular objective functions for multiple alignment generalizes ideas from optimally aligning two sequences. The pairwise-alignment problem [21] can be phrased as that of finding a minimum mutation path between two sequences. Formally, given costs for inserting or deleting a character and for substituting one character of the alphabet for another, the problem is to find a minimum-cost mutation path from one sequence to the other. The cost of this path is the *edit distance* between them. An optimal alignment of two sequences of length l can be computed effectively by dynamic programming [14, 21] in $O(l^2)$ time. The generalization to multiple sequences leads to the sum-of-pairs objective.

The *sum-of-pairs* (SP) objective for multiple alignment is to minimize the sum, over all pairs of sequences, of the pairwise distance between them *in the alignment* (where the distance of two sequences in an alignment with l columns is obtained by adding up the costs of the pairs of characters appearing at positions $1, \ldots, l$).

Pioneering work of Sankoff and Kruskal [17] and Sankoff, Morel, and Cedergren [18] led to an exponential-time dynamic programming solution to the SP-alignment problem. A straightforward implementation requires time proportional to $2^n l^n$ for a problem with n sequences each of length at most l. Considering that in typical real-life instances l can be a few hundred, the basic dynamic programming approach turns out to be infeasible for all but very small problems. Carrillo and Lipman [5] have introduced some bounding criteria which reduce the time and space requirements of dynamic programming and make solvable problems for $n \leq 6$ and $l \leq 200$. However, constructing *optimal* alignments is bound to be computationally expensive, since the problem has been shown to be NP-complete (Wang and Jiang, [20]). Despite these very expensive solution methods, the SP-objective is implemented in several popularly available multiple alignment packages such as MACAW [19] and MSA [13].

2.2. Approximation algorithms via routing cost trees. The first approximation algorithm for the SP-alignment problem was by Gusfield [9]. It had a performance ratio of $2 - \frac{2}{n}$ where n is the number of sequences aligned. This was slightly improved to $2 - \frac{3}{n}$ by Pevzner [15]. The best-known approximation algorithm for this problem is due to Bafna, Lawler, and Pevzner [2], which achieves a ratio of $2 - \frac{r}{n}$ for any fixed value of r. The running time is exponential in r. Notice that this is not a PTAS for the problem, and no polynomial-time approximation scheme is known yet for the SP-alignment problem.

Gusfield's approximation algorithm for the SP-alignment problem is based on the 2-approximation for minimum routing cost trees due to Wong [22]. Gusfield's algorithm uses a folklore approach to multiple alignment guided by a tree, due to Feng and Doolittle [8]: Given a spanning tree on the complete graph on the sequences to be aligned, the multiple alignment guided by the tree is built recursively as follows. First, remove a leaf sequence l in the tree attached to sequence v by a tree edge (l, v), and align the remaining sequences recursively. Then, reinsert the leaf sequence into the alignment guided by an optimal pairwise alignment between the pair l and v. If this optimal pairwise alignment introduces a gap in v, insert the same gap in the recursively computed alignment for the tree without the leaf. Since the cost of aligning a blank to a blank is assumed to be zero, the resulting alignment has the property that for every pair related by a tree edge, the cost of the induced pairwise alignment equals their edit distance. By the triangle inequality on edit-distances, the SP-cost of the alignment derived from this spanning tree can be upper-bounded by the routing cost of the tree.

Wong's 2-approximation algorithm considers the shortest path tree rooted at every vertex in turn, and picks the one with minimum routing cost. For graphs with metric distances obeying the triangle inequality, every shortest path tree is isomorphic to a star. Furthermore, in this case, Wong's analysis shows that the best star has routing cost at most twice the total cost of the graph itself. The cost of the graph in this case is the sum of pairwise edit distances between sequences, which is a lower bound on the SP-cost. Thus, Gusfield observed that a multiple alignment derived from the best center-star gives a 2-approximation for the SP-alignment problem.

2.3. Tree-driven SP-alignment. Despite the popularity of the SP-objective, most of the currently available methods for finding alignments use a *progressive* approach of incrementally building the alignment adding sequences one at a time with no performance guarantee on the SP-cost. The Feng–Doolittle procedure can be viewed as one such procedure. The advantage of such approaches is their low running time, but the shortcoming is that the order in which the sequences are merged into the alignment determines its cost.

In trying to define a middle ground between the SP-objective and the more practical progressive methods, we introduce the tree-driven SP-alignment method: apply the Feng–Doolittle procedure to the *best possible* spanning tree in the complete graph on the sequences. By our reasoning above, the tree that gives the best upper bound on the SP-cost of the alignment is the one with the minimum routing cost. Thus, our PTAS for routing cost trees may be useful in finding good trees for applying any progressive alignment method such as the Feng–Doolittle procedure.

2.4. Generalized SP-alignments. A simple generalization of the SP objective for multiple alignments is to weight the different sequence pairs in the alignment differently in the objective function. Given a priority value r_{ij} for the pair i, j of sequences, the *generalized sum-of-pairs* objective for multiple alignment is to minimize the sum, over all pairs of sequences, of the pairwise distance between them in the alignment multiplied by the priority value of the pair. This allows one to increase the priority of aligning some pairs while down-weighting others, using other information (such as evolutionary) to decide on the priorities. An extreme case of assigning priorities is the *threshold* objective.

In an evolutionary context, a multiple alignment is used to reconstruct the blocks or motifs in a single ancestral sequence from which the given sequences have evolved. However, if the evolutionary events of the ancestral sequence occur randomly at a certain rate over the course of time, and independently at each location (character) of the string, after a sufficiently long time, the mutated sequence appears essentially like a random sequence compared to the initial ancestral sequence. If we postulate a threshold time beyond which this happens, this translates roughly to a threshold edit distance between the pair of sequences. The threshold objective sets r_{ij} to be one for all pairs of input sequences whose edit-distance is less than this threshold and zero for other pairs which are more distant. In this way we try to capture the most information about closely related pairs in the objective function by setting an appropriate threshold.

In the same vein as Gusfield [9], Theorem 1.2 can be used to approximate the generalized SP objective within an $O(\log^2 n)$ factor on inputs with n sequences. Let d_{ij} denote the edit distance between sequences i and j. The theorem guarantees a tree whose communication cost using the r_{ij} values given by the priority function is at most $O(\log^2 n)$ times $\sum_{i,j} r_{ij} d_{ij}$, which is a lower bound on the generalized SP value of any alignment. The Feng–Doolittle procedure guarantees that the generalized SP value of the resulting alignment is at most the communication cost of the tree which in turn is at most $O(\log^2 n)$ times the generalized SP value of any alignment.

3. Definitions.

Throughout the paper we will be referring to a given weighted, connected, undirected graph $G = (V, E, w)$, where we assume $V = \{1, \dots, n\}$ and w is a nonnegative edge weight function, not necessarily metric. For a subset $S \subseteq V$, by $\mathcal{P}(S)$ we denote the set of all unordered pairs of elements of S.

DEFINITION 3.1. *Let $G = (V, E, w)$ and $i, j \in V$. Let $S = (V_S, E_S, w)$ be a subgraph of G. By $SP(S, i, j)$ we denote a shortest path from i to j on S. When S is a tree, $SP(S, i, j)$ denotes the unique path between i and j.*

DEFINITION 3.2. *Let S be a subgraph of G and $i, j \in V$. The weight of S is denoted by $w(S) = \sum_{e \in E_S} w(e)$. The distance of i and j in S is denoted by $d_S(i, j) := w(SP(S, i, j))$. We define $d_G(i, S) = \min_{j \in V_S} d_G(i, j)$. If T is a tree and $S \subset T$, we denote the value $w(SP(T, i, j) \cap S)$ by $w_S(T, i, j)$.*

DEFINITION 3.3. *Let S be a subgraph of G. The* routing cost *of S is defined as $C(S) = \sum_{(i,j) \in \mathcal{P}(V_S)} d_S(i, j)$.*

DEFINITION 3.4. *Given a graph $G = (V, E, w)$, the* minimum routing cost spanning tree problem (MRCT) *is to find a spanning tree $\widehat{T}_G$ of G such that $C(\widehat{T}_G)$ is minimum.*

DEFINITION 3.5. *A* metric graph $G = (V, E, w)$ *is a complete graph in which* $w(i, j) \geq 0$ *and* $w(i, j) + w(j, k) \geq w(i, k)$ *for all* $i \neq j \neq k \in V$.

DEFINITION 3.6. *The* metric closure *of* G *is the complete weighted graph* $\bar{G} = (V, \mathcal{P}(V), \delta)$, *where* $\delta(i, j) := d_G(i, j)$ *for all* $(i, j) \in \mathcal{P}(V)$. *Note that* $\bar{G}$ *is a metric graph.*

DEFINITION 3.7. *Given a metric graph* G, *the* metric minimum routing cost spanning tree problem *(*ΔMRCT*) is to find a spanning tree* T *of* G *such that* $C(T)$ *is minimum.*

4. A reduction from the general to the metric case.

Let $G = (V, E, w)$ and $\bar{G} = (V, \mathcal{P}(V), \delta)$ be its metric closure. In this section, we present an algorithm which can transfer a spanning tree of $\bar{G}$ into a spanning tree of G without increasing cost. This implies that we can solve the MRCT problem on G by solving the same problem on $\bar{G}$. An edge (a, b) in $\bar{G}$ is termed a *bad edge* if $(a, b) \notin E$ or $w(a, b) > \delta(a, b)$. For any bad edge $e = (a, b)$, there must exist a path $P \neq e$ such that $w(P) = \delta(a, b)$. Given any spanning tree T of $\bar{G}$, the algorithm iteratively replaces bad edges (if any) in T with edges from the path defining the weight of the edge until there are no more bad edges in the tree. Since the resulting tree Y has no bad edge, it can be thought of as a spanning tree of G with the same cost. It will be shown later that the iteration will be executed at most $O(n^2)$ times and the cost is never increased while replacing the bad edges. The algorithm listed below details how to obtain Y from T.

Algorithm Remove_bad
Input: a spanning tree T of $\bar{G}$
Output : a spanning tree Y of G (i.e., without any bad edge) such that $C(Y) \leq C(T)$.

```
Compute all-pairs shortest paths of $G$.
while there exists a bad edge in $T$                                  (1)
    Pick a bad edge $(a, b)$. Root $T$ at $a$.
    /* assume $SP(G, a, b) = (a, x, ..., b)$ and $y$ is the father of $x$ in $T$ */
    if $b$ is not an ancestor of $x$ then
        $Y_1 = T \cup (x, b) - (a, b)$
        $Y_2 = Y_1 \cup (a, x) - (x, y)$
    else
        $Y_1 = T \cup (a, x) - (a, b)$
        $Y_2 = Y_1 \cup (b, x) - (x, y)$
    endif
    if $C(Y_1) < C(Y_2)$ then
        $Y = Y_1$
    else
        $Y = Y_2$
    endif
    $T = Y$                                                           (2)
endwhile
```

We assume that the shortest paths obtained in the beginning of the algorithm have the following property: If the obtained shortest path between a and b is $(a, x) \cup P$, then P is the obtained shortest path between x and b. Note that since x is on the shortest a-b path, $\delta(a, b) = \delta(a, x) + \delta(x, b)$.

PROPOSITION 4.1. *The loop* (1) *is executed at most* $O(n^2)$ *times.*

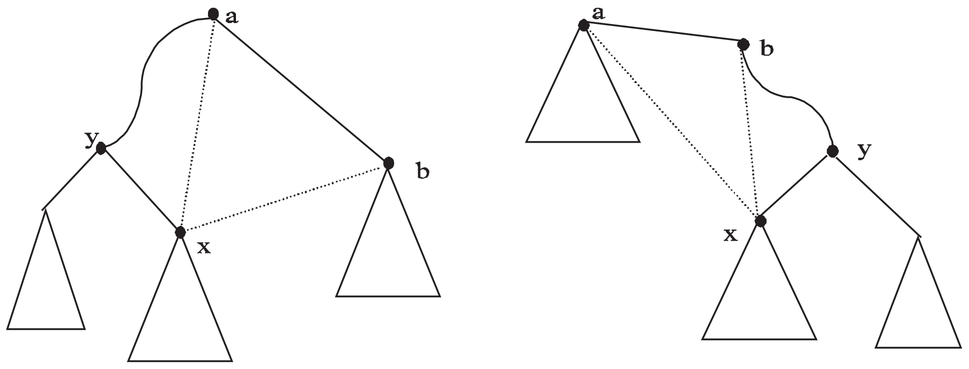

FIG. 4.1. *Remove bad edge (a, b). Case 1 (left) and Case 2 (right).*

Proof. For each bad edge $e = (a, b)$, let $l(e)$ be the number of edges in $SP(G, a, b)$ and $f(T) = \sum_{\text{bad } e} l(e)$. Since $l(e) \leq n - 1$, $f(T) < n^2$. Since $l(x, b) < l(a, b)$ and (a, x) is not a bad edge, it is easy to check that $f(T)$ decreases by at least 1 at each loop iteration. □

PROPOSITION 4.2. *Before instruction* (2) *is executed, $C(Y) \leq C(T)$.*

Proof. For any node v, define $S_v = \{u | v \text{ is an ancestor of } u \text{ on } T\} \cup \{v\}$. Also, let $C(T, S_1, S_2) = \sum_{i \in S_1, j \in S_2} d_T(i, j)$.

Case 1. (see Figure 4.1.) $x \in S_a - S_b$. If $C(Y_1) \leq C(T)$, the result follows. Otherwise, let $S_1 = S_a - S_b$ and $S_2 = S_a - S_b - S_x$. Since the distance between any two vertices both in S_1 (or both in S_b) does not change, we have

$$\begin{aligned}
&C(T) < C(Y_1) \\
\Rightarrow\ &C(T, S_1, S_b) < C(Y_1, S_1, S_b) \\
\Rightarrow\ &|S_b| C(T, a, S_1) + |S_1||S_b| \delta(a, b) < |S_b| C(T, x, S_1) + |S_1||S_b| \delta(x, b) \\
\Rightarrow\ &C(T, a, S_1) + |S_1| \delta(a, b) < C(T, x, S_1) + |S_1| \delta(x, b) \\
\Rightarrow\ &C(T, a, S_1) < C(T, x, S_1) - |S_1| \delta(a, x).
\end{aligned}$$

The last inequality follows from the property of the shortest path lengths alluded to earlier.

Also,

$$C(Y_2) - C(T) = (C(Y_2, S_2, S_x) - C(T, S_2, S_x)) + (C(Y_2, S_b, S_1) - C(T, S_b, S_1)).$$

Since $d_{Y_2}(i, j) \leq d_T(i, j)$ for $i \in S_b$ and $j \in S_1$, the second term is not positive, and

$$\begin{aligned}
&C(Y_2) - C(T) \\
&\leq C(Y_2, S_2, S_x) - C(T, S_2, S_x) \\
&= |S_x| C(T, a, S_2) + |S_2||S_x| \delta(a, x) - |S_x| C(T, x, S_2) \\
&= |S_x| ((C(T, a, S_1) - C(T, a, S_x)) + \ |S_2| \delta(a, x) - (C(T, x, S_1) - C(T, x, S_x))) \\
&= |S_x| ((C(T, a, S_1) - C(T, x, S_1)) + \ |S_2| \delta(a, x) + (C(T, x, S_x) - C(T, a, S_x))) \\
&< |S_x| \left(-|S_1| \delta(a, x) + |S_2| \delta(a, x)\right) \\
&\leq 0.
\end{aligned}$$

Case 2. $x \in S_b$. The case is identical to Case 1 if we reroot the tree at b and follow the analysis in Case 1 exchanging the roles of a and b. □

As a direct consequence of Propositions 4.1 and 4.2 we obtain the following lemma.

LEMMA 4.3. *Given a spanning tree T of $\bar{G}$, the algorithm Remove_bad constructs a spanning tree Y of G with $C(Y) \le C(T)$ in $O(n^3)$ time.*

The above lemma implies that $C(\widehat{T}_G) \le C(\widehat{T}_{\bar{G}})$. Since, for any edge, the weight on the original graph is no less than the weight on the metric closure, it is easy to see that $C(\widehat{T}_G) \ge C(\widehat{T}_{\bar{G}})$. Therefore, we have the following corollary.

COROLLARY 4.4. $C(\widehat{T}_G) = C(\widehat{T}_{\bar{G}})$.

COROLLARY 4.5. *If there is a $(1+\varepsilon)$-approximation algorithm for* ΔMRCT *with time complexity $O(f(n))$, then there is a $(1+\varepsilon)$-approximation algorithm for* MRCT *with time complexity $O(f(n)+n^3)$.*

Proof. Let G be the input graph for a MRCT problem. We can construct $\bar{G}$ in time $O(n^3)$ (see, e.g., [7]). If there is a $(1+\varepsilon)$-approximation algorithm for the ΔMRCT problem, we can compute in time $O(f(n))$ a spanning tree T_1 of $\bar{G}$ such that $C(T_1) \le (1+\varepsilon)C(\widehat{T}_{\bar{G}})$. Using Algorithm Remove_bad, we can then construct a spanning tree T_2 of G such that $C(T_2) \le C(T_1) \le (1+\varepsilon)C(\widehat{T}_{\bar{G}}) = (1+\varepsilon)C(\widehat{T}_G)$. The overall time complexity is then $O(f(n)+n^3)$. ◻

5. A PTAS for the ΔMRCT problem.

5.1. Overview. As described in the previous section, the fact that the costs w may not obey the triangle inequality is irrelevant, since we can simply replace these costs by their metric closure. Therefore, in this and the following sections we may assume that $G = (V, E, w)$ is a metric graph. We remind the reader that $n = |V|$. Also, for a subgraph G' of G, we use $V(G')$ to denote the vertex set of G'.

To establish the performance guarantee, we use k-stars, i.e., trees with no more than k internal nodes. In section 6 we show that for any constant k, the minimum routing cost k-star can be determined in polynomial (in n) time. In order to show that a k-star achieves a $(1+\epsilon)$ approximation, we show that, for any tree T and constant $\delta \le 1/2$:

1. It is possible to determine a δ-separator (a particular subtree of T to be defined later), and the separator can be cut into several δ–paths such that the total number of cut nodes and leaves of the separator is at most $\lceil \frac{2}{\delta} \rceil - 3$ (Lemma 5.9).
2. Using the separator, T can be converted into a $(\lceil \frac{2}{\delta} \rceil - 3)$-star $X(T)$, whose internal nodes are just those cut nodes and leaves. The routing cost of $X(T)$ satisfies $C(X(T)) \le (1 + \frac{\delta}{1-\delta})C(T)$ (Lemma 5.13).

By using $T = \widehat{T}_G$, $\delta = \frac{\epsilon}{1+\epsilon}$ and finding the best $(\lceil \frac{2}{\delta} \rceil - 3)$-star K, we obtain $C(K) \le C(X(\widehat{T}_G)) \le (1+\frac{\delta}{1-\delta})C(\widehat{T}_G) = (1+\epsilon)C(\widehat{T}_G)$, i.e., the desired approximation.

5.2. The δ-spine of a tree.

DEFINITION 5.1. *Let T be a spanning tree of G and S be a connected subgraph of T. A* branch *of S is a connected component of $T \setminus S$. Let $\delta \le 1/2$ be a positive number. If $|V(B)| \le \delta n$ for every branch B of S, then S is a δ-*separator *of T. A δ-separator S is* minimal *if any proper subgraph of S is not a δ-separator of T.*

Intuitively, a δ-separator is like a "center" of the tree. Starting from any node, there are sufficiently many nodes which cannot be reached without touching the separator. To illustrate the concept of separator, we examine the simplest case for $\delta = 1/2$. For any tree T, there always exists a $1/2$-separator which contains only one vertex. That is, we can always cut a tree at a node c such that each branch contains at most

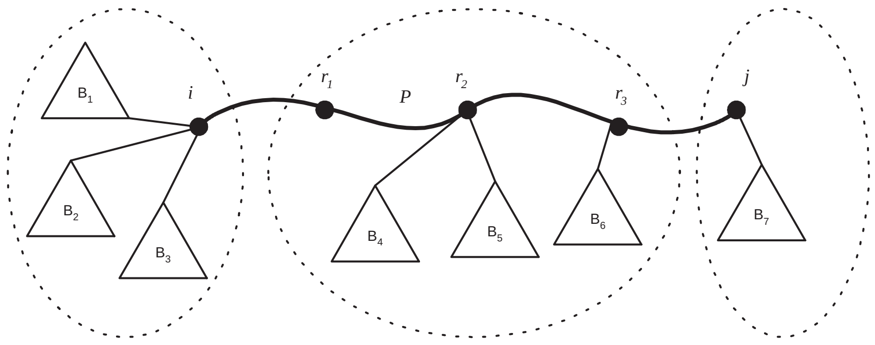

FIG. 5.1. *$B_1, \ldots, B_7$ are branches of P. $VB(T, P, i) = \{i\} \cup V(B_1) \cup V(B_2) \cup V(B_3)$. P^c is the number of vertices in $\{r_1, r_2, r_3\} \cup V(B_4) \cup V(B_5) \cup V(B_6)$.*

half of the nodes. Such a node is usually called the *centroid* of the tree in the literature. Note that this also shows the existence of a minimal δ-separator for any $\delta \leq 0.5$.

If we construct a star X centered at the centroid c, the routing cost will be at most twice that of T. This can be easily shown as follows. First, if i and j are two nodes not in the same branch, $d_T(i, j) = d_T(i, c) + d_T(j, c)$. Consider the total distance of all *ordered* pairs of nodes on T. This value is exactly $2C(T)$ by the definition. For any node i, since each branch contains no more than half of the nodes, the term $d_T(i, c)$ will be counted in the total distance at least n times, $n/2$ times for i to others, and $n/2$ times for others to i. Hence, we have $2C(T) \geq n \sum_i d_T(i, c)$. Since $C(X) = (n-1) \sum_i d_G(i, c)$, it follows that $C(X) \leq 2C(T)$. The idea in this paper can be thought as a generalization of the above method. However, the proof is much more involved.

DEFINITION 5.2. *Let T be a spanning tree of G and S be a connected subgraph of T. For any vertex i in S, $VB(T, S, i)$ denotes the set of vertex i and the vertices in the branches connected to i.*

DEFINITION 5.3. *Let $P = SP(T, i, j)$ in which $|VB(T, P, i)| \geq |VB(T, P, j)|$. We define $P^a = |VB(T, P, i)|$, $P^b = |VB(T, P, j)|$, and $P^c = n - |VB(T, P, i)| - |VB(T, P, j)|$. Assume $P = (i, r_1, r_2, \ldots, r_h, j)$. Define $Q(P) = \sum_{1 \leq x \leq h} |VB(T, P, r_x)| \times d_T(r_x, i)$.*

The above notations are defined to simplify the expressions. P^a and P^b are the numbers of vertices that are hanging off the two endpoints of the path. Note that we always assume $P^a \geq P^b$. In the case that P contains only one edge, $P^c = 0$. The notations are illustrated in Figure 5.1.

LEMMA 5.4. *Let S be a minimal δ-separator of T. If i is a leaf of S, then $|VB(T, S, i)| > \delta n$.*

Proof. If S contains only one vertex, the result is trivial since $|VB(T, S, i)| = n$. Otherwise, if $|VB(T, S, i)| \leq \delta n$, deleting i from S we still get a δ-separator. This is a contradiction to S being minimal. $\square$

DEFINITION 5.5. *Let $1 \leq k \leq n$. A* k-star *is a spanning tree of G which has no more than k internal nodes. The set of all k-stars is denoted by $k^*(G)$. T is a* minimum k-star *if $T \in k^*(G)$ and $C(T) \leq C(Y)$ for all $Y \in k^*(G)$.*

We now turn to the notions of δ-path and δ-spine. Informally, a δ-path is a path such that not too many nodes (at most $\delta n/2$) are hanging off its internal nodes. A δ-spine is a set of edge-disjoint δ-paths, whose union is a minimal δ-separator. That is, a δ-spine is obtained by cutting the minimal δ-separator into δ-paths. In the case

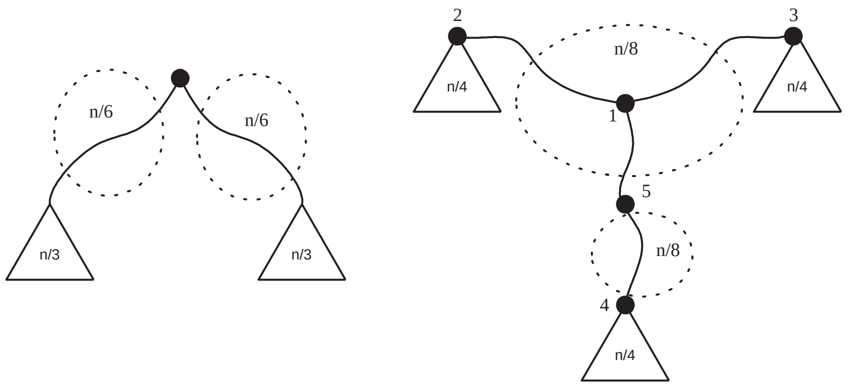

FIG. 5.2. *Trees with maximum value for the size of the minimum cut and leaf set.*

that the minimal δ-separator contains just one node, the only δ-spine is the empty set.

DEFINITION 5.6. *Given a spanning tree T of G, and $0 < \delta \leq 0.5$, a δ-path of T is a path P such that $P^c \leq \delta n/2$.*

DEFINITION 5.7. *Let $0 < \delta \leq 0.5$. A* δ-spine *$Y = \{P_1, P_2, ..., P_h\}$ of T is a set of pairwise edge-disjoint δ-paths in T such that $S = \bigcup_{1 \leq i \leq h} P_i$ is a minimal δ-separator of T. Furthermore, for any pair of distinct paths P_i and P_j in the spine, we require that either they do not intersect or, if they do, the intersection point is an endpoint of both paths.*

DEFINITION 5.8. *Let Y be a δ-spine of a tree T. $CAL(Y)$ (which stands for the* cut and leaf set *of Y) is the set of the endpoints of the paths in Y. In the case that Y is empty, the CAL set contains only one node which is the δ-separator of T. Formally $CAL(Y) = \{u | \exists P \in Y, v \in T : P = SP(T, u, v)\}$ if Y is not empty, and otherwise $CAL(Y) = \{u | u$ is the minimal δ-separator $\}$.*

Two trees achieving the maximum value for the size of the minimum CAL set for $\delta = 1/3$ ($|CAL(Y)| = 3$) and $\delta = 1/4$ ($|CAL(Y)| = 5$) are depicted in Figure 5.2. Next, we show that for any tree, there always exists a (1/3)-spine Y_1 such that $|CAL(Y_1)| \leq 3$ and a (1/4)-spine Y_2 such that $|CAL(Y_2)| \leq 5$.

LEMMA 5.9. *For any constant $0 < \delta \leq 0.5$, and spanning tree T of G, there exists a δ-spine Y of T such that $|CAL(Y)| \leq \lceil 2/\delta \rceil - 3$.*

Proof. Let S be a minimal δ-separator of T. S is a tree. Let U_1 be the set of leaves in S, U_2 be the set of vertices which have more than two neighbors in S, and $U = U_1 \cup U_2$. Let $h = |U_1|$. Clearly, $|U| \leq 2h - 2$. Let Y_1 be the set of paths obtained by cutting S at all the vertices in U_2. For example, for the tree on the right side of Figure 5.2, $U_1 = \{2, 3, 4\}$; $U_2 = \{1\}$; Y_1 contains $SP(T, 1, 2)$, $SP(T, 1, 3)$, and $SP(T, 1, 4)$. For any $P \in Y_1$, if $P^c > \delta n/2$ then P is called a *heavy* path. It is easy to check that Y_1 satisfies the requirements of a δ-spine except that there may exist some heavy paths. Suppose P is not a δ-path. We can break it up into δ-paths by the following process. First find the longest prefix of P starting at one of its endpoints and ending at some internal vertex, i, say, in the path, that determines a δ-path. Now we break P at vertex i. Then we repeat the breaking process on the remaining suffix of P starting at i stripping off the next δ-path and so on. In this way P can be cut into δ-paths by breaking it in at most $\lceil 2P^c/(\delta n) \rceil - 1$ vertices. Since there are at least δn nodes hung at each leaf,

$$\sum_{P\in Y_1} P^c < n - h\delta n.$$

Assume U_3 to be the minimal vertex set for cutting the heavy paths to result in a δ-spine Y of T. We have

$$|U_3| \leq \lceil 2\,(n - h\delta n)\,/\,(\delta n)\rceil - 1 = \lceil 2/\delta\rceil - 2h - 1.$$

So, $|CAL(Y)| = |U| + |U_3| \leq \lceil 2/\delta\rceil - 3.$ □

5.3. Lower bound.

DEFINITION 5.10. *The* routing load *of an edge e in T is the number $e^a e^b$ of pairs in T connected by a path containing e.*

The following lemma is immediate.

LEMMA 5.11. *For any spanning tree T of G, $C(T) = \sum_{e\in T} e^a e^b w(e)$.*

LEMMA 5.12. *Let Y be a δ-spine of a spanning tree T of G and $S = \bigcup_{P\in Y} P$ be a minimal δ-separator of T. Then*

$$C(T) \geq (1-\delta)n\sum_{v\in V} d_T(v,S) + \sum_{P\in Y}\left(P^b(P^a+P^c)w(P) + (P^a - P^b)Q(P)\right).$$

Proof. Since $e^a \geq (1-\delta)n$ for any edge $e \in T\setminus S$, we have

$$\begin{aligned}
C(T) &= \sum_{e\in T} e^a e^b w(e)\\
&\geq \sum_{e\in T\setminus S}(1-\delta)ne^b w(e) + \sum_{e\in S} e^a e^b w(e)\\
&\geq (1-\delta)n\sum_{v\in V} d_T(v,S) + \sum_{P\in Y}\sum_{e\in P} e^a e^b w(e).
\end{aligned}$$

Now we simplify the second term. Assume $P = (r_0, r_1, r_2, \ldots, r_h)$ in which $|VB(T,P,r_0)| \geq |VB(T,P,r_h)|$. Let $|VB(T,P,r_i)| = n_i$ for $1 \leq i \leq h-1$ and $e_i = (r_{i-1}, r_i)$ for $1 \leq i \leq h$.

$$\begin{aligned}
&\sum_{e\in P} e^a e^b w(e)\\
&= \sum_{i=1}^{h}\left(P^a + P^c - \sum_{j=i}^{h-1} n_j\right)\left(P^b + \sum_{j=i}^{h-1} n_j\right) w(e_i)\\
&\geq \sum_{i=1}^{h} P^b\left(P^a + P^c\right) w(e_i) + \left(P^a - P^b\right)\sum_{i=1}^{h}\sum_{j=i}^{h-1} n_j w(e_i)\\
&\quad + \sum_{i=1}^{h}\left(\sum_{j=i}^{h-1} n_j\right)\left(P^c - \sum_{j=i}^{h-1} n_j\right) w(e_i)\\
&\geq P^b(P^a+P^c)w(P) + (P^a - P^b)\sum_{j=1}^{h-1} n_j\left(\sum_{i=1}^{j} w(e_i)\right)\\
&= P^b\left(P^a + P^c\right) w(P) + (P^a - P^b)Q(P).
\end{aligned}$$

This completes the proof. □

5.4. From trees to stars.

LEMMA 5.13. *For any constant $0 < \delta \leq 0.5$, there exists a spanning tree $X \in (\lceil 2/\delta \rceil - 3)^*(G)$ such that $C(X) \leq \frac{1}{1-\delta} C(\widehat{T}_G)$.*

Proof. Let $T = \widehat{T}_G = (V, E, w)$ and $n = |V|$. Also, let $Y = \{P_i | 1 \leq i \leq h\}$ be a δ-spine of T in which $|CAL(Y)| \leq \lceil 2/\delta \rceil - 3$. Note that the set of all the edges in Y form a δ-separator S. Assume $P_i = SP(T, u_i, v_i)$ and $|VB(T, P_i, u_i)| \geq |VB(T, P_i, v_i)|$.

We construct a spanning tree whose internal nodes are exactly the CAL set of the δ-spine we just identified. We connect these nodes by short-cutting paths along the spine to include a set of acyclic edges with the same skeletal structure as the spine. All vertices in subtrees hanging off the CAL nodes of the spine are connected directly to their closest node in the spine. Along a δ-path in the spine, all the internal nodes and nodes in subtrees hanging off internal nodes are connected to one of the two endpoints of this path (note that both are in the CAL set of the spine) in such a way as to minimize the resulting routing cost. This is the spanning tree used to argue the upper bound on the routing cost in the proof.

More formally, construct a subgraph $R \subset G$ with vertex set $CAL(Y)$ and edge set $E_r = \{(u_i, v_i) | 1 \leq i \leq h\}$. Trivially, R is a tree. Let $f(i)$ be an indicator variable such that if $\left(P_i^a - P_i^b\right) P_i^c w(P_i) - n\left(2Q(P_i) - P_i^c w(P_i)\right) \geq 0$ then $f(i) = 1$, else $f(i) = 0$. The indicator variable $f(i)$ determines the endpoint of P_i to which all the internal nodes and nodes hanging off such internal nodes will be directly connected. We construct a spanning tree X of G where the edge set E_x is determined by the following rules:

1. $R \subset X$.
2. If $q \in VB(T, S, r)$, then $(q, r) \in E_x$, for any $r \in \{u_i, v_i | 1 \leq i \leq h\}$.
3. For the vertex set $V_i = V - VB(T, P_i, u_i) - VB(T, P_i, v_i)$, if $f(i) = 1$, then $\{(q, u_i) | q \in V_i\} \subset E_x$, else $\{(q, v_i) | q \in V_i\} \subset E_x$. That is, the vertices in V_i are either all connected to u_i or all connected to v_i.

It is easy to see that $X \in (\lceil 2/\delta \rceil - 3)^*(G)$. Let's consider the cost of X.

$$\begin{aligned} C(X) &= \sum_{e \in E_x} e^a e^b w(e) \\ &= \sum_{e \in E_r} e^a e^b w(e) + (n-1) \sum_{e \in E_x - E_r} w(e). \end{aligned}$$

First, for any $e = (u_i, v_i) \in E_r$,

$$\begin{aligned} e^a e^b w(e) &\leq \left(P_i^a + f(i) P_i^c\right)\left(P_i^b + (1 - f(i)) P_i^c\right) w(P_i) \\ &= P_i^a P_i^b w(P_i) + \left(f(i) P_i^b + (1 - f(i)) P_i^a\right) P_i^c w(P_i). \end{aligned}$$

Recall that for subset of edges $S \subset T$, $w_S(T, i, j)$ stands for $w(SP(T, i, j) \cap S)$. Second, by the triangle inequality,

$$\begin{aligned} \sum_{e \in E_x - E_r} w(e) &\leq \sum_{v \in V} d_T(v, S) + \sum_{i=1}^{h} \sum_{v \in V_i} \left(f(i) w_S(T, v, u_i) + (1 - f(i)) w_S(T, v, v_i)\right) \\ &= \sum_{v \in V} d_T(v, S) + \sum_{i=1}^{h} \left(f(i) Q(P_i) + (1 - f(i))\left(P_i^c w(P_i) - Q(P_i)\right)\right). \end{aligned}$$

Thus,

$$\begin{aligned} C(X) &\leq \sum_{i=1}^{h} P_i^a P_i^b w(P_i) + n \sum_{v\in V} d_T(v,S) \\ &\quad + \sum_{i=1}^{h} \min\{P_i^b P_i^c w(P_i) + nQ(P_i), P_i^a P_i^c w(P_i) + n(P_i^c w(P_i) - Q(P_i))\}. \end{aligned}$$

Since the minimum of two numbers is not larger than their weighted mean, we have

$$\begin{aligned} &\min\{P_i^b P_i^c w(P_i) + nQ(P_i), P_i^a P_i^c w(P_i) + n\left(P_i^c w(P_i) - Q(P_i)\right)\} \\ &\leq \left(P_i^b P_i^c w(P_i) + nQ(P_i)\right) \frac{P_i^a}{P_i^a + P_i^b} + \left(P_i^a P_i^c w(P_i) + n\left(P_i^c w(P_i) - Q(P_i)\right)\right) \frac{P_i^b}{P_i^a + P_i^b}. \end{aligned}$$

Then,

$$\begin{aligned} C(X) &\leq \sum_{i=1}^{h} P_i^a P_i^b w(P_i) + n \sum_{v\in V} d_T(v,S) + \sum_{i=1}^{h} \frac{\left(2P_i^a P_i^b P_i^c + nP_i^b P_i^c\right) w(P_i)}{P_i^a + P_i^b} \\ &\quad + \sum_{i=1}^{h} \frac{(P_i^a - P_i^b) nQ(P_i)}{P_i^a + P_i^b} \\ &= n \sum_{v\in V} d_T(v,S) + \sum_{i=1}^{h} \frac{w(P_i)}{P_i^a + P_i^b} \left(\left(P_i^a P_i^b + P_i^b P_i^c\right) n + P_i^a P_i^b P_i^c\right) \\ &\quad + \sum_{i=1}^{h} \frac{(P_i^a - P_i^b) nQ(P_i)}{P_i^a + P_i^b}. \end{aligned}$$

The simplification in the last inequality uses the observation that for any i, we have $P_i^a + P_i^b + P_i^c = n$. By Lemma 5.12,

$$C(X) \leq C(T) \max_{1\leq i\leq h} \left\{ \frac{1}{1-\delta}, \frac{n}{P_i^a + P_i^b} + \frac{P_i^a P_i^c}{(P_i^a + P_i^b)(P_i^a + P_i^c)} \right\}.$$

Since $P_i^c \leq \delta n/2$,

$$\begin{aligned} &\frac{n}{P_i^a + P_i^b} + \frac{P_i^a P_i^c}{(P_i^a + P_i^b)(P_i^a + P_i^c)} \\ &\leq \frac{n}{P_i^a + P_i^b} + \frac{P_i^c}{P_i^a + P_i^b} \\ &= \frac{n + P_i^c}{n - P_i^c} \leq \frac{2+\delta}{2-\delta} \leq \frac{1}{1-\delta}. \end{aligned}$$

This completes the proof. □

In the following section we will show that it is possible to determine the minimum k-star of a graph in polynomial time. In fact, we have the following lemma.

LEMMA 5.14. *The minimum k-star of a graph G can be constructed in time $O(n^{2k})$.*

The proof is delayed to the next section. The following theorem establishes the time-complexity of our PTAS.

THEOREM 5.15. *There exists a PTAS for the* ΔMRCT *problem, which can find a* $(1{+}\varepsilon)$*-approximation solution in* $O(n^\rho)$ *time complexity where* $\rho = 2\lceil 2/\varepsilon \rceil - 2$.

Proof. By Lemma 5.13, there exists a spanning tree $X \in (\lceil 2/\delta \rceil - 3)^*(G)$ such that $C(X) \leq \frac{1}{1-\delta} C(\widehat{T}_G)$. For finding a $(1{+}\varepsilon)$-approximation solution, we set $1/\delta = (1/\varepsilon) + 1$ and find a minimum k-star with $k = \lceil 2/\delta \rceil - 3 = \lceil 2/\varepsilon \rceil - 1$. The time complexity is $O(n^\rho)$ where $\rho = 2\lceil 2/\varepsilon \rceil - 2$ from Lemma 5.14. ◻

The result in Theorem 1.1 is immediately derived from Theorem 5.15 and Corollary 4.5.

6. Finding the best *k*-star.

In this section we describe an algorithm for finding the minimum routing cost k-star in G for a given value of k. As mentioned before, given an accuracy parameter $\epsilon > 0$, we apply this algorithm for $k = \lceil \frac{2}{\epsilon} - 1 \rceil$ and return the minimum routing cost k-star as a $(1+\epsilon)$-approximate solution.

For a given k, to find the best k-star, we consider all possible subsets S of vertices of size k, and for each such choice, find the best k-star where the remaining vertices have degree one.

6.1. A polynomial-time method.

First, we verify that the overall complexity of this step is polynomially bounded for any fixed k. Any k-star can be described by a triple $(S, \tau, \mathcal{L})$, where $S = \{v_1, \ldots, v_k\} \subseteq V$ is the set of k distinguished vertices which may have degree more than one, τ is a spanning tree topology on S, and $\mathcal{L} = (L_1, \ldots, L_k)$, where $L_i \subseteq V \setminus S$ is the set of vertices connected to vertex $v_i \in S$.

Let $l = (l_1, \ldots, l_k)$ be a nonnegative k-vector[2] such that $\sum_{i=1}^{k} l_i = n - k$. We say that a k-star $(S, \tau, \mathcal{L})$ has the configuration (S, τ, l) if $l_i = |L_i|$ for all $1 \leq i \leq k$. For a fixed k, the total number of configurations is $O(n^{2k-1})$ since there are $\binom{n}{k}$ choices for S, k^{k-2} possible tree topologies on k vertices, and $\binom{n-1}{k-1}$ possible such k-vectors. (To see this, observe that every such vector can be put in correspondence with picking $k-1$ among $n-1$ linearly ordered elements and using the cardinalities of the segments between consecutively picked segments as the components of the vector.) Note that any two k-stars with the same configuration have the same routing load on their corresponding edges. We define $\alpha(S, \tau, l)$ to be the minimum routing cost k-star with configuration (S, τ, l).

Note that any vertex v in $V \setminus S$ that is connected to a node $s \in S$ contributes a term of $w(v, s)$ multiplied by its routing load of $n-1$. Since all these routing loads are the same, the best way of connecting the vertices in $V \setminus S$ to nodes in S is obtained by finding a minimum-cost way of matching up the nodes of $V \setminus S$ to those in S which obey the degree constraints on the nodes of S imposed by the configuration, where the costs are the distances w. This problem can be solved in polynomial time for a given configuration (by a straightforward reduction to an instance of minimum-cost perfect matching). The above minimum-cost perfect matching problem, also called the *assignment* problem, has been well studied and several efficient algorithms can be found in [1]. For instance, by using an $O(n^3)$ algorithm for the assignment problem, the overall complexity would be $O(n^{2k+2})$ for finding the best k-star.

6.2. A faster method.

We now show how the minimum k-stars for the different configurations can be computed more efficiently by carefully ordering the matching problems for the configurations and exploiting the common structure of two consecutive problems. In particular, we show how we can obtain the optimal solution of any configuration in this order by performing a single augmentation on the optimal

[2]For any $r \in Z^+$, an r-vector is an integer vector with r components.

solution of the previous configuration. Thus, we show (Lemma 6.2) how to compute $\alpha(S, \tau, l)$ for a given configuration in time $O(nk)$.

Let W_{ab} be the set of all nonnegative a-vectors whose entries add up to a constant b. In $W_{ab} \times W_{ab}$, we introduce the relation $\sim$ as $l \sim l'$ if there exist $1 \leq s, t \leq a$ such that

$$l'_i = \begin{cases} l_i - 1 & \text{if } i = s, \\ l_i + 1 & \text{if } i = t, \\ l_i & \text{otherwise.} \end{cases}$$

For a pair l and l' such as the above, we say that l' *is obtained from* l *by* s *and* t.

Let $r = |W_{ab}| = \binom{a+b-1}{a-1}$. The following proposition shows that the elements of W_{ab} can be linearly ordered as $l^1, \ldots, l^r$ so that $l^{i+1} \sim l^i$ for all $1 \leq i \leq r-1$.

PROPOSITION 6.1. *For all positive integers a, b, there exists a permutation $\pi^{a,b}$ of W_{ab} such that $\pi^{a,b}_1$ is the lexicographic minimum, $\pi^{a,b}_r$ is the lexicographic maximum, and $\pi^{a,b}_{i+1} \sim \pi^{a,b}_i$ for all $i = 1, \ldots, r-1$.*

Proof. By induction. The claim is clearly true when $a = 1$ for any b. Assume the claim is true for all b when $a = m - 1$. For $a = m$ construct the ordering as follows: first, the elements for which $l_1 = 0$, ordered by applying $\pi^{a-1,b}$ to $(l_2, \ldots, l_a)$; then the elements for which $l_1 = 1$, ordered according to *decreasing* $\pi^{a-1,b-1}$. In general each block for which $l_1 = h$ is ordered by applying $\pi^{a-1,b-h}$ to $(l_2, \ldots, l_a)$, forward or backward according to the parity of h. Note that $\pi^{a,b}_{i+1} \sim \pi^{a,b}_i$ within one block. Furthermore, at block boundaries the part $(l_2, \ldots, l_a)$ is either a lexicographic minimum or maximum so that it is feasible to increase by one l_1. Finally, it is obvious that the first and the last of the constructed ordering are the lexicographic minimum and maximum respectively. ∎

According to Proposition 6.1 we can order the elements of $W_{k,(n-k)}$ as $l^1, \ldots, l^r$, where $r = \binom{n-1}{k-1}$. Note that $l^1 = (0, \ldots, 0, n-k)$ and $l^r = (n-k, 0, \ldots, 0)$. In the remainder of this section, we shall prove the following lemma.

LEMMA 6.2. *$\alpha(S, \tau, l^{i+1})$ can be computed from $\alpha(S, \tau, l^i)$ in $O(nk)$ time.*

Proof. We shall show that $\alpha(S, \tau, l^{i+1})$ can be found from $\alpha(S, \tau, l^i)$ by means of a shortest path computation. A similar argument is used in [1, Exercise 10.20]; for solving a minimum cost flow problem given the solution of another minimum cost flow problem which differs by only one unit capacity arc.

For convenience, let us rename the vertices so that $S = \{1, \ldots, k\}$. Let $l^i = (|L_1|, \ldots, |L_k|)$ and $(S, \tau, \mathcal{L}) = \alpha(S, \tau, l^i)$. Let us define an auxiliary weighted digraph $D(\mathcal{L}) = (V, A, \delta)$ in which the arc set is $A = \{(u, v) | u \in V \setminus S, v \in S\} \cup \{(u, v) | u \in S, v \in L_u\}$ and $\delta(u, v) = w(u, v)$ if $u \notin S$, and $\delta(u, v) = -w(u, v)$ if $u \in S$. For a node in S, the weight on an outgoing arc reflects the cost reduction for removing a leaf from its neighbors, and the weight on an incoming arc reflects the increase in cost for connecting a leaf to the node.

It is immediately seen that any cycle (not necessary simple) in the graph describes a way of changing $(S, \tau, \mathcal{L})$ into another k-star with the same configuration, and the difference in cost between the new and the old k-stars is given by $(n-1)$ times the length of the cycle. Because $(S, \tau, \mathcal{L})$ is optimal for its configuration, there is no negative length cycle in $D(\mathcal{L})$.

Similarly, if l^{i+1} is obtained from l^i by s and t, then any path from s to t in $D(\mathcal{L})$ changes $(S, \tau, \mathcal{L})$ into a k-star with configuration (S, τ, l^{i+1}). Conversely, any k-star with configuration (S, τ, l^{i+1}) can be obtained by a path from s to t and possibly some cycles. Since positive length cycles contribute positive cost and there is no negative length cycle, it is clear that there is a path P from s to t, changing $\alpha(S,\tau,l^i)$ into $\alpha(S,\tau,l^{i+1})$, which is simple. To see that it must be a shortest s-t path, let P' be any path from s to t, which changes $\alpha(S,\tau,l^i)$ into a k-star K'. Since K' has the same configuration of $\alpha(S,\tau,l^{i+1})$, the difference between their costs is given by $(n-1)(\delta(P')-\delta(P))$. Therefore, we conclude that P must be the shortest path from s to t in $D(\mathcal{L})$. We now show how such a shortest path can be computed in $O(kn)$ time.

Consider any shortest path $(u_1, v_1, u_2, \dots, v_{h-1}, u_h)$ between two nodes $u_i \in S$ and $v_i \in V \setminus S$ in $D(\mathcal{L})$. Take two consecutive edges (u_i, v_i) and (v_i, u_{i+1}) in the path. Since the path is shortest, v_i must be such as to minimize the sum of the two edge lengths. Recall that $\delta(u_i, v_i) = -w(u_i, v_i)$ and $\delta(v_i, u_{i+1}) = w(v_i, u_{i+1})$. Then, we have that the sum of the two edge lengths is $\min_{v_i \in L_i}\{w(v_i, u_{i+1}) - w(u_i, v_i)\}$. Therefore, to find the shortest path from s to t on $D(\mathcal{L})$, it is enough to construct a complete digraph $D'(\mathcal{L})$ with vertex set S and lengths δ', in which $\delta'(i,j) = \min_{v\in L_i}\{w(v,j) - w(i,v)\}$. It is easy to see that the length of the shortest path from s to t on $D'(\mathcal{L})$ is the same as the one on $D(\mathcal{L})$. Given the graph $D'(\mathcal{L})$, a shortest s-t path (and also the corresponding path on $D(\mathcal{L})$) can be found in $O(k^2)$ time. Finally, to construct $D'(\mathcal{L})$, for each vertex $i \in S$, we have to find $k-1$ minima (one for every other $j \in S$), each over a set of l_i elements. Adding up, the total time complexity is $(k-1)\sum_{i=1}^{k} l_i = (k-1)(n-k) = O(nk)$. $\square$

We are now able to prove Lemma 5.14, i.e., that a minimum k-star can be found in time $O(n^{2k})$.

Proof. When S and τ are fixed, to find an optimum k-star we begin by $\alpha(S,\tau,l^1)$, which is readily obtained by setting $L_k = V \setminus S$. Then, using Lemma 6.2, we compute the optimal k-stars for configurations $l^2, \dots, l^r$, and we report the best overall.

In general, a minimum routing cost k-star in G can be found in time $O(n^{2k})$, given by $\binom{n}{k}$ choices for S, k^{k-2} possible tree topologies, and for each fixed S and τ, $\binom{n-1}{k-1}$ configurations, of cost $O(nk)$ each. $\square$

7. Optimal communication spanning trees. We begin with a few definitions following Bartal [3]. Let V be a set of n points and let M be a metric space defined over V. The distance between i and j in M is denoted by $d_M(i,j)$. A metric N over V dominates another metric M over V if for every pair $i,j \in V$, we have $d_N(i,j) \geq d_M(i,j)$.

Definition 7.1. *A metric N over V α-approximates a metric M over V if it dominates M and for every $i,j \in V$, we have $d_N(i,j) \leq \alpha \cdot d_M(i,j)$.*

Define a tree (or additive) metric over V as a metric space corresponding to paths in a tree which contains all the points of V. Note that we allow the tree defining the additive metric to contain points other than those in V.

We are interested in tree metrics that approximate any given metric M. However, even for the simple metric induced by arranging the nodes of V in a cycle, if we restrict ourselves to approximating this by tree metrics, $\alpha = \Omega(|V|)$ [3, 16]. Hence we turn to the following notion.

Definition 7.2. *Let M be a metric space over V. A set of metric spaces S over V α-probabilistically-approximates M, if every metric space in S dominates M and there exists a probability distribution over metric spaces $N \in S$ such that for every $i,j \in V$, $E(d_N(i,j)) \leq \alpha \cdot d_M(i,j)$.*

Bartal's main result is the following theorem.

Theorem 7.3 (see [3]). *For any metric space on V, it can be $O(\log^2 |V|)$-probabilistically approximated by a set of tree metrics on V. Furthermore, the tree* *metrics and the distribution over them can be computed in polynomial time.*

As has been observed earlier [12], it is not hard to transform the tree metrics in this theorem into spanning tree metrics, namely, those that do not contain any extra points other than those in V. We use the above theorem to approximate the given metric M by spanning tree metrics N. By using a spanning tree N randomly picked from this collection according to the given distribution as the solution, the expected value of its communication cost is $\sum_{ij} r_{ij} d_N(i,j) \leq O(\log^2 |V|) \sum_{ij} r_{ij} d_M(i,j)$ by linearity of expectation. By repeatedly picking a few trees and using the best one, this bound is achieved with high probability, giving the result in Theorem 1.2. As mentioned earlier, this bound has been improved and derandomized in [4, 6].

Acknowledgments. Thanks to Sampath Kannan for describing the relevance of the threshold objective for multiple alignments. We also thank Tao Jiang and Howard Karloff for suggesting the merger of two different works to obtain this joint paper. Finally, we thank the referees for their valuable comments.

COMPLEXITY OF DECIDING SENSE OF DIRECTION[*]

PAOLO BOLDI[†] AND SEBASTIANO VIGNA[†]

Abstract. In this paper we prove that deciding whether a distributed system (represented as a colored digraph with n nodes) has weak sense of direction is in AC^1 (using n^6 processors). Moreover, we show that deciding sense of direction is in P. Our algorithms can also be used to decide in AC^1 whether a colored graph is a Cayley color graph.

1. Introduction.

The theory of distributed computing aims at understanding the nature of cooperation in a distributed environment, where processing is carried on by agents with autonomous computing abilities, which can communicate by exchanging messages along communication links. The topological structure of such systems can be described by a graph, with nodes representing agents and arcs representing links. Each node has a local (partial) view of the system, and it associates a different label (color) with each of its incident links; in general, the color assigned to a certain link by a node may differ from the one assigned to the same link by the partner, because colors are assigned locally.

The solution to many problems in a distributed system can be greatly simplified by using colorings with special properties. In this paper we analyze from the point of view of complexity theory a property known as *(weak) sense of direction* [FMS98]; more precisely, we study the complexity of deciding whether a network with a given coloring has (weak) sense of direction or not.

Sense of direction can be intuitively described as follows. Suppose that every time a message passes through a link, it picks up the color of the link. At destination, the message will possess the entire string of colors of the links it passed through along its route. Our problem is to tell whether two messages have been sent by the same source or not, just by looking at their strings of colors. Since each node assigns a different color to each of its incident links, if every agent has a complete view of the system (and of every local coloring as well), the problem can be solved by an easy local algorithm that uses a linear backtracking technique to single out the source. But is there a way to solve the problem *globally*, with a unique function that also abstracts partially from the overall knowledge of the system? This possibility depends on some consistency property of the coloring.

Properties of global consistency have been known and used informally for a long time (see, for instance, [SAN84, LMW86, AvLSZ89]), but they were not formalized until [FMS98]: that definition, now widely accepted, allowed their systematic study. In the present paper, we will characterize for the first time weak sense of direction in a combinatorial manner and show that it can be decided efficiently in parallel;

namely, we will prove that the presence of weak sense of direction can be decided in logarithmic time using n^6 processors.

However, having weak sense of direction is in general not enough for practical purposes. What one usually wants is the possibility of coding the identity of the source locally in each node, without using a complete path to decode it (see, for instance, [FMS97]). In other words, each node should be able to infer the local name of the source simply using the color of the link from which the message has arrived, and the name under which the next-to-last node on the path knows the source. This property is known as *sense of direction*: again, we will characterize it combinatorially, and we will show that it is decidable in sequential polynomial time.

The upper bounds we derive are the first nontrivial ones for these decision problems, even though the algorithms we propose are not practical (due to the high number of processors, in the first case, and to the high degree of the polynomial bound, in the second case). In the last section we give some concluding remarks and notice that our results apply also to the recognition of Cayley color graphs.

2. Definitions. A *directed graph* (or, in short, a graph) G is given by a set V of n nodes and a set $A \subseteq V \times V$ of arcs. We write $P[x, y] \subseteq A^*$ for the set of paths from the node x to the node y.

An *(arc) coloring* of a graph G is a function $\lambda : A \to \mathcal{L}$, where $\mathcal{L}$ is a finite set of colors.[1] We say that λ is *deterministic* iff

$$\lambda(\langle x, y\rangle) = \lambda(\langle x, z\rangle) \implies y = z,$$

that is, if the automaton described by the transition graph G with coloring λ is deterministic. We shall frequently shift between graph-theoretic and automata-theoretic concepts when talking about a colored graph.

Our (colored) graphs will be always represented by (colored) adjacency matrices, that is, $n \times n$ matrices such that the entry indexed by $x, y \in V$ will contain 0 if no arc connects x to y; otherwise, it will contain a positive integer representing the color of the arc (or 1, if the graph has no coloring).

Given a graph G deterministically colored by λ (we shall omit in the future to mention that λ is deterministic; all colorings in this paper are such), let

$$L(x, y) = \{\, \lambda^*(\pi) \mid \pi \in P[x, y]\,\},$$

where $\lambda^* : A^* \to \mathcal{L}^*$ is defined by

$$\lambda^*(\langle x_1, x_2\rangle\langle x_2, x_3\rangle \cdots \langle x_{k-1}, x_k\rangle) = \lambda(\langle x_1, x_2\rangle)\lambda(\langle x_2, x_3\rangle) \cdots \lambda(\langle x_{k-1}, x_k\rangle).$$

In other words, $L(x, y)$ is the language recognized by G when x is the initial state and y is the final state. For all $I \subseteq V^2$ let

$$L_I = \bigcup_{\langle x,y\rangle \in I} L(x, y)$$

(of course, $L(x, y) = L_{\{\langle x,y\rangle\}}$). Notice that $\varepsilon \in L(x, x) \neq \varnothing$.

A *local naming* for G is a family of injective functions $\beta = \{\beta_x : V \to \mathcal{N}\}_{x \in V}$, with $\mathcal{N}$ a finite set, called the *name space*. Intuitively, each node x of G gives to each

[1] We remark that throughout this paper $|\mathcal{L}|$ is polynomially bounded in n. In particular, we can restrict without loss of generality to situations in which $|\mathcal{L}| \leq n^2$, for no more than n^2 colors can be actually "used" by λ.

other node y a name $\beta_x(y)$ taken from the name space. Since we require injectivity, we have that necessarily $|\mathcal{N}| \geq n$. We shall also write $\beta : V \times V \to \mathcal{N}$ for the "unindexed" local naming, that is, $\beta(x, y) = \beta_x(y)$.

Given a colored graph endowed with a local naming, a function $f : L_{V^2} \to \mathcal{N}$ is a (consistent) *coding function* iff

$$\forall x, y \in V \quad \forall \pi \in P[x, y], \qquad f(\lambda^*(\pi)) = \beta_x(y).$$

A coding function translates the coloring of the path along which two nodes x, y are connected into the name that x gives to y. Note that although the resulting name is *local* (i.e., x and z might choose different elements of the name space for the same node y), the coding function is *global*.

A coloring λ is a *weak sense of direction* for a graph G iff for some local naming there is a coding function.[2] We shall also say that a colored graph *has* weak sense of direction, or that λ *gives* weak sense of direction to G.

As an example, consider a $p \times q$ torus, where the links have the standard *compass coloring* (North/South/East/West). Each node with coordinates $\langle i, j\rangle$ (where $i \in \mathbf{Z}_p$, $j \in \mathbf{Z}_q$) gives to a node with coordinates $\langle h, k\rangle$ the local name $\langle i - h, j - k\rangle$. If a message arrives through a path colored by v, the receiver knows the sender under the local name $f(v) = \langle \#_N(v) - \#_S(v), \#_E(v) - \#_W(v)\rangle$, where $\#_N(v)$ is the number of occurrences of the "North" color in v, and so on. On the other hand, if we reverse the North/South coloring at just one node, then the resulting graph has no sense of direction, because there is no global way to detect whether the string "North North North" corresponds to a first-coordinate offset of 1 or 3.

Finally, a (consistent) *decoding function* is a map $h : \mathcal{L} \times \mathcal{N} \to \mathcal{N}$ that satisfies

$$\forall \langle x, y\rangle \in A \quad \forall z \in V \quad \forall \pi \in P[y, z], \qquad h(\lambda(\langle x, y\rangle), f(\lambda^*(\pi))) = \beta_x(z).$$

A decoding function translates the name given by y to z into the name given by x to z, knowing only the color of the arc connecting x and y. Note that, as in the case of the coding function, h is *global*.

A coloring λ is a *sense of direction* for a graph G iff for some local naming there is a coding function and a decoding function. Our previous example has also trivially sense of direction (just add the contribution of the last color).

The model of computation we use is a *common* CRCW PRAM (i.e., concurrent reads and writes are allowed, and all the processors participating to a concurrent write must write the same value). We shall denote with AC^k the class of problems that are solvable in time $O((\log n)^k)$ using a polynomial number of processors. (The classes AC^k were originally defined using boolean circuits, but they can be equivalently characterized in terms of parallel complexity; see [KR90].)

The notions of equivalence relation and partition will be used interchangeably, and equivalence relations will be represented using boolean matrices. Thus, if R is an equivalence relation, we shall indifferently write $x \; R \; y$, $R(x, y) = 1$ or $x, y \in I \in R$ (i.e., x and y belong to the same class I of the partition induced by R). If R and S are equivalence relations, we shall write $R \leq S$ whenever R is finer than S as an equivalence relation, that is, if $R \subseteq S$ (we shall also say that S is coarser than R). We

[2]Elsewhere weak sense of direction has been defined in a slightly different way by considering only nonempty paths. It is easy to check that the algorithms described here can be immediately adapted to that definition just by assuming $\varepsilon \notin L(x, x)$ and, consequently, performing a transitive (nonreflexive) closure of the matrix M in Proposition 4.1.

shall use the same notation, with the same meaning, for the associated partitions and boolean matrices. Composition of relations (or, equivalently, product of matrices) will be denoted by juxtaposition and reflexive-transitive closure of R by R^*.

We remark a difference with the notation of [FMS98]. Instead of using undirected, connected graphs with a coloring that is node dependent, we consider general colored directed graphs,[3] in which an arc from x to y represents the existence of a link *from y to x*; this apparently unnatural convention makes our presentation much simpler,[4] and it allows us to use a more standard way of coloring graphs, which highlights naturally the connections with automata and regular languages.

3. Coding functions and internal monodromy.

We will now give a purely combinatorial condition on the coloring of a graph that will be proved equivalent to being a weak sense of direction. From now onwards we shall work with finite graphs and stick to the notation of section 2 without further remarks.

DEFINITION 3.1. *Given a set X, a partition Π of X^2 is said to be* (internally) monodrome *iff*

$$\forall I \in \Pi, \qquad \langle x, y\rangle, \langle x, z\rangle \in I \implies y = z.$$

The previous definition will be extensively used throughout the paper. Note that an equivalence relation that is finer than a monodrome one is also monodrome.

THEOREM 3.2. *Let T be the equivalence relation on V^2 defined as the transitive closure of*

$$\langle x, y\rangle \sim \langle x', y'\rangle \iff L(x, y) \cap L(x', y') \neq \varnothing.$$

Then λ is a weak sense of direction iff T is monodrome.

The proof of the theorem is preceded by two lemmata. Intuitively, each element I of T will be an element of the name space. The name under which x knows y is precisely the (unique) $I \in T$ such that $\langle x, y\rangle \in I$. The idea behind the proof is that whenever the same string v of colors appears on two different paths of the graph, say from x to y and from x' to y', then necessarily $\beta_x(y) = f(v) = \beta_{x'}(y')$.

LEMMA 3.3. *Let $G = (V, A)$ be a graph with a weak sense of direction given by a coloring λ, and let β and f be the corresponding local naming and coding function; then, there exists a monodrome partition Π of V^2 such that $\Pi \geq T$ and $|\Pi| \leq |\mathcal{N}|$ (recall that $\mathcal{N}$ is the codomain of β).*

Proof. We will show that the nonempty fibers of β (i.e., the nonempty counter-images of singletons) form a monodrome partition Π of V^2 that is coarser than T (and, of course, $|\mathcal{N}| \geq |\operatorname{im}(\beta)| = |\Pi|$). Monodromy is trivial, as it is equivalent to injectivity of the naming functions β_x. Now suppose $\langle x, y\rangle, \langle x', y'\rangle \in I \in T$; then there is a chain

$$\langle x, y\rangle = \langle x_1, y_1\rangle, \langle x_2, y_2\rangle, \ldots, \langle x_k, y_k\rangle = \langle x', y'\rangle$$

such that $w_i \in L(x_i, y_i) \cap L(x_{i+1}, y_{i+1}) \neq \varnothing$ for $1 \leq i \leq k-1$. Thus, $\beta_{x_i}(y_i) = f(w_i) = \beta_{x_{i+1}}(y_{i+1})$, which implies that $\beta_x(y) = \beta_{x'}(y')$, that is, $\langle x, y\rangle, \langle x', y'\rangle \in J \in \Pi$. ∎

LEMMA 3.4. *For every monodrome partition $\Pi \geq T$ there exists a local naming β and a coding function f with name space Π.*

[3]It is easy to extend our results to graphs with parallel arcs if the set of arcs between two nodes is represented by a vector of integers, one for each color.

[4]The case studied in [FMS98] can be recovered by considering graphs that are symmetric, loopless, and strongly connected.

Proof. First of all, note that the nonempty L_I's form a partition of L_{V^2} when I ranges over T (which is monodrome). Indeed, if $w \in L_I \cap L_J$, then $w \in L(x,y) \cap L(x',y')$ for some $\langle x,y\rangle \in I, \langle x',y'\rangle \in J$. But then necessarily $I = J$. Of course, the partition Π enjoys a fortiori the same property.

Now let $\beta_x(y)$ be the unique element of Π containing $\langle x,y\rangle$, and let $f(w)$ be the unique $I \in \Pi$ such that $w \in L_I$. Then, β is a local naming and f is a coding function.

1. If $\beta_x(y) = \beta_x(z)$, then there is an element of Π including $\langle x,y\rangle$ and $\langle x,z\rangle$. But the definition of monodrome partition implies $y = z$.

2. If $\pi \in P[x,y]$ and $\lambda^*(\pi) = w$, then $w \in L(x,y)$. Now, if $I \in \Pi$ is the unique element of Π that contains $\langle x,y\rangle$, then

$$f(\lambda^*(\pi)) = f(w) = I = \beta_x(y). \qquad \square$$

The proof of Theorem 3.2 is now trivial. If G has weak sense of direction, T is the refinement of a monodrome partition by Lemma 3.3, and it is thus monodrome. On the other hand, by taking $\Pi = T$ in Lemma 3.4 we obtain a weak sense of direction from a graph G with T monodrome.

Note that even though monodromy and weak sense of direction are equivalent, it might still be the case that monodrome partitions coarser than T do not give the best possible (i.e., smallest) name spaces. Nonetheless, Lemmas 3.3 and 3.4 together guarantee that optimal naming is equivalent to optimal partitioning: indeed, if a weak sense of direction uses p names, then by Lemma 3.3 there is a monodrome partition coarser than T with $q \leq p$ classes, and in turn this partition gives by Lemma 3.4 a weak sense of direction using q names.

4. The decision problem for weak sense of direction.

Using the results of section 3 we will now establish that deciding whether a given colored graph G with n nodes has weak sense of direction is in AC^1 (using n^6 processors).

4.1. Checking monodromy.

In this section we will show how to build T using reflexive-transitive closures of suitable matrices.

PROPOSITION 4.1. *Let G be a graph with coloring λ. Let M be the $n^2 \times n^2$ boolean matrix defined by*

$$M(\langle x,x'\rangle,\langle y,y'\rangle) = 1 \iff \langle x,y\rangle,\langle x',y'\rangle \in A \ \wedge\ \lambda(\langle x,y\rangle) = \lambda(\langle x',y'\rangle).$$

Then

$$L(x,y) \cap L(x',y') \neq \varnothing \iff M^*(\langle x,x'\rangle,\langle y,y'\rangle) = 1.$$

Intuitively, the matrix M is the noncolored adjacency matrix of the (categorical) *product graph* $G \times G$, which has an arc colored by α between the nodes $\langle x,x'\rangle$ and $\langle y,y'\rangle$ iff G has arcs colored by α between x,y and between x',y'.

Proof. We have $L(x,y) \cap L(x',y') \neq \varnothing$ iff there is a string $w = \alpha_1\alpha_2\cdots\alpha_k$ such that $x \cdot w = y$ and $x' \cdot w = y'$,[5] that is, iff there are paths

$$\langle x, x\cdot\alpha_1\rangle\langle x\cdot\alpha_1, x\cdot\alpha_1\alpha_2\rangle\cdots\langle x\cdot\alpha_1\alpha_2\cdots\alpha_{k-1}, x\cdot w = y\rangle$$

and

$$\langle x', x'\cdot\alpha_1\rangle\langle x'\cdot\alpha_1, x'\cdot\alpha_1\alpha_2\rangle\cdots\langle x'\cdot\alpha_1\alpha_2\cdots\alpha_{k-1}, x'\cdot w = y'\rangle.$$

[5]We are again considering G as an automaton, and we are denoting by the dot operator the right action of the alphabet $\mathcal{L}$ on states; in other words, $x \cdot \alpha$ is the state reached from x along the unique arc colored by α, if it exists.

By the definition of M, $M(\langle z, z'\rangle, \langle z \cdot \alpha, z' \cdot \alpha\rangle) = 1$ whenever both $z \cdot \alpha$ and $z' \cdot \alpha$ are defined. Thus, $L(x, y) \cap L(x', y') \neq \varnothing$ is equivalent to reachability (i.e., reflexive-transitive closure) of $\langle y, y'\rangle$ from $\langle x, x'\rangle$ in the graph having M as adjacency matrix. ◻

The previous proposition implies that $T = N^*$, where N is the matrix obtained from M^* using the following permutation:

$$N(\langle x, y\rangle, \langle x', y'\rangle) = M^*(\langle x, x'\rangle, \langle y, y'\rangle).$$

Once the matrix T has been computed, the monodromy condition is written as follows:

$$\forall x, y, z \in V, \quad T(\langle x, y\rangle, \langle x, z\rangle) = 1 \implies y = z.$$

As a matter of fact, this condition has a simple formulation in terms of submatrices: if we divide T into n^2 submatrices of size $n \times n$, the n submatrices on the diagonal have to be identities.

4.2. Weak sense of direction is in $\mathbf{AC}^1$. We are now going to show that the operations described in the previous section can be realized using a logarithmic number of steps and n^6 processors. We first give a formal definition of our problem.

PROBLEM 4.1. WEAK SENSE OF DIRECTION.

Instance: *A graph G with coloring λ.*

Question: *Is λ a weak sense of direction?*

THEOREM 4.2. WEAK SENSE OF DIRECTION *is in AC^1.*

Proof. Given a colored graph G with n nodes, we can compute the matrix M (using the notation of the previous section) in constant time using n^4 processors (i.e., one processor per entry of M). Then we can compute M^* in logarithmic time using n^6 processors (see [KR90]). But N can be computed from M using n^4 processors and constant time, after which $T = N^*$ can be computed again in logarithmic time using n^6 processors. Monodromy of T can be trivially checked in constant time using n^3 processors. ◻

An $O(n^{4.752} \log n)$ sequential algorithm for weak sense of direction can be easily obtained from the results of section 4.1 by using fast boolean matrix multiplication [CW90]. With respect to this trivial sequential solution, the large number of processors used in the algorithm of Theorem 4.2 causes a nonnegligible $O(n^{1.248})$ loss of work. We also state the following result.

THEOREM 4.3. *The local naming β associated to a given T can be computed in constant time using n^6 processors.*

Proof. Given a row of T, we can compute the index of the column of the first nonzero element using n^4 processors and a constant number of steps.[6] This index identifies uniquely each equivalence class (of course, $\beta_x(y)$ is exactly the index associated to the row $\langle x, y\rangle$), and the thesis follows computing such indices in parallel for the n^2 rows of T. ◻

5. Decoding functions and left regularity. We now attack the problem of characterizing colored graphs that have sense of direction, that is, a decoding function, besides a local naming and a coding function. Note that weakness is not a "fake" notion: there are colored graphs that have weak sense of direction but do not have a decoding function. An example follows.

[6]Given a boolean vector $\mathtt{v}$ of m elements, we can compute the index of its first nonzero entry as follows: we first compute (in constant time and using $m(m+1)/2$ processors) a new vector $\mathtt{w}$ whose ith entry is $v_1 \vee v_2 \vee \cdots \vee v_i$. Then we set up m processors so that the ith processor outputs its index iff $w_{i-1} \neq w_i$ ($w_0 = 0$ by definition).

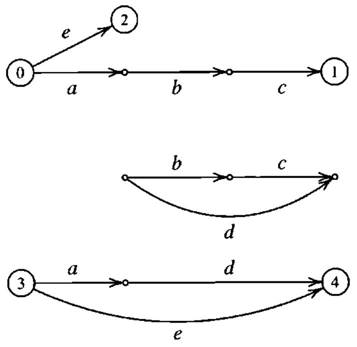

FIG. 5.1. *A graph with strictly weak sense of direction.*

The characterization of section 3 makes it clear that the graph of Figure 5.1 has weak sense of direction. (The only sets $L(x, y)$ with more than one element are $\{bc, d\}$ and $\{ad, e\}$.) Moreover, we are forced to set $f(bc) = f(d)$ for any coding function f. But as soon as we suppose the existence of a decoding function h, we obtain

$$\beta_0(1) = h(a, f(bc)) = h(a, f(d)) = \beta_3(4) = f(e) = \beta_0(2),$$

which is clearly impossible because β_0 is injective. (This example can be easily modified to obtain a symmetric connected graph with the same property—just add all arcs that are necessary assigning to each new arc a new color.)

DEFINITION 5.1. *Let G be a graph with coloring λ. A partition Π of V^2 is said to be* left regular *iff*

$$\forall I \in \Pi \quad \forall \alpha \in \mathcal{L}, \quad \exists J \in \Pi, \qquad \alpha L_I \cap L_{V^2} \subseteq L_J.$$

If a colored graph admits a left-regular monodrome partition $\Pi \geq T$, the language L_I ($I \in \Pi$), when prefixed with α, gives a sublanguage αL_I of some L_J, $J \in \Pi$. In other words, if two strings v, w live in the same language L_I, they cannot be "separated" by an α-prefixing. Note that if $\alpha L_I \cap L_{V^2} \neq \varnothing$, then J is unique.

THEOREM 5.2. *A graph G with coloring λ has sense of direction iff it admits a left-regular monodrome partition $\Pi \geq T$.*

Proof. If G admits a left-regular monodrome partition $\Pi \geq T$, we set up f and β as in Lemma 3.4, and we define $h(\alpha, f(v))$ for $\alpha \in \mathcal{L}$, $v \in L_I$ as the unique $J \in \Pi$ such that $\alpha L_I \cap L_{V^2} \subseteq L_J$ (the choice of v is, of course, irrelevant). Trivially, this definition makes h into a decoding function.

Consider now a graph G for which the coloring λ is a sense of direction. Recalling the notation of Lemma 3.3, we write Π for the monodrome partition obtained by considering the nonempty fibers of β. Thus, we can identify elements in Π with elements of the image of β. We just have to prove that Π is left regular.

Given $\alpha \in \mathcal{L}$ and $I \in \Pi$, consider strings $w_1, w_2 \in L_I$ such that $\alpha w_1, \alpha w_2 \in L_{V^2}$. Thus, we have nodes x_1, x_2 such that $x_1 \cdot \alpha w_1$ and $x_2 \cdot \alpha w_2$ are both defined. Then we have

$$\beta_{x_1}(x_1 \cdot \alpha w_1) = h(\alpha, f(w_1)) = h(\alpha, f(w_2)) = \beta_{x_2}(x_2 \cdot \alpha w_2),$$

so each string in $\alpha L_I \cap L_{V^2}$ belongs to the same L_J, $J \in \Pi$. ◻

The problem we face when using left regularity to check for the existence of a decoding function is that in principle we should check *all* possible monodrome partitions coarser than T, and such a test would clearly lead to a combinatorial explosion. The next few theorems will be helpful in reducing the computational burden of Definition 5.1.

DEFINITION 5.3. *For each $\alpha \in \mathcal{L}$, the relation $C_\alpha \subseteq V^2 \times V^2$ is defined by*

$$\langle x, y\rangle \; C_\alpha \; \langle x', y'\rangle \iff \alpha L(x,y) \cap L(x',y') \neq \varnothing.$$

For each relation $R \subseteq V^2 \times V^2$ and for each $w = \alpha_1\alpha_2 \cdots \alpha_k \in \mathcal{L}^*$, we also set

$$(CR)_w = C_{\alpha_1} R C_{\alpha_2} R \cdots C_{\alpha_k} R.$$

The operator $(-)^{C_\mathcal{L}}$, which transforms relations on V^2, is defined by

$$R^{C_\mathcal{L}} = \Big(\sum_{w \in \mathcal{L}^*} ((CR)_w)^T R (CR)_w \Big)^*.$$

We observe that $(-)^{C_\mathcal{L}}$, when applied to a *symmetric* relation, always gives an *equivalence* relation. Moreover, it is monotone (i.e., $R \leq S$ implies $R^{C_\mathcal{L}} \leq S^{C_\mathcal{L}}$), and $R \leq R^{C_\mathcal{L}}$.

PROPOSITION 5.4. *A partition Π of V^2 coarser than T is left regular iff $C_\mathcal{L}\Pi \leq \Pi$.*

Proof. We have that

$$\begin{aligned}
\Pi^{C_\mathcal{L}} \leq \Pi &\iff \Big(\sum_{w \in \mathcal{L}^*} ((C\Pi)_w)^T \Pi (C\Pi)_w \Big)^* \leq \Pi \\
&\iff \forall w \in \mathcal{L}^* \quad ((C\Pi)_w)^T \Pi (C\Pi)_w \leq \Pi \\
&\iff \forall \alpha \in \mathcal{L} \quad \Pi C_\alpha^T \Pi C_\alpha \Pi \leq \Pi \\
&\iff \forall \alpha \in \mathcal{L} \quad C_\alpha^T \Pi C_\alpha \leq \Pi.
\end{aligned}$$

Moreover, for every $I, J \in \Pi$ and $\alpha \in \mathcal{L}$,

$$\begin{aligned}
&\alpha L_I \cap L_{V^2} \subseteq L_J \\
&\iff \Big(\alpha \bigcup_{\langle x,y\rangle \in I} L(x,y) \Big) \cap L_{V^2} \subseteq L_J \\
&\iff \forall \langle \bar{x}, \bar{y}\rangle \in I \quad \alpha L(\bar{x}, \bar{y}) \cap L_{V^2} \subseteq L_J \\
&\iff \forall \langle \bar{x}, \bar{y}\rangle \in I \quad \forall \langle x, y\rangle \in V^2 \quad \alpha L(\bar{x}, \bar{y}) \cap L(x,y) \subseteq L_J \\
&\iff \forall \langle \bar{x}, \bar{y}\rangle \in I \quad \forall \langle x, y\rangle \in V^2 \quad \alpha L(\bar{x}, \bar{y}) \cap L(x,y) \neq \varnothing \Rightarrow \langle x, y\rangle \in J,
\end{aligned}$$

and the last condition is straightforwardly equivalent to $C_\alpha^T \Pi C_\alpha \leq \Pi$. ◻

We are now ready to characterize graphs that admit monodrome, left-regular partitions coarser than T.

DEFINITION 5.5. *We denote with U the least partition coarser than T and closed under $(-)^{C_\mathcal{L}}$; said otherwise, U is the least partition coarser than T such that $U^{C_\mathcal{L}} \leq U$.*

Note that since $U^{C_\mathcal{L}} \geq U$ by definition, closure under $(-)^{C_\mathcal{L}}$ can be equivalently stated by saying that $U^{C_\mathcal{L}} = U$. The partition U certainly exists because the class of equivalence relations coarser than T and closed under $(-)^{C_\mathcal{L}}$ is nonempty and closed under intersection.

THEOREM 5.6. *A graph G with coloring λ has sense of direction iff U is monodrome.*

Proof. If G has sense of direction then by Theorem 5.2 there is a left-regular monodrome partition coarser than T and, by minimality, coarser than U; thus, U is monodrome. For the other direction, just take $\Pi = U$ and use again Theorem 5.2. ∎

Finally, we show how to compute U explicitly.

THEOREM 5.7. *$U = (\cdots((T)^{C_\mathcal{L}})^{C_\mathcal{L}}\cdots)^{C_\mathcal{L}}$ (n^2 times).*

Proof. By a trivial argument of domain theory, U can be obtained by iterating the $(-)^{C_\mathcal{L}}$ operator over T until a fixed point is reached. However, T can have at most n^2 equivalence classes, and each application of $(-)^{C_\mathcal{L}}$ decreases this number by at least 1, hence the thesis. ∎

6. The decision problem for sense of direction.

Using the results of the previous section we will now establish that one can decide in (sequential) polynomial time whether a given colored graph G with n nodes has sense of direction.

6.1. Checking left regularity.

There are two main steps for computing $(-)^{C_\mathcal{L}}$: determining the matrices (relations) C_α and computing $\sum_{\alpha\in\mathcal{L}} C_\alpha \otimes C_\alpha$ (with $\otimes$ we denote the Kronecker product of matrices). This is sufficient because of the following proposition.

PROPOSITION 6.1. *Given a relation $R \subseteq V^2 \times V^2$, let $\hat{R}$ be defined by*

$$\hat{R} = \left(\sum_{\alpha\in\mathcal{L}} C_\alpha \otimes C_\alpha\right)(R \otimes R).$$

Then

$$\langle x, y\rangle \quad \sum_{w\in\mathcal{L}^*} ((CR)_w)^T R (CR)_w \quad \langle x', y'\rangle \tag{6.1}$$

iff there are $\langle \bar{x}, \bar{y}\rangle, \langle \bar{x}', \bar{y}'\rangle$ such that $\langle \bar{x}, \bar{y}\rangle\ R\ \langle \bar{x}', \bar{y}'\rangle$ and

$$\langle\langle \bar{x}, \bar{y}\rangle, \langle \bar{x}', \bar{y}'\rangle\rangle\ \hat{R}^*\ \langle\langle x, y\rangle, \langle x', y'\rangle\rangle. \tag{6.2}$$

Proof. Since

$$\hat{R} = \left(\sum_{\alpha\in\mathcal{L}} C_\alpha \otimes C_\alpha\right)(R \otimes R) = \sum_{\alpha\in\mathcal{L}} C_\alpha R \otimes C_\alpha R,$$

we have that (6.2) holds iff there is a word $w = \alpha_1\alpha_2\cdots\alpha_k \in \mathcal{L}^*$ such that

$$\langle\langle \bar{x}, \bar{y}\rangle, \langle \bar{x}', \bar{y}'\rangle\rangle\ C_{\alpha_1}RC_{\alpha_2}R\cdots C_{\alpha_k}R \otimes C_{\alpha_1}RC_{\alpha_2}R\cdots C_{\alpha_k}R\ \langle\langle x, y\rangle, \langle x', y'\rangle\rangle,$$

that is, such that

$$\langle \bar{x}, \bar{y}\rangle\ (CR)_w\ \langle x, y\rangle \quad \wedge \quad \langle \bar{x}', \bar{y}'\rangle\ (CR)_w\ \langle x', y'\rangle. \tag{6.3}$$

But (6.1) is equivalent to the existence of a word $w \in \mathcal{L}^*$ such that

$$\langle x, y\rangle\ ((CR)_w)^T R (CR)_w\ \langle x', y'\rangle,$$

which in turn is equivalent to the existence of pairs $\langle \bar{x}, \bar{y}\rangle\ R\ \langle \bar{x}', \bar{y}'\rangle$ satisfying (6.3), or equivalently (6.2). ∎

Thus, given the matrices C_α we can compute $R^{C_\mathcal{L}}$ as follows:

(1) compute $(R \otimes R)\hat{R}^*$;

(2) create a new $n^2 \times n^2$ matrix S such that $S(\langle x, y\rangle, \langle x', y'\rangle) = 1$ iff there is a $\langle \bar{x}, \bar{y}\rangle \in V^2$ satisfying $\langle\langle \bar{x}, \bar{y}\rangle, \langle \bar{x}, \bar{y}\rangle\rangle\ (R \otimes R)\hat{R}^*\ \langle\langle x, y\rangle, \langle x', y'\rangle\rangle$;

(3) compute S^*, which is exactly $R^{C_{\mathcal{L}}}$.

We start by showing how to compute the C_α's by means of the same techniques we used in proving Proposition 4.1. We shall add to each node of G a bunch of $|\mathcal{L}|$ incoming arcs starting from new "artificial" nodes and apply again the product construction.

Proposition 6.2. *Let the graph $H = (W, B)$ be defined as follows: $W = V + V \times \mathcal{L}$, $B = A \cup \{\langle\langle x, \alpha\rangle, x\rangle \mid x \in V, \alpha \in \mathcal{L}\}$. Let us extend the coloring λ of G to a coloring $\mu : B \to \mathcal{L}$ by setting $\mu(\langle\langle x, \alpha\rangle, x\rangle) = \alpha$. Let D be the $(n+n|\mathcal{L}|)^2 \times (n+n|\mathcal{L}|)^2$ matrix*

$$D(\langle s, s'\rangle, \langle t, t'\rangle) = 1 \iff \langle s, t\rangle, \langle s', t'\rangle \in B \ \wedge\ \mu(\langle s, t\rangle) = \mu(\langle s', t'\rangle),$$

where s, s', t, t' range over W. Then, for all $x, x', y, y' \in V$,

$$D^*(\langle\langle x, \alpha\rangle, x'\rangle, \langle y, y'\rangle) = 1 \iff \alpha L(x, y) \cap L(x', y') \neq \varnothing.$$

Proof. As in the proof of Proposition 4.1, we have that $D^*(\langle\langle x, \alpha\rangle, x'\rangle, \langle y, y'\rangle) = 1$ iff there is a word $w = \alpha_1\alpha_2 \cdots \alpha_k$ such that $\langle x, \alpha\rangle \cdot w = y$ and $x' \cdot w = y'$. But by construction of H this happens iff $n > 0$, $\alpha_1 = \alpha$, $\alpha_2 \cdots \alpha_k \in L(x, y)$ and $\alpha_1\alpha_2 \cdots \alpha_k \in L(x', y')$—in other words, iff $\alpha L(x, y) \ni w \in L(x', y')$. ◻

Corollary 6.3. *$C_\alpha(\langle x, y\rangle, \langle x', y'\rangle) = D^*(\langle\langle x, \alpha\rangle, x'\rangle, \langle y, y'\rangle)$.*

We finally have the following theorem.

Theorem 6.4. *Given a relation $R \subseteq V^2 \times V^2$, $C_{\mathcal{L}}R$ can be computed in logarithmic time using a polynomial number of processors.*

Proof. Recalling that $|\mathcal{L}| \leq n^2$ it is easy to see that the matrix D (with the notation of Proposition 6.2) can be built in constant time using a polynomial number of processors. Then, we just have to perform a series of transitive closures, products, and permutations, which can be computed in logarithmic time using a polynomial number of processors. The details are left to the reader. ◻

6.2. Sense of direction is in P. We now come to the main theorem of this section. We start again by formalizing our problem.

Problem 6.1. Sense of Direction.

Instance: *A graph G with coloring λ.*

Question: *Is λ a sense of direction?*

Theorem 6.5. Sense of Direction *is in P.*

Proof. We can compute T in logarithmic time using n^6 processors; thus, we can a fortiori compute it sequentially in polynomial time. To compute U, we just have to iterate n^2 times $(-)^{C_{\mathcal{L}}}(-)$ over T (see Definition 5.5), and this task can be carried out in polynomial time, since each iteration requires a fortiori polynomial sequential time by Theorem 6.4, and the number of iterations is polynomial. By Theorem 5.6, we can decide whether our graph has sense of direction by checking the monodromy of U, which can be done in $O(n^3)$ steps. ◻

Note that since the operator $(-)^{C_{\mathcal{L}}}$ is computable in parallel logarithmic time, and the bound on the number of iterations provided by Theorem 5.7 is very rough, it is an interesting open problem to characterize large classes of graphs for which a (poly)logarithmic number of iterations suffices. The number of processors that are necessary to compute $(-)^{C_{\mathcal{L}}}$ is, however, rather large, and so is, correspondingly, the polynomial bound on sequential time.

7. Conclusions.

The positive results we presented about the decision problem for (weak) sense of direction of a *colored* graph should not obscure the fact that the next and most important open problem is to decide how many colors are really sufficient to give (weak) sense of direction to a graph. More precisely, we could ask, given a graph G and a positive integer k, whether there is a (weak) sense of direction λ for G using at most k colors. Note that k is always bounded from below by the maximum outdegree of the graph, so in particular we could also ask which graphs can be given a (weak) sense of direction using a number of colors equal to the maximum outdegree.

As shown in [BV97], the outregular graphs with such a (weak) sense of direction are exactly the Cayley color graphs (i.e., Cayley graphs with the natural coloring obtained associating to each arc the element of the group that generated it). Thus, we can use the algorithm described in section 4 to recognize Cayley color graphs in parallel logarithmic time. (To our knowledge, this is the first complexity result on the recognition of Cayley color graphs.) The result above implies also that the problem of deciding whether a given graph is a Cayley graph can be reduced to deciding whether the graph is outregular and can be given a (weak) sense of direction using a number of colors equal to its outdegree; surprisingly, however, no results (in particular, no hardness results) are known about the recognition of Cayley graphs.

Acknowledgments. We would like to thank Carlo "Mere" Mereghetti for many useful discussions and Gianfrancesco "Frank" Ravasio for his careful proofreading.

RIGOROUS TIME/SPACE TRADE-OFFS FOR INVERTING FUNCTIONS*

AMOS FIAT† AND MONI NAOR‡

Abstract. We provide rigorous time/space trade-offs for inverting any function. Given a function f, we give a time/space trade-off of $TS^2 = N^3q(f)$, where $q(f)$ is the probability that two random elements (taken with replacement) are mapped to the same image under f. We also give a more general trade-off, $TS^3 = N^3$, that can invert *any* function at *any* point.

1. Introduction.

Time/space trade-offs occur in many searching tasks. Typical examples are a $TS^2 = \tilde{O}(2^n)$ time/space trade-off for knapsack-like problems [15, 17, 10], algorithms for solving the discrete log problem [16], etc. In this paper we investigate time/space trade-offs for inverting functions.

Hellman [12] was the first to study this problem. He suggests a general time/space trade-off to invert one-way functions. Let the domain be $D = \{1, \ldots, N\}$, and let $f : D \mapsto D$ be the function to be inverted. Suppose that f is given in a black box manner, i.e., on input x the value $f(x)$ appears as output. To invert $f(x)$, a simple exhaustive search requires time $\tilde{O}(N)$ and constant space. (Throughout, we ignore low-order polylogarithmic factors in time/space requirements and use the $\tilde{O}$ notation. We say that $f \in \tilde{O}(g)$ if there exists some c such that $f \in O(g \cdot \log^c(g))$.) An extreme alternative is to precompute a table with N entries whose ith location contains the preimage of i. Constructing such a table requires preprocessing time and space $\tilde{O}(N)$, but later requires only $O(1)$ time per function inversion.

Hellman's motivation is a chosen cleartext attack on block ciphers. Given a block encryption algorithm, $E_k(x)$, consider the function f that maps the encryption key k to the encryption of a fixed cleartext block B under k, $f(k) = E_k(B)$. Inverting such a function is equivalent to breaking the encryption scheme under a fixed cleartext attack. An eavesdropper that wants to listen to many communications may find that $\tilde{O}(N)$ time per transmission is too expensive or causes an unacceptable delay. Because of the differing costs of time and memory, a memory of size $O(N)$ might be absolutely too large, while a preprocessing time of $O(N)$ may be feasible. This

motivates the search for time/space trade-offs that require less than $\tilde{O}(N)$ time per function inversion and also require less than $\tilde{O}(N)$ space.

Hellman assumes in his analysis that the function f that is to be inverted is a random function. He also postulates that functions obtained by minor modifications to f (permuting the output bits) can be modeled as independently chosen random functions. Under these presuppositions, Hellman's scheme [12] requires $\tilde{O}(N)$ time for preprocessing and time/space T/S per function inversion, where T and S satisfy $TS^2 = \tilde{O}(N^2)$.

We find it difficult to give an exact characterization of the assumptions actually required for Hellman's scheme to work. We cannot characterize the set of functions for which the Hellman time/space trade-off is applicable. While the construction may work for specific functions, such as the Data Encryption Standard (DES) key to ciphertext, it seems to be very difficult to prove this. We note that taking f to be polynomial time indistinguishable from a random function is insufficient.

It is possible to give functions for which Hellman's time/space construction will fail. In fact, it is relatively simple for a cryptanalyst to design a cryptographic scheme that causes the Hellman scheme to fail completely, paying for this through the inconvenience that the encryption scheme is not invertible for some negligible fraction of the keys. Our goal in this paper is to give a rigorous time/space trade-off construction that works for any function.

In this paper we give an algorithm for constructing time/space trade-offs, denoted A. Algorithm A consists of a preprocessing phase and an online inversion phase.

Our main result in this paper can be summarized in the following theorem.

THEOREM 1.1. *For any function $f : D \mapsto D$, $|D| = N$, and for any choice of values (S,T) that obey $TS^3 = N^3$, the preprocessing phase of A requires time $\tilde{O}(N)$ and space $\tilde{O}(S)$, producing a time space data structure of space $\tilde{O}(S)$.*

With probability $1 - 1/N$, over the coin tosses of the preprocessing phase, the data structure produced by the preprocessing phase allows the online inversion phase to invert f at any point y in the range of f in time $\tilde{O}(T)$.

An interesting point in this trade-off is that $T = S = N^{3/4}$. We also show that this time/space trade-off can be improved for some functions where we can bound the average number of domain elements that map to the same range value. In particular, for functions where the maximum number of domain elements that map to any range value is polylogarithmic in N, we can give a trade-off of $TS^2 = N^2$; an interesting point in this trade-off is that $T = S = N^{2/3}$.

The principle ideas used in this paper are as follows:

1. We build a table of high indegree points in the graph induced by f; this table is used to construct functions that bypass these points. This allows a better cover of the domain by random chains.
2. We use k-wise independent functions to substitute for the random functions assumed by the Hellman trade-off. An appropriate choice of parameters allows us to do so without harm.
3. We choose a specific order of events during the inversion process and allow dependencies between different k-wise independent functions. These changes are harmless and allow us to compute these k-wise independent functions in nearly constant *amortized* time.

Section 2 of this paper gives an overview of the Hellman trade-off; section 3 introduces the rigorous trade-off; section 4 describes our scheme and its analysis, while restricting the function f to be not "trivial to invert in space S." (Intuitively, if a function f is trivial to invert in space S, it implies that f is generally not useful for cryptographic applications in a scenario where the cryptanalyst has space S.) For completeness, we describe how to modify our construction to deal with trivial to invert functions in section 5; concluding the proof of Theorem 1.1, we also consider various extensions to the scheme. The last section gives some open problems associated with this work.

2. The Hellman construction.

We now review the Hellman construction, which is the starting point of our scheme. First suppose that the function $f : D \mapsto D$, $D = \{1, \ldots, N\}$ is a permutation. In this case there is an elegant time/space trade-off of $T \cdot S = \tilde{O}(N)$: consider the graph induced by f, where vertices are points in the domain and directed edges describe f's operation on the point. Since f is a permutation, this graph splits into disjoint cycles. If a cycle is less than T in length, do nothing. If the cycle is longer than T, store a set of "shortcut elements" along the cycle so that no two are farther apart than T vertices. Each one of these shortcut elements points to its closest predecessor; that is, if the shortcut elements are T apart, then z points to $f^{-T}(z)$. Now, given $y = f(x)$, it can be inverted by following the directed graph. If a pointer element is found, then follow the pointer and continue as before; stop when y is reached again. The immediate predecessor to y is its inverse.

Unfortunately, this does not work for functions f that are not permutations, and the time/space trade-off is worse. Hellman's breakthrough was to consider many related functions such that if any one of them can be inverted, then so can f. Hellman dealt with a random function $f : D \mapsto D$ and postulated that functions obtained by minor modifications to f (permuting the output bits) can be modeled as independently chosen random functions. We describe Hellman's functions differently, as the composition of f with a random function.

The Hellman trade-off curve allows one to choose space S and inversion time T subject to $TS^2 = N^2$, $|D| = N$. The values S and T are a function of three scheme parameters ℓ, m, and t, where $S = \ell m$, $T = \ell t$, and are subject to the constraints $t^2 m \leq N$ and $mt\ell = N$.

For concreteness we'll assume $\ell = m = t = N^{1/3}$, giving the most interesting trade-off point $T = N^{2/3}$, $S = N^{2/3}$. Choose $\ell = N^{1/3}$ different functions $h_i : D \mapsto D$, where $h_i(x)$ has the form $g_i(f(x))$ and g_i is a random function. For every h_i function, $1 \leq i \leq \ell$, Hellman suggests taking $m = N^{1/3}$ randomly selected points $x_{i1}, x_{i2}, \ldots, x_{i,m}$ and storing a table with m entries. Let $t = N^{1/3}$; every entry is a pair: x_{ij} and the tth iterate of h_i on x_{ij}, denoted $h_i^t(x_{ij})$ (see Figure 2.1). The table is sorted (or hashed) by $h_i^t(x_{ij})$ so that table lookup of x_{ij}, given $h_i^t(x_{ij})$, takes no more than $O(\log N)$ time. This table requires space $\tilde{O}(m) = \tilde{O}(N^{1/3})$ per h_i function and thus space $\tilde{O}(m \cdot \ell) = \tilde{O}(N^{2/3})$ for all $\ell = N^{1/3}$ tables.

To invert f at a point y, Hellman's trade-off repeats the following process for all $1 \leq i \leq \ell$. Compute the values $h_i(y), h_i^2(y), \ldots$; if you find a value $h_i^j(y)$ in the table associated with function h_i, then follow the link (the appropriate table entry) and continue applying h_i. If during this process you find a value z such that $h_i(z) = g_i(y)$, then check to see if $f(z) = y$. It can be shown that this will indeed be the case with constant probability under the appropriate idealized assumptions.

If f and the functions g_i are all independent random functions, $O(1)$ time computable, then f can be inverted at a random point with $\Omega(1)$ probability in time $\tilde{O}(\ell \cdot t) = \tilde{O}(N^{2/3})$. Under the same set of assumptions, f can be inverted at a random point with constant probability and time/space requirements obeying $TS^2 = \tilde{O}(N^2)$.

The difficulty with Hellman's construction is that it requires completely random

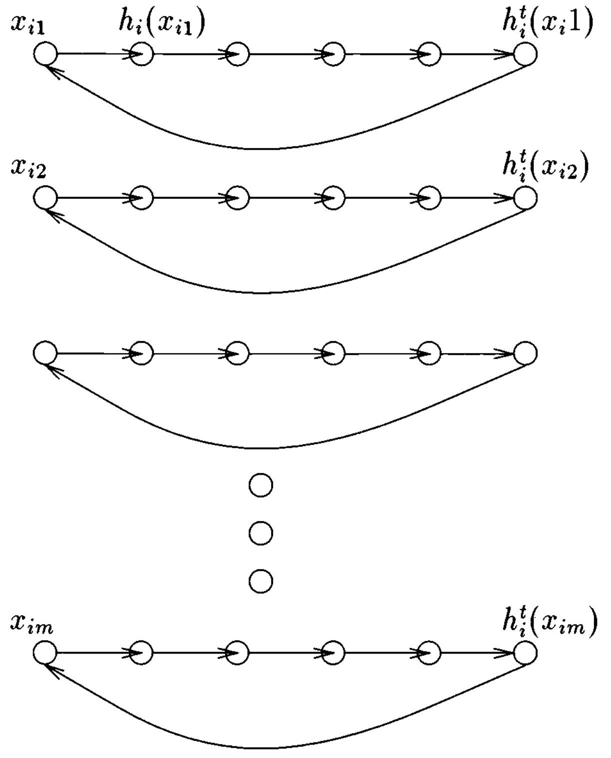

FIG. 2.1. *The chains for a specific function h_i.*

and independent g_i's, but it is not clear of course how to come up with such functions.

3. Outline of results and methodology. We do not want to assume that f has any particular structure; specifically, we do not want to assume that f is random. An adversary may devise f so as to cause the Hellman's basic cryptanalytic time/space trade-off to fail. There exist cryptographically sound functions f, e.g., polynomial time indistinguishable from a truly random function, for which Hellman's time/space trade-off fails. This occurs since the entire trade-off scheme deals with *super-polynomial* values.

Consider a function f with the property that some set of $N^{1-\epsilon}$ domain elements map to the same image, $\epsilon < 1/3$. Such a function may be polynomial time indistinguishable from a random function. Even if one assumes that random $O(1)$ time computable g_i functions are available, the Hellman time/space scheme fails with overwhelming probability. A cryptographer might devise the cryptographic scheme so that only $N-N^{1-\epsilon}$ of the keys induce a permutation, while the other keys map all cleartext values to zero. The Hellman attack on this scheme will fail.

Another assumption we wish to remove is that the random functions g_i are available. If every g_i function is described by a long table of truly random entries, then the time/space trade-off above becomes meaningless. We will use k-wise independence to limit the storage requirements of our g_i functions. We will show that an appropriate choice of k will ensure that the cryptanalytic scheme works. However, for any construction of k-wise independent functions, computing the function requires more than $\tilde{O}(1)$ time. We then show how to modify the scheme so that the FFT algorithm can be used to reduce the *amortized* computation cost of our k-wise independent g_i.

Since f can be determined by an adversary, we cannot assume anything about the structure of f. Let $I(y)$ denote the number of preimages for y under f, $I(y) = |\{x \in D | f(x) = y\}|$. We call $I(y)$ the *indegree* of y.

Images y with many preimages under f imply images $g_i(y)$ with many preimages under h_i.

Consider the sequence $I(0), I(1), \ldots, I(N)$. We are interested in the probability that two randomly chosen elements from the domain D have the same image. We denote this probability by

$$q(f) = \frac{\sum_{i=0}^{N} I(i)^2}{N^2}.$$

Under the assumptions of random g_i functions, and given $q(f)$, we can modify the parameters of the Hellman time/space trade-off of section 2 to obtain a generalized trade-off. If the g_i's are random functions, then $q(h_i) = q(g_i \circ f) \leq q(f) + 1/N$ with high probability. Any point on the time/space trade-off curve

$$T \cdot S^2 = N^3 \cdot q(f) \tag{3.1}$$

can be obtained.[1]

We now sketch the argument as to why the above trade-off is possible. Let ℓ denote the number of functions, m the number of chains per function, and t the length of each chain. Set m and t such that $m \cdot t^2 \cdot q(f) \leq 1$. We can argue that for all i, the union of all m chains contains $\Theta(m \cdot t)$ elements with high probability. Setting $\ell \cdot t \cdot m \geq N$ implies that the union of all $m \cdot \ell$ chains contains a constant fraction of all images with high probability.

In section 4 we show that we can obtain the trade-off of (3.1) without recourse to unprovable assumptions on the functions g_i. Instead, we give explicit provable constructions.

We give an alternative trade-off, which works for any function f, of arbitrary $q(f)$ such that any point on the time/space trade-off curve

$$T \cdot S^3 = N^3 \tag{3.2}$$

can be obtained.

The trade-off of (3.2) is better than the trade-off of (3.1) whenever $S > 1/q(f)$. This trade-off makes use of $O(S)$ memory so as to reduce the "effective probability of collision" to $1/S$ instead of $1/q(f)$. Thus if we modify trade-off (3.1) by replacing $q(f)$ with the "effective probability of collision," trade-off (3.2) becomes a special case. As mentioned above, we will get a low "effective probability of collision" by designing the h_i functions so as to avoid high indegree nodes under f. We give a construction to a single data structure that obeys the above trade-offs with respect to space and time, but each element can be inverted with constant probability. By repeating the construction we get that *all* of the elements can be inverted with high probability.

[1]This trade-off is not the best possible at the endpoints $T = N$ or $S = N$, in which case we can do better.

4. The construction.

4.1. Preliminaries. The function to be inverted, f, maps the domain D of size N onto itself. We may consider $D = \{1, \ldots, N\}$.

DEFINITION 4.1. *A function $f : D \mapsto D$ is said to be trivial to invert in space S if storing the S highest indegree images in a table allows one to invert $f(x)$ by table lookup for all $x \in D' \subset D$ such that $|D'| \geq N/2$.*

By definition, all functions are trivial to invert in space N. Throughout this section, we always assume that f is *not* trivial to invert in space S. If f is trivial to invert, table lookup takes care of most of the cases. We can handle trivial to invert functions as well. (See section 5.)

In the construction, we use several tables in which pairs of the form (x, y) are stored. Given a value y we need to search to see whether a pair with y is stored in the table. This can be implemented by either binary search or by hashing (see, e.g., [2, 6, 11, 9]). In any case, this is a low-order multiplicative factor that vanishes in the $\tilde{O}$ notation.

DEFINITION 4.2. *Let G be a family of functions such that for all $g \in G : g : D \mapsto R$ (where D and R are some finite sets). Let g be chosen uniformly at random from G. We call G k*-wise independent *if for all* distinct $x_1, x_2, \ldots x_k \in D$ *the random variables $g(x_1), g(x_2), \ldots, g(x_k)$ are independent and uniformly distributed in R.*

Families of k-wise independent functions have been studied and applied extensively in recent years (cf. [3, 6, 7, 8, 14, 19]). A useful property is that if G is k-wise independent, then for all $1 \leq i \leq k$, for all $x_1, x_2, \ldots, x_i \in D$ and $v_1, v_2, \ldots v_{i-1} \in R$, the distribution of $g(x_i)$ given that $(g(x_1) = v_1, g(x_2) = v_2, \ldots, g(x_{i-1}) = v_{i-1})$ is uniform in R. For our application we will need a family of functions $g : \{1, \ldots, N\} \times \{1, \ldots, N\} \mapsto \{1, \ldots, N\}$.

4.2. The scheme. Our scheme uses the parameters ℓ, t, and m to define a point on the time/space trade-off curve. We have space $S = \tilde{O}(\ell \cdot m)$ and inversion time $T = \tilde{O}(\ell \cdot t)$. The restrictions on t, ℓ, and m are that $t \leq \ell$, $t \geq 8 \log(4m)$, and $t \cdot \ell \cdot m = N$. We also use another parameter k, which is set $8 \cdot t$ in this section. This parameter is one of the few things we have to change in order to also handle trivial to invert functions in section 5. In order to achieve the time/space trade-off given in (3.2) we also use the constraint $mk^2 \leq S$, and to achieve the time/space trade-off given in (3.1) we use the constraint $mk^2 \leq 1/q(f)$.

To simplify explanations, we define $\tilde{S}$ to be $3S \cdot \log^2 N$; we actually use $\tilde{S}$ space, not S. For $S = N^\delta$, $0 < \delta < 1$, the difference between S and $\tilde{S}$ disappears in the $\tilde{O}$. The other values in the trade-off follow trivially.

Set $k = 8 \cdot t$. (This is one of the few things we have to change in order to handle trivial to invert functions as well.) The scheme uses a family G of k-wise independent functions $g : D \times \{1, \ldots, N\} \mapsto D$. In all ℓ functions, $g_1, g_2, \ldots, g_\ell$ are applied, where each g_i is uniformly distributed in G. The scheme requires that for any $1 \leq i < j \leq \ell$ the random variables g_i and g_j are independent, i.e., given the value of g_i at all the points we learn nothing about g_j. The family G and the method by which the ℓ functions are chosen is described in section 4.4. As we shall see, $g_1, g_2, \ldots, g_\ell$ are *not* completely independent.

The scheme described in the following section yields only that any element has a constant probability (over the coin flips of the preprocessing phase) of being inverted successfully. However, by repeating the full scheme (both preprocessing and the on-line inversion) $O(\log N)$ times, we can get that with probability of at least $1 - 1/N$

all range members can be inverted successfully in one of the schemes (this $O(\log N)$ term is absorbed in the $\tilde{O}$ notation).

4.2.1. Preprocessing for one data structure. The preprocessing phase consists of two stages: a choice of table A and a choice of the chains. Table A will contain pairs of values of the form $\langle x, f(x)\rangle$, sorted or hashed so that it is easy to see if $f(x)$ is in the table and to find the corresponding entry x. Table A is constructed by a random process: choose $\tilde{S}$ random values $x_1, \ldots, x_{\tilde{S}} \in D$, and store pairs $\langle x_i, f(x_i)\rangle$ in A.

Remark. Table A is used to check if a point y has high indegree. If y has high indegree, then there is high probability that $y = f(x)$ will appear in A. The preimage of y under f is used only to invert y itself, but the main use of table A is to avoid the high indegree points during the search. We use the notation $y \in A$ to mean that there is an entry of the form $\langle x, y\rangle$ in A.

The choice of A defines the functions g_i^* and h_i: For $1 \le i \le \ell$, define $g_i^*(x) = g_i(x, j)$, where $1 \le j \le k/2$ is the smallest value such that $f(g_i(x, j)) \notin A$.[2] If there is no such j, then $g_i^*(x)$ is undefined. Define $h_i(x) = g_i^*(f(x))$ (or leave undefined if $g_i^*(f(x))$ is undefined). Evaluating $h_i(x)$ requires j evaluations of f and g_i. Note that for any $x \in D$ the expected value of j (assuming that f is not trivial to invert) is $O(1)$.

The second preprocessing stage consists of choosing the chains that are supposed to cover all of the range. It is done in the following way. For all $1 \le i \le \ell$:

1. For all $1 \le j \le m$ pick x_{ij} at random from D.
2. Compute pairs of the form $(h_i^t(x_{ij}), x_{ij})$. If $h_i^t(x_{ij})$ is undefined or if computing $h_i^t(x_{ij})$ requires more than $k/2$ invocations of g_i, then discard x_{ij}. (Recall that evaluation of h_i at different points may result in a different number of invocations of g_i. Here we are interested in the total number of invocations.)
3. Store a table T_i with m entries $(h_i^t(x_{ij}), x_{ij})$.

Define a *chain* rooted at x_{ij} to be the set $\{h_i^p(x_{ij}) | 1 \le p \le t\}$. Define the ith *cluster*, $1 \le i \le \ell$, to be the set

$$C_i = \{h_i^p(x_{ij}) | 1 \le p \le t, 1 \le j \le m\}.$$

Every cluster C_i is the union of m chains of length t. The chains may overlap one another. (Two chains are said to overlap if they share one or more elements.) We say that an image $y = f(x)$ is *contained* in the chain rooted at x_{ij} if for some $w \in \{h_i^p(x_{ij}) | 0 \le p \le t-1\}$ we have $f(w) = y$. We say that y is in the ith cluster if for some $1 \le j \le m$ it is contained in the chain rooted at x_{ij}.

4.2.2. On-line inversion. We now explain how the tables constructed in the preprocessing phase are used to invert f. Given $y = f(x)$ we apply the following procedure to invert it:

- Search if $y \in A$. If found, then we're done; the inverse is the x such that $\langle x, y\rangle$ is in A.
- Otherwise, for all $1 \le i \le \ell$,
    1. Set $u_i = g_i^*(y)$ and h_i (i.e., they do not participate in the online inversion).
    2. Repeat for $p = 0$ to $t - 1$:
        (a) Search for u_i in T_i. If found ($u_i = h_i^t(x_{ij})$ for some j), then set z to be $h_i^{t-p}(x_{ij})$. If $f(z) = y$, then we have found a preimage for y.

[2]Recall that each $g_i : D \times \{1, \ldots, N\} \mapsto D$.

(b) Set $u_i \leftarrow h_i(u_i)$ if defined. Otherwise, discard u_i.

This concludes the description of the scheme, except for how the g_i's are chosen, represented, and computed.

4.3. Analysis of the scheme. We now turn to the analysis of the scheme. In this section, we use the assumption that computing the g_i functions can be done in $O(1)$ time. This will be justified in section 4.4. Since f is arbitrary, all we know about $q(f)$ is that $1/N \leq q(f) \leq 1$. The net result of our construction of table A is to reduce the effective $q(f)$ so that $q(h_i) \in O(1/S)$ with high probability. That is, given a choice of table A and given that x_1 and x_2 are chosen at random in D, we consider

$$Q_A = \text{Prob}[f(x_1) = f(x_2) \text{ and } f(x_1), f(x_2) \notin A].$$

We know that $Q_A \leq q(f)$. However, we can treat Q_A as a random variable over the probability space defined by choices of A according to the preprocessing phase of the algorithm $\mathcal{A}$. What we show is that with high probability Q_A is less than $1/S$ over this probability space.

LEMMA 4.1. *For any function f with probability at least $1 - 1/\log N$ over the random choices of A,*

$$Q_A \leq 1/S.$$

Proof. Let $I(1), I(2), \ldots, I(N)$ be the sequence of indegrees under f, i.e., $I(j) = |\{x | f(x) = j\}|$. The probability that $f(x) \notin A$ is $(1 - I(f(x))/N)^{\tilde{S}}$. Thus,

$$\begin{aligned}
E[Q_A] &= \text{Prob}[f(x_1) = f(x_2) \text{ and } f(x_1) \notin A] \\
&= \sum_{i=1}^{N} \frac{I(i)^2}{N^2} \cdot \left(1 - \frac{I(i)}{N}\right)^{\tilde{S}} \\
&= \sum_{\{j | I(j) > \frac{N}{S \log N}\}} \frac{I(j)^2}{N^2} \cdot \left(1 - \frac{I(j)}{N}\right)^{\tilde{S}} + \sum_{\{j | I(j) \leq \frac{N}{S \log N}\}} \frac{I(j)^2}{N^2} \cdot \left(1 - \frac{I(j)}{N}\right)^{\tilde{S}}.
\end{aligned}$$

We deal with each term separately. Recall that $\tilde{S} = S \log^2 N$.

$$\begin{aligned}
\sum_{\{j | I(j) > \frac{N}{S \log N}\}} \frac{I(j)^2}{N^2} \cdot \left(1 - \frac{I(j)}{N}\right)^{\tilde{S}} &\leq N \cdot 1 \cdot \left(1 - \frac{1}{S \log N}\right)^{\tilde{S}} \\
&\leq N \cdot 1/N^3 \\
&= 1/N^2.
\end{aligned}$$

The sum $\sum_{i=i}^{j} x_i^2$ subject to the constraints $\sum_{i=1}^{j} x_i \leq c$ and $x_i \leq b$ is maximized by taking c/b x_i's equal to b and setting the rest equal to zero. This is used in the following analysis:

$$\begin{aligned}
\sum_{\{j | I(j) \leq \frac{N}{S \log N}\}} \frac{I(j)^2}{N^2} \cdot \left(1 - \frac{I(j)}{N}\right)^{\tilde{S}} &\leq \sum_{\{j | I(j) \leq \frac{N}{S \log N}\}} \frac{I(j)^2}{N^2} \\
&\leq S \log N \frac{N^2}{N^2 S^2 \log^2 N} \\
&= \frac{1}{S \log N}.
\end{aligned}$$

Thus, from Markov's inequality we get that $\text{Prob}[Q_A > 1/S]$ is at most $\frac{1}{\log N}$, which suffices for our purposes. By a more careful analysis we can get a much smaller probability. $\square$

Fix $y = f(x)$; if $y \in A$, we can invert f on y via table lookup in A. Thus, we should handle only the case that $I(y) \leq N/S$ since otherwise the probability that $y \notin A$ is at most $1/N$. We assume from now on that $y \notin A$. Let V_i be the event that $f(x)$ is in the ith cluster. The main lemma we require is as follows.

LEMMA 4.2. *For all functions f, for all $y = f(x)$, and for all choices of m, t, and S such that $mt^2 < S/2$, assuming $Q_A \leq 1/S$, then either $y \in A$ or*

$$\text{Prob}[V_i] \geq \frac{mt}{2N}.$$

To prove the lemma we need the following claims.

CLAIM 4.1. *Assuming $Q_A \leq 1/S$, the probability that a chain rooted at x_{ij} contains less than t different elements is at most* $1/2m$.

Proof. We first compute the probability that the chain rooted at x_{ij} is discarded at step 2 of the preprocessing phase and show that it is negligible. Then we bound the probability that the chain cycles on h.

For a chain to be discarded at step 2 of the preprocessing phase it may be the case that more than $k/2$ applications of g_i were invoked. This occurs if through the attempted computation of h_i, $k/2$ invocations of g_i were performed altogether, while less than t of them gave images x such that $f(x)$ was not in table A. Since g_i is $(k = 8 \cdot t)$-wise independent, it follows that the probability that this occurs is at most the probability that a sequence of $k/2$ tosses of a coin contains at least $k/2 - t$ tails (the event g_i maps to a value x such that $f(x) \in A$) and less than t heads (the event g_i maps to a value x such that $f(x) \notin A$) with probabilities $p < 1/2$ for tails (by the assumption that f is not trivial to invert). By the Chernoff bound (see Theorem A.1 in [4]) this probability is at most $e^{-t^2/k} = e - t/8 \leq 1/4m$.

Even if the chain rooted at x_{ij} is not discarded, it may contain less than t different elements in case h_i cycles. This occurs if $f(z_1) = f(z_2) \notin A$, where z_1 and z_2 are two values encountered in the development of the chain either as x_{ij} or as the outcome of g_i. From the k-wise independence of g_i and the fact that g_i was invoked at most $k/2$ times in each chain we have that z_1 and z_2 are uniformly distributed at D. The probability that two such elements collide under f and not in A is at most $1/S$ by the assumption that $Q_A \leq 1/S$ is at most $1/S$. There are at most $\binom{k/2}{2}$ candidates for such pairs, so the probability that this is the case is bounded by

$$\frac{\binom{k/2}{2}}{S} < \frac{k^2}{8S} \leq \frac{1}{8m}.$$

Note that if $g_i(z_1, j_1) = g_i(z_2, j_2)$ but $f(g_i(z_1, j_1)) \in A$, where $z_1 \neq z_2$ are two values encountered in the development of the chain as the outcome of f and $1 \leq j_1, j_2 \leq N$ are the appropriate indices, then a cycle does *not* occur.

The probability that the chain is *not* discarded and that it does *not* cycle on h_i is thus at least $1 - /2m$. $\square$

Let E_{ij}^y be the event that the chain rooted at x_{ij} contains y, and let $p_y = \text{Prob}[E_{ij}^y]$.

CLAIM 4.2. *For any $y = f(x)$ such that $I(y) \leq N/S$, and for parameters as defined in Lemma* 4.2, *either $y \in A$ or*

$$p_y \geq (1 - 1/2m) \cdot \frac{t}{N}$$

under the assumption that $Q_A \leq 1/S$.

Proof. Let $w_1, w_2, \ldots, w_{k/2}$ be independent random variables uniformly distributed in D. These random variables define the random choices of the chain: each time g_i is invoked at a new point we treat its value as the next w_a (here we are using the k-wise independence of g_i). In case the chain cycles, the rest of the variables are never used, as is the case following t successful hits in the set outside A. We are interested in the event that *the chain defined by* $w_1, w_2, \ldots, w_{k/2}$ *is not discarded* and $f(w_a) = y$ *for* $1 \leq a \leq k/2$*, which is among the first* t *elements of* $w_1, w_2, \ldots, w_{k/2}$ *such that* $f(w_i) \notin A$. There are t possible places where y can appear in the chain. For each such location the probability that y is hit is at least $1/N$. Given that y is hit in the jth position, the probability that the chain is discarded or contains less than t elements is at most $1/2m$, from the analysis of Claim 4.1 (using the facts that $Q_A \leq 1/S$ and $I(y) \leq N/S$). Therefore with probability of at least $(1 - 1/2m) \cdot \frac{t}{N}$ we have that the chain contains y and is not discarded. □

From the inclusion/exclusion principle,

$$\text{Prob}[V_i] \geq \sum_{j=1}^{m} \text{Prob}[E_{ij}^y] - \sum_{j<j' \in \{1,\ldots,m\}} \text{Prob}[E_{ij}^y \cap E_{ij'}^y]. \tag{4.1}$$

The next claim says that although E_{ij}^y and $E_{ij'}^y$ are *not* independent, we can bound their correlation.

CLAIM 4.3. *Assuming $Q_A \leq 1/S$ and $I(y) \leq N/S$,* $\text{Prob}[E_{ij'}^y \cap E_{ij}^y] \leq \frac{1}{2m-1} \cdot p_y$.

Proof. The probability of the event $E_{ij'}^y \cap E_{ij}^y$ is dominated by the following: Let $w_1, w_2, \ldots, w_{k/2}$ and $w'_1, w'_2, \ldots, w'_{k/2}$ be random variables uniformly distributed in D. Let q_y be the probability that the following two conditions hold:

1. There exists $1 \leq a \leq k/2$ such that $f(w_a) = y$ and w_a is among the first t elements of $w_1, w_2, \ldots, w_{k/2}$ such that $f(w_i) \notin A$.
2. There are $1 \leq b, c \leq k/2$ such that $f(w_b) = f(w'_c) \notin A$.

That is, we are adding to $E_{ij'}^y \cap E_{ij}^y$ all the cases that chain x_{ij} hits y but cycles and the cases where the two chains collide after y is hit. By Claim 4.2 the probability that condition 1 is satisfied is at most $p_y/(1-1/2m) = p_y \frac{2m}{2m-1}$. Given that condition 1 is satisfied, the probability that condition 2 holds is at most $(k/2)^2/S \leq 1/4m$. Therefore

$$\text{Prob}[E_{ij'}^y \cap E_{ij}^y] \leq q_y \leq \frac{2m}{4m(2m-1)} \cdot p_y < \frac{1}{2m-1} \cdot p_y. \qquad \square$$

From the last claim, it follows that (4.1) is bounded from below by

$$m \cdot p_y - \binom{m}{2} \cdot p_y \cdot \frac{1}{2m-1} \geq m p_y \left(1 - \frac{m-1}{2m-1}\right) \geq \frac{mt}{2N},$$

where the last inequality holds from Claim 4.2. It follows that $\text{Prob}[V_i] \geq \frac{mt}{2N}$. □

LEMMA 4.3. *Assuming $Q_A \leq 1/S$,* $\text{Prob}[\cup_{i=1}^{\ell} V_i] \geq \frac{1}{4}$.

Proof. Given table A, the events V_i and V_j are independent since the functions g_i and g_j are independent. (Note that prior to the choice of A, the events may not be independent since V_i's imply a successful choice of A, which effects $\text{Prob}[V_j]$.) We therefore have ℓ identical experiments where each is successful with probability $p \geq \frac{mt}{2N}$, and we are interested in the probability that at least one of them is successful.

This is minimized when $p = \frac{mt}{2N}$ and from inclusion/exclusion

$$\begin{aligned}\text{Prob}[\cup_{i=1}^{\ell} V_i] &\geq \sum_{i=1}^{\ell} \text{Prob}[V_i] - \sum_{1\leq i<j\leq \ell} \text{Prob}[V_i \cap V_j] \\ &\geq \frac{\ell \cdot m \cdot t}{2N} - \binom{\ell}{2} \cdot \frac{m^2 t^2}{4N^2} \\ &\geq \frac{1}{2} \cdot \frac{\ell \cdot m \cdot t}{N} - \frac{1}{8} \cdot \frac{\ell^2 m^2 t^2}{N^2} \\ &\geq \frac{1}{4}. \qquad \square\end{aligned}$$

We now turn to the analysis of the run time of the scheme. For each cluster $1 \leq i \leq \ell$ we have to apply g_i and f at most $k/2$ times at step 2(b). In addition we must consider the complexity of step 2(a), i.e., the number of times a chain is traced. Fix $y = f(x)$. Consider stage 2(a) of the inversion procedure above: For cluster i, F_i is defined to be a random variable that counts the number of times the test "$f(C) = y$" fails. This failure is called a false alarm.

LEMMA 4.4. $E[F_i] \leq 1$.

Proof. Any y and every h_i induces a chain $u_i = g_i^*(y), h_i(u_i), h_i^2(u_i), \ldots, h_i^t(u_i)$. A false alarm at the ith cluster occurs if for some $1 \leq j \leq m$ the chain rooted at y and one of the chains rooted at x_{ij} overlap. There are m such chains, and from Claim 4.3 the probability that two chains merge is bounded by $(k/2)^2/S \leq 1/4m$. Hence the expected number of false alarms is bounded by 1. $\square$

Thus, false alarms increase the time required per cluster by at most a factor of 2. Therefore the total expected complexity of online inversion is $O(k \cdot \ell)$, and the following precursor to the main theorem holds.

THEOREM 4.5. *For any function f not trivial to invert in space S, and for any image $y = f(x)$, the probability that $f^{-1}(y)$ is found is $\Omega(1)$ and the expected number of evaluations of f and the g_i's required to invert $f(x)$ is $\tilde{O}(t \cdot \ell)$. The space $S = \tilde{O}(\ell \cdot m)$ and the preprocessing time is $\tilde{O}(N)$.* $\square$

4.4. Construction of the g_i's. We now specify how to choose the g_i's so that they can be computed efficiently. We do not know how to construct a family of k-wise independent functions so that evaluating a function in the family at a given point requires only $\tilde{O}(1)$ time. Instead we show how to construct a family so that the total computation can be amortized to $\tilde{O}(1)$ time. We change the order of operations in the basic time/space scheme. We do not process cluster by cluster but rather advance one step in every cluster simultaneously. In order to simplify the definition of the g_i's, encode their domain (which is $D \times \{1, \ldots, N\}$) as $\{1, \ldots, N^2\}$ and the range as $\{1, \ldots, N\}$. We actually construct functions $g_i : \{1, \ldots, N^2\} \mapsto \{1, \ldots, N^2\}$, but by simply chopping part of the output we can obtain $g_i : \{1, \ldots, N^2\} \mapsto \{1, \ldots, N\}$ and then consider it as an element of D.

Construct $g_1, g_2, \ldots, g_\ell$ as follows: We work in the finite field $GF[N^2]$ (N is a power of 2), and all computations are in this field. For $0 \leq j \leq k-1$ pick a_j and b_j randomly and independently in $GF[N^2]$. Encode i as an element of $GF[N^2]$ in some arbitrary manner and let g_i be the polynomial of degree $k-1$ whose jth coefficient is $a_j \cdot i + b_j$. That is,

$$g_i(x) = \sum_{j=0}^{k-1} (a_j \cdot i + b_j) x^j.$$

PROPOSITION 4.6. *A function g_i chosen in this manner is k-wise independent.*

Proof. Because each g_i is a random polynomial of degree $k-1$, the proposition follows from [3]. □

From the pairwise independence of polynomials of degree 1, and the random choice of the a and b values above, the set of the $2k$ coefficients of g_i and g_j are independent and we have the following proposition (which was used in Lemma 4.3).

PROPOSITION 4.7. *For all $1 \le i < j \le \ell$, the polynomials g_i and g_j are independent as defined in section* 4.2.

To compute $g_1(x_1), g_2(x_2), \ldots, g_\ell(x_\ell)$, note the following:

$$\begin{aligned} g_i(x) &= \sum_{j=0}^{k-1} (a_j \cdot i + b_j) x^j \\ &= i \cdot \sum_{j=0}^{k-1} a_j x^j + \sum_{j=0}^{k-1} b_j x^j. \end{aligned}$$

Define

$$A(x) = \sum_{j=0}^{k-1} a_j x^j$$

and

$$B(x) = \sum_{j=0}^{k-1} b_j x^j.$$

Thus, $g_i(x) = i \cdot A(x) + B(x)$. Using FFT we can amortize the cost of computing A and B. We can compute $A(x_1), A(x_2), \ldots, A(x_\ell)$ and $B(x_1), B(x_2), \ldots, B(x_\ell)$ at a cost of $O(k \log \ell + \ell)$. (See [1, Chapter 7].) Given $A(x_1), A(x_2), \ldots, A(x_\ell)$ and $B(x_1), B(x_2), \ldots, B(x_\ell)$, computing $g_i(x_i) = i \cdot A(x_i) + B(x_i)$ for all $1 \le i \le \ell$ can be done at a cost of ℓ.

Thus, the total number of operations required to advance one function computation in all g_i is $O(k \log \ell + \ell) = O(t \log \ell + \ell)$.

LEMMA 4.8. *Computing $g_1, g_2, \ldots, g_\ell$ at points $x_1, x_2, \ldots, x_\ell$ can be done in time $O(t \log \ell + \ell)$.*

In order to achieve the time/space trade-off (3.2), given any T and S, set $t = N/S$, $m = N/T$, and $\ell = TS/N$. If $TS^3 = N^3$, then the two constraints of section 4.2, $t \le \ell$ and $mk^2 \le S$, are satisfied, and since we may assume that $S < N/8 \log N$, we also have that $t \ge 8 \log(4m)$. Therefore by Theorem 4.5 we have the desired time and space.

In order to achieve the time/space trade-off (3.1), given any T and S such that $T \cdot S^2 = N^3 q(f)$, set $t = N/S$, $m = N/T$, and $\ell = TS/N$. Note that we have $t \le \ell$, $mk^2 \le 1/q(f)$, and $k/S \le k^2 q(f)$. The conditions $mk^2 \le 1/q(f)$ and $k/S \le k^2 q(f)$ are sufficient to replace the constraint $mk^2 \le S$ in the proofs of Claims 4.1, 4.2, and 4.3. Therefore we have the following corollary.

COROLLARY 4.9. *Any function f which is not trivial to invert in space S can be inverted at any point with high probability using either time/space trade-offs:*

$$\begin{aligned} &T \cdot S^2 = N^3 \cdot q(f) \text{ or} \\ &T \cdot S^3 = N^3. \end{aligned}$$

5. Extensions. For simplicity we have assumed in section 4 that the function f is not trivial to invert in space S. To complete the proof of Theorem 1.1 we must also deal with this case.

If the S highest indegree images cover a substantially large fraction of the domain, then our scheme may suffer degradation in performance since we cannot claim that when evaluating $h_i(x)$ the expected number of evaluations of f and g_i is $O(1)$. On the other hand, in this case table A covers a larger fraction of images and thus the effective domain size is smaller. We will see how to exploit this fact.

Suppose that following the first stage of the preprocessing phase it turns out that the number of elements in $D' = \{x \in D | f(x) \notin A\}$ is $N' < N/2$ (i.e., the function is trivial to invert in space S). Since all $x \notin D'$ are handled by A, we need to construct a scheme that covers only D', thus raising the possibility of improving only the complexity. Our problem is that we do not know how to construct g_i's that map into D' and not D, so we may need more applications of the g_i's in order to assure that we land in D'. For S and T set $m = N/T$ and $\ell = TS/N$ as before, but set $t = N'/S$ and $k = 8N/N' \cdot t = 8N/S$. Note that $t \cdot \ell \cdot m = N'$ and $mk^2 \leq S$ and given that $TS^3 \geq N^3$, then $k \leq \ell$ (this last point is significant for the amortization of computing the g_i's).

Therefore almost all the analysis of sections 4.3 and 4.4 is applicable and in particular the space is $\tilde{O}(S)$ and the time is $\tilde{O}(T)$. The only point we should change is in the proof of Claim 4.1. We must recompute the probability that a chain rooted at x_{ij} is discarded since g_i was invoked more than $k/2$ times. However, this means that in order to find t members of D' more than $k/2 = 4 \cdot N/N' \cdot t$ trials were needed, where in each time the probability of hitting a member of D' is N'/N. The probability that this occurs is at most the probability that a sequence of $k/2$ tosses of a coin contains at least $k/2 - t$ tails (i.e., the event g_i maps to a value x such that $f(x) \in A$) and less than t heads (the event g_i maps to a value x such that $f(x) \notin A$) with probability $p = N'/N$ for heads (by the assumption that $|D'| = N'$). By the Chernoff bound (see Theorem A.13 of [4]) this value is at most $e^{-9t^2/4t}$, which is smaller than $1/m$. This concludes the proof of Theorem 1.1.

Finally, we note that $q(f)$ need not be given explicitly in order to choose the best time/space trade-off. We can consider an additional "proposal" stage in which a function f is studied to determine what time/space trade-offs can be used to invert it. By estimating $q(f)$ we can check which trade-off to use: if $S > 1/q(f)$, we use the trade-off $T \cdot S^3 = N^3$, otherwise we use $T \cdot S^2 = N^3 \cdot q(f)$. Note that estimating the ith bit of $q(f)$ requires 2^i time. We can obtain a slightly pessimistic trade-off by taking a slightly higher value for $q(f)$.

The "proposal" stage should also consider how $q(h_i)$ drops as a function of S. We can estimate $q(h_i)$ by estimating the probability that two elements collide under f given that they *do not* map to any of the S images with largest indegrees. Even if $q(f)$ is big, $q(h_i)$ might drop very quickly as a function of S, becoming much smaller than $1/S$.

6. Open problems. The most challenging problem in this area of investigation is whether the time/space trade-off for inverting functions can be reduced to $T \cdot S = N$. For permutations this is true and Yao [20] has shown that this is tight for permutations. Shamir and Spencer [18] consider schemes of the basic Hellman form, where functions are represented as a collection of chains indicated by their start and end locations, and show that $TS^2 = N^2$ is optimal for these algorithms.

Acknowledgments. We thank Noga Alon and Uri Feige for fruitful discussions. We thank the diligent referees for their many helpful comments.

BUBBLES: ADAPTIVE ROUTING SCHEME FOR HIGH-SPEED DYNAMIC NETWORKS*

SHLOMI DOLEV†, EVANGELOS KRANAKIS‡, DANNY KRIZANC‡, AND DAVID PELEG§

Abstract.
This paper presents the first dynamic routing scheme for high-speed networks. The scheme is based on a hierarchical *bubbles* partition of the underlying communication graph. Dynamic routing schemes are ranked by their *adaptability*, i.e., the maximum number of sites to be updated upon a topology change. An advantage of our scheme is that it implies a small number of updates upon a topology change. In particular, for the case of a bounded degree network it is proved that our scheme is optimal in its adaptability by presenting a matching tight lower bound. Our bubble routing scheme is a combination of a distributed routing database, a routing strategy, and a routing database update. It is shown how to perform the routing database update on a dynamic network in a distributed manner.

Key words. adaptability, dynamic, fiber optics, communication network, routing

1. Introduction.

1.1. Motivation.

The advent of fiber-optic technology dramatically changes the characteristics of distributed networks. It also improves the capabilities of distributed networks because it gives them the potential of supporting new services such as multimedia and real-time applications. Traditional algorithms designed for the point-to-point classical model of distributed networks may neither fit the new characteristics of the high-speed network nor support the new tasks it is capable of achieving. The relation between the bandwidth of a fiber-optic cable (on the order of hundreds of Gigabits per second) and the speed of a processor implies a bottleneck in the process time rather than in the communication time. Therefore, high-speed networks use a fast switching subsystem in order to utilize the power of the fiber-optic cables.

Algorithms for basic tasks that match the new network structure are of interest. In (high-speed) distributed networks, messages are used for communication between different sites. A message sent from one site to another is transferred through the network according to a *routing scheme*. The routing scheme ensures that the message

is forwarded toward its destination. The routing scheme serves the basic communication primitive in the network—message delivery. Being such a basic component, the performance of the distributed network as a whole may be dominated by the quality of the routing scheme. Thus, finding an efficient routing scheme is one of the most important tasks in dealing with distributed networks.

Imagine a network in which users may be connected and disconnected upon request. Users may migrate from one geographic region to another, causing a change in the demand for services at different parts of the network. Assume further that the network spans the entire world and a single user (or a network junction) changes its location from one street in New York to another. Is it reasonable to update the *entire* network with a new routing database? We would not like the *entire* distributed network to be updated upon each such dynamic change. In fact we would like to *minimize* the effect of a topology change as much as possible.

Beyond planned topology changes, such as user migration, some transient topology changes may take place due to a failure of communication links or processors. One would like the network to automatically change the routing database to reflect the new topology upon the change. The resources used by such a distributed routing database update (messages and time) have an inherent relation with the number of sites that have to change their portion of the distributed routing database.

We distinguish between *static* and *dynamic* routing schemes. A *static* routing scheme is a combination of a distributed routing database and a fitting routing strategy. The routing database is tailored to the network topology. Whenever the network changes its topology, a new distributed routing database is assigned to the network, possibly changing the routing database portion of each processor. A *dynamic* routing scheme has in addition a fitting routing database update. Upon a topology change (e.g., link addition or removal) this fitting routing database update would change the distributed database only in a *limited* number of sites. We rank the dynamic routing schemes by their *adaptability*, i.e., the maximum number of sites to be updated upon a topology change. By this definition static routing schemes are associated with adaptability that is in the order of the number of nodes in the network.

The efficiency of a dynamic routing scheme is measured not only by its adaptability. It is also measured by the time and memory complexities associated with it. The time performance is measured by a *super-hop count*, defined as the maximum number of super-hops, or routing steps, needed to route a message from a given source to a given destination, where the maximum is taken over all possible origin–destination pairs. A more precise definition of the routing process in high-speed networks and the notion of super-hops will be given later. The memory complexity is the total number of bits used for the routing database. We remark that there is an interesting relation between the adaptability and the memory requirement; i.e., it is clear that the worst case in terms of adaptability and memory requirement is when the entire topology is stored in the memory of each processor. Roughly speaking, both the adaptability and the memory requirements gain when the processors have less information on the system.

1.2. Previous work. Many clever routing schemes and lower bounds for the resources required for routing in point-to-point networks (e.g., wide area networks) were presented in the past. Following the pioneering work of [13, 14], which originated the approach of using hierarchical clustering [2] strategies for memory-efficient routing, came a number of papers which attempted to characterize and bound the resource tradeoffs involved. The first set of studies along this line were mostly designed for special classes of networks like trees [16], complete networks [18], and grids [19]. Routing schemes for general networks were presented in [15, 4, 6]. These studies focused on the design of routing schemes with compact routing tables and low stretch factors. The *stretch factor* of a routing scheme is defined as the maximum ratio, over all pairs of nodes in the network, between the length of the route provided for them by the routing scheme, and the actual distance between them in the network.

Unfortunately, most of the success in this field is for static networks. Few papers consider the dynamic property of the network. The following quotation is taken from [16]: “In actual network the topology may vary in time; in particular, nodes or links may be added or deleted.” In [16] a partial solution is present for limited cases of topology changes that keep the network in a tree structure. In [7], the routing scheme of [6] is extended to the dynamic case for general networks. However, as argued in [1], network changes in static routing schemes (such as [15, 3, 6] or the derived dynamic scheme [7]) “require expensive pre-processing to reconstruct the routing scheme over the whole network. The newly constructed structure is used until the next change....” In contrast, [1] contains a routing scheme for the restricted case of dynamic growing trees. The solution of [1] can handle neither link nor processor failures, nor can it be applied to the case of general graphs.

These papers all deal with the traditional point-to-point communication model. Those solutions are not applicable for fiber-optic high-speed networks, since the stretch measure (based on actual distances) is no longer the predominant cost parameter relevant to such networks, given their specific characteristics. Furthermore, the issue of adaptability is not handled by any of the aforementioned papers. In particular, the solutions provided in the these papers for the dynamic version of the problem might require database updates in all the nodes of the network following a single topology change.

Recently, static routing schemes for high-speed networks were presented in [12, 10]. The schemes statically assign links along a path to act as a virtual long link. Both papers attempt to simultaneously optimize three cost parameters, namely, the super-hop count, the memory size, and the link load. However, in [12, 10] adaptability is not addressed explicitly, and in the resulting solutions a single topology change may in some cases require the entire routing database to be updated. Hence the solution might be impractical in a dynamically changing environment.

1.3. Contributions of this paper. In this work we present the first dynamic routing scheme for high-speed networks. We present a family of hierarchical *bubbles* schemes. The intuition behind this structure is the behavior of natural bubbles. Assume a partition of a space into bubbles. Whereas bubbles may shrink (members are disconnected) or expand and/or blow up (new members are inserted), we want to avoid total change of the bubble structure upon a change at a single bubble. We define an upper and lower threshold for the size of a bubble. When the upper threshold is reached, the bubble is split into two bubbles. When the lower threshold is reached, the bubble is combined with a single neighboring bubble which “swallows” the small bubble (and then is split if necessary).

The bubbles scheme exhibits a tradeoff between the number of super-hops needed for routing on the one hand, and the adaptability and memory requirement parameters on the other hand. Namely, the more super-hops are allowed, the less memory is needed to store the routing database and the more efficient it becomes to adapt the scheme to dynamic changes. Denote by δ the maximum number of neighboring nodes with which each node in the network may be directly connected. For the case of

	Super-hop count	Memory required	Adaptability	Model
Multiple trees	1	$O(n^2 \log n)$	n	
Single leader	2	$O(n^2 \log \delta)$	n	
Basic bubbles	k	$O(k\delta n^{1+1/k} \log \delta)$	$O(3^k \delta^2 n^{1/k})$	Node failures
Basic bubbles	k	$O(k\delta n^{1+1/k} \log \delta)$	$O(3^k \delta n^{1/k})$	Link failures
Edge-bubbles	k	$O(kn^{1+1/k} \log \delta)$	$O(3^k \delta n^{1/k})$	Node failures
Edge-bubbles	k	$O(kn^{1+1/k} \log \delta)$	$O(3^k n^{1/k})$	Link failures

FIG. 1. *Comparison of routing schemes.*

constant δ we prove that our scheme is optimal in its adaptability by presenting a matching tight lower bound. Note that this is the case in many settings in reality, where the number of communication ports of a single processor is limited. Our bubble routing scheme is a combination of a distributed routing database, a routing strategy, and a routing database update. We present a distributed routing database update strategy for dynamic changing networks.

The rest of the paper is organized as follows. The definition of the problem and two examples for basic routing schemes appear in section 2. These two schemes are given as examples for our complexity measures and a basis for comparison with the bubbles scheme, which is presented in section 4. Section 5 presents an improved scheme, based on a somewhat more involved bubble partitioning algorithm. See Figure 1 for a summary of the comparison among the different schemes. Note that we typically choose k to be a small constant, with a value much smaller than $\log n$. Section 6 presents a lower bound on the adaptability of any routing scheme. The distributed update of the bubbles routing database appears in section 7. Concluding remarks are given in section 8.

2. Definition of the problem.

2.1. High-speed dynamic network. We consider the high-speed model of a communication network as described in [8, 5, 9]. The network is described by an undirected graph $G = (V, E)$. The nodes, $V = \{1, \ldots, n\}$, represent the processors of the network (where n is essentially an upper bound on the number of processors in a connected component). The edges of the graph represent bidirectional communication channels between the processors.

The network is *dynamic* in the strong sense: processors and links may crash and recover arbitrarily. However, the number of edges connected to a node P, which we call the *degree* of P, does not exceed some predefined value. We denote the maximum degree of nodes in the network by δ.

Each processor consists of two components, a *switching subsystem* and a *node control unit*, which are connected by a virtual link. The *switching subsystem* is a fast and simple hardware device that switches arriving packets to the appropriate communication link or to its node control unit. Within the switching subsystem each communication link (including the virtual link to the switching subsystems' node control unit) has a unique label. When a packet p arrives at a switching subsystem and the header of p contains at least one label, then the switching subsystem removes the first label, l, and the shortened packet is sent on the link with label l. The *node control unit* of each processor contains the processing hardware and software necessary to extract the information content of messages (delivered in the packets), do internal computation, and generate packets to be forwarded to other nodes via the processor's switching subsystem.

In this model a packet consists of the entire path from the sender to the receiver. For example, when the packet length is 50 bytes and the degree of nodes in the network is $\delta = 5$, then a packet may contain 5^{50} different addreses. This is more than enough for every existing network. Moreover, note that the first packet in a connection may mark the path (by the connection identifier) for the next packets that are related to the same connection—thus not every packet contains the entire path. Due to the above network architecture, it is assumed that a message sent from any processor, P, to any destination, Q, in the network may arrive in one time unit provided the labels along the entire path from P to Q are known to P. We refer to such a routing step as a *super-hop*.[1] In case the entire path is not known to P, the message may be sent through a number of super-hops. In each super-hop, the sender packs the message in a packet whose header contains the route description to the next intermediate destination, and advancing the message to that destination. Since the overhead of preparing the packets dominates the transmission time, the cost of the entire routing process is proportional to the number of super-hops it involves.

2.2. Complexity measures for routing schemes. The routing of packets in the network is done according to a *distributed routing database* maintained by the node control unit and a fitting *routing strategy* and *database update*.

Super-hop count. The *super-hop count* of a routing scheme bounds the maximum number of super-hops (or, packet generation and transmission steps) required in order to send a message from one node control unit to another. Obviously, a single packet transmission is sufficient when every processor knows the entire topology (including the link labels). Thus, the super-hop count can be thought of as measuring the ratio between the maximum number of packets *generated* by the routing scheme and the optimal number of packets that must be generated in order to deliver a message sent from one node control unit to another. It is interesting to note that in that sense, the super-hop count of a routing scheme in the high-speed model essentially plays a similar role to that played by the *stretch factor* measure in routing schemes for traditional computer networks (cf. [15, 3, 6]).

Memory. The memory complexity is the total number of bits maintained by the node control units for the routing data-structure.

Adaptability. A single topology change $\mathcal{C}$ occurs when a single processor or a single link joins (or recovers) or leaves (or crashes) the system. Note that for any two topologies G_1 and G_2 there exist a finite sequence of single topology changes $\mathcal{C}_1, \mathcal{C}_2, \ldots$ that transfer G_1 into G_2. For example, the sequence can start with adding all the processors that do not appear in G_1 but do appear in G_2, one processor at a time. Then links are added in a similar fashion. Finally, links and then processors are removed to form G_2. Ideally a topology change causes only a very limited number of processors to change their portion of the routing distributed database. Thus, we choose the *adaptability measure* to be the maximum number of processors that have to change their portion of the routing distributed database upon a single topology change. A similar measure, called the *adjustment measure*, is proposed in [11].

We shall first ignore the issue of *how* the routing database is updated upon a topology change and count only the number of processors that have to change their routing

[1]Certain routing models devised for asynchronous transfer mode networks use more elaborate mechanisms and distinguish between several types of "super-hops," e.g., routing along virtual channels or virtual paths. Here, we follow the simple, unified model of automatic network routing (ANR) of [8, 9].

database. Then we present a distributed update for the bubble routing scheme, which we call *bubbles update*.

Distributed adaptability. This is the maximal number of node control units that have to participate in the distributed routing database update upon a single topology change. Clearly, the distributed adaptability is greater than the adaptability since every node control unit that has to change its portion of the routing distributed database participates in the distributed database update, and in addition, other node control units may participate in the distributed update without changing their routing database portion.

3. Examples of basic routing schemes.

In this section we present two basic routing schemes with adaptability n.

3.1. The multiple spanning trees scheme.

The simplest routing scheme for our network is the *multiple spanning trees* routing scheme.

Routing distributed database. The routing distributed database is a description of a spanning tree of the entire topology at each processor.

Routing strategy. The routing strategy is to use the entire path given by the routing distributed database.

Routing update. The routing update has to change the distributed routing database upon every processor addition and removal as well as upon removal of a link used as part of a spanning tree by some processor. The update would change the spanning trees representation in an obvious way.

The following lemma states the super-hop count, memory, and adaptability properties of the multiple trees routing scheme.

LEMMA 3.1. *The multiple trees routing scheme has the following properties:*

1. *super-hop count* $= 1$,
2. *memory requirement* $= n^2(\log n + \log \delta)$,
3. *adaptability* $= n$.

Proof. The super-hop count of this scheme is clearly 1, since a single packet is generated for the delivery of a message.

Property 2 holds since $n(\log n + \log \delta)$ bits are required in order to describe a spanning tree with link labels for every processor (say, in parenthesized form).

Property 3 follows from the fact that a single recovery of a processor or a link requires the update of the tree of every processor. □

3.2. The single leader scheme.

Routing distributed database. Only a single processor, L, has a spanning tree of the entire topology. Every other processor, P, has the path description to L, $path_L$. Thus, $path_L$ is a list of link labels that defines a path from P to L.

Routing strategy. To deliver a message m to a processor Q, a packet $(path_L, Q, m)$ is sent to the leader L, and then L sends a packet $(path_Q, m)$ to Q.

Routing update. The routing update has to change the distributed routing database upon leader failure, processors' addition, processors' removal, failure of a link along a path used by some processor to reach the leader, and addition of a link that connects two connected components. For a given choice of a single leader, the update is defined in a natural way.

The following lemma states the super-hop count, memory requirements, and adaptability properties of the single leader routing scheme.

LEMMA 3.2. *The single leader routing scheme has the following properties:*

1. *super-hop count* $= 2$,

2. *memory requirement* $= n(\log n + \log \delta) + n(n-1)\log \delta$,
3. *adaptability* $= n$.

Proof. The super-hop count is 2 since at most two packets are generated for each message.

The memory requirements of the scheme are as follows. The description of a spanning tree of the entire topology requires $n(\log n + \log \delta)$ bits, as in the proof of Lemma 3.1. The description of a path from a processor P to L includes at most n link labels. Each link label requires $\log \delta$ bits. Thus, each processor but L uses at most $n \log \delta$ bits for the routing database.

Finally, if all the paths to the leader L, as well as the spanning tree stored by L, include a certain link e (say, adjacent to L), then the failure of e (while preserving the connectivity of the communication graph) is a topology change that will cause every processor to change its topology database; hence the adaptability is n. $\square$

4. The bubble routing scheme.

In this section we present our main result, which is a novel dynamic graph partitioning technique, used in conjunction with a new routing scheme for dynamic high-speed networks. We introduce a new type of hierarchical partitioning scheme for general graphs, with certain desirable properties. We then present a graph partitioning algorithm that constructs such a partition. Then we explain how to maintain the properties of the partition (most notably, the size bounds on connected components) upon a dynamic change. Finally, we present our routing scheme, which is based on the hierarchical partition.

The partitioning scheme uses a spanning tree of the communication graph. The partition of the spanning tree into connected components called bubbles is done in levels. The first level is a single bubble that includes $x_1 = n$ nodes. The second level partitions the single bubble into bubbles (i.e., connected components) of at least x_2 (where $x_2 < x_1/\delta$) nodes and no more than δx_2 nodes. In general, the bubble partition of level i partitions the bubble of level $i-1$ into bubbles of at least x_i nodes and no more than δx_i nodes. A failure of a link that belongs to the spanning tree may disconnect a number of bubbles on several levels. We present a scheme to maintain the bubble partition with few changes as long as the communication graph is still connected. Assume that a bubble of level i is partitioned because of a link failure. One or two of the resulting bubble parts may contain fewer than x_i nodes. In such a case each part is combined with a neighboring bubble. Each of the two new combined bubbles may include more than δx_i nodes and therefore require a split. This fact and the fact that the partition on level $i+1$ is a refinement of the partition on level i imply that (at most) three edges should be removed from level $i+1$, namely, the failed link of level i and the two edges that are removed from bubbles of level i because of the split operations. The details follow.

4.1. The bubble partition.

DEFINITION 4.1. *Given a graph G and parameters $0 < a < b$, an $[a, b]$-*bubble partition *of G is a partition of the nodes of G into disjoint* connected *components called* bubbles, *$\mathcal{P} = \{\mathcal{B}^1, \ldots, \mathcal{B}^r\}$, such that the size of each bubble $\mathcal{B}$ (i.e., the number of nodes it contains) satisfies $a \le |\mathcal{B}| \le b$.*

Let us next describe a partitioning algorithm based on a technique presented in [17]. Given a n-node graph G with maximum degree δ and a parameter $1 \le x \le n$, the algorithm produces an $[x, \delta x]$-bubble partition for G. To be more precise, as a preprocessing step we choose an arbitrary node of the graph, R, and construct a spanning tree, $\mathcal{T}_R$, rooted at R with edges directed towards the leaves. The partitioning

```
(1) While $\mathcal{T}$ contains more than $\delta x$ nodes do:
        (a) Mark every node $P$ in $\mathcal{T}$ by $M_P$, the total number of nodes in the
            subtree $\mathcal{T}_P$ rooted at $P$.
        (b) Find a node $P$ with the property that $M_P \geq x$, but all of its children
            $Q$ satisfy $M_Q < x$.
        (c) Make $\mathcal{T}_P$ into a bubble.
        (d) Remove this bubble and the edge connecting $P$ to its parent from $\mathcal{T}$.
        End_while
(2) Make $\mathcal{T}$ into a bubble and terminate.
```

FIG. 2. Algorithm PARTITION($\mathcal{T}, x$).

algorithm is then applied to this tree. The algorithm, PARTITION($\mathcal{T}, x$), is described in Figure 2.

LEMMA 4.1. *Algorithm* PARTITION($\mathcal{T}_R, x$) *produces an* $[x, \delta x]$*-bubble partition of* G.

Proof. Obviously, each bubble constructed in step (1c) is of size at least x and no larger than δx.

We now show that every execution of the loop in step (1) succeeds in finding a candidate node P as required in (1b). Since step (1) is performed only as long as $M_R > \delta x$, R itself trivially satisfies the first requirement, namely, $M_R > x$. It now suffices to show that every tree $\mathcal{T}_Q$ of size $M_Q \geq x$ has a node P as required. This is proved by simple induction on the size of the tree, beginning at size x. For the inductive step we note that if Q has no child with more than x nodes in its subtree $\mathcal{T}_Q$, then Q can be taken as the required P; otherwise, let S be the child of Q with $M_S \geq x$ and apply the inductive hypothesis to $\mathcal{T}_S$, to find a suitable node P in it.

The fact that any execution of the loop in step (1) results in a new bubble and that $\mathcal{T}_R$ is finite implies the termination of the algorithm.

Finally, we show that when the algorithm terminates, $x \leq M_R \leq \delta x$; hence the last bubble is legal as well. The termination condition of the loop implies that when it terminates, $M_R \leq \delta x$. If the number of nodes in the entire graph G is also smaller than δx, then this is the only bubble, and we are done (since $x \leq n$ by choice of x). Otherwise, there exists at least one more bubble. Examine the last removal executed at step (1d) before the termination of the algorithm. Right before this removal, M_R is at least $\delta x + 1$, and as a result of the removal, no more than $(\delta - 1)(x - 1) + 1$ nodes are removed from $\mathcal{T}_R$, leaving at least $\delta x + 1 - (\delta - 1)x + (\delta - 1) - 1 = x + \delta - 1 \geq x$ nodes that are still connected to R. ∎

Theorem 4.2 is implied by the existence of the partition algorithm.

THEOREM 4.2. *For every n-node graph G with maximum degree δ and parameter* $1 \leq x \leq n$, *G has an* $[x, \delta x]$*-bubble partition.* ∎

Next we define special hierarchies of bubble partitions. Given two partitions $\mathcal{P}$ and $\mathcal{P}'$, we say that $\mathcal{P}$ is a *refinement* of $\mathcal{P}'$ if each bubble of $\mathcal{P}$ is fully contained in some bubble of $\mathcal{P}'$ (or equivalently, each bubble of $\mathcal{P}'$ is partitioned into bubbles of $\mathcal{P}$).

DEFINITION 4.2. *Given a graph G and a list of k integer parameters* $\bar{x} = (x_1, x_2, \ldots, x_k, x_{k+1})$, *where* $x_1 = n$, $x_i > \delta x_{i+1}$, *and* $x_{k+1} = 1$, *an* $\bar{x}$-hierarchical bubbles partition *of G is a collection of k partitions $\mathcal{P}_i$, $1 \leq i \leq k$, with the following properties:*

1. *For every* $1 \leq i \leq k$, $\mathcal{P}_i$ *is an* $[x_i, \delta x_i]$*-bubble partition.*
2. *For every* $1 < i \leq k$, $\mathcal{P}_i$ *is a* refinement *of* $\mathcal{P}_{i-1}$.

```
(1) Choose an arbitrary node of the graph, $R$.
(2) Construct a spanning tree $\mathcal{T}_R$ rooted at $R$ with edges directed towards the
        leaves.
(3) Let the first level partition $\mathcal{P}_1$ consist of a single bubble covering the entire
        graph.
(4) For $i = 2$ to $k$ do:
        For every bubble $\mathcal{B}$ of partition $\mathcal{P}_{i-1}$ do:
        (a) Let $\mathcal{T}(\mathcal{B})$ be the portion of $\mathcal{T}_R$ that spans the bubble $\mathcal{B}$.
        (b) Apply Algorithm PARTITION$(\mathcal{T}(\mathcal{B}), x_i)$ to $\mathcal{T}(\mathcal{B})$.
        (c) Add the resulting bubbles to the current level partition $\mathcal{P}_i$.
```

FIG. 3. Algorithm HIERARCHY$(\bar{x})$.

In what follows, we choose the parameters $\bar{x}$ as $x_i = \lceil n^{(k-i+1)/k} \rceil$. This choice satisfies the requirements of the definition, so long as $n^{1/k} \geq \delta$. We use $\mathcal{B}_i$ to denote a bubble at level i. For every bubble $\mathcal{B}_i$ let $\mathcal{T}(\mathcal{B}_i)$ be a representation of the subtree of the spanning tree $\mathcal{T}$ that spans the bubble $\mathcal{B}_i$. (Hereafter we refer to both the description of the spanning tree and the spanning tree itself as $\mathcal{T}(\mathcal{B}_i)$.) Thus, each of the k partitions $\mathcal{P}_i$, $1 \leq i \leq k$, defines a *forest* $\mathcal{F}_i = \bigcup_{\mathcal{B} \in \mathcal{P}_i} \mathcal{T}(\mathcal{B})$. Note that $\mathcal{F}_1$ is identical to the spanning tree $\mathcal{T}$.

We note the following properties of the hierarchical partition. Since each bubble of level i is composed of the union of some bubbles of level $i+1$, the spanning tree $\mathcal{T}(\mathcal{B}_i)$ is a combination of the spanning trees of those bubbles. Hence $\mathcal{F}_{i+1} \subseteq \mathcal{F}_i$ for every $1 \leq i \leq k-1$, and $\mathcal{F}_1$, corresponding to the single bubble containing the whole network, is the entire tree $\mathcal{T}$.[2] These properties will be maintained as invariants of the hierarchical partition throughout the updates performed upon topology changes and are important for the analysis of the scheme, as will be shown later on.

The hierarchical bubble partition of a graph is constructed level by level by Algorithm HIERARCHY$(\bar{x})$, described in Figure 3.

It is clear that $\mathcal{P}_1$ is an $[n, \delta n]$-bubbles partition. Since for every $i > 1$ the partition $\mathcal{P}_i$ is obtained from $\mathcal{P}_{i-1}$ by splitting each bubble $\mathcal{B}$ separately, using Algorithm PARTITION$(\mathcal{T}(\mathcal{B}), x_i)$, the requirements of Definition 4.2 are clearly met, establishing the following theorem.

THEOREM 4.3. *Every graph has an $\bar{x}$-hierarchical bubbles partition.* □

Figure 4 depicts a partition of a graph into bubbles. First, a spanning tree is constructed (the upper part of the figure). Then the spanning tree is partitioned into bubbles of levels 2 and 3 (lower parts of the figure).

4.2. Dynamic maintenance of the partition. In order to use the bubble partition over time in a dynamically changing environment, it is necessary to be able to maintain a legal partition in the presence of link and node failures and recoveries. One point that we need to address first when dealing with the dynamic case is that of failures that disconnect the network. Our policy in such a case is to treat each connected component separately but still to use the global parameters, $\bar{x}$. This has the implication that certain connected components cannot be partitioned in some of the lower levels of the hierarchy, since they are too small. In particular, if a certain connected component G' of the graph has less than x_i (but at least x_{i+1}) nodes, then on levels 1 through i there is a single bubble encompassing the entire connected

[2]We say that $\mathcal{F}_{i+1} \subseteq \mathcal{F}_i$ when every tree in $\mathcal{F}_{i+1}$ is a subtree in $\mathcal{F}_i$.

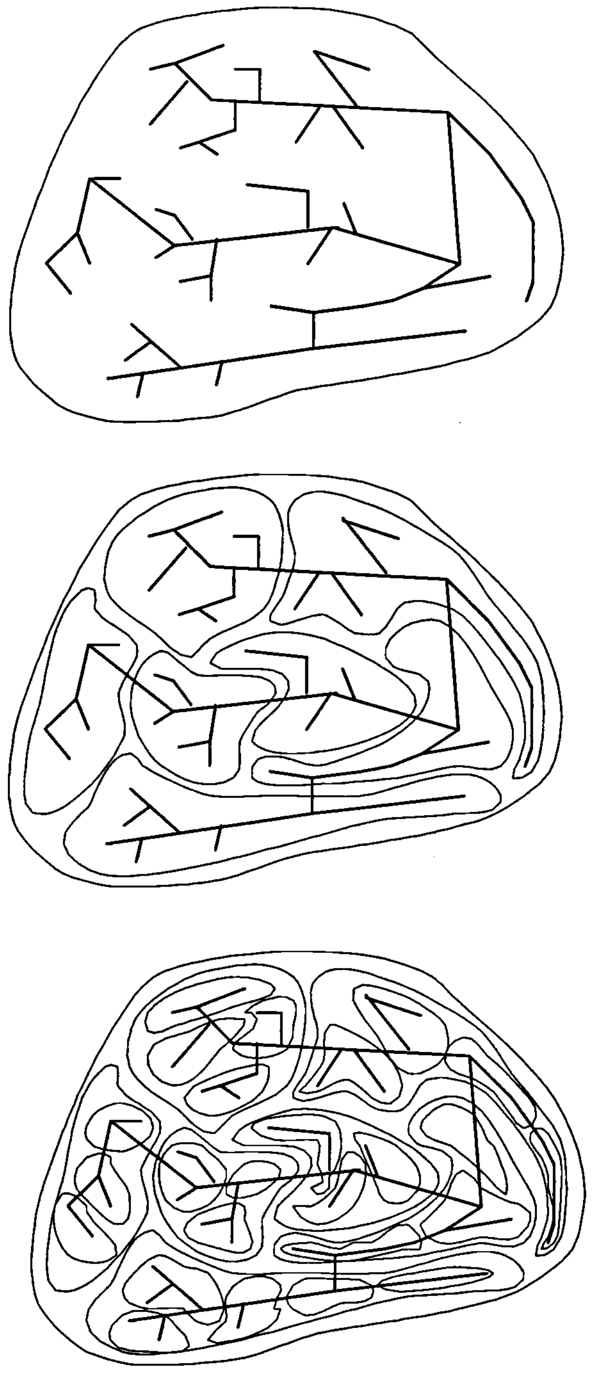

FIG. 4. *Bubble partition $k = 3$.*

```
Input:   Two tree-neighboring level $l$ bubbles $\mathcal{B}'_l$ and $\mathcal{B}''_l$.
Action:
    Connect $\mathcal{T}(\mathcal{B}'_l)$ and $\mathcal{T}(\mathcal{B}''_l)$ using their connecting link.
Output:   A combined bubble $\mathcal{B}_l$.
```

FIG. 5. Procedure COMBINE($\mathcal{B}'_l, \mathcal{B}''_l$).

```
Input:   A (typically oversized) bubble $\mathcal{B}_l$.
Action:
    Select one of the nodes of $\mathcal{B}_l$ to be the root $R$.
    Direct $\mathcal{T}(\mathcal{B}_l)$ from $R$ towards the leaves.
    Execute Algorithm PARTITION($\mathcal{T}(\mathcal{B}_l), x_l$).
Output:   An $[x_l, \delta x_l]$-bubbles partition of $\mathcal{B}_l$.
```

FIG. 6. Procedure SPLIT($\mathcal{B}_l$).

component. This bubble is said to be *illegal*, since it is smaller than the allowed lower bound. The implication of such a situation is that once a connecting link recovers, it is necessary to reorganize the partition in order to "legalize" the bubble structure.

We now present the strategy for handling each topology change. For now, the strategy we describe is centralized, as if an outside operator changes the distributed routing database. Later, in section 7, we discuss a distributed implementation of our maintenance strategy. We use the following definition.

DEFINITION 4.3. *Two bubbles $\mathcal{B}'_l$ and $\mathcal{B}''_l$, both at level $l > 1$, are said to be* tree-neighboring *with respect to (w.r.t.) the level $l - 1$ forest $\mathcal{F}_{l-1}$ if there exists an edge of $\mathcal{F}_{l-1}$ that connects them. We refer to this tree link as the* connecting link *of $\mathcal{T}(\mathcal{B}'_l)$ and $\mathcal{T}(\mathcal{B}''_l)$.*

Our maintenance activities are based on employing two basic operations, or "Procedures," COMBINE($\mathcal{B}'_l, \mathcal{B}''_l$) and SPLIT($\mathcal{B}_l$), described in Figures 5 and 6, responsible for combining and splitting bubbles, respectively. These two basic procedures are used as building blocks for our update operations.

Let us next describe another procedure, named Procedure REMOVE($e, \mathcal{F}_l, \mathcal{F}_{l-1}$), that handles the removal of a link e from the forest of spanning trees of the level $l > 1$ bubbles partition, $\mathcal{F}_l$. This removal can be the result of either the link's failure, or the restructuring of bubbles at the next lower level, $l - 1$, that caused the removal of this link from $\mathcal{F}_{l-1}$. In any case, it is assumed that e does not appear in $\mathcal{F}_{l-1}$. The computation of the new forest $\mathcal{F}'_l$, that no longer contain e, is based on the current forest for level $l-1$, $\mathcal{F}_{l-1}$, in the sense that the only edges that are added to $\mathcal{F}'_l$ during the procedure's execution are also edges of $\mathcal{F}_{l-1}$. Procedure REMOVE($e, \mathcal{F}_l, \mathcal{F}_{l-1}$), described next in Figure 7, relies on the assumption that both $\mathcal{F}_{l-1}$ and $\mathcal{F}_l$ span legal bubbles partitions (of level $l - 1$ and l, respectively). However, it is not assumed that $\mathcal{F}_l$ is a refinement of $\mathcal{F}_{l-1}$.

It is important to understand that Procedure REMOVE ends up not only removing the specified link e from $\mathcal{F}_l$ but also removing some *additional* links, as well as adding some links to $\mathcal{F}_l$, in its attempt to regain the legality of the partition. In particular,

```
Input:   Edge $e$ for removal, forests $\mathcal{F}_l$ and $\mathcal{F}_{l-1}$ spanning legal partitions.
Action:
  The removal of $e$ causes the partition of a single bubble, say $\mathcal{B}_l$, into two portions,
  denoted $\mathcal{B}_l'$ and $\mathcal{B}_l''$.
  For each of these two portions $\hat{\mathcal{B}}$ do:
      1. If the size of $\hat{\mathcal{B}}$ is still greater than $x_l$, then make it into an independent
         bubble without change.
      2. Otherwise, if it is too small, then do the following:
          (a) Find some bubble $\tilde{\mathcal{B}}$ of $\mathcal{F}_l$ that is a tree-neighbor of $\hat{\mathcal{B}}$ w.r.t. $\mathcal{F}_{l-1}$.
          (b) Merge $\tilde{\mathcal{B}}$ and $\hat{\mathcal{B}}$ into $\bar{\mathcal{B}}$ by invoking procedure Combine($\tilde{\mathcal{B}}, \hat{\mathcal{B}}$).
          (c) If $\bar{\mathcal{B}}$ includes more than $\delta x_l$ nodes, then split it by invoking proce-
              dure Split($\bar{\mathcal{B}}$).
Output:   Forest $\mathcal{F}_l'$.
```

Fig. 7. Procedure Remove$(e, \mathcal{F}_l, \mathcal{F}_{l-1})$.

the following scenario may take place during the operation of removing e on level l. Suppose the removal of e breaks bubble $\mathcal{B}_l$ into two portions. We then apply Combine operations to the broken portions, combining them with tree-neighboring level l bubbles. The resulting combined bubbles might be too large, in which case we apply a Split operation to each of them and thus remove additional edges from each.

In the next lemma we establish some basic properties of Procedure Remove and, in particular, prove that the above mentioned phenomenon is bounded.

Lemma 4.4. 1. *If $\mathcal{F}_l$ is the spanning forest of a legal $[x_l, \delta x_l]$-bubbles partition, then after the execution of Procedure* Remove$(e, \mathcal{F}_l, \mathcal{F}_{l-1})$ *and removing the edge e, the output forest $\mathcal{F}_l'$ represents a legal $[x_l, \delta x_l]$-bubbles partition as well.*

2. *Every edge added to $\mathcal{F}_l'$ during the execution of* Remove$(e, \mathcal{F}_l, \mathcal{F}_{l-1})$ *is an edge of $\mathcal{F}_{l-1}$.*

3. *The number of edges removed from $\mathcal{F}_l$ during the execution of* Remove$(e, \mathcal{F}_l, \mathcal{F}_{l-1})$ *is at most* 3.

Proof. It is easy to verify (by simple case by case inspection) that, assuming we start with a legal bubble partition, then each bubble generated during the update process is connected, and the different bubbles are disjoint and cover the entire graph.

For proving part 1, we need to argue that in the output partition every bubble is in the right size range. For establishing the upper size bound, $|\mathcal{B}| \le \delta x_l$, we rely on the fact that whenever the algorithm merges a bubble and it becomes too large, it is split.

For proving that $|\mathcal{B}| \ge x_l$, we rely on the fact that whenever the algorithm creates a bubble $\hat{\mathcal{B}}$ that is too small (as the result of the edge removal), it is combined with a tree-neighboring bubble $\tilde{\mathcal{B}}$, such that their combined size is at least x_l at this time.

The only point that needs to be verified in order to complete the above proof of part 1 is that whenever some portion $\hat{\mathcal{B}}$ of a broken bubble is too small and needs to be combined with a tree-neighboring bubble, the existence of a suitable tree-neighboring bubble $\tilde{\mathcal{B}}$ is guaranteed.

To see this, let $\mathcal{B}_{l-1}$ be a level $l-1$ bubble that includes at least one node of $\hat{\mathcal{B}}$, say v. Since level $l-1$ bubbles are always larger than level l bubbles, $\mathcal{B}_{l-1}$ is a connected component that includes more nodes than $\hat{\mathcal{B}}$ does; hence there must be a node w that is not within $\hat{\mathcal{B}}$ but is within $\mathcal{B}_{l-1}$. A path from v to w in $\mathcal{T}(\mathcal{B}_{l-1})$ must include a link connecting $\mathcal{B}'_l$ to a tree-neighboring level l bubble.

Property 2 follows immediately from the procedure and the definition of a tree-neighboring bubble.

It remains to prove property 3, namely, to show that the procedure removes at most two more edges in addition to the intended e itself. To see this, observe that if a bubble $\bar{\mathcal{B}}$ is created in step 2 by combining bubbles $\tilde{\mathcal{B}}$ and $\hat{\mathcal{B}}$, then $|\hat{\mathcal{B}}| \le x_l$ and $|\tilde{\mathcal{B}}| \le \delta x_l$; hence $|\bar{\mathcal{B}}| \le (\delta+1)x_l$. This implies that Procedure Split($\bar{\mathcal{B}}$) will erase a single edge, splitting $\bar{\mathcal{B}}$ into precisely two new bubbles. This is because the very first splitting operation in Procedure Partition($\mathcal{T}(\bar{\mathcal{B}}), x_l$) will create a bubble of size at least x_l, leaving the remaining portion of the bubble $\bar{\mathcal{B}}$ with fewer than δx_l nodes and thus terminating the procedure. Since steps 1 and 2 of Procedure Remove are executed at most twice, the claim follows. $\square$

The observation made just before Lemma 4.4, combined with claim 3 of the lemma, has the following important implication. Consider a single topology change in the form of the failure of a link e_1, requiring us to remove e_1 on some level l (and possibly also in other levels). This change might in fact cause us to remove up to two other edges, e_2 and e_3, on level $l+1$. But removing each of these three edges e_j on level $l+1$ may in turn cause the removal of two other edges, resulting in a total of nine removals on level 2. More generally, this single topology change might result in up to (but no more than) 3^{i-1} link removal operations in each level i.

Consequently, whenever we need to remove an edge from the partition of some level i, we typically need to immediately fix the partitions of all higher levels, $i+1$ through k, as well. This is done via Procedure RemoveAll. The procedure fixes the bubble partitions $\mathcal{P}_l$ at each level $i \le l \le k$, one at a time, starting from level i and moving up. At each level l, the procedure outputs a corrected forest $\mathcal{F}'_l$. The computation of the new bubble partition of level l, $\mathcal{P}'_l$, and the corresponding forest $\mathcal{F}'_l$, is based on the recently computed forest for level $l-1$, $\mathcal{F}'_{l-1}$, and the old forest $\mathcal{F}_l$ of level l before the topology change. Suppose the procedure already computed the new partition up to and including level $l-1$. As a result, there is a number of edges that appear in $\mathcal{F}_l$ and do not appear in $\mathcal{F}'_{l-1}$ (since they have already been removed on that level). The procedure removes each tree link of $\mathcal{F}_l - \mathcal{F}'_{l-1} = \{e_1, e_2, \ldots, e_m\}$ from $\mathcal{F}_l$. This is done sequentially, edge by edge, and the forest $\mathcal{F}_l$ is modified at each edge removal step to reflect the change. Hence the sequence of link removals creates a sequence of forests $\mathcal{F}_l = \mathcal{F}_l^{(0)}, \mathcal{F}_l^{(1)}, \ldots, \mathcal{F}_l^{(m)} = \mathcal{F}'_l$, where the update for removing e_j leads from $\mathcal{F}_l^{(j-1)}$ to $\mathcal{F}_l^{(j)}$.

It remains to describe the modification of the forest $\mathcal{F}_l^{(j-1)}$ due to the removal of e_j. If e_j is not in $\mathcal{F}_l^{(j-1)}$, nothing need be done. Otherwise, if the removal of e_j causes the partition of some bubble, then we invoke Procedure Remove($e_j, \mathcal{F}_l^{(j-1)}, \mathcal{F}_{l-1}$) to remove the edge and correct $\mathcal{F}_l^{(j-1)}$ into $\mathcal{F}_l^{(j)}$. Again, it is assumed that e_j does not appear in $\mathcal{F}_{l-1}$ and that all edges added to $\mathcal{F}'_l$ or higher partitions during the procedure's execution belong to $\mathcal{F}_{l-1}$. The procedure relies on the assumption that initially, $\mathcal{F}_l$ (for every $i-1 \le l \le k$) spans a legal bubbles partition. Procedure RemoveAll is described formally in Figure 8.

Lemma 4.5. 1. *If $\mathcal{F}_l$ is the spanning forest of a legal $[x_l, \delta x_l]$-bubbles partition for every $i-1 \le l \le k$, then after the execution of Procedure* RemoveAll(e, i) *and removing the edge e, the output forest $\mathcal{F}'_l$ represents a legal $[x_l, \delta x_l]$-bubbles partition,*

```
Input:  Edge $e$ for removal,
   forests $\mathcal{F}_l$ for $i-1 \le l \le k$ spanning legal partitions.

Action:
  Let $\mathcal{F}'_i \leftarrow$ REMOVE$(e, \mathcal{F}_i, \mathcal{F}_{i-1})$.
  For $l = i+1$ to $k$ do:
      1. Let $\{e_1, e_2, \dots, e_m\} = \mathcal{F}_l - \mathcal{F}'_{l-1}$.
      2. Let $\mathcal{F}_l^{(0)} \leftarrow \mathcal{F}_l$.
      3. For $j = 1$ to $m$ do:
           If $e_j$ is in $\mathcal{F}_l^{(j-1)}$, then invoke $\mathcal{F}_l^{(j)} \leftarrow$ REMOVE$(e_j, \mathcal{F}_l^{(j-1)}, \mathcal{F}_{l-1})$.
      4. Let $\mathcal{F}'_l \leftarrow \mathcal{F}_l^{(m)}$.
Output:  Forests $\mathcal{F}'_l$ for $i \le l \le k$.
```

FIG. 8. Procedure REMOVEALL(e, i).

as well, for every $i \le l \le k$.

2. *The output partition $\mathcal{P}'_l$ is a refinement of $\mathcal{P}'_{l-1}$ (i.e., $\mathcal{F}'_l \subseteq \mathcal{F}'_{l-1}$) for every $i \le l \le k$.*

3. *The number of edges removed from $\mathcal{F}_l$ during the execution of* REMOVEALL(e, i) *is at most 3^{l-i+1} for every $i \le l \le k$.*

Proof. Claim 1 follows directly from claim 1 of Lemma 4.4. Moreover, this property holds throughout the process, that is, after the procedure completes handling levels 1 through l and works on level $l+1$, in the internal stage after the procedure has completed handling the removal of the first j edges, and has reached the intermediate forest $\mathcal{F}^{(j)}$, the claim holds for this $\mathcal{F}^{(j)}$.

Claim 2 holds only for the final partition constructed for each level. That is, in intermediate points along the computation of the procedure for some level $l+1$, the intermediate level $l+1$ forest $\mathcal{F}_{l+1}^{(j)}$ might not obey this relationship w.r.t. $\mathcal{F}_l$ (i.e., it may not be that $\mathcal{F}_{l+1}^{(j)} \subseteq \mathcal{F}_l$).

For the final partitions, the claim follows from the fact that in constructing the new level l forest $\mathcal{F}'_{l+1}$, the procedure removes from the original level $l+1$ forest $\mathcal{F}_{l+1}$ any edge of $\mathcal{F}_{l+1} - \mathcal{F}'_l$.

Claim 3 follows directly from claim 3 of Lemma 4.4. □

Note that Lemma 4.5 holds for the case of legal bubbles; i.e., the connected component includes at least x_l nodes. Similar arguments hold for the case in which the connected component is smaller.

Until this stage we described the algorithm used to construct the bubble partition and basic procedures for maintaining the partition. Now we detail how those procedures are invoked in each of the four possibilities for topology changes.

Link removal. If the removal of the link e does not partition the spanning tree of any bubble, then no change of the hierarchical bubble partition is required. If the spanning tree of a bubble is disconnected by removing e, then the link removal is handled at each level starting from level 1 and moving up. At level 1, if the communication graph is still connected, then a nontree link is promoted to be a tree link in order to retain the connectivity of the entire spanning tree, $\mathcal{T}$. The removal itself is then performed by applying Procedure REMOVEALL$(e, 2)$.

Link addition. An addition of a link that does not connect two previously separated connected components does not change the routing database. An addition of a link that does connect two previously disconnected components G' and G'' is handled as follows. Let $\mathcal{T}(\mathcal{B}'_1)$ and $\mathcal{T}(\mathcal{B}''_1)$ be the spanning trees of G' and G'', respectively, before the link addition. Connect $\mathcal{T}(\mathcal{B}'_1)$ with $\mathcal{T}(\mathcal{B}''_1)$ by invoking Procedure Combine$(\mathcal{B}'_1, \mathcal{B}''_1)$, using the new link to form a spanning tree $\mathcal{T}(\mathcal{B}_1)$ of the new connected communication graph.

Continue with levels 2 up to k, one at a time. For level $2 \leq i \leq k$, if the new link connects two legal bubbles, then no update operations are triggered by level i. Otherwise, when the new link connects at least one illegal bubble, combine the illegal bubble with the new tree-neighboring bubble (using Procedure Combine), and split the combined bubble (using Procedure Split) if necessary. The split operation may result in the need to remove a link e at the next level. This is handled by invoking the link removal procedure RemoveAll(e, i) described above. Then the update for level $i + 1$ may be started.

Node addition or removal. Both the addition and the removal of a node can be described in terms of addition and removal of links. The addition is handled by first adding a link that connects two separated connected components one of which is the single node. Then adding the rest of the links one by one. Node removal is done by removing one link at a time and then removing the node.

In order to argue about the correctness of the dynamic update procedures, two main claims need to be established, namely, that at the end of each update operation, each partition $\mathcal{P}_i$ is a legal $[x_i, \delta x_i]$-bubble partition and that the entire hierarchy is a hierarchical bubble partition. These claims are naturally implied by the properties established earlier regarding Procedures Remove and RemoveAll.

Theorem 4.6. *At the end of each update operation, each partition $\mathcal{P}_i$ is a legal $[x_i, \delta x_i]$-bubble partition and the entire hierarchy is a hierarchical bubble partition.*

Proof. We prove the theorem for link removal and addition updates since node additions or removals are reduced to links removals or additions. Link removal employs Procedure RemoveAll. By Lemma 4.5 the result of the procedure is a legal bubble partition. In the case of link addition, each Combine execution is followed by Split and RemoveAll (if required) to result in a legal partition. ∎

4.3. The routing scheme. Next we describe the distributed routing database by the use of the bubble partition.

Routing distributed database. Start by constructing a hierarchical bubbles partition for the network. For every bubble $\mathcal{B}_k$ at level k, define the nodes that reside in $\mathcal{B}_k$ as its *members*, and choose one of these nodes to be the *leader* of the bubble, denoted $L(\mathcal{B}_k)$. In general, for level $i < k$, define the *members* of a bubble $\mathcal{B}_i$ to be all the leaders of level $i + 1$ bubbles that reside in the connected component of $\mathcal{B}_i$. Then choose one of these members to be the bubble's leader, $L(\mathcal{B}_i)$. (The single bubble of level 1, $\mathcal{B}_1$, will have no use for a leader.)

In Figure 9 we illustrate the way the members of the bubbles are chosen. The members of a bubble at level 3 are the nodes that reside in the bubble (omitted from the figure description). For each bubble at level 3 a single leader is chosen (e.g., A, D, or E); this leader is a member of the bubble of level 2 in which it resides. For every bubble at level 2 a leader is chosen among its members (e.g., D or G). These chosen leaders are members of level 1. The tree $\mathcal{T}(\mathcal{B}_i)$ is known to every member of $\mathcal{B}_i$. Note that in particular, every member of $\mathcal{B}_1$ maintains in its memory $\mathcal{T}(\mathcal{B}_1)$, which is a spanning tree of the entire communication graph. Note that for load balancing reasons the representation of the spanning tree can be extended to include the full

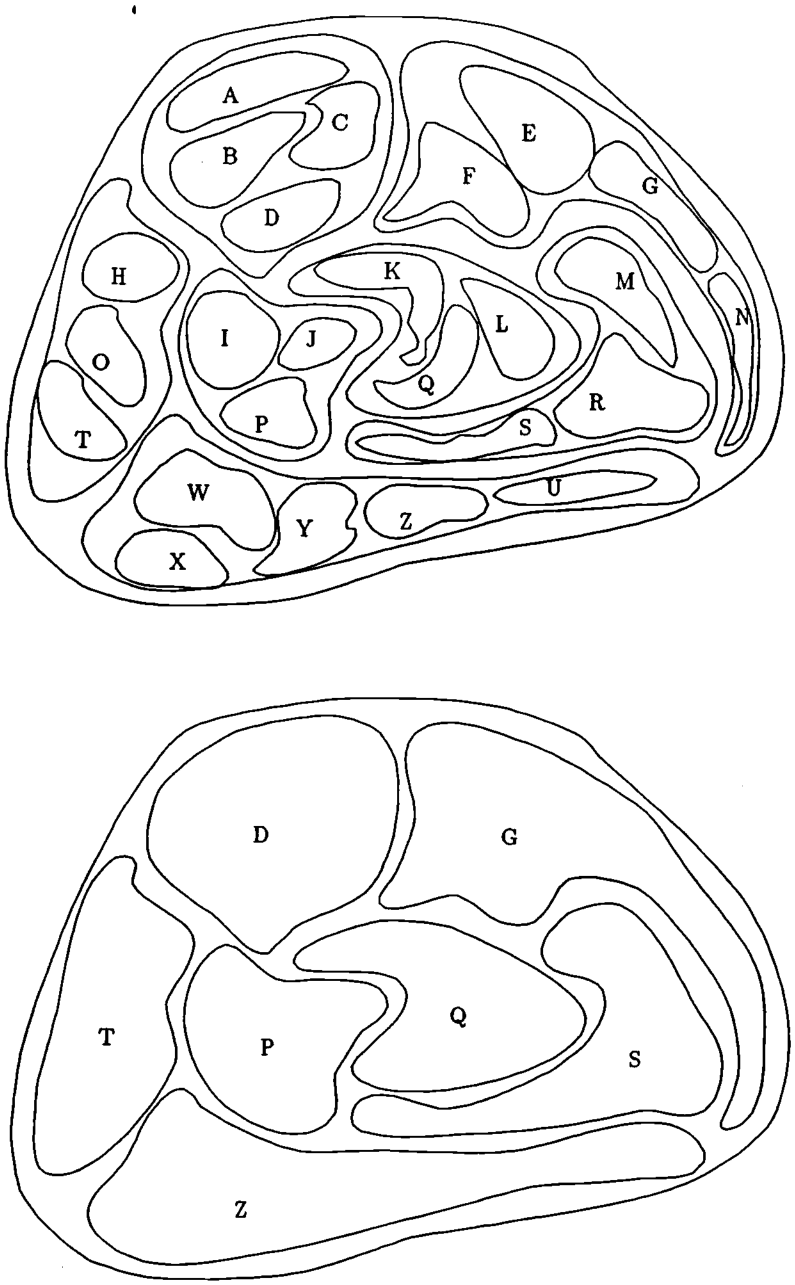

FIG. 9. *The members at level* 2 *and level* 1.

topology of the bubble, if desired, thereby increasing the memory requirement by a factor of δ. The precise method of choosing paths to avoid congestion is beyond the scope of this paper.

Routing strategy. P delivers a message m to a processor Q by the following procedure. Let $i_1 \geq k$ be the lowest level in which P is a member, and let $\mathcal{B}_{i_1}$ be its *home bubble.* Then P searches for Q in the spanning tree description $\mathcal{T}(\mathcal{B}_{i_1})$. If Q is not found in $\mathcal{T}(\mathcal{B}_{i_1})$, then P sends the packet $(path_{L_1}, Q, m)$ to $L_1 = L(\mathcal{B}_{i_1})$, the leader of $\mathcal{B}_{i_1}$. This leader, L_1, repeats the process. That is, let $i_2 < i_1$ be the lowest level in which L_1 is a member, and let $\mathcal{B}_{i_2}$ be its home bubble. Then L_1 searches for Q in the spanning tree description $\mathcal{T}(\mathcal{B}_{i_2})$, and if Q is not found, then L_1 sends the packet $(path_{L_2}, Q, m)$ to $L_2 = L(\mathcal{B}_{i_2})$.

This process must terminate (at a member of $\mathcal{B}_1$ in the worst case) since every member of $\mathcal{B}_1$ has a spanning tree description of the entire communication graph, namely, $\mathcal{T}(\mathcal{B}_1)$.

Routing update. Whenever we apply Procedure COMBINE$(\mathcal{B}'_l, \mathcal{B}''_l)$, the members of the combined bubble have to be updated regarding the new tree. Likewise, whenever we apply SPLIT$(\mathcal{B}_l)$, the members of the two split bubbles have to be updated. Finally, upon adding a new link for reconnecting the tree $\mathcal{T}$, every member of $\mathcal{B}_1$ (namely, every level 2 leader) is updated with the new tree $\mathcal{T}$, similar to any other COMBINE operation.

Analysis. We now turn to analyzing the complexity of the routing scheme. Let us first establish some basic properties of the hierarchical bubble partition. For uniformity of treatment, let us define $x_{k+1} = 1$. Recall that the size of each bubble at level i is in the range $[x_i, \delta x_i]$. Define $\pi_i = \delta x_i / x_{i+1}$. As shown in the next lemma, π_i serves as an estimate for the population of level i bubbles.

LEMMA 4.7. *The number of members in a bubble of level i is at most π_i.*

Proof. A bubble $\mathcal{B}$ of level i has at most δx_i nodes. For $i = k$, every node is a member, and we are done. Now consider $i < k$. The nodes of $\mathcal{B}$ are partitioned into bubbles of level $i+1$, each of which contains at least x_{i+1} nodes. Hence the number of level $i+1$ bubbles contained in $\mathcal{B}$ is at most $\delta x_i / x_{i+1}$. The members of $\mathcal{B}$ are precisely the leaders of these bubbles. The claim follows. □

LEMMA 4.8. *The total number of members in all level i bubbles is at most n/x_{i+1}.*

Proof. For $i = k$, all nodes are members. For $i < k$, the members of level i bubbles are precisely all leaders of level $i+1$ bubbles. Their number is at most n/x_{i+1}, since each such bubble is of size at least x_{i+1}. □

The next three lemmas state the super-hop count, the memory requirement, and the adaptability of the bubble routing scheme.

LEMMA 4.9. *The super-hop count of the bubble routing scheme is bounded by k.*

Proof. In the worst case a processor P that is only a member in level k sends a packet to its bubble leader, Q, which is a member at level $k-1$, and so on. With no more than $k-1$ packets a member of level 1 is reached; this member knows $\mathcal{T}(\mathcal{B}_1)$ and sends a direct packet to the destination of the message. □

LEMMA 4.10. *The memory requirement for the bubble routing scheme is bounded from above by $n(\log n + \log \delta) \sum_{1 \le i \le k} \pi_i$.*

Proof. Every processor maintains a spanning tree of the lowest bubble it is a member of. The members of bubbles at level i maintain a spanning tree of at most δx_i nodes, which requires $\delta x_i(\log n + \log \delta)$ bits. There are at most n/x_{i+1} members altogether at level i, so the memory requirement for the ith level is $\delta x_i(\log n + \log \delta) \cdot n/x_{i+1} = n(\log n + \log \delta)\pi_i$ bits. □

LEMMA 4.11. *The adaptability of the bubble routing scheme is bounded from above by $\delta \sum_{1 \le i \le k} 3^{i-1}\pi_i$ and by only $\sum_{1 \le i \le k} 3^{i-1}\pi_i$ in the link-failure model.*

Proof. The number of processors that change their routing database is greatest when a processor is removed. This number is bounded from above by the effect of removal of δ links one at a time.

The removal of a link that partitions a spanning tree of a bubble at every level implies the largest number of updates. On level 1, such a link removal requires at most n/x_2 updates of the members of $\mathcal{B}_1$.

We continue our analysis according to the description of the link removal procedure. Note that by claim 3 of Lemma 4.5, at most 3^{i-1} edges are removed at level i as the result of a single edge removal at level 1. Since each link belongs to at most one bubble on each level, this bounds also the number of level i bubbles whose topology has undergone changes as a result of this removal.

The routing database must be updated at every member of a bubble whose topology was changed. Hence the total number of members (on all levels) whose routing database must be updated upon a link removal is bounded by $\sum_{1\le i\le k} 3^{i-1}\pi_i$.

The total number of processors that are updated upon a node removal is no more than $\delta\sum_{1\le i\le k} 3^{i-1}\pi_i$. Both claims of the lemma follow. $\square$

We now fix $x_i = \lceil n^{(k-i+1)/k}\rceil$ for $1 \le i \le k$. Then $\sum_{1\le i\le k}\pi_i = k\delta n^{1/k}$ and $\sum_{1\le i\le k} 3^{i-1}\pi_i = \frac{1}{2}(3^k-1)\delta n^{1/k}$. The following theorem summarizes the properties of the bubbles routing scheme.

THEOREM 4.12. *The bubble routing scheme has the following properties:*

1. *super-hop count* $= k$,
2. *memory requirement* $= k\delta n^{1+1/k}(\log n + \log\delta)$,
3. *adaptability* $= 3^k\delta^2 n^{1/k}$ *in the node-failure model and* $3^k\delta n^{1/k}$ *in the link-failure model.* $\square$

5. Improved partitioning: Edge-bubble partition.

5. Improved partitioning: Edge-bubble partition. The bubble routing scheme as described above is efficient when δ is small, and in particular, for bounded degree networks there is a little significance to this factor. However, if δ is large (close to n) and we consider only link failures, the bubble scheme may not compare favorably even with the simple multiple trees scheme, because of the occurrences of δ in the expression for adaptability (and in the expression for memory). For such a case it is desirable to get rid of the dependence of the complexities on δ. Note that a δ factor for the adaptability is inherent to the problem if we consider a model that allows node failures and recoveries. This δ factor is based on the fact that a node addition can cause the connection of δ previously disconnected components.

We now present a modified partitioning scheme called the *edge-bubble partition*, which eliminates a δ factor (occurring in both the bound of adaptability and memory) at the cost of using a somewhat more complex partition and algorithm. Recall that in order to partition the communication graph into node disjoint connected components, the bubble scheme presented above allows the range of the bubble size to be $[x, \delta x]$. It turns out that it is possible to form a bubblelike partition of a tree into *edge-disjoint* trees (i.e., with bubbles possibly sharing nodes), such that the size (i.e., number of edges) of each tree is between x and $3x$.

DEFINITION 5.1. *Given a graph* $G = (V, E)$ *and parameters* $0 < a < b$, *an* $[a, b]$ edge-bubble partition *of* G *is a (possibly node-overlapping) cover of* V *by a collection of edge-disjoint* connected *trees called* bubbles, $\{\mathcal{B}_1, \ldots, \mathcal{B}_q\}$, *where* $\mathcal{B}_i = (V_i, E_i)$, *with the property* $E_i \cap E_j = \emptyset$ *for every* $1 \le i < j \le q$.

Intuitively, the modified scheme can be thought of as utilizing the idea of transforming the tree $\mathcal{T}$ at hand into a *logical* tree $\hat{\mathcal{T}}$ of maximum degree 3 and applying the previous solution to this logical tree. The transformation can be achieved by splitting each node P of degree d into d copies $P_1, \ldots, P_d$, connected by a simple chain, and hanging exactly one child Q_i of P off each copy P_i (see Figure 10).

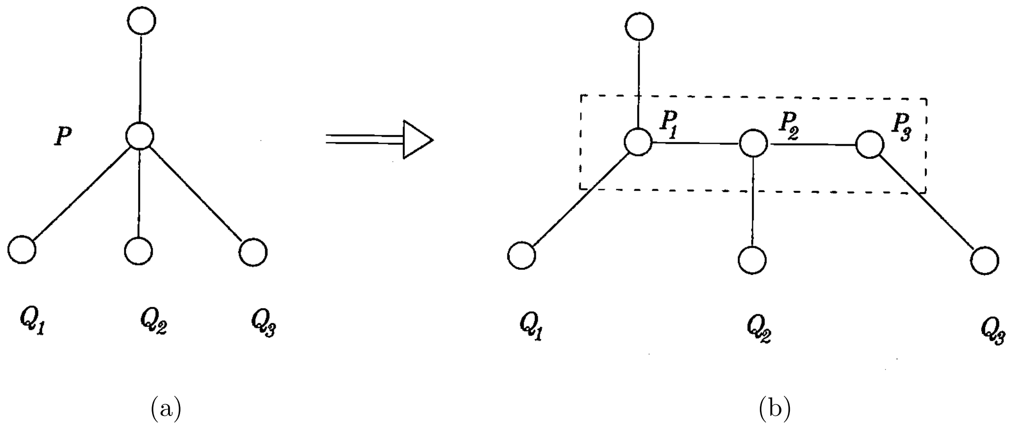

FIG. 10. (a) *A node P of degree* 3. (b) *P is split into three logical copies* P_1, P_2, P_3.

The bubbles solution on the logical tree is simulated on the actual network by requiring each node P to simulate the behavior of its d logical copies. Some care is still needed with respect to the modification procedures, and in particular, it is necessary to specify how a node P reacts to topological changes in terms of reorganizing its internal (logical) structure—for example, as a result of a combine operation that changed its root (and made its former parent into a child and one of its former children into its new parent). In what follows, the resulting algorithm is described directly (rather than via the intuitive simulation method discussed above), in order to gain better understanding concerning its behavior.

We next present an overview of a partitioning algorithm, that given an n-node graph G and a parameter $1 \leq x \leq n$, produces an $[x, 3x]$ edge-bubble partition for G. The new algorithm is similar in nature to Algorithm PARTITION (Figure 2). The essential differences between the two algorithms are that in the new algorithm (i) M_P is the total number of *edges* in the subtree $\mathcal{T}_P$, and (ii) The treatment of a node P found in step (2) of the algorithm, namely, a node P satisfying $M_P \geq x$, such that all of P's children Q satisfy $M_Q < x$, is different. For a particular edge e from P to one of its children, Q, we define a subtree, $\mathcal{T}_e$, rooted at e to be the subtree rooted at Q together with e. Recall that the previous algorithm simply makes the subtree $\mathcal{T}_P$ rooted at P into one bubble, containing, in particular, all the subtrees rooted at P's children. In contrast, the new algorithm will select *some* of the subtrees $\mathcal{T}_e$ rooted at P's outgoing edges of total size greater than x but not exceeding $2x$. The selected subtrees are now merged into an edge-connected bubble. This bubble is removed from the tree. We note that the resulting bubbles are of size $[x, 3x]$, since the partition of the last bubble into two bubbles of size in the range $[x, 2x]$ might not be possible in the case of P having three outgoing edges for which the subtree rooted at each of them is of size less than x but greater than, say, $3x/4$.

We proceed with a more formal description of the algorithm. As in the previous algorithm, a preprocessing step involves constructing a downward-directed spanning tree $\mathcal{T}_R$ for the graph, rooted at an arbitrary node R. The algorithm then partitions this tree into bubbles (see Figure 11).

```
(1) While $\mathcal{T}$ contains more than $3x$ nodes do:
        (a) Mark every node $P$ in $\mathcal{T}$ by $M_P$, the total number of edges in the
            subtree $\mathcal{T}_P$ rooted at $P$.
        (b) Find a node $P$ with the property that $M_P \geq x$, but all of its children
            $Q$ satisfy $M_Q < x$.
        (c) Let $E_P = (e_1, e_2, \ldots, e_i)$ be the edges connecting $P$ to its children.
            Let $n_i$ be the number of edges in the subtree connected to $P$ by
            $e_i$ (including $e_i$). Let $j$ be the minimal index $j$ such that $x \leq$
            $\sum_{i=1}^{j} n_i \leq 2x$.
        (d) Make the edges of the subtrees connected to $P$ by $e_1, e_2, \ldots, e_j$
            (including the edges $e_1, e_2, \ldots, e_j$ themselves) into a bubble.
        (e) Remove this bubble from $\mathcal{T}$.
        End_while
(2) Make $\mathcal{T}$ into a bubble and terminate.
```

FIG. 11. Algorithm EDGEPARTITION(x).

LEMMA 5.1. *Algorithm* EDGEPARTITION(x) *produces an* $[x, 3x]$ *edge-bubble partition of* G.

Proof. The proof is a variant of that of Lemma 4.1. Step (1c) guarantees, by the choice of j, that the selected collection is of total size no greater than $2x$.

Showing that every execution of step (1) succeeds in finding a candidate node P as required in (1b) follows just as in the proof of Lemma 4.1. Hence termination of the algorithm follows in the same way too.

Next, we show that when the algorithm terminates, $x \leq M_R \leq 3x$; hence the last bubble is within the correct size range as well. The termination condition of step (1) implies that when the algorithm terminates, $M_R \leq 3x$. If the number of nodes in the entire graph G is also smaller than $3x$, then this is the only bubble and we are done. Otherwise, there exists at least one more bubble. Examine the last removal executed at step (1c) before the termination of the algorithm. Right before this disconnection M_R is greater than $3x$, and during the disconnection no more than $2x$ edges are removed from $\mathcal{T}_R$, leaving at least (a set of) x edges that are still connected to R (i.e., a path from R to each of the edges in this set consists of only edges of the set). □

Theorem 5.2 is implied by the existence of the partition algorithm.

THEOREM 5.2. *For every* n*-node graph* G *and parameter* $1 \leq x \leq n$, G *has an* $[x, 3x]$ *edge-bubble partition.*

Figure 12 depicts a step in the partition of a graph into edge-bubbles. The tree of the (remaining) graph is depicted in the top portion of the figure. It is assumed that $x = 6$ and hence the partition takes place only in the node of level 2 for which every subtree has less than 6 edges. The partition gathered the first two subtrees to be a bubble of size greater than 6 and not exceeding 12.

Again, for our routing schemes we will use hierarchies of edge-bubble partitions, defined as follows.

DEFINITION 5.2. *Given a graph* G *and a list of* k *integer parameters* $\bar{x} = (x_1, x_2, \ldots, x_k, x_{k+1})$, *where* $x_1 = n$, $x_{k+1} = 1$, *and* $x_i > 3x_{i+1}$, *an* $\bar{x}$-hierarchical edge-bubbles partition *of* G *is a collection of* k *edge-bubbles partitions* $\mathcal{P}_i$, $1 \leq i \leq k$, *with the following properties.*

1. *For every* $1 \leq i \leq k$, $\mathcal{P}_i$ *is an* $[x_i, 3x_i]$ *edge-bubble partition.*
2. *For every* $1 < i \leq k$, $\mathcal{P}_i$ *is a refinement of* $\mathcal{P}_{i-1}$.

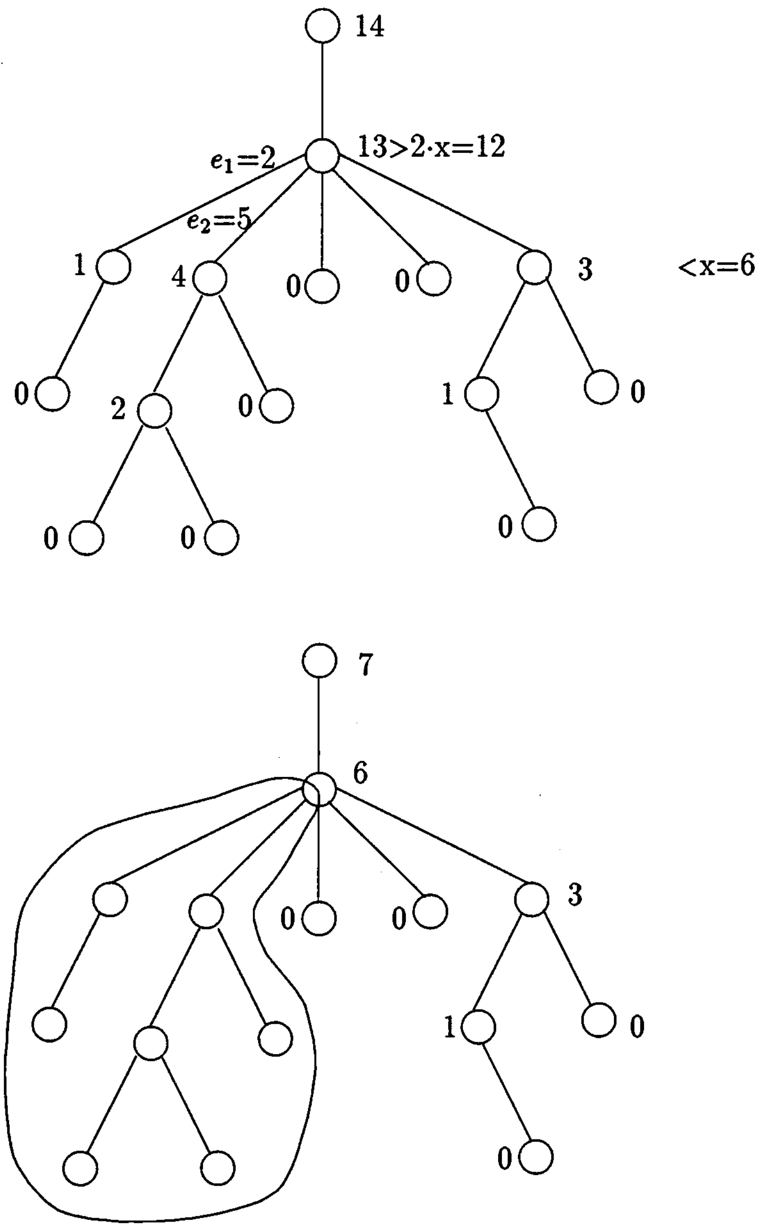

FIG. 12. *A step of the edge-bubbles partition.*

Similar to the previous section, we choose the parameters $\bar{x}$ as $x_i = \lceil n^{(k-i+1)/k} \rceil$.

The hierarchical edge-bubble partition of a graph is constructed by Algorithm EDGEHIER($\bar{x}$) in a manner similar to Algorithm HIERARCHY($\bar{x}$) of section 4, except that the partitioning algorithm invoked is EDGEPARTITION rather than PARTITION. The requirements of Definition 5.2 are clearly met, giving the following theorem.

Input: Two edge-tree-neighboring level l bubbles $\mathcal{B}'_l$ and $\mathcal{B}''_l$.

Action: Connect $\mathcal{T}(\mathcal{B}'_l)$ and $\mathcal{T}(\mathcal{B}''_l)$ using their connecting node.

Output: A combined bubble $\mathcal{B}_l$.

FIG. 13. Procedure EDGECOMBINE($\mathcal{B}'_l, \mathcal{B}''_l$).

Input: A (typically oversized) bubble $\mathcal{B}_l$ and $\mathcal{F}_{l+1}$.

Action: Select one of the nodes of $\mathcal{B}_l$ to be the root R.
Direct $\mathcal{T}(\mathcal{B}_l)$ from R towards the leaves.
Execute steps (1) to (2) of the Algorithm EDGEPARTITION(x_l) (ordered w.r.t. $\mathcal{F}_{l+1}$).

Output: An $[x_l, 3x_l]$ edge-bubbles partition of $\mathcal{B}_l$.

FIG. 14. Procedure EDGESPLIT($\mathcal{B}_l, \mathcal{F}_{l+1}$).

THEOREM 5.3. *Every graph has a hierarchical edge-bubble partition.*

5.1. Dynamic maintenance. Dynamic maintenance of the bubbles is carried out in much the same way as with the basic algorithm of section 4.

The combine and split procedures for the edge partition bubbles appear in Figures 13 and 14. We use the following definition for *edge-tree-neighboring.*

DEFINITION 5.3. *Two bubbles $\mathcal{B}'_l$ and $\mathcal{B}''_l$, both at level l, are said to be* edge-tree-neighboring *w.r.t. the level $l-1$ forest $\mathcal{F}_{l-1}$ if there exist two edges $e' \in \mathcal{B}'_l$ and $e'' \in \mathcal{B}''_l$ adjacent to the same node such that both e' and e'' are in the same bubble of $\mathcal{F}_{l-1}$. We refer to the shared adjacent node of e' and e'' as the* connecting node *of $\mathcal{T}(\mathcal{B}'_l)$ and $\mathcal{T}(\mathcal{B}''_l)$.*

It turns out that the order of the edges $e_1, e_2, \ldots, e_i$ of step (1c) of Algorithm EDGEPARTITION is crucial in the context of dynamic maintenance of the hierarchical partition. When a bubble of level l is split, it might split bubbles of level $l+1$. We would like to minimize the number of bubbles at level $l+1$ that are split because a split of level l took place. Toward this end, we specify the order of the edges $e_1, e_2, \ldots, e_i$ in a way that ensures that at most one bubble of level $l+1$ is split because of a split operation of a bubble in level l. The next definition uses e_0 to denote the edge connecting P with its parent in $\mathcal{T}$.

DEFINITION 5.4. *The execution of Algorithm* EDGEPARTITION *is said to be* ordered w.r.t. $\mathcal{F}_{l+1}$ *if in step* (1c) *of Algorithm* EDGEPARTITION*, the edges $E_P = (e_1, e_2, \ldots, e_i)$ are ordered according to $\mathcal{F}_{l+1}$ in such a way that, for every bubble $\mathcal{B}_{l+1}$, the edges of E_P that belong to $\mathcal{B}_{l+1}$ appear in one contiguous subsequence of E_P. In addition, if e_0 belongs to $\mathcal{B}'_{l+1}$, then the contiguous subsequence of edges in the ordered E_P that belong to $\mathcal{B}'_{l+1}$ (if any) is ordered last among the other contiguous subsequences.*

Procedures EDGEREMOVE and EDGEREMOVEALL appear in Figures 15 and 16. The next lemma states some basic properties of procedure REMOVE.

LEMMA 5.4. 1. *If $\mathcal{F}_l$ is the spanning forest of a legal $[x_l, 3x_l]$ edge-bubble partition, then after the execution of Procedure* EDGEREMOVE($e, \mathcal{F}_l, \mathcal{F}_{l-1}, \mathcal{F}_{l+1}$) *and removing edge e, the output forest $\mathcal{F}'_l$ represents a legal $[x_l, 3x_l]$ edge-bubble partition as well.*

Input: Edge e for removal, forest $\mathcal{F}_l$, $\mathcal{F}_{l-1}$ and $\mathcal{F}_{l+1}$ spanning a legal partition.

Action:

```
The removal of $e_i$ causes the partition of a single bubble, say $\mathcal{B}_l$, into two portions,
denoted $\mathcal{B}'_l$ and $\mathcal{B}''_l$. Let $\hat{\mathcal{B}}_l$ be an edge-tree-neighboring of $\mathcal{B}_l$ and w.l.o.g. of $\mathcal{B}'_l$.
For $\hat{\mathcal{B}} = \mathcal{B}'_l$ and then $\hat{\mathcal{B}} = \mathcal{B}''_l$ do:
    1. If the size of $\hat{\mathcal{B}}$ is still greater than $x_l$, then make it into an independent
       bubble without change.
    2. Otherwise, if it is too small, then do the following:
        (a) If $\hat{\mathcal{B}} = \mathcal{B}'_l$ then let $\tilde{\mathcal{B}}$ be $\hat{\mathcal{B}}_l$.
            Else find some bubble $\tilde{\mathcal{B}}$ of $\mathcal{F}_l$ that is an edge-tree-neighbor of $\hat{\mathcal{B}}$
            w.r.t. $\mathcal{F}_{l-1}$.
        (b) Merge $\tilde{\mathcal{B}}$ and $\hat{\mathcal{B}}$ into $\bar{\mathcal{B}}$ by invoking procedure EdgeCombine($\tilde{\mathcal{B}}, \hat{\mathcal{B}}$).
        (c) If $\bar{\mathcal{B}}$ includes more than $3x_l$ nodes, then split it by invoking proce-
            dure EdgeSplit (ordered w.r.t. $\mathcal{F}_{l+1}$).
```

Output: Forest $\mathcal{F}'_l$.

FIG. 15. Procedure EDGEREMOVE$(e, \mathcal{F}_l, \mathcal{F}_{l-1}, \mathcal{F}_{l+1})$.

2. *Every two bubbles combined into a single bubble of $\mathcal{F}'_l$ during the execution of* EDGEREMOVE$(e, \mathcal{F}_l, \mathcal{F}_{l-1}, \mathcal{F}_{l+1})$ *resides in a single bubble of $\mathcal{F}_{l-1}$.*

Proof. It is easy to verify (by simple case-by-case inspection) that, assuming we start with a legal bubbles partition, each bubble generated during the update process is connected and that the different bubbles are disjoint and cover the entire graph.

For proving part 1, we need to argue that in the output partition, every bubble is in the right size range. For establishing the upper size bound, $|\mathcal{B}| \leq 3x_l$, we rely on the fact that whenever the algorithm merges a bubble and it becomes too large, it is split.

For proving that $|\mathcal{B}| \geq x_l$, we rely on the fact that whenever the algorithm creates a bubble $\hat{\mathcal{B}}_j$ that is too small (as the result of an edge removal operation), it is combined with a tree-neighboring bubble $\tilde{\mathcal{B}}$ that is of size at least x_l.

The only point that needs to be verified in order to complete the above proof, is that whenever some portion $\hat{\mathcal{B}}$ of a broken bubble is too small and needs to be combined with a tree-neighboring bubble, the existence of a suitable tree-neighboring bubble $\tilde{\mathcal{B}}$ is guaranteed.

To see this, let $\mathcal{B}_{l-1}$ be a level $l-1$ bubble that includes at least one node of $\hat{\mathcal{B}}$, say v. Since level $l-1$ bubbles are always larger than level l bubbles, $\mathcal{B}_{l-1}$ is a connected component that includes more edges than $\hat{\mathcal{B}}$ does, hence there must be an edge w that is not within $\hat{\mathcal{B}}$ but is within $\mathcal{B}_{l-1}$. A path in $\mathcal{T}(\mathcal{B}_{l-1})$ from v to one of the nodes attached to w must include a node connecting $\hat{\mathcal{B}}$ to an edge-tree-neighboring level l bubble.

Property 2 follows immediately from the procedure and the definition of an edge-tree-neighboring bubble. ◻

The following lemma uses Lemma 5.4 to prove some properties of Procedure REMOVEALL.

LEMMA 5.5. 1. *If $\mathcal{F}_l$ is the spanning forest of a legal $[x_l, 3x_l]$ edge-bubble partition for every $i \leq l \leq k$, then after the execution of Procedure* REMOVEALL(e, i) *and*

```
Input:  Edge $e$ for removal, forests $\mathcal{F}_l$ for $i-1 \le l \le k$ spanning legal partitions.

Action:
  Let $\mathcal{F}'_i \leftarrow$ EdgeRemove($e, \mathcal{F}_i, \mathcal{F}_{i-1}$).
  For $l = i+1$ to $k$ do:
      1. Let $\{\mathcal{B}_1, \mathcal{B}_2, \dots, \mathcal{B}_m\}$ be all the bubbles such that, $\mathcal{B}_j$, $1 \le j \le m$, resides
         in more than a single bubble of $\mathcal{F}_{l-1}$.
      2. Let $\mathcal{F}_l^{(0)} \leftarrow \mathcal{F}_l$.
      3. For $j = 1$ to $m$ do:
         (a) Partition $\mathcal{B}_j$ into $\{\mathcal{B}_{j_1}, \mathcal{B}_{j_2}, \dots, \mathcal{B}_{j_x}\}$ such that each $\mathcal{B}_{j_y}$, $1 \le y \le x$,
             is the maximal portion of $\mathcal{B}_j$ that resides in a single bubble of $\mathcal{F}_{l-1}$.
         (b) For $y = 1$ to $x$ do:
              i. Make $\mathcal{B}_{j_y}$ a bubble.
             ii. If the size of $\mathcal{B}_{j_y}$ is too small then find an edge-tree-neighboring
                 bubble of $\mathcal{B}_{j_y}$, $\mathcal{B}'_j$, EdgeCombine($\mathcal{B}_{j_y}, \mathcal{B}'_j$). If the resulting
                 bubble, $\mathcal{B}''_j$, is a too big bubble then EdgeSplit($\mathcal{B}''_j, \mathcal{F}_{l+1}$)
                 (ordered w.r.t. $\mathcal{F}_{l+1}$).
      4. Let $\mathcal{F}'_l \leftarrow \mathcal{F}_l^{(m)}$.

Output:  Forests $\mathcal{F}'_l$ for $i \le l \le k$.
```

FIG. 16. Procedure EdgeRemoveAll(e, i).

removal of the edge e, the output forest $\mathcal{F}'_l$ *represents a legal* $[x_l, 3x_l]$ *edge-bubble partition for every* $i \le l \le k$.

2. *The output partition* $\mathcal{P}'_l$ *is a refinement of* $\mathcal{P}'_{l-1}$ *(i.e.,* $\mathcal{F}'_l \subseteq \mathcal{F}'_{l-1}$*) for every* $i \le l \le k$.

Proof. Claim 1 follows directly from claim 1 of Lemma 5.4 and the EdgeCombine and EdgeSplit procedures applied to the portions of the bubbles. Note that in the execution of EdgeCombine($\mathcal{B}_{j_y}, \mathcal{B}'_j$), $\mathcal{B}'_j$ is not a portion of $\mathcal{B}_j$ and thus is a legal-sized bubble. Moreover, as in Lemma 4.5, this property holds throughout the process, namely, for each intermediate forest $\mathcal{F}^{(j)}$.

Claim 2 holds (again as in Lemma 4.5) only for the final partition constructed for each level.

For the final partitions, the claim follows from the fact that in constructing the new level l forest $\mathcal{F}'_{l+1}$, the procedure handles every bubble portion. □

The update operations are handled in a similar fashion to the first bubble partition operations, yielding the next theorem.

THEOREM 5.6. *At the end of each update operation, each partition* $\mathcal{P}_i$ *is a legal* $[x_i, 3x_i]$ *edge-bubble partition, and the entire hierarchy is a hierarchical edge-bubble partition.*

5.2. The routing scheme. The routing proceeds as in section 4. The only points to note are the following.

A node with adjacent edges $e_1, e_2, \dots, e_j$ is a member of every bubble at level k to which one of its edges belongs. For each bubble of level k, a single *leader-edge* is elected from among the edges of the bubble—then one of the adjacent node of the leader-edge is elected to be the leader (node) of the bubble. Note that a single node may function as a leader of several (up to δ) bubbles.

The elected leader-edge and the elected leader (node) are members of the bubble of level $k-1$ at which the elected leader-edge resides. For each bubble of level $k-1$, $\mathcal{B}_{k-1}$, a single leader-edge is elected from among its edge members. The elected edge and the leader of level $k-1$ attached to it are members of the bubble of level $k-2$ at which the elected edge resides. This membership definition is naturally extended to the next lower levels. Similar to the node partition bubbles, a member of a bubble maintains the spanning tree portion of the bubble.

Analysis. The next three lemmas state the super-hop count, the memory requirement, and the adaptability of the edge-bubble routing scheme. The end result is very similar to the analysis of section 4, except that π_i is redefined as $\pi_i = 3x_i/x_{i+1}$. The proof of the next lemma is identical to the proof of Lemma 4.9.

LEMMA 5.7. *The super-hop count of the edge-bubble routing scheme is bounded by k.*

LEMMA 5.8. *The memory requirement for the edge-bubble routing scheme is bounded from above by $n(\log n + \log \delta)\sum_{1\le i\le k}\pi_i$.*

Proof. For every edge e such that the lowest level bubble that e is a member of is $\mathcal{B}_i$ there is an adjacent processor that maintains a description of $\mathcal{T}(\mathcal{B}_i)$. A bubble of level i includes at most $3x_i$ edges. The total number of bits required for such a description of a tree is $3x_i(\log n + \log \delta)$. Since there are at most n/x_{i+1} edge members altogether at level i, the memory requirements for the ith level is $3x_i(\log n + \log \delta)\cdot n/x_{i+1} = n(\log n + \log \delta)\pi_i$ bits. □

LEMMA 5.9. *The adaptability of the edge-bubble routing scheme is bounded from above by $\delta\sum_{1\le i\le k}3^{i-1}\pi_i$ and by only $\sum_{1\le i\le k}3^{i-1}\pi_i$ in the link-failure model.*

Proof. The number of processors that change their routing database is greatest when a processor is removed. This number is bounded from above by the effect of removal of δ links, one at a time.

The removal of a link that partitions a spanning tree of a bubble at every level implies the largest number of updates. On level 1, such a link removal requires at most n/x_2 updates of the members of $\mathcal{B}_1$.

We continue our analysis according to the description of the link removal procedure. Since we use ordered partition whenever EDGEREMOVE is invoked, a partition of a bubble at level l results with partition of up to three bubbles of level $l+1$. The bubble in which the partition of level l occurred and two other neighboring bubbles.

Thus, at most 3^{i-1} bubbles are partitioned at level i as the result of a single edge removal at level 1. Hence the total number of members (on all levels) whose routing database must be updated upon a link removal is bounded by $\sum_{1\le i\le k}3^{i-1}\pi_i$.

The total number of processors that are updated upon a node removal is no more than $\delta\sum_{1\le i\le k}3^{i-1}\pi_i$. Both claims of the lemma follow. □

We now fix $x_i = \lceil n^{(k-i+1)/k}\rceil$ for $1 \le i \le k$. Then $\sum_{1\le i\le k}\pi_i = k\delta n^{1/k}$ and $\sum_{1\le i\le k}3^{i-1}\pi_i = \frac{1}{2}(3^k-1)\delta n^{1/k}$. The following theorem summarizes the properties of the edge-bubble routing scheme.

THEOREM 5.10. *The edge-bubble routing scheme has the following properties:*

1. *super-hop count $= k$,*
2. *memory requirement $= kn^{1+1/k}(\log n + \log \delta)$,*
3. *adaptability $= 3^k\delta n^{1/k}$ in the node-failure model and $3^k n^{1/k}$ in the link-failure model.* □

6. Lower bound. In this section we prove a lower bound on the adaptability for graphs with bounded degree δ and super-hop count k. For the purpose of establishing the lower bound, we consider a single destination for all messages and then derive a tree of superhops, rather than of links.

Given any source-oblivious routing scheme with super-hop count k, we build a spanning tree T_k as follows. The root of the spanning tree is a processor P. Assume that every processor is to send a message m to P, and connect each processor Q with the destination of its first packet when Q sends m to P. The *depth* of a tree is the maximal number of edges from the root to a leaf.

CLAIM 6.1. *T_k is of depth no more than k.*

Proof. Otherwise the super-hop count is greater than k. □

CLAIM 6.2. *There exists at least one node with at least $(n/2)^{1/k}$ children in T_k.*

Proof. There are n processors in T_k and the depth of T_k is k. Letting Δ denote the maximum out-degree of T_k, the number of nodes in the tree satisfies $n \leq \sum_{0 \leq i \leq k} \Delta^i \leq 2\Delta^k$ (as $\Delta \geq 2$, implied by $n > k$). Hence $\Delta \geq (n/2)^{1/k}$. □

THEOREM 6.3. *Any source-oblivious routing scheme with super-hop count k has adaptability $\Omega(n^{1/k})$ in a communication graph of constant degree.*

Proof. Let Q be a processor that has at least $(n/2)^{1/k}$ children in T_k. The existence of Q is implied by Claim 6.2. The node Q is connected to the rest of the processors in G by at most δ links. Thus, by the pigeon-hole principle there must be a link, (Q, R), used by a set C of at least $(n/2)^{1/k}/\delta$ processors in sending their first packet to carry the message to P. We now show a sequence of at most three topology changes, involving *edge* removals and additions only, that implies $(n/2)^{1/k}/(3\delta)$ adaptability.

If a disconnection of (Q, R) does not partition the communication graph, then obviously this topology change alone forces all $(n/2)^{1/k}/\delta$ processors of the set C to change their routing database.

Now we analyze the case in which the removal of the link (Q, R) does partition the graph. We need to show that there exists a sequence of changes that preserve the bound on the degree δ and forces an omission of the link (Q, R) from the routing tables. We claim there are two different cases.

Case 1. Before the disconnection of (Q, R), the graph G is a tree, and the number of processors is greater than two. In this case, following the disconnection of (Q, R) there must be at least one leaf $X \notin \{Q, R\}$, say, w.l.o.g. in the connected component of Q. Then one more topology change, involving the reconnection of X to R, is possible without exceeding δ. As a result of this change, the graph becomes connected again, and the nodes of the set C are forced to change their routing database to use the resulting tree for reaching P.

Case 2. Before the disconnection of (Q, R), the graph G contains at least one cycle. In this case, following the disconnection one of the connected components must contain a cycle (otherwise no partition would take place). Let (X, Y) be a link in this cycle and w.l.o.g. assume that (X, Y) is in Q's connected component and that $X \neq Q$. Disconnect (X, Y) and connect X to R. Again the connection of X to R is possible without exceeding δ.

Thus at most three topology changes cause $(n/2)^{1/k}/\delta$ processors to change their routing database. □

7. Distributed bubble update.

7. Distributed bubble update. So far we have not been concerned with the issue of how to distribute the bubble update algorithm. Still the upper bound described for the adaptability of the bubble routing scheme is useful for the case of manually adding and removing links and nodes. This is the case for telephone networks, where new users may be connected and existing users may be disconnected. However, our results are made stronger by handling topology changes automatically while keeping the low adaptability. That is, the number of node control units that participate in the distributed automatic update together with the number of node control units that must change their portion of the routing distributed database is low. For the sake of keeping a low adaptability, we introduce a distributed bubble update algorithm that can cope with transient failures and recoveries as well as permanent disconnection and connections.

The main idea for the distributed bubble update is to have the processors neighboring a topology change to be the *monitors* of the change. The task of a monitor is (1) to collect information on the tree structure it belongs to and on the existing routing database, (2) to try to merge with other neighboring trees, and (3) to modify the existing routing database to fit the current topology. The modification should be performed in a way that involves the least number of node control units.

Toward this end it is assumed that each switching subsystem has a *sack variable* which may be modified by the node control unit. This sack variable contains the processor's portion of the distributed routing database. The sack variable can be collected by a special arriving message. We also assume that an arriving message may be concatenated with the label of the link through which it arrived. Note that no direct modification of the set of labels or the sack variable by an arriving message is allowed.

The links of the spanning tree $\mathcal{T}(\mathcal{B}_1)$ are distributively marked on the edges of the system. The two endpoints of a tree link are marked by a label t. In the following, we use the term *marked tree* to be the graph obtained by the set of marked links and the nodes they connect. Upon failure of a tree link the marked tree of a connected component may essentially be a marked forest that has to be fused to a new marked tree. Each tree in the forest is an autonomous entity with a monitor. The monitors of trees in the forest negotiate in order to promote a nontree link into a tree link. Upon such a promotion the number of trees (and monitors) in the forest is reduced by one. More details follow.

A monitor is associated with the time of the topology change that created it. We assume the existence of a synchronized clock at every processor. Each monitor uses the marked tree it belongs to for *tree broadcast with feedback* (in short, TBF). The TBF collects the information in the sacks of every processor that belongs to the tree and delivers the information to the monitor. The monitor initiates the TBF by sending a message with its identifier, the timestamp of its creation, and a TB (tree-broadcast) label on every marked tree link. Every switch that receives a message m of type TB concatenates the unique label of the link through which m arrived to the end of the message and forwards a copy of the message to each link that is labeled t except the link through which m arrived. If no other tree link exists (the switch is a leaf in the marked tree), then the switch modifies the message as follows: TB is replaced by TF (tree feedback), the labels at the end become the address of the message (that transfer it back to the TBF initiator), and the content of the sack is concatenated to the end of the message. When a switch receives a TF message it removes the first label of the message that arrived and concatenates the value of its sack to the tail of the message.

A processor P starts to act as a monitor when either of the tree links attached to it fails or an attached link recovers. A monitor marks the label that leads from its switching subsystem to itself by the label m. This enables the switching subsystem to deliver a copy of every BF message to its node control unit when the node control unit is a monitor. Then the monitor collects information on its tree and the distributed routing database of this tree. This is done by the tree broadcast with feedback mechanism. Whenever a tree broadcast with feedback of another monitor arrives at (the node control unit of) P and the timestamp of the arriving TBF is greater (breaking ties by the monitors identifiers), P stops being a monitor.

Upon receiving the information from the tree broadcast with feedback, P checks whether there are neighboring processors that do not belong to its tree. If such neighboring processor exists, then P sends a *promote* message to the processor Q attached to the link with the highest lexicographic order that leads to a neighboring tree. (For purposes of this lexicographic ordering, the name of a link is defined as the pair of identifiers of the two processors that are attached to it, where the first identifier in the pair is always greater than the second.) Then Q becomes the monitor and queries the other side about the possibilities of merging. Upon receiving an accept message, the link changes its status to a tree link, and the monitor with the smaller identifier sends the information collected in its TBF to its neighbor. At the same time it stops being a monitor. When there is no further possibility of merging, the corrections of the routing database are sent by the monitor to the appropriate node control units, and the processor that acted as a monitor resumes operation as a regular processor.

LEMMA 7.1. *In every instance of time and for every connected component, if the marked tree does not span the entire connected component, then for each tree in the forest there exists at least one monitor.*

Proof. This is true in the first instance of the system. Further topology changes keep this invariant. A monitor stops existing only when another monitor exists in the same tree or when the marked tree spans the entire connected component. □

LEMMA 7.2. *If no monitor exists in a connected component, then the distributed routing database of this connected component is correct.*

Proof. For every connected component of more than a single processor, there has been an instance in which one processor of this connected component has been a monitor, i.e., the instance that follows a connection of any two neighboring processors by a link. The last processor that stopped being a monitor in this connected component must have finished the corrections of the distributed routing database. □

LEMMA 7.3. *At some time following the last topology change, no monitor exists.*

Proof. The tree broadcast with feedback terminates. Then the monitor may wait for a promotion of a link into a tree link. Assume toward contradiction that the monitor waits for some link promotion forever. This in turn implies that the monitor of the other tree portion is waiting on another edge that has a greater identifier. Since links that are to be promoted into tree links are chosen according to lexicographic order, this chain of waiting monitors is finite and must end with two monitors waiting on the same edge. □

THEOREM 7.4. *The distributed adaptability is of the adaptability order.*

Proof. Only monitors and the node control units that have to change their distributed routing database participate in the distributed bubbles update. The number of monitors is no more than 2δ for a topology change: at most δ are directly influenced and another δ are the result of monitor migration.

Note that, during the correction process of the distributed routing database by one monitor, a topology change might take place, stopping the update before it is completed. Nevertheless, the partial correction process took place in a limited number of bubbles (as explained for the centralized case), leaving most of the bubbles unaffected.

Thus, the number of node control units that have to change their distributed routing database following c topology changes is $O(ck3^{k-1}\delta^2 n^{1/k})$.

The theorem is proved since the additional $O(\delta)$ monitors do not change the $O(k3^{k-1}\delta^2 n^{1/k})$ adaptability. □

8. Concluding remarks.

In this paper we defined new measures for the efficiency of routing schemes for high-speed dynamic networks. We presented the concept of the bubble partition of a graph to support routing in high-speed dynamic networks. We believe that the resulting bubble partitioning technique may be of independent interest in other contexts as well. Our routing scheme is efficient in terms of the number of routing steps (super-hop count), memory, and adaptability. The routing scheme also supports load balancing of traffic by allowing each processor to forward a message along a randomly chosen path within its bubble (the path does not necessarily belong to the bubble tree). The scheme has been proven optimal in its adaptability for a network of bounded degree and for a small constant k by a matching lower bound.

A number of variants of our scheme are possible in different contexts. We briefly discuss some of them next.

8.1. The programmable model.

The basic model as described assumes that the labels associated with each link are fixed and permanent. A natural variant of this model is one in which it is assumed that the switching subsystem permits the node control unit to configure the link labels dynamically, or in other words, that the link labels are programmable. This assumption is commonly made in the high-speed model, including PARIS (cf. [5]), and in fact, it is often assumed that each link may have a *set* of usable labels. We shall refer to this variant of the model as the *programmable model*.

A possible implementation enabling this assumption is as follows. Each port in the processor has a permanent (hard-wired) *physical id*. In addition, the link has a logical label, which can be changed from time to time. The switching subsystem maintains a *conversion mechanism*, enabling it to translate any given logical label into the appropriate physical port id. Hence upon the arrival of a message, the switching subsystem removes the first label l, consults the mechanism for the appropriate physical port id, and forwards the message to that port for transmission.

For the programmable model, a simple variant of the single-leader routing scheme can be implemented with $O(n \log n)$ memory requirements (as opposed to $O(n^2 \log n)$ of the original single-leader scheme). The necessary modifications are as follows. Given the spanning tree, each processor labels its link upward in the tree (toward the root L) by 0. (The rest of the links may be labeled arbitrarily with a nonzero value.) A message with zero in its header that arrives at a nonroot is forwarded through the link labeled zero without shortening the message. For the first part of each message transmission, namely, the path from v to L, the processor v attaches the label zero to the message header. The root maintains the entire tree topology and forwards arriving messages to their destinations, using nonzero labels.

8.2. Constrained bubble partitions.

The second variant is related to special restrictions on the bubble partition. For some cases the bubble partition might be restricted due to other constraints, e.g., geographic constraints. For instance, one would not like to have two bubbles (say, at level 2) cover the network in the United States, such that one of the bubbles includes Japan and the other includes the United Kingdom; instead a single bubble for the United States is preferred. Our bubble partition can take into account such considerations by ignoring some of the communication links during the bubble partition in some levels.

1. Introduction.

In this paper, we give a polynomial-time algorithm for the following problem: Given a degree sequence in which each degree is bounded from above by a constant, select, uniformly at random (u.a.r.), an unlabelled connected multigraph with the given degree sequence. We also give a polynomial-time algorithm for the following related problem: Given a molecular formula, select, u.a.r, a *structural isomer* having the given formula. A molecular formula [18] simply gives the number of atoms of each kind that occur in a molecule. A *structural formula* [17] is a method of representing the way in which the atoms in a molecule are linked together. A *structural isomer* is a structural formula, viewed as an unlabelled multigraph in which the vertices are of several different kinds.

Some of the structural isomers corresponding to a given molecular formula are chemically irrelevant due to geometric (and other) constraints. Nevertheless, counting all of the structural isomers corresponding to a given formula is a long-standing open problem for which no practical general solution has been found [18]. Solutions do exist for certain restricted cases of chemical compounds [16, 17, 18]. Benecke et al. [2], Faulon [8], and Wieland, Kerber, and Laue [21] have developed (and coded) algorithms for *listing* all of the structural isomers corresponding to a given molecular formula. These programs typically allow the user to prescribe and forbid substructures and some of the programs deal with geometric constraints. These programs are useful if the number of structural isomers corresponding to the relevant formula is sufficiently small, so the isomers can all be listed. Faulon has argued [10] that randomly sampling structural isomers is useful for structural elucidation and molecular design in cases in which the number of isomers is too large to list them all. He [9] has developed a program for randomly sampling structural isomers and has used it for chemical applications such as a statistical study of the potential energy distribution of the isomers of C_8H_{10} and the structural elucidation of several compounds.

Faulon's program applies to a realistic chemical problem including 3-D simulation of molecules and chemical analysis. However, his methods are heuristic. By contrast, we study an idealization of the problem (randomly sampling structural isomers without regard to geometric and other chemical constraints) but we achieve rigorous performance guarantees—polynomial-time computation and exactly uniform generation. Thus, we describe the first polynomial-time algorithm that uniformly samples structural isomers given a molecular formula. Our isomer-sampling algorithm is based on our algorithm for uniformly sampling unlabelled connected multigraphs with a given degree sequence.

1.1. Previous work. Uniformly sampling *labelled* multigraphs with a given bounded-degree sequence can be done in polynomial time by dynamic programming. More sophisticated techniques exist for a wider class of degree sequences—see, for example, Jerrum and Sinclair [13] and McKay and Wormald [14]—but it is not known how to apply these techniques to the problem of sampling *unlabelled* multigraphs. Nijenhuis and Wilf [15] showed how to uniformly sample unlabelled rooted trees with a specified number of vertices. This approach was extended by Wilf [22], who showed how to uniformly sample free (unrooted) trees. Their algorithms are based on an inductive definition (i.e., a generating function) for the trees. This approach will be systematized by Flajolet, Zimmerman, and Van Cutsem in a forthcoming paper [12].

More complicated techniques are required when the graphs to be sampled are not trees. Dixon and Wilf [7] were the first to give an algorithm for uniformly sampling unlabelled graphs with a specified number, n, of vertices. Their algorithm is based on Burnside's lemma. First, a permutation of the n vertices is chosen with the appropriate probability and then a graph is chosen u.a.r. from those graphs which are fixed by the chosen permutation. The choice of the permutation requires a calculation of the number of unlabelled graphs with n vertices. Wormald's algorithm [25] avoids doing this expensive calculation. Instead, it achieves a uniform distribution by restarting itself when appropriate. Wormald's method can also be used to sample r-regular graphs u.a.r. for any fixed degree $r \geq 3$. The method relies on the fact that most unlabelled r-regular graphs are rigid (without nontrivial symmetries) when $r \geq 3$. This is not true for $r = 1$ or $r = 2$.

1.2. Outline of our algorithm. Our algorithm for sampling unlabelled connected multigraphs with a given degree sequence combines the above ideas with other ideas from the field of random graphs. A natural approach to the problem is the approach of Wormald—first generate a permutation of the vertices, then generate a random connected multigraph fixed by the permutation, and finally use rejection/restarting to obtain the correct distribution. However, this approach relies heavily on the fact that many of the desired structures are rigid (so the algorithm will be likely to choose the identity permutation, which leads to a quick result without restarting). This is not the case for the set of unlabelled connected multigraphs with a given degree sequence, because the degree sequence may have many vertices of degree 1 and 2. Thus, we first reduce our problem to that of sampling unlabelled connected multigraphs with degree sequences that do not have any vertices of degree 1 or 2. Every multigraph G is associated with a unique "core" which has no vertices of degree 1 or 2. To generate G, we will generate the core of G and we will then extend the core by adding trees and chains of trees to obtain G.

For the generation of the core, we work in the configuration model of Bender and Canfield [1], Bollobás [4], and Wormald [23]. The correctness of our algorithm follows from a careful analysis of unlabelled configurations in which all block sizes are at least 3. This analysis extends Bollobás's analysis of unlabelled regular graphs [3]. Our algorithm rejects the generated core if it is not connected. The fact that this does not happen too often follows from a result of Wormald [24]. After generating the core of our random multigraph, we extend the core by adding trees and chains of trees. This part of our algorithm is based on the generating function approach mentioned earlier. An alternative approach, also based on generating functions, is to use Pólya's theorem. This approach was used to enumerate molecules with certain specified "frames" (a frame is somewhat similar to a core) by Pólya and Read [16] and others.

1.3. Outline of this paper. Section 2 sets up the machinery that we will use to reduce the general multigraph problem to the problem in which the degree sequence has no vertices of degree 1 or 2. Section 3 solves the problem when there are no vertices of degree 1 or 2. Section 4 describes the tools that we will use to lift the solution from section 3 to a solution for general degree sequences. Section 5 gives our sampling algorithm and proves that it is correct. Section 6 extends our result to the chemical problem—given a molecular formula, select, u.a.r., a structural isomer having the given formula.

2. Cores and colored configurations.

A d-rooted *multigraph* is a tuple $G = (V, E, r_0, \dots, r_{d-1})$, in which V is the *vertex set* of G, E is the *edge multiset* of G, and $r_0, \dots, r_{d-1}$ are distinct roots in V. Each element of E is an unordered pair of vertices. The expression $E(v, w)$ denotes the multiplicity of (v, w) in E. A *cycle* of G is a (closed, simple) path from a vertex v to itself that uses each edge (x, y) at most $E(x, y)$ times. (If any edge is used twice then the path is in fact of length 2.) We use the term *rooted multigraph* to refer to any d-rooted multigraph (for any d, including $d = 0$), and we use the term *multigraph* to refer to any 0-rooted multigraph. A rooted *tree* is a connected rooted multigraph (in fact a graph) with no cycles. The definitions imply that a connected unicyclic multigraph is either a connected unicyclic graph or a multigraph obtained from a tree by doubling one of its edges.

The *degree* of vertex v in a rooted multigraph $G = (V_n, E)$ is

$$d(v) = 2\,E(v, v) + \sum_{w \in V, w \neq v} E(v, w).$$

Let Δ be any fixed constant. In this paper we will be concerned with rooted multigraphs whose vertices have degree at most Δ. The *degree sequence* of such a rooted multigraph G is the sequence $\mathbf{n} = n_0, \dots, n_\Delta$, where n_i denotes the number of vertices of G with degree i. The integers $n_0, \dots, n_\Delta$ are represented in *unary,* so the input size of the degree sequence $\mathbf{n} = n_0, \dots, n_\Delta$ is $n = n_0 + \cdots + n_\Delta$. (Similarly, the input size of degree sequence $\mathbf{n}' = n'_0, \dots, n'_\Delta$ will be denoted $n' = n'_0 + \cdots + n'_\Delta$.) Let V_n be the set $\{v_1, \dots, v_n\}$, and $\mathcal{G}_\mathbf{n}$ the set containing

- every connected multigraph with degree sequence $\mathbf{n}$ and vertex set V_n that has at least two cycles, and
- every 1-rooted connected tree with degree sequence $\mathbf{n}$ and vertex set V_n, and
- every 1-rooted connected unicyclic multigraph with degree sequence $\mathbf{n}$ and vertex set V_n, in which the root is part of the cycle.

Two d-rooted multigraphs $G = (V, E, r_0, \dots, r_{d-1})$ and $G' = (V', E', r'_0, \dots, r'_{d-1})$ are said to be *isomorphic* (written $G \cong G'$) if there is a bijection π from V to V' such that, for all unordered pairs (v, w) of vertices in V, $E(v, w) = E'(\pi(v), \pi(w))$, and for all roots r_j of G, $\pi(r_j) = r'_j$. Note that if $V = V'$ then π can be viewed as a permutation of the vertices in V. Isomorphism induces an equivalence relation on $\mathcal{G}_{\mathbf{n}}$ and the equivalence classes are called isomorphism classes. We use the notation $\widetilde{\mathcal{G}}_{\mathbf{n}}$ to denote the set of isomorphism classes of $\mathcal{G}_{\mathbf{n}}$. If a rooted multigraph G is isomorphic to some $G' \in \mathcal{G}_{\mathbf{n}}$ then we use the notation $\Psi(G)$ to denote the isomorphism class of G'. For any isomorphism class $U \in \widetilde{\mathcal{G}}_{\mathbf{n}}$ we use the notation $\Psi^{-1}(U)$ to denote the lexicographically least member of U.

We consider two nondeterministic transformations which may be applied to a rooted multigraph G with vertex set V and edge multiset E. Similar transformations were used by Zhan in [26].

T_1: Choose a degree-1 vertex v other than the root of G. Remove v from V and the edge containing v from E.

T_2: If T_1 cannot be applied to G, choose a degree-2 vertex v other than the root of G such that for vertices $w \neq v$ and $x \neq v$, (v, w) and (v, x) are in E. (We allow $w = x$, but naturally insist that (v, w) and (v, x) are taken to be distinct elements from the edge multiset.) Remove v from V. Remove (v, w) and (v, x) from E and add (w, x) to E.

Note that the transformations T_1 and T_2 do not change the labels of vertices. A rooted multigraph $G \in \mathcal{G}_{\mathbf{n}}$ is *irreducible* if neither transformation T_1 nor T_2 can be applied to it.

OBSERVATION 2.1. *If $G \in \mathcal{G}_{\mathbf{n}}$ and G can be transformed into G' by T_1 or T_2 then, for some $\mathbf{n}'$ with $n' < n$, $\Psi(G') \in \widetilde{\mathcal{G}}_{\mathbf{n}'}$.*

Informally, Observation 2.1 says that the transformations T_1 and T_2 preserve the properties of being connected and of having at least two cycles.

OBSERVATION 2.2. *If $G \in \mathcal{G}_{\mathbf{n}}$ and some sequence of T_1 and T_2 transform G into G', then the sequence is of length less than n.*

We say that a degree sequence $\mathbf{n}$ is *irreducible* if any of the following applies, and that it is *degenerate* if one of the first two possibilities applies.

1. $\mathbf{n}$ describes the single-vertex multigraph. That is, $n_0 = 1$ and $n_i = 0$ for $i \neq 0$.
2. $\mathbf{n}$ describes the single-self-loop multigraph. That is, $n_2 = 1$ and $n_i = 0$ for $i \neq 2$.
3. $\mathbf{n}$ describes multigraphs without low-degree vertices. That is, $n_0 = n_1 = n_2 = 0$ and $n_i > 0$ for some $i \in [3, \ldots, \Delta]$.

We say that a rooted multigraph is *degenerate* if its degree sequence is degenerate.

OBSERVATION 2.3. *$G \in \mathcal{G}_{\mathbf{n}}$ is irreducible iff its degree sequence is irreducible.*

LEMMA 2.4. *If $G \in \mathcal{G}_{\mathbf{n}}$ and G can be transformed into irreducible rooted multigraphs G_1 and G_2 using a sequence of transformations T_1 and T_2, then $G_1 = G_2$.*

Proof. Suppose G has vertex set V and edge multiset E. We will show that if G can be transformed into distinct rooted multigraphs G_1 and G_2 by a single transformation, then there is a rooted multigraph G_3 such that a (possibly empty) sequence of transformations transforms G_1 into G_3 and another (possibly empty) sequence of transformations transforms G_2 into G_3. Thus, the transformation process is *locally confluent* [20]. As the process terminates in finite time (see Observation 2.2), it is *confluent,* which implies the result [20].

Suppose that T_1 with choice v transforms G into G_1 and T_1 with choice $w \neq v$ transforms G into G_2. Note that $(v, w) \notin E$ (otherwise, either v or w would be the root of G). Let G_3 be the result of applying T_1 to G_1 with choice w. Then T_1 with choice v transforms G_2 into G_3.

Suppose that T_2 with choice v transforms G into G_1 and T_2 with choice $w \neq v$

transforms G into G_2. Note that (v, w) does not appear twice in E (otherwise, either v or w would be the root of G). Let G_3 be the result of applying T_2 to G_1 with choice w. Then T_2 with choice v transforms G_2 into G_3. $\square$

Note that the proof of Lemma 2.4 would have failed if we had included unrooted trees and unicyclic graphs in $\mathcal{G}_{\mathbf{n}}$. It is for this reason that the definition of $\mathcal{G}_{\mathbf{n}}$ is slightly more complicated that might be expected. As we observed in Observation 2.2, a rooted multigraph G can only be transformed a finite number of times before an irreducible rooted multigraph G' is reached. G' is called the *core* of G and is denoted by $\mathrm{Core}\,(G)$. $\mathrm{Core}\,(G)$ is uniquely defined, by Lemma 2.4.

LEMMA 2.5. *If G_1 and G_2 are in $\mathcal{G}_{\mathbf{n}}$ and $\pi(G_1) = G_2$, then $\pi(\mathrm{Core}\,(G_1)) = \mathrm{Core}\,(G_2)$.*

Proof. Consider a sequence of transformations that transforms G_1 into $\mathrm{Core}\,(G_1)$. Now apply this sequence of transformations to G_2, but choose $\pi(v)$ instead of v for each vertex v that is chosen. Clearly, the result is $\mathrm{Core}\,(G_2)$. Thus, $v \notin \mathrm{Core}\,(G_1)$ exactly when $\pi(v) \notin \mathrm{Core}\,(G_2)$. $\square$

Lemma 2.5 implies that if $G_1 \cong G_2$, then $\mathrm{Core}\,(G_1) \cong \mathrm{Core}\,(G_2)$. (This property was also used by Zhan [26].) We use the notation $\widetilde{\mathcal{G}}_{\mathbf{n},\mathbf{n}'}$ to denote the set $\{U \in \widetilde{\mathcal{G}}_{\mathbf{n}} \mid \Psi(\mathrm{Core}\,(\Psi^{-1}(U))) \in \widetilde{\mathcal{G}}_{\mathbf{n}'}\}$; loosely, $\widetilde{\mathcal{G}}_{\mathbf{n},\mathbf{n}'}$ is the set of unlabelled connected multigraphs with degree sequence $\mathbf{n}$ whose cores have degree sequence $\mathbf{n}'$. We will need the following definitions. Let $\mathcal{B}$ be an (infinite) set containing one representative from each isomorphism class of the set of 1-rooted trees. A *tree-chain* with two roots is constructed from any sequence $T_1, \dots, T_k$ of 1-rooted trees as follows: If the sequence is empty, then the tree-chain consists of r_0 and r_1 and an edge between them. Otherwise, the tree-chain graph is constructed as follows: Choose distinct labels for the vertices of $T_1, \dots, T_k$. Let $r'_1, \dots, r'_k$ be the roots of $T_1, \dots, T_k$. For $i \in [1, \dots, k-1]$, add edge (r'_i, r'_{i+1}). Add the new roots r_0 and r_1 and edges (r_0, r'_1) and (r'_k, r_1). For every tree-chain G, we use the notation $R(G)$ to denote the tree-chain constructed from G by swapping r_0 and r_1. Let $\mathcal{P}$ be a set containing one representative from each isomorphism class of tree-chains. (Note that the two roots of a tree-chain are distinguishable, and any isomorphism of tree-chains must respect this distinction.)

In the following definition of "coloring," colors will encode information that is lost while forming the core. We will use colorings to recover an original rooted multigraph from its core. A *coloring* of a rooted multigraph G is a function λ that maps each vertex in the vertex set of G to an element of $\mathcal{B}$ and each edge in the edge multiset of G to an element of $\mathcal{P}$.

We will describe a function Γ that maps each colored rooted multigraph (G, λ) to an isomorphism class. $\Gamma(G, \lambda)$ is constructed as follows, where V denotes the vertex set of G and E denotes the edge multiset of G: Start with the collection of rooted trees $\{\lambda(v) \mid v \in V\} \cup \{\lambda(e) \mid e \in E\}$. Let the roots of the resulting forest be the roots of those trees that correspond to the roots of G. For each edge $(u, w) \in E$ with $u \le w$, identify root r_0 of $\lambda(u, w)$ with the root of the tree $\lambda(u)$ and root r_1 of $\lambda(u, w)$ with the root of the tree $\lambda(w)$. Relabel to avoid name clashes. Let $\Gamma(G, \lambda)$ be the isomorphism class of the resulting rooted multigraph.

Given a degree sequence $\mathbf{n}$, let $m = \frac{1}{2}\sum_i i\, n_i$ and let $B_{\mathbf{n}}$ be the lexicographically least partition of the point set $R_{\mathbf{n}} = \{1, \dots, 2m\}$ into *blocks* (subsets) such that, for each i, there are n_i blocks of size i. A d-rooted *configuration* C with degree sequence $\mathbf{n}$ [1, 4] is a tuple $(R_{\mathbf{n}}, B_{\mathbf{n}}, P, r_0, \dots, r_{d-1})$ where P is a partition of the points in $R_{\mathbf{n}}$ into *pairings,* which are unordered pairs of points and $r_0, \dots, r_{d-1}$ are distinct blocks (roots). We use the phrase *configuration* to mean a 0-rooted configuration and the phrase *rooted configuration* to mean a d-rooted configuration for any d (including $d = 0$). We let Multigraph (C) denote the rooted multigraph obtained from C by identifying the points in each block. We say that C is *connected* if Multigraph (C) is connected. If $\mathbf{n}$ is degenerate, let $\mathcal{C}_{\mathbf{n}}$ be the set containing the 1-rooted configuration with degree sequence $\mathbf{n}$. For all other irreducible degree sequences $\mathbf{n}$, let $\mathcal{C}_{\mathbf{n}}$ be the set containing all connected unrooted configurations with degree sequence $\mathbf{n}$.

A *coloring* of a rooted configuration $C = (R, B, P)$ is a function λ that maps each block $b \in B$ to an element of $\mathcal{B}$ and each pairing $p \in P$ to an element of $\mathcal{P}$. The function Γ is defined in terms of the corresponding function for rooted multigraphs. In particular, $\Gamma(C, \lambda)$ is defined to be equal to $\Gamma(\text{Multigraph}\,(C), \lambda)$. We use the notation $\mathcal{C}_{\mathbf{n},\mathbf{n}'}$ to denote the set $\{(C, \lambda) \mid C \in \mathcal{C}_{\mathbf{n}'} \text{ and } \Gamma(C, \lambda) \in \widetilde{\mathcal{G}}_{\mathbf{n},\mathbf{n}'}\}$.

For degree sequence $\mathbf{n}'$ let $K_{\mathbf{n}'}$ denote the *Kranz* group [6] operating on the points in $R_{\mathbf{n}'}$. Each permutation π in $K_{\mathbf{n}'}$ is associated with a tuple $(\pi_0, \ldots, \pi_{|B_{\mathbf{n}'}|})$ where π_0 is a permutation of blocks and π_i for $i > 0$ is a permutation of the points within block i. To apply π to $R_{\mathbf{n}'}$, one first permutes the blocks using π_0, and then permutes the points within block i (for each i) using π_i. A rooted configuration $C_1 = (R_{\mathbf{n}'}, B_{\mathbf{n}'}, P_1, r_{0,1}, \ldots, r_{d-1,1})$ is said to be *isomorphic* to a rooted configuration $C_2 = (R_{\mathbf{n}'}, B_{\mathbf{n}'}, P_2, r_{0,2}, \ldots, r_{d-1,2})$ if there is a permutation $\pi = (\pi_0, \ldots, \pi_{|B_{\mathbf{n}'}|}) \in K_{\mathbf{n}'}$ such that for all pairings $(u, v) \in P_1$ we have $(\pi(u), \pi(v))$ in P_2 and for all $j \in [0, d-1]$ we have $\pi_0(r_{j,1}) = r_{j,2}$. The colored rooted configuration $C_1' = (C_1, \lambda_1)$ is said to be *isomorphic* to the colored rooted configuration $C_2' = (C_2, \lambda_2)$ if there is an isomorphism $\pi = (\pi_0, \ldots, \pi_{|B_{\mathbf{n}'}|})$ between C_1 and C_2 such that for all blocks $b \in B_{\mathbf{n}'}$, $\lambda_1(b) = \lambda_2(\pi_0(b))$ and for all pairings $(u, v) \in P_1$, $\lambda_1(u, v) = \lambda_2(\pi(u), \pi(v))$. Note that if $(C_1, \lambda_1) \cong (C_2, \lambda_2)$ and $(C_1, \lambda_1) \in \mathcal{C}_{\mathbf{n},\mathbf{n}'}$, then $(C_2, \lambda_2) \in \mathcal{C}_{\mathbf{n},\mathbf{n}'}$. We use the notation $\widetilde{\mathcal{C}}_{\mathbf{n},\mathbf{n}'}$ to denote the set of isomorphism classes in $\mathcal{C}_{\mathbf{n},\mathbf{n}'}$. The *automorphism group* of rooted configuration C (denoted $\text{Aut}(C)$) is the group of isomorphisms between C and itself. The *colored automorphism group* of rooted colored configuration (C, λ) (denoted $\text{Aut}(C, \lambda)$) is the group of isomorphisms between (C, λ) and itself.

LEMMA 2.6. *If $G \in \mathcal{G}_{\mathbf{n}}$ and C is a rooted configuration such that* Multigraph $(C) \cong$ Core (G)*, then there is a coloring λ such that $\Psi(G) = \Gamma(C, \lambda)$.*

Proof. The process of forming core Core (G) with vertex set V and edge multiset E can be viewed as deleting a tree $h(v)$ for each node $v \in V$ and a tree-chain $h(u, v)$ for each edge $(u, v) \in E$. Suppose that $\pi(\text{Multigraph}\,(C)) = \text{Core}\,(G)$. Let λ be a coloring of Multigraph (C) defined by $\lambda(v) = h(\pi(v))$ and

$$\lambda(u, v) = \begin{cases} h(\pi(u), \pi(v)) & \text{if } \pi(u) < \pi(v), \\ R(h(\pi(u), \pi(v))) & \text{otherwise}, \end{cases}$$

where we assume the endpoints of the edge (u, v) are normalized so that $u < v$. Then $G \in \Gamma(\text{Multigraph}\,(C), \lambda)$ so $G \in \Gamma(C, \lambda)$. ☐

LEMMA 2.7. *Suppose that C_1 and C_2 are rooted configurations with irreducible degree sequence $\mathbf{n}'$. If $\Gamma(C_1, \lambda_1) = \Gamma(C_2, \lambda_2)$, then $(C_1, \lambda_1) \cong (C_2, \lambda_2)$.*

Proof. Let G_1 be the multigraph obtained in the construction of $\Gamma(C_1, \lambda_1)$. Make sure that the relabelling that occurs in the construction of G_1 does not change the labels of the vertices of Multigraph (C_1). Similarly, let G_2 be the multigraph obtained in the construction of $\Gamma(C_2, \lambda_2)$ in which the labels of the vertices of Multigraph (C_2) are unchanged. Now, by the definition of Γ, Core (G_1) = Multigraph (C_1) and Core (G_2) = Multigraph (C_2). Suppose that $\pi(G_1) = G_2$. Then $\pi(\text{Multigraph}\,(C_1)) =$ Multigraph (C_2), by Lemma 2.5. Thus, $\lambda_1(v) = \lambda_2(\pi(v))$ for any vertex v in the vertex set of Multigraph (C_1). Furthermore, for any unordered pair (u, v) of vertices, and any color ℓ, the number of copies of (u, v) in the edge multiset of Multigraph(C_1) that are colored ℓ by λ_1 is equal to the number of copies of $(\pi(u), \pi(v))$ in the edge multiset of Multigraph(C_2) that are colored ℓ by λ_2. Hence, π can be extended to an isomorphism mapping (C_1, λ_1) to (C_2, λ_2). □

COROLLARY 2.8. *There is a bijection between* $\widetilde{\mathcal{G}}_{\mathbf{n},\mathbf{n}'}$ *and* $\widetilde{\mathcal{C}}_{\mathbf{n},\mathbf{n}'}$.

Proof. The corollary follows from Lemmas 2.6 and 2.7. □

LEMMA 2.9. *Each isomorphism class in* $\widetilde{\mathcal{C}}_{\mathbf{n},\mathbf{n}'}$ *comes up* $|K_{\mathbf{n}'}|$ *times in*

$$\{(C, \lambda, \pi) \mid (C, \lambda) \in \mathcal{C}_{\mathbf{n},\mathbf{n}'} \quad \textit{and} \quad \pi \in \mathrm{Aut}(C, \lambda)\}.$$

Proof. This is a straightforward application of Burnside's Lemma [6]. □

3. Sampling irreducible multigraphs. The goal of this section is a polynomial-time algorithm that takes as input an irreducible degree sequence, $\mathbf{n}$, and samples, u.a.r., a pair (C, π), where $C \in \mathcal{C}_{\mathbf{n}}$ is a rooted connected configuration with degree sequence $\mathbf{n}$, and $\pi \in K_{\mathbf{n}}$ is an automorphism of C. This is straightforward if $\mathbf{n}$ is degenerate, so we focus on the nondegenerate case in which $n_0 = n_1 = n_2 = 0$ and $n_i > 0$ for some $i \in [3, \ldots, \Delta]$. In this case, $\mathcal{C}_{\mathbf{n}}$ is the set of connected unrooted configurations with degree sequence $\mathbf{n}$. (The configurations are unrooted because every connected multigraph in which each vertex has degree at least 3 has more than one cycle.) Thus, our goal is equivalent to generating, u.a.r., an unlabelled connected multigraph (possibly with self-loops) with degree sequence $\mathbf{n}$. So we obtain a solution to our basic problem in the special case in which all vertex degrees are at least 3. The techniques described in section 2 provide a reduction from the case of general degrees sequences to the restricted ones considered here, as we shall see in section 5.

Our approach borrows freely from Bollobás's treatment of unlabelled regular graphs [3], though we find it more convenient to work throughout with configurations in place of (multi)graphs. Recall that $2m = \sum_i in_i$. We say that a triple (s, s_2, s_3) of nonnegative integers is *legal* if $2s_2 + 3s_3 \le s \le 2m$. For every legal triple (s, s_2, s_3), let $K_{\mathbf{n}}(s, s_2, s_3)$ denote the set of permutations in $K_{\mathbf{n}}$ that contain exactly s_2 transpositions, s_3 3-cycles, and move exactly s points in all. For convenience, we introduce $s_4 = (s - 2s_2 - 3s_3)/4$; note that s_4 is not necessarily an integer. Of course, only three of the four parameters need to be specified in any situation, but the freedom to move between different triples according to context is convenient.

To generate the pair (C, π) we first select a legal triple (s, s_2, s_3), then a permutation $\pi = K_{\mathbf{n}}(s, s_2, s_3)$, and finally a configuration $C \in \mathrm{Fix}\,\pi$, where $\mathrm{Fix}\,\pi$ denotes the set of configurations with degree sequence $\mathbf{n}$ that are fixed by π. In the unlikely event that C is not connected, we return $\perp$ (see Figure 1 and Theorem 3.3). (Informally, we say that the algorithm "rejects" if $\perp$ is returned, and that it "accepts" otherwise.) For every legal triple (s, s_2, s_3), define

$$(1) \qquad F_{\mathbf{n}}(s, s_2, s_3) = \left\lceil 4 \times \frac{(2m)!}{m!\,2^m} \times \left(\frac{6s_2}{m^2}\right)^{s_2/2} \left(\frac{3s_3}{m^3}\right)^{s_3/2} \left(\frac{21s_4}{m^4}\right)^{s_4/2} \right\rceil.$$

The significance of $F_{\mathbf{n}}(s, s_2, s_3)$, as we shall see presently, is that it is a uniform upper bound on $|\,\mathrm{Fix}\,\pi|$ over all $\pi \in K_{\mathbf{n}}(s, s_2, s_3)$. Note that in (1), and throughout the proof of Lemma 3.1 below, we shall encounter expressions such as

$$\left(\frac{6s_2}{m^2}\right)^{s_2/2}$$

that are formally undefined when s_2 (or s_3 or s_4 or s) is equal to 0. The intended meaning is the limit as the variable in question (here s_2) tends to 0 from above. In all cases the upshot is that the factor concerned is 1 when the variable is 0. Note that $F_{\mathbf{n}}(s, s_2, s_3)$ is the square-root of a rational number, rounded up, and hence can be computed exactly in polynomial time. Define

$$W_{\mathbf{n}}(s, s_2, s_3) = |K_{\mathbf{n}}(s, s_2, s_3)| \times F_{\mathbf{n}}(s, s_2, s_3), \tag{2}$$

and let

$$W_{\mathbf{n}} = \sum_{s, s_2, s_3} W_{\mathbf{n}}(s, s_2, s_3), \tag{3}$$

where the sum is over all legal triples (s, s_2, s_3). Observe that $W_{\mathbf{n}}$ is a bound on the size of the set of pairs (C, π) we wish to sample from.

The proposed sampling procedure is conceptually very simple and is presented in Figure 1 towards the end of this section. Its analysis rests on the following technical lemma.

LEMMA 3.1. *With $F_{\mathbf{n}}(s, s_2, s_3)$, $W_{\mathbf{n}}(s, s_2, s_3)$, and $W_{\mathbf{n}}$ defined as above,*

1. $|\operatorname{Fix}()| = \frac{1}{4} F_{\mathbf{n}}(0, 0, 0)$*, where* () *denotes the identity permutation in* $K_{\mathbf{n}}$*;*
2. $|\operatorname{Fix} \pi| \leq F_{\mathbf{n}}(s, s_2, s_3)$*, for all* $\pi \in K_{\mathbf{n}}(s, s_2, s_3)$*;*
3. $W_{\mathbf{n}} \leq A\, W_{\mathbf{n}}(0, 0, 0)$*, where A depends only on* Δ*.*

Proof. The total number of configurations with degree sequence $\mathbf{n}$ is equal to the number of ways of choosing m pairings in a set of size $2m$. All configurations are fixed by the identity permutation, so we have

$$|\operatorname{Fix}()| = (2m-1)(2m-3)\cdots 3 \cdot 1 = \frac{(2m)!}{m!\, 2^m}.$$

Comparing the above expression with the definition of $F_{\mathbf{n}}(s, s_2, s_3)$ already gives us part 1 of the lemma.

An asymptotic expression for the number of configurations can be obtained using the usual Stirling's approximation. For our purposes, it is convenient to have absolute upper and lower bounds, which can be obtained using a more refined version of Stirling's approximation due to Robbins [19] (or see [5, p. 4]):

$$\left(\frac{2m}{\mathrm{e}}\right)^m \leq \frac{(2m)!}{m!\, 2^m} \leq \sqrt{2} \left(\frac{2m}{\mathrm{e}}\right)^m. \tag{4}$$

While we are on the subject of Stirling's formula, let us note for future reference the following slight strengthening of a familiar bound on binomial coefficients:

$$\sum_{i=0}^{t} \binom{n}{i} \leq \left(\frac{\mathrm{e}n}{t}\right)^t. \tag{5}$$

To verify this inequality, first observe that the right-hand side is monotonically increasing (viewed as a real function) for $t \in (0, 1)$ and is greater than 2^n for $t \geq n/3$. In the case $t < n/3$, the ratio between successive terms on the left-hand side exceeds 2, so the sum is bounded by the sum of a geometric series with common ratio 1/2. Thus

$$\sum_{i=0}^{t} \binom{n}{i} \leq 2\binom{n}{t} \leq \frac{2n^t}{t!} \leq n^t \left(\frac{\mathrm{e}}{t}\right)^t,$$

again using a sufficiently strong form of Stirling's approximation.

Consider $C \in \operatorname{Fix}\pi$, with $\pi \in K_{\mathbf{n}}(s, s_2, s_3)$. Each point in a 3-cycle of π must be paired with a point in a *different* 3-cycle, and the other two pairings of C incident at the first cycle are then forced. Thus $|\operatorname{Fix}\pi| = 0$ unless s_3 is even, in which case C induces a set of "higher level pairings" on the 3-cycles of π. Given these higher level pairings, there are $3^{s_3/2}$ ways to choose the pairings themselves. In all there are

$$\frac{s_3!\,3^{s_3/2}}{(s_3/2)!\,2^{s_3/2}} \le \sqrt{2}\left(\frac{3s_3}{\mathrm{e}}\right)^{s_3/2}$$

ways to choose the restriction of C to the 3-cycles of π. For transpositions, the calculation is similar, except we must now allow for the pairing to join the two points in a single transposition. But this new freedom can only blow up the number of choices by (crudely) a factor 2^{s_2}, so that there are at most

$$\sqrt{2}\left(\frac{8s_2}{\mathrm{e}}\right)^{s_2/2}$$

ways to choose the restriction of C to the transpositions of π. An optimization over the distribution of cycle lengths greater than 3 confirms that the number of ways of choosing the restriction of C to those cycles is at most

$$\sqrt{2}\left(\frac{16s_4}{\mathrm{e}}\right)^{s_4/2},$$

the bound we would obtain by assuming all the remaining cycles have length exactly 4. The number of ways of extending C to the fixed points of π is clearly bounded by

$$\sqrt{2}\left(\frac{2m}{\mathrm{e}}\right)^{(2m-s)/2} \le \sqrt{2} \times \frac{(2m)!}{m!\,2^m} \times \left(\frac{2m}{\mathrm{e}}\right)^{-s/2},$$

where we have used the other part of inequality (4). Multiplying these four bounds together, recalling $s = 2s_2 + 3s_3 + 4s_4$, yields the following upper bound on $|\operatorname{Fix}\pi|$:

$$|\operatorname{Fix}\pi| \le 4 \times \frac{(2m)!}{m!\,2^m} \times \left(\frac{2\mathrm{e}s_2}{m^2}\right)^{s_2/2} \left(\frac{3\mathrm{e}^2 s_3}{8m^3}\right)^{s_3/2} \left(\frac{\mathrm{e}^3 s_4}{m^4}\right)^{s_4/2};$$

comparing this expression with (1) defining $F_{\mathbf{n}}(s, s_2, s_3)$ gives us the second part of Lemma 3.1.

For the third part, we introduce a more refined partitioning of the group $K_{\mathbf{n}}$ according to cycle structure. For each cycle of a permutation $\pi \in K_{\mathbf{n}}$, we distinguish whether the cycle touches more than one block of $R_{\mathbf{n}}$ (type 1), or whether its action is entirely confined to a single block (type 2). We write, for example, $s_2 = s_2' + s_2''$, where s_2' is the number of type 1 transpositions and s_2'' the number of type 2 transpositions. The prime and double prime convention is applied consistently, so that we write $s = s' + s''$, where s' is the total number of points contained in all type 1 cycles and s'' the number in all type 2 cycles. Naturally, s_4' and s_4'' are defined by $s' = 2s_2' + 3s_3' + 4s_4'$ and $s'' = 2s_2'' + 3s_3'' + 4s_4''$. Denote by

$$K_{\mathbf{n}}(s, s_2', s_3'; s'', s_2'', s_3'') \subseteq K_{\mathbf{n}}(s' + s'', s_2' + s_2'', s_3' + s_3'')$$

the set of permutations with s_2' type 1 transpositions, s_2'' type 2 transpositions, and so on.

The strategy for establishing the final part of the lemma is to (i) compute an upper bound on $|K_{\mathbf{n}}(s', s_2', s_3'; s'', s_2'', s_3'')|$, (ii) optimize over the feasible region to obtain an upper bound on $|K_{\mathbf{n}}(s, s_2, s_3)|$ and hence on $W_{\mathbf{n}}(s, s_2, s_3)$, and (iii) sum over feasible s, s_2, s_3 to obtain an upper bound on $W_{\mathbf{n}}$. Our upper bound for (i) will be of the form $\kappa'(s_2', s_3', s_4') \times \kappa''(s_2'', s_3'', s_4'')$, where κ' and κ'' are bounds on the number of ways of choosing the type 1 cycles and type 2 cycles, respectively. The latter is more tractable, so we deal with it first.

Let $\pi \in K_{\mathbf{n}}(s', s_2', s_3'; s'', s_2'', s_3'')$. The number of ways of choosing the $i \le s_2''$ blocks containing the s_2'' type 2 transpositions in π is at most

$$\sum_{i=0}^{s_2''} \binom{n}{i} \le \left(\frac{\mathrm{e}n}{s_2''}\right)^{s_2''},$$

using inequality (5), and so the total number of ways of choosing the transpositions themselves is at most

$$\left(\frac{\mathrm{e}cn}{s_2''}\right)^{s_2''},$$

where $c = \Delta!$. Similar bounds hold for the longer cycles, yielding an overall bound of

$$\kappa''(s_2'', s_3'', s_4'') = \left(\frac{\mathrm{e}cn}{s_2''}\right)^{s_2''} \left(\frac{\mathrm{e}cn}{s_3''}\right)^{s_3''} \left(\frac{\mathrm{e}cn}{s_4''}\right)^{s_4''} \tag{6}$$

on the number of ways of choosing all the type 2 cycles.

We now consider the type 1 cycles of π. Denote by $B = B(s', s_2', s_3')$ the set of integer triples (b, b_2, b_3) satisfying

$$b_2, b_3 \ge 0, \quad 2b_2 + 3b_3 \le b, \quad 3b + [2s_2' - 6b_2] + [3s_3' - 9b_3] \le s', \tag{7}$$

where $[x] = \max\{x, 0\}$. The intended interpretation of (b, b_2, b_3) is as follows: b is the total number of blocks moved by π, b_2 is the number of transpositions of blocks induced by π, and b_3 is the number of 3-cycles on blocks induced by π. The significance of B is that it contains, as we shall demonstrate, all feasible choices for (b, b_2, b_3) consistent with (s', s_2', s_3').

Only the final inequality of (7) requires explanation. The weaker inequality $3b \le s'$ is easy enough to justify, as each block contains at least 3 points, so we just have to account for the other two terms. If a block contains $p \ge 4$ points, regard $p - 3$ of the points as constituting an "excess." All s_2' type 1 transpositions in π must be contained within the $2b_2$ blocks that are transposed by π. If $2s_2' > 6b_2$, then $2s_2' - 6b_2$ points in type 1 cycles must be in the excess. Similarly, if $3s_3' > 9b_3$, then $3s_3' - 9b_3$ further points in type 1 cycles must be in the excess. This justifies the final inequality in (7).

Applying a crude bound on the number of ways of choosing the type 1 cycles, given (b, b_2, b_3), we have

$$\sum_{(b,b_2,b_3)\in B} \frac{(cn)^b}{b_2!\, b_3!} \le (s'+1)^3 \max\left\{\frac{(cn)^b}{b_2!\, b_3!} : (b, b_2, b_3) \in B\right\} \tag{8}$$

as a bound on the number of ways of choosing the type 1 cycles. The right-hand side of (8) presents a small optimization problem. We claim that at the maximum, $b_2 \geq \lfloor s_2'/3 \rfloor$ (otherwise $b_2 \leftarrow b_2 + 1$ and $b \leftarrow b + 2$ leads to an improvement), and $b_3 \geq \lfloor s_3'/3 \rfloor$ (otherwise $b_3 \leftarrow b_3 + 1$ and $b \leftarrow b + 3$ does), and in any case $b \leq s'/3$. So, from (8), and using the lower bound $b! \geq (b/e)^b$, the number of ways of choosing the type 1 cycles is at most $\kappa'(s_2', s_3', s_4')$, where

$$\kappa'(s_2', s_3', s_4') = (s'+1)^5 (cn)^{s'/3} \left(\frac{3\mathrm{e}}{s_2'}\right)^{s_2'/3} \left(\frac{3\mathrm{e}}{s_3'}\right)^{s_3'/3} \tag{9}$$

$$= (s'+1)^5 \left(\frac{3\mathrm{e}c^2n^2}{s_2'}\right)^{s_2'/3} \left(\frac{3\mathrm{e}c^3n^3}{s_3'}\right)^{s_3'/3} (cn)^{4s_4'/3}. \tag{10}$$

The extra factor $(s'+1)^2$ in (9) takes account of the floor functions. Our upper bound for $|K_{\mathbf{n}}(s', s_2', s_3'; s'', s_2'', s_3'')|$ is thus

$$|K_{\mathbf{n}}(s', s_2', s_3'; s'', s_2'', s_3'')| \leq \kappa'(s_2', s_3', s_4') \times \kappa''(s_2'', s_3'', s_4''),$$

where $\kappa'(s_2', s_3', s_4')$ and $\kappa''(s_2'', s_3'', s_4'')$ are as defined in (6) and (10).

The next stage is to bound $|K_{\mathbf{n}}(s, s_2, s_3)|$. Clearly we have

$$|K_{\mathbf{n}}(s, s_2, s_3)| \leq \sum_S \kappa'(s_2', s_3', s_4') \times \kappa''(s_2'', s_3'', s_4'')$$

$$\leq (s+1)^3 \max_S \Big\{\kappa'(s_2', s_3', s_4') \times \kappa''(s_2'', s_3'', s_4'')\Big\}, \tag{11}$$

where S is the region

$$S = \Big\{(s_2', s_3', s_4', s_2'', s_3'', s_4'') \in (\mathbb{R}^+)^6 : \\ s_2' + s_2'' = s_2,\ s_3' + s_3'' = s_3, \text{ and } s_4' + s_4'' = s_4\Big\}.$$

If we bound the $(s'+1)^5$ factor in κ' simply by $(s+1)^5$, then the factors in s_2', s_2'', in s_3', s_3'', and in s_4', s_4'' appearing in the objective function of (11) separate out, and we can optimize over each pair separately.

- The s_4 factor is

$$(cn)^{4s_4'/3} \left(\frac{\mathrm{c}\mathrm{e}n}{s_4''}\right)^{s_4''} \leq (cn)^{4s_4/3}, \tag{12}$$

  since the maximum is achieved at $s_4' = s_4$ and $s_4'' = 0$.
- The s_3 factor is

$$\left(\frac{3\mathrm{e}c^3n^3}{s_3'}\right)^{s_3'/3} \left(\frac{\mathrm{e}^3c^3n^3}{(s_3'')^3}\right)^{s_3''/3} \leq 2\left(\frac{\mathrm{e}^3c^3n^3}{s_3'}\right)^{s_3'/3} \left(\frac{\mathrm{e}^3c^3n^3}{s_3''}\right)^{s_3''/3} \tag{13}$$

$$\leq 2\left(\frac{2\mathrm{e}^3c^3n^3}{s_3}\right)^{s_3/3}. \tag{14}$$

  Inequality (13) uses the fact that $x^{-x} \leq 2x^{-x/3}$ for all positive x, and inequality (14) follows from symmetry and unimodality.

- The s_2 factor is

$$\left(\frac{3\mathrm{e}c^2n^2}{s_2'}\right)^{s_2'/3}\left(\frac{\mathrm{e}^3c^3n^3}{(s_2'')^3}\right)^{s_2''/3} \le 2\left(\frac{\mathrm{e}^3c^3n^3}{(s_2')^2}\right)^{s_2'/3}\left(\frac{\mathrm{e}^3c^3n^3}{(s_2'')^2}\right)^{s_3''/3}$$
$$\le 2\left(\frac{4\mathrm{e}^3c^3n^3}{s_2^2}\right)^{s_2/3}, \tag{15}$$

by similar considerations to the previous case.

Plugging (12), (14), and (15) into (11) gives

$$|K_{\mathbf{n}}(s,s_2,s_3)| \le 4(s+1)^8\left(\frac{4\mathrm{e}^3c^3n^3}{s_2^2}\right)^{s_2/3}\left(\frac{2\mathrm{e}^3c^3n^3}{s_3}\right)^{s_3/3}(cn)^{4s_4/3},$$

which, on recalling the definitions (1) and (2) of $F_{\mathbf{n}}(s,s_2,s_3)$ and $W_{\mathbf{n}}(s,s_2,s_3)$, leads to

$$W_{\mathbf{n}}(s,s_2,s_3) \le 32(s+1)^8 \times \frac{(2m)!}{m!\,2^m} \times \left(\frac{c_2}{s_2}\right)^{s_2/6}\left(\frac{c_3s_3}{n^3}\right)^{s_3/6}\left(\frac{c_4s_4^3}{n^4}\right)^{s_4/6}, \tag{16}$$

where c_2, c_3, and c_4 are constants depending only on c and hence only on Δ. (The multiplicative factor has been boosted from 16 to 32 to allow for the ceiling function in the definition of $F_{\mathbf{n}}(s,s_2,s_3)$.)

To finish off the proof of the final part of Lemma 3.1, we merely need to sum (16) over all legal triples (s,s_2,s_3):

$$\begin{aligned}
W_{\mathbf{n}} &= \sum_{s,s_2,s_3} W_{\mathbf{n}}(s,s_2,s_3)\\
&\le 32 \times \frac{(2m)!}{m!\,2^m} \times \sum_{s_2}\left(\frac{c_2}{s_2}\right)^{s_2/6}\sum_{s_3,s_4}(2s_2+3s_3+4s_4+1)^8\left(\frac{c_3\Delta}{3n^2}\right)^{s_3/6}\left(\frac{c_4\Delta^3}{64n}\right)^{s_4/6}\\
&\approx 32 \times \frac{(2m)!}{m!\,2^m} \times \sum_{s_2}\left(\frac{c_2}{s_2}\right)^{s_2/6}(2s_2+1)^8\\
&\approx 4c' \times \frac{(2m)!}{m!\,2^m} = c'\,W_{\mathbf{n}}(0,0,0),
\end{aligned}$$

where c' depends only on c_2, hence only on Δ. ∎

LEMMA 3.2. *There is a polynomial-time algorithm for computing $|K_{\mathbf{n}}(s,s_2,s_3)|$, and hence for computing $W_{\mathbf{n}}(s,s_2,s_3)$ and $W_{\mathbf{n}}$. There is also a polynomial-time algorithm for sampling, u.a.r., a permutation from $K_{\mathbf{n}}(s,s_2,s_3)$.*

Proof. By partitioning $|K_{\mathbf{n}}(s,s_2,s_3)|$, first according to the length of the first induced cycle on blocks, and then on the exact pattern of cycles within those blocks (at most $\Delta!$ possibilities), we obtain an inductive formula for $|K_{\mathbf{n}}(s,s_2,s_3)|$. Only polynomially many distinct assignments to the parameters $\mathbf{n}$, s, s_2, and s_3 arise during the induction, so $|K_{\mathbf{n}}(s,s_2,s_3)|$ can be computed in time polynomial in n by dynamic programming. ∎

THEOREM 3.3. *The procedure* CONFIGSAMPLE *presented in Figure* 1 *is correct:* (a) *the probability that the algorithm returns a value other than $\perp$ is bounded away from* 0*;* (b) *for any configuration $C \in \mathcal{C}_{\mathbf{n}}$ with degree sequence $\mathbf{n}$, and any automorphism $\pi \in \mathrm{Aut}(C)$ of C, the probability that the pair (C,π) is returned by* CONFIG-SAMPLE *is a constant, namely $W_{\mathbf{n}}^{-1}$, independent of C and π; and* (c) *the procedure*

Step 1. If $\mathbf{n}$ is degenerate, let C be the sole member of $\mathcal{C}_{\mathbf{n}}$, choose $\pi \in \mathrm{Aut}(C)$ u.a.r., and output (C, π). Otherwise, perform Steps 2–6.
Step 2. Choose the triple (s, s_2, s_3) with probability $W_{\mathbf{n}}(s, s_2, s_3)/W_{\mathbf{n}}$.
Step 3. Choose $\pi \in K_{\mathbf{n}}(s, s_2, s_3)$, u.a.r.
Step 4. Choose $C \in \mathrm{Fix}\,\pi$, u.a.r.
Step 5. If C is not connected, output $\perp$ and halt.
Step 6. With probability $|\mathrm{Fix}\,\pi|/F_{\mathbf{n}}(s, s_2, s_3)$ output (C, π); otherwise output $\perp$.

FIG. 1. *Procedure* CONFIGSAMPLE *for sampling a pair* (C, π).

CONFIGSAMPLE *runs in time polynomial in n, provided the maximum degree Δ is bounded. Indeed, we have the following strengthening of the first part:* (d) *the probability that a pair with $\pi = ()$ is returned is bounded away from* 0.

Proof. By the second part of Lemma 3.1, the acceptance probability in Step 6 is well defined. By the third part of Lemma 3.1, the particular triple $(0, 0, 0)$ is selected in Step 2 with probability at least A^{-1}, which is bounded away from 0. This forces the identity permutation to be selected in Step 3. In this case, the probability of acceptance in Step 5 is bounded away from 0. By Bollobás (see [5, page 48] and Bender and Canfield [1], the probability that a random configuration with degree sequence $\mathbf{n}$ corresponds to a simple graph is bounded away from 0. Each simple graph corresponds to an equal number of configurations, and by Wormald [24], the probability that a simple graph with degree sequence $\mathbf{n}$ is connected is bounded away from 0.) By the first part of Lemma 3.1, we know that the pair $(C, ())$ survives Step 6 with probability $\frac{1}{4}$. This deals with (a) and its strengthening (d).

Now consider an arbitrary pair (C, π) satisfying $C \in \mathrm{Fix}\,\pi$, and suppose $\pi \in K_{\mathbf{n}}(s, s_2, s_3)$. For (C, π) to be generated, a certain well defined event must occur at each step of the algorithm. The probability that (C, π) is generated is simply the product of these four probabilities:

$$\frac{W_{\mathbf{n}}(s, s_2, s_3)}{W_{\mathbf{n}}} \times \frac{1}{|K_{\mathbf{n}}(s, s_2, s_3)|} \times \frac{1}{\mathrm{Fix}\,\pi} \times \frac{\mathrm{Fix}\,\pi}{F_{\mathbf{n}}(s, s_2, s_3)} = \frac{1}{W_{\mathbf{n}}},$$

which is clearly independent of C and π, as asserted in (b).

According to Lemma 3.2 the procedure can be implemented to run in polynomial time. ∎

4. Sampling unlabelled trees. The previous section showed how to sample, u.a.r., an unlabelled connected multigraph with a specified irreducible nondegenerate degree sequence. In section 5 we will show how to sample, u.a.r., an unlabelled connected multigraph with *any* specified degree sequence $\mathbf{n}$. Our basic strategy will be to select an irreducible degree sequence $\mathbf{n}'$ such that $n' \leq n$ with the "appropriate" probability, sample u.a.r. an unlabelled connected multigraph G' with degree sequence $\mathbf{n}'$, and finally color G' to obtain a multigraph G with degree sequence $\mathbf{n}$. (G' will be the core of G as defined in section 2.) Instead of constructing G' directly, we will select a pair (C', π) as described in section 3 such that $C' \in \mathcal{C}_{\mathbf{n}'}$ and $\pi \in \mathrm{Aut}(C')$. Then we will choose a coloring λ such that $\Gamma(C', \lambda) \in \widetilde{\mathcal{G}}_{\mathbf{n}}$. The process of choosing $\mathbf{n}'$ and λ involves counting and sampling unlabelled rooted trees. We provide the relevant tree results in this section.

The basic framework in which we will work is as follows: We will consider "structures" (trees with one or more root), each of which has a "weight" (a $(\Delta+2)$-tuple of integers). The weight of a d-rooted n-vertex tree G (which is denoted $\mu(G)$) is the tuple $(n-d, i_0, \ldots, i_\Delta)$, where i_r is the number of vertices of degree r, *excluding* the roots. We let $\mathbb{T}_1$ denote the 1-rooted tree consisting of a single vertex and $\mathbb{T}_2$ denote the 2-rooted tree consisting of a single edge. We define the following operations on trees. If G is a 1-rooted tree, we let $[d]G$ denote the 1-rooted tree obtained by taking d copies of G, identifying the roots of the d copies, and then relabelling the remaining vertices of trees $2, \ldots, d$ to avoid name clashes. If G and G' are 1-rooted trees, we let $G \times G'$ denote the tree obtained by identifying their roots and relabelling the remaining vertices of G' to avoid name clashes. If G is a tree-chain and G' is a 1-rooted tree then we let $G * G'$ denote the tree-chain constructed from G and G' as follows. Root r_1 of G is disconnected from its neighbor, v, in G, and is connected to the root of G'. The root of G' is connected to v. The vertices in G' are then relabelled to avoid name clashes. If G is a d-rooted tree and G' is a d'-rooted tree, we let $G+G'$ be the $(d+d')$-rooted tree obtained by relabelling the vertices and roots of G' to avoid name clashes.

Following Flajolet, Zimmerman, and Van Cutsem [11], we form sets of structures inductively from $\{\mathbb{T}_1\}$ and $\{\mathbb{T}_2\}$ using the following constructors.

- $S + S'$: The disjoint union of S and S'.
- For $d > 1$, $[d]S$: $\{[d]G \mid G \in S\}$.
- $S \times S'$: $\{G \times G' \mid G \in S, G' \in S'\}$.
- If all structures in S' have a single root of a given degree, $S * S'$: $\{G * G' \mid G \in S, G' \in S'\}$.
- $S \cdot S'$: $\{G + G' \mid G \in S, G' \in S'\}$.

The constructors $+$ and $\cdot$ are from [11], which also considers other constructors. We use the notation $m \cdot S$ as an abbreviation for the disjoint union of m copies of S, $S + \cdots + S$, and we use the notation S^m as an abbreviation for the Cartesian product of m copies of S, $S \cdots S$.

A *specification* of sets $S_0, \ldots, S_r$ (which is sometimes referred to as a specification of S_r) is defined to be a sequence of equations

$$m_0 \cdot S_0 = \Psi_0()\,,\ m_1 \cdot S_1 = \Psi_1(S_0)\,,\ \ldots\,,\ m_r \cdot S_r = \Psi_r(S_0, \ldots, S_{r-1})\,,$$

where $m_0, \ldots, m_r$ are positive integers and, for $i \in [0, \ldots, r]$, Ψ_i is a term built from $\{\mathbb{T}_1\}$, $\{\mathbb{T}_2\}$, and $S_0, \ldots, S_{i-1}$ using the constructors. An ℓ-specification is a specification using ℓ constructors.[1] For every set S of structures, we use the notation $S(i_0, \ldots, i_j)$ to denote the set

$$\{s \in S \mid \text{for some } i_{j+1}, \ldots, i_{\Delta+1},\ \mu(s) = (i_0, \ldots, i_{\Delta+1})\}.$$

The generating function for the set S is a function $s(x_0, \ldots, x_{\Delta+1})$ such that the coefficient of $x_0^{i_0} \cdots x_{\Delta+1}^{i_{\Delta+1}}$ in $s(x_0, \ldots, x_{\Delta+1})$, which is denoted

$$[x_0^{i_0} \cdots x_{\Delta+1}^{i_{\Delta+1}}]\, s(x_0, \ldots, x_{\Delta+1}),$$

is equal to $|S(i_0, \ldots, i_{\Delta+1})|$. The following is a straightforward extension of the results of Flajolet, Zimmerman, and Van Cutsem [11].

[1]For this, we count the constructor $[d]$ in $[d]S$ as d constructors.

THEOREM 4.1. *Given an ℓ-specification for sets $S_0,\dots,S_r$, a set of equations for the corresponding generating functions is obtained automatically by the following translation rules:*

$$\begin{array}{ll}
m\cdot S = S'+S'' & \Rightarrow s(x_0,\dots,x_{\Delta+1}) = (1/m)(s'(x_0,\dots,x_{\Delta+1})+s''(x_0,\dots,x_{\Delta+1}));\\
m\cdot S = [d]S' & \Rightarrow s(x_0,\dots,x_{\Delta+1}) = (1/m)s'(x_0^d,\dots,x_{\Delta+1}^d);\\
m\cdot S = S'\times S'' & \Rightarrow s(x_0,\dots,x_{\Delta+1}) = (1/m)(s'(x_0,\dots,x_{\Delta+1})\cdot s''(x_0,\dots,x_{\Delta+1}));\\
m\cdot S = S' * S'' & \Rightarrow s(x_0,\dots,x_{\Delta+1}) =\\
 & \qquad (x_{r+2}/m)(s'(x_0,\dots,x_{\Delta+1})\times s''(x_0,\dots,x_{\Delta+1})),\\
 & \qquad \textit{where } r \textit{ is the degree of the roots of the structures in } S'';\\
m\cdot S = S'\cdot S'' & \Rightarrow s(x_0,\dots,x_{\Delta+1}) = (1/m)(s'(x_0,\dots,x_{\Delta+1})\times s''(x_0,\dots,x_{\Delta+1})).
\end{array}$$

Furthermore, there is a polynomial p such that all coefficients

$$[x_0^{i'_0}\dots x_{\Delta+1}^{i'_{\Delta+1}}]S_j(x_0,\dots,x_{\Delta+1})$$

for which $j\in[0,\dots,r]$ and every i'_γ is at most i_γ can be computed in at most $p(i_0,\dots,i_{\Delta+1},r,\ell)$ steps and a member of $S_j(i_0,\dots,i_{\Delta+1})$ can be sampled u.a.r. in $p(i_0,\dots,i_{\Delta+1},r,\ell)$ steps.

Proof. The coefficients of $S_0,\dots,S_r$ can be computed in order and stored in a table. Sampling u.a.r. from $S_j(i_0,\dots,i_{\Delta+1})$ is accomplished as follows. If $m\cdot S_j=\{\mathbb{T}_1\}$ or $m\cdot S_j=\{\mathbb{T}_2\}$, this is straightforward. If $m\cdot S_j=S_a+S_b$, sample u.a.r. from $S_a(i_0,\dots,i_{\Delta+1})$ with probability

$$|S_a(i_0,\dots,i_{\Delta+1})|/|S_j(i_0,\dots,i_{\Delta+1})|,$$

and from $S_b(i_0,\dots,i_{\Delta+1})$ with the remaining probability. If $m\cdot S_j=[d]S_a$, then recursively sample from $S_a(i_0/d,\dots,i_{\Delta+1}/d)$ and make d copies of the resulting structure. If $m\cdot S_j=S_c\times S_d$, evaluate

$$N_{\mathbf{i}'}=|S_c(i'_0,\dots,i'_{\Delta+1})|\times|S_d(i_0-i'_0,\dots,i_{\Delta+1}-i'_{\Delta+1})|$$

for all tuples $\mathbf{i}'=(i'_0,\dots,i'_{\Delta+1})$ (other than $\mathbf{i}'=(0,\dots,0)$ and $\mathbf{i}'=(i_0,\dots,i_{\Delta+1})$) in which every i'_γ satisfies $0\le i'_\gamma\le i_\gamma$. Choose $\mathbf{i}'$ with probability $N_{\mathbf{i}'}/\sum_{\mathbf{j}'}N_{\mathbf{j}'}$. Recursively sample structures from $S_c(i'_0,\dots,i'_{\Delta+1})$ and $S_d(i_0-i'_0,\dots,i_{\Delta+1}-i'_{\Delta+1})$ and combine the structures. The cases in which $m\cdot S_j=S_c * S_d$ and $m\cdot S_j=S_c\cdot S_d$ are handled similarly, except that in the case $m\cdot S_j=S_c*S_d$ we replace i_{r+2} with $i_{r+2}-1$. $\square$

We will now use the above framework to show how to count and sample unlabelled rooted trees. Let S_r be the set containing one representative from each isomorphism class in the set of 1-rooted trees with degree-r roots. We will first give a sequence of equations to define the sets $S_r(n)$ in terms of the constructors and we will then argue that the definition is a specification (that is, the equations can be ordered in such a way that each equation depends only on sets previously defined). The set of equations is adapted from Nijenhuis and Wilf [15]. First, note that $S_0(0)=\{\mathbb{T}_1\}$ and $S_0(n)=\emptyset$ for $n\ne 0$. Furthermore, $S_r(0)=\emptyset$ for $r\ne 0$. For $n>0$, we have

$$S_1(n)=\sum_{\substack{0\le r\le\Delta-1\\ i_0+\cdots+i_\Delta=n-1}} S_r(n-1,i_0,\dots,i_r,i_{r+1}-1,i_{r+2},\dots,i_\Delta),\ \text{and}$$

$$n\cdot S_r(n)=\sum_{\substack{1\le s\le r\\ 1\le sd\le n}} d\cdot([s]S_1(d+1)\times S_{r-s}(n-sd))\ \text{ for } r>1.$$

The first equation expresses the correspondence between $n+1$-vertex trees rooted at a vertex of degree 1 and n-vertex trees with unrestricted root degree. The second equation expresses a construction for trees which has the property that each unlabelled $n+1$-vertex tree is represented n times: choose numbers s, d satisfying $1 \leq s \leq r$ and $1 \leq sd \leq n$; choose a tree τ' with $n+1-sd$ vertices, rooted at a vertex of degree $r-s$, and a tree τ'' with $d+1$ vertices rooted at a vertex of degree 1; take s copies of τ' and one copy of τ'' and identify all the roots (the identified vertices constitute the new root). Make d copies of the resulting rooted tree. Nijenhuis and Wilf [15, p. 274] give a combinatorial proof of the equation by establishing an explicit bijection between the figures enumerated by the left and right sides.

To see that the sequence of equations given is a specification, consider a 2-dimensional table. The first $r+1$ entries of column n correspond to sets $S_0(n), \ldots, S_r(n)$ (in the given order). The remaining entries correspond to the sets $[s]S_1(n/s+1)$, where $s > 1$ divides n. Note that the equation corresponding to each table entry only uses sets corresponding to smaller rows or columns of the table. Thus, we have a specification for the sets $S_r(n)$.

As we described in the beginning of this section, our algorithm in section 5 will sample u.a.r. a coloring λ of a configuration $C = (R_{\mathbf{n}'}, B_{\mathbf{n}'}, P)$ such that $\Gamma(C, \lambda) \in \widetilde{\mathcal{G}}_{\mathbf{n}}$. Recall that a coloring λ of C is a mapping from $B_{\mathbf{n}'}$ to $\mathcal{B}$ (the set of block-colors), and from P to $\mathcal{P}$ (the set of pairing-colors). The blocks in $B_{\mathbf{n}'}$ are ordered and the pairings in P can be ordered according to the ordering of the blocks, so a coloring may be specified as a sequence of n' block-colors followed by a sequence of $m' = \frac{1}{2}\sum_i in'_i$ pairing colors. Thus, the set of available colorings depends only on $\mathbf{n}$ and $\mathbf{n}'$. Let $\Lambda_{\mathbf{n},\mathbf{n}'}$ denote the set of available colorings. Given the specification for the set $S_r(n)$, we can derive specifications for $\mathcal{B}$, $\mathcal{P}$, and therefore, $\Lambda_{\mathbf{n},\mathbf{n}'}$. We start by observing that $\mathcal{B} = S_0 + \cdots + S_\Delta$. Let $\mathcal{P}_\ell$ denote the set containing one representative from each isomorphism class of length-ℓ tree-chains (thus, $\mathcal{P} = \mathcal{P}_0 + \mathcal{P}_1 + \mathcal{P}_2 + \cdots$). A specification for $\mathcal{P}$ is as follows:

$$\begin{aligned}
&\mathcal{P}_0 = \{\mathbb{T}_2\},\\
&\mathcal{P}_\ell = (\mathcal{P}_{\ell-1} * S_0) + \cdots + (\mathcal{P}_{\ell-1} * S_{\Delta-2}).
\end{aligned}$$

Let $L_{\mathbf{n}', r_0, \ldots, r_{n'}}$ denote the set of colorings of a configuration with degree sequence $\mathbf{n}'$ in which the block-coloring for the ith block is a tree whose root has degree r_i. Then the set $L_{\mathbf{n}', r_0, \ldots, r_{n'}}$ can be specified using the equation

$$L_{\mathbf{n}', r_0, \ldots, r_{n'}} = \mathcal{P}^{m'} \cdot S_{r_0} \cdots S_{r_{n'}}.$$

Finally, note that $\Lambda_{\mathbf{n},\mathbf{n}'}$ is the disjoint union, over all (polynomially many) choices of $r_0, \ldots, r_{n'}$ of $L_{\mathbf{n}', r_0, \ldots, r_{n'}}(n - n'', n_0 - n''_0, \ldots, n_\Delta - n''_\Delta)$, where

$$n''_i = \left|\{j : 1 \leq j \leq n' \text{ and } v_j + r_j = i\}\right|,$$

where v_i denotes the size of the ith block in $B_{\mathbf{n}'}$.

Thus, we have a specification for $\Lambda_{\mathbf{n},\mathbf{n}'}$. While some of the sets used in the specification such as $\mathcal{P}$ and $S_0, \ldots, S_\Delta$ are infinite, these sets are made up by taking the disjoint union of finite subsets. Accordingly, there is a polynomial-sized specification for $\Lambda_{\mathbf{n},\mathbf{n}'}$ and the following is a corollary of Theorem 4.1.

COROLLARY 4.2. *There is a polynomial p such that computing $|\Lambda_{\mathbf{n},\mathbf{n}'}|$ and sampling u.a.r. from $\Lambda_{\mathbf{n},\mathbf{n}'}$ take at most $p(n)$ steps.*

Step 1. Select a degree sequence $\mathbf{n}'$ such that $n' \leq n$ according to the probability distribution $p_{\mathbf{n}}$.

Step 2. Select a pair (C, π) using the procedure ConfigSample developed in section 3 (see Figure 1), with parameter $\mathbf{n}'$. If that procedure returns $\perp$, then output $\perp$ and halt; otherwise the result is a pair selected u.a.r. from the set of pairs (C, π), with $C \in \mathcal{C}_{\mathbf{n}'}$ and $\pi \in \mathrm{Aut}(C)$.

Step 3. Select a coloring λ u.a.r. from $\Lambda_{\mathbf{n},\mathbf{n}'}$.

Step 4. If $\pi \in \mathrm{Aut}(C, \lambda)$ then let G be any rooted multigraph in $\Gamma(C, \lambda)$; otherwise output $\perp$ and halt.

Step 5. If G has at least two cycles then output $\Psi(G)$. Otherwise, let k be the number of nonisomorphic 1-rooted multigraphs with the same vertex and edge set as G. (The choice of root is arbitrary in the case of trees, but must be on the cycle in the case of unicyclic multigraphs.) With probability k^{-1} output $\Psi(G)$; otherwise output $\perp$.

Fig. 2. *Procedure* MultiSample *for sampling u.a.r. from* $\widetilde{\mathcal{H}}_{\mathbf{n}}$.

5. Sampling unlabelled multigraphs. Let $\mathcal{H}_{\mathbf{n}}$ be the set of connected multigraphs with degree sequence $\mathbf{n}$ and vertex set V_n and let $\widetilde{\mathcal{H}}_{\mathbf{n}}$ be the set of isomorphism classes of $\mathcal{H}_{\mathbf{n}}$. In this section, we will describe a procedure MultiSample that samples u.a.r. from $\widetilde{\mathcal{H}}_{\mathbf{n}}$. The procedure will first (see Steps 1–4 of Figure 2) sample u.a.r. from $\widetilde{\mathcal{G}}_{\mathbf{n}}$ and will then use rejection to obtain a uniform distribution on $\widetilde{\mathcal{H}}_{\mathbf{n}}$.

All the components of MultiSample are now ready: section 2 introduced the machinery that we will use to reduce the general problem to the special case in which $\mathbf{n}$ is irreducible, section 3 solved the irreducible case, and section 4 described the tools that we will use to lift the solution for the irreducible case up to a solution for general degree sequences. It remains only to assemble the pieces.

Given a degree sequence $\mathbf{n}$, let the probability distribution $p_{\mathbf{n}}$ assign probability

$$p_{\mathbf{n}}(\mathbf{n}') = \frac{W_{\mathbf{n}'}\,|\Lambda_{\mathbf{n},\mathbf{n}'}|}{M\,|K_{\mathbf{n}'}|} \tag{17}$$

to irreducible degree sequences satisfying $n' \leq n$, and zero probability to the others. Here,

$$M = \sum_{\mathbf{n}'} \frac{W_{\mathbf{n}'}\,|\Lambda_{\mathbf{n},\mathbf{n}'}|}{|K_{\mathbf{n}'}|}$$

is the normalizing factor required to form a probability distribution. (The sum is over irreducible degree sequences $\mathbf{n}'$ such that $n' \leq n$. The fact that this is the right summation follows from Observation 2.3.) The significance of $p_{\mathbf{n}}$ is that it is the "correct" distribution from which to sample the degree sequence of the core. This is the final ingredient in the sampling procedure MultiSample, which is presented in Figure 2.

Lemma 5.1. *The procedure* MultiSample *presented in Figure* 2 *is correct:* (a) *the probability that the algorithm produces an output other than* $\perp$ *is* $\Omega(n^{-1})$*;* (b) *for each isomorphism class* $U \in \widetilde{\mathcal{H}}_{\mathbf{n}}$*, the probability that* U *is returned by* MultiSample *is a constant, namely* M^{-1}*, independent of* U*; and* (c) *the procedure* MultiSample *runs in time polynomial in* n*, assuming the maximum degree* Δ *is bounded.*

Proof. The procedure successfully completes Step 2 precisely if some value other than $\perp$ is returned by procedure ConfigSample; the probability of this event is bounded away from 0, by part (a) of Theorem 3.3. Indeed, part (d) of that theorem tells us more: namely that the automorphism $\pi \in \mathrm{Aut}(C)$ returned by ConfigSample is the identity with probability bounded away from 0. But if $\pi = ()$, Step 4 is guaranteed to be successful. The probability that Step 5 is successful is at least $1/n$. This completes the proof of (a).

We now proceed to compute the probability that a certain isomorphism class $U \in \widetilde{\mathcal{H}}_{\mathbf{n}}$ appears as output. We start by showing that, after Step 4, the probability that G is in any given class in $\widetilde{\mathcal{G}}_{\mathbf{n}}$ is M^{-1}. Let U be a class in $\widetilde{\mathcal{G}}_{\mathbf{n}}$. By Lemma 2.4, U has a uniquely defined core with degree sequence $\mathbf{n}'$, say. By Lemma 2.7, a condition for U to be returned in Step 4 is that the degree sequence $\mathbf{n}'$ is selected in Step 1, an event which occurs with the probability $p_{\mathbf{n}}(\mathbf{n}')$, given in (17). Now fix attention on a particular triple (C, π, λ), satisfying $C \in \mathcal{C}_{\mathbf{n}'}$ and $\pi \in \mathrm{Aut}(C, \lambda)$. By Theorem 3.3, the probability that (C, π, λ) is selected in Steps 2 and 3, conditioned on the particular choice of degree sequence $\mathbf{n}'$, is $(W_{\mathbf{n}'}\,|\Lambda_{\mathbf{n},\mathbf{n}'}|)^{-1}$. By Corollary 2.8 and Lemma 2.9, exactly $|K_{\mathbf{n}'}|$ of these triples correspond to the desired output U. Thus, again conditioned on the choice of $\mathbf{n}'$, the probability that U is returned is

$$\frac{|K_{\mathbf{n}'}|}{W_{\mathbf{n}'}\,|\Lambda_{\mathbf{n},\mathbf{n}'}|}.$$

Multiplying this expression by the probability (17) that degree sequence $\mathbf{n}'$ is selected in Step 1, we see that the overall probability that U is returned at the end of Step 4 is a constant, in fact M^{-1}. If $U \in \widetilde{\mathcal{H}}_{\mathbf{n}}$ has at least 2 cycles, it comes up once in $\widetilde{\mathcal{G}}_{\mathbf{n}}$. Otherwise, it appears k times in $\widetilde{\mathcal{G}}_{\mathbf{n}}$, where k is as in Figure 2. By accepting U only with probability k^{-1}, the output distribution after Step 5 is uniform on $\widetilde{\mathcal{H}}_{\mathbf{n}}$.

Step 1 is polynomial time by Lemma 3.2 and Corollary 4.2; Step 2 is polynomial time by Theorem 3.3; and Step 3 by Corollary 4.2. Step 4 is clearly polynomial time. Step 5 is reducible to isomorphism of 1-rooted trees, which can conveniently be decided by a recursive canonical labelling scheme: if the root is the only vertex, assign it label `()`; otherwise let $l_1, l_2, \ldots, l_t$ be the labels of the t subtrees of the root, ordered lexicographically, and assign label $(l_1 l_2 \ldots l_t)$ to the root. By induction, two 1-rooted trees are isomorphic iff their root labels are equal. Thus, we have established (c). $\square$

6. Sampling molecules. In this section we extend our results to the chemical problem—given a molecular formula, select, u.a.r., a structural isomer having the given formula. We start by extending the algorithm in section 5 so that it can be used to uniformly sample unlabelled connected *self-loop-less* multigraphs with a given degree sequence. For this we use procedure MultiSample, except that if the output has a self-loop, it is rejected. If the degree sequence of the core is nondegenerate, then the core will be a simple graph with probability bounded away from 0 (see section 3) so the probability of rejection is not too high. If the degree sequence of the core is degenerate, then the rejection probability will also be low, provided that n is sufficiently large.

The modified version of procedure MultiSample, which uniformly samples unlabelled connected self-loop-less multigraphs with a given degree sequence, solves the following problem: Given a molecular formula in which each atom has a distinct valence, select, u.a.r., a structural isomer having the given formula.[2] We can further

[2]For some chemical applications, such as applications in which valences are variable, it may be appropriate to modify the rejection phase so that some self-loops are allowed in the final output.

modify procedure MultiSample so that it can be used to uniformly sample structural isomers even when the molecular formula has different atoms with the same valence. Formally, we fix t *types* of vertices and we interpret a typed degree sequence

$$n_{0,1},\ldots,n_{0,t},\ldots,n_{\Delta,1},\ldots,n_{\Delta,t}$$

as a requirement that a multigraph have $n_{i,j}$ degree-i vertices of type j. An isomorphism between typed multigraphs must map each vertex to a vertex of the same type. Procedure MultiSample can be extended in a straightforward way to give a polynomial-time algorithm that takes as input a typed degree sequence and selects, u.a.r., an unlabelled connected multigraph with the given degree sequence. The generation of the core is as before, except that the definition of the group $K_{\mathbf{n}}$ changes since blocks can only be mapped to other blocks of the same type. The inductive specifications in section 4 must be modified slightly to account for the types, so the choice of $\mathbf{n}'$ is modified accordingly. The choice of the coloring λ is also modified slightly. The coloring of each block must have a root that has the same type as the block and a coloring of a pairing between blocks of types i and j must have roots of types i and j, respectively. Everything else is as before.

Acknowledgments. We thank Jean-Loup Faulon for proposing the problem and explaining the chemical applications. We also thank Alan Frieze for suggesting the use of the core.

COMPUTATIONAL SAMPLE COMPLEXITY[*]

SCOTT E. DECATUR[†], ODED GOLDREICH[‡], AND DANA RON[§]

Abstract. In a variety of PAC learning models, a trade-off between time and information seems to exist: with unlimited time, a small amount of information suffices, but with time restrictions, more information sometimes seems to be required. In addition, it has long been known that there are concept classes that can be learned in the absence of computational restrictions, but (under standard cryptographic assumptions) cannot be learned in polynomial time (regardless of sample size). Yet, these results do not answer the question of whether there are classes for which learning from a small set of examples is computationally infeasible, but becomes feasible when the learner has access to (polynomially) more examples.

To address this question, we introduce a new measure of learning complexity called *computational sample complexity* that represents the number of examples sufficient for *polynomial time* learning with respect to a fixed distribution. We then show concept classes that (under similar cryptographic assumptions) possess arbitrarily sized gaps between their standard (information-theoretic) sample complexity and their computational sample complexity. We also demonstrate such gaps for learning from membership queries and learning from noisy examples.

Key words. computational learning theory, information vs. efficient computation, pseudorandom functions, error correcting codes, wire-tap channel

1. Introduction.

In this work, we examine the effects of computational restrictions on the number of examples needed for learning from random examples or membership queries. It has long been known that there are concept classes, containing only concepts that are implementable by "small" Boolean circuits, which can be learned in the absence of computational restrictions, yet cannot be learned (using any hypothesis class) in polynomial time (under standard cryptographic assumptions) [Val84, KV94, AK91, Kha93]. Yet, these results do not answer the question of whether there are classes for which learning from a small set of examples is computationally infeasible, but becomes feasible when the learner has access to (polynomially) more examples. Such a phenomenon seems to be present in various learning problems (described below) and we focus on this trade-off between information and computation.

The most common method of learning from examples in the PAC setting is through the use of Occam algorithms [BEHW87, BEHW89]. These are algorithms that take as input a set of labeled examples and output a concept from the target

class that is consistent with the given set of examples. Blumer et al. give an upper bound on the number of examples sufficient for an Occam algorithm to provide a good hypothesis. This bound depends on the PAC accuracy and confidence parameters and the Vapnik–Chervonenkis dimension (VC-Dimension) [VC71] of the target class. The general lower bound on the number of examples required for learning [EHKV89] nearly matches (within a logarithmic factor) the upper bound for Occam algorithms. Thus, the sample complexity for learning is essentially tight when we have an algorithm that finds a consistent concept from the target class.

While Occam algorithms exist for all classes,[1] not all such algorithms are computationally efficient. Yet, for some of these classes learning is still feasible, although the *known* computationally efficient algorithms use more examples than does the Occam algorithm for the class. In these situations, computational restrictions appear to *impair* learning by requiring more data, but do not completely *preclude* learning. For example, it is NP-hard to find a k-term-DNF formula[2] consistent with a set of data labeled by a k-term-DNF formula [PV88]. The computationally efficient algorithm most commonly used for learning k-term-DNF works by finding a consistent hypothesis from a hypothesis class (kCNF) that strictly contains the target class. In using this larger class, the Occam algorithm requires a sample size dependent on n^k (the VC-Dimension of kCNF) as opposed to $k \cdot n$ (the VC-Dimension of k-term-DNF) as would be possible if the hypothesis class were k-term-DNF itself. Thus, although k-term-DNF learning is feasible, there is a gap between the sample size sufficient for learning k-term-DNF in the absence of computational restrictions and the sample size of known algorithms for computationally efficient learning.[3]

When the learner is allowed to make queries, we again see the phenomenon in which efficient learning seems to require more information than learning without such restrictions. One such example is the learning of deterministic finite automata (DFAs). Angluin's algorithm for this class [Ang87] can be viewed as drawing the standard Occam-sized sample and outputting a DFA consistent with it. But in order to efficiently find this consistent DFA, the algorithm makes many additional membership queries.

We also find computational restrictions to effect sample size when learning from examples corrupted with noise. In the absence of computational restrictions, any PAC-learnable class can also be learned in the presence of classification noise rate $\eta = 1/2 - \gamma < 1/2$ using a factor of $\Theta(1/\gamma^2)$ more examples than the noise-free case [Lai88, Tal94]. This increase is information theoretically required [Sim93, AD96]. Yet for many classes, when computation is restricted in the presence of noisy data, the sample complexity of known algorithms is increased by more than $\Theta(1/\gamma^2)$. Furthermore, this larger increase occurs even for classes that have computationally efficient noise-free Occam algorithms with optimal sample complexity, i.e., classes with no gap in their noise-free sample complexities. One very simple class exhibiting these properties is the class of monotone Boolean conjunctions.

Thus, it appears that in a variety of learning models (PAC, PAC with queries, and PAC with noise) there may exist a trade-off between time and information—with unlimited time, a small amount of information will suffice, but with time restrictions,

[1]In this work, we restrict our attention to classes of functions that can be represented by polynomially sized circuits.

[2]A k-term-DNF formula is a disjunctive normal form Boolean formula with at most constant k terms.

[3]Note that the possibility remains of there being an algorithm that learns using the "Occam number of examples" but does not learn by outputting a consistent k-term-DNF formula.

more information is required. None of the cases described above provably requires the additional examples, yet researchers have been unable to close these gaps. In this work, we describe classes of functions for which we prove (based on cryptographic assumptions) a quantitative gap between the size of the sample required for learning a class and the size of the sample required for learning it efficiently.

Our main results. We focus our attention on learning under the uniform distribution. As discussed later in this section, this seems to be an appropriate and natural choice for demonstrating sample complexity gaps. Let $\mathcal{C} = \bigcup_n C_n$ be a concept class, where each C_n consists of Boolean functions over $\{0,1\}^n$. The (*information theoretic*) *sample complexity* of $\mathcal{C}$, denoted $\mathsf{itsc}(\mathcal{C}; n, \epsilon)$, is the sample size (as a function of n and ϵ) needed for learning the class (without computational limitations) under the uniform distribution with approximation parameter ϵ and confidence 9/10. The *computational sample complexity* of $\mathcal{C}$, denoted $\mathsf{csc}(\mathcal{C}; n, \epsilon)$ is the sample size needed for learning the class in polynomial time under the uniform distribution with approximation parameter ϵ and confidence 9/10. In both cases, when the class is clear, we may omit it from the notation.

Definition 1.1 (admissible gap functions). *A function $g : \mathcal{N} \times \mathcal{R} \mapsto \mathcal{R}$ is called* admissible *if*

1. $g(\cdot,\cdot)$ *is polynomial-time computable;*
2. (bounded growth in n) *for every $\epsilon > 0$, $1 \leq g(n,\epsilon) \leq \mathrm{poly}(n)$;*
3. (monotonicity in ϵ) *for every $\epsilon, \epsilon' > 0$ such that $\epsilon < \epsilon'$, $g(n,\epsilon) \geq g(n,\epsilon')$;*
4. (smoothness in ϵ) *there exists a constant $a \geq 1$ so that for every $\epsilon > 0$, $g(n,\epsilon) \leq a \cdot g(n, 2\epsilon)$.*

For example, the function $g(n,\epsilon) \overset{\text{def}}{=} \frac{n^d}{\epsilon^{d'}}$ is admissible for every $d, d' \geq 0$. Our main result is that any admissible function can serve as a gap between the sample complexity of some concept class and the computational sample complexity of the same class. This gives the following theorem.

Theorem 1.2 (basic model). *Let $g : \mathcal{N} \times \mathcal{R} \mapsto \mathcal{R}$ be an admissible function, and $k : \mathcal{N} \times \mathcal{R} \mapsto \mathcal{R}$ be of the form $k(n,\epsilon) = \frac{n^d}{\epsilon}$, where $d \geq 2$. Suppose that one-way functions exist* (cf. [Gol95]).[4] *Then there exists a concept class $\mathcal{C}$ that has sample complexity*

$$\mathsf{itsc}(n,\epsilon) = \Theta(k(n,\epsilon))$$

and computational sample complexity

$$\mathsf{csc}(n,\epsilon) = \Theta(g(n,\epsilon) \cdot k(n,\epsilon)).$$

Furthermore, $\log_2 |C_n| = O(n^{d+1})$ and each function in C_n has a $\mathrm{poly}(n)$*-size circuit.*

In the above, and in all subsequent theorems, one-way functions are merely used to construct pseudorandom functions [HILL, GGM86]. Assuming either that RSA is a one-way function or that the Diffie–Hellman key exchange is secure, one can construct pseudorandom functions in $\mathcal{NC}$ (cf. [NR95]), and so all of our "gap theorems" will follow with concept classes having $\mathcal{NC}$ circuits.

[4]Here and in all our other conditional results, the computational sample complexity lower bounds hold for $\epsilon = 1/\mathrm{poly}(n)$ under standard complexity assumptions (i.e., the existence of one-way functions.) For smaller values of ϵ these bounds hold assuming slightly nonstandard yet reasonable complexity assumptions.

	NOISE FREE		NOISE RATE $\eta = 0.25$	
	ITSC	CSC	ITSC	CSC
Item 1	$k(n, \epsilon)$	$g_1 \cdot g_2 \cdot k(n, \epsilon)$	$k(n, \epsilon)$	$g_1 \cdot g_2^2 \cdot k(n, \epsilon)$
Item 2	$k(n, \epsilon)$	$k(n, \epsilon)$	$k(n, \epsilon)$	$\frac{1}{n^2} \cdot (k(n, \epsilon))^2$

FIG. 1.1. *The results of Theorem* 1.4 *(with* Θ*-notation omitted). For general noise rate* $\eta = 0.5 - \gamma \geq 0.25$, *both ITSC and CSC increase linearly in* $1/\gamma^2$.

We next consider classification noise at rate $\eta < \frac{1}{2}$. That is, the label of each example is flipped with probability η, independently of all other examples. In this case we add $\gamma \overset{\text{def}}{=} \frac{1}{2} - \eta > 0$ as a parameter to the sample complexity functions (e.g., $\mathsf{itsc}(\mathcal{C}; n, \epsilon, \gamma)$). We obtain the next theorem.

THEOREM 1.3 (noisy model). *Let* $g : \mathcal{N} \times \mathcal{R} \mapsto \mathcal{R}$ *be an admissible function and* $k : \mathcal{N} \times \mathcal{R} \mapsto \mathcal{R}$ *be of the form* $k(n, \epsilon) = \frac{n^d}{\epsilon}$, *where* $d \geq 2$. *Suppose that one-way functions exist. Then there exists a concept class* $\mathcal{C}$ *which, in the presence of noise at rate* $\eta = \frac{1}{2} - \gamma$, *has sample complexity*

$$\mathsf{itsc}(n, \epsilon, \gamma) = \Theta\left(k(n, \epsilon)/\gamma^2\right)$$

and computational sample complexity

$$\mathsf{csc}(n, \epsilon, \gamma) = \Theta\left(g(n, \epsilon) \cdot k(n, \epsilon)/\gamma^2\right).$$

Furthermore, each function in C_n *has a* poly(n)*-size circuit.*

We stress that the above holds for every noise rate and in particular for the noise-free case (where $\eta = 0$ and $\gamma = 1/2$). Thus, we have for every $\gamma > 0$

$$\frac{\mathsf{csc}(n, \epsilon, \gamma)}{\mathsf{itsc}(n, \epsilon, \gamma)} \quad = \quad \Theta\left(\frac{\mathsf{csc}(n, \epsilon)}{\mathsf{itsc}(n, \epsilon)}\right) \quad = \quad \Theta\left(g(n, \epsilon)\right).$$

In particular, the computational sample complexity for moderate noise is of the same order of magnitude as in the noise-free case (i.e., $\mathsf{csc}(n, \epsilon, \frac{1}{4}) = \Theta(\mathsf{csc}(n, \epsilon))$). This stands in contrast to the following theorem in which the ratio between the two (i.e., $\frac{\mathsf{csc}(n, \epsilon, \frac{1}{4})}{\mathsf{csc}(n, \epsilon)}$) may be arbitrarily large, while $\mathsf{itsc}(n, \epsilon, \frac{1}{4}) = \Theta(\mathsf{itsc}(n, \epsilon))$ still holds (as it always does). See Figure 1.1.

THEOREM 1.4 (noise, revisited). *Let* $g_1, g_2 : \mathcal{N} \times \mathcal{R} \mapsto \mathcal{R}$ *be admissible functions and* $k : \mathcal{N} \times \mathcal{R} \mapsto \mathcal{R}$ *be of the form* $k(n, \epsilon) = \frac{n^d}{\epsilon}$, *where* $d \geq 2$. *Suppose that one-way functions exist. Then*

1. *there exists a concept class* $\mathcal{C}$ *which,*
   - *in the presence of noise at rate* $\eta = \frac{1}{2} - \gamma \geq \frac{1}{4}$, *has sample complexity*

     $$\mathsf{itsc}(n, \epsilon, \gamma) = \Theta(k(n, \epsilon)/\gamma^2)$$

     and computational sample complexity

     $$\mathsf{csc}(n, \epsilon, \gamma) = \Theta(g_1(n, \epsilon) \cdot (g_2(n, \epsilon))^2 \cdot k(n, \epsilon)/\gamma^2);$$

   - *whereas the noise-free complexities are*

     $$\mathsf{itsc}(n, \epsilon) = \Theta(k(n, \epsilon)) \quad \textit{and} \quad \mathsf{csc}(n, \epsilon) = \Theta(g_1(n, \epsilon) \cdot g_2(n, \epsilon) \cdot k(n, \epsilon)),$$

     respectively;

Information Theoretic	Computational Measures	
ITSC = ITQC	CQC	CSC
$k(n,\epsilon)$	$g_1 \cdot k(n,\epsilon)$	$g_1 \cdot g_2 \cdot k(n,\epsilon)$

Fig. 1.2. *The results of Theorem* 1.5 *(with* Θ*-notation omitted).*

2. *there exists a concept class* $\mathcal{C}$ *which,*
   - *in the presence of noise at rate* $\eta = \frac{1}{2} - \gamma \geq \frac{1}{4}$, *has sample complexity*

$$\mathsf{itsc}(n,\epsilon,\gamma) = \Theta(k(n,\epsilon)/\gamma^2)$$

and computational sample complexity

$$\mathsf{csc}(n,\epsilon,\gamma) = \Theta\left(\frac{(k(n,\epsilon))^2}{n^2 \cdot \gamma^2}\right);$$

   - *whereas the noise-free complexities are*

$$\mathsf{csc}(n,\epsilon) = \Theta(\mathsf{itsc}(n,\epsilon)) = \Theta(k(n,\epsilon)).$$

Furthermore, each function in C_n *has a* poly(n)*-size circuit.*

Theorem 1.3 follows as a special case of item 1 by setting $g_2 \equiv 1$. Using item 2 we get that for every $\alpha > 0$ and for every $\gamma \leq 1/4$, $\mathsf{csc}(n,\epsilon,\gamma) = \Omega(\mathsf{csc}(n,\epsilon)^{2-\alpha}/\gamma^2)$.

We now turn to learning with membership queries. The (*information theoretic*) *query complexity* of $\mathcal{C}$, denoted $\mathsf{itqc}(\mathcal{C}; n, \epsilon)$, is the number of membership queries (as a function of n and ϵ) needed for learning the class (without computational limitations) under the uniform distribution with approximation parameter ϵ and confidence 9/10. The *computational query complexity* of $\mathcal{C}$, denoted $\mathsf{cqc}(\mathcal{C}; n, \epsilon)$, is the number of queries needed for learning the class in polynomial time under the uniform distribution with approximation parameter ϵ and confidence 9/10. We obtain (see also Figure 1.2) the following.

Theorem 1.5 (query model). *Let* $g_1, g_2 : \mathcal{N} \times \mathcal{R} \mapsto \mathcal{R}$ *be two admissible functions and* $k : \mathcal{N} \times \mathcal{R} \mapsto \mathcal{R}$ *be of the form* $k(n,\epsilon) = \frac{n^d}{\epsilon}$, *where* $d \geq 2$. *Suppose that one-way functions exist. Then there exists a concept class* $\mathcal{C}$ *which has query complexity*

$$\mathsf{itqc}(n,\epsilon) = \Theta(k(n,\epsilon)) = \Theta(\mathsf{itsc}(n,\epsilon)),$$

computational query complexity

$$\mathsf{cqc}(n,\epsilon) = \Theta(g_1(n,\epsilon) \cdot k(n,\epsilon)),$$

and computational sample complexity

$$\mathsf{csc}(n,\epsilon) = \Theta(g_1(n,\epsilon) \cdot g_2(n,\epsilon) \cdot k(n,\epsilon)).$$

Furthermore, each function in C_n *has a* poly(n)*-size circuit.*

Note that we may set $g_2 \equiv 1$ and obtain

$$\mathsf{csc}(n,\epsilon) = \Theta(\mathsf{cqc}(n,\epsilon)) = \Theta(g_1(n,\epsilon) \cdot \mathsf{itqc}(n,\epsilon))$$

(and $\mathsf{itsc}(n,\epsilon) = \Theta(\mathsf{itqc}(n,\epsilon))$).

Uniform vs. distribution-free learning. Above, we show that in a variety of settings there exists a concept class exhibiting a sample complexity gap when learning occurs with respect to the uniform distribution. We note that in all our theorems the information theoretic upper bounds hold, within a factor of n, with respect to distribution-free learning.[5] Thus, there exist concept classes for which efficient learning *under the uniform distribution* (is possible but) requires vastly larger sample sizes than the *distribution-free* information theoretic upper bound.

One may wonder whether there exists a concept class exhibiting similar sample complexity gaps with respect to every distribution. Clearly, degenerate distributions preclude such results. Alternatively, one may wonder whether, for every distribution, there exists a class that exhibits sample complexity gaps. Again, such results are precluded by degenerate distributions. Thus, we believe that an appropriate goal is to demonstrate gaps on fixed distributions, the uniform distribution being the most natural and well studied.[6]

Although the above notion of a gap cannot exist for a single concept class across all distributions, a different notion of distribution-free gap can exist. Specifically, we may consider a gap between: (1) an upper bound on the information-theoretic distribution-free sample complexity and (2) a lower bound on the distribution-free sample complexity of an efficient learner that is *tight* (i.e., has a matching upper bound). More precisely, let the (*distribution-free information theoretic*) *sample complexity* of $\mathcal{C}$, denoted $\mathcal{ITSC}(\mathcal{C}; n, \epsilon)$, be the sample size (as a function of n and ϵ) needed for learning the class (without computational limitations); and let the *distribution-free computational sample complexity* of $\mathcal{C}$, denoted $\mathcal{CSC}(\mathcal{C}; n, \epsilon)$, be the sample size needed for learning the class in polynomial time. We stress that an upper bound for any of these measures refers to all possible distributions, whereas a lower bound merely refers to one (possibly "pathological") distribution. In fact, such pathological distributions are used in the result below.

THEOREM 1.6 (distribution-free). *Let p be a polynomial so that $p(n) \geq n$, and suppose that one-way functions exist. Then there exists a concept class $\mathcal{C}$ so that $\mathcal{ITSC}(n, \epsilon) = O(n/\epsilon)$, whereas $\mathcal{CSC}(n, \epsilon) = \Theta(p(n)/\epsilon)$. Furthermore, each function in C_n has a* poly(n)*-size circuit.*

Note that the gap shown in the theorem is polynomially in n (independent of ϵ). Thus, we do not get arbitrary admissible gaps as in Theorem 1.2. We note that the computational sample complexity under the uniform distribution for this class is $\Theta(p(n) \cdot \min\{\log(1/\epsilon), \log p(n)\})$.

Techniques. The basic idea is to consider concepts that consist of two parts: The first part of the concept is determined by a pseudorandom function (cf. [GGM86]), while the second part encodes the seed of such a function. Since it is infeasible to infer a pseudorandom function, the computational-bounded learner is forced to retrieve the seed of the function which is sparsely encoded in the second part. This sparse encoding makes retrieval very costly in terms of sample complexity; yet, the computationally-*un*bounded learner is not affected by it.

The basic idea described above suffices for establishing a gap between the computational sample complexity and the information-theoretic sample complexity for a fixed ϵ. Additional ideas are required in order to have a construction that works for any ϵ, and for which one may provide tight (up to a constant factor) bounds on each

[5]In Theorem 1.5 the upper bounds hold in the distribution-free case, without any extra factor.

[6]We note that our techniques may be used to show similar sample complexity gaps on distributions other than the uniform distribution.

of the two complexities. One of these ideas is the construction of concept classes, called *equalizers*, for which the computational sample complexity upper bound is of the same order as the information-theoretic lower bound. A result of this form follows.

THEOREM 1.7 (equalizers). *Let $p(\cdot)$ be any polynomial.*

1. (noisy-sample equalizer) *There exists a concept class $\mathcal{S} = \cup_n S_n$, with concepts realizable by polynomial-size circuits, such that*

$$\mathsf{itsc}(\mathcal{S}; n, \epsilon, \gamma) \;=\; \Theta(\mathsf{csc}(\mathcal{S}; n, \epsilon, \gamma)) \;=\; \Theta(p(n)/\epsilon\gamma^2).$$

2. (query equalizer) *There exists a concept class $\mathcal{S} = \cup_n S_n$, with concepts realizable by polynomial-size circuits, such that*

$$\mathsf{itqc}(\mathcal{S}; n, \epsilon) \;=\; \Theta(\mathsf{csc}(\mathcal{S}; n, \epsilon)) \;=\; \Theta(p(n)/\epsilon).$$

Another idea used in our proofs is the introduction and utilization of a novel (probabilistic) coding scheme. In addition to the standard coding theoretic requirements, this scheme has the property that any constant fraction of the bits in the (randomized) code word yields no information about the message being encoded. We also use this coding scheme to obtain efficient constructions for the wire-tap channel problem (cf. [Wyn75])—see Proposition 2.3. We believe that this probabilistic coding scheme is of independent interest.

Organization. After introducing the cryptographic tools we shall need, we establish the separation of computational sample complexity from (information theoretic) sample complexity in the basic model. This result (i.e., Theorem 1.2) may be derived as a special case of the other results, but we chose to present a self-contained and simpler proof of the separation in the basic model: All that is needed are our new coding scheme (presented in section 2) and the basic construction (presented in section 3).

To establish separation in the noise and query models, we use a more general construction. This construction utilizes the equalizers of Theorem 1.7 (presented in section 4). The general construction itself is presented in section 5 and is used to derive Theorems 1.2 through 1.5.

Theorem 1.6 is proven in section 6. We note that this proof is much simpler than any other proof in the paper and that it can be read without reading any of the other sections.

2. Cryptographic tools.

In subsection 2.1 we review known definitions and results regarding pseudorandom functions. In subsection 2.2 we present a computationally efficient (randomized) coding scheme which on top of the standard error-correction features has a secrecy feature. Specifically, a small fraction of (the uncorrupted) bits of the code word yield no information about the message being encoded.

2.1. Pseudorandom functions.

Loosely speaking, pseudorandom functions are easy to evaluate yet look like random functions to any computationally restricted observer who may obtain their value at inputs of its choice.

DEFINITION 2.1 (pseudorandom functions [GGM86]). *Let $\ell : \mathcal{N} \mapsto \mathcal{N}$ be a polynomially-bounded length function and $\mathcal{F} = \{F_n : n \in \mathcal{N}\}$ where $F_n = \{f_\alpha : \alpha \in \{0,1\}^n\}$ is a (multi)set of 2^n Boolean functions over the domain $\{0,1\}^{\ell(n)}$. The family $\mathcal{F}$ is called a* pseudorandom family *if*

- (easy to evaluate) *there exists a polynomial-time algorithm A so that $A(\alpha, x) = f_\alpha(x)$ for every $\alpha \in \{0,1\}^*$ and $x \in \{0,1\}^{\ell(|\alpha|)}$; the string α is called the* seed *of f_α;*

- (pseudorandomness) *for every probabilistic polynomial-time oracle machine M, every positive polynomial p, and all sufficiently large n's,*

$$\left|\Pr_{f\in F_n}(M^f(1^n)=1) - \Pr_{g\in R_n}(M^g(1^n)=1)\right| < \frac{1}{p(n)},$$

where R_n denotes the set of all $(2^{2^{\ell(n)}})$ Boolean functions over the domain $\{0,1\}^{\ell(n)}$.

Pseudorandom functions exist if and only if there exist one-way functions (cf. [GGM86] and [HILL]). Pseudorandom functions that can be evaluated by $\mathcal{NC}$ circuits (one circuit per each function) exist[7], assuming either that RSA is a one-way function or that the Diffie–Hellman key exchange is secure (cf. [NR95]).

2.2. A probabilistic coding scheme. We present an efficient probabilistic encoding scheme having constant *rate* (information/code word ratio), constant (efficient) *error-correction* capability for which a (small) constant fraction of the code word bits yield no information about the plain message. Note that a scheme as described above cannot be deterministic (as each bit in a deterministic coding scheme carries information).

THEOREM 2.2. *There exist constants $c_{\rm rate}, c_{\rm err}, c_{\rm sec} < 1$ and a pair of probabilistic polynomial-time algorithms, (E, D), so that*

1. (constant rate) $|E(x)| = |x|/c_{\rm rate}$ *for all* $x \in \{0,1\}^*$;
2. (linear error correction) *for every $x \in \{0,1\}^*$ and every $e \in \{0,1\}^{|E(x)|}$ that has at most $c_{\rm err} \cdot |E(x)|$ ones,*

$$\Pr(D(E(x) \oplus e) = x) \;=\; 1,$$

where $\alpha \oplus \beta$ denotes the bit-by-bit exclusive-or of the strings α and β; Algorithm D is in fact deterministic;

3. (partial secrecy) *loosely speaking, a substring containing $c_{\rm sec} \cdot |E(x)|$ bits of $E(x)$ does not yield information on x. Namely, let I be a subset of $\{1, \ldots, |\alpha|\}$, and let α_I denote the substring of α corresponding to the bits at locations $i \in I$. Then for every $n \in \mathcal{N}$, $m = n/c_{\rm rate}$, $x, y \in \{0,1\}^n$, $I \subset \{1, \ldots, m\}$, $|I| \le c_{\rm sec} \cdot m$, and $\alpha \in \{0,1\}^{|I|}$,*

$$\Pr(E(x)_I = \alpha) \;=\; \Pr(E(y)_I = \alpha).$$

Furthermore, $E(x)_I$ is uniformly distributed over $\{0,1\}^{|I|}$.

In addition, on input x, algorithm E uses $O(|x|)$ coin tosses.

Items 1 and 2 are standard requirements of coding theory, first met by Justesen [Jus72]. What is nonstandard in the above is item 3. Indeed, item 3 is impossible if one insists that the encoding algorithm (i.e., E) be deterministic.

Proof. Using a "nice" error correcting code, the key idea is to encode the information by first augmenting it by a sufficiently long random padding. To demonstrate this idea, consider an $2n$-by-m matrix M defining a constant-rate/linear-error-correction (linear) code. That is, the string $z \in \{0,1\}^{2n}$ is encoded by $z \cdot M$. Further suppose that the submatrix defined by the last n rows of M and any $c_{\rm sec} \cdot m$ of its columns is of full rank (i.e., rank $c_{\rm sec} \cdot m$). Then, we define the following probabilistic coding, E, of strings of length n. To encode $x \in \{0,1\}^n$, we first uniformly select $y \in \{0,1\}^n$, let $z = xy$ and output $E(x) = z \cdot M$. Clearly, the error-correction features of M are

[7] Actually, these circuits can be constructed in polynomial-time given the seed of the function.

inherited by E. To see that the secrecy requirement holds consider any sequence of $c_{\rm sec} \cdot m$ bits in $E(x)$. The contents of these bit locations is the product of z by the corresponding columns in M; that is, $z \cdot M' = x \cdot A + y \cdot B$, where M' denotes the submatrix corresponding to these columns in M, and A (resp., B) is the matrix resulting by taking the first (resp., last) n rows of M'. By hypothesis B is full rank, and therefore $y \cdot B$ is uniformly distributed (and so is $z \cdot M'$ regardless of x).

What is missing in the above is a specific construction satisfying the hypothesis as well as allowing efficient decoding. Such a construction can be obtained by mimicking Justesen's construction [Jus72]. Recall that Justesen's code is obtained by composing two codes: Specifically, an *outer* linear code over an n-symbol alphabet is composed with an *inner* random linear code.[8] The outer code is obtained by viewing the message as the coefficients of a polynomial of degree $t-1$ over a field with $\approx 3t$ elements and letting the code word consist of the values of this polynomial at all field elements. Using the Berlekamp–Welch Algorithm [BW86], one can efficiently retrieve the information from a code word provided that at most t of the symbols (i.e., the values at field elements) were corrupted. We obtain a variation of this outer-code as follows: Given $x \in \{0,1\}^n$, we set $t \stackrel{\rm def}{=} 2n/\log_2(3n)$, and view x as a sequence of $\frac{t}{2}$ elements in GF$(3t)$.[9] We uniformly select $y \in \{0,1\}^n$ and view it as another sequence of $\frac{t}{2}$ elements in GF$(3t)$. We consider the degree $t-1$ polynomial defined by these t elements, where x corresponds to the high-order coefficients and y to the low-order ones. Clearly, we preserve the error-correcting features of the original outer code. Furthermore, any $t/2$ symbols of the code word yield no information about x. To see this, note that the values of these $t/2$ locations are obtained by multiplying a t-by-$t/2$ Vandermonde with the coefficients of the polynomial. We can rewrite the product as the sum of two products, the first being the product of a $t/2$-by-$t/2$ Vandermonde with the low-order coefficients. Thus, a uniform distribution on these coefficients (represented by y) yields a uniformly distributed result (regardless of x).

Next, we obtain an analogue of the inner code used in Justesen's construction. Here the aim is to encode information of length $\ell \stackrel{\rm def}{=} \log_2 3t$ (i.e., the representation of an element in GF$(3t)$) using code words of length $O(\ell)$. Hence, we do not need an efficient decoding algorithm, since maximum likelihood decoding via exhaustive search is affordable (as $2^\ell = O(t) = O(n)$). Furthermore, any code that can be specified by $\log(n)$ many bits will do (as we can try and check all possibilities in poly(n)-time), which means that we can use a randomized argument provided that it utilizes only $\log(n)$ random bits. For example, we may use a linear code specified by a (random) 2ℓ-by-4ℓ Toeplitz matrix.[10] Using a probabilistic argument one can show that with positive probability such a random matrix yields a "nice" code as required in the motivating discussion.[11] In the rest of the discussion, one such good Toeplitz matrix is fixed.

We now get to the final step in mimicking Justesen's construction: the composition of the two codes. Recall that we want to encode $x \in \{0,1\}^n$ and that using a random string $y \in \{0,1\}^n$ we have generated a sequence of $3t$ values in GF$(3t)$, denoted $x_1, \ldots, x_{3t}$, each represented by a binary string of length ℓ. (This was done by

[8] Our presentation of Justesen's code is inaccurate but suffices for our purposes.

[9] Here we assume that $3t$ is a prime power. Otherwise, we use the first prime power greater than $3t$. Clearly, this has a negligible effect on the construction.

[10] A Toeplitz matrix, $T = (t_{i,j})$, satisfies $t_{i,j} = t_{i+1,j+1}$ for every i, j.

[11] The proof uses the fact that any (nonzero) linear combination of rows (columns) in a random Toeplitz matrix is uniformly distributed.

the outer code.) Now, using the inner code (i.e., the Toeplitz matrix) and additional $3t$ random ℓ-bit strings, denoted $y_1, \ldots, y_{3t}$ we encode each of the above x_i's by a 4ℓ-bit long string. Specifically, x_i is encoded by the product of the Toeplitz matrix with the vector $x_i y_i$.

Clearly, we preserve the error-correcting features of Justesen's construction [Jus72]. The secrecy condition is shown analogously to the way in which the error correction feature is established in [Jus72]. Specifically, we consider the partition of the code word into consecutive 4ℓ-bit long subsequences corresponding to the code words of the inner code. Given a set I of locations (as in the secrecy requirement), we consider the relative locations in each subsequence, denoting the induced locations in the ith subsequence by I_i. We classify the subsequences into two categories depending on whether the size of the induced I_i is above the secrecy threshold for the inner code. By a counting argument, only a small fraction of the subsequences have I_i's above the threshold. For the rest we use the secrecy feature of the inner code to state that no information is revealed about the corresponding x_i's. Using the secrecy feature of the outer code, we conclude that no information is revealed about x. $\square$

Efficient coding for the wire-tap channel problem. Using Theorem 2.2, we obtain an efficient coding scheme for (a strong version of) the wire-tap channel problem (cf. [Wyn75]). Actually, we consider a seemingly harder version introduced by Csiszár and Körner [CK78]. To the best of our knowledge no *computationally efficient* coding scheme was presented for this problem before.[12]

PROPOSITION 2.3. *Let* (E, D) *be a coding scheme as in Theorem* 2.2 *and let* $\mathsf{bsc}_p(\alpha)$ *be a random process that represents the transmission of a string* α *over a binary symmetric channel with crossover probability*[13] p. *Then,*

1. (error correction) *for every* $x \in \{0,1\}^*$

$$\Pr(D(\mathsf{bsc}_{\frac{c_{\mathrm{err}}}{2}}(E(x))) = x) \;=\; 1 - \exp(-\Omega(|x|));$$

2. (secrecy) *for every* $x \in \{0,1\}^*$

$$\sum_{\alpha \in \{0,1\}^{|E(x)|}} \left| \Pr(\mathsf{bsc}_{\frac{1}{2} - \frac{c_{\mathrm{sec}}}{4}}(E(x)) = \alpha) \;-\; 2^{-|E(x)|} \right|$$

is exponentially vanishing in $|x|$.

Proof. Item 1 follows by observing that, with overwhelmingly high probability, the channel complements less than a c_{err} fraction of the bits of the code word. Item 2 follows by representing $\mathsf{bsc}_{(1-\gamma)/2}(\alpha)$ (where $\gamma = c_{\mathrm{sec}}/2$) as a two-stage process: In the first stage each bit of α is set (to its current value) with probability γ, independently of the other bits. In the second stage each bit that was not set in the first stage is assigned a uniformly chosen value in $\{0,1\}$. Next, we observe that, with overwhelmingly high probability, at most $2\gamma|E(x)| = c_{\mathrm{sec}}|E(x)|$ bits were set in the first stage. Suppose that this is indeed the case. Then, applying Item 3 of Theorem 2.2, the bits set in Stage 1 are uniformly distributed regardless of x, and due to Stage 2 the bits that are not set in Stage 1 are also random. $\square$

[12]We note that Maurer has shown that this version of the problem can be reduced to the original one by using bidirectional communication [Mau91]. Crépeau (private communication, April 1997) has informed us that, using the techniques in [BBCM95, CM97], one may obtain an alternative efficient solution to the original wire-tap channel problem, again by using bidirectional communication.

[13]The *crossover probability* is the probability that a bit is complemented in the transmission process.

Remark 2.1. The above proof can be easily adapted to assert that, with overwhelmingly high probability, no information about x is revealed when obtaining both $\frac{c_{\rm sec}}{2} \cdot |E(x)|$ of the bits of $E(x)$ as well as the entire $\mathsf{bsc}_{\frac{1}{2}-\frac{c_{\rm sec}}{8}}(E(x))$.

3. Proof of Theorem 1.2. We start by describing a construction that satisfies the gap requirement of Theorem 1.2 for a fixed ϵ, say $\epsilon = 0.1$. That is, we only show that there exists a concept class $\mathcal{C}$ which for $\epsilon = 0.1$ has sample complexity $\mathsf{itsc}(n, \epsilon) = \Theta(k(n, \epsilon))$ and computational sample complexity $\mathsf{csc}(n, \epsilon) = \Theta(g(n, \epsilon) \cdot k(n, \epsilon))$. The construction is later generalized to handle variable ϵ.

3.1. Motivation: Construction for constant ϵ. We view a function $f \in C_n$ as an array of 2^n bits. This array is divided into the following three (consecutive) *slices* which have sizes 2^{n-1}, 2^{n-2}, and 2^{n-2}, respectively.

Slice I: This slice, called the *pseudorandom slice*, is determined by a pseudorandom function $f_s : \{0,1\}^{n-1} \to \{0,1\}$, where the seed s is of length n. (See subsection 2.1.)

Slice II: This slice, called the *seed encoder*, is determined by the above-mentioned seed s and an additional string r of length $O(n)$. More precisely, first we employ the probabilistic encoding scheme of subsection 2.2 to encode the message s using r as the randomness required by the scheme. The result is a code word of length $m \stackrel{\rm def}{=} O(n)$. Next we repeat each bit of the code word in $\frac{2^{n-2}}{g(n,0.1)\cdot k(n,0.1)}$ specified locations. All other locations in this slice are set to zero.

Slice III: This slice, called the *sample equalizer*, is determined by a binary string u of length $k(n, 0.1)$. The slice consists entirely of $k(n, 0.1)$ blocks of equal length, each repeating the corresponding bit of u. The purpose of this slice is to dominate the (information theoretic) sample complexity and allow us to easily derive tight bounds on it.

Information theoretic bounds. Applying Occam's Razor [BEHW87] to the class $\mathcal{C}$, we obtain $\mathsf{itsc}(\mathcal{C}; n, 0.1) = O(\log |C_n|) = O(n+O(n)+k(n, 0.1)) = O(k(n, 0.1))$, where the last equality is due to $k(n, 0.1) > n$. On the other hand, in order to learn a function in the class with error at most 0.1, it is necessary to learn Slice III with error at most 0.4. Thus, by virtue of Slice III alone, we have

$$\mathsf{itsc}(\mathcal{C}; n, 0.1) \geq \mathsf{itsc}(\text{Slice III}; n, 0.4) \geq 0.2 \cdot k(n, 0.1)$$

where the last inequality is due to the fact that learning a random string with error ϵ requires obtaining at least $1 - 2\epsilon$ of its bits. Thus, we have established the desired information-theoretic bounds. We now turn to analyzing the computational sample complexity.

Computational lower bound. The computationally bounded learner cannot learn Slice I from examples (or even queries) in the slice. Still, it must learn Slice I with error at most 0.2. Hence, the role of Slice I is to force the computationally bounded learner to obtain the function's seed from Slice II. By Item 3 of Theorem 2.2, in order to attain any information (from Slice II) regarding the seed, the learner must obtain $\Omega(n)$ bits of the code word (residing in Slice II). By Item 1 of Theorem 2.2, this means obtaining a constant fraction of the bits of the code word. Recall that the probability of getting any bit in the code word is $\frac{O(n)}{g(n,0.1)\cdot k(n,0.1)}$. Therefore, by a Chernoff bound, for every fraction $\alpha < 1$ there exists a constant $\beta < 1$ such that the probability of obtaining a fraction α of the code word given $(\beta \cdot g(n, 0.1) \cdot k(n, 0.1))$ examples is exponentially small. Thus, $\mathsf{csc}(\mathcal{C}; n, 0.1) = \Omega(g(n, 0.1) \cdot k(n, 0.1))$.

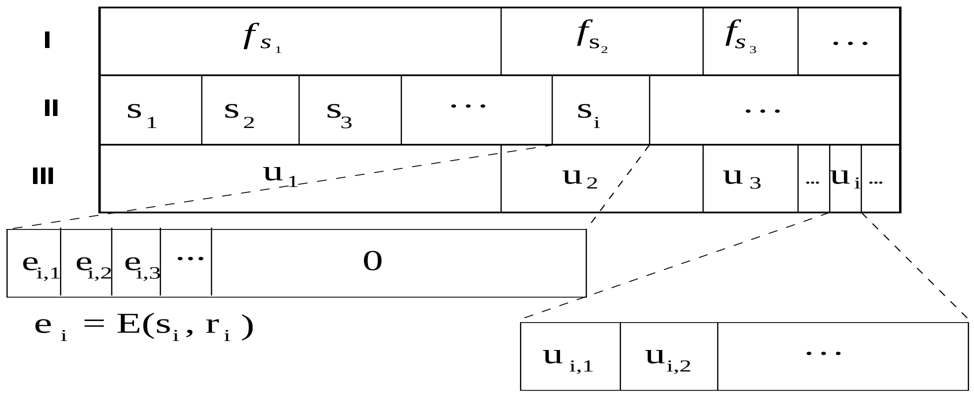

FIG. 3.1. *Construction for Theorem* 1.2.

Computational upper bound. By Chernoff bound a sample of $O(g(n, 0.1) \cdot k(n, 0.1))$ examples contains, with overwhelmingly high probability, an occurrence of each bit of the code word of the seed. Thus, by (a special case of) Item 2 of Theorem 2.2, the learner can efficiently retrieve the seed and so derive all of Slices I and II of the concept. However, by $g(n, 0.1) \geq 1$, the above sample will also allow obtaining (with high probability) all but at most a 0.1 fraction of the bits in Slice III, and thus $\mathsf{csc}(\mathcal{C}; n, 0.1) = O(g(n, 0.1) \cdot k(n, 0.1))$.

3.2. General construction—variable ϵ. We adopt the basic structure of the construction above, except that each of the three slices is further subpartitioned into *blocks*. Specifically, each slice has $t \stackrel{\text{def}}{=} n - \log_2 O(n)$ (consecutive) blocks, so that each block corresponds to a different possible value of $\epsilon = 2^{-i}$, for $i = 1, \ldots, t$. We start with a detailed description of each of the three slices (see Figure 3.1).

Slice I: *The pseudorandom part.* The ith block has size 2^{n-1-i} and is determined by a pseudorandom function $f_{s_i} : \{0,1\}^{n-1-i} \to \{0,1\}$, where the seed s_i is of length n. Note that the blocks are shrinking in size and that they are all pseudorandom.

Slice II: *The seeds encoder.* Here the blocks are of equal size $B \stackrel{\text{def}}{=} \frac{1}{t} \cdot 2^{n-2}$. The ith block encodes the ith seed, s_i, using an additional string r_i of length $O(n)$. Let e_i be the code word obtained by employing the probabilistic encoding scheme (of Theorem 2.2) on input s_i using randomness r_i. Recall that $m \stackrel{\text{def}}{=} |e_i| = O(n)$. The ith block is further divided into m (consecutive) *information fields*, each of size $\frac{2^{n-2}}{g(n,2^{-i}) \cdot k(n,2^{-i})}$, and an additional *empty field* (of size $B - \frac{m \cdot 2^{n-2}}{g(n,2^{-i}) \cdot k(n,2^{-i})}$). Thus the m information fields have relative density $\frac{m \cdot t}{g(n,2^{-i}) \cdot k(n,2^{-i})} = \Theta(\frac{n^2}{g(n,2^{-i}) \cdot k(n,2^{-i})})$ with respect to the total size B of the block. All bits in the jth information field are set to the value of the jth bit of e_i, and all bits in the empty field are set to zero.

Slice III: The sample equalizer. The ith block has size $B_i \stackrel{\text{def}}{=} 2^{n-2-i}$ and is determined by a binary string u_i of length $K \stackrel{\text{def}}{=} 2^{-i} \cdot k(n, 2^{-i}) = n^d$. The ith block is further divided into K (consecutive) subblocks, each of size $\frac{B_i}{K}$. All bits in the jth subblock are set to the value of the jth bit of u_i. Note that the blocks are shrinking in size and that for each block it is possible to obtain most bits in the block by viewing $\Theta(K)$ random examples residing in it.

We first observe that Slice III above gives rise to a concept class for which tight bounds of the form $k(n,\epsilon) = \mathrm{poly}(n)/\epsilon$, on the information theoretic and computational sample complexities, can be given.

PROPOSITION 3.1. *For* Slice III *described above we have*

1. $\mathsf{itsc}(\text{Slice III}; n, 4\epsilon) = \Omega(k(n,\epsilon))$;
2. $\mathsf{csc}(\text{Slice III}; n, \epsilon) = O(k(n,\epsilon))$.

Proof. Item 1. Let $i \stackrel{\text{def}}{=} \lfloor \log_2(1/8\epsilon) \rfloor$. In order to learn Slice III with error at most 4ϵ, one must learn the ith block reasonably well. Specifically, one must obtain examples from at least half of the K subblocks of the ith block, and hence must have at least $K/2$ examples in the ith block. By Chernoff bound, this implies that the total number of random samples must be at least $2^i \cdot \frac{K}{4} = 2^{i-2}\epsilon \cdot k(n,\epsilon) > 2^{-7} \cdot k(n,\epsilon)$. Item 1 follows.

Item 2. On the other hand, we consider the fraction of the third slice that is determined (with constant probability close to 1) given a sample of $16 \cdot k(n,\epsilon) = 16K/\epsilon$ random examples. It suffices to show that the total area left undetermined in the first $\ell \stackrel{\text{def}}{=} \lceil \log_2(4/\epsilon) \rceil$ blocks is at most an $\epsilon/2$ fraction of the total domain (since the remaining blocks cover at most an $\epsilon/2$ fraction of the total). Fixing any $i \leq \ell$, we consider the expected number of subblocks determined in the ith blocks (out of the total K subblocks). A subblock is determined if and only if we obtain a sample in it, and the probability for the latter event not to occur in $16K/\epsilon$ trials is

$$\left(1 - \frac{2^{-i}}{K}\right)^{16K/\epsilon} = \exp\left(-\frac{16}{2^i \cdot \epsilon}\right). \tag{3.1}$$

It follows that the expected fraction of bits that are not determined in the first ℓ blocks is bounded above by

$$\sum_{i=1}^{\ell} 2^{-i} \cdot 2^{-\frac{16}{2^i \epsilon}} = \sum_{j=0}^{\ell-1} 2^{-(\ell-j)} \cdot 2^{-\frac{16}{2^{\ell-j} \cdot 2^{-\ell+2}}} \tag{3.2}$$

$$= 2^{-\ell} \cdot \sum_{j=0}^{\ell-1} 2^j \cdot 2^{-2^{j+2}} \tag{3.3}$$

$$< \frac{\epsilon}{4} \cdot 2^{-4} \sum_{j=0}^{\infty} 2^{-j} \tag{3.4}$$

$$< \frac{\epsilon}{32} \tag{3.5}$$

where (3.4) follows from the fact that $\forall j \geq 0,\ 2^{j-4\cdot 2^j} \leq 2^{-4} \cdot 2^{-j}$. Item 2 follows. □

LEMMA 3.1. *The concept class described above has* (information theoretic) *sample complexity* $\mathsf{itsc}(n,\epsilon) = \Theta(k(n,\epsilon))$.

Proof. Clearly, it suffices to learn each of the three slices with error ϵ. Applying Occam's Razor [BEHW87] to Slices I and II of the class, we obtain

$$\mathsf{itsc}(\text{Slices I and II}; n, \epsilon) = O(n^2/\epsilon) = O(k(n,\epsilon)),$$

where the last equality is due to the hypothesis regarding the function $k(\cdot,\cdot)$ (i.e., that it is $\Omega(n^2/\epsilon)$). Using Item 2 of Proposition 3.1, we obtain $\mathsf{itsc}(\text{Slice III}; n, \epsilon) \leq \mathsf{csc}(\text{Slice III}; n, \epsilon) = O(k(n,\epsilon))$, and $\mathsf{itsc}(n,\epsilon) = O(k(n,\epsilon))$ follows. (Note that in order to obtain the desired tight bound we cannot simply apply Occam's Razor to Slice III since it is determined by roughly $2n \cdot K = 2n \cdot \epsilon \cdot k(n, \epsilon)$ bits.)

On the other hand, in order to learn a function in the class, we must learn Slice III with error at most 4ϵ. Using Item 1 of Proposition 3.1, we obtain $\mathsf{itsc}(\text{Slice III}; n, 4\epsilon) = \Omega(k(n, 4\epsilon))$, and $\mathsf{itsc}(n, \epsilon) = \Omega(k(n, 4\epsilon)) = \Omega(k(n, \epsilon))$ follows. □

LEMMA 3.2. *The concept class described above has* computational *sample complexity* $\mathsf{csc}(n, \epsilon) = \Theta(g(n, \epsilon) \cdot k(n, \epsilon))$.

Proof. Using Item 2 of Proposition 3.1, we have that $\mathsf{csc}(\text{Slice III}; n, \epsilon) = O(k(n, \epsilon))$, and using $g(n, \epsilon) \geq 1$ we infer that Slice III can be efficiently learned with ϵ error given a sample of size $O(g(n, \epsilon) \cdot k(n, \epsilon))$. Next we show that such a sample suffices for learning Slice I and Slice II as well. Since the information fields in the ith block of Slice II have density bounded above by 2^{-i}, in order to learn Slice II with error at most ϵ, it suffices to learn the first $\ell \overset{\text{def}}{=} \lceil \log_2(4/\epsilon) \rceil$ with error at most $\epsilon/2$. However, such an approximation might not suffice for learning Slice I sufficiently well. Nonetheless, we next show that a sample of size $O(g(n, \epsilon) \cdot k(n, \epsilon))$ suffices for efficiently determining (*exactly*) the first ℓ seeds (residing in the first ℓ blocks of Slice II) and thus determining the first ℓ blocks of Slice I.

Let $i \leq \ell$ and consider the m information fields in the ith block of the seed encoder. Suppose that for some constant c' (to be specified), we have $2c' \cdot (g(n, \epsilon) \cdot k(n, \epsilon))$ random examples. Then the expected number of examples residing in the information fields of the ith block is

$$2c' \cdot (g(n, \epsilon) \cdot k(n, \epsilon)) \cdot \frac{m}{g(n, 2^{-i}) \cdot k(n, 2^{-i})} \ . \tag{3.6}$$

Since $g(n, \epsilon) \cdot k(n, \epsilon) = \Omega(g(n, 2^{-i})k(n, 2^{-i}))$, for a suitable constant c'' (that depends on c' and on the constants in the $\Omega(\cdot)$ notation), this expected number is $2c''m$. With overwhelmingly high probability (i.e., $1 - \exp(-\Omega(m))$), there are at least $c''m$ examples in the information fields of the ith block (for every $i \leq \ell$). We set c' so that c'' will be such that, with overwhelmingly high probability, such a sample will miss at most $c_{\text{err}} \cdot m$ of these fields, where c_{err} is the constant in Item 2 of Theorem 2.2 (e.g., $c'' = 2/c_{\text{err}}$ will suffice). Invoking Item 2 of Theorem 2.2 (for the special case in which there are no errors but part of the code word is missing), we obtain the seed encoded in the ith block of Slice II. Since the probability of failure on a particular block is negligible, with very high probability we obtain the seeds in all the first ℓ blocks of Slice II. This concludes the proof of the upper bound.

We now turn to the lower bound and let $i \overset{\text{def}}{=} \lfloor \log_2(1/4\epsilon) \rfloor$. Considering the ith block of Slice I, we will show that too small a sample does not allow information regarding the ith seed to be obtained from Slice II. This will lead to the failure of the computational bounded learner, since without such information the ith block of Slice I looks totally random (to this learner). Specifically, let c_{sec} be the constant in Item 3 of Theorem 2.2, and let $c' = 2/c_{\text{sec}}$. Suppose the learner is given

$$c'' \cdot g(n, \epsilon) \cdot k(n, \epsilon) \quad < \quad c' \cdot g(n, 2^{-i})k(n, 2^{-i}) \tag{3.7}$$

random examples. (The constant c'' is such that the last inequality holds.) Then, using a Chernoff bound we infer that, with overwhelmingly high probability, we will have at most

$$2c' \cdot (g(n, 2^{-i}) \cdot k(n, 2^{-i})) \cdot \frac{m}{g(n, 2^{-i}) \cdot k(n, 2^{-i})} \quad = \quad 2c'm \quad = \quad c_{\text{sec}}m \tag{3.8}$$

random examples in the information fields of the ith block of Slice II. Invoking Item 3 of Theorem 2.2, this yields no information regarding the seed encoded in the ith block of Slice II. Thus, the computationally bounded learner cannot predict any unseen point in the ith block of Slice I better than at random. This means that its error is greater than allowed (i.e., $\geq 2^{-i-1} > \epsilon$). Thus, $\mathsf{csc}(n,\epsilon) > c'' \cdot g(n,\epsilon)k(n,\epsilon)$, where c'' is a constant as required. □

4. The two equalizers (proof of Theorem 1.7). In this section we show that (1) the sample equalizer (i.e., Slice III) described in section 3.2 can be used to prove the first item in Theorem 1.7 (noisy-sample equalizer); (2) another construction, based on *interval functions,* can be used to prove the second item of the theorem (query equalizer).

4.1. Noisy-sample equalizer (item 1 of Theorem 1.7). As noted above, we use Slice III of the construction in section 3.2. Here we think of a concept in the class $\mathcal{S} = \cup_n \mathcal{S}_n$ as being an array of size 2^n (as opposed to 2^{n-2} when it serves as the third slice of a concept). The number of subblocks in each of the $t = n - O(\log(n))$ blocks is $p(n)$. The proof follows the structure of the proof of Proposition 3.1.

LEMMA 4.1. $\mathsf{itsc}(\mathcal{S}, n, \epsilon, \gamma) = \Omega\left(\frac{p(n)}{\epsilon\gamma^2}\right)$.

Proof. Let $i \stackrel{\text{def}}{=} \lfloor \log_2(1/2\epsilon) \rfloor$. In order to learn a function in the class $\mathcal{S}_n$, one must learn the ith block reasonably well. Specifically, one must obtain sufficiently many examples from the ith block or else the information we obtain on the bits residing in this block is too small. In particular, we claim that we must have at least $\Omega(p(n)/\gamma^2)$ examples in the ith block. We prove the claim by noting that it corresponds to the classical information theoretic measure of the mutual information (cf., [CT91]) that these samples provide about the string residing in this block. Each example provides information on a single bit residing in the block and the amount of information is merely the capacity of a binary symmetric channel with crossover probability $\eta = \frac{1}{2} - \gamma$. That is, each example yields $1 - H_2(\eta)$ bits of information, where H_2 is the binary entropy function, which satisfies $1 - H_2(0.5 - \gamma) \approx \Theta(\gamma^2)$. The claim follows by additivity of information.

Let $c > 0$ be a constant so that we must have at least $p(n)/c\gamma^2$ examples in the ith block. Then, in order to have (with high probability) at least $p(n)/c\gamma^2$ examples in the ith block, the total number of random samples must be at least $2^i \cdot \frac{p(n)}{2c\gamma^2} = \Omega\left(\frac{p(n)}{\epsilon\gamma^2}\right)$. □

LEMMA 4.2. $\mathsf{csc}(\mathcal{S}, n, \epsilon, \gamma) = O\left(\frac{p(n)}{\epsilon\gamma^2}\right)$.

Proof. We consider the fraction of a concept in S_n that can be correctly inferred by a sample of $O(p(n)/\epsilon\gamma^2)$ random examples. It suffices to show that the total area left incorrectly inferred in the first $\ell \stackrel{\text{def}}{=} \lceil \log_2(4/\epsilon) \rceil$ blocks is at most an $\epsilon/2$ fraction of the total domain (since the remaining blocks cover at most an $\epsilon/2$ fraction of the total). Fixing any $i \leq \ell$, we consider the expected number of subblocks incorrectly inferred in the ith block (out of the total $p(n)$ subblocks). We use the obvious inference rule—a majority vote. Thus, a subblock is correctly inferred if and only if a strict majority of the examples obtained from it are labeled correctly. (Having obtained examples from this subblock is clearly a necessary condition for having a strict majority.) Using a Chernoff bound, the probability that we do not have the correct majority in $O(p(n)/\epsilon\gamma^2)$ trials is at most $\exp(-\Omega(2^{-i+1}/\epsilon))$. As in the proof of Proposition 3.1, it follows that the expected fraction of bits that are incorrectly inferred in the first ℓ blocks is bounded above by $\epsilon/20$, and the lemma follows. □

4.2. Query equalizer (Item 2 of Theorem 1.7). For every n, we consider the following concept class $\mathcal{S}_n$. Each concept in the class consists of $p(n)$ blocks of equal size $Q \overset{\text{def}}{=} 2^{n-2}/p(n)$. Each block corresponds to an interval function. Namely, the bit locations in each block are associated with $[Q] \overset{\text{def}}{=} \{1, \dots, Q\}$, and the bits themselves are determined by a pair of integers in $[Q]$. If the ith block is associated with a pair (u_i, v_i), then the jth bit in this block is 1 if and only if $u_i \le j \le v_i$. Note that pairs (u_i, v_i) with $u_i > v_i$ determine an all-zero block.

LEMMA 4.3. $\mathsf{itqc}(\mathcal{S}, n, \epsilon) = \Omega(p(n)/\epsilon)$.

Proof. We start by bounding the expected relative error of the algorithm on a single block when making at most q queries to this block. Later we discuss the implication of such a bound on the total error on S_n. □

The single block case. Suppose first that the learner is deterministic. Then, no matter how it chooses its q queries, there exists an interval of relative length $1/q$ that is never queried. Hence the algorithm cannot distinguish the case in which the target concept is all 0's and the case in which the target concept has 1's only in the nonqueried interval, and it must have error at least $1/2q$ on at least one of these concepts.

Next, we consider a probabilistic learner that makes q queries, all of them answered by 0 (as would be the case for the all-zero concept). Then, for every $\delta > 0$, there must exist an interval of relative length δ/q (i.e., actual length $\delta Q/q$) so that the probability that a query was made in this interval is below δ. We again consider the all-zero concept and the concept that has 1's only in this interval. We consider a $1 - \delta$ fraction of the runs of the algorithm in which no query is made to the above interval. In these runs the algorithm cannot distinguish the all-zero concept from the other concept. Thus, with probability $\frac{1-\delta}{2}$ the algorithm has error at least $\delta/2q$ (on some concept). If we set $\delta = 0.2$ and $q = \frac{1}{100\epsilon}$, then we have that with probability at least 0.4 the error is at least 10ϵ on one of the two concepts.

Back to the concept class S_n. To analyze the execution of a learning (with queries) algorithm on a (complete) concept in S_n, we consider the following game, consisting of two stages. In the *first stage*, the algorithm makes q queries in each block. The algorithm is not charged for any of these queries. In the *second stage*, the algorithm makes a choice, for each block, whether to output a hypothesis for this block or to ask for additional queries. In the latter case it is supplied with an infinite number of queries (for this block) and gets charged only for the q original queries made in the first stage. At the end of the second stage the algorithm must output a hypothesis for each of the remaining blocks. The algorithm is required to output hypotheses which together form an ϵ-approximation of the target. Clearly, the charges incurred in the above game provide a lower bound on the actual query complexity of any learning algorithm. The following claim refers to our charging convention.

Claim: *Any algorithm that learns S_n with ϵ error and confidence* 0.9 *incurs a charge of at least* $0.04 \cdot p(n) \cdot q$.

Proof. Consider the following mental experiment in which an algorithm executes only the first stage, and all its queries are answered "0" (as if each block corresponds to the empty interval function). For each i, let I_i be an interval (of maximum length) in the ith block such that the probability that a query is made (in the above mental experiment) to this interval is below δ (for $\delta = 0.2$). Employing the analysis of the single-block case, it follows that $|I_i| \ge \frac{\delta}{q} \cdot Q$ for every i.

We next define a distribution on $2^{p(n)}$ possible target concepts: For the ith block, independently, with probability 1/2, the interval I_i is chosen (to determine the ith block), and with probability 1/2, the empty interval is chosen. Now consider a full (two-stage) execution of an algorithm that learns S_n with ϵ error and confidence 0.9, when the target is chosen according to the above distribution. Since the bound on the error and confidence of the algorithm are with respect to a worst-case choice of a target concept, it must still hold that, with probability at least 0.9 over the randomization of the algorithm *and* the random choice of the target, the error of the algorithm is at most ϵ.

Suppose, in contradiction, that this algorithm incurs charge less than $0.04p(n) \cdot q$ (where $q = (100\epsilon)^{-1}$ is as above). Then, for at least a 0.96 fraction of the blocks, the algorithm outputs a hypothesis at the end of the first stage. By our assumption on the algorithm, with probability at least 0.9, the overall error in these hypotheses must be bounded by ϵ, and so at most one-ninth of these blocks may have *relative* error greater than 10ϵ (as otherwise the overall error is at least $0.96 \cdot \frac{1}{9} \cdot 10\epsilon > \epsilon$). But this implies that, on a uniformly selected block, with probability at least $0.9 \cdot 0.96 \cdot \frac{8}{9} > 0.6$, the algorithm has relative error smaller than 10ϵ while making at most q queries to the block. However, the last assertion contradicts our analysis of the single block case. Specifically, the algorithm queries the relevant interval $I = I_i$ of the ith block with probability at most $\delta = 0.2$, and so for a random concept assigned to this block (uniformly chosen to be either I or the empty interval), with probability at least 0.8/2, the algorithm error will be at least $\frac{|I|/2}{Q} \geq \frac{0.1}{q} = 10\epsilon$. □

Combining the above discussion with the claim, the lemma follows.

LEMMA 4.4. $\mathsf{csc}(\mathcal{S}, n, \epsilon) = O(p(n)/\epsilon)$.

Proof. The computationally bounded learner simply finds a minimal consistent hypothesis for each block in the concept. Namely, for the ith block it lets $\hat{u}_i \in [Q]$ be the smallest index of an example labeled 1 that belongs to ith block, and it lets $\hat{v}_i \in [Q]$ be the largest index of an example labeled 1 in the ith block. If no example in the block is labeled 1, then it lets $\hat{u}_i = [Q]$, and $\hat{v}_i = 1$ (so the hypothesis is all 0).

Assume the learner is given a sample of size $bp(n)/\epsilon$ $(= b \cdot k(n, \epsilon))$ for some constant $b > 1$. Then, for any particular block, the expected number of examples that fall in the block is b/ϵ, and the probability that fewer than $b/(2\epsilon)$ belong to the block is $\exp(-\Omega(b/\epsilon))$. Thus, by Markov's inequality, for sufficiently large b, the probability that the fraction of blocks receiving fewer than $b/2\epsilon$ examples exceeds $\epsilon/2$ is a small constant. It remains to show that with high probability the total error in the blocks receiving a sufficient number of examples is at most $\epsilon/2$. To this end we show that for each such block, the expected error, relative to the size of the block, is at most ϵ/b' for some constant b'.

Consider a particular block that receives at least $s = b/(2\epsilon)$ examples. Let the interval defining the block be $[u, v]$, and let the hypothesis of the learner be $[\hat{u}, \hat{v}]$. First note that by definition of the algorithm, $[\hat{u}, \hat{v}]$ is always a subinterval of $[u, v]$, and hence we have only one-sided error. In particular, in the case that $u > v$ (i.e., the target interval is empty), the error of the hypothesis is 0. Thus assume $u \leq v$. For the sake of the analysis, if $\hat{u} > \hat{v}$ (i.e., the learner did not observe any positive example in the block, and the hypothesis is all 0), redefine $\hat{u}$ to be $v + 1$ and $\hat{v}$ to be v. By definition, the hypothesis remains all 0. Let $\zeta_{\mathrm{L}} \overset{\mathrm{def}}{=} (\hat{u} - u)/Q$, and $\zeta_{\mathrm{R}} \overset{\mathrm{def}}{=} (v - \hat{v})/Q$. The error of the hypothesis (relative to the block) is the sum of these two random variables. We next bound the expected value of ζ_{L} (the expected value of ζ_{R} is bounded analogously).

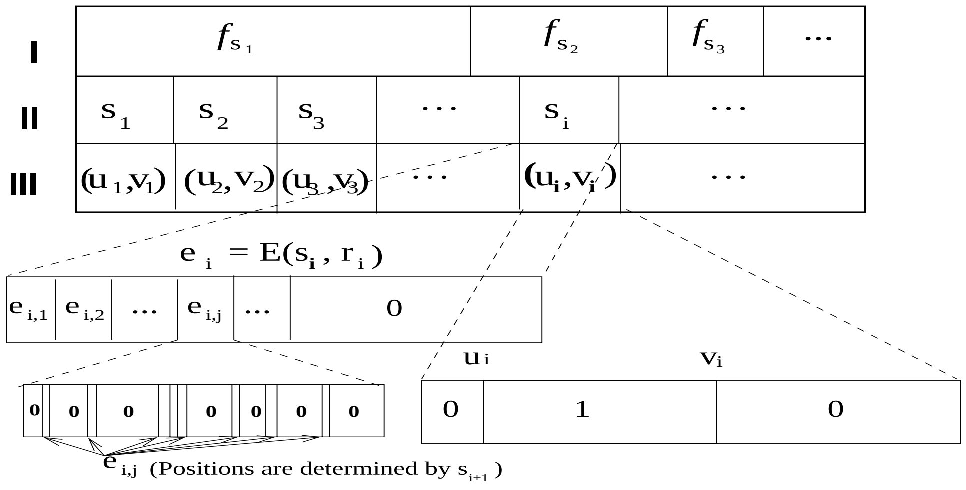

FIG. 5.1. *The general construction with the query equalizer* (*analyzed in Item* 2 *of Theorem* 1.7).

For any integer a, the probability that $\zeta_L > a \cdot \frac{1}{s}$ is the probability that no example fell between u and $u + (a/s) \cdot Q$, which is $(1 - a/s)^s < \exp(-a)$. Therefore,

$$\text{Exp}(\zeta_L) < \sum_{a=0}^{s-1} \Pr\left(\frac{a}{s} < \zeta_L \leq \frac{a+1}{s}\right) \cdot \frac{a+1}{s} \tag{4.1}$$

$$< \sum_{a=0}^{s-1} \Pr\left(\zeta_L > \frac{a}{s}\right) \cdot \frac{a+1}{s} \tag{4.2}$$

$$< \frac{1}{s} \sum_{a=0}^{\infty} (a+1)e^{-a} \tag{4.3}$$

$$< 3/s \;=\; 6\epsilon/d. \tag{4.4}$$

Thus, the (total) expected error of the algorithm on all blocks that receive at least $s = b/(2\epsilon)$ examples is bounded by $12\epsilon/b$. □

5. The general construction.

We adopt the structure of the construction presented in section 3. Specifically, the pseudorandom slice remains the same here, and the sample equalizer is one of the two equalizers analyzed in section 4 (depending on the application). The main modification is in the seed encoder slice (Slice II). For an illustration of the construction, see Figure 5.1.

As in section 3, we encode each seed using the probabilistic coding scheme of Theorem 2.2. In section 3 we repeated each resulting bit (of each encoded seed) in each bit of a corresponding information field, where the information fields occupied only a small fraction of Slice II and their locations were fixed. Here we augment this strategy by having only a few of the bits of these information fields equal the corresponding bit and the rest be set to zero. Thus, only a few locations in each information field are really informative. Furthermore, the locations of the informative bits will not be known a priori but will rather be "random" (as far as the computational bounded learner is concerned). This strategy effects the computational bounded learner both in the query and noisy models. Using queries the computational bounded learner may focus on the informative fields but it cannot hit informative bits within these fields any better than at random. In the presence of noise, the learner has an even harder time determining whether an informative bit is obtained or not.

Suppose that a ρ fraction of the bits in an information field are really informative. Then to distinguish a 0 from a 1 (with constant confidence) the learner must observe $\Theta(1/\rho)$ examples from the information field. Things become even harder in the presence of classification noise at rate $\eta = 0.5 - \gamma$, say, greater than 0.2. In this case, when getting an example in the information field, or even making a query to the information field, the answer may be 0 both in case the bit is not informative (and the answer is correct) and in case the bit is informative. The latter case happens with probability $0.5 + \gamma$ (resp., $0.5 - \gamma$) when the real information is 0 (resp., 1). Thus, in case the information bit is 0 (resp., 1), the answer is 0 with probability $1 - \eta$ (resp., with probability $(1 - \rho) \cdot (0.5 + \gamma) + \rho \cdot (0.5 - \gamma) = 1 - \eta - 2\rho\gamma$). As $1 - \eta$ is bounded away from (both 0 and 1), distinguishing an encoding of 0 from an encoding of 1 (with constant confidence) requires $\Theta(1/(\rho\gamma)^2)$ queries/examples from the information field.

The above discussion avoids the question of how we can make the informative locations be "random" (as far as the computational bounded learner is concerned). These "random" locations must be part of the specification of the concepts in the class. We cannot have truly random locations if we want to maintain a polynomial-size description of individual concepts. The use of pseudorandom functions is indeed a natural solution. There is still a problem to be resolved—the computational bounded learner must be able to obtain the locations of "information" for those blocks that it needs to learn. Our solution is to use the $(i + 1)$st pseudorandom function (from Slice I) in order to specify the locations in which information regarding the ith seed is given (in Slice II).

The following description is in terms of two density functions, denoted $\rho_1, \rho_2 : \mathcal{N} \times \mathcal{R} \mapsto \mathcal{R}$. Various instantiations of these functions will yield all the results in the paper. Each function in the concept class consists of the three slices, and each slice is further subpartitioned into *blocks* as described below.

Slice I*: The pseudorandom part.* This is exactly as in section 3. That is, the ith block has size 2^{n-1-i} and is determined by a pseudorandom function $f_{s_i} : \{0,1\}^{n-1-i} \rightarrow \{0,1\}$, where the seed s_i is of length n.

Slice II*: The seeds encoder.* As in section 3, this slice is partitioned into $t = n - \log_2 n - O(1)$ blocks (of equal size) so that the ith block has size $B \stackrel{\text{def}}{=} \frac{1}{t} \cdot 2^{n-2}$ and encodes the ith seed, s_i, using an additional string r_i of length $O(n)$. Let e_i be the code word obtained by employing the probabilistic encoding scheme on input s_i using randomness r_i. Recall that $m \stackrel{\text{def}}{=} |e_i| = O(n)$. The ith block is further divided into m (consecutive) *information fields*, each of size $\rho_1(n, 2^{-i}) \cdot \frac{B}{m}$, and an additional *empty field* (of size $(1 - \rho_1(n, 2^{-i}) \cdot B)$.

A $\rho_2(n, 2^{-i})$ fraction of the bits in the jth information field are set to the value of the jth bit of e_i. These bits are called *informative* and their locations are determined ("randomly") by a pseudorandom function, $h_{s_{i+1}} : \{0,1\}^n \mapsto \{0,1\}^n$ (this function uses the $(i + 1)$st seed!). The remaining bits in each information field as well as all bits of the empty field are set to zero.

A few details are to be specified. First, bit locations in Slice II are associated with strings of length $n - 2$. Thus, bit location $\alpha \in \{0,1\}^{n-2}$ that is inside an information field is informative if and only if $h_{s_{i+1}}(11\alpha)$ is among the first $2^n \cdot \rho_2(n, 2^{-i})$ strings in the lexicographic order of all n-bit long strings. The pseudorandom functions (over the domain $\{0,1\}^{n-i-1}$) used in Slice I are determined by the same seeds by letting $f_{s_i}(z) = \mathsf{lsb}(h_{s_i}(0^{i+1}z))$, where $\mathsf{lsb}(\sigma_n \cdots \sigma_1) = \sigma_1$ is the least significant bit of $\sigma_n \cdots \sigma_1$.[14] Thus, there is no "computational observable" interference between the randomness used for determining informative locations and the randomness used in Slice I.

Note that Slice II in the construction of section 3 is obtained by setting $\rho_1(n,\epsilon) = \frac{tm}{g(n,\epsilon)k(n,\epsilon)}$ and $\rho_2 \equiv 1$.

Slice III*: The equalizer.* In this slice we use one of the two equalizers analyzed in Theorem 1.7 (depending on the application).

5.1. Analysis of Slices I and II. It will be convenient to analyze the concept class that results from the above by omitting Slice III (the equalizer). We refer to the resulting class as to the *core* class.

FACT 5.1. *The core class has information theoretic sample complexity* $\mathsf{itsc}(n,\epsilon,\gamma) = O(n^2/\epsilon\gamma^2)$, *which in turn is* $O(k(n,\epsilon)/\gamma^2)$.

Proof. The proof follows from the "noisy Occam razor" [Lai88]. $\square$

We are not interested in an information theoretic lower bound for the core class since the equalizer will dominate the information theoretic complexities. Thus, we turn to analyze the computational complexities of the core class.

LEMMA 5.2. *The core class has*

1. *computational* (noiseless) sample *complexity* $\mathsf{csc}(n,\epsilon) = \Theta(\frac{n^2}{\rho_1(n,\epsilon)\cdot\rho_2(n,\epsilon)})$, *provided that* $\frac{1}{(\rho_1\cdot\rho_2)}$ *is an admissible function and that it is lower bounded by* $1/\epsilon$.
2. *for* $\gamma \le \frac{1}{4}$, *computational* (noisy) sample *complexity* $\mathsf{csc}(n,\epsilon,\gamma) = \Theta(\frac{n^2}{\rho_1(n,\epsilon)\cdot\rho_2(n,\epsilon)^2\cdot\gamma^2})$, *provided that* $\frac{1}{\rho_1\cdot\rho_2^2}$ *is an admissible function and that it is lower bounded by* $1/\epsilon$.
3. *computational* query *complexity* $\mathsf{cqc}(n,\epsilon) = \Theta(\frac{n}{\rho_2(n,\epsilon)})$, *provided that* $\frac{1}{\rho_2}$ *is an admissible function and that it is lower bounded by* $1/\epsilon$.

Proof. Item 1 (noiseless sample complexity). This item follows by observing that arguments used in Lemma 3.2 can be modified to obtain the desired bound. Consider the ith block of Slice II. We first note that a random example hits an information field of the ith block with probability $\rho_1(n,2^{-i})/t$ (i.e., with probability $1/t$ it falls in the ith block and conditioned on being in the ith block it falls in an information field with probability $\rho_1(n,2^{-i})$). Thus, the probability of hitting a specific information field (out of the $m = \Theta(n)$ fields) is $\frac{\rho_1(n,2^{-i})}{t\,m} = \Theta(\frac{\rho_1(n,2^{-i})}{n^2})$. We also know that a random example in an information field is informative (i.e., depends on the encoded bit) with probability $\rho_2(n,2^{-i})$ and is set to zero otherwise.

For the lower bound, consider the ith block for $i \overset{\text{def}}{=} \lfloor \log(1/4\epsilon) \rfloor$. Similar to what was shown in the lower bound of Lemma 3.2, for an appropriate constant c'', a sample of size $c'' \cdot \frac{n^2}{(\rho_1(n,\epsilon)\cdot\rho_2(n,\epsilon)}$ will contain informative examples in less than $c_{\text{sec}}\, m$ of the information fields in the ith block (where c_{sec} is the constant in Item 3 of Theorem 2.2). As a result, the ith seed cannot be obtained and the error of the learner on Slice I is too large.

The proof of the upper bound is easily adapted as well. As in the proof of Lemma 3.2 we have that for a sufficiently large constant c', with very high probability, a sample of size $c' \cdot n^2/(\rho_1(n,\epsilon)\cdot\rho_2(n,\epsilon))$ will contain at least one informative example in all but a small constant fraction of the m information fields in the ith block, for

[14]Our description assumes "pseudorandom functions" mapping n-bit strings to n-bit strings, whereas the definition given in section 2.1 refers to functions mapping n-bit strings to a single bit. However, given pseudorandom functions of the latter type, one can easily construct functions as used here; see [Gol95].

every $i \leq \ell \overset{\text{def}}{=} \lceil \log(8/\epsilon) \rceil$. The only difference here is that while seeing a 1 in an information field in fact means that the bit encoded in it is 1, seeing only 0's in the field only provides statistical evidence towards 0. Thus, while in Lemma 3.2 we only had to deal with missing informative examples (that encode seeds), here we might have errors when inferring that the bit encoded is 0. However, the coding scheme (of Theorem 2.2) allows a constant fraction (i.e., c_{err}) of errors, and hence we can handle a constant fraction of errors in each of the first ℓ blocks. Note that the ℓ corresponding seeds determine not only the first ℓ blocks of Slice I but also the locations of informative bits in the first $\ell - 1$ blocks of Slice II.

Item 2 (noisy sample complexity). The additional difficulty we encounter here (as compared to Item 1 above) is that due to the noise it does not suffice to "hit" informative examples inside information fields in order to infer the encoded bit. Namely, each example (informative or not) has an incorrect label with probability $\eta = \frac{1}{2} - \gamma$. Therefore, seeing a 1 in an information field does not necessarily mean that it is an informative example and the field encodes the bit 1, but rather it could be a noisy bit in an information field encoding the bit 0.

However, there is clearly still a difference between information fields that encode 1, and those that encode 0: In case an information field encodes 0, a random example in it will be labeled 1 with probability η. On the other hand, in case an information field encodes 1, a random example in it will be labeled 1 with probability $\rho_2(n, 2^{-i}) \cdot (1 - \eta) + (1 - \rho_2(n, 2^{-i})) \cdot \eta = \eta + 2\gamma\rho_2(n, 2^{-i})$. Thus, we need to distinguish a 0–1 sample with expectation η from a 0–1 sample with expectation $\eta + \Theta(\gamma\, \rho_2(n, 2^{-i}))$. This is feasible (with high probability) using $O(1/(\gamma^2\, \rho_2(n, 2^{-i}))$ examples. Since our coding scheme can suffer a constant fraction of errors, we can allow that a small fraction of information fields will receive fewer than the required number of examples, and that among those receiving the desired number, a small fraction will be determined incorrectly. The upper bound follows.

For η that is bounded below by some constant (say, $\eta \geq 1/4$), a sample of size $\Omega(1/(\rho_2(n, 2^{-i})\gamma)^2)$ is also required to distinguish between the two cases discussed above with probability greater than, say $1/2 + c_{\text{sec}}/8$, where c_{sec} is the constant defined in Item 3 of Theorem 2.2. Suppose that a sample of size $c'm/(\rho_2(n, 2^{-i})\gamma)^2$ falls in the ith block of Slice II. Then, for sufficiently small c', at most $c_{\text{sec}}/2$ information fields receive a sufficient number of examples. Hence, even if all these information fields are correctly inferred, by Remark 2.1, with very high probability no information about the ith seed will be revealed. In particular, this holds for $i = \lfloor \log_2(1/4\epsilon) \rfloor$. We conclude that, for $\gamma \leq 1/4$,

$$\mathsf{csc}(n, \epsilon, \gamma) = \Theta\left(\frac{n^2}{\rho_1(n, \epsilon)} \cdot \frac{1}{(\rho_2(n, \epsilon) \cdot \gamma)^2} \right). \tag{5.1}$$

Item 3. Using arguments similar to those applied above we show that $O(n/\rho_2(n, \epsilon))$ queries suffice for efficiently determining the first $\ell \overset{\text{def}}{=} \lceil \log_2(8/\epsilon) \rceil$ seeds residing in the first ℓ blocks of Slice II. Specifically, we use a $2^{-\ell-4+i}$ fraction of the $c' \cdot (n/\rho_2(n, \epsilon))$ queries as a random sample into the information fields of the ith block, for $i = 1, \ldots, \ell$ (and ignore the empty fields in all blocks). Thus, we have $c' \cdot 2^{-\ell-4+i} \cdot (n/\rho_2(n, \epsilon)) = 2c'' \cdot m/\rho_2(n, 2^{-i})$ random examples in the ith block, where c'' is a constant related to the constant c'. With overwhelmingly high probability we'll obtain at least $c''m$ informative bits. For a suitable choice of the constants (c' and c''), this suffices to recover the ith seed for every $i \leq \ell$. Observe that the only part in which we have used queries is in the skewing of the random examples among the various blocks.

We now turn to the lower bound and let $i \stackrel{\text{def}}{=} \lfloor \log_2(1/4\epsilon) \rfloor$. Considering the ith block of Slice I, we show that, as long as the informative locations in the ith block of Slice II are unknown, too few queries do not allow us to obtain information regarding the ith seed. This will lead to the failure of the computational bounded learner, since without such information the ith block of Slice I looks totally random (to this learner). The actual argument starts from the last block (i.e., tth block) and proceeds up to the ith block. Assuming that the learner has no knowledge of the jth seed, for $j > i$, we show that he obtains no knowledge of the $j-1$st seed. On top of what is done in the analogous part of the proof of Lemma 3.2, we need to argue that having no knowledge of the jth seed puts the learner in the same situation as if it has selected its queries at random: We can think of it making a query and then having a random biased coin determine if this query (into the seed encoder) carries information. $\square$

5.2. Applications of Lemma 5.2. Combining the analysis of the core class (i.e., Lemma 5.2) with the adequate equalizer of Theorem 1.7, we derive all main results of this paper. Before we do so, recall that Theorem 1.2 is a special case of Theorem 1.3 (i.e., with noise equals zero; $\gamma = 1/2$), whereas the latter is a special case of the first item of Theorem 1.4 (i.e., with $g_2 \equiv 1$). Thus, we focus on proving Theorems 1.4 and 1.5.

Proof of Theorem 1.4. In order to prove the first item, we set $\rho_1(n,\epsilon) \stackrel{\text{def}}{=} \frac{n^2}{g_1(n,\epsilon)\cdot k(n,\epsilon)}$ and $\rho_2(n,\epsilon) \stackrel{\text{def}}{=} \frac{1}{g_2(n,\epsilon)}$. By Item 1 of Theorem 1.7 and Fact 5.1, we have $\mathsf{itsc}(n,\epsilon,\gamma) = \Theta(k(n,\epsilon)/\gamma^2)$. Invoking Item 1 of Lemma 5.2, we have $\mathsf{csc}(n,\epsilon) = \Theta(g_1(n,\epsilon)g_2(n,\epsilon)\cdot k(n,\epsilon))$. Invoking Item 2 of Lemma 5.2, we have $\mathsf{csc}(n,\epsilon,\gamma) = \Theta(g_1(n,\epsilon)g_2(n,\epsilon)^2 \cdot k(n,\epsilon)/\gamma^2)$, for every $\gamma \le 1/4$. Thus, the first item follows.

In order to prove the second item, we set $\rho_1(n,\epsilon) \stackrel{\text{def}}{=} 1$ and $\rho_2(n,\epsilon) \stackrel{\text{def}}{=} \frac{n^2}{k(n,\epsilon)}$. Again, we have $\mathsf{itsc}(n,\epsilon,\gamma) = \Theta(k(n,\epsilon)/\gamma^2)$, and invoking Items 1 and 2 of Lemma 5.2, we have $\mathsf{csc}(n,\epsilon) = \Theta(k(n,\epsilon))$ and $\mathsf{csc}(n,\epsilon,\gamma) = \Theta(k(n,\epsilon)^2/n^2\gamma^2))$, for every $\gamma \le 1/4$. Thus, the second item of the theorem follows. (Actually, we can obtain a more general result by setting $\rho_1(n,\epsilon) \stackrel{\text{def}}{=} n^{-(d-a-2)}\epsilon^{1-\beta}$ and $\rho_2(n,\epsilon) \stackrel{\text{def}}{=} n^{-d}\epsilon^{\beta}$, for any $a \in [0, d-2]$ and $\beta \in [0,1]$.)

Proof of Theorem 1.5*, for $g_2 \ge n$.* Here we set $\rho_1(n,\epsilon) \stackrel{\text{def}}{=} \frac{n}{g_2(n,\epsilon)}$ and $\rho_2(n,\epsilon) \stackrel{\text{def}}{=} \frac{n}{g_1(n,\epsilon)\cdot k(n,\epsilon)}$, and the hypothesis $g_2(n,\epsilon) \ge n$ guarantees that $\rho_1(n,\epsilon) \le 1$ as required by the admissibility condition. By Item 2 of Theorem 1.7 and Fact 5.1, we have $\mathsf{itqc}(n,\epsilon) = \Theta(k(n,\epsilon)) = \Theta(\mathsf{itsc}(n,\epsilon))$. Invoking Item 1 of Lemma 5.2, we have $\mathsf{csc}(n,\epsilon) = \Theta(g_1(n,\epsilon)g_2(n,\epsilon)\cdot k(n,\epsilon))$. Invoking Item 3 of Lemma 5.2, we have $\mathsf{cqc}(n,\epsilon) = \Theta(g_1(n,\epsilon)\cdot k(n,\epsilon))$. The theorem follows.

5.3. Proof of Theorem 1.5 (for arbitrary g_2). The core class (analyzed in Lemma 5.2) provides a computationally bounded learner that uses queries, which is an advantage over a computationally bounded learner that uses only uniformly distributed examples. Whereas the former may focus its queries on the first $\log_2(2/\epsilon)$ blocks of Slice II, the latter may not. Thus, typically, using queries entitles an advantage of a factor of $n/\log(1/\epsilon)$ in trying to learn Slice II above. To close this gap (and allow us to establish Theorem 1.5 for arbitrary g_2), we modify Slice II as follows. The basic idea is to randomly permute the locations of the information fields of the various blocks. Thus the query-learner is forced to look for the bits it needs in all possible locations (rather than "zoom-in" on the appropriate block).

Slice II (*modified*). Let $t \stackrel{\text{def}}{=} n/\log_2 n$ (rather than $t = n-\log_2 n$). This slice is partitioned into $t \cdot m$ fields of equal size, $F \stackrel{\text{def}}{=} \frac{1}{tm} \cdot 2^{n-2}$, where m is (as before) the length of the encoding of an n-bit long seed. Unlike the above construction, we do not have a common empty field (instead each field contains an informative part and an empty part as described below). We use m permutations over $\{1,\ldots,t\}$, denoted $\pi_1,\ldots,\pi_m$, to determine the correspondence between fields and seed-information. Specifically, the jth bit of the ith seed is "encoded" in field number $(j-1)\cdot t + \pi_j(i)$. (The permutations are part of the description of the concept.) Each field corresponding to one of the bits of the ith seed consists of two parts. The first part, containing the first $\rho_1(n, 2^{-i}) \cdot F$ bits of the field, carries information about the corresponding bit of the seed; whereas the second part (the rest of the field's bits) is uncorrelated to the seed. Loosely speaking, the *informative part* contains the results of independent coin flips each with bias $\rho_2(n, 2^{-i})$ towards the correct value of the corresponding bit (i.e., the probability that the answer is correct is 0.5 + bias); whereas the rest contains the results of independent unbiased coin flips. Actually, the random choices are implemented by a pseudorandom function determined by the $i+1$st seed.

LEMMA 5.3. *Assume that $\frac{1}{\rho_1}$ and $\frac{\epsilon}{\rho_2^2}$ are admissible functions. Then the modified core class has*

1. *computational* (noise-less) sample *complexity* $\mathsf{csc}(n,\epsilon) = \Theta\left(\frac{n^2}{\rho_1(n,\epsilon)\cdot\rho_2(n,\epsilon)^2}\right)$.
2. *computational* query *complexity* $\mathsf{cqc}(n,\epsilon) = \Theta\left(\frac{n^2}{\rho_2(n,\epsilon)^2}\right)$.

Proof. We follow the structure of the proof of Lemma 5.2, indicating the necessary modifications.

Item 1. Considering Slice II, we note that a random example hits an information part of a field belonging to the ith seed with probability $\rho_1(n, 2^{-i})/t$. Intuitively, $\Theta(\rho_2(n, 2^{-i})^{-2})$ such hits are required for obtaining reliable information from this field.

For the lower bound, we assume that the learner is given the permutations π_j for free. Still, the arguments used in Lemma 5.2 imply that it needs $\Omega(\rho_2(n, 2^{-i})^{-2} \cdot m)$ hits in the fields of the ith seed in order to recover this seed. Using $t, m = \Omega(n)$, the lower bound follows.

The proof of the upper bound is to be adapted as here we cannot assume that the permutations π_j are known to the learner. For $i = 1,\ldots,\log_2(8/\epsilon)$, the learner determines the ith seed as follows. For $j = 1,\ldots,m$, the learner determines the value of the jth bit in the encoding of the ith seed. It considers only examples in the $\rho_1(n, 2^{-i}) \cdot F$ prefix of each of the relevant fields; that is, fields with indices $(j-1)\cdot t+1,\ldots,(j-1)\cdot t+t$. For each such field it estimates the bias of the field. With high constant probability, the estimated bias of field $(j-1)\cdot m+\pi_j(i)$ is approximately $\rho_2(n, 2^{-i})$ and, under our assumption on ρ_2, every other field corresponding to the jth bit of an encoding of some other seed, has significantly different bias in its $\rho_1(n, 2^{-i}) \cdot F$ prefix. Thus, this bit is obtained correctly with high constant probability. As usual, this allows us to decode correctly the entire seed. Having the ith seed we may determine the ith pseudorandom function as well as the "encoding" of the bits of the $i-1$st code word (i.e., one may efficiently determine the value of each bit in each of the fields corresponding to the $i-1$st seed). The upper bound follows.

Item 2. The upper bound follows easily by the obvious adaptation of the above learning strategy (i.e., when trying to determine the jth bit in the encoding of the ith seed the learner makes queries only to the $\rho_1(n, 2^{-i}) \cdot F$ prefix of each of the relevant fields).

For the lower bound we need to modify the argument given above (as here we cannot afford giving away the permutations π_j for free). In fact, the whole point of the modification was to deprive the learner of such information. Still, when arguing about the ith seed, for $i = \log_2(4/\epsilon)$, we may give the learner $\pi_j(1), \ldots, \pi_j(i-1)$ $(\forall j)$ for free. We may assume without loss of generality that the learner does not make queries to these fields (i.e., to a field with index $(j-1) \cdot t + \pi_j(\ell)$ for $\ell < i$ and any j). Based on our encoding scheme, the learner must infer $\Omega(m)$ of the bits in the encoding of the ith seed. For each bit it must discover $\pi_j(i)$ and make $\Omega\left(\frac{1}{\rho_2(n,2^{-i})}\right)$ queries. However, for every j and $\ell \geq i$, the field corresponding to the jth bit of the encoding of the ℓth seed has bias (in its $\rho_1(n, 2^{-i}) \cdot F$ prefix) that is bounded above by $\rho_2(n, 2^{-i})$. Hence, for each j, the learner must perform $\Omega(n/(\rho_2(n, 2^{-i})^2)$ queries to these fields in order to infer the desired bit. The lower bound follows. ◻

Deriving Theorem 1.5. To prove Theorem 1.5 (in its general form), we set $\rho_1(n,\epsilon) \stackrel{\text{def}}{=} \frac{1}{g_2(n,\epsilon)}$ and $\rho_2(n,\epsilon) \stackrel{\text{def}}{=} \sqrt{\frac{n^2}{g_1(n,\epsilon)\cdot k(n,\epsilon)}}$. Invoking Item 1 of Lemma 5.3, we have $\mathsf{csc}(n,\epsilon) = \Theta(g_1(n,\epsilon)g_2(n,\epsilon) \cdot k(n,\epsilon))$. Invoking Item 2 of Lemma 5.3, we have $\mathsf{cqc}(n,\epsilon) = \Theta(g_1(n,\epsilon) \cdot k(n,\epsilon))$. So all that is left is to analyze $\mathsf{itsc}(n,\epsilon)$ and $\mathsf{itqc}(n,\epsilon)$, the information theoretic sample and query complexity of the entire class. By Item 2 of Theorem 1.7, both information theoretic complexities of Slice III are $\Theta(k(n,\epsilon))$. By Occam's Razor [BEHW87], the (information theoretic) sample complexity is at most $O(s/\epsilon)$, where 2^s is the number of concepts in the core class. Here we have $s = t \cdot n + m \cdot \log_2(t!)$, where the term $t \cdot n < n^2$ is due to the t seeds and $m \cdot \log_2(t!) = O(mt \log t)$ is due to the $m = O(n)$ permutations. We use[15] $t = O(n/\log n)$ to obtain $mt \cdot \log t = O(n^2)$, which in turn yields $s/\epsilon = O(k(n,\epsilon))$. Hence, $\mathsf{itqc}(n,\epsilon) = \Theta(k(n,\epsilon)) = \Theta(\mathsf{itsc}(n,\epsilon))$, and the theorem follows.

6. Proof of Theorem 1.6.

Here we merely use a pseudorandom generator [BM84, Yao82]. Specifically, we need a generator, G, which stretches seeds of length n into sequences of length $p(n)$. The concept class, $\mathcal{C} = \{C_n\}$, will correspond to all possible choices of a seed for the generator. Specifically, for every seed $s \in \{0,1\}^n$, we get a concept $f_s \in C_n$ defined so that $f_s(x) \stackrel{\text{def}}{=} \sigma_i$, where σ_i is the ith bit of $G(s)$ and x belongs to the ith subset in a "nice" $p(n)$-way partition of $\{0,1\}^n$ (e.g., a partition by lexicographic order in which all parts are of about the same size).

By Occam's Razor [BEHW87], the above concept class has $\mathcal{ITSC}(n,\epsilon) = O(n/\epsilon)$. On the other hand, considering a variation of the standard lower-bound distribution (i.e., which assigns probability $1-4\epsilon$ uniformly to all instances in a single subset and is uniform on all other instances), we derive the computational lower bound. Specifically, using $0.1 \cdot p(n)/\epsilon$ samples, with overwhelmingly high probability, the learner only sees $p(n)/2$ different bits of the pseudorandom sequence. As far as a computationally bounded learner is concerned, the rest of the sequence is random and so it will fail with probability at least $\frac{1}{2}$ when trying to predict any example corresponding to an unseen bit. Thus, $\mathcal{CSC}(n,\epsilon) > 0.1 \cdot p(n)/\epsilon$.

It is not hard to see that $10 \cdot p(n)/\epsilon$ samples allow efficient learning up to error ϵ (with respect to any distribution) and so $\mathcal{CSC}(n,\epsilon) \leq 10 \cdot p(n)/\epsilon$.

[15]Alternatively, we could use $t = n - O(\log n)$ (as in previous constructions) and derive the theorem for $k(n,\epsilon) = \Omega(n^2 \log n)/\epsilon$.

A FASTER AND SIMPLER ALGORITHM FOR SORTING SIGNED PERMUTATIONS BY REVERSALS[*]

HAIM KAPLAN[†], RON SHAMIR[†], AND ROBERT E. TARJAN[‡]

Abstract. We give a quadratic time algorithm for finding the minimum number of reversals needed to sort a signed permutation. Our algorithm is faster than the previous algorithm of Hannenhalli and Pevzner and its faster implementation by Berman and Hannenhalli. The algorithm is conceptually simple and does not require special data structures. Our study also considerably simplifies the combinatorial structures used by the analysis.

Key words. sorting permutations, reversal distance, computational molecular biology

1. Introduction.

In this paper we study the problem of sorting signed permutations by reversals. A *signed permutation* is a permutation $\pi = (\pi_1, \ldots, \pi_n)$ on the integers $\{1, \ldots, n\}$, where each number is also assigned a sign of plus or minus. A *reversal*, $\rho(i,j)$, on π transforms π to

$$\begin{aligned}\pi' &= \pi\rho(i,j)\\ &= (\pi_1, \ldots, \pi_{i-1}, -\pi_j, -\pi_{j-1}, \ldots, -\pi_i, \pi_{j+1}, \ldots, \pi_n).\end{aligned}$$

The minimum number of reversals needed to transform one permutation to another is called the *reversal distance* between them. The problem of *sorting signed permutations by reversals* is to find, for a given signed permutation π, a sequence of reversals of minimum length that transforms π to the identity permutation $(+1, +2, \ldots, +n)$.

The motivation for studying the problem arises from molecular biology: Concurrent with the fast progress of the human genome project, genetic and DNA data on many model organisms are accumulating rapidly, and consequently the ability to compare genomes of different species has grown dramatically. One of the best ways of checking similarity between genomes on a large scale is to compare the order of appearance of identical genes in the two species. In the thirties, Dobzhansky and Sturtevant [7] had already studied the notion of inversions in chromosomes of *drosophila*. In the late eighties, Jeffrey Palmer demonstrated that different species may have essentially the same genes, but the gene order may differ between species. Taking an abstract perspective, the genes along a chromosome can be thought of as points along a line. Numbers identify particular genes and, since genes have directionality, the

signs correspond to their direction. Palmer and others have shown that the difference in order may be explained by a small number of reversals [17, 18, 19, 20, 12]. These reversals correspond to evolutionary changes during the history of the two genomes, so the number of reversals reflects the evolutionary distance between the species. Hence, given two such permutations, their reversal distance measures their evolutionary distance.

Mathematical analysis of genome rearrangement problems was initiated by Sankoff [22, 21]. Kececioglu and Sankoff [16] gave the first constant-factor polynomial approximation algorithm for the problem and conjectured that the problem is NP-hard. Bafna and Pevzner [3] and more recently Christie [6] improved the approximation factor, and additional studies have revealed the rich combinatorial structure of rearrangement problems [15, 14, 2, 9, 10]. Quite recently, Caprara [5] has established that sorting *unsigned* permutations is NP-hard, using some of the combinatorial tools developed by Bafna and Pevzner [3].

In 1995, Hannenhalli and Pevzner [11] showed that the problem of sorting a *signed* permutation by reversals is polynomial. They proved a duality theorem that equates the reversal distance with the sum of three combinatorial parameters (see Theorem 2.3 below). Based on this theorem, they proved that sorting signed permutations by reversals can be done in $O(n^4)$ time. More recently, Berman and Hannenhalli [4] described a faster implementation that finds a minimum sequence of reversals in $O(n^2\alpha(n))$ time, where α is the inverse of Ackerman's function [1] (see also [23]).

In this study we give an $O(n^2)$ algorithm for sorting a signed permutation of n elements, thereby improving upon the previous best-known bound [4]. In fact, if the reversal distance is r, our algorithm requires $O(r \cdot n + n\alpha(n))$ time. In addition to giving a better time bound, our work considerably simplifies both the algorithm and the combinatorial structure needed for the analysis, as follows:

- The basic object we work with is an implicit representation of the overlap graph, to be defined later, in contrast with the interleaving graph in [11] and [4]. The overlap graph is combinatorially simpler than the interleaving graph. As a result, it is easier to produce a representation for the overlap graph from the input, and to maintain it while searching for reversals.
- As a consequence of our ability to work with the overlap graph, we need not perform any "padding transformations," nor do we have to work with "simple permutations" as in [11] and [4].
- We deal with the unoriented and oriented parts of the permutation separately, which makes the algorithm much simpler.
- The notion of a *hurdle*, one of the combinatorial entities defined by [11] for the duality theorem, is simplified and is handled in a more symmetric manner.
- The search for the next reversal is much simpler and requires no special data structures. Our algorithm computes connected components only once, and any simple implementation of it suffices to obtain the quadratic time bound. In contrast, in [4] a logarithmic number of connected component computations may be performed per reversal, using the union-find data structure.

The paper is organized as follows: Section 2 gives the necessary preliminaries. Section 3 gives an overview of our algorithm. Sections 4 and 5 give the details of our algorithm. We summarize our results and suggest some further research in section 6.

2. Preliminaries.

This section gives the basic background, primarily the theory of Hannenhalli and Pevzner, on which we base our algorithm. The reader may find it helpful to refer to Figure 2.1, in which the main definitions are illustrated. We start with some definitions for unsigned permutations. Let $\pi = (\pi_1, \dots, \pi_n)$ denote a permutation of $\{1, \dots, n\}$. Augment π to a permutation on $n+2$ vertices by adding $\pi_0 = 0$ and $\pi_{n+1} = n+1$ to the permutation. A pair (π_i, π_{i+1}), $0 \le i \le n$, is called a *gap.* Gaps are classified into two types. A gap (π_i, π_{i+1}) is a *breakpoint* of π if and only if $|\pi_i - \pi_{i+1}| > 1$; otherwise, it is an *adjacency* of π. We denote by $b(\pi)$ the number of breakpoints in π.

A *reversal*, $\rho(i,j)$, on a permutation π transforms π to

$$\begin{aligned}\pi' &= \pi\rho(i,j)\\ &= (\pi_1, \dots, \pi_{i-1}, -\pi_j, -\pi_{j-1}, \dots, -\pi_i, \pi_{j+1}, \dots, \pi_n).\end{aligned}$$

We say that a reversal $\rho(i,j)$ *acts on* the gaps (π_{i-1}, π_i) and (π_j, π_{j+1}).

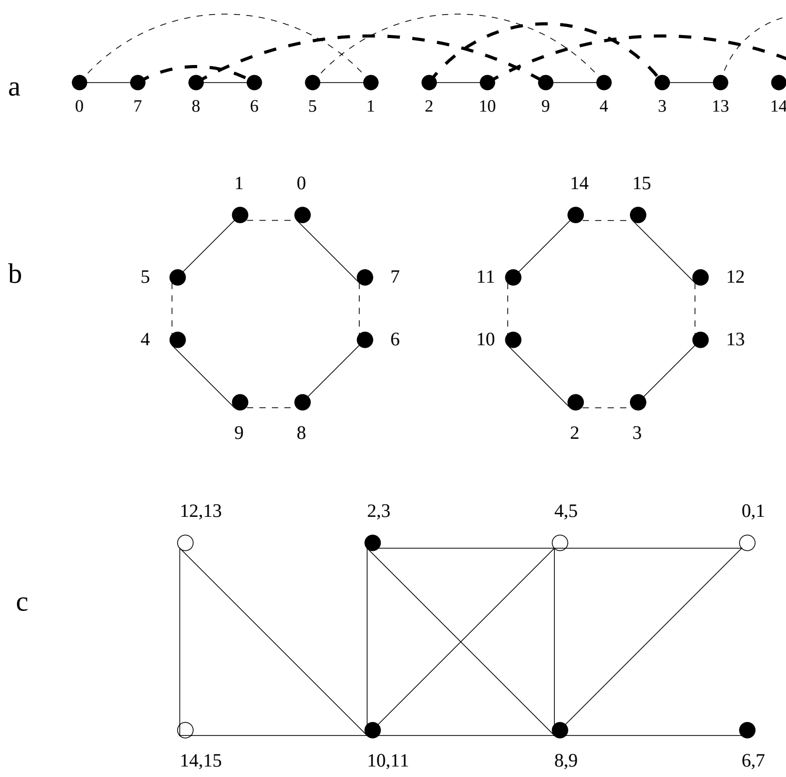

FIG. 2.1. (a) *The breakpoint graph,* $B(\pi)$, *of the permutation* $\pi = (4, -3, 1, -5, -2, 7, 6)$. *Black edges are solid, gray edges are dashed, and oriented edges are bold.* (b) $B(\pi)$ *decomposes into two disjoint alternating cycles.* (c) *The overlap graph,* $OV(\pi)$. *Black vertices correspond to oriented edges.*

2.1. The breakpoint graph. The *breakpoint graph* $B(\pi)$ of a permutation $\pi = (\pi_1, \dots, \pi_n)$ is an edge-colored graph on $n+2$ vertices $\{\pi_0, \pi_1, \dots, \pi_{n+1}\} = \{0, 1, \dots, n+1\}$. We join vertices π_i and π_j by a *black edge* if (π_i, π_j) is a breakpoint in π and by a *gray edge* if (i,j) is a breakpoint in π^{-1}.

We define a one-to-one mapping u from the set of signed permutations of order n into the set of unsigned permutations of order $2n$ as follows. Let π be a signed permutation. To obtain $u(\pi)$, replace each positive element x in π by $2x-1, 2x$ and each negative element $-x$ by $2x, 2x-1$. For any signed permutation π, let $B(\pi) = B(u(\pi))$. Note that in $B(\pi)$ every vertex is either isolated or incident to exactly one black edge and one gray edge. Therefore, there is a unique decomposition of $B(\pi)$ into cycles. The edges of each cycle alternate between gray and black. Refer to a reversal $\rho(i,j)$ such that i is odd and j even as an *even reversal.* The reversal $\rho(2i+1, 2j)$ on $u(\pi)$ mimics the reversal $\rho(i+1, j)$ on π. Thus, sorting π by reversals is equivalent to sorting the unsigned permutation $u(\pi)$ by even reversals. Henceforth we will consider the latter problem, and by a reversal we will always mean an even reversal. Let $b(\pi) = b(u(\pi))$ and let $c(\pi)$ be the number of cycles in $B(\pi)$.

Figure 2.1(a) shows the breakpoint graph of the permutation $\pi = (4, -3, 1, -5, -2, 7, 6)$. It has eight breakpoints and decomposes into two alternating cycles, i.e., $b(\pi) = 8$ and $c(\pi) = 2$. The two cycles are shown in Figure 2.1(b). Figure 2.2(a) shows the breakpoint graph of $\pi' = (4, -3, 1, 2, 5, 7, 6)$, which has seven breakpoints and decomposes into two cycles.

For an arbitrary reversal ρ on a permutation π, define $\Delta b(\pi, \rho) = b(\pi\rho) - b(\pi)$ and $\Delta c(\pi, \rho) = c(\pi\rho) - c(\pi)$. When the reversal ρ and the permutation π are clear from the context, we will abbreviate $\Delta b(\pi, \rho)$ by Δb and $\Delta c(\pi, \rho)$ by Δc. As Bafna and Pevzner [3] observed, the following values are taken by Δb and Δc depending on the types of the gaps $\rho(i,j)$ acts on:

(1) two adjacencies: $\Delta c = 1$ and $\Delta b = 2$;
(2) a breakpoint and an adjacency: $\Delta c = 0$ and $\Delta b = 1$;
(3) two breakpoints each belonging to a different cycle: $\Delta b = 0$, $\Delta c = -1$;
(4) two breakpoints of the same cycle C :
  (a) (π_i, π_{j+1}) and (π_{i-1}, π_j) are gray edges: $\Delta c = -1$, $\Delta b = -2$,
  (b) exactly one of (π_i, π_{j+1}) and (π_{i-1}, π_j) is a gray edge: $\Delta c = 0$, $\Delta b = -1$,
  (c) neither (π_i, π_{j+1}) nor (π_{i-1}, π_j) is a gray edge, and when breaking C at i and j vertices $i-1$ and $j+1$ end up in the same path: $\Delta b = 0$, $\Delta c = 0$,
  (d) neither (π_i, π_{j+1}) nor (π_{i-1}, π_j) is a gray edge, and when breaking C at i and j vertices $i-1$ and $j+1$ end up in different paths: $\Delta b = 0$, $\Delta c = 1$.

Call a reversal *proper* if $\Delta b - \Delta c = -1$, i.e., it is either of type 4a, 4b, or 4d. We say that a reversal ρ *acts on* a gray edge e if it acts on the breakpoints which correspond to the black edges incident with e. A gray edge is *oriented* if a reversal acting on it is proper; otherwise it is *unoriented.* Notice that a gray edge (π_k, π_l) is oriented if and only if $k+l$ is even. For example, the gray edge $(0,1)$ in the graph of Figure 2.1(a) is unoriented, while the gray edge $(7,6)$ is oriented.

2.2. The overlap graph. Two intervals on the real line *overlap* if their intersection is nonempty but neither properly contains the other. A graph G is an *interval overlap graph* if one can assign an interval to each vertex such that two vertices are adjacent if and only if the corresponding intervals overlap (see, e.g., [8]). For a permutation π, we associate with a gray edge (π_i, π_j) the interval $[i,j]$. The *overlap graph* of a permutation π, denoted $OV(\pi)$, is the interval overlap graph of the gray edges of $B(\pi)$. Namely, the vertex set of $OV(\pi)$ is the set of gray edges in $B(\pi)$, and two vertices are connected if the intervals associated with their gray edges overlap. We shall identify a vertex in $OV(\pi)$ with the edge it represents and with its interval in the representation. Thus, the endpoints of a gray edge are actually the endpoints of the interval representing the corresponding vertex in $OV(\pi)$. Note that all the endpoints of intervals in this representation are distinct integers. A connected component of $OV(\pi)$ that contains an oriented edge is called an *oriented component*; otherwise, it is called an *unoriented component.*

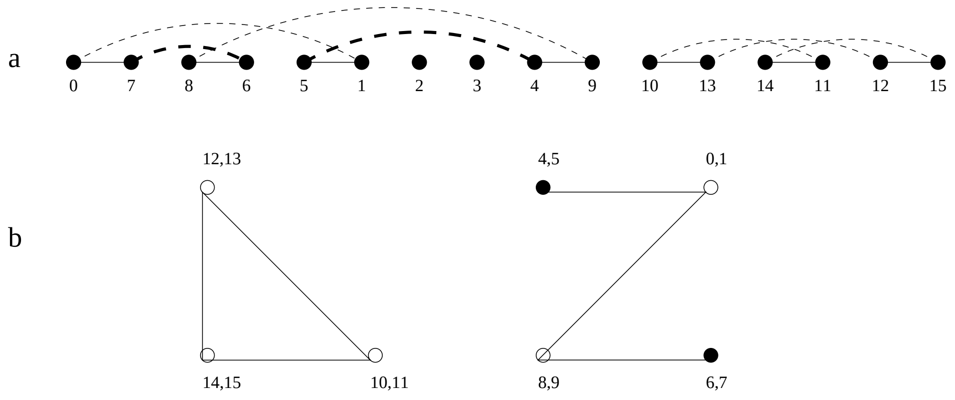

FIG. 2.2. (a) *The breakpoint graph of* $\pi' = (4, -3, 1, 2, 5, 7, 6)$. π' *was obtained from* π *of Figure* 2.1 *by the reversal* $\rho(7, 10)$ *or, equivalently, by the reversal defined by the gray edge* $(2, 3)$. (b) *The overlap graph of* π'.

Figure 2.1(c) shows the interval overlap graph for $\pi = (4, -3, 1, -5, -2, 7, 6)$. It has only one oriented component. Figure 2.2(b) shows the overlap graph of the permutation $\pi' = (4, -3, 1, 2, 5, 7, 6)$, which has two connected components, one oriented and the other unoriented.

2.3. The connected components of the overlap graph. Let X be a set of gray edges in $B(\pi)$. Define $\min(X) = \min\{i \mid (\pi_i, \pi_j) \in X\}$, $\max(X) = \max\{j \mid (\pi_i, \pi_j) \in X\}$, and $span(X) = [\min(X), \max(X)]$. Equivalently, one can look at the interval overlap representation of $OV(\pi)$ mentioned above and define the span of a set of vertices X as the minimum interval which contains all the intervals of vertices in X.

The major object our algorithm will work with is $OV(\pi)$, though for efficiency considerations we will avoid generating it explicitly. In contrast, Pevzner and Hannenhalli worked with the *interleaving graph* H_π, whose vertices are the alternating cycles of $B(\pi)$. Two cycles C_1 and C_2 are connected by an edge in H_π if and only if there exists a gray edge $e_1 \in C_1$ and a gray edge $e_2 \in C_2$ that overlap.

The following lemma and its corollary imply that the partition imposed by the connected components of $OV(\pi)$ on the set of gray edges is identical to the one imposed by the connected components of H_π.

LEMMA 2.1. *If* M *is a set of gray edges in* $B(\pi)$ *that corresponds to a connected component in* $OV(\pi)$, *then* $\min(M)$ *is even and* $\max(M)$ *is odd.*

Proof. Assume $\min(M)$ is odd. Then $\pi_{\min(M)} + 1$ and $\pi_{\min(M)} - 1$ must both be in $span(M)$ (i.e., there exist $l_1, l_2 \in span(M)$ such that $\pi_{l_1} = \pi_{\min(M)} + 1$ and $\pi_{l_2} = \pi_{\min(M)} - 1$). Thus $\pi_{\min(M)}$ is neither the maximum nor the minimum element in the set $\{\pi_i \mid i \in span(M)\}$. Hence, either the maximum element or the minimum element in $span(M)$ is π_j for some $\min(M) < j < \max(M)$. By the definition of $B(\pi)$ there must be a gray edge (π_j, π_l) for some $l \notin span(M)$, contradicting the fact that M is a connected component in $OV(\pi)$. The proof that $\max(M)$ is odd is similar. ∎

As an illustration of Lemma 2.1, consider Figure 2.2(a). Let $M_1 = \{(0, 1), (4, 5), (8, 9), (6, 7)\}$ and $M_2 = \{(10, 11), (12, 13), (14, 15)\}$. Then $span(M_1) = [0, 9]$ and $span(M_2) = [10, 15]$.

COROLLARY 2.2. *Every connected component of* $OV(\pi)$ *corresponds to the set of gray edges of a union of cycles.*

Proof. Assume by contradiction that C is a cycle whose gray edges belong to at least two connected components in $OV(\pi)$. Assume M_1 and M_2 are two of these components such that there are two consecutive gray edges $e_1 \in M_1$ and $e_2 \in M_2$ along C. Since the spans of different connected components in $OV(\pi)$ cannot overlap there are two different cases to consider.

(1) *span*$(M_2) \subseteq$ *span*(M_1) (the case *span*$(M_1) \subseteq$ *span*(M_2) is symmetric). Since e_1 and e_2 are in different components they cannot overlap. Thus, either the right endpoint of e_2 is even and equals $\max(M_2)$ or the left endpoint of e_2 is odd and equals $\min(M_2)$. In both cases we have a contradiction to Lemma 2.1.

(2) *span*(M_2) and *span*(M_1) are disjoint intervals. Without loss of generality assume that $\max(M_1) < \min(M_2)$. The right endpoint of e_1 is even and equals $\max(M_1)$, which contradicts Lemma 2.1. ▯

Note that, in particular, Corollary 2.2 implies that an overlap graph cannot contain isolated vertices.

2.4. Hurdles. Let $\pi_{i_1}, \pi_{i_2}, \dots, \pi_{i_k}$ be the subsequence of $0, \pi_1, \dots, \pi_n, n+1$ consisting of those elements incident with gray edges that occur in unoriented components of $OV(\pi)$. Order $\pi_{i_1}, \pi_{i_2}, \dots, \pi_{i_k}$ on a circle CR such that π_{i_j} follows $\pi_{i_{j-1}}$ for $2 \leq j \leq k$ and π_{i_1} follows π_{i_k}. Let M be an unoriented connected component in $OV(\pi)$. Let $E(M) \subset \{\pi_{i_1}, \pi_{i_2}, \dots, \pi_{i_k}\}$ be the set of endpoints of the edges in M. An unoriented component M is a *hurdle* if the elements of $E(M)$ occur consecutively on CR.

This definition of a hurdle is different from the one given by Hannenhalli and Pevzner [11]. It is simpler in the sense that minimal hurdles and the maximal ones do not have to be treated in different ways. Using Corollary 2.2 above, one can prove that the hurdles as we have defined them are identical to the ones defined by Hannenhalli and Pevzner. Let $h(\pi)$ denote the number of hurdles in a permutation π.

A hurdle is *simple* if when one deletes it from $OV(\pi)$ no other unoriented component becomes a hurdle, and it is a *super hurdle* otherwise. A *fortress* is a permutation with an odd number of hurdles all of which are super hurdles.

The following theorem was proved by Hannenhalli and Pevzner.

THEOREM 2.3 (see [11]). *The minimum number of reversals required to sort a permutation π is $b(\pi) - c(\pi) + h(\pi)$, unless π is a fortress, in which case exactly one additional reversal is necessary and sufficient.*

3. Overview of our algorithm. Denote by $d(\pi)$ the reversal distance of π, i.e., $d(\pi) = b(\pi) - c(\pi) + h(\pi) + 1$ if π is a fortress and $d(\pi) = b(\pi) - c(\pi) + h(\pi)$ otherwise.

Following the theory developed in [11], it turns out that given a permutation π with $h(\pi) > 0$ one can perform $t = \lceil h(\pi)/2 \rceil$ reversals and transform π into a permutation π' such that $h(\pi') = 0$ and $d(\pi') = d(\pi) - t$. If $OV(\pi)$ has unoriented components then our algorithm first finds t such reversals that transform π into a π' which has only oriented components.

Our method of "clearing the hurdles" uses the theory developed by Hannenhalli and Pevzner. In section 5 we describe an efficient implementation of this process which uses the implicit representation of the overlap graph $OV(\pi)$. Our implementation runs in $O(n)$ time assuming $OV(\pi)$ is already partitioned into its connected components. Recently, Berman and Hannenhalli [4] gave an $O(n\alpha(n))$ algorithm for computing the connected components of an interval overlap graph given implicitly by its representation. Using their algorithm we can clear the hurdles from a permutation in $O(n\alpha(n))$ time.

The overlap graph of π', $OV(\pi')$, has only oriented components. In section 4 we prove that in the neighborhood of any oriented gray edge e there is an oriented gray edge e_1 (e_1 could be the same as e) such that a reversal acting on e_1 does not create new hurdles. Call such a reversal a *safe reversal*. We develop an efficient algorithm to locate a safe reversal in a permutation with at least one oriented gray edge. Our algorithm uses only an implicit representation of the overlap graph and runs in $O(n)$ time.

The second stage of our algorithm repeatedly finds a safe reversal and performs it as long as $OV(\pi)$ is not empty. Clearly the overall complexity is $O(r \cdot n + n\alpha(n))$, where r is the number of reversals required to sort π'.

3.1. Representing the overlap graph. We assume that the input is given as a sequence of n signed integers representing π^0. First the permutation $\pi = u(\pi^0)$ is constructed as described in section 2.1 and stored in an array. We also construct an array representing π^{-1}. It is straightforward to verify that with these two arrays we can determine for each element in π whether it is a left or a right endpoint of a gray edge in constant time. In case the element is an endpoint of a gray edge, we can also find the other endpoint and check whether the edge is oriented in constant time.

Thus the arrays π and π^{-1} comprise a representation of $OV(\pi)$. Our algorithm will maintain these two arrays while carrying out the reversals that it finds. The time to update the arrays is proportional to the length of the interval being reversed, which is $O(n)$. We shall give a high-level presentation of our algorithm and use primitives like "Scan the oriented gray edges in increasing left endpoint order." It is easy to see how to implement these primitives using the arrays π and π^{-1}; we shall omit the details.

It is easy to produce a list of the intervals in the representation of $OV(\pi)$ sorted by either the left or right endpoint from the arrays π and π^{-1}. It is also possible to maintain them without increasing the asymptotic time bound of the algorithm. In practice it may be faster to maintain such lists instead of, or in addition to π and π^{-1}.

4. Eliminating oriented components. First we introduce some notation. Recall that the vertices of $OV(\pi)$ are the gray edges of $B(\pi)$. In order to avoid confusion we will usually refer to them as vertices of $OV(\pi)$. Hence a vertex of $OV(\pi)$ is *oriented* if the corresponding gray edge is oriented, and it is *unoriented* otherwise. Let e be a vertex in $OV(\pi)$. Denote by $r(e)$ the reversal acting on the gray edge corresponding to e. Denote by $N(e)$ the set of neighbors of e in $OV(\pi)$ including e itself. Denote by $ON(e)$ the subset of $N(e)$ containing the oriented vertices and by $UN(e)$ the subset of $N(e)$ containing the unoriented vertices.

In this section we prove that if an oriented vertex e exists in $OV(\pi)$ then there exists an oriented vertex $f \in ON(e)$ such that $r(f)$ is proper and safe. We also describe an algorithm that finds a proper safe reversal in a permutation that contains at least one oriented edge.

We start with the following useful observation.

OBSERVATION 4.1. *Let e be a vertex in $OV(\pi)$ and let $\pi' = \pi r(e)$. $OV(\pi')$ could be obtained from $OV(\pi)$ by the following operations.* (1) *Complement the graph induced by $OV(\pi)$ on $N(e) - \{e\}$, and flip the orientation of every vertex in $N(e) - \{e\}$.* (2) *If e is oriented in $OV(\pi)$, then remove it from $OV(\pi)$.* (3) *If there exists an oriented edge e' in $OV(\pi)$ with $r(e) = r(e')$, then remove e' from $OV(\pi)$.*

Note that if e is an oriented vertex in a component M of $OV(\pi)$, $M - \{e\}$ may split into several components in $OV(\pi')$. (Compare Figures 2.1(c) and 2.2(b).) Denote these components by $M'_1(e), \ldots, M'_k(e)$, where $k \geq 1$. We will refer to $M'_i(e)$ simply as M'_i whenever e is clear from the context.

Let C be a clique of oriented vertices in $OV(\pi)$. We say that C is *happy* if for every oriented vertex $e \notin C$ and every vertex $f \in C$ such that $(e, f) \in E(OV(\pi))$ there exists an oriented vertex $g \notin C$ such that $(g, e) \in E(OV(\pi))$ and $(g, f) \notin E(OV(\pi))$. For example, in the overlap graph shown in Figure 2.1(c) $\{(2, 3), (10, 11)\}$ and $\{(6, 7)\}$ are happy cliques, but $\{(2, 3), (10, 11), (8, 9)\}$ is not. Our first theorem claims that one of the vertices in any happy clique defines a safe proper reversal.

THEOREM 4.1. *Let C be a happy clique and let e be a vertex in C such that $|UN(e')| \leq |UN(e)|$ for every $e' \in C$. Then the reversal $r(e)$ is safe.*

Proof. Let $\pi' = \pi r(e)$ and assume by contradiction that $M'_i(e)$ is unoriented for some $1 \leq i \leq k$. Clearly $N(e) \cap M'_i \neq \emptyset$.

Assume there exists $y \in N(e) \cap M'_i$ such that $y \notin C$. Clearly y must be oriented in $OV(\pi)$ and, since C is happy, it must also have an oriented neighbor y' such that $(y', e) \notin E(OV(\pi))$. Since y' is not adjacent to e in $OV(\pi)$ it stays oriented and adjacent to y in $OV(\pi')$, in contradiction with the assumption that M'_i is unoriented. Hence we may assume that $N(e) \cap M'_i \subseteq C$.

Let $y \in N(e) \cap M'_i$ and let $z \in UN(e)$. Vertex z is oriented in $OV(\pi')$ and if it is adjacent to y in $OV(\pi')$ we obtain a contradiction. Hence, z and y are not adjacent in $OV(\pi')$, so they must be adjacent in $OV(\pi)$. Hence we obtain that $UN(e) \subseteq UN(y)$ in $OV(\pi)$. Corollary 2.2 implies that component M'_i cannot contain y alone. Thus y must have a neighbor x in M'_i. Since $N(e) \cap M'_i \subseteq C$, vertex x is not adjacent to e in $OV(\pi)$. Thus we obtain that $(x, y) \in OV(\pi)$, $(x, e) \notin OV(\pi)$, and x is unoriented in $OV(\pi)$. Since we have already proved that $UN(e) \subseteq UN(y)$, this implies that $UN(e) \subset UN(y)$, in contradiction with the choice of e. □

For example, Theorem 4.1 implies that the reversal defined by the gray edge $(10, 11)$ is a safe proper reversal for the permutation of Figure 2.1 (a) since it corresponds to the vertex with maximum unoriented degree in the happy clique $\{(2, 3), (10, 11)\}$. On the other hand, the reversal defined by $(2, 3)$ creates a new unoriented component, as it yields the permutation shown in Figure 2.2.

The following theorem proves that a happy clique exists in the neighborhood of any oriented edge.

THEOREM 4.2. *Let e be an oriented vertex in $OV(\pi)$. There exists an oriented vertex $f \in ON(e)$ such that for $\pi' = \pi r(f)$, all the components in $OV(\pi')$ are oriented.*

Proof. By Theorem 4.1 it suffices to show that there exists a happy clique C in $ON(e)$.

Let $Ext(e) = \{x \in ON(e) \mid$ there exists $y \in ON(x)$ such that $y \notin ON(e)\}$. That is, $Ext(e)$ contains all oriented neighbors of e which have oriented neighbors outside of $ON(e)$.

Case 1. $Ext(e) = ON(e) - \{e\}$. Set $C = \{e\}$.

Case 2. $Ext(e) \subset ON(e) - \{e\}$. Let $D^0 = ON(e) - Ext(e)$. For $j \geq 0$, while D^j is not a clique let K^j be a maximal clique in D^j and define $D^{j+1} = D^j - K^j$. Let D^k, $k \geq 0$ be the final clique and set $C = D^k$.

It is straightforward to verify that in each of the two cases C is indeed a happy clique. □

In the next section we describe an algorithm that will find an oriented edge e such that $r(e)$ is safe given the representation of $OV(\pi)$ described in section 3.1. The algorithm first finds a happy clique C and then searches for the vertex with maximum unoriented degree in C. According to Theorem 4.1 this vertex defines a safe reversal.

Even though Theorem 4.2 guarantees the existence of a happy clique in the neighborhood of any fixed oriented vertex, our algorithm does not search in one particular such neighborhood. We will prove that the algorithm is guaranteed to find a happy clique assuming that there exists at least one oriented edge. Therefore the algorithm provides an alternative proof to a weaker version of Theorem 4.2 that claims only the existence of a happy clique somewhere in the graph.

4.1. Finding a happy clique. In this section we give an algorithm that locates a happy clique in $OV(\pi)$. Let $e_1, \ldots, e_k$ be the oriented vertices in $OV(\pi)$ in increasing left endpoint order. The algorithm traverses the oriented vertices in $OV(\pi)$ according to this order. Let $L(e)$ and $R(e)$ be the left and right endpoints, respectively, of vertex e in the realization of $OV(\pi)$. After traversing $e_1, \ldots, e_i$, $1 \le i \le k$, the algorithm maintains a happy clique C_i in the subgraph of $OV(\pi)$ induced by these vertices. Assume $|C_i| = j$, $j \le i$ and let $e_{i_1}, \ldots, e_{i_j}$ be the vertices in C_i where $i_1 < i_2 < \ldots < i_j$. The vertices of C_i are maintained in a linked list, ordered in increasing left endpoint order. If there exists an interval that contains all the intervals in C_i, then the algorithm maintains a minimal such interval t_i. The clique C_i and the vertex t_i (if it exists) satisfy the following invariant.

INVARIANT 4.1.

(1) Every vertex $e_l \notin C_i$, $l \le i$, such that $L(e_{i_1}) < L(e_l)$ must be adjacent to t_i, i.e., $R(e_l) > R(t_i)$.

(2) Every vertex $e_l \notin C_i$, $L(e_l) < L(e_{i_1})$ that is adjacent to a vertex in C_i is either adjacent to an interval e_p such that $R(e_p) < L(e_{i_1})$ or adjacent to t_i.

The fact that C_i is happy in the subgraph induced by $e_1, \ldots, e_i$ follows from this invariant. We initialize the algorithm by setting $C_1 = \{e_1\}$. Initially, t_1 is not defined. Let the current interval be e_{i+1}. If $R(e_{i_j}) < L(e_{i+1})$ then C_i is guaranteed to be happy in $OV(\pi)$ since all remaining oriented vertices are not adjacent to C_i. Hence the algorithm stops and returns C_i as the answer. See Figure 4.1(a).

We now assume that $L(e_{i+1}) \le R(e_{i_j})$ and show how to obtain C_{i+1} and t_{i+1}. We have to consider the following cases.

Case 1. The interval t_i is defined and $R(t_i) < R(e_{i+1})$. Continue with $C_{i+1} = C_i$ and $t_{i+1} = t_i$. See Figure 4.1(b).

Case 2. The interval t_i is not defined or $R(e_{i+1}) \le R(t_i)$.

(a) $R(e_{i_j}) < R(e_{i+1})$ and $L(e_{i+1}) \le R(e_{i_1})$. C_{i+1} is obtained by adding e_{i+1} to C_i and $t_{i+1} = t_i$. See Figure 4.1(c).

(b) $R(e_{i_j}) < R(e_{i+1})$ and $L(e_{i+1}) > R(e_{i_1})$. The clique C_{i+1} consists of e_{i+1} alone and $t_{i+1} = t_i$. See Figure 4.1(d).

(c) $R(e_{i+1}) < R(e_{i_j})$. As in the previous case $C_{i+1} = \{e_{i+1}\}$. In this case t_{i+1} is set to e_{i_j}, the last interval in C_i. See Figure 4.1(e).

The following theorem proves that the algorithm above produces a happy clique.

THEOREM 4.3. *Let C_l be the current clique when the algorithm stops. Then C_l is a happy clique in $OV(\pi)$.*

Proof. A straightforward induction on the number of oriented vertices traversed by the algorithm proves that C_l and t_l satisfy Invariant 4.1.

The algorithm stops either when $R(e_{i_j}) < L(e_{l+1})$ or when l is equal to the number of oriented vertices. In either case since C_l is happy in the subgraph induced by $e_1, \ldots, e_l$ it must be happy in $OV(\pi)$. ∎

The running time of the algorithm is proportional to the number of oriented vertices traversed since a constant amount of work is performed for each such vertex.

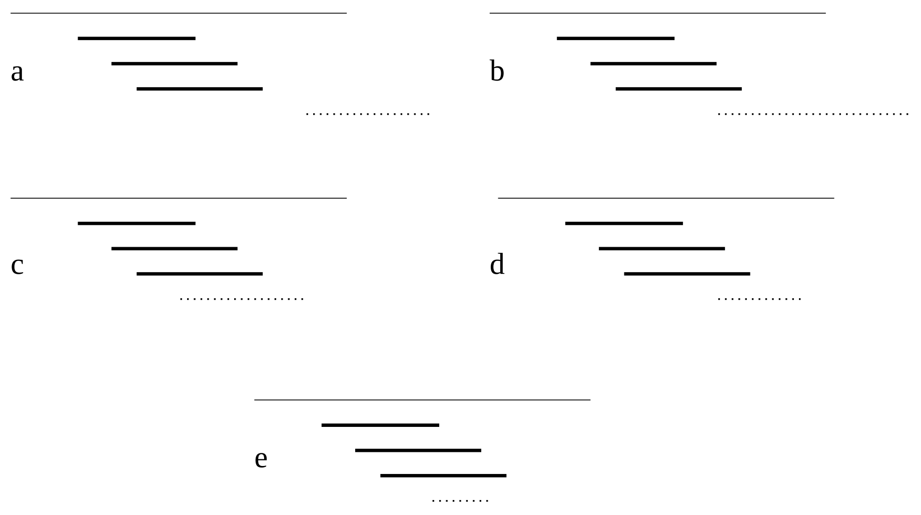

FIG. 4.1. *The various cases of the algorithm for finding a happy clique. The topmost interval is always t_i. The three thick intervals comprise C_i. The dotted interval corresponds to e_{i+1}.*

4.2. Searching the happy clique. After locating a happy clique C in $OV(\pi)$ we need to search it for a vertex with a maximum number of unoriented neighbors. In this section we give an algorithm that performs this task.

Let $e_1, \ldots, e_j$ be the intervals in C ordered in increasing left endpoint order. Clearly, $L(1) < L(2) < \cdots < L(j) < R(1) < R(2) < \cdots < R(j)$. Thus the endpoints of the j vertices in C partition the line into $2j+1$ disjoint intervals $I_0, \ldots, I_{2j}$, where $I_0 = (-\infty, L(1)]$, $I_l = (L(l), L(l+1)]$ for $1 \le l < j$, $I_j = (L(j), R(1)]$, $I_l = (R(l-j), R(l-j+1)]$ for $j < l < 2j$ and $I_{2j} = (R(j), \infty)$. The algorithm consists of the following three stages.

Stage 1. Let e be an unoriented vertex that has a nonempty intersection with the interval $[L(1), R(j)]$. Mark each of e's endpoints with the index of the interval that contains it.

Stage 2. Let o be an array of j counters, each corresponding to a vertex in C. The intention is to assign values to o such that the sum $\sum_{i=1}^{l} o[i]$ is the unoriented degree of the vertex $e_l \in C$. The counters are initialized to zero. For each unoriented vertex e that overlaps with the interval $[L(1), R(j)]$ we change at most four of the counters as follows. Let I_l and I_r be the intervals in which $L(e)$ and $R(e)$ occur, respectively. We may assume $l < r$ as otherwise e is not adjacent to any vertex in C and we can ignore it. We continue according to one of the following cases.

Case 1. $r \le j$. All the vertices from e_{l+1} to e_r are adjacent to e: we increase $o[l+1]$ and decrease $o[r+1]$ (if $r < j$).

Case 2. $j \le l$. All the vertices from e_{l-j+1} to e_{r-j} are adjacent to e: we increase $o[l-j+1]$ and decrease $o[r-j+1]$ (if $r < 2j$).

Case 3. $l < j$ and $j < r$. Let $m = \min\{l, r-j\}$. If $m > 0$ then all the vertices from e_1 to e_m are adjacent to e: we increase $o[1]$ and decrease $o[m+1]$. Similarly let $M = \max\{l, r-j\}$. If $M < j$ then the vertices from e_{l+1} to e_j are adjacent to e: we increase the counter $o[l+1]$.

Stage 3. Compute $f = \max_l \{\sum_{i=1}^{l} o[i] | 1 \le l \le j\}$. Return e_f.

The following theorem summarizes the result of this section. We omit the proof, which is straightforward.

THEOREM 4.4. *Given a clique C, the vertex $e_f \in C$ computed by the algorithm above has maximum unoriented degree among the vertices in C.*

The complexity of the algorithm is proportional to the size of C plus the number of unoriented vertices in $OV(\pi)$, and hence is $O(n)$.

5. Clearing the hurdles.

In case there are unoriented components in $OV(\pi)$, there exists a sequence $r_1, \dots r_t$ of t reversals that transform π into π' such that $d(\pi') = d(\pi) - t$, where $t = \lceil h(\pi)/2 \rceil$. In this section we summarize the characterization given by Hannenhalli and Pevzner for these t reversals and outline how to find them using our implicit representation of $OV(\pi)$.

We will use the following definitions. A reversal *merges* hurdles H_1 and H_2 if it acts on two breakpoints: one incident with a gray edge in H_1 and the other incident with a gray edge in H_2. Recall the circle CR defined in section 2, in which the endpoints of the edges in the unoriented components of $OV(\pi)$ are ordered consistently with their order in π. Two hurdles H_1 and H_2 are *consecutive* if their sets of endpoints $E(H_1)$ and $E(H_2)$ occur consecutively on CR; i.e., there is no hurdle H such that $E(H)$ separates $E(H_1)$ and $E(H_2)$ on CR.

The following lemmas were essentially proved by Hannenhalli and Pevzner though stated differently in their paper.

LEMMA 5.1 (see [11]). *Let π be a permutation with an even number (say $2k$) of hurdles. Any sequence of $k-1$ reversals each of which merges two nonconsecutive hurdles followed by a reversal merging the remaining two hurdles will transform π into π' such that $d(\pi') = d(\pi) - k$ and π' has only oriented components.*

LEMMA 5.2 (see [11]). *Let π be a permutation with an odd number (say $2k+1$) of hurdles. If at least one hurdle H is simple, then a reversal acting on two breakpoints incident with edges in H transforms π into π' with $2k$ hurdles such that $d(\pi') = d(\pi) - 1$. If π is a fortress then a sequence of $k-1$ reversals merging pairs of nonconsecutive hurdles followed by two additional merges of pairs of consecutive hurdles (one merges two original hurdles and the next merges a hurdle created by the first and the last original hurdle) will transform π into π' such that $d(\pi') = d(\pi) - (k+1)$ and π' has only oriented components.*

We now outline how to turn these lemmas into an algorithm that finds a particular sequence of reversals $r_1, \dots, r_t$ with the properties described above. First $OV(\pi)$ is decomposed into connected components as described in [4]. Then one has to identify those unoriented components that are hurdles. This task can be done by traversing the endpoints of the circle CR, counting the number of elements in each run of consecutive endpoints belonging to the same component. If a run contains all endpoints of a particular unoriented component M, then M is a hurdle.

In a similar fashion one can check for each hurdle, whether it is a simple hurdle or a super hurdle. While traversing the cycle, a list of the hurdles in the order they occur on CR is created. At the next stage this list is used to identify the correct hurdles to merge.

We assume that, given an endpoint, one can locate its connected component in constant time. It is easy to verify that the data can be maintained so that this is possible.

THEOREM 5.3. *Given $OV(\pi)$ decomposed into its connected components, the algorithm outlined above finds t reversals such that when we apply them to π we obtain a π' which is hurdle-free and has $d(\pi') = d(\pi) - t$. The algorithm can be implemented to run in $O(n)$ time.*

Proof. Correctness follows from Lemmas 5.1 and 5.2. The time bound is achieved if we always merge hurdles that are separated by a single hurdle. If the ith merge merged hurdles H_1 and H_2 that are separated by H, then H should be merged in the $(i+1)$st merge. Carrying out the merges this way guarantees that the span of each hurdle H overlaps at most two merging reversals, the second of which eliminates H. □

6. Summary.

Figure 6.1 gives a schematic description of the algorithm.

```
algorithm SIGNED REVERSALS($\pi$);
/* $\pi$ is a signed permutation */
1. Compute the connected components of $OV(\pi)$.
2. Clear the hurdles.
3. while $\pi$ is not sorted do :
   /* iteration */
   begin
      a. find a happy clique $C$ in $OV(\pi)$.
      b. find a vertex $e_f \in C$ with maximum unoriented
      degree, and perform a safe reversal on $e_f$;
      c. update $\pi$ and the representation of $OV(\pi)$.
   end
end  4. output the sequence of reversals.
```

FIG. 6.1. *An algorithm for sorting signed permutations.*

THEOREM 6.1. *Algorithm* SIGNED REVERSALS *finds the reversal distance r in $O(n\alpha(n) + r \times n)$ time, and in particular in $O(n^2)$ time.*

Proof. The correctness of the algorithm follows from Theorem 2.3, Theorem 4.1, and Lemmas 5.1 and 5.2.

Step 1 takes $O(n\alpha(n))$ time by the algorithm of Berman and Hannenhalli [4]. Step 2 takes $O(n)$ time by Theorem 5.3. Step 3 takes $O(n)$ time per reversal, by the discussion in section 4. □

It is an intriguing open question whether a faster algorithm for sorting signed permutations by reversals exists. It certainly might be the case that one can find an optimal sequence of reversals faster. To date, no nontrivial lower bound is known for this problem.

Acknowledgments. We thank Donald Knuth, Sridhar Hannenhalli, Pavel Pevzner, and Itsik Pe'er for their comments on a preliminary version of this paper.

COMPRESSION OF LOW ENTROPY STRINGS WITH LEMPEL–ZIV ALGORITHMS[*]

S. RAO KOSARAJU[†] AND GIOVANNI MANZINI[‡]

Abstract. We compare the compression ratio of the Lempel–Ziv algorithms with the empirical entropy of the input string. This approach makes it possible to analyze the performance of these algorithms without any assumption on the input and to obtain worst case results. We show that in this setting the standard definition of optimal compression algorithm is not satisfactory. In fact, although Lempel–Ziv algorithms are optimal according to the standard definition, there exist families of *low entropy strings* which are not compressed optimally. More precisely, the compression ratio achieved by LZ78 (resp., LZ77) can be much higher than the zeroth order entropy H_0 (resp., the first order entropy H_1).

For this reason we introduce the concept of λ-optimal algorithm. An algorithm is λ-optimal with respect to H_k if, loosely speaking, its compression ratio is asymptotically bounded by λ times the kth order empirical entropy H_k. We prove that LZ78 cannot be λ-optimal with respect to any H_k with $k \geq 0$. Then, we describe a new algorithm which combines LZ78 with run length encoding (RLE) and is 3-optimal with respect to H_0. Finally, we prove that LZ77 is 8-optimal with respect to H_0, and that it cannot be λ-optimal with respect to H_k for any $k \geq 1$.

Key words. data compression, Lempel–Ziv parsing, empirical entropy

1. Introduction.

The most widely used data compression algorithms are based on the well known procedures LZ77 and LZ78 [23, 24]. These procedures compress the input string by replacing phrases with a pointer to a previous occurrence of the same phrase. This simple scheme achieves a good compression ratio and both coding and decoding can be done on-line very efficiently.

Given the practical relevance of Lempel–Ziv algorithms, many efforts have been done to analyze their performance. In [23] it is shown that LZ77 is optimal for a certain family of sources, and in [24] it is shown that LZ78 achieves asymptotically the best compression ratio attainable by a finite-state compressor. Other results have been obtained assuming that the input string is a random sequence $\{X_i\}_{-\infty}^{+\infty}$ which is stationary, ergodic, and takes values from a finite alphabet. Under these hypotheses, it has been shown that LZ77 and LZ78 are optimal, that is, their compression rate approaches the entropy of the random sequence [16, 20, 24]. Similar results have been obtained also for other variants of the Lempel–Ziv algorithms [2, 10, 18, 19, 22] and considering different probability distributions for the input string [6, 8].

More recently, a careful analysis of the Lempel–Ziv parsing rules (see, for example, [7, 17, 21]) and the use of renewal theory have made it possible to estimate the *redundancy* of Lempel–Ziv algorithms, that is, the amount by which the expected compression ratio exceeds the entropy of the source (the redundancy is therefore a measure of the speed at which the compression ratio approaches the entropy). In [9, 14] it is shown that for LZ78 and many of its variants the redundancy is $O\big((\log n)^{-1}\big)$, where n is the length of the input string. In [15] it is shown that for two variants of LZ77 the redundancy is $O(\log\log n/\log n)$. Note that for both families of algorithms we also have bounds on the size of the constants hidden in the big-o notation. Finally, in [21] it is shown that for the fixed database version of LZ78 the redundancy is *lower bounded* by $\Omega(\log\log n/\log n)$.

Although these results have great theoretical value, they are not completely satisfying since the same string s can be generated by ergodic sources with different entropies. In addition, most of these results do not hold for every string but only in the average case or for a set of strings which has probability one in the underlying probabilistic model.

In order to get results which hold for every string, in this paper we analyze the performance of the Lempel–Ziv algorithms under a different perspective. Instead of making assumptions on the input, we consider the so-called *empirical entropy* which is based on a probability distribution defined implicitly by the input string. More precisely, for any string s, we define the kth order entropy $H_k(s)$ by looking at the number of occurrences of each symbol following each k-length substring inside s. We say that an algorithm is *coarsely optimal* if, for all k, there exists a function f_k, with $\lim_{n\to\infty} f_k(n) = 0$, such that for any string s the compression ratio $\rho(s)$ is bounded by

$$\rho(s) \le H_k(s) + f_k(|s|). \tag{1}$$

In other words, an algorithm is coarsely optimal if its compression ratio differs from $H_k(s)$ by a quantity which depends only on the length $|s|$ and vanishes as $|s| \to \infty$. The coarse optimality of LZ78 has been proven by Plotnik et al. [11, Corollary 3] and in section 4 we show that LZ77 is coarsely optimal as well.

Having defined optimality using (1), we can analyze an important phenomenon which went undetected using the previous approaches. If a string s is such that $\lim_{|s|\to\infty} H_k(s) = 0$, it is possible that (1) holds with a function f_k such that $H_k(s) = o(f_k(|s|))$. Hence, we could have a coarsely optimal algorithm with a compression ratio much higher than the entropy. To avoid this counterintuitive phenomenon, it is natural to require that the function f_k is such that $f_k(|s|) = o(H_k(s))$. Unfortunately, it is possible to prove that, even for $k = 0$, neither LZ78 nor LZ77 is optimal according to this more satisfactory definition (Lemmas 3.1 and 4.7). For this reason we introduce the concept of λ-optimality with respect to the kth order entropy H_k. Loosely speaking, the compression ratio of a λ-optimal algorithm must be bounded by $\lambda H_k(s) + o(H_k(s))$. Therefore, a λ-optimal algorithm is guaranteed to compress efficiently also the *low entropy strings*, that is, those strings such that $H_k(s) \to 0$.

In this paper we prove that LZ78 cannot be λ-optimal with respect to any H_k with $k \ge 0$. This is not surprising since it is well known that LZ78 is not able to compress efficiently long runs of identical symbols. Then, we describe an algorithm which combines LZ78 with RLE which is 3-optimal with respect to H_0. Finally, we prove that LZ77 is 8-optimal with respect to H_0, and that it cannot be λ-optimal with respect to H_k for any $k \ge 1$. Our techniques are of general interest since they rely on properties of LZ78 and LZ77 which are shared by other compression algorithms based on parsing such as LZW, LZC, and LZSS (see [1, 13] for a description of these variants).

In [14, 15] Savari analyzes several variants of LZ78 and LZ77 and compares their output size to the empirical entropy of the string. For the compression ratio of these algorithms Savari proves a bound of the form $g\big(k, |s|, H_k(s)\big) H_k(s) +$ lower order terms. The function g is given explicitly for each algorithm, and additional bounds are given for the case $H_k(s) = 0$. The analysis is not limited to the case in which each symbol depends on the k previous symbols, but considers also more general models. However, the results in [14, 15] are valid only if $H_k(s)/|s|$ is bounded away from zero and therefore do not apply to the low entropy strings. For this reason these bounds complement the coarse optimality results for LZ78 and LZ77, but are not directly related with the concept of λ-optimality, which is mainly concerned with the compression of the low entropy strings.

The results of this paper do not aim to substitute results based on probabilistic assumptions. The latter are very deep and rich and they provide information also for the nonprobabilistic setting (see, for example, the results on the empirical entropy in [11, 14, 15]). One of the merits of our worst case analysis is that, as we will see, it provides new insight on Lempel–Ziv algorithms by revealing strengths and weaknesses which cannot be properly analyzed in the probabilistic setting.

2. Definitions and notation.

Let s be a string of length n over the alphabet $\mathcal{A} = \{\alpha_1, \ldots, \alpha_h\}$, and let n_i denote the number of occurrences of the symbol α_i inside s. We define the zeroth order entropy as

$$H_0(s) = -\sum_{i=1}^{h} \frac{n_i}{n} \log\left(\frac{n_i}{n}\right),$$

where we assume $0 \log 0 = 0$. The value $|s|H_0(s)$ represents the output size of an ideal compressor which uses $-\log \frac{n_i}{n}$ bits for coding the symbol α_i. Although, as we will see, it is by no means easy to compress a string up to its zeroth order entropy, often even this is not enough. For example, suppose we want to compress an English text. Clearly, we would like to take advantage not only of the different frequencies of the single letters, but also of the fact that these frequencies depend upon the context. The degree of compression that we can achieve by considering a context of length k, is expressed by the conditional kth order entropy $H_k(s)$ defined as follows. For any string w and $\alpha_i \in \mathcal{A}$, let $n_{w\alpha_i}$ denote the number of occurrences in s of the string w followed by α_i. Let $n_w = \sum_i n_{w\alpha_i}$. We define

$$H_k(s) = -\frac{1}{|s|} \sum_{w \in \mathcal{A}^k} \left(\sum_{i=1}^{h} n_{w\alpha_i} \log\left(\frac{n_{w\alpha_i}}{n_w}\right)\right). \tag{2}$$

The value $|s|H_k(s)$ is the output size of an ideal algorithm which uses $-\log(n_{w\alpha_i}/n_w)$ bits for the symbol α_i when it appears after the "context" w. This means that the code for α_i depends on the k characters preceding it. Note that we are assuming that this algorithm codes the first k characters of s for free. As k increases, the entropy $H_k(s)$ is defined in terms of longer, and therefore more accurate, contexts. It is not difficult to prove that H_k is a decreasing function of k.

Formula (2) is not the only possible definition of entropy in terms of frequencies of characters. Another definition found in the literature is

$$H'_k(s) = -\frac{1}{k} \sum_{w \in \mathcal{A}^k} \frac{n_w}{n} \log\left(\frac{n_w}{n}\right),$$

that is, H'_k is the first order entropy of the k-letter words. Disregarding low order terms, we have $H'_k(s) \simeq \frac{1}{k}[H_1(s) + \cdots + H_k(s)]$ (we get an equality if we consider also the k-letter words which wrap around the string s). Since $H_k(s)$ decreases with k, we have $H'_k(s) \geq H_k(s)$. Since we are interested in bounding the output size of compression algorithms in terms of the entropy, by considering H_k we get stronger results.

Having defined the kth order entropy, we can define the class of optimal compression algorithms. The natural extension of the definition given in the information theoretic setting (see, for example, [5]) is the following.

DEFINITION 2.1. *A compression algorithm* $\mathtt{A}$ *is* coarsely optimal*, if for all* $k \geq 0$ *there exists a function* f_k*, with* $\lim_{n\to\infty} f_k(n) = 0$*, such that for all strings* s *we have*

$$\frac{\mathtt{A}(s)}{|s|} \leq H_k(s) + f_k(|s|), \tag{3}$$

where $\mathtt{A}(s)$ *denotes the output size of algorithm* $\mathtt{A}$ *on input* s*.*

As we have already pointed out, the above definition is not completely satisfactory since, if $H_k(s) \ll f_k(|s|)$, we can have an optimal algorithm for which the compression ratio is much greater than the entropy. For this reason, we introduce a more restrictive definition of optimality in which we require that the difference between the compression ratio and the kth-order entropy is a lower order term.

DEFINITION 2.2. *A compression algorithm* $\mathtt{A}$ *is* λ-optimal *with respect to* H_k*, if it is coarsely optimal and there exists a function* g_k*, with* $g_k(t) = o(t)$*, such that for any string* s *with* $H_k(s) \neq 0$

$$\mathtt{A}(s) \leq \lambda|s|H_k(s) + g_k(\mathtt{A}(s)), \tag{4}$$

where $\mathtt{A}(s)$ *denotes the output size of algorithm* $\mathtt{A}$ *on input* s*.*

Note that (4) implies that $g_k(\mathtt{A}(s)) = o(|s|H_k(s))$. We use (4) since it is easier to prove that a certain quantity is a lower order term with respect to the output size of the algorithm rather than with respect to the usually unknown kth order entropy. Note also that λ-optimality is defined with respect to a single entropy H_k. As we will see, to ask (4) to hold for every $k \geq 0$ would be too strong a requirement. However, a λ-optimal algorithm must be coarsely optimal; hence (3) must hold for every $k \geq 0$. By studying the λ-optimality of an algorithm we measure how well it behaves when the input is a low entropy string; this is something which is not possible using the concept of coarse optimality alone.

In this paper we make use of the following lemma which is a generalization of a similar result proven in [5] for stationary ergodic sequences.

LEMMA 2.3. *Let* $y_1, \ldots, y_t$ *denote a parsing of the string* s *such that each word* y_i *appears at most* M *times. For any* $k \geq 0$ *we have*

$$t \log t \leq |s|H_k(s) + t \log\left(\frac{|s|}{t}\right) + t \log M + \Theta(kt + t)\,. \qquad \square \tag{5}$$

The proof of this lemma is given in the appendix. Note that if the words in the parsing are all distinct the above inequality becomes

$$t \log t \leq |s|H_k(s) + t \log\left(\frac{|s|}{t}\right) + \Theta(kt + t)\,. \tag{6}$$

In the rest of the paper we use the following notation. The length of the output produced by the compression algorithm $\mathtt{A}$ on input s is denoted by $\mathtt{A}(s)$. The compression ratio achieved is $\rho(s) = \mathtt{A}(s)/|s|$. Given a nonempty string s, s^- will denote the string obtained from s by removing the last character. If $|s| > 1$, we set $s^{--} = (s^-)^-$. Given k words $w_1, w_2, \dots, w_k$, their concatenation will be denoted by $w_1 w_2 \cdots w_k$.

3. Compression of low entropy strings with `LZ78`. In this section we consider the algorithm `LZ78`. First, we show that for certain strings `LZ78` compression ratio is well above the zeroth order entropy H_0. Then we prove that by combining `LZ78` with RLE we get a new algorithm which is 3-optimal with respect to H_0.

The algorithm `LZ78` works as follows (see [1] for details). Assuming the words $w_1, w_2, \dots, w_{i-1}$ have been already parsed, `LZ78` selects the ith word as the longest word that can be obtained by adding a single character to a previous word. Hence, $w_i^- = w_j$ for some $j < i$, but unless w_i is the last word in the parsing, we have $w_i \neq w_k$, for all $k < i$. As soon as w_i has been found, `LZ78` outputs an encoding of the pair (j, α_i), where j is such that $w_i^- = w_j$ and α_i is the last character of w_i. If we are working with an alphabet with h symbols, such encoding takes $\lceil \log i \rceil + \lceil \log h \rceil$ bits (all logarithms in this paper are taken to the base 2). Hence, if the input string is parsed into t words, the output of `LZ78` has size $t \log t + t \log h + O(t)$. In the following we assume that all the words are distinct since this greatly simplifies our analysis and changes the word count by at most one.

LEMMA 3.1. *There exists a constant $c > 0$ such that for every $n \geq 1$ there exists a string s of length n satisfying* $\mathtt{LZ78}(s)/|s| \geq c\sqrt{n}H_0(s)$.

Proof. Consider the string $s = 01^{(n-1)}$. `LZ78` parses s into $\Theta(\sqrt{n})$ words, hence the compression ratio is $\Theta((\log n)/\sqrt{n})$, whereas $H_0(s) = (\log n)/n$. □

Despite all the optimality results for `LZ78`, we can hardly say that it compresses optimally the string s. As we have already pointed out, using the standard definition of optimal compression given by (3), the problem is that if $H_k(s) \to 0$ and $H_k(s) = o(f_k(|s|))$, the compression ratio $\rho(s)$ can be much higher than $H_k(s)$.

Lemma 3.1 suggests that the inability of `LZ78` to compress efficiently low entropy strings is due to the inability to cope with long runs of identical symbols. In view of this, it is natural to ask if we can compress optimally also the low entropy strings by combining `LZ78` with RLE. RLE is a technique frequently used when the input may contain long runs of identical symbols. RLE is used either as a fast stand-alone compressor, or as a preprocessing step for more complex compression procedures. We now present an algorithm, which we call $\mathtt{LZ78}_{RL}$, which follows the latter approach and uses RLE as a preprocessing step for `LZ78`.

3.1. The algorithm $\mathtt{LZ78}_{RL}$. In this section we describe and analyze an algorithm which combines `LZ78` with RLE. We underline that our analysis does not rely on the particular parsing realized by `LZ78`. Indeed, the analysis is based only on the two facts that `LZ78` parses the input string into distinct words, and that its output size is $t \log t + O(t)$, t being the number of words in the parsing. Hence, our analysis can be applied also to other parsing-based compression algorithms. With some additional work it can be applied also to the algorithms `LZW` and `LZC` (the core of the Unix utility `compress`) in which the same word can appear in the parsing more than once.

Let s denote a string over the alphabet $\mathcal{A}$, and let s' be a substring of s. We call s' an *α-segment* if it contains only the symbol α, and the two symbols adjacent to s' are different from α. Let $\mathtt{0}$ denote a symbol not belonging to $\mathcal{A}$. For $m > 0$, $\alpha \in \mathcal{A}$, let $B(\alpha^m)$ denote the string obtained by writing m in binary using α as 1 and $\mathtt{0}$ as 0. For example, $B(\alpha\alpha\alpha\alpha\alpha) = \alpha\mathtt{0}\alpha$. Given the string s, we define the run length encoding of s as the string $\tilde{s}$ obtained from s by replacing each δ-segment δ^m with the string $B(\delta^m)$. For example, if $s = \alpha\alpha\alpha\beta\beta\alpha\gamma\gamma\gamma\gamma$, then

$$\tilde{s} = \alpha\alpha\beta\mathtt{0}\alpha\gamma\mathtt{00}.$$

Clearly, given $\tilde{s}$ we can obtain s. In fact, δ is always the first symbol in $B(\delta^m)$, and we know that we have reached the end of a δ-segment when we encounter a symbol different from δ or $\mathtt{0}$. Note that, since $|B(\delta^m)| = \lfloor \log m \rfloor + 1 \le m$, we have $|\tilde{s}| \le |s|$. In the following $\mathtt{LZ78}_{RL}$ will denote the algorithm which applies `LZ78` to the string $\tilde{s}$.

Our implementation of RLE is certainly somewhat different from the more common strategy to use a byte to store a repetition count for the last seen character. However, this simpler strategy is not powerful enough to make `LZ78` overcome the problem outlined in Lemma 3.1. An obvious drawback of our RLE implementation is that it requires an extra character not belonging to $\mathcal{A}$. Note that this is not a problem when RLE is used together with algorithms like `LZW` and `LZC` which never output single characters. We have also devised a RLE strategy in which we do not need to extend the alphabet. However, this alternative encoding is less efficient, and when combined with `LZ78` it produces an algorithm which is 6-optimal with respect to H_0 ($\mathtt{LZ78}_{RL}$ is 3-optimal with respect to H_0; see Theorem 3.6).

THEOREM 3.2. *The algorithm* $\mathtt{LZ78}_{RL}$ *is coarsely optimal with respect to the entropy* $H_k(s)$*, for any* $k \ge 0$.

Proof. Let t denote the number of words in the `LZ78` parsing of the string $\tilde{s}$. In the Appendix (Lemma B.1) we show that this parsing induces a t-word parsing of the string s in which each word appears at most $2\log|s|$ times. By (5) we get

$$t\log t \le |s|H_k(s) + t\log\left(\frac{|s|}{t}\right) + t\log\log|s| + \Theta(kt)\,. \tag{7}$$

Since `LZ78` parses $\tilde{s}$ into distinct words, we have (see, for example, [5, Lemma 12.10.1]) $t = O\Big(\frac{|\tilde{s}|}{\log|\tilde{s}|}\Big) = O\Big(\frac{|s|}{\log|s|}\Big)$. Hence, $\log|s| = O\Big(\frac{|s|}{t}\Big)$, and (7) becomes

$$t\log t \le |s|H_k(s) + 2t\log\left(\frac{|s|}{t}\right) + \Theta(kt)\,.$$

Since $t = O\Big(\frac{|s|}{\log|s|}\Big)$, we get

$$\frac{t\log t}{|s|} \le H_k(s) + O\left(\frac{\log\log|s|}{\log|s|} + \frac{k}{\log|s|}\right),$$

which proves the coarse optimality of $\mathtt{LZ78}_{RL}$. □

We now show that, in addition to being coarsely optimal, the algorithm $\mathtt{LZ78}_{RL}$ compresses almost optimally (with respect to H_0) also the low entropy strings. In our analysis we will use the following notation. Given a string s over the alphabet $\mathcal{A} = \{\alpha_1, \dots, \alpha_h\}$, for $i = 1, \dots, h$, let n_i denote the number of occurrences of α_i in s. We assume that $n_1 = \max_i n_i$, we set $r = n_2 + n_3 + \cdots + n_h$, and $\tau = \frac{|s|}{r}$. Define

$$G(n_1, n_2, \dots, n_h) = |s|H_0(s) = -\sum_{i=1}^{h} n_i \log\left(\frac{n_i}{|s|}\right). \tag{8}$$

By setting $F(x) = x\log x$, we get the following alternative representation of G:

$$G(n_1, \dots, n_h) = F(n_1 + n_2 + \cdots + n_h) - [F(n_1) + F(n_2) + \cdots + F(n_h)]\,. \tag{9}$$

In the following, we will use the two forms $|s|H_0(s)$ and $G(n_1,\dots,n_h)$ interchangeably.

Let t denote the number of words into which LZ78 parses the string s. By (6), we know that

$$\texttt{LZ78}(s) \le |s|H_0(s) + t\log\left(\frac{|s|}{t}\right) + \Theta(t)\,. \tag{10}$$

Using elementary calculus one can easily prove that

$$t\log(|s|/t) \le t\log\tau + \max[G(n_1,\dots,n_h) - t\log t, t\log\log t + 2t],$$

which yields

$$\texttt{LZ78}(s) \le |s|H_0(s) + t\log\tau + O(t\log\log t)\,. \tag{11}$$

The following lemma formalizes the intuitive notion that as $\tau = \frac{|s|}{r}$ increases, the value $|s|H_0(s)$ becomes much smaller than $|s|$.

LEMMA 3.3. *For any string s, we have $H_0(s) \le \frac{\log(\tau h e)}{\tau}$.*

Proof. Let $n = |s|$. Using elementary calculus we get

$$\begin{aligned} G(n_1,\dots,n_h) &= G(n_1, n-n_1) + G(n_2,\dots,n_h)\\ &\le G(n-n/\tau, n/\tau) + (n/\tau)\log h\\ &= (n/\tau)[F(\tau) - F(\tau-1) + \log h]\\ &\le (n/\tau)[\log(\tau e) + \log h], \end{aligned}$$

where we have used that F is convex and $F'(t) = \log(et)$. ∎

The following two lemmas bound the entropy and the length of the "encoded" string $\tilde{s}$ in terms of the entropy of s.

LEMMA 3.4. *For any string s, we have $|\tilde{s}|H_0(\tilde{s}) \le |s|H_0(s) + |\tilde{s}|$.*

Proof. For $i = 1,\dots,h$, let m_i denote the number of occurrences of α_i inside $\tilde{s}$, and z_i denote the number of 0's created converting the α_i-segments. Let $v_i = m_i + z_i$. By (9), we have

$$\begin{aligned} |\tilde{s}|H_0(\tilde{s}) &= G\left(m_1,\dots,m_h,\sum_{i=1}^h z_i\right)\\ &= F\left(m_1+\cdots+m_h+\sum_{i=1}^h z_i\right) - \left[\sum_{i=1}^h F(m_i) + F\left(\sum_{i=1}^h z_i\right)\right]\\ &\le F(v_1+\cdots+v_h) - \sum_{i=1}^h [F(m_i) + F(z_i)]. \end{aligned}$$

By Jensen inequality, we know that $F(m_i) + F(z_i) \ge 2F(v_i/2) = F(v_i) - v_i$, hence

$$\begin{aligned} |\tilde{s}|H_0(\tilde{s}) &\le F(v_1+\cdots+v_h) - \sum_{i=1}^h [F(v_i) - v_i]\\ &= G(v_1,\dots,v_h) + \sum_{i=1}^h v_i\\ &\le |s|H_0(s) + |\tilde{s}|. \qquad ∎ \end{aligned}$$

LEMMA 3.5. *For any string s, we have $|\tilde{s}| \le 2|s|H_0(s)$.*

Proof. Let $n_1 = \max_i n_i$, $r = |s| - n_1 = n_2 + \cdots + n_h$. If $n_1 \le |s|/2$, we have

$$|s|H_0(s) = \sum_{i=1}^{h} n_i \log\left(\frac{|s|}{n_i}\right) \ge \sum_{i=1}^{h} n_i = |s| \ge |\tilde{s}|,$$

and the lemma follows. If $n_1 > |s|/2$, then

$$\begin{aligned}|s|H_0(s) &\ge n_1 \log\left(\frac{n_1 + r}{n_1}\right) + \sum_{i=2}^{h} n_i \log\left(\frac{|s|}{r}\right)\\ &= r \log\left(1 + \frac{r}{n_1}\right)^{\frac{n_1}{r}} + r \log\left(\frac{|s|}{r}\right).\end{aligned}$$

Since, $(1 + 1/t)^t \ge 2$, for $t \ge 1$, we have

$$|s|H_0(s) \ge r + r \log\left(\frac{|s|}{r}\right). \tag{12}$$

In order to bound $|\tilde{s}|$, we note that the string s contains at most $r + 1$ α_1-segments. Hence,

$$|\tilde{s}| \le \sum_{i=1}^{r+1} (\log q_i + 1) + \sum_{i=2}^{h} n_i,$$

with $q_1 + \cdots + q_{r+1} = n_1$. From the concavity of $\log t$ we obtain

$$|\tilde{s}| \le (r + 1) \log\left(\frac{n_1}{r + 1}\right) + 2r + 1.$$

For $r = 1$, we have

$$\frac{|\tilde{s}|}{2|s|H_0(s)} \le \frac{2 \log n_1 + 1}{2 + 2 \log(n_1 + 1)} \le 1.$$

For $r \ge 2$, we set $t = n_1/r$, and we get

$$\frac{|\tilde{s}|}{2|s|H_0(s)} \le \frac{2r + (r + 1) \log t + 1}{2r + 2r \log(1 + t)}.$$

A straightforward computation shows that for $t \ge 1$, $2r \log(1 + t) \ge (r + 1) \log t + 1$, and the lemma follows. ◻

We are now ready to establish the main result of this section.

THEOREM 3.6. *The algorithm* $\texttt{LZ78}_{RL}$ *is 3-optimal with respect to H_0.*

Proof. We have already shown that $\texttt{LZ78}_{RL}$ is coarsely optimal (Theorem 3.2). Hence, we need to prove that for any string s with $H_0(s) \ne 0$ we have

$$\texttt{LZ78}_{RL}(s) \le 3|s|H_0(s) + \text{lower order terms.}$$

By (11) we know that

$$\texttt{LZ78}_{RL}(s) \le |\tilde{s}|H_0(\tilde{s}) + t \log \tau + O(t \log \log t),$$

where t denotes the number of words in the LZ78 parsing of the string $\tilde{s}$. If $\tau \le 16h$ the theorem trivially holds, since, by Lemmas 3.4 and 3.5, we have $|\tilde{s}|H_0(\tilde{s}) \le 3|s|H_0(s)$. Assume now $\tau > 16h$. By (10), we know that

$$\mathtt{LZ78}_{RL}(s) \le |\tilde{s}|H_0(\tilde{s}) + t\log\left(\frac{|\tilde{s}|}{t}\right) + O(t)\,.$$

It is straightforward to verify that, for $0 < x < |\tilde{s}|$, we have $x\log(\tilde{s}/x) \le (|\tilde{s}|\log e)/e \le (2|\tilde{s}|)/3$. Hence, we can write

$$\mathtt{LZ78}_{RL}(s) \le |\tilde{s}|H_0(\tilde{s}) + (2|\tilde{s}|)/3 + O(t)\,.$$

Since $\tau > 16h$, we have $\frac{\log(\tau he)}{\tau} \le \frac{5}{6}$. Thus, by Lemmas 3.3 and 3.5 we have

$$\begin{aligned}\mathtt{LZ78}_{RL}(s) &\le |\tilde{s}|\left(\frac{\log(\tau he)}{\tau}\right) + \frac{2}{3}|\tilde{s}| + O(t)\\ &\le \frac{3}{2}|\tilde{s}| + O(t)\\ &\le 3|s|H_0(s) + O(t)\,.\end{aligned}$$

This completes the proof. ∎

4. Compression of low entropy strings with LZ77**.** In this section we consider the algorithm LZ77. First, we prove that this algorithm is coarsely optimal according to Definition 2.1. This is not surprising since it is known that LZ77 compresses much better than LZ78. In view of the results of section 3, what is more interesting is to understand how well LZ77 compresses the low entropy strings. To this end, we prove that LZ77 is 8-optimal with respect to H_0. We also show that this result cannot be substantially improved: we present a family of low entropy strings for which $\mathtt{LZ77}(s) \ge 2.5|s|H_0(s)$ and we prove that LZ77 cannot be λ-optimal with respect to H_1.

The algorithm LZ77 works as follows (see [1] for details). Assuming the words $w_1, w_2, \dots, w_{i-1}$ have been already parsed, LZ77 selects the ith word as the longest word that can be obtained by adding a single character to a substring of $(w_1w_2\cdots w_i)^{--}$. Hence, w_i has the property that w_i^- is a substring of $(w_1\cdots w_i)^{--}$, but w_i is not a substring of $(w_1\cdots w_i)^-$. Note that although this is a recursive definition there is no ambiguity. In fact, if $|w_i| > 1$ at least the first character of w_i belongs to $w_1w_2\cdots w_{i-1}$. Once w_i has been found, LZ77 outputs an encoding of the triplet (p_i, l_i, α_i), where p_i is the starting position of w_i^- within $w_1w_2\cdots w_{i-1}$, $l_i = |w_i|$, and α_i is the last character of w_i.

Compared to LZ78, the algorithm LZ77 parses the input into fewer words and generally achieves a better compression. In addition, it still has the nice property that both coding and decoding can be done in $O(|s|)$ time (see [12]). Note that in the original formulation of LZ77 [23] p_i is allowed to denote a position only within the last L characters of $w_1w_2\cdots w_{i-1}$ (the so called "sliding window"). The use of a sliding window makes the coding procedure faster, and in most cases it affects the compression ratio only slightly. However, as we will see (Lemma 4.3), if the window has a fixed size the algorithm cannot be coarsely optimal.

4.1. Coarse optimality of LZ77**.** To analyze the compression ratio achieved by LZ77 we need to specify the encoding of the triplet (p_i, l_i, α_i) representing the ith word in the parsing of s. For our analysis we assume the following simple scheme.

Since $1 \le p_i \le \sum_{j<i} l_j$, we use $\left\lceil \log(\sum_{j<i} l_j) \right\rceil$ bits for encoding p_i. Assuming the input alphabet has h symbols, we use $\lceil \log h \rceil$ bits for encoding α_i. Finally, since we cannot bound in advance the size of l_i, we use a scheme which allows the encoding of unbounded integers. More precisely, we code l_i using $1 + \lfloor \log l_i \rfloor + 2\lfloor \log(1 + \lfloor \log i \rfloor) \rfloor$ bits (for details on this and other similar schemes, see, for example, [3]). Although there are other possible methods for describing these triplets, we believe our analysis can be adapted to all "reasonable" encodings.

Assuming we use the above encoding scheme for each word in the parsing, the output of LZ77 has size

$$\mathtt{LZ77}(s) = \sum_{i=1}^{t} \Big(\log(\textstyle\sum_{j<i} l_j) + \log l_i + 2\log(1 + \log l_i) \Big) + O(t)\,.$$

Obviously, $(\sum_{j<i} l_j) \le |s|$. In addition, from the concavity of the function $\log x + 2\log(1+\log x)$, we get $\sum_i (\log l_i + 2\log(1+\log l_i)) \le t[\log(|s|/t) + 2\log(1+\log(|s|/t))]$. Hence,

$$\mathtt{LZ77}(s) \le t\log|s| + t\log\left(\frac{|s|}{t}\right) + O(t\log\log(|s|/t))\,,$$

or, equivalently,

$$\mathtt{LZ77}(s) \le t\log t + 2t\log\left(\frac{|s|}{t}\right) + O(t\log\log(|s|/t))\,. \tag{13}$$

Since LZ77 parses its input into distinct words, we can use (6) which yields

$$\mathtt{LZ77}(s) \le |s|H_k(s) + 3t\log\left(\frac{|s|}{t}\right) + O\left(kt + t\log\log\left(\frac{|s|}{t}\right)\right). \tag{14}$$

We can now easily prove that LZ77 is optimal according to Definition 2.1.

THEOREM 4.1. *The algorithm* LZ77 *is coarsely optimal.*

Proof. Let t denote the number of words in the LZ77 parsing. Since the words are distinct, we have $t = O\Big(\frac{|s|}{\log|s|}\Big)$. From (14) we get

$$\frac{\mathtt{LZ77}(s)}{|s|} \le H_k(s) + O\bigg(\frac{\log\log|s|}{\log|s|} + \frac{k}{\log|s|}\bigg)\,,$$

which proves the optimality of LZ77. ∎

Despite the above optimality result, the following lemma shows that, if $H_1(s) \to 0$, LZ77 compression ratio can be asymptotically greater than H_1.

LEMMA 4.2. *There exists a constant $c > 0$ such that for every $n > 1$ there exists a string s of length $|s| \ge n$ satisfying*

$$\frac{\mathtt{LZ77}(s)}{|s|} \ge c\,\frac{\log|s|}{\log\log|s|}H_1(s).$$

Proof. Consider the following string:

$$s = 1\,0^k\,2^{2^k}\,1\,101\,10^21\,10^31\,10^41\cdots10^k1.$$

We have $|s| = 2^k + O(k^2)$. A simple computation shows that $|s|H_1(s) = k \log k + O(k)$. The LZ77 parsing of s is

$$1 \quad 0 \quad 0^{(k-1)}2 \quad 2^{(2^k-1)}1 \quad 101 \quad 10^21 \quad 10^31 \quad \cdots \quad 10^k1.$$

For $i \geq 5$, we have $\sum_{j<i} l_j > 2^k$. Hence, the encoding of p_i takes $\Omega(k)$ bits. Since there are $k+4$ words, we have $\mathtt{LZ77}(s) = \Omega(k^2)$ and the lemma follows. ∎

Let us comment on the above lemma. We can clearly see that the inefficiency of LZ77 is due to the cost of encoding p_i, and it is possible that, using a clever encoding, we can reduce LZ77 output size significantly. However, for any encoding scheme we have been able to think of, it was always possible to find a "bad" string which LZ77 is not able to compress up to the first order entropy. Lemma 4.2 also shows that it is sometimes not convenient to search for the longest match over the entire parsed portion of the input string. Indeed, a common practice is to restrict the search to a sliding window containing the last L characters seen by the algorithm (this is in fact the original formulation of LZ77 found in [23]). This strategy, which we call $\mathtt{LZ77}_L$, usually reduces dramatically the cost of encoding the pointers p_i's, at the expense of a moderate increment in the number of words. For example, for $k < L < 2^k$, $\mathtt{LZ77}_L$ parses the string given in the proof of Lemma 4.2 in $k+5$ words. The output size is $\approx k(\log k + \log L)$ which, for $L = k^{O(1)}$, differs from $|s|H_1(s)$ only by a constant factor. Unfortunately, the following lemma shows that $\mathtt{LZ77}_L$ is not coarsely optimal since it sometimes fails to compress up to the kth order entropy when $k \geq L-1$.

LEMMA 4.3. *The algorithm* $\mathtt{LZ77}_L$ *is not coarsely optimal for any* $L > 0$.

Proof. For $k = L-1$ and $n > 0$, we exhibit a string s of length $2kn+1$ such that $|s|H_k(s) = \Theta(\log n)$ and $\mathtt{LZ77}_L(s) = \Theta(n)$. Let

$$s = (0^k1^k)^n1.$$

The $\mathtt{LZ77}_L$ parsing of s consists of the following $2n+1$ words

$$0 \quad 0^{k-1}1 \quad 1^{k-1}0 \quad 0^{k-1}1 \quad \cdots \quad 1^{k-1}0 \quad 0^{k-1}1 \quad 1^k.$$

To see this, consider for example the situation after the parsing of the third word. The unparsed portion of the string is $0^{k-1}1^k0^k1^k0^k\cdots$. Since at that moment the sliding window contains 1^k0, the only possible match is the one starting at the last character of the sliding window. Hence, every word has length at most k and $\mathtt{LZ77}_L(s) = \Theta(n)$. Note that LZ77 parses the above string into four words only.

For the computation of $H_k(s)$ we notice that s contains only $2k$ distinct k-letter words, namely

$$0^i1^{k-i}, \quad i = 1, \ldots, k \qquad \text{and} \qquad 1^i0^{k-i} \quad i = 1, \ldots, k.$$

In addition, every occurrence of a word 0^i1^{k-i} is always followed by a 1, and, for $i < k$, every occurrence of 1^i0^{k-i} is followed by a 0. Finally, the word 1^k is followed $n-1$ times by a 0 and once by a 1. As a result, we have $|s|H_k(s) = \Theta(\log n)$ and the lemma follows. ∎

4.2. λ-optimality of LZ77.

We now show that LZ77 is 8-optimal with respect to H_0. We start our analysis with the following lemma which establishes an optimality result for the number of words in the LZ77 parsing.

LEMMA 4.4. *Let* $w_1, w_2, \ldots, w_t$ *denote the* LZ77 *parsing of the string* s. *Suppose* $y_1, y_2, \ldots, y_{t'}$ *is another parsing of* s *such that, for* $i = 1, \ldots, t'$, $|y_i| = 1$ *or* y_i^- *is a substring of* $(y_1 \cdots y_i)^{--}$. *Then,* $t \leq t'$.

Proof. One can easily prove by induction that, for $j = 1, \ldots, t$, the string $y_1 y_2 \cdots y_j$ is a prefix of $w_1 w_2 \cdots w_j$. ∎

Given a string s, in the following n_i will denote the number of occurrences of α_i in s. We assume $n_1 = \max_i n_i$, and we set $r = |s| - n_1$. The following lemma provides a bound on the number of words in the `LZ77` parsing in terms of r. The bound is tight when $r \ll |s|$.

LEMMA 4.5. *Let t denote the number of words in which the algorithm* `LZ77` *parses the string s. We have $t \leq 2(r+1)$.*

Proof. We prove the lemma by showing that there exists a parsing $y_1 y_2 \cdots y_{t'}$, $t' \leq 2(r+1)$, for s which satisfies the hypothesis of Lemma 4.4. Let k denote the number of α_1-segments appearing inside s. Since there are r characters different from α_1 we have $1 \leq k \leq r+1$. Consider the following parsing. Each α_1-segment and the character following it is parsed in two words: the first consisting of the single character α_1, the second of the form $\alpha_1^k \alpha_j$. After this, we are left with at most $r-k+1$ unparsed characters, all of them different from α_1. By parsing these characters using length-one words, we get a parsing for s consisting of $2k + (r-k+1) \leq 2(r+1)$ words. ∎

We are now ready to establish the main result of this section.

THEOREM 4.6. *The algorithm* `LZ77` *is* 8*-optimal with respect to H_0.*

Proof. We have already shown that `LZ77` is coarsely optimal (Theorem 4.1). Hence, we need to prove that, for any string s with $H_0(s) \neq 0$, we have

$$\texttt{LZ77}(s) \leq 8|s|H_0(s) + \text{lower order terms.}$$

Let t denote the number of words in the `LZ77` parsing of s, and let r be defined as in Lemma 4.5. We consider four cases.

Case 1. $1 \leq r < 6$.

By Lemma 4.5 we know that $t \leq 12$. Using (13) we get

$$\texttt{LZ77}(s) \leq 2t\left(\log \frac{|s|}{t}\right) + O(t \log\log(|s|/t)). \tag{15}$$

Let $g(x) = x\log(|s|/x)$. For $0 < x < (|s|/e)$, we have $g'(x) > 0$. Since $r+1 \leq 2r$, we get

$$t \log\left(\frac{|s|}{t}\right) \leq 4r \log\left(\frac{|s|}{r}\right) \leq 4\left[\sum_{i=2}^{h} n_i \log\left(\frac{|s|}{n_i}\right)\right] \leq 4|s|H_0(s).$$

Combining this inequality with (15) we get the thesis.

Case 2. $6 \leq r < 3|s|/7e$.

By Lemma 4.5 we know that $t \leq 2(r+1) \leq \frac{7}{3}r \leq |s|/e$. Reasoning as in Case 1 we get

$$t \log\left(\frac{|s|}{t}\right) \leq \frac{7}{3}\left[r \log\left(\frac{|s|}{r}\right)\right] \leq \frac{7}{3}|s|H_0(s).$$

Substituting this inequality into (14) we get the thesis.

Case 3. $3|s|/7e \leq r < |s|/2$.

Let $G(n_1, n_2)$ be defined as in (8). We have

$$|s|H_0(s) \geq G(|s|-r, r) = |s|G(1 - \tfrac{r}{|s|}, \tfrac{r}{|s|}) \geq |s|G\left(1 - 3/(7e), 3/(7e)\right) \geq |s|/2.$$

By elementary calculus we know that, for $0 < x < |s|$, $x \log(|s|/x) \leq (|s|/e) \log e \leq 2|s|/3$. Hence

$$t \log\left(\frac{|s|}{t}\right) \leq \frac{2|s|}{3} \leq \frac{4}{3}|s|H_0(s).$$

Substituting this inequality into (14) we get the thesis.

Case 4. $r \geq |s|/2$.

Since, for $i = 1, \ldots, h$, $n_i < |s|/2$ we have

$$|s|H_0(s) = \sum_{i=1}^{h} n_i \log\left(\frac{|s|}{n_i}\right) \geq |s|.$$

Combining this inequality with the fact that $t \log(|s|/t) \leq 2|s|/3$ we get $\texttt{LZ77}(s) \leq 3|s|H_0(s) + O(t \log\log(\frac{|s|}{t}))$, and the theorem follows. □

Finally, we show that the above theorem cannot be substantially improved since there exists an infinite family of strings such that the compression ratio of LZ77 is greater than $2.5H_0$.

Lemma 4.7. *For every n, there exists a string s of length $|s| \geq n$ such that $\frac{\texttt{LZ77}(s)}{|s|} \geq 2.5H_0(s)$.*

Proof. Consider the following string

$$s = 010^4 10^9 1 \cdots 10^{i^2} 1 \cdots 10^{k^2} 1.$$

We have $|s| = k^3/3 + O\big(k^2\big)$, and $|s|H_0(s) = 2k \log k + O(k)$. The LZ77 parsing of s is

$$0 \quad 1 \quad 00 \quad 0^2 10^5 \quad 0^4 10^{10} \quad \cdots \quad 0^{2(i-1)} 10^{i^2+1} \quad \cdots \quad 0^{2(k-2)} 10^{(k-1)^2+1} \quad 0^{2(k-1)} 1.$$

Let p_i and l_i denote, respectively, the starting position and the length of the ith word. We have $l_i = \Theta\big(i^2\big)$. Hence, neglecting the log log term, encoding l_i takes $\approx 2 \log i + \log\log i$ bits. Similarly, since $\sum_{j<i} l_j = \Theta\big(i^3\big)$, encoding p_i takes $\approx 3 \log i$ bits. Neglecting lower order terms, the output size of LZ77 is therefore $5(\sum_{i \leq k} \log i) \approx 5k \log k$ bits, and the lemma follows. □

5. Conclusions. In order to analyze the performance of the Lempel–Ziv algorithms without any assumption on the input, we have compared the compression ratio of LZ77 and LZ78 with the so-called empirical entropy of the input string. We have shown that the standard definition of optimal compression does not take into account the performance of compression algorithms when the input is a low entropy string. For this reason we have introduced the concept of λ-optimality which makes it possible to measure how well an algorithm performs when the input is a low entropy string. We have proven that by combining LZ78 with RLE we get an algorithm which is 3-optimal with respect to H_0, and that LZ77 is 8-optimal with respect to H_0.

A natural open question is whether there exist parsing-based compression algorithms which are λ-optimal with respect to H_k for $k \geq 1$. Theorem 4.2 shows that LZ77 is not λ-optimal for $k \geq 1$ and one can easily verify that the same is true for $\texttt{LZ78}_{RL}$ as well. Theorem 4.2 also shows that to improve LZ77 performance one should try to reduce the cost of the backward pointers. Some interesting ideas in this direction are described in [1, section 3.4] and [4]. Lemma 4.3 shows that the simple use of a fixed size sliding window does not yield an optimal algorithm. However, the algorithm $\texttt{LZ77}_L$ deserves further investigation for several reasons. First, it is the variant which is the basis for the most popular compressors (`zip`, `gzip`, `arj`, `lha`, `zoo`, etc.). Second, we have been able to show that its compression ratio can be higher than H_k only when $k \geq L-1$. Since in typical implementations $L \approx 10^5$, our result has only a theoretical value. An interesting open problem is to prove or disprove that for $\texttt{LZ77}_L$ inequalities (3) and (4) hold for $k \leq \theta(L)$ for some appropriate function θ.

Appendix A. Proof of Lemma 2.3. In this appendix we prove Lemma 2.3. Our proof follows closely the proof given in [5, section 12.10] for a similar result involving the entropy of a stationary ergodic source.

Let $s = x_1 x_2 \cdots x_{n+k}$ be a string of length $n+k$. For $w \in \mathcal{A}^k$ and $\alpha \in \mathcal{A}$ let $n_{w\alpha}$ and n_w be defined as in section 2. We define the empirical probability $P(w\alpha)$ as $P(w\alpha) = n_{w\alpha}/n_w$ (if $n_w = 0$ we set $P(w\alpha) = 0$). For $i > k$ let s_i denote the length-k string preceding x_i in s. Using this notation, the kth order entropy can be written as

$$|s|H_k(s) = -\sum_{i=k+1}^{n+k} \log P(s_i x_i). \tag{16}$$

Let $v = v_1 v_2 \cdots v_h$ and $w = w_1 \cdots w_k$ be two strings over $\mathcal{A}$. For $i = 1, \dots, h$ let $w^{(i)}$ denote the length-k string preceding the symbol v_i in wv (for example, $w^{(2)} = w_2 \cdots w_k v_1$). We define

$$\mathcal{P}(wv) = \prod_{i=1}^{h} P(w^{(i)} v_i). \tag{17}$$

The value $\mathcal{P}(wv)$ corresponds to the conditional probability $P(v|w)$ introduced in Lemma 12.10.3 of [5]. The following lemma shows that, in some sense, $\mathcal{P}$ does behave as a conditional probability.

LEMMA A.1. *For any string w and $l \geq 1$ we have $\sum_{v \in \mathcal{A}^l} \mathcal{P}(wv) \leq 1$.*

Proof. We prove the result by induction on l. If $l = 1$ we have $\sum_{\alpha \in \mathcal{A}} \mathcal{P}(w\alpha) = \sum_{\alpha \in \mathcal{A}} P(w\alpha) \leq 1$. For $l > 1$, let $v = v_1 \cdots v_l$ and $v' = v_2 \cdots v_l$. We have

$$\begin{aligned}
\sum_{v \in \mathcal{A}^l} \mathcal{P}(wv) &= \sum_{v \in \mathcal{A}^l} P(wv_1) \mathcal{P}(w^{(2)} v') \\
&= \sum_{\alpha \in \mathcal{A}} P(w\alpha) \left(\sum_{v' \in \mathcal{A}^{l-1}} \mathcal{P}(w^{(2)} v') \right) \\
&\leq \sum_{\alpha \in \mathcal{A}} P(w\alpha) \\
&\leq 1. \qquad \square
\end{aligned}$$

COROLLARY A.2. *Let $V = \{v_1, \dots, v_m\}$ be a collection of length-l strings in which each v_i appears at most M times. For any string w we have*

$$\sum_{v \in V} \mathcal{P}(wv) \leq M. \qquad \square$$

Let $y_1, \dots, y_c$ denote any parsing of the string $x_{k+1} \cdots x_{n+k}$, and let z_i denote the length-k substring preceding y_i in $s = x_1 \cdots x_{n+k}$. For $l \geq 1$ and $w \in \mathcal{A}^k$ we define c_{lw} as the number of words y_i such that $|y_i| = l$ and $z_i = w$. By construction, the values c_{lw} satisfy

$$\sum_{l,w} c_{lw} = c, \qquad \sum_{l,w} l c_{lw} = n. \tag{18}$$

The following lemma is a generalization of Ziv's inequality [5, Lemma 12.10.3].

LEMMA A.3. *Let $y_1, \ldots, y_c$ denote a parsing of the string $x_{k+1} \cdots x_{n+k}$ in which each word appears at most M times. We have*

$$|s|H_k(s) \geq \sum_{w \in \mathcal{A}^k,\, l \geq 1} c_{lw} \log c_{lw} - c \log M.$$

Proof. By (16) and (17) we have

$$\begin{aligned}
|s|H_k(s) &= -\sum_{i=k+1}^{n+k} \log P(s_i x_i) \\
&= -\sum_{i=1}^{c} \log \mathcal{P}(z_i y_i) \\
&= -\sum_{l,w} \sum_{|y_i|=l,\ z_i=w} \log \mathcal{P}(z_i y_i) \\
&= -\sum_{l,w} c_{lw} \left(\sum_{|y_i|=l,\ z_i=w} \frac{1}{c_{lw}} \log \mathcal{P}(z_i y_i) \right).
\end{aligned}$$

By Jensen's inequality and Corollary A.2 we get

$$\begin{aligned}
|s|H_k(s) &\geq -\sum_{l,w} c_{lw} \log\left(\sum_{|y_i|=l,\ z_i=w} \frac{1}{c_{lw}} \mathcal{P}(z_i y_i) \right) \\
&\geq -\sum_{l,w} c_{lw} \left(\log \frac{1}{c_{lw}} + \log\left(\sum_{|y_i|=l,\ z_i=w} \mathcal{P}(z_i y_i) \right) \right) \\
&\geq \sum_{l,w} c_{lw} \log c_{lw} - c \log M. \qquad \square
\end{aligned}$$

THEOREM A.4. *Let $y_1, \ldots, y_c$ denote a parsing of the string $x_{k+1} \cdots x_{n+k}$ in which each word appears at most M times. We have*

$$c \log c \leq |s|H_k(s) + c \log M + c \left(k \log |\mathcal{A}| + \log \frac{n}{c} \right) + \Theta(c).$$

Proof. Let $\pi_{lw} = c_{lw}/c$. We have

$$\begin{aligned}
\sum_{l,w} c_{lw} \log c_{lw} &= c\left(\sum_{l,w} \frac{c_{lw}}{c} (\log \frac{c_{lw}}{c} + \log c) \right) \\
&= c \log c + c\left(\sum_{l,w} \pi_{lw} \log \pi_{lw} \right).
\end{aligned}$$

By (18), the values π_{lw} satisfy

$$\sum_{l,w} \pi_{lw} = 1, \qquad \sum_{l,w} l \pi_{lw} = n/c. \tag{19}$$

Using Lagrange multipliers to maximize $-\sum_{l,w} \pi_{lw} \log \pi_{lw}$ under the constraint (19), or reasoning as in the proof of [5, Theorem 12.10.1] we get

$$-\sum_{l,w} \pi_{lw} \log \pi_{lw} \leq k \log |\mathcal{A}| + \log \left(1 + \frac{n}{c} \right) + \frac{n}{c} \log \left(1 + \frac{c}{n} \right).$$

Combining the above inequalities with Lemma A.3 we get

$$c\log c \le |s|H_k(s) + c\log M + c\left(k\log|\mathcal{A}| + \log\left(1+\frac{n}{c}\right) + \frac{n}{c}\log\left(1+\frac{c}{n}\right)\right).$$

The thesis follows observing that $\log(1+c/n)^{(n/c)} \le \log e$ and $\log(1+n/c) \le \log(n/c) + (c/n)\log e$. ◻

Proof of Lemma 2.3. Let $s = x_1 \cdots x_n$ with $n > k$. Let $y_1, \dots, y_t$ denote a parsing of s in which each word appears at most M times. This parsing induces a parsing of $x_{k+1}\cdots x_n$ in which each word appears at most $M+1$ times. The thesis follows by Theorem A.4. ◻

Appendix B. $\texttt{LZ78}_{RL}$-induced parsing.

LEMMA B.1. *Let $\tilde{s}$ be derived from s as described in section 3, and let $w_1, w_2, \dots, w_t$ denote the* LZ78 *parsing of $\tilde{s}$. Then, it is possible to build a parsing $w'_1, w'_2, \dots, w'_t$ of s such that each word appears at most $2\log|s|$ times.*

Proof. The parsing of $w'_1, w'_2, \dots, w'_t$ is defined as follows. For $i = 1, \dots, |\tilde{s}|$, we associate to the ith character of $\tilde{s}$ a nonempty string ω_i with the property that

$$s = \omega_1\omega_2\cdots\omega_{|\tilde{s}|}. \tag{20}$$

Then, from each word w_j in the parsing of $\tilde{s}$ we get the word w'_j by simply concatenating the strings ω_i's corresponding to the characters of w_j.

The strings ω_i's are defined by partially reversing the binary encoding utilized for the construction of the string $\tilde{s}$. More precisely, let $b = b_l b_{l-1}\cdots b_1 b_0$, $b_i \in \{\alpha, \mathtt{0}\}$ denote the encoding of the α-segment α^m (that is, with the notation of section 3 $b_l \cdots b_0 = B(\alpha^m)$). We associate to each character b_j the string $\omega(b_j)$ defined by

$$\omega(b_j) = \begin{cases} \alpha & \text{if } j = l; \\ \alpha^{2^j} & \text{if } j < l \text{ and } b_j = \mathtt{0}; \\ \alpha^{2^{j+1}} & \text{if } j < l \text{ and } b_j = \alpha. \end{cases} \tag{21}$$

Note that, for $j < l$, $\omega(b_j)$ contains 2^j more α's than if we simply had reversed the binary encoding. This is done at the expense of b_l (which translates to a single α) with the purpose of ensuring that every $\omega(b_j)$ is nonempty. One can easily verify that $\omega(b_l)\omega(b_{l-1})\cdots\omega(b_0) = \alpha^m$, which proves that the strings ω_i's satisfy (20).

We now show that in the parsing $w'_1, w'_2, \dots, w'_t$ each word appears at most $2\log|s|$ times. Since the words w_j's are distinct, we need to show that when we replace the single characters with the strings ω_i's, at most $2\log|s|$ distinct words translate into the same word. To prove this we introduce the following notation. For each substring σ of $\tilde{s}$ we denote by $\omega(\sigma)$ the string obtained by replacing each character of σ with the corresponding ω_i's. For $\alpha \in \mathcal{A}$, we denote with $B_{ij}(\alpha^m)$ the string obtained by removing from $B(\alpha^m)$ the first i and the last j characters. For example,

$$B_{10}(\alpha^5) = \mathtt{0}\alpha, \qquad B_{01}(\alpha^4) = \alpha\mathtt{0}, \qquad B_{00}(\alpha^{17}) = \alpha\mathtt{000}\alpha.$$

Finally, given any string $\sigma \in \{\alpha, \mathtt{0}\}^*$ we denote with $\mathtt{Bin}(\sigma)$ the integer we get by replacing α with 1 and interpreting the result as a binary number. For example,

$$\mathtt{Bin}(\alpha) = \mathtt{Bin}(\mathtt{00}\alpha) = 1, \qquad \mathtt{Bin}(\alpha\mathtt{00}) = 4.$$

By construction we know that $\tilde{s}$ consists in a concatenation of "compressed" α-segments. Hence, a generic word w_i in the parsing of $\tilde{s}$ has the form[1]

$$w_i = B_{r0}(\alpha_{i_1}^{n_1})B(\alpha_{i_2}^{n_2})\cdots B(\alpha_{i_{k-1}}^{n_{k-1}})B_{0s}(\alpha_{i_k}^{n_k}).$$

We have

$$\begin{aligned}\omega(w_i) &= \omega(B_{r0}(\alpha_{i_1}^{n_1}))\,\omega(B(\alpha_{i_2}^{n_2}))\,\cdots\,\omega(B(\alpha_{i_{k-1}}^{n_{k-1}}))\,\omega(B_{0s}(\alpha_{i_k}^{n_k}))\\ &= \omega(B_{r0}(\alpha_{i_1}^{n_1}))\,\alpha_{i_2}^{n_2}\,\cdots\,\alpha_{i_{k-1}}^{n_{k-1}}\,\omega(B_{0s}(\alpha_{i_k}^{n_k})).\end{aligned} \tag{22}$$

Thus, in order to count how many distinct w_i's translate into the same word, we need to study when two distinct strings σ_1, σ_2 of the form

$$\sigma_1 = B_{i0}(\alpha^{n_1}) \qquad \sigma_2 = B_{j0}(\alpha^{n_2})$$

or

$$\sigma_1 = B_{0i}(\alpha^{m_1}) \qquad \sigma_2 = B_{0j}(\alpha^{m_2}),$$

are such that $\omega(\sigma_1) = \omega(\sigma_2)$.

Consider first the case $\sigma_1 = B_{i0}(\alpha^{n_1}), \sigma_2 = B_{j0}(\alpha^{n_2})$. By (21) we know that the number of α's in $\omega(\sigma_1)$ is given by

$$|\omega(\sigma_1)| = |\omega(B_{i0}(\alpha^{n_1}))| = \begin{cases}\mathtt{Bin}(\sigma_1), & \text{if } i = 0;\\ \mathtt{Bin}(\sigma_1) + 2^{|\sigma_1|} - 1, & \text{if } i > 0;\end{cases}$$

and a similar result holds for $\omega(\sigma_2)$. We now show that $\omega(\sigma_1) = \omega(\sigma_2)$ with $\sigma_1 \neq \sigma_2$ only if $i = 0$ and $j \neq 0$ or, vice versa, $i \neq 0$ and $j = 0$. If $i = j = 0$, then

$$|\omega(\sigma_1)| = |\omega(\sigma_2)| \quad\Rightarrow\quad \mathtt{Bin}(\sigma_1) = \mathtt{Bin}(\sigma_2) \quad\Rightarrow\quad \sigma_1 = \sigma_2.$$

In fact, we cannot have, say, $\sigma_1 = \mathtt{000}\sigma_2$, since $\sigma_1 = B_{00}(\alpha^{n_1})$ and its leading character is different from `0` by construction. Assume now $i, j \neq 0$. If $|\sigma_1| = |\sigma_2|$, then

$$|\omega(\sigma_1)| = |\omega(\sigma_2)| \quad\Rightarrow\quad \mathtt{Bin}(\sigma_1) = \mathtt{Bin}(\sigma_2),$$

which again implies $\sigma_1 = \sigma_2$ since the two strings have the same length. Finally, if $i, j \neq 0$ and $|\sigma_1| \neq |\sigma_2|$, for example, $|\sigma_1| > |\sigma_2|$, we have

$$\begin{aligned}|\omega(\sigma_1)| &= \mathtt{Bin}(\sigma_1) + 2^{|\sigma_1|} - 1\\ &\geq 2^{|\sigma_2|} + 2^{|\sigma_2|} - 1\\ &> \mathtt{Bin}(\sigma_2) + 2^{|\sigma_2|} - 1\\ &= |\omega(\sigma_2)|,\end{aligned}$$

which implies $\omega(\sigma_1) \neq \omega(\sigma_2)$. In summary, we can conclude that there exist at most two distinct strings $\sigma_1 = B_{i0}(\alpha^{n_1}), \sigma_2 = B_{j0}(\alpha^{n_2})$ such that $\omega(\sigma_1) = \omega(\sigma_2)$.

Consider now the case $\sigma_1 = B_{0i}(\alpha^{m_1}), \sigma_2 = B_{0j}(\alpha^{m_2})$. By (21) we get that the number of α's in $\omega(\sigma_1)$ is given by

$$|\omega(\sigma_1)| = |\omega(B_{0i}(\alpha^{m_1}))| = \mathtt{Bin}(\sigma_1)2^i - 2^i - 1 = 1 + (\mathtt{Bin}(\sigma_1) - 1)2^i. \tag{23}$$

[1]We are assuming that w_i contains at least two distinct characters of $\mathcal{A}$. Therefore, we do not consider the case $w_i = B_{jk}(\alpha^n)$ which, however, can be handled with a similar analysis.

We observe that we can have $\omega(\sigma_1) = \omega(\sigma_2)$ with $\sigma_1 \neq \sigma_2$ only if $i \neq j$. In fact, if $i = j$, by (23) we have

$$|\omega(\sigma_1)| = |\omega(\sigma_2)| \quad \Rightarrow \quad \mathtt{Bin}(\sigma_1) = \mathtt{Bin}(\sigma_2),$$

which implies $\sigma_1 = \sigma_2$, since the leading character of both strings is different from 0. Note that, by construction, the length of every "compressed" α-segment $B(\alpha^n)$ is at most $\log|s|$. Hence, the above observation implies that there can be at most $\log|s|$ distinct strings $\sigma_1, \dots, \sigma_k$, $\sigma_i = B_{0j_i}(\alpha^{n_i})$, such that $\omega(\sigma_1) = \omega(\sigma_2) = \cdots = \omega(\sigma_k)$. In fact, the indices j_i's must be distinct and none of them can be greater than $\log|s|$.

We can now conclude our analysis of the induced parsing $w'_1, \dots, w'_t$. Since there are only two possible distinct prefixes and $\log|s|$ possible distinct suffixes which translate to the same substring, by (22) we have that at most $2\log|s|$ (distinct) words, w_i's, can translate to the same w'_j.

This completes the proof. $\square$

VERTICAL DECOMPOSITION OF SHALLOW LEVELS IN 3-DIMENSIONAL ARRANGEMENTS AND ITS APPLICATIONS[*]

PANKAJ K. AGARWAL[†], ALON EFRAT[‡], AND MICHA SHARIR[§]

Abstract. Let $\mathcal{F}$ be a collection of n bivariate algebraic functions of constant maximum degree. We show that the combinatorial complexity of the vertical decomposition of the $(\leq k)$-level of the arrangement $\mathcal{A}(\mathcal{F})$ is $O(k^{3+\varepsilon}\psi(n/k))$ for any $\varepsilon > 0$, where $\psi(r)$ is the maximum complexity of the lower envelope of a subset of at most r functions of $\mathcal{F}$. This bound is nearly optimal in the worst case and implies the existence of shallow cuttings, in the sense of [J. Matoušek, *Comput. Geom.*, 2 (1992), pp. 169–186], of small size in arrangements of bivariate algebraic functions. We also present numerous applications of these results, including (i) data structures for several generalized 3-dimensional range-searching problems; (ii) dynamic data structures for planar nearest- and farthest-neighbor searching under various fairly general distance functions; (iii) an improved (near-quadratic) algorithm for minimum-weight bipartite Euclidean matching in the plane; and (iv) efficient algorithms for certain geometric optimization problems in static and dynamic settings.

1. Introduction.

In this paper we extend the recent range-searching techniques of Matoušek [52] and of Agarwal and Matoušek [6] to arrangements of bivariate algebraic functions and derive many applications of the new techniques. As one motivation, consider the following *dynamic nearest-neighbor searching* problem: We dynamically maintain a set S of points in the plane under some metric δ. At any time, we wish to answer nearest-neighbor queries, in which we specify a point q and ask for the point of S nearest to q under the metric δ.

If δ is the Euclidean metric, a standard lifting transformation to $\mathbb{R}^3$ (as in [30]) reduces the problem to that of dynamically maintaining the lower envelope of planes in $\mathbb{R}^3$ so that, at any time during the maintenance, we can answer efficiently queries in which we specify a point $q \in \mathbb{R}^2$ and ask for the plane attaining the lower envelope at q. Using the parametric-searching technique of [4], this problem can be solved by a dynamic range-searching mechanism in which we wish to determine whether a query point in $\mathbb{R}^3$ lies below all the planes in the current set. The techniques in [6, 52] are based on the notion of *shallow cuttings*: Given an arrangement $\mathcal{A}$ of n planes in $\mathbb{R}^3$ and parameters $k, r \leq n$, there exists a $(1/r)$-*cutting* of the first k

levels of $\mathcal{A}$ of size $O(r(1 + kr/n)^2)$, i.e., there exists a decomposition of the (union of the) cells constituting these levels into $O(r(1 + kr/n)^2)$ simplices, so that the interior of each simplex is intersected by at most n/r planes. Using the existence of such shallow cuttings, Matoušek [52] constructs an efficient static data structure for halfspace-emptiness queries in $\mathbb{R}^3$; it requires $O(n \log \log n)$ storage and $O(n \log n)$ preprocessing time and answers a halfspace-emptiness query in $O(\log^2 n)$ time (see also [11]). This structure was later dynamized in [6]. These techniques also apply to arrangements of hyperplanes in higher dimensions.

Although these techniques can be extended to arrangements of curves in the plane, they fail for arrangements of general surfaces in three and higher dimensions. Such an arrangement does arise, for example, in the nearest-neighbor searching problem if the underlying distance function δ is not Euclidean. A specific case of this kind, which we will face in one of our applications (minimum-weight bipartite Euclidean matching in the plane), is where each point $s \in S$ has an additive weight $w(s)$ and the distance from a query point q to s is defined as $|qs| + w(s)$, where $|qs|$ is the Euclidean distance between these points. To tackle such cases efficiently, we need to extend the results of [6, 52] to the case of arrangements of more general functions, and this is one of the main goals of this paper.

The main technical result that we establish is the existence of shallow cuttings of small size in arrangements of (the graphs of) low-degree algebraic bivariate functions. To obtain such cuttings, we use the technique of *vertical decomposition* of cells in arrangements. This technique, described in detail in [18], is the only known general-purpose technique for decomposing cells in such arrangements into a small number of subcells of *constant description complexity* (that is, semialgebraic subcells, each defined by a constant number of polynomial equalities and inequalities, each of constant maximum degree). It is well known that the complexity of the vertical decomposition of a cell (2-face) C in a planar arrangement of low-degree algebraic curves is proportional to the number of vertices of C. However, this property does not hold in higher dimensions (even for an arrangement of planes in $\mathbb{R}^3$): One can construct a cell in an arrangement of n planes in $\mathbb{R}^3$ that has $O(n)$ vertices and whose vertical decomposition consists of $\Omega(n^2)$ subcells. In three dimensions, the complexity (number of subcells) of the vertical decomposition of the *entire* arrangement of n low-degree algebraic bivariate functions is shown in [18] to be close to $O(n^3)$ and is thus almost optimal (in higher dimensions, though, the bounds are considerably weaker; see [18, 24, 28, 37] for some partial results). No similarly sharp bounds were known for the vertical decomposition of the cells that lie only in the first k levels of the arrangement (even for arrangements of planes). Using a standard probabilistic analysis technique by Clarkson and Shor ([25]; see also [66]), one can easily show that the combinatorial complexity of these (undecomposed) cells is $O(k^3\psi(n/k))$, where $\psi(r)$ is the maximum combinatorial complexity of the lower envelope of any subset of at most r of the given surfaces. For low-degree algebraic bivariate functions, the results of [38, 65] imply that $\psi(n) = O(n^{2+\varepsilon})$, for any $\varepsilon > 0$,[1] but in certain favorable cases, such as the case of planes, this complexity is smaller.

The first main result of the paper, derived in section 2, is that the combinatorial complexity of the vertical decomposition of the cells in the first k levels of the

[1]Throughout this paper, ε denotes an arbitrarily small positive constant and $g(n) = O(f(n) \cdot n^{\varepsilon})$ means that for any given $\varepsilon > 0$, we can choose a constant c_{ε} so that $g(n) \le c_{\varepsilon} f(n) \cdot n^{\varepsilon}$. A complexity bound of the form $O(f(n) \cdot n^{\varepsilon})$ for an algorithm means that for any prespecified $\varepsilon > 0$, we can tune the algorithm so that its complexity is bounded by $c_{\varepsilon} f(n) \cdot n^{\varepsilon}$ for an appropriate constant c_{ε}.

arrangement is $O(k^{3+\varepsilon}\psi(n/k))$. This bound is close to optimal in the worst case. We then apply this bound to obtain a sharp bound on the size of shallow cuttings in arrangements of bivariate functions. Specifically, we show, in Theorem 3.1, that there exists a $(1/r)$-cutting of the first k levels in an arrangement of n low-degree, algebraic, bivariate functions in $\mathbb{R}^3$, as above, whose size is $O(q^{3+\varepsilon}\psi(r/q))$, where $q = k(r/n)+1$. This bound is almost tight in the worst case and almost coincides with the bound given in [52] for the case of planes. The proof adapts the analysis technique of [52]. If $r = O(1)$, a $(1/r)$-cutting of this size can be computed in $O(n)$ time.

An immediate consequence of Theorem 3.1 is an efficient algorithm for the following problem: Preprocess a set $\mathcal{F}$ of n bivariate functions into a data structure so that all functions whose graphs lie below a query point in $\mathbb{R}^3$ can be reported efficiently. We present a data structure of size $O(\psi(n)n^{\varepsilon})$, which can be constructed in $O(\psi(n)n^{\varepsilon})$ time, so that a query can be answered in $O(\log n + \xi)$ time, where ξ is the output size. If we are interested only in determining whether w lies below the graphs of all functions of $\mathcal{F}$, the query time is $O(\log n)$. (Here we are assuming a model of computation in which various operations involving a constant number of fixed-degree algebraic functions can be performed in $O(1)$ time; see below for details.) We can also modify this structure to obtain an efficient data structure for maintaining a set of bivariate algebraic functions dynamically, as above, so that we can efficiently determine whether a query point lies below all the function graphs in the current set. The modified data structure also requires $O(\psi(n)n^{\varepsilon})$ storage, the cost of an update is $O(\psi(n)/n^{1-\varepsilon})$, and a query can be answered in $O(\log n)$ time.[2] The technique for constructing these data structures adapts ideas from [6, 52]. Data structures with similar bounds are given in [6, 11, 21, 52] for a set of linear functions.

We also obtain an efficient algorithm for constructing and searching in the first k levels of an arrangement of n bivariate functions, as above. These levels can be constructed in $O(k^{3+\varepsilon}n^{\varepsilon}\psi(n/k))$ time, in an appropriate model of computation, and can be stored into a data structure of similar size so that we can determine, in $O(\log n)$ time, whether the level of a query point $p \in \mathbb{R}^3$ with respect to the arrangement is at most k and, if so, return the level of p.

We next apply the new mechanisms to a variety of geometric problems. First, in section 6, we derive an efficient technique for dynamically maintaining a set S of points (or more general objects) in the plane so that we can efficiently compute the nearest neighbor (or the farthest neighbor) of a query point in the current set of points, under any "reasonable" distance function δ (defined more precisely later), which can be fairly arbitrary and does not have to satisfy any metric-like properties. Assume that the complexity of the lower (or upper) envelope of the functions $f_i(\mathbf{x}) = \delta(p_i, \mathbf{x})$, over all objects p_i in the current set S, is at most $g(|S|)$. (This is the same as the complexity of the nearest (or farthest) neighbor Voronoi diagram of S if δ is a metric or a convex distance function.) Then our solution requires $O(g(n)n^{\varepsilon})$ storage, $O(g(n)/n^{1-\varepsilon})$ time for each update, and $O(\log n)$ time for each nearest- (or farthest-)neighbor query. We give applications of this technique to dynamic maintenance of a bichromatic closest pair between two planar point sets, under any "reasonable" metric, and of a minimum spanning tree of a planar point set under any L_p metric.

Another application of our technique is an improved algorithm for computing a

[2]Throughout this paper, the update-time bounds are amortized. We believe that the same bounds can be achieved in the worst case, using the known (albeit complicated) techniques of [60]. Nevertheless, for the sake of simplicity we will stick to amortized bounds, which will not affect the applications that we study here.

minimum-weight bipartite Euclidean matching for point sets in the plane (see section 7). That is, we are given a set of n blue points and a set of n red points in the plane, and we wish to find a matching between the blue points and the red points that minimizes the sum of the distances between the pairs of matched points. Our solution is based on the algorithm of Vaidya [70], which requires a data structure for answering nearest-neighbor queries in a dynamic setting, where the distance to each of the maintained sites is the Euclidean distance plus some additive weight associated with the site. Using our dynamic nearest-neighbor searching technique, we can improve the running time of Vaidya's algorithm from $O(n^{2.5} \log n)$ to $O(n^{2+\varepsilon})$. We also obtain an $O(n^{7/3+\varepsilon})$ algorithm for an arbitrary "reasonable" metric. Recently, Varadarajan [72] has obtained an improved algorithm for the nonbipartite case, for which the above nearest-neighbor searching mechanism is not sufficient.

Another application of our results is to dynamic maintenance of the intersection of congruent balls in $\mathbb{R}^3$, in the strong sense that we wish to determine, after each update, whether the current intersection is empty. For this, we combine our technique with the variant of parametric searching recently proposed in [69]. We obtain a data structure of size $O(n^{1+\varepsilon})$, which can be updated in $O(n^{\varepsilon})$ time per insertion/deletion and which supports "intersection-emptiness" queries in $O(\log^4 n)$ time.

We next apply our technique in section 9 to another problem in geometric optimization, namely, the *dynamic smallest stabbing-disk* problem: We maintain dynamically a set $\mathcal{C}$ of (possibly intersecting) simply shaped, compact, convex sets in the plane, and we wish to compute, after each insertion or deletion of such a set, the smallest disk, or the smallest homothetic copy of any compact convex set of simple shape, that intersects all the sets in the current $\mathcal{C}$. The case in which we have points instead of general convex sets was recently studied in [6]. Our solution requires $O(n^{1+\varepsilon})$ storage and preprocessing and recomputes the smallest stabbing disk after each update in $O(n^{\varepsilon})$ time. A byproduct of our analysis, which we believe to be of independent interest, is a near-linear bound on the complexity of the farthest-neighbor Voronoi diagram of (possibly intersecting) simply shaped, compact, convex sets in the plane, under any simply shaped, convex distance function. The bound is linear for (possibly intersecting) line segments under the Euclidean distance.

We finally present, in section 10, a few more applications, where most of the details are omitted. The paper concludes in section 11 with a discussion of our results and with some open problems. The collection of applications described in this paper is by no means exhaustive, and the new techniques obtained in this paper have many additional applications. The main message of this paper, in our opinion, is that there is a real need to adapt and extend range-searching and related techniques that were originally developed for arrangements of planes or hyperplanes to arrangements of algebraic surfaces. This adaptation is by no means easy, and the present study achieves it only for 3-dimensional arrangements, but it significantly enlarges the scope of range-searching applications.

2. Vertical decomposition of levels in 3-dimensional arrangements.

Let $\mathcal{F}$ be a collection of n bivariate functions satisfying the following conditions:[3]

(F1) Each $f \in \mathcal{F}$ is a continuous, totally defined, algebraic function of constant maximum degree b.

(F2) The functions in $\mathcal{F}$ are in *general position.* This excludes degenerate con-

[3]Abusing the notation slightly, we will not distinguish between a function and its graph. We will use $\mathcal{F}$ to denote a collection of functions as well as the family of surfaces representing their graphs.

figurations where four function graphs meet at a point, a pair of graphs are tangent to each other, etc.

With some modifications of the analysis, we can also handle the case in which the functions in $\mathcal{F}$ are only partially defined and the boundary of the domain of each function is defined by a constant number of polynomial equalities and inequalities of constant maximum degree, say, b, too. The simplest way of doing this is to extend each $f \in \mathcal{F}$ to a totally defined function by forming the Minkowski sum of the graph of f with a sufficiently narrow vertical cone, whose equation is $z = c\sqrt{x^2 + y^2}$, for a sufficiently large c and by taking the lower boundary of this sum as the graph of the extended function. The resulting extended functions are easily seen to be totally defined continuous functions, each of whose graphs is a semialgebraic set of constant description complexity. One can then check that the analysis given below also applies to collections of such functions. Concerning the general position assumption, we refer the reader to the papers [38, 65] for more details about the definition and properties of this concept. Following arguments given in these papers, it will follow that no real loss of generality is made by assuming general position, in the sense that the maximum combinatorial complexity of the structures we study here is attained when functions are in general position.

The *arrangement* of $\mathcal{F}$, denoted as $\mathcal{A}(\mathcal{F})$, is the subdivision of $\mathbb{R}^3$ induced by the graphs of the functions in $\mathcal{F}$ (see [66] for more details). We will refer to the 3-dimensional cells of $\mathcal{A}(\mathcal{F})$ simply as the *cells* of $\mathcal{A}(\mathcal{F})$. The complexity of a cell C, denoted as $|C|$, is the number of faces of all dimensions on the boundary of C. The *level* in $\mathcal{A}(\mathcal{F})$ of a point $p = (x_p, y_p, z_p) \in \mathbb{R}^3$, denoted as $\mu(p) = \mu_{\mathcal{F}}(p)$, is defined as the number of functions $f \in \mathcal{F}$ for which $z_p > f(x_p, y_p)$. The level of all points lying on a face ϕ (of any dimension) of $\mathcal{A}(\mathcal{F})$ is the same, which we denote by $\mu(\phi)$. The *k-level* of $\mathcal{A}(\mathcal{F})$, for any $0 \le k \le n-1$, is the closure of the union of all 2-dimensional faces of $\mathcal{A}(\mathcal{F})$ whose level is k; the 0-level (resp., $(n-1)$-level) is the graph of the lower (resp., upper) envelope of $\mathcal{F}$. The *$(\le k)$-level* of $\mathcal{A}(\mathcal{F})$, denoted as $\mathcal{A}_{\le k}(\mathcal{F})$, is the collection of all cells of $\mathcal{A}(\mathcal{F})$ whose level is at most k. Let

$$\psi(\mathcal{F}, k) = \sum_{C \in \mathcal{A}_{\le k}(\mathcal{F})} |C|$$

denote the combinatorial complexity of $\mathcal{A}_{\le k}(\mathcal{F})$. Let $\mathbf{F}$ denote a (possibly infinite) family of bivariate functions that satisfies (F1), and let

$$\psi(n, k) = \psi^{\mathbf{F}}(n, k)$$

be any upper bound on the quantity $\max_{\mathcal{F}} \ \psi(\mathcal{F}, k)$, where the maximum is taken over all collections $\mathcal{F} \subseteq \mathbf{F}$ of at most n functions (that satisfy (F1) and (F2)). To simplify the presentation, we will also use $\psi(n)$ to denote $\psi(n, 0)$ and will allow n in this notation to be any real nonnegative number.

A straightforward application of the probabilistic analysis technique of Clarkson and Shor [25] (see also [66]) implies that

$$\psi(n, k) = O(k^3 \psi(n/k)). \tag{2.1}$$

We also note that, by the results of [38, 65], we always have $\psi(n) = O(n^{2+\varepsilon})$, where the constant of proportionality depends on ε and on the maximum degree of the given surfaces. Hence, in the worst case we have $\psi(n, k) = O(k^{1-\varepsilon} n^{2+\varepsilon})$. However, these bounds can be much smaller for certain favorable underlying families $\mathbf{F}$. A typical

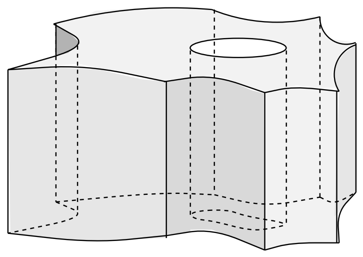

FIG. 2.1. *Vertical decomposition: A subcell created in step* I.

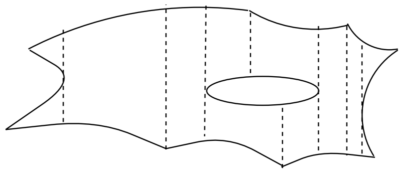

FIG. 2.2. *Vertical decomposition: step* II.

example is the case of Voronoi diagrams, where each function $f \in \mathbf{F}$ has the form $f(x, y) = \rho((x, y), q)$. Here ρ is a fixed metric and q is an arbitrary point in the plane. In this case $\psi(n) = O(n)$, so $\psi(n, k) = O(nk^2)$.

Because of technical reasons, we make the following assumption on $\mathbf{F}$.

(F3) The upper bound $\psi(n)$ on the complexity of the lower envelope (and also of the upper envelope) of any collection $\mathcal{F} \subseteq \mathbf{F}$ of n functions is of the form $\psi(n) = n^\alpha \beta(n)$, where $\alpha \le 2$ is a constant and $\beta(n)$ is a positive function so that for any $\delta > 0$, the sequence $\beta(n)/n^\delta$ is eventually nonincreasing and $\lim_{n\to\infty} \beta(n)/n^\delta = 0$.

This assumption involves no real loss of generality. In fact, all known bounds for $\psi(n)$ have this form with either $\alpha = 1$ or $\alpha = 2$.

The *vertical decomposition* of a (3-dimensional) cell $C \in \mathcal{A}(\mathcal{F})$, denoted as $C^\star$, is defined in the following standard manner (see [18, 66] for more details):

I. For each edge e of ∂C, we erect a z-vertical wall from e, which is the union of all maximal z-vertical segments passing through points of e and lying within (the closure of) C. The collection of these walls partitions C into subcells, each of which has a unique top facet (2-dimensional face) and a unique bottom facet, each contained in some facet of C. Every z-vertical line cuts such a subcell in a (possibly empty) interval; see Figure 2.1.

II. We take each of the cells Δ generated in the first step, project it onto the xy-plane, and construct the 2-dimensional vertical decomposition of the projection Δ_2 of Δ by erecting, from each vertex of Δ_2 and from each locally x-extreme point of $\partial\Delta_2$, a maximal y-vertical segment contained in the closure of Δ_2. These segments partition Δ_2 into trapezoidal-like subcells; each subcell $\tau_2 \subseteq \Delta_2$ induces a subcell τ of Δ, obtained by intersecting Δ with the vertical cylinder $\tau_2 \times \mathbb{R}$ (see Figure 2.2).

The cells obtained in this two-step decomposition form the vertical decomposition of C. We define $\mathcal{A}^\star_{\le k}(\mathcal{F})$ (resp., $\mathcal{A}^\star(\mathcal{F})$), the vertical decomposition of $\mathcal{A}_{\le k}(\mathcal{F})$ (resp., of $\mathcal{A}(\mathcal{F})$), as the union of the vertical decompositions of all cells in $\mathcal{A}_{\le k}(\mathcal{F})$ (resp., in $\mathcal{A}(\mathcal{F})$). The complexity of such a vertical decomposition is the total number of its cells. Abusing the notation slightly, we will use $\mathcal{A}^\star(\mathcal{F})$ to denote a spatial subdivision as well as a set of cells. Notice that for each cell $\tau \in \mathcal{A}^\star(\mathcal{F})$, there is a subset $D = D(\tau)$ of at most six functions of $\mathcal{F}$ so that $\tau \in \mathcal{A}^\star(D)$. Since all the functions in $\mathcal{F}$ have constant maximum degree, it follows that each cell of $\mathcal{A}^\star(\mathcal{F})$ has *constant description complexity* (in the sense defined above) [18], a property that is crucial for the construction of cuttings, which will be studied in the next section. We refer to the set $D(\tau)$ as the set of functions *defining* the cell τ. The main result of this section is the following theorem.

THEOREM 2.1. *Let $\mathcal{F}$ be a collection of n bivariate functions satisfying conditions* (F1)–(F3). *For any integer $k \le n$ and any $\varepsilon > 0$, the combinatorial complexity of $\mathcal{A}^\star_{\le k}(\mathcal{F})$ is $O(k^{3+\varepsilon}\psi(n/k))$, where the constant of proportionality depends on ε and on the maximum degree of the functions in $\mathcal{F}$.*

Proof. Let C be a cell of $\mathcal{A}_{\le k}(\mathcal{F})$, and let Δ be a subcell of C created in step I of the vertical decomposition. If $|\Delta|$ is the number of vertical edges in Δ plus the number of locally x-extremal points of edges of $\mathcal{A}_{\le k}(\mathcal{F})$ on $\partial\Delta$, then step II partitions Δ into $O(|\Delta| + 1)$ subcells. Indeed, each vertical edge of Δ (resp., each locally x-extremal point as above) corresponds to a vertex of Δ_2 (resp., to a locally x-extremal point on an edge of $\partial\Delta_2$), and the number of subcells in the 2-dimensional vertical decomposition of Δ_2 is easily seen to be proportional to 1 plus the number of vertices of Δ_2 plus the number of locally x-extremal points on the edges of $\partial\Delta_2$. Summing over all cells of $\mathcal{A}_{\le k}(\mathcal{F})$, the number of subcells in $\mathcal{A}^\star_{\le k}(\mathcal{F})$ is proportional to the sum of the number of vertical edges in the subcells created in step I, the number of edges of $\mathcal{A}_{\le k}(\mathcal{F})$, and the number of subcells created in step I that do not contain any vertical edge or any locally x-extremal point on an edge of $\mathcal{A}_{\le k}(\mathcal{F})$. The third quantity is bounded by $O(k^3\psi(n/k))$ because each such subcell contains at least one edge or face of $\mathcal{A}_{\le k}(\mathcal{F})$ and each such feature of $\mathcal{A}_{\le k}(\mathcal{F})$ can be incident to $O(1)$ subcells.

Hence, it suffices to bound the number of vertical edges in the subcells created in step I. There are two types of vertical edges of Δ:

(V1) a z-vertical segment erected from a vertex of C, or

(V2) the intersection segment of two z-vertical walls erected from two edges e, e' of C, where e lies on the top portion of ∂C and e' lies on the bottom portion of ∂C.

Since the number of vertical edges of type (V1) is bounded by the number of vertices in C, the total number of such edges, over all cells of $\mathcal{A}_{\le k}(\mathcal{F})$, is at most $O(k^3\psi(n/k))$. Hence, it suffices to bound the number of vertical edges of type (V2).

If two edges e, e' of C generate a vertical edge of type (V2), then their xy-projections must intersect. Furthermore, every intersection point between the xy-projections of any two edges of ∂C, one on the upper portion and one on the bottom portion of ∂C, generates exactly one vertical edge of type (V2) (this follows from the fact that the cell C is xy-monotone). We obtain an upper bound on the number of these intersection points over all cells in $\mathcal{A}_{\le k}(\mathcal{F})$, which in turn yields an upper bound on the number of cells in $\mathcal{A}^\star_{\le k}(\mathcal{F})$.

For a fixed pair of edges $e, e' \in \mathcal{A}(\mathcal{F})$ such that $\mu(e') < \mu(e)$, we define (e, e', σ) to be an *edge-crossing* if σ is an intersection point of the xy-projections of the (relative interiors of the) edges e and e'; see Figure 2.3. Let ℓ_σ denote the z-vertical line passing through σ. We define the *crossing number* of (e, e', σ) to be $\mu(e) - \mu(e') - 2$, which, by our general position assumption, is equal to the number of functions whose graphs intersect ℓ_σ strictly between e and e'. For an integer $\rho \le \mu(e) - 2$, let $\mathcal{C}_\rho(e) = \mathcal{C}_\rho(e, \mathcal{F})$ denote the set of edge-crossings of the form (e, e', σ) whose crossing number is ρ; we

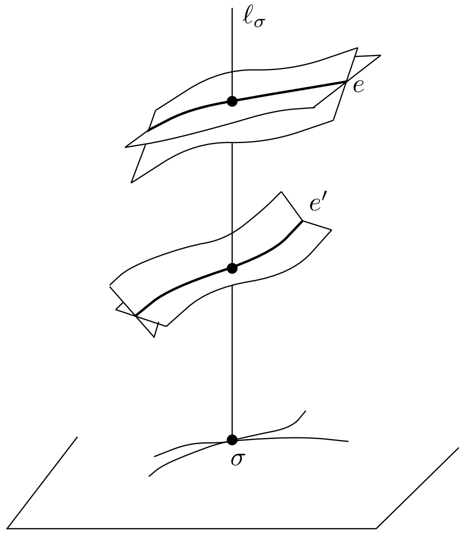

FIG. 2.3. *An edge-crossing* (e, e', σ).

put $\mathcal{C}_\rho(e, \mathcal{F}) = \emptyset$ for $\rho > \mu(e) - 2$. Set

$$\omega_\rho(e, \mathcal{F}) = |\mathcal{C}_\rho(e, \mathcal{F})| \quad \text{and} \quad \omega_{\leq\rho}(e, \mathcal{F}) = \sum_{i=0}^{\rho} \omega_i(e, \mathcal{F}).$$

Define

$$\varphi_\rho(\mathcal{F}, k) = \sum_{e \in \mathcal{A}_{\leq k}(\mathcal{F})} \omega_\rho(e, \mathcal{F})$$

to be the number of edge-crossings in $\mathcal{A}_{\leq k}(\mathcal{F})$ whose crossing number is ρ. Set

$$\varphi_\rho(n, k) = \max\ \varphi_\rho(\mathcal{F}, k),$$

where the maximum is taken over all subsets $\mathcal{F} \subseteq \mathbf{F}$ of size at most n. The corresponding quantities $\varphi_{\leq\rho}(\mathcal{F}, k)$ and $\varphi_{\leq\rho}(n, k)$ are defined in an obvious and analogous manner.

As follows from the above considerations, our goal is to show that

$$\varphi_0(n, k) \leq ck^{3+\varepsilon}\psi(n/k) \tag{2.2}$$

for some appropriate constant c (depending on ε and on the maximum degree of the functions in $\mathbf{F}$). This will be achieved by deriving a recurrence relationship for $\varphi_0(n, k)$, whose solution will yield the desired bound. The recurrence is obtained using the following counting argument, which borrows ideas from Agarwal, Schwarzkopf, and Sharir [8].

Let e be an edge of $\mathcal{A}_{\leq k}(\mathcal{F})$, and let C be the cell of $\mathcal{A}(\mathcal{F})$ lying immediately below e. Let V_e be the vertical 2-manifold obtained as the union of all z-vertical rays emanating from the points of e in the negative z-direction. The intersection of the graph of each function $f \in \mathcal{F}$ with V_e is an algebraic arc $f^{(e)}$ of constant maximum

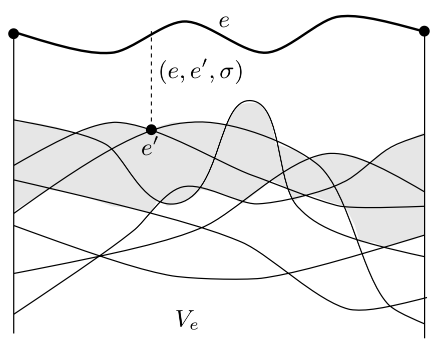

FIG. 2.4. *The arrangement $\mathcal{A}^{(e)}(\mathcal{F})$; the shaded region consists of points whose levels are between* 3 *and* 6.

degree, so each pair of these arcs intersect in at most a constant number of points, say, s, which depends only on the maximum degree b of the functions of $\mathcal{F}$. Let $\mathcal{A}^{(e)}(\mathcal{F})$ denote the cross section of $\mathcal{A}(\mathcal{F})$ with V_e. See Figure 2.4 for an illustration. The following lemma is a simple but crucial observation.

LEMMA 2.2. *Let e' be an edge of $\mathcal{A}_{\le k}(\mathcal{F})$ such that $\mu(e') < \mu(e)$. Then (e,e',σ) is an edge-crossing with crossing number ξ if and only if the intersection point $e' \cap \ell_\sigma$ is a vertex at level $\mu(e) - \xi - 2$ in $\mathcal{A}^{(e)}(\mathcal{F})$.*

The lemma implies that each edge-crossing of the form (e,e',σ) with zero crossing number corresponds to a vertex of the cross section $C^{(e)}$ of C with V_e (which lies on the lower portion of ∂C). Let $\mathcal{F}^{(e)} \subseteq \mathcal{F}$ be the set of functions that appear on the lower portion of $\partial C^{(e)}$, and let $t_e = |\mathcal{F}^{(e)}|$. For each function $f \in \mathcal{F}^{(e)}$, we consider the cross section $f^{(e)}$ of f within V_e, as defined above. It is easily seen that the lower portion of $\partial C^{(e)}$ is the upper envelope of the functions in $\tilde{\mathcal{F}}^{(e)} \equiv \{f^{(e)} \mid f \in \mathcal{F}^{(e)}\}$. By the standard Davenport–Schinzel theory [9, 39, 66],

$$\omega_0(e,\mathcal{F}) \le \lambda_s(t_e), \tag{2.3}$$

where s is as above and where $\lambda_s(t)$ is the (near-linear) maximum length of a (t,s)-Davenport–Schinzel sequence.

Since the endpoints of all arcs in $\tilde{\mathcal{F}}^{(e)}$ lie on the vertical boundary of V_e and $\mu(e) \le k$, it is easily seen that $t_e \le k$, and thus $\omega_0(e,\mathcal{F}) \le \lambda_s(k)$. Summing these bounds over all edges of $\mathcal{A}_{\le k}(\mathcal{F})$, we get

$$\varphi_0(\mathcal{F},k) = \sum_{e \in \mathcal{A}_{\le k}(\mathcal{F})} \omega_0(e,\mathcal{F}) \le \lambda_s(k)\psi(\mathcal{F},k).$$

This yields the following weaker bound on $\varphi_0(n,k)$:

$$\varphi_0(n,k) \le \lambda_s(k)\cdot\psi(n,k) \le c_1\lambda_s(k)k^3\psi(n/k) \tag{2.4}$$

for some constant c_1. The bound in (2.4) is asymptotically what we want for $k = O(1)$, and it is at most k times the desired bound for larger values of k.

We proceed now to prove the sharper bound that we are after. We fix (a sufficiently small) $\varepsilon > 0$ and choose some threshold constant k_0 (depending on ε) so that

$$4^\varepsilon k < c\lambda_s(k) < k^{1+\varepsilon^2/2} \tag{2.5}$$

for all $k > k_0$ and for some absolute constant c whose value will be determined later (the upper and lower bounds on $\lambda_s(k)$ in [9] imply that such a k_0 exists). If $k \le k_0$, then the bound asserted in Theorem 2.1 follows from (2.4) with an appropriate choice of the constant of proportionality. Henceforth, we assume that $k > k_0$. Put

$$q = \left\lceil (c\lambda_s(k)/k)^{1/\varepsilon} \right\rceil ;$$

$q \ge 4$, provided that k_0 is sufficiently large.

As above, fix an edge e of $\mathcal{A}_{\le k}(\mathcal{F})$, and continue to use the notations introduced above. If $t_e \le q$, then, by Lemma 2.2, $\omega_0(e, \mathcal{F})$, which is the same as the number of vertices of $C^{(e)}$, is at most $\lambda_s(q)$. Since the number of edges in $\mathcal{A}_{\le k}(\mathcal{F})$ is at most $\psi(n, k)$, the overall number of edge-crossings with crossing number 0 and involving such edges e is at most $\lambda_s(q)\psi(n, k)$.

Next, assume that $t_e > q$. Let f, f' be a pair of distinct functions in $\mathcal{F}^{(e)}$. By continuity, f and f' must intersect within V_e at least once. Thus each function $f \in \mathcal{F}^{(e)}$ must cross at least $t_e - 1$ other functions of $\mathcal{F}$ within V_e; that is, each function $f \in \mathcal{F}^{(e)}$ is incident to at least $t_e - 1$ vertices of $\mathcal{A}^{(e)}(\mathcal{F})$. Since the graph of f contains points at level $\mu(e) - 2$ in this cross section, it follows that f is incident to at least q vertices of $\mathcal{A}^{(e)}(\mathcal{F})$ whose levels are between $\mu(e) - q - 2$ and $\mu(e) - 2$. The number of vertices of $\mathcal{A}^{(e)}(\mathcal{F})$ whose levels fall in this range is therefore $\Omega(t_e q)$, which, by (2.3), implies that

$$\begin{aligned} \omega_{\le q}(e, \mathcal{F}) = \Omega(t_e q) &= \Omega\left(q t_e \cdot \frac{\omega_0(e, \mathcal{F})}{\lambda_s(t_e)} \right) \\ &\ge \frac{q}{\beta(k)} \cdot \omega_0(e, \mathcal{F}), \end{aligned} \tag{2.6}$$

where $\beta(k) = \Theta(\lambda_s(k)/k)$ is an extremely slowly growing function of k [9, 39].

Summing (2.6) over all edges e of $\mathcal{A}_{\le k}(\mathcal{F})$ for which $t_e > q$, adding the bound for the other edges of $\mathcal{A}_{\le k}(\mathcal{F})$, and observing that each edge-crossing between any two edges of $\mathcal{A}_{\le k}(\mathcal{F})$ with crossing number at most q is counted in this manner exactly once, we obtain

$$\varphi_0(\mathcal{F}, k) = \sum_{e \in \mathcal{A}_{\le k}(\mathcal{F})} \omega_0(e, \mathcal{F}) \le \frac{\beta(k)}{q} \varphi_{\le q}(\mathcal{F}, k) + \lambda_s(q)\psi(n, k),$$

which implies

$$\varphi_0(n, k) \le \frac{\beta(k)}{q} \varphi_{\le q}(n, k) + \lambda_s(q)\psi(n, k) \; . \tag{2.7}$$

In Lemma 2.3 below, we obtain the following upper bound on $\varphi_{\le q}(n, k)$:

$$\varphi_{\le q}(n, k) \le A(q + 1)^4 \varphi_0 \left(\left\lceil \frac{2n}{q+1} \right\rceil, \left\lceil \frac{2k}{q+1} \right\rceil \right) \tag{2.8}$$

for a constant $A > 0$. Substituting (2.1) and (2.8) in (2.7) and using the fact that $q > 4$, we obtain that

$$\varphi_0(n, k) \le B \left[(q + 1)^3 \beta(k) \varphi_0 \left(\left\lceil \frac{2n}{q+1} \right\rceil, \left\lceil \frac{2k}{q+1} \right\rceil \right) + \lambda_s(q) k^3 \psi\left(\frac{n}{k}\right) \right], \tag{2.9}$$

where $B > 0$ is another constant. The solution of (2.9) is

$$\varphi_0(n,k) \le Dk^{3+\varepsilon}\psi\left(\frac{n}{k}\right), \tag{2.10}$$

where $D = D(\varepsilon)$ is a sufficiently large constant depending on ε. The proof is by double induction on k and n. First, as already noted, the bound holds for $k \le k_0$ with an appropriate choice of D. For $k > k_0$ and for $n = k$, we have

$$\varphi_0(n,k) = O(n^3\beta(n)) \;=\; O(k^3\beta(k)) \;\le\; Dk^{3+\varepsilon}\psi(n/k),$$

provided D is chosen sufficiently large.

For $k > k_0$ and $n > k$, we have, by the induction hypothesis,

$$\varphi_0(n,k) \le B\left[(q+1)^3\beta(k)D\left\lceil\frac{2k}{q+1}\right\rceil^{3+\varepsilon}\psi\left(\left\lceil\frac{2n}{q+1}\right\rceil \Big/ \left\lceil\frac{2k}{q+1}\right\rceil\right) + \lambda_s(q)k^3\psi\left(\frac{n}{k}\right)\right].$$

Since

$$\left\lceil\frac{2n}{q+1}\right\rceil \Big/ \left\lceil\frac{2k}{q+1}\right\rceil \le \frac{2n}{k} \tag{2.11}$$

and, by condition (F3), $\psi(2n/k) \le c'\psi(n/k)$ for a constant $c' > 0$, we obtain

$$\varphi_0(n,k) \le Dk^{3+\varepsilon}\psi\left(\frac{n}{k}\right)\left[Bc'\frac{\beta(k)}{(q+1)^\varepsilon} + \frac{B}{D}\frac{\lambda_s(q)}{k^\varepsilon}\right].$$

Since

$$q = \left\lceil\left(\frac{c\lambda_s(k)}{k}\right)^{1/\varepsilon}\right\rceil$$

and $k^{1+\varepsilon^2/2} > c\lambda_s(k)$ (see (2.5)), we have

$$(q+1)^\varepsilon > c\frac{\lambda_s(k)}{k} = \Omega(\beta(k)) \quad \text{and} \quad q \le \left\lceil k^{\varepsilon/2}\right\rceil.$$

Hence, $\lambda_s(q) = o(k^\varepsilon)$, and we thus obtain

$$Bc'\frac{\beta(k)}{(q+1)^\varepsilon} + \frac{B}{D}\frac{\lambda_s(q)}{k^\varepsilon} < 1,$$

provided that c and k_0 are chosen sufficiently large. Hence,

$$\varphi_0(n,k) \le Dk^{3+\varepsilon}\psi\left(\frac{n}{k}\right).$$

This establishes Theorem 2.1. □

To complete the above proof, we establish the promised lemma.

LEMMA 2.3. *Let $n > k > q$ be three natural numbers. There exists a constant $A > 0$ such that*

$$\varphi_{\le q}(n,k) \le A(q+1)^4\varphi_0\left(\left\lceil\frac{2n}{q+1}\right\rceil, \left\lceil\frac{2k}{q+1}\right\rceil\right).$$

Proof. We prove the lemma using a probabilistic argument that is similar to, though slightly different from, the one used by Clarkson and Shor [25]; see also [64].

Set $p = 1/(q+1)$. We choose a subset $R \subseteq \mathcal{F}$ by selecting each function of $\mathcal{F}$ independently with probability p, so the expected size of R is np. Set $k' = \lceil 2kp \rceil$, and let us bound from below the expected value of $\varphi_0(R, k')$. For an edge-crossing (e, e', σ), let $I(e, e', \sigma)$ denote the indicator function whose value is 1 if the level of $e \cap \ell_\sigma$ in $\mathcal{A}(R)$ is at most k' and $(e, e', \sigma) \in \mathcal{C}_0(e, R)$. Otherwise, $I(e, e', \sigma) = 0$. Then

$$\begin{aligned} \mathbf{E}[\varphi_0(R, k')] &= \sum_{e \in \mathcal{A}(\mathcal{F})} \sum_{j=0}^{\mu(e)-2} \sum_{(e,e',\sigma) \in \mathcal{C}_j(e,\mathcal{F})} \Pr[\, I(e, e', \sigma) = 1 \,] \\ &\geq \sum_{e \in \mathcal{A}_{\leq k}(\mathcal{F})} \sum_{j=0}^{q} \sum_{(e,e',\sigma) \in \mathcal{C}_j(e,\mathcal{F})} \Pr[\, I(e, e', \sigma) = 1 \,]. \end{aligned} \tag{2.12}$$

Fix an edge-crossing $(e, e', \sigma) \in \mathcal{C}_j(e, \mathcal{F})$ with $e \in \mathcal{A}_{\leq k}(\mathcal{F})$, and $j \leq q$. Let f_1, f_2 (resp., f_3, f_4) be the functions of $\mathcal{F}$ whose intersection curve contains e (resp., e'). Notice that $f_1, \ldots, f_4$ are distinct. It is easily seen that $I(e, e', \sigma) = 1$ if and only if the following three events occur simultaneously:

(E_1) $\{f_1, f_2, f_3, f_4\} \subseteq R$.

(E_2) None of the j functions of $\mathcal{F}$ whose graphs intersect ℓ_σ between e and e' is chosen in R.

(E_3) Among the $\mu(e) - j - 2$ functions whose graphs intersect ℓ_σ below e', at most $k' - 2$ are chosen in R. That is, $\mu_R(e' \cap \ell_\sigma) \leq k' - 2$.

Since the subevents E_1, E_2, E_3 are independent, we have

$$\Pr[\, I(e, e', \sigma) = 1 \,] = \Pr[\, E_1 \,] \cdot \Pr[\, E_2 \,] \cdot \Pr[\, E_3 \,].$$

We have $\Pr[\, E_1 \,] = p^4$ and $\Pr[\, E_2 \,] = (1-p)^j$. Therefore, it suffices to obtain a lower bound on $\Pr[E_3]$.

First consider the case where $q \geq k/6$. $\mu_R(e' \cap \ell_\sigma)$ is obviously at most $k' - 2$ if none of the functions whose graphs intersect ℓ_σ below e' are chosen in R. Therefore

$$\Pr[\, E_3 \,] \geq (1-p)^{\mu(e)-j-2} > (1-p)^{k-j} \geq (1-p)^{6q-j}.$$

Consequently,

$$\begin{aligned} \Pr[\, I(e, e', \sigma) = 1 \,] &\geq p^4 (1-p)^j (1-p)^{6q-j} \\ &= \frac{1}{(q+1)^4} \left(1 - \frac{1}{q+1}\right)^{6q} \\ &> \frac{1}{e^6} \cdot \frac{1}{(q+1)^4}. \end{aligned} \tag{2.13}$$

The last inequality follows from the fact that $(1 - 1/(q+1))^q > 1/e$.

Next, assume that $q < k/6$. First, observe that $\Pr[E_3] = 1$ for $\mu(e) \leq k'$, so we may assume that $\mu(e) > k'$. If we let $g_1, \ldots, g_m$, for $m = \mu(e) - j - 2 < k$, denote the functions whose graphs intersect ℓ_σ below e', and define X_i to be the random variable whose value is 1 if $g_i \in R$ and 0 otherwise, then

$$\mu_R(e' \cap \ell_\sigma) = \sum_{i=1}^{m} X_i.$$

By definition, X_i is 1 with probability p and 0 with probability $1-p$. Therefore

$$\mathbf{E}[\,\mu_R(e' \cap \ell_\sigma)\,] \;=\; mp < kp$$

and, by Markov's inequality,

$$\Pr[\,\mu_R(e' \cap \ell_\sigma) > k'-2\,] \;<\; \frac{kp}{k'-2} \quad\le\; \frac{kp}{2kp-2}.$$

Hence,

$$\begin{aligned}\Pr[\,E_3\,] &= 1 - \Pr[\,\mu_R(e' \cap \ell_\sigma) > k'-2\,] \\ &> 1 - \frac{1}{2(1-1/kp)}.\end{aligned}$$

Since $q < k/6$, we have

$$kp \;=\; \frac{k}{q+1} \;\ge\; \frac{k}{2q} \;>\; 3,$$

which implies

$$\Pr[\,E_3\,] \;>\; 1 - \frac{1}{2(1-1/3)} \;=\; \frac{1}{4}.$$

Therefore

$$\Pr[\,I(e,e',\sigma)=1\,] \;\ge\; p^4(1-p)^q \cdot \frac{1}{4}.$$

Since $p = 1/(q+1)$ and $(1-1/(q+1))^q > 1/e$, we have

$$\Pr[\,I(e,e',\sigma)=1\,] \;\ge\; \frac{1}{4e}\cdot\frac{1}{(q+1)^4} \;>\; \frac{1}{e^6}\cdot\frac{1}{(q+1)^4}. \tag{2.14}$$

Substituting (2.13) and (2.14) into (2.12), we get

$$\begin{aligned}\mathbf{E}[\,\varphi_0(R,k')\,] &\ge \sum_{e\in\mathcal{A}_{\le k}(\mathcal{F})}\sum_{j=0}^{q}\frac{1}{e^6(q+1)^4}\cdot\varphi_j(e,\mathcal{F}) \\ &= \frac{1}{e^6(q+1)^4}\varphi_{\le q}(\mathcal{F},k).\end{aligned} \tag{2.15}$$

On the other hand,

$$\begin{aligned}\mathbf{E}[\,\varphi_0(R,k')\,] &\le \sum_{i\ge 0}\Pr[2ipn \le |R| < 2(i+1)pn]\cdot\varphi_0\left(\lceil 2(i+1)pn\rceil, k'\right) \\ &\le \varphi_0\left(\lceil 6pn\rceil, k'\right) + \sum_{i\ge 3}\Pr[|R|\ge 2ipn]\cdot\varphi_0(\lceil 2(i+1)pn\rceil, k').\end{aligned} \tag{2.16}$$

The weak bound on $\varphi_0(m,k)$ in (2.4) and the fact that $\psi(m) = O(m^{2+\varepsilon})$ imply that for any $\rho \ge 1$,

$$\varphi_0(\rho m, k') \le \rho^3\varphi_0(m,k'). \tag{2.17}$$

We use the following form of Chernoff's bound to estimate the second term in (2.16); see [57, p. 72]. Let n be an integer, and for $1 \le i \le n$, let X_i be a random variable which is 1 with probability p and 0 with probability $1-p$. Assume that the X_i's are independent, and put $X = \sum_{i=1}^{n} X_i$. Then for any $\delta > 2e$,

$$\Pr[\, X > \delta np \,] \; < \; 2^{-\delta np}. \tag{2.18}$$

If we let X_i be a random variable which is 1 if the ith function in $\mathcal{F}$ is in R and 0 otherwise, then $|R| = X$. Since $p = 1/(q+1) \ge 1/n$, (2.18) implies that for $i \ge 3$,

$$\Pr[\, |R| > 2inp \,] < 2^{-2i}. \tag{2.19}$$

Substituting (2.17) and (2.19) into (2.16), we obtain

$$\begin{aligned}\mathbf{E}[\, \varphi_0(R,k') \,] &\le 3^3\varphi_0(\lceil 2pn\rceil, k') + \sum_{i\ge 3} 2^{-2i}(i+1)^3 \cdot \varphi_0(\lceil 2pn\rceil, k') \\ &\le A'\varphi_0\left(\left\lceil \frac{2n}{q+1}\right\rceil, \left\lceil \frac{2k}{q+1}\right\rceil\right), \qquad (2.20)\end{aligned}$$

where

$$A' = 3^3 + \sum_{i\ge 3}(i+1)^3 2^{-2i} > 0$$

is a constant. Combining (2.15) and (2.20), we obtain

$$\begin{aligned}\varphi_{\le q}(n,k) &\le e^6(q+1)^4 \cdot A'\varphi_0\left(\left\lceil \frac{2n}{q+1}\right\rceil, \left\lceil \frac{2k}{q+1}\right\rceil\right) \\ &\le A(q+1)^4\varphi_0\left(\left\lceil \frac{2n}{q+1}\right\rceil, \left\lceil \frac{2k}{q+1}\right\rceil\right) \qquad (2.21)\end{aligned}$$

for an appropriate constant A. This completes the proof of the lemma and thus also of Theorem 2.1. $\square$

As promised in the beginning of the section, an inspection of the proof of Theorem 2.1 shows that it continues to apply, with minor and straightforward modifications, to the cases of partially defined or piecewise-algebraic functions. We therefore obtain the following result.

COROLLARY 2.4. *Let $\mathcal{F}$ be a collection of n partially defined, or piecewise-algebraic, bivariate functions, each of constant description complexity and satisfying conditions* (F2)–(F3). *For any integer $k \le n$, the combinatorial complexity of $\mathcal{A}^{\star}_{\le k}(\mathcal{F})$ is $O(k^{3+\varepsilon}\psi(n/k))$ for any $\varepsilon > 0$, where the constant of proportionality depends on ε and on the maximum complexity of any of the functions in $\mathcal{F}$.*

3. Shallow cuttings. In this section we first define $(1/r)$-cuttings of $\mathcal{A}_{\le k}(\mathcal{F})$ and then prove the existence of such cuttings with small size.

Let $\mathcal{F}$ be a collection of bivariate functions satisfying conditions (F1) and (F3). We call a region (or cell) $\Delta \subseteq \mathbb{R}^3$ *primitive* if there exists a set $D = D(\Delta)$ of at most six functions in $\mathcal{F}$ such that $\Delta \in \mathcal{A}^{\star}(D)$ and *weakly primitive* if it is the intersection of two primitive cells. For a primitive or a weakly primitive cell Δ, let $\mathcal{F}_\Delta \subseteq \mathcal{F}$ be the set of functions whose graphs intersect the interior of Δ and put $n_\Delta = |\mathcal{F}_\Delta|$. A set Ξ of pairwise openly disjoint weakly primitive cells is called a $(1/r)$-*cutting of* $\mathcal{A}_{\le k}(\mathcal{F})$

if the union of Ξ contains $\mathcal{A}_{\leq k}(\mathcal{F})$ and if $n_\Delta \leq n/r$ for every $\Delta \in \Xi$. We also refer to such a cutting as a *shallow cutting* in the arrangement $\mathcal{A}(\mathcal{F})$.

By the ε-net theory [40] and the result of [18], there exists a $(1/r)$-cutting of the entire $\mathcal{A}(\mathcal{F})$ that consists of $O(r^3\beta(r)\log^3 r)$ *primitive* cells, where $\beta(r)$ is the extremely slowly growing function defined in the previous section. Moreover, if r is a constant, such a cutting can be constructed in $O(n)$ deterministic time, using the technique of [50]. We now prove the existence of small-size $(1/r)$-cuttings of $\mathcal{A}_{\leq k}(\mathcal{F})$.

THEOREM 3.1. *Let $\mathcal{F}$ be a collection of n bivariate functions, as above, and let $k, r < n$ be integers. Set $q = k(r/n) + 1$. Then there exists a $(1/r)$-cutting Ξ of $\mathcal{A}_{\leq k}(\mathcal{F})$ whose size is at most $C_1 q^{3+\varepsilon}\psi(r/q)$, where $C_1 = C_1(\varepsilon)$ is an appropriate constant. Moreover, if $r = O(1)$, a $(1/r)$-cutting of this size can be computed in $O(n)$ time.*

Matoušek [52] proved a similar result for the case of linear functions. We follow his proof, but we need to enhance it with additional machinery.

Proof. For a subset $\mathcal{G} \subseteq \mathcal{F}$ and an integer $j < n$, let $\mathcal{T}_j(\mathcal{G})$ be the set of primitive cells Δ in $\mathcal{A}^\star(\mathcal{G})$ that lie completely in $\mathcal{A}_{\leq j}(\mathcal{F})$ (i.e., the level of all points in Δ with respect to $\mathcal{F}$ is at most j). In other words,

$$\mathcal{T}_j(\mathcal{G}) = \{\Delta \in \mathcal{A}^\star(\mathcal{G}) \mid \mu_{\mathcal{F}}(p) \leq j \text{ for all } p \in \Delta\}.$$

Let $\mathcal{T}_j = \bigcup_{\mathcal{G} \subseteq \mathcal{F}} \mathcal{T}_j(\mathcal{G})$.

Fix $p = r/n$. Choose a subset $R \subseteq \mathcal{F}$ by selecting each function of $\mathcal{F}$ independently with probability p. For each cell $\Delta \in \mathcal{A}^\star(R)$ that has a point whose level with respect to $\mathcal{F}$ is at most k, we do the following. If $|n_\Delta| \leq n/r$, we add Δ to Ξ. Otherwise, suppose that $(t-1)n/r < n_\Delta \leq tn/r$ for some integer $t > 1$. (We then say that the *excess* of such a Δ is t.) We compute a $(1/t)$-cutting Ξ_Δ of $\mathcal{A}(\mathcal{F}_\Delta)$, which consists of $O(t^3\beta(t)\log^3 t)$ primitive cells, clip each cell of Ξ_Δ within Δ, and add the resulting (weakly primitive) cells to Ξ. This yields a $(1/r)$-cutting Ξ of $\mathcal{A}_{\leq k}(\mathcal{F})$. We now show that the expected size of Ξ is as asserted in the theorem.

Let $\eta(p, t, j)$ denote the expected number of those cells Δ in $\mathcal{T}_j(R)$ whose excess is at least t. If any cell $\Delta \in \mathcal{A}^\star(R)$ with excess t intersects $\mathcal{A}_{\leq k}(\mathcal{F})$, then the level of all points of Δ with respect to $\mathcal{F}$ is at most $k + tn/r$. This is easily seen to imply

$$\mathbf{E}[|\Xi|] \ \leq \ \eta(p, 0, k) + \sum_{t \geq 1} O(t^3\beta(t)\log^3 t) \cdot \eta\left(p, t, k + \left\lceil \frac{tn}{r} \right\rceil\right).$$

A primitive cell $\Delta \in \mathcal{T}_j$ appears in $\mathcal{T}_j(R)$ if and only if $D(\Delta) \subseteq R$ and $\mathcal{F}_\Delta \cap R = \emptyset$. Using the same argument as in [52] (see also [7, 20]), one can show that for $t \geq 1$,

$$\eta(p, t, j) \leq c2^{-t} \cdot \eta\left(\frac{p}{t}, 0, j\right) \tag{3.1}$$

for a constant $c > 0$. We prove in Lemma 3.2 below that for any $0 < p < 1$ and for any integer $l < n$,

$$\eta(p, 0, k) = O\left((1 + kp)^\varepsilon (kp)^3 \psi\left(\frac{n}{k}\right) + (kp)^2 \min\left\{\psi\left(\frac{n}{k}\right), \left(\frac{n}{k}\right)^2\right\}\right). \tag{3.2}$$

By (3.1) and (3.2), for $t \geq 1$, we obtain

(3.3)
$$\eta\left(p, t, k + \left\lceil \frac{tn}{r} \right\rceil\right) = O\left(2^{-t}\left(1 + \frac{p(k + \lceil tn/r \rceil)}{t}\right)^{\varepsilon}\left(\frac{p(k + \lceil tn/r \rceil)}{t}\right)^{3}\psi\left(\frac{n}{k + tn/r}\right)\right)$$
$$= O\left(2^{-t}q^{3+\varepsilon}\psi\left(\frac{r}{q}\right)\right).$$

The last two inequalities follow because

$$\frac{p(k + \lceil tn/r \rceil)}{t} = \left(\frac{pk}{t} + \frac{\lceil tn/r \rceil}{tn/r}\right) \leq 2 + kp = 2q$$

and

$$\frac{n}{k + tn/r} = \frac{r}{t + kp} \leq \frac{r}{1 + kp} = \frac{r}{q};$$

in particular, the second term in (3.2) is dominated by the first term.

Next, we prove that

$$\eta(p, 0, k) = O\left(q^{3+\varepsilon}\psi\left(\frac{r}{q}\right)\right).$$

If $kp \geq 1$, then by (3.2),

$$\eta(p, 0, k) = O\left((1 + kp)^{\varepsilon}(kp)^{3}\psi\left(\frac{n}{k}\right)\right).$$

Condition (F3) allows us to write

$$\psi\left(\frac{n}{k}\right) = \left(\frac{n}{k}\right)^{\alpha}\beta\left(\frac{n}{k}\right)$$

for some constant $\alpha \leq 2$ and an appropriate small function β. Therefore,

$$(1 + kp)^{\varepsilon}(kp)^{3}\psi\left(\frac{n}{k}\right) = (1 + kp)^{3+\varepsilon}\left(\frac{kp}{1 + kp}\right)^{3}\left(\frac{np}{kp}\right)^{\alpha}\beta\left(\frac{np}{kp}\right)$$
$$= O\left(q^{3+\varepsilon}\left(\frac{kp}{1 + kp}\right)^{3-\alpha}\psi\left(\frac{np}{1 + kp}\right)\right)$$
$$= O\left(q^{3+\varepsilon}\psi\left(\frac{r}{q}\right)\right).$$

The first inequality follows because (F3) is easily seen to imply that $\beta(\rho m) = O(\beta(m))$ for any $\rho \leq 2$, say.

On the other hand, if $kp < 1$ and $\alpha = 2 - \delta$, for some $\delta > 0$, then $q \leq 2$ and (3.2) implies that

$$\eta(p, 0, k) = O\left((1 + kp)^{\varepsilon}(kp)^{2}\psi\left(\frac{n}{k}\right)\right)$$
$$= O\left(q^{2+\varepsilon}\left(\frac{kp}{1 + kp}\right)^{2}\left(\frac{np}{kp}\right)^{2-\delta}\beta\left(\frac{np}{kp}\right)\right)$$
$$= O\left(q^{2+\varepsilon}\left(\frac{kp}{1 + kp}\right)^{\delta}\left(\frac{r}{q}\right)^{\alpha}\beta\left(\frac{r}{q}\cdot\frac{1 + kp}{kp}\right)\right)$$
$$= O\left(q^{3+\varepsilon}\psi\left(\frac{r}{q}\right)\right).$$

The last inequality follows because, by (F3), $\beta(\rho m) \leq \rho^{\delta}\beta(m)$ for any $\rho \geq 1$ and for any $\delta > 0$, provided that m is sufficiently large.

Finally, if $kp < 1$ and $\alpha = 2$, then again $q \leq 2$ and (3.2) implies that

$$\begin{aligned}
\eta(p,0,k) &= O\left((1+kp)^{\varepsilon}(kp)^3\psi\left(\frac{n}{k}\right) + (kp)^2\left(\frac{n}{k}\right)^2\right)\\
&= O\left(q^{3+\varepsilon}\left(\frac{kp}{1+kp}\right)\left(\frac{np}{1+kp}\right)^2\beta\left(\frac{np}{kp}\right) + r^2\right)\\
&= O\left(q^{3+\varepsilon}\psi\left(\frac{r}{q}\right) + q^2\left(\frac{r}{q}\right)^2\right)\\
&= O\left(q^{3+\varepsilon}\psi\left(\frac{r}{q}\right)\right).
\end{aligned}$$

Hence,

$$\begin{aligned}
\mathbf{E}[\,|\Xi|\,] &= O\left(q^{3+\varepsilon}\psi\left(\frac{r}{q}\right)\right) + \sum_{t\geq 1} O(t^3 2^{-t}\beta(t)\log^3 t)\cdot O\left(q^{3+\varepsilon}\psi\left(\frac{r}{q}\right)\right)\\
&= O\left(q^{3+\varepsilon}\psi\left(\frac{r}{q}\right)\right).
\end{aligned}$$

Finally, observe that the proof of this theorem is constructive, so we immediately obtain a randomized algorithm for computing Ξ. If $r = O(1)$, then the expected running time is $O(n)$. The algorithm can be made deterministic using the method of conditional probabilities, as described in [16, 50]. ◻

To complete the analysis, we establish the promised lemma.

LEMMA 3.2. *For any real number $0 < p < 1$ and for any integer $k < n$,*

$$\eta(p,0,k) = O\left((1+kp)^{\varepsilon}(kp)^3\psi\left(\frac{n}{k}\right) + (kp)^2\min\left\{\psi\left(\frac{n}{k}\right), \left(\frac{n}{k}\right)^2\right\}\right).$$

Proof. Let R be, as above, a random subset of $\mathcal{F}$ obtained by choosing each element of $\mathcal{F}$ independently with probability p. We want to bound the expected number of those primitive cells Δ in $\mathcal{A}^{\star}(R)$ that belong to $\mathcal{T}_k(R)$, i.e., the level of all points in Δ with respect to $\mathcal{F}$ is at most k. Each cell $\Delta \in \mathcal{A}^{\star}(R)$ is of one of the following three types (these types are not mutually exclusive):

(C1) Δ contains a vertex v of $\mathcal{A}(R)$; if $\Delta \in \mathcal{T}_k(R)$, then $\mu_{\mathcal{F}}(v) \leq k$.

(C2) Δ has a vertical face parallel to the yz-plane and tangent to an edge e of $\mathcal{A}(R)$ at some point w; if $\Delta \in \mathcal{T}_k(R)$, then $\mu_{\mathcal{F}}(w) \leq k$.

(C3) Δ has a vertical edge induced by an edge-crossing $(e, e', \sigma) \in \mathcal{C}_0(e, R)$ for some $e \in \mathcal{A}(R)$. If $\Delta \in \mathcal{T}_k(R)$, then $\mu_{\mathcal{F}}(e \cap \ell_{\sigma}) \leq k$.

A vertex $v \in \mathcal{A}_{\leq k}(\mathcal{F})$ appears as a vertex of $\mathcal{A}(R)$ if and only if the three functions whose graphs contain v are chosen in R. Moreover, under the general position assumption, each vertex of $\mathcal{A}(R)$ appears in $O(1)$ cells of $\mathcal{A}^{\star}(R)$. Therefore, the expected number of cells in $\mathcal{T}_k(R)$ of type (C1) is at most

$$\begin{aligned}
O\Bigg(\sum_{v\in\mathcal{A}_{\leq k}(\mathcal{F})} \Pr\left[\, v \text{ is a vertex of } \mathcal{A}(R)\,\right]\Bigg) &= O(p^3\psi(n,k)) = O((kp)^3)\psi\left(\frac{n}{k}\right)\\
&= O((1+kp)^{\varepsilon}(kp)^3)\left(\frac{n}{k}\right).
\end{aligned}$$

Similarly, the number of cells in $\mathcal{T}_k(R)$ of type (C2) can be bounded by

$$O\Bigl(\sum_w \Pr\left[\, w \text{ appears in } \mathcal{A}(R)\,\right]\Bigr),$$

where the sum is taken over all locally x-extremal points on the edges of $\mathcal{A}_{\leq k}(\mathcal{F})$. The probability of such a point appearing in $\mathcal{A}_{\leq k}(\mathcal{F})$ is p^2. By conditions (F1) and (F2), the number of x-extremal points in the relative interior of the edges of $\mathcal{A}_{\leq k}(\mathcal{F})$ is $O(n^2)$. On the other hand, another application of the Clarkson–Shor technique [25] implies that the number of such x-extremal points is $O(k^2\psi'(n/k))$, where $\psi'(n/k)$ is the number of x-extremal points in the relative interior of the edges of the lower envelope of at most n/k functions of $\mathcal{F}$. Since $\psi'(n/k) \leq \psi(n/k)$, we can bound the number of type (C2) cells by

$$O\left((kp)^2 \min\left\{\psi\left(\frac{n}{k}\right), \left(\frac{n}{k}\right)^2\right\}\right).$$

Next, consider the cells of type (C3). Let

$$\Phi(R,k) = \bigcup_{e\in\mathcal{A}(R)} \left\{(e,e',\sigma) \in \mathcal{C}_0(e,R) \mid \mu_{\mathcal{F}}(e\cap \ell_\sigma) \leq k\right\}.$$

In order to bound the expected number of cells of type (C3), it suffices to obtain an upper bound on the expected value of $|\Phi(R,k)|$.

We proceed as in the proof of Lemma 2.3. Let e be an edge of $\mathcal{A}_{\leq k}(\mathcal{F})$, and let $(e,e',\sigma) \in \mathcal{C}_j(e,\mathcal{F})$ for some $0 \leq j \leq k-2$. The edge-crossing (e,e',σ) contributes (exactly) one edge-crossing to $\Phi(R,k)$ if and only if the four functions of $\mathcal{F}$ defining e and e' are chosen in R and none of the j functions whose graphs intersect the line ℓ_σ between e and e' is chosen in R. The probability that (e,e',σ) gives rise to one edge-crossing in $\Phi(R,k)$ is thus $p^4(1-p)^j$. Since every edge-crossing of $\Phi(R,k)$ is of this form, we obtain

$$\begin{aligned}
\mathbf{E}\bigl[|\Phi(R,k)|\bigr] &= \sum_{j=0}^{k-2} \sum_{e\in\mathcal{A}_{\leq k}(\mathcal{F})} \sum_{(e,e',\sigma)\in\mathcal{C}_j(e,\mathcal{F})} p^4(1-p)^j \\
&= \sum_{j=0}^{k-2} p^4(1-p)^j \varphi_j(\mathcal{F},k) \\
&= p^4\varphi_0(\mathcal{F},k) + \sum_{j=1}^{k-2} p^4(1-p)^j \left(\varphi_{\leq j}(\mathcal{F},k) - \varphi_{\leq j-1}(\mathcal{F},k)\right) \\
&\leq p^4(1-p)^{k-2}\varphi_{\leq k-2}(n,k) + \sum_{j=0}^{k-3} p^5(1-p)^j \varphi_{\leq j}(n,k) \\
&\leq p^4(1-p)^{k-2}\cdot A(k-1)^4\varphi_0\left(\left\lceil\frac{2n}{k-1}\right\rceil, \left\lceil\frac{2k}{k-1}\right\rceil\right) \\
&\quad + \sum_{j=0}^{k-3} p^5(1-p)^j \cdot A(j+1)^4\varphi_0\left(\left\lceil\frac{2n}{j+1}\right\rceil, \left\lceil\frac{2k}{j+1}\right\rceil\right) \\
&\qquad \text{(applying Lemma 2.3)}
\end{aligned}$$

$$
\begin{aligned}
&\le Ap^4(1-p)^{k-2}(k-1)^4 \cdot D\left\lceil \frac{2k}{k-1}\right\rceil^{3+\varepsilon} \psi\left(\frac{2n}{k}\right) \\
&\quad + \sum_{j=0}^{k-3} Ap^5(1-p)^j(j+1)^4 \cdot D\left\lceil \frac{2k}{j+1}\right\rceil^{3+\varepsilon} \psi\left(\frac{2n}{k}\right) \\
&\qquad \text{(applying (2.10))} \\
&= O\left((kp)^{3+\varepsilon}\psi\left(\frac{n}{k}\right)\right)\left[p(k-1)(1-p)^{k-2} + \sum_{j=0}^{k-3} p^2(j+1)(1-p)^j\right] \\
&= O\left((1+kp)^{\varepsilon}(kp)^3\psi\left(\frac{n}{k}\right)\right).
\end{aligned}
$$

The last inequality follows from the fact that the sum in the square brackets is $1-(1-p)^{k-1} \le 1$. This completes the proof of the lemma and thus the proof of Theorem 3.1. $\square$

Remark 3.3. We note that if $\mathcal{F}$ is a collection of n univariate functions, then $\mathcal{A}^\star(\mathcal{F})$ has only $O(n^2)$ cells and $\psi(n,k) = O(k^2\lambda_s(n/k))$, where s is the maximum number of intersections between the graphs of any pair of functions in $\mathcal{F}$. Following the preceding analysis, one can obtain the following result.

THEOREM 3.4. *Let $\mathcal{F}$ be a collection of n univariate algebraic functions, each of constant maximum degree, and let $k, r < n$ be integers. Set $q = k(r/n)+1$. Then there exists a $(1/r)$-cutting Ξ of $\mathcal{A}_{\le k}(\mathcal{F})$ whose size is at most $O(q^2\lambda_s(r/q))$. Moreover, if $r = O(1)$, a $(1/r)$-cutting of this size can be computed in $O(n)$ time.*

4. Range searching.

An immediate consequence of Theorem 3.1 is an efficient solution of the following problem: Given a set $\mathcal{F} \subseteq \mathbf{F}$ of n bivariate functions satisfying the conditions (F1) and (F3), preprocess it into a (static) data structure, so that for a query point $p = (x_p, y_p, z_p)$, the subset $\{f \in \mathcal{F} \mid f(x_p, y_p) < z_p\}$ can be reported efficiently. We also want to update $\mathcal{F}$ dynamically by inserting and deleting functions of $\mathbf{F}$ into/from $\mathcal{F}$.

Chazelle et al. [18] have shown that $\mathcal{F}$ can be preprocessed in time $O(n^{3+\varepsilon})$ into a (static) data structure of size $O(n^{3+\varepsilon})$ so that a query can be answered in $O(\log n + \xi)$ time, where ξ is the output size. In this section we present a data structure that uses $O(\psi(n) \cdot n^{\varepsilon})$ storage and preprocessing time, answers a query in $O(\log n + \xi)$ time, and can be updated dynamically at a small (amortized) cost. We first present a static data structure and then explain how to dynamize it.

4.1. A static data structure.

We construct a tree data structure T to answer queries of the above form. Each node v of T is associated with a subset $\mathcal{F}^v \subseteq \mathcal{F}$ and a weakly primitive cell $\Delta_v \subseteq \mathbb{R}^3$. The root is associated with $\mathcal{F}$ and with the entire $\mathbb{R}^3$. Fix a sufficiently large constant r and set $k = \lfloor 2n/r \rfloor$. If $|\mathcal{F}|$ is less than some prespecified constant n_0, then T consists of just the root. Otherwise, we compute a $(1/r)$-cutting Ξ of $\mathcal{A}_{\le k}(\mathcal{F})$, whose size, by Theorem 3.1 and (F3), is $O(\psi(r))$ (where the constant of proportionality is independent of r). For each cell $\Delta \in \Xi$, let $\mathcal{F}_\Delta^- \subseteq \mathcal{F}$ be the set of functions whose graphs either intersect Δ or lie below Δ. If $|\mathcal{F}_\Delta^-| > 3n/r$, we discard Δ because Δ lies completely above $\mathcal{A}_{\le k}(\mathcal{F})$. Otherwise, we create a child $v = v_\Delta$ of the root, corresponding to Δ, put $\Delta_v = \Delta$ and $\mathcal{F}^v = \mathcal{F}_\Delta^-$, and recursively preprocess $\mathcal{F}^v$ (in this recursive processing, we use the same parameter r and set $k = \lfloor 2|\mathcal{F}^v|/r \rfloor$). The recursion stops when we reach nodes v with $|\mathcal{F}^v| \le n_0$. If $S(n)$ denotes the maximum space used by the data structure, on any set $\mathcal{F}$ of n functions of $\mathbf{F}$, then we obtain the recurrence

$$S(n) \leq \begin{cases} c_0, & n \leq n_0, \\ c_1\psi(r) \cdot S(3n/r) + c_2 n, & n > n_0, \end{cases}$$

where c_0, c_1, c_2 are appropriate constants (independent of r). Recall that, by (F3), the bound $\psi(n)$ can be written as $n^\alpha\beta(n)$, where $1 \leq \alpha \leq 2$ is some constant and where $\limsup_{n\to\infty} \beta(n)/n^\delta = 0$ for any $\delta > 0$. The solution of the recurrence is

$$S(n) \leq B\psi(n) \cdot n^\varepsilon,$$

for any $\varepsilon > 0$, where B depends on ε. The proof is by induction on n. The claim holds for all $n \leq n_0$, provided that B is chosen sufficiently large. For larger values of n we have, by the induction hypothesis,

$$\begin{aligned} S(n) &\leq c_1\psi(r) \cdot B\psi\left(\frac{3n}{r}\right) \cdot \left(\frac{3n}{r}\right)^\varepsilon + c_2 n \\ &\leq c_1 B r^\alpha \beta(r) \left(\frac{3n}{r}\right)^\alpha \beta\left(\frac{3n}{r}\right) \cdot \left(\frac{3n}{r}\right)^\varepsilon + c_2 n \\ &\leq B \cdot n^\alpha \beta(n) \cdot n^\varepsilon \left[\frac{3^{\alpha+\varepsilon} c_1 \beta(r)}{r^\varepsilon} + \frac{c_2 n^{1-\alpha-\varepsilon}}{B\beta(n)}\right] \\ &\leq B\psi(n) n^\varepsilon, \end{aligned}$$

provided that r and B are chosen sufficiently large (as functions of ε). The preprocessing time of the data structure is also easily seen to be $O(\psi(n) \cdot n^\varepsilon)$.

Let p be a query point. To answer the query for p, we trace a path in T, starting from the root. Suppose we are at a node v. If v is a leaf or if there is no child w of v for which $p \in \Delta_w$, we explicitly check for each $f \in \mathcal{F}^v$ (the set of functions associated with v) whether p lies above the graph of f, and we report those functions which satisfy this condition. The time spent at v is then $O(|\mathcal{F}^v|)$, but then either $|\mathcal{F}^v| \leq n_0$ or p lies above the $\lfloor 2|\mathcal{F}^v|/r \rfloor$-level in $\mathcal{A}(\mathcal{F}^v)$, so we report at least $\lfloor 2|\mathcal{F}^v|/r \rfloor$ functions. If there is a child w of v such that $p \in \Delta_w$, we recursively visit that child. The overall query time is $O(\log n + \xi)$, where ξ is the output size of the query. Hence, we obtain the following result.

THEOREM 4.1. *Given a family* $\mathbf{F}$ *of bivariate functions satisfying* (F1) *and* (F3) *and a set* $\mathcal{F} \subseteq \mathbf{F}$ *of size* n*, we can preprocess* $\mathcal{F}$ *(in an appropriate model of computation) in time* $O(\psi(n) \cdot n^\varepsilon)$ *into a data structure* $\Pi(\mathcal{F})$ *of size* $O(\psi(n) \cdot n^\varepsilon)$*, so that all* ξ *functions whose graphs lie below a query point* p *can be reported in time* $O(\log n + \xi)$.

Remark 4.2. If we are interested only in determining whether a query point lies below the graphs of all the functions of $\mathcal{F}$, we can construct the minimization diagram, $M(\mathcal{F})$, of $\mathcal{F}$ and preprocess $M(\mathcal{F})$ for planar point-location queries. The size of the data structure is $O(\psi(n))$, and a query can be answered in time $O(\log n)$; see, for example, [66].

4.2. A dynamic data structure. We can dynamize the above data structure using the technique of Agarwal and Matoušek [6]. Since the basic idea is the same, we give only a brief description of the structure. For the sake of simplicity, we describe a data structure that handles only deletions; insertions can then be handled using standard decomposition techniques [6, 15].

We need the following lemma, which is an easy consequence of a result by Chazelle et al. [18], but we give a somewhat simpler proof.

LEMMA 4.3. *Let Ξ be a cutting in $\mathbb{R}^3$ consisting of t cells. Ξ can be preprocessed in time $O(t^3)$ into a data structure of size $O(t^3)$, so that we can determine in $O(\log t)$ time the cell of Ξ containing a query point p, or we can conclude that there is no such cell.*

Proof. Assume that the faces of Ξ are xy-monotone, which will hold in our applications. (However, the proof also holds when this is not the case, by appropriately decomposing each face of the cutting cells (each of which is assumed to have constant description complexity) into a constant number of xy-monotone subfaces.) Project each face onto the xy-plane. Let Ξ^* be the set of the resulting planar patches. For a point $p \in \mathbb{R}^2$, let $\Lambda(p)$ be the list of faces of Ξ, sorted in the $+z$-direction, that intersect the z-vertical line passing through p. We compute the arrangement $\mathcal{A}(\Xi^*)$. Since the interiors of all cells of Ξ are pairwise disjoint, $\Lambda(p)$ is same for all points within a face of $\mathcal{A}(\Xi^*)$. For each face $\phi \in \mathcal{A}(\Xi^*)$, we store this sorted list, denoted by $\Lambda(\phi)$. This requires a total of $O(t^3)$ space and can be computed in time $O(t^3)$. (In fact, the storage and preprocessing time can be improved to $O(t^2)$ and $O(t^2 \log t)$, respectively, using persistent data structures, but the weaker bounds suffice for our purpose.) To locate a point $w \in \mathbb{R}^3$ in Ξ, we first find the face of $\mathcal{A}(\Xi^*)$ that contains the xy-projection of w and then search with w in the appropriate list $\Lambda(\phi)$ to determine the cell of Ξ containing w. If Ξ does not cover the entire $\mathbb{R}^3$, then the search in $\Lambda(\phi)$ can also determine whether w lies outside Ξ. For example, in the case of shallow cuttings, if w lies above all faces in $\Lambda(\phi)$, we can conclude that w does not lie in any cell of Ξ. □

We are now in position to describe the data structure. The overall data structure, denoted as $\Psi(\mathcal{F})$, is a tree of constant depth. Each node v of $\Psi(\mathcal{F})$ is associated with a subset $\mathcal{F}^v \subseteq \mathcal{F}$. The subtree rooted at any node of $\Psi(\mathcal{F})$ is reconstructed periodically after performing some deletions. Let m_v (resp., m) be the size of $\mathcal{F}^v$ (resp., $\mathcal{F}$) when the structure was last reconstructed, and let n_v (resp., n) denote the size of the current set $\mathcal{F}^v$ (resp., $\mathcal{F}$). Set $r = m^\delta$ for some sufficiently small $\delta > 0$. (The value of r is the same for all nodes of the tree, and it is updated only when the entire structure $\Psi(\mathcal{F})$ is reconstructed.) We reconstruct the subtree rooted at v after performing $m_v/2r$ deletions from that subtree. Hence, $n_v \geq m_v(1 - 1/2r)$. A function $f \in \mathcal{F}$ is said to be *relevant* for a cell Δ if the graph of f either intersects Δ or lies below Δ.

If $|\mathcal{F}| \leq r$, $\Psi(\mathcal{F})$ consists of a single node at which we preprocess $\mathcal{F}$ into the range-searching data structure, $\Pi(\mathcal{F})$, provided in Theorem 4.1. Otherwise, the root u of $\Psi(\mathcal{F})$ stores the following information:

(i) a partition of $\mathcal{F}^u$ into pairwise-disjoint sets $\mathcal{F}_1, \ldots, \mathcal{F}_t$, where $t \leq \lceil 1/\delta^2 \rceil$;

(ii) a cutting Ξ_i for each $1 \leq i \leq t$. Initially, Ξ_i is a $(1/r)$-cutting of $\mathcal{A}_{\leq k}(\bigcup_{j \geq i} \mathcal{F}_j)$, where $k = \lfloor m/r \rfloor$ and each function of $\mathcal{F}_i$ is relevant for at most

$$\kappa = 2C_1 \frac{\psi(r)}{r^{1-\delta}} \tag{4.1}$$

cells of Ξ_i, where C_1 is the constant arising in (4.2) below;

(iii) a data structure for point-location queries for each Ξ_i, as in Lemma 4.3;

(iv) a pointer to the subtree $\Psi(\mathcal{F}_{i,\Delta})$ for every i and for every $\Delta \in \Xi_i$, where $\mathcal{F}_{i,\Delta} \subseteq \mathcal{F}_i$ is the set of functions relevant for Δ;

(v) for each $1 \leq i \leq t$ and for every $f \in \mathcal{F}_i$, we store the set $L(f)$ of cells $\Delta \in \Xi_i$ for which f is relevant;

(vi) a counter $dcount_u$, which is initially set to $m/2r$;

(vii) the range-searching data structure $\Pi_u = \Pi(\mathcal{F}^u)$ on $\mathcal{F}^u$, as provided in Theorem 4.1.

This information is computed as follows. We first construct Π_u in $O(\psi(m)m^\varepsilon)$ time, using Theorem 4.1. Next, we construct the $\mathcal{F}_i$'s and Ξ_i's. Suppose we have already computed $\mathcal{F}_1, \ldots, \mathcal{F}_{i-1}$. Let $\overline{\mathcal{F}}_i = \mathcal{F}^u - (\mathcal{F}_1 \cup \cdots \cup \mathcal{F}_{i-1})$, and let $m_i = |\overline{\mathcal{F}}_i|$. If $m_i \leq m/r$, then Ξ_i consists of just one sufficiently large primitive cell and $\mathcal{F}_i = \overline{\mathcal{F}}_i$. Otherwise, set

$$r_i = r\frac{m_i}{m} \quad \text{and} \quad k = \left\lfloor \frac{m}{r} \right\rfloor = \left\lfloor \frac{m_i}{r_i} \right\rfloor.$$

Using Theorem 3.1, we compute a $(1/r_i)$-cutting Ξ_i for $\mathcal{A}_{\leq k}(\overline{\mathcal{F}}_i)$ whose size is at most $C_1\psi(r_i)$. For each cell $\Delta \in \Xi_i$, let $\overline{\mathcal{F}}_{i,\Delta} \subseteq \overline{\mathcal{F}}_i$ be the set of functions relevant for Δ. We have $|\overline{\mathcal{F}}_{i,\Delta}| \leq k + m_i/r_i \leq 2m_i/r_i$. Therefore

$$\sum_{\Delta \in \Xi_i} |\overline{\mathcal{F}}_{i,\Delta}| \leq C_1 \frac{2m_i}{r_i}\psi(r_i) \; = \; 2C_1 m_i \frac{\psi(r_i)}{r_i}. \tag{4.2}$$

We call a function "good" if it is relevant for at most κ cells. Then (4.2) implies that the number of "bad" functions is at most

$$2C_1 m_i \frac{\psi(r_i)}{r_i} \bigg/ 2C_1 \frac{\psi(r)}{r^{1-\delta}} \; = \; \frac{m_i}{r^\delta} \cdot \frac{\psi(r_i)}{r_i} \bigg/ \frac{\psi(r)}{r} \; \leq \; \frac{m_i}{m^{\delta^2}}.$$

Let $\mathcal{F}_i$ be the set of good functions of $\overline{\mathcal{F}}_i$. We now repeat the construction for $\overline{\mathcal{F}}_{i+1} = \overline{\mathcal{F}}_i - \mathcal{F}_i$. The above analysis implies that $|\overline{\mathcal{F}}_i| \leq m^{1-i\delta^2}$, so the process terminates after at most $\lceil 1/\delta^2 \rceil$ steps. The construction of the structure is now completed by recursively building the data structure $\Psi(\mathcal{F}_{i,\Delta})$ for each $\Delta \in \Xi_i$. (The remaining pointers, lists, and counters are trivial to produce.) The size of the data structure and the preprocessing time are both $O(\psi(n)n^\varepsilon)$, arguing as in [6], and the choice of r ensures that the depth of $\Psi(\mathcal{F})$ is $O(1)$.

Deleting a function. We first describe how to delete a function f from $\mathcal{F}$. We traverse $\Psi(\mathcal{F})$ in a top-down fashion. Suppose we are at a node v. If v is a leaf or $dcount_v = 1$, we reconstruct $\Psi(\mathcal{F}^v)$, including Π_v, with the current set of functions in $\mathcal{F}^v$. Otherwise, we decrease the variable $dcount_v$ by 1, and for each cell $\Delta \in L(f)$, we delete f from $\Psi(\mathcal{F}_{i,\Delta})$ recursively. In this case, we do not modify Π_v, so it may contain some of the functions that have been deleted. Following the same analysis as in [6], we can show that the (amortized) deletion time is $O(\psi(n)/n^{1-\varepsilon})$.

Answering a query. Let p be a query point. We again traverse $\Psi(\mathcal{F})$ in a top-down fashion. Suppose we are at a node v. If v is a leaf, we report in $O(\log n + \xi)$ time all ξ functions of $\mathcal{F}^v$ whose graphs lie below p, using the secondary range-searching data structure Π_v. (Note that if v is a leaf, then Π_v does not store any function that has already been deleted.) If v is an internal node, then for each i, we find in $O(\log n)$ time the cell $\Delta_i \in \Xi_i$ that contains p, using the point-location data structure of Lemma 4.3. If Δ_i is defined for every i, we recursively search in $\Psi(\mathcal{F}_{i,\Delta})$ for all $i \leq t$. Otherwise, there is an $i \leq t$ such that p does not lie in any cell of Ξ_i. Let ξ_v (resp., ξ'_v) be the number of functions in $\mathcal{F}^v$ at present (resp., when $\Psi(\mathcal{F}^v)$ was last constructed) whose graphs lie below p. Then $\xi'_v > m_v/r$. At most $m_v/2r$ functions have been deleted since $\Psi(\mathcal{F}^v)$ was last constructed; therefore

$$\xi_v \geq \xi'_v - m_v/2r > \xi'_v - \xi'_v/2 = \xi'_v/2.$$

We query Π_v and report those functions of the query output that have not been deleted so far. The time spent at v is $O(\log n + \xi'_v) = O(\log n + \xi_v)$. The total query time is thus $O(\log n + \xi)$, where ξ is the total output size. We have thus shown the following.

THEOREM 4.4. *Given a family* $\mathbf{F}$ *of* n *bivariate functions satisfying* (F1) *and* (F3) *and a subset* $\mathcal{F} \subseteq \mathbf{F}$ *of size* n*, we can preprocess* $\mathcal{F}$ *(in an appropriate model of computation) in time* $O(\psi(n)\cdot n^{\varepsilon})$ *into a data structure of size* $O(\psi(n)\cdot n^{\varepsilon})$*, so that all* ξ *functions whose graphs lie below a query point can be reported in time* $O(\log n+\xi)$ *and a function* $f \in \mathbf{F}$ *can be inserted into or deleted from* $\mathcal{F}$ *in* $O(\psi(n)/n^{1-\varepsilon})$ *(amortized) time. The same dynamic data structure can be used to determine in* $O(\log n)$ *time whether a query point lies below the graphs of all the functions in the current set* $\mathcal{F}$*.*

5. Computing the ($\le k$)-level. Next, consider the problem of computing $\mathcal{A}_{\le k}(\mathcal{F})$, where $\mathcal{F} \subseteq \mathbf{F}$ is a set of n bivariate functions satisfying (F1) and (F3) and k is any integer $< n$. If $\mathcal{F}$ is a set of linear functions in $\mathbb{R}^3$, this can be done by the randomized algorithm of [1] (see also [27, 58, 59]), whose expected time is $O(nk^2 + n\log^3 n)$, but this algorithm does not extend to nonlinear functions. The algorithm that we present below computes all 0-, 1-, and 2-dimensional faces of $\mathcal{A}_{\le k}(\mathcal{F})$, along with their incidence relations. A slight enhancement of the algorithm can store $\mathcal{A}_{\le k}(\mathcal{F})$ into a data structure, so that for a query point p, we can determine in $O(\log n)$ time whether $\mu_{\mathcal{F}}(p) \le k$, and, if so, we return the value of $\mu_{\mathcal{F}}(p)$. We construct $\mathcal{A}_{\le k}(\mathcal{F})$ using a divide-and-conquer algorithm, based on our shallow cutting theorem, as follows. A similar algorithm was developed by Clarkson [23] for computing the ($\le k$)-level in an arrangement of hyperplanes.

Choose a sufficiently large constant integer parameter r. If $k \ge n/r$, construct the entire arrangement $\mathcal{A}(\mathcal{F})$ and output the first k levels. The time and storage required are $O(n^3 \log n)$ and $O(n^3)$, respectively. This can be done using one of several known techniques; e.g., for each function $f \in \mathcal{F}$, we compute the intersection curves of f with all the other functions of $\mathcal{F}$ and then compute, by a line-sweep algorithm that takes $O(n^2 \log n)$ time, all the faces of $\mathcal{A}_{\le k}(\mathcal{F})$ that lie on the graph of f.

Otherwise, the parameter $q = 1 + kr/n$ is at most 2. Using Theorem 3.1, we compute in $O(n)$ time a $(1/r)$-cutting Ξ of size $O(\psi(r))$ for $\mathcal{A}_{\le k}(\mathcal{F})$. For each cell $\Delta \in \Xi$, compute the set $\mathcal{F}_\Delta$ of the functions whose graphs cross Δ and the set $\mathcal{F}^-_\Delta$ of the functions whose graphs pass fully below Δ. If $|\mathcal{F}^-_\Delta| > k$, then discard Δ. For the remaining cells, we have $|\mathcal{F}_\Delta| \le n/r$ and $k' = |\mathcal{F}^-_\Delta| \le k$. We now construct recursively $\mathcal{A}_{\le k-k'}(\mathcal{F}_\Delta)$, repeat this construction over all cells of Ξ, and glue together the resulting outputs. The gluing step involves merging those faces which are computed by separate subproblems and which are portions of the same face of $\mathcal{A}(\mathcal{F})$. This can be accomplished in time proportional to the total output size by a rather straightforward procedure, operating on each surface separately, whose details are omitted.

Let $T(n,k)$ denote the maximum time needed to construct $\mathcal{A}_{\le k}(\mathcal{F})$, where $|\mathcal{F}| = n$. Then we obtain the following recurrence:

$$T(n,k) \le \begin{cases} c_1\psi(r)\cdot T\left(\dfrac{n}{r}, k\right) + c_2 n, & \text{for } k < n/r, \\ c_3 n^3 \log n, & \text{for } k \ge n/r, \end{cases}$$

where c_1, c_2, c_3 are appropriate constants. It is easily seen, arguing as in the analysis leading to Theorem 4.1, that the solution of this recurrence is

$$T(n,k) = O(k^3 n^{\varepsilon} \psi(n/k)),$$

which is close to optimal in the worst case. Hence, we obtain the following result.

THEOREM 5.1. *Let* $\mathbf{F}$ *be a family of bivariate functions satisfying* (F1) *and* (F3). *Given a set* $\mathcal{F} \subseteq \mathbf{F}$ *of size* n *and an integer parameter* $k \leq n$, *we can construct* $\mathcal{A}_{\leq k}(\mathcal{F})$ *in time* $O(k^3 n^\varepsilon \psi(n/k))$ *in an appropriate model of computation.*

If we want to store $\mathcal{A}_{\leq k}(\mathcal{F})$ into a data structure for answering point-location queries of the form described above, we keep the cuttings obtained during the above recursive construction in a tree-like structure T. This yields a data structure similar to the one described in the previous section.

For a point p, we answer a query as follows. We trace a path in T from the root down, maintaining a global count of the number of functions that are known to pass below p. Initially we set this count to 0. When we visit a node v, we locate p (by brute force) in the cutting Ξ_v associated with v. If no cell of the cutting contains p, we report that p lies above the k-level and stop. Otherwise, let Δ be the cell of Ξ_v containing p. We add $k' = |\mathcal{F}_\Delta^-|$ to the global count and continue the search at the child of v associated with Δ. When we reach a leaf of T, we explicitly test each of the constant number of functions stored at that leaf whether it passes below p, update the global count accordingly, and output its final value. We thus obtain the following result.

THEOREM 5.2. *Given a collection* $\mathcal{F}$ *of* n *bivariate functions satisfying* (F1)–(F3) *and an integer parameter* $k < n$, *we can preprocess* $\mathcal{A}_{\leq k}(\mathcal{F})$ *into a data structure of size* $O(k^3 n^\varepsilon \psi(n/k))$, *in time* $O(k^3 n^\varepsilon \psi(n/k))$, *so that for any query point* p, *we can determine in* $O(\log n)$ *time whether* $\mu_{\mathcal{F}}(p) \leq k$ *and, if so, we compute the value of* $\mu_{\mathcal{F}}(p)$.

6. Nearest-neighbor searching.

Let $S = \{p_1, \ldots, p_n\}$ be a set of n points in the plane, and let $\delta(\cdot, \cdot)$ be a given "distance function" defined on $\mathbb{R}^2 \times \mathbb{R}^2$. Normally, we would take δ to be a metric or a convex distance function, but many of the results obtained below apply for more general "reasonable" functions δ. The function δ is called *reasonable* if the family

$$\mathbf{F} = \{\delta((x,y),(a_1,a_2)) \mid (a_1,a_2) \in \mathbb{R}^2\}$$

satisfies conditions (F1) and (F3) of section 2. For example, all L_p metrics, for integer $1 \leq p \leq \infty$, are reasonable. Here we do not assume any metric-like properties of δ, so δ can be fairly arbitrary. We want to store S into a data structure so that points can be inserted into or deleted from S and for any query point q, we can efficiently compute a *nearest neighbor* of q in S under the function δ (i.e., we want to return a point $p_i \in S$ so that $\delta(q, p_i) = \min_{1 \leq j \leq n} \delta(q, p_j)$). We may also want to return k nearest neighbors of a query point for some $k \geq 1$. Let

$$\mathcal{F} = \{f_i(x,y) = \delta((x,y), p_i) \mid 1 \leq i \leq n\}.$$

For a given point q, finding a nearest neighbor of q in S is equivalent to computing a function of $\mathcal{F}$ that attains the lower envelope $E_{\mathcal{F}}$ of $\mathcal{F}$ at q. Notice that the complexity of the lower envelope $E_{\mathcal{F}}$ is the same as the complexity of the Voronoi diagram of S under the distance function δ [31] if δ is indeed a metric or a convex distance function.

The nearest-neighbor searching problem, also known as the post-office problem, has been widely studied because of its numerous applications [4, 6, 23, 53], but most of the work to date deals with the case where δ is the L_1, L_2, or L_∞ metric and where S does not change dynamically. If δ is a reasonable function, then we can construct the minimization diagram of the resulting envelope $E_{\mathcal{F}}$ and preprocess it for planar point-location queries. Therefore a nearest-neighbor query can be answered in $O(\log n)$ time using $O(n^{2+\varepsilon})$ storage, but this data structure is difficult to dynamize. On the other hand, using the range-searching data structures of Agarwal and Matoušek [5], S can be preprocessed in $O(n \log n)$ time into a linear-size data structure so that a query can be answered in $O(n^{1/2+\varepsilon})$ time. This data structure can be updated in $O(\log^2 n)$ time per insertion or deletion. Since the Agarwal–Matoušek technique will be useful for our applications, we describe it briefly. Let

$$\Gamma = \{\delta((x,y),(\alpha,\beta)) \le r \mid \alpha,\beta,r \in \mathbb{R}\}$$

be the set of all "disks" under the distance function δ. We preprocess S, in $O(n \log n)$ time, into a linear size data structure for the counting version of Γ-range searching (in which, for any given $\gamma \in \Gamma$, we want to compute $|S \cap \gamma|$), as described in [5]. Using this data structure for a query point q and a real parameter r, we can determine in $O(n^{1/2+\varepsilon})$ time whether the distance between q and its nearest neighbor in S is less than, greater than, or equal to r. Plugging this procedure into the parametric-searching technique of Megiddo [55] (in the same manner as in [4]), we can answer a nearest-neighbor query, under the distance function δ, in $O(n^{1/2+\varepsilon})$ time. This structure, however, fails to answer a query in $O(\log n)$ time even for the Euclidean metric.

In this section we present a data structure, based on Theorem 4.4, that uses only $O(\psi(n) \cdot n^{\varepsilon})$ space and preprocessing time, answers a query in $O(\log n)$ time, and inserts or deletes a point in $O(\psi(n)/n^{1-\varepsilon})$ time. Moreover, it can also report k nearest neighbors of a query point in time $O(\log n + k)$. These bounds are significantly better than the previously mentioned bounds if we allow insertions/deletions or if we want to answer k-nearest-neighbor queries. As an example, for the case of L_p metrics, we can obtain a nearest-neighbor searching data structure of size $O(n^{1+\varepsilon})$ that can answer a query in $O(\log n)$ time (or a k-nearest-neighbor query in time $O(\log n + k)$) and that can insert/delete a point in $O(n^{\varepsilon})$ time. Compared with the data structure described in [6], we improve the query time significantly at a slight increase in the update time and in the size of the data structure.

6.1. A static data structure. As in section 4, we first describe a static data structure. This data structure is more complicated than simply storing the Voronoi diagram of S (or, more generally, the minimization diagram of the envelope $E_{\mathcal{F}}$), but it allows us to answer efficiently k-nearest-neighbor queries. We preprocess S, or, rather, the associated collection $\mathcal{F}$, into the range-searching data structure $\Pi(\mathcal{F})$ of Theorem 4.1. For a point $q \in \mathbb{R}^2$, we find a function of $\mathcal{F}$ that attains $E_{\mathcal{F}}$ at q, and thus find a nearest neighbor of q in S, as follows. Let $\vec{\ell}$ be the vertical line in $\mathbb{R}^3$ passing through q and oriented in the $(+z)$-direction. We trace a path in the tree-structure $T = \Pi(\mathcal{F})$, starting from the root. Suppose we are at a node $v \in T$; v is associated with a subset $\mathcal{F}^v \subseteq \mathcal{F}$ and a weakly primitive cell Δ_v. Inductively, assume that $E_{\mathcal{F}}(q) = E_{\mathcal{F}^v}(q)$. If v is a leaf, we explicitly search for a function of $\mathcal{F}^v$ that attains $E_{\mathcal{F}^v}$ at q, report that function, and terminate the query. Recall that if v is not a leaf, then each child of v is associated with a cell of a $(1/r)$-cutting Ξ_v of $\mathcal{A}_{\le k}(\mathcal{F}^v)$ (for appropriate parameters r and k). We determine the highest cell Δ of Ξ_v (in the $(+z)$-direction) intersected by $\vec{\ell}$. Since Ξ_v covers $\mathcal{A}_{\le k}(\mathcal{F}^v)$, Δ is the last cell in Ξ_v intersecting $\vec{\ell}$, and $\mathcal{F}_{\Delta}^-$ contains all functions of $\mathcal{F}^v$ whose graphs either intersect Δ or lie below Δ, it easily follows that $E_{\mathcal{F}_{\Delta}^-}(q) = E_{\mathcal{F}^v}(q) = E_{\mathcal{F}}(q)$. Hence, we can recursively search at the child w corresponding to Δ (where $\mathcal{F}^w = \mathcal{F}_{\Delta}^-$). The overall query time is obviously $O(\log n)$.

6.2. A dynamic data structure. If S is allowed to change dynamically, we use the dynamic data structure described in section 4 with the following modification. For a $(1/r)$-cutting Ξ, we now need a data structure that, for a given query point q in the xy-plane, can determine in $O(\log|\Xi|)$ time the highest cell of Ξ intersected by the vertical line $\vec{\ell}$ passing through q. As in Lemma 4.3, we project the facets of cells in Ξ onto the xy-plane, let Ξ^* be the set of resulting regions in the plane, and compute the arrangement $\mathcal{A}(\Xi^*)$. Since the (interiors of) cells in Ξ are pairwise disjoint, the highest cell of Ξ intersected by a vertical line erected from any point within a face $\phi \in \mathcal{A}(\Gamma)$ is the same. By storing this cell for each face ϕ and by preprocessing $\mathcal{A}(\Xi^*)$ for planar point location queries, we can compute in $O(\log|\Xi|)$ time the highest cell of Ξ intersected by a vertical line.

A query is answered as follows: Suppose we are at a node v. If v is a leaf, we compute $E_{\mathcal{F}^v}(q)$, using the procedure just described (or the simpler one that stores explicitly the lower envelope). Otherwise, for each Ξ_i, we find in $O(\log n)$ time the highest cell Δ intersected by $\vec{\ell}$ by locating q in $\mathcal{A}(\Xi_i^*)$ (as in Lemma 4.3). For each $1 \leq i \leq t$, we recursively compute the function f_i that attains the lower envelope $E_{\mathcal{F}_{i,\Delta}}$ at q. Finally, we return the function that attains the envelope of $\{f_1, \ldots, f_t\}$ at q. Since the procedure visits $O(1)$ nodes and spends $O(\log n)$ time at each node, the overall query time is $O(\log n)$. Updating the structure is done as in section 4.

THEOREM 6.1. *Let S be a set of n points in the plane and let δ be any reasonable distance function, as above. We can preprocess S in time $O(\psi(n)n^\varepsilon)$ into a data structure of size $O(\psi(n)n^\varepsilon)$ so that a nearest-neighbor query in S can be answered in $O(\log n)$ time. Moreover, we can insert and delete points into/from S in $O(\psi(n)/n^{1-\varepsilon})$ time per update operation. Here $\psi(n)$ is an upper bound, satisfying* (F3)*, for the maximum complexity of the envelope $E_{\mathcal{F}}$, as defined above (if δ is a metric or a convex distance function, then $\psi(n)$ is also (an upper bound for) the maximum complexity of the Voronoi diagram of a set of n points in the plane, under the distance function δ).*

Remark 6.2. For a point q, finding a farthest neighbor of q in S is equivalent to finding a function of $\mathcal{F}$ that attains the upper envelope of $\mathcal{F}$ at q. By reversing the direction of the z-axis, we can use the same data structure for answering farthest-neighbor queries.

6.3. Reporting the κ nearest (farthest) neighbors. The above query procedures can be modified, so that for a query point q and an integer $\kappa \leq n$, we can compute the κ nearest (or farthest) neighbors of q in S in time $O(\log n + \kappa)$. Consider the static data structure, for instance. We again follow a path of the tree, starting from the root. If we are at a leaf v or at a node v with $|\mathcal{F}^v| \leq 3\kappa r$, we explicitly check all functions of $\mathcal{F}^v$ to determine the κ nearest neighbors of q in S and terminate the query. Otherwise, we find the highest cell of Ξ_v intersected by the corresponding vertical line $\vec{\ell}$ and recursively visit that child. For the dynamic version, the query procedure is somewhat more involved, but a query can still be answered in $O(\log n + \kappa)$ time. Hence, we have the following theorem.

THEOREM 6.3. *Let S be a set of n points in the plane, and let δ be any reasonable distance function, as above. We can preprocess S in time $O(\psi(n)n^\varepsilon)$ into a data structure of size $O(\psi(n)n^\varepsilon)$, so that for a given point p and an integer $\kappa \leq n$, the κ nearest (or farthest) neighbors of p can be computed in $O(\log n + \kappa)$ time. Moreover, a point can be inserted into or deleted from S in $O(\psi(n)/n^{1-\varepsilon})$ time.*

6.4. Some special cases. If δ is an L_p-metric, for any integer $1 \le p \le \infty$, then $\psi(n) = O(n)$ [45]. Similarly, if δ is an *(additive) weighted Euclidean* metric, i.e., each point $p_i \in S$ has a weight w_i and $\delta(q, p_i) = d(q, p_i) + w_i$, where $d(\cdot, \cdot)$ is the Euclidean distance, then also $\psi(n) = O(n)$ [46]. A linear bound also holds when the sites are pairwise-disjoint line segments [47]. Hence, we obtain the following result.

COROLLARY 6.4. *Let S be a set of n points in the plane, and let δ be any L_p-metric or any weighted Euclidean metric. We can preprocess S in $O(n^{1+\varepsilon})$ time into a data structure of size $O(n^{1+\varepsilon})$ so that points can be inserted into or deleted from S in time $O(n^{\varepsilon})$ per update and a nearest-neighbor query can be answered in $O(\log n)$ time. We can also construct a data structure with the same performance bounds for the case when S is a set of n pairwise disjoint segments (or other simply shaped objects) in the plane and δ is the Euclidean metric. In all these cases, the k nearest neighbors of a query point in the plane can be reported in time $O(\log n + k)$.*

Space/query-time trade-off. If the bound $\psi(n)$ is rather large, say, $O(n^{2+\varepsilon})$, we can obtain a space/query-time trade-off by combining Theorem 6.1 with the linear-size data structure of [5] for nearest-neighbor searching, mentioned at the beginning of this section, in a rather standard manner [22]. For example, if $\psi(n) = O(n^{2+\varepsilon})$, then for any parameter $n \le m \le n^2$, we can store S into a data structure of size $O(m^{1+\varepsilon})$ so that a nearest-neighbor query can be answered in time $O(n^{1+\varepsilon}/\sqrt{m})$. Insertions and deletions can be performed in $O(m^{1+\varepsilon}/n)$ time, per update. Hence, we can conclude the following.

THEOREM 6.5. *Let S be a set of n points in the plane, $n \le m \le n^2$ be a real parameter, and δ be a reasonable distance function, as above. We can preprocess S in time $O(m^{1+\varepsilon})$ into a data structure of size $O(m^{1+\varepsilon})$ so that a nearest-neighbor (or a farthest-neighbor) query can be answered in $O(n^{1+\varepsilon}/\sqrt{m})$ time. Moreover, we can insert and delete points in $O(m^{1+\varepsilon}/n)$ time per update.*

Remark 6.6. If the number of queries and the number of updates are both $O(n)$, then an optimal choice for m is $n^{4/3}$, for which the entire sequence of operations can be performed in $O(n^{4/3+\varepsilon})$ time.

The dynamic bichromatic closest-pair problem. Next, we consider the following dynamic bichromatic closest-pair problem: Let R and B be two sets of points in the plane, of a total of at most n points. We wish to update R and B dynamically and to return the closest pair between R and B after each update operation.[4] We use the following result of Eppstein [35].

LEMMA 6.7. *Let R and B be two sets of points in the plane, with a total of at most n points. Let δ be a distance function for which we can store a set of n points into a data structure that supports insertions, deletions, and nearest-neighbor queries in $O(T(n))$ time per operation. Then a closest pair between R and B can be maintained in $O(T(n)\log n)$ time per insertion and in $O(T(n)\log^2 n)$ time per deletion.*

If δ is an L_p metric or any weighted Euclidean metric, then by Corollary 6.4, $T(n) = O(n^{\varepsilon})$. On the other hand, if δ is any reasonable distance function, then by choosing $m = n^{4/3}$ in Theorem 6.5, $T(n) = O(n^{1/3+\varepsilon})$. Plugging these values into the above lemma, we obtain the following result.

THEOREM 6.8. *Let R and B be two sets of points in the plane, with a total of n points. We can store $R \cup B$ in a dynamic data structure of size $O(n^{1+\varepsilon})$ that maintains a closest pair in $R \times B$, under any L_p-metric or any weighted Euclidean metric, in $O(n^{\varepsilon})$ time per insertion or deletion. If we use an arbitrary, reasonable*

[4]A *closest pair* between R and B under a distance function δ is a pair of points $p \in R$, $q \in B$ such that $\delta(p, q) = \min_{p' \in R, q' \in B} \delta(p', q')$.

distance function, then the storage increases to $O(n^{4/3+\varepsilon})$ *and the update time to* $O(n^{1/3+\varepsilon})$.

Using this theorem and extending the analysis of Agarwal et al. [2], as done in [35], we can obtain an efficient procedure for maintaining a minimum spanning tree T of a set of points under any L_p metric, as follows. For an angle $\alpha \leq \pi/2$ and a unit vector d, let $Cone(d, \alpha) = \{\mathbf{x} \mid \angle(\mathbf{x}, d) \leq \alpha\}$. We call a pair of point sets P, Q *α-separated* if there exist a point z and a direction d such that $P \subseteq z + Cone(-d, \alpha)$ and $Q \subseteq z + Cone(d, \alpha)$. Let α_0 be a sufficiently small angle, and let

$$\mathcal{C} = \{(P_1, Q_1), \ldots, (P_u, Q_u)\}$$

be a family of α_0-separated pairs such that for every pair $p, q \in S$, there is an i with $p \in P_i$ and $q \in Q_i$; we will refer to $\mathcal{C}$ as an *α_0-cover* of S. Consider the graph G whose vertices are the points of S and whose edges are pairs of points (p_i, q_i), $1 \leq i \leq u$, so that (p_i, q_i) is a δ-closest pair between P_i and Q_i, where δ is an L_p-metric. The weight of an edge (p_i, q_i) is $\delta(p_i, q_i)$. Following the same argument used by Agarwal et al. [2, Lemmas 1–4], but extending their Lemma 3 to the case of an L_p-metric, one can show that G contains a minimum spanning tree of S as a subgraph.

Using a standard divide-and-conquer approach, an α_0-cover $\mathcal{C}$ of S, with the property that each point of S is contained in $O(\log^2 n)$ pairs, can be constructed in $O(n \log^2 n)$ time; see, e.g., [2]. Moreover, $\mathcal{C}$ can be maintained in $O(\log^2 n)$ time per insertion or deletion. Insertion or deletion of a point changes $O(\log^2 n)$ edges of the graph G, and Theorem 6.8 implies that the new edges can be found in $O(n^\varepsilon \log^2 n)$ time. The problem of maintaining a minimum spanning tree of S now reduces to maintaining the family $\mathcal{C}$, a closest pair for each pair $(P_i, Q_i) \in \mathcal{C}$, and a minimum spanning tree of the resulting graph G. Holm, de Lichtenberg, and Thorup [41] have shown that a minimum spanning tree of a graph with n vertices can be updated in $O(\log^4 n)$ time for each insertion or deletion of an edge into/from the graph. Hence we obtain the following result.

THEOREM 6.9. *A minimum spanning tree of a set of n points in the plane, under any L_p-metric, can be maintained in $O(n^\varepsilon)$ time for each insertion or deletion operation using $O(n^{1+\varepsilon})$ storage.*

Remark 6.10. We believe that Theorem 6.9 also holds for more general metrics, but we did not attempt such a generalization in this paper.

7. Minimum-weight bipartite Euclidean matching.

Let $P = \{p_1, \ldots, p_n\}$ and $Q = \{q_1, \ldots, q_n\}$ be two sets of points in the plane. We wish to compute a *minimum-weight bipartite Euclidean matching* M of P and Q. A matching of P and Q is a set of n pairs $(p, q) \in P \times Q$ such that each point of $P \cup Q$ appears in exactly one pair. The weight of a pair is the Euclidean distance between its points, and the weight of a matching is the sum of the weights of its pairs. The standard *Hungarian method* [43, 44] yields an $O(n^3)$-time algorithm for computing M. Exploiting the fact that the weights are Euclidean distances, Vaidya obtained an $O(n^{2.5} \log n)$-time algorithm for computing M [70]. A number of efficient algorithms have been developed for computing a minimum-weight bipartite Euclidean matching when P and Q have some special structure [10, 17, 49], but no progress has been made when P and Q are arbitrary sets of points in the plane. Recently, Efrat and Itai [33] have proposed an $O(n^{1.5+\varepsilon})$-time algorithm for computing a bottleneck Euclidean bipartite matching, in which one wishes to minimize the maximum weight of an edge in the matching.

In this section, we show that Vaidya's algorithm, for arbitrary sets P, Q, can be modified so that its running time improves to $O(n^{2+\varepsilon})$. One can equally consider the nonbipartite version of the problem, where we are given just one set P of $2n$ points in the plane and wish to compute a minimum-weight Euclidean matching in P, that is, a partition of P into n pairs of points so that the sum of the intrapair Euclidean distances is minimized. Vaidya has also given in [70] an $O(n^{2.5} \log n)$-time algorithm for the nonbipartite case. Recently, the bound was improved by Varadarajan to $O(n^{1.5} \log n)$ [72].

For the sake of completeness, we first give a brief sketch of Vaidya's algorithm for the bipartite case and then show how it can be improved using the new machinery of this paper.

The bipartite matching problem can be formulated as a linear program:

$$\begin{array}{lll} \min & \sum_{i,j} d(p_i, q_j) x_{ij} \quad \text{subject to} & \\ & \sum_{j=1}^{n} x_{ij} = 1, & i = 1, \ldots, n, \\ & \sum_{i=1}^{n} x_{ij} = 1, & j = 1, \ldots, n, \\ & x_{ij} \geq 0, & i, j = 1, \ldots, n, \end{array}$$

where (p_i, q_j) is an edge of M if and only if $x_{ij} = 1$. The dual linear program is

$$\begin{array}{lll} \max & \sum_{i} \alpha_i + \sum_{j} \beta_j \quad \text{subject to} & \\ & \alpha_i + \beta_j \leq d(p_i, q_j), & i, j = 1, \ldots, n, \end{array}$$

where α_i (resp., β_j) is the dual variable associated with the point p_i (resp., q_j).

The Hungarian method computes a matching in n phases, each of which augments the matching by one edge and updates the dual variables. Let X be the current matching computed so far by the algorithm. Initially, we set $X = \emptyset$, $\alpha_i = 0$, and $\beta_j = \min_i \ d(p_i, q_j)$ for all i, j. An edge (p_i, q_j) is called *admissible* if $d(p_i, q_j) = \alpha_i + \beta_j$. A vertex of $P \cup Q$ is called *exposed* if it is not incident to any edge of X. An *alternating path* is one that alternately traverses edges of X and edges not in X, starting with an edge not in X. An alternating path between two exposed vertices is called an *augmenting path*.

During each phase, we search for an augmenting path consisting only of admissible edges, as follows. For each exposed point $q \in Q$, we grow (in an implicit manner) an "alternating tree" whose paths are alternating paths starting at q. More precisely, each point of $P \cup Q$ in an alternating tree is reachable from its root by an alternating path that consists only of admissible edges. For a point w of P (resp., Q), the path leading to w ends at an edge not in X (resp., in X). Let S (resp., T) denote the set of points of Q (resp., P) that lie in any alternating tree. In the beginning of each phase, S is the set of exposed vertices of Q and $T = \emptyset$. Let

$$\delta = \min_{p_i \in P - T, q_j \in S} \{d(p_i, q_j) - \alpha_i - \beta_j\}.$$

At each step, the algorithm takes one of the following actions, depending on whether $\delta = 0$ or $\delta > 0$:

Case 1. $\delta = 0$. Let (p_i, q_j), for $p_i \in P - T$ and $q_j \in S$ be an admissible edge ($\delta = 0$ implies that such an edge must exist). If p_i is an exposed vertex, an augmenting path has been found, so the algorithm moves to the next phase (see below for more details).

Otherwise, let q_k be the vertex such that $(p_i, q_k) \in X$. The algorithm adds the edges (p_i, q_j) and (p_i, q_k) to all the alternating trees that contain the vertex q_j. It also adds the point p_i to T and the point q_k to S.

Case 2. $\delta > 0$. The algorithm updates the dual variables, as follows. For each vertex $p_i \in T$, it sets $\alpha_i = \alpha_i - \delta$, and for each $q_j \in S$, it sets $\beta_j = \beta_j + \delta$.

The algorithm repeats these steps until it reaches an exposed vertex of P, thereby obtaining an augmenting path. If an augmenting path Π is found, we delete the edges of $\Pi \cap X$ from the current matching X, add the other edges of Π to X (thereby increasing the size of the current matching by 1), and move to the next phase. This completes the description of the algorithm. Further details of the algorithm and the proof of its correctness can be found in [44, 70].

For arbitrary graphs, each step can be implemented in $O(n)$ time. Since there are at most n phases and each phase consists of $O(n)$ steps, the total running time of the above procedure is $O(n^3)$. Vaidya suggested the following approach to expedite the running time of each step. Maintain a variable Δ and associate a weight $w(\cdot)$ with each point in $P \cup Q$. In the beginning of each phase, $\Delta = 0$ and $w(p_i) = \alpha_i$, $w(q_j) = \beta_j$ for each $1 \le i, j \le n$. During each step, the weights and Δ are updated, but the values of the dual variables remain unchanged. This is done as follows. If Case 1 occurs, then we set $w(p_i) = \alpha_i + \Delta$ and $w(q_k) = \beta_k - \Delta$ and do not change the value of Δ. If Case 2 occurs, then we set $\Delta = \Delta + \delta$ and do not change the weights. Notice that for each $q_j \in S$, the current value of β_j is equal to $w(q_j) + \Delta$, and, similarly, for each $p_i \in T$, the current value of α_i is equal to $w(p_i) - \Delta$. Also, the current value of the dual variables for other points is equal to their values at the beginning of the phase. At the end of each phase, the value of the dual variables can be computed from Δ and from the weights of the corresponding points. The weight of each point changes only once during a phase, namely, when it is added either to S or to T. Moreover, at any time during a phase,

$$\delta = \min_{p_i \in P-T, q_j \in S} \{d(p_i, q_j) - w(p_i) - w(q_j)\} - \Delta.$$

Hence, δ can be computed during each step by maintaining the weighted closest pair between S and $P - T$. Since each step requires at most two update operations (inserting a point into S and deleting a point from $P - T$), each step can be performed in $O(n^\varepsilon)$ time by the algorithm provided in Theorem 6.8. (The current setup is slightly different than that of section 6, because here the weighted distance between two points subtracts weights associated with both points. Nevertheless, the analysis of section 3 leading to Theorem 4.4 and the way in which this theorem is used in section 6 still apply.) If the distance between two points is measured by an arbitrary reasonable distance function, each step of the above algorithm will require $O(n^{1/3+\varepsilon})$ time with an appropriately increased storage (the distance function continues to be reasonable when weights are added to the points, as above). We can thus conclude the following.

THEOREM 7.1. *Given two sets P, Q, each consisting of n points in the plane, a minimum-weight bipartite Euclidean matching between P and Q can be computed in $O(n^{2+\varepsilon})$ time, using $O(n^{1+\varepsilon})$ space. If we use an arbitrary, reasonable distance function for computing distances between points of P and Q, a minimum-weight bipartite matching between P and Q can be computed in time $O(n^{7/3+\varepsilon})$, using $O(n^{4/3+\varepsilon})$ space.*

The above algorithm can be extended to obtain faster algorithms for several other problems related to the bipartite matching. For example, consider the following *Euclidean transportation* problem, which is a generalization of the minimum-weight bipartite Euclidean matching problem: Let $P = \{p_1, \ldots, p_u\}$ be a set of u "supply" points in the plane, each with a supply value a_i, and let $Q = \{q_1, \ldots, q_v\}$ be a set of v "demand" points in the plane, each with a demand value b_j, such that $\sum_{i=1}^{u} a_i = \sum_{j=1}^{v} b_j$. Assume that the cost of transporting unit commodity from p_i to q_j is $d(p_i, q_j)$. We wish to find out how to satisfy all the demands at the minimum cost. Atkinson and Vaidya [13] gave an $O((u+v)^{2.5}\log(u+v)\log N)$-time algorithm, where $N = \max\{\max_i a_i, \max_j b_j\}$. Plugging Theorem 6.8 into their algorithm, we can improve the running time to $O((u+v)^{2+\varepsilon}\log N)$. See [14, 44, 70] for some other applications.

8. Maintaining the intersection of congruent balls in three dimensions.

The next application of our techniques is an efficient algorithm for dynamically maintaining the intersection of congruent balls in $\mathbb{R}^3$, under insertions and deletions of balls. With no loss of generality, we assume that the balls have radius 1. For a point $p \in \mathbb{R}^3$, let $B(p)$ denote the ball of radius 1 centered at p. Let S be a set of n points in $\mathbb{R}^3$. Let $\mathcal{B} = \mathcal{B}(S) = \{B(p) \mid p \in S\}$, and let $K(S) = \bigcap_{p\in S} B(p)$ be the common intersection of $\mathcal{B}$. We wish to maintain $K(S)$ as we update S dynamically by inserting and deleting points. Although the complexity of $K(S)$ is $O(n)$ [36], a sequence of m updates in S may cause $\Omega(mn + m^2)$ changes in the structure of $K(S)$, even if we perform only insertions. Consequently, we cannot hope to maintain $K(S)$ explicitly if we seek fast update time. Instead, we store $K(S)$ into a data structure so that a number of different types of queries can be answered efficiently. The simplest query is whether a query point p lies in $K(S)$. A stronger type of query is to determine efficiently, after each update, whether $K(S)$ is empty. In this section, we present a data structure that answers these two queries efficiently.

Let $B^+(p)$ (resp., $B^-(p)$) denote the region consisting of all points that lie in or above (resp., in or below) $B(p)$. Let $K^+(S) = \bigcap_{p\in S} B^+(p)$ and $K^-(S) = \bigcap_{p\in S} B^-(p)$. If we regard the boundary of each region $B^+(p)$ for $p \in S$ as the graph of a partially defined bivariate function, then (the nonvertical portion of) $\partial K^+(S)$ is the graph of the upper envelope of these functions restricted to the domain, $D(S)$, of intersection of the xy-projections of the balls $B(p)$, $p \in S$. We denote this upper envelope by $z = F^+(\mathbf{x})$. The same argument as in [36] implies that $K^+(S)$ also has linear complexity. In fact, the surfaces $\partial B^+(p)$ behave similar to a family of pseudoplanes—any pair of them intersects in a single connected unbounded curve (or does not intersect at all), and, assuming general position, any triple of them intersects at a single point (or does not intersect at all). Similar and symmetric properties hold for the region $K^-(S)$, and we use the notation $z = F^-(\mathbf{x})$ to denote the graph of its (nonvertical) boundary.

A query point $p = (p_x, p_y, p_z)$ lies in $K(S)$ if and only if $F^+(p_x, p_y) \le p_z \le F^-(p_x, p_y)$. Therefore, the problem of determining whether $p \in K(S)$ reduces to evaluating $F^+(p_x, p_y)$ and $F^-(p_x, p_y)$. By Theorem 6.1, we can store $\{B^+(p) \mid p \in S\}$ and $\{B^-(p) \mid p \in S\}$ into two data structures, each of size $O(n^{1+\varepsilon})$, so that a point can be inserted into or deleted from S in $O(n^\varepsilon)$ time and so that for a query point $p = (p_x, p_y, p_z)$, the functions $F^+(p_x, p_y)$ and $F^-(p_x, p_y)$ can be evaluated in $O(\log n)$ time.[5]

The same data structure can be used to determine whether $K(S)$ is empty, although this is a considerably more involved operation. Observe that the boundaries

[5]This is an example where the given bivariate functions are only partially defined, so we use Corollary 2.4 instead of Theorem 2.1.

of the regions $K^+(S)$ and $K^-(S)$ are both (weakly) xy-monotone—one of them is a convex surface and the other is concave. These properties can be exploited to obtain a fast procedure for detecting (after each update) whether $K^+(S)$ and $K^-(S)$ intersect by applying a variant of the parametric searching technique [55], as proposed by Toledo [69]. For the sake of completeness, we include here a brief description of this technique in the context of the problem under consideration.

We wish to find a point $\mathbf{x}^* \in \mathbb{R}^2$ such that $F^+(\mathbf{x}^*) \leq F^-(\mathbf{x}^*)$; this point will serve as a witness to the fact that $K^+(S)$ and $K^-(S)$ intersect. In fact, we will seek a point $\mathbf{x}^*$ at which

$$F^{\Delta}(\mathbf{x}^*) \stackrel{\text{def}}{=} F^+(\mathbf{x}^*) - F^-(\mathbf{x}^*)$$

is minimized; the minimum is negative if and only if the regions $K^+(S)$ and $K^-(S)$ intersect. Let A_s denote the query procedure that computes $F^{\Delta}(\mathbf{x})$ for a given $\mathbf{x}$ in $O(\log n)$ time.

We first consider the 1-dimensional problem, where for a given line $\ell : x = c$, we wish to find a point $\mathbf{y}^* = (c, y^*) \in \ell$ that minimizes F^{Δ}. We execute the query procedure A_s without knowing the value $\mathbf{y}^*$. This procedure makes $O(\log n)$ comparisons, each of which involves computing the sign of a univariate, constant-degree polynomial $g(y)$ in the y-coordinate y^* of $\mathbf{y}^*$. We compute the roots $y_1, \ldots, y_p$ of g, and evaluate $F^{\Delta}(c, y_i)$ for $1 \leq i \leq p$. Set $y_0 = -\infty$ and $y_{p+1} = +\infty$. Since F^{Δ} is convex, by examining the local behavior of $F^{\Delta}(c, \cdot)$ at each y_i (using an appropriate straightforward extension of the preceding procedure), we can determine whether $\mathbf{y}^* = (c, y_i)$ for some $0 \leq i \leq p+1$; if not, we can determine the open interval (y_i, y_{i+1}) that contains y^*. We can thus compute the sign of g at $\mathbf{y}^*$. Proceeding in this manner, we can compute the value of $\mathbf{y}^*$. Since F^{Δ} is convex over the entire xy-plane (or rather over the convex 2-dimensional domain $D(S)$), the above procedure can be extended to determine whether the global minimum $\mathbf{x}^*$ of F^{Δ} lies to the left of ℓ, to the right of ℓ, or on ℓ, simply by examining the local behavior of F^{Δ} in the neighborhood of $\mathbf{y}^*$. In the third case, the procedure can return the value of $\mathbf{x}^* = \mathbf{y}^*$ and terminate. The total running time of this procedure is $O(\log^2 n)$, because we spend $O(\log n)$ time at each comparison and the algorithm makes $O(\log n)$ comparisons.

Using the above 1-dimensional procedure as a subroutine, we can compute $\mathbf{x}^*$ as follows. We now run the query procedure of Theorem 6.1 in a generic manner at $\mathbf{x}^*$. Each comparison now involves computing the sign of a bivariate, constant-degree polynomial $\pi(\mathbf{x})$. Let $\vee\pi$ denote the set of roots of π. We compute Collins's cylindrical algebraic decomposition Π of $\mathbb{R}^2$ so that the sign of π is invariant within each cell of Π [12, 26, 61]. Our aim is to determine the cell $\tau \in \Pi$ that contains $\mathbf{x}^*$, thereby determining the sign of π at $\mathbf{x}^*$.

The cells of Π are delimited by $O(1)$ y-vertical lines—each passing through a self-intersection point of $\vee\pi$ or through a point of vertical tangency of $\vee\pi$; see Figure 8.1. For each vertical line ℓ, we run the standard 1-dimensional parametric-searching procedure to determine which side of ℓ contains $\mathbf{x}^*$. If any of these substeps returns $\mathbf{x}^*$, we are done. Otherwise, we obtain a vertical strip σ that contains $\mathbf{x}^*$. We still have to search through the cells of Π within σ, which are stacked one above the other in the y-direction, to determine which of them contains $\mathbf{x}^*$. We note that the number of roots of π along any vertical line $\ell : x = x_0$ within σ is the same, that each root varies continuously with x_0, and that their relative y-order is the same for each vertical line. In other words, the roots of $\vee\pi$ in σ constitute a collection of disjoint, x-monotone arcs $\gamma_1, \ldots, \gamma_t$ whose endpoints lie on the boundary lines of σ. We can regard each γ_i

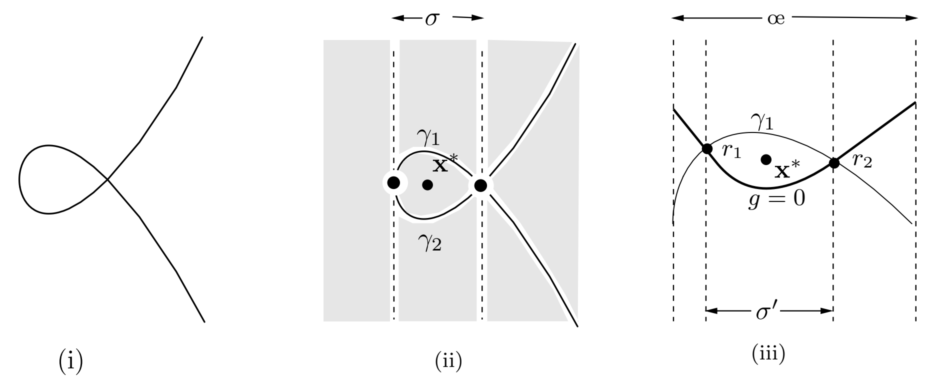

FIG. 8.1. (i) *The set* $\vee\pi$ *of roots of* π. (ii) *The cylindrical algebraic decomposition of* π. (iii) *The curves* $g = 0$ *and* γ_1.

as the graph of a univariate function $\gamma_i(x)$.

Next, for each γ_i we determine whether $\mathbf{x}^*$ lies below, above, or on γ_i. Let x^* be the (unknown) x-coordinate of $\mathbf{x}^*$, and let ℓ be the vertical line $x = x^*$. If we knew x^*, we could have run A_s at each $\gamma_i \cap \ell$ and could have located $\mathbf{x}^*$ with respect to γ_i, as desired. Since we do not know x^*, we execute the 1-dimensional procedure, described above, generically, on the line ℓ, with the intention of simulating it at the unknown point $\mathbf{x}_i = \gamma_i \cap \ell$. This time, performing a comparison involves computing the sign of some bivariate, constant-degree polynomial g at $\mathbf{x}_i$ (we prefer to treat g as a bivariate polynomial, although we could have eliminated one variable by restricting $\mathbf{x}$ to lie on γ_i). We compute the roots $r_1, \ldots, r_u$ of g that lie on γ_i, and set r_0 and r_{u+1} to be the left and right endpoints of γ_i, respectively. As above, we compute the index j so that $\mathbf{x}^*$ lies in the vertical strip σ' bounded between r_j and r_{j+1}. Notice that the sign of g is the same for all points on γ_i within the strip σ', so we can now compute the sign of g at $\mathbf{x}_i$.

When the generic algorithm being simulated at $\mathbf{x}_i$ terminates, it returns a constant-degree polynomial $F_i(x, y)$, corresponding to the value of F^Δ at $\mathbf{x}_i$ (i.e., $F_i(\mathbf{x}_i) = F^\Delta(\mathbf{x}_i)$), and a vertical strip $\sigma_i \subseteq \sigma$ that contains $\mathbf{x}^*$. Let $\rho_i(x) = F_i(x, \gamma_i(x))$. Let γ_i^+ (resp., γ_i^-) be the copy of γ_i translated by an infinitesimally small amount in the $(+y)$-direction (resp., $(-y)$-direction), i.e., $\gamma_i^+(x) = \gamma_i(x) + \varepsilon$ (resp., $\gamma_i^-(x) = \gamma_i(x) - \varepsilon$), where $\varepsilon > 0$ is an infinitesimal. We next simulate the algorithm at $\mathbf{x}_i^+ = \gamma_i^+ \cap \ell$ and $\mathbf{x}_i^- = \gamma_i^- \cap \ell$. We thus obtain two functions $\rho_i^+(x)$, $\rho_i^-(x)$ and two vertical strips σ_i^+, σ_i^-. Let $\hat{\sigma}_i = \sigma_i \cap \sigma_i^+ \cap \sigma_i^-$. We need to evaluate the signs of $\rho_i(x^*) - \rho_i^+(x^*)$ and $\rho_i(x^*) - \rho_i^-(x^*)$ to determine the location of $\mathbf{x}^*$ with respect to γ_i (this is justified by the convexity of F^Δ). We compute the x-coordinates of the intersection points of (the graphs of) $\rho_i, \rho_i^+, \rho_i^-$ that lie inside $\hat{\sigma}_i$. Let $x_1 \le x_2 \le \cdots \le x_s$ be these x-coordinates, and let x_0, x_{s+1} be the x-coordinates of the left and right boundaries of $\hat{\sigma}_i$, respectively. By running A_s on the vertical lines $x = x_j$, for $1 \le j \le s$, we determine the index $0 \le j \le s$ so that the vertical strip $\sigma_i = [x_j, x_{j+1}] \times \mathbb{R}$ contains $\mathbf{x}^*$. Notice that the signs of polynomials $\rho_i(x) - \rho_i^+(x), \rho_i(x) - \rho_i^-(x)$ are fixed for all $x \in [x_j, x_{j+1}]$. By evaluating $\rho_i, \rho_i^+, \rho_i^-$ for any $x_0 \in [x_j, x_{j+1}]$, we can compute the signs of $\rho_i(x^*) - \rho_i^+(x^*)$ and of $\rho_i(x^*) - \rho_i^-(x^*)$.

Repeating this procedure for all γ_i's, we can determine the cell of Π that contains $\mathbf{x}^*$ and thus resolve the comparison involving π. We then resume the execution of the generic algorithm.

The execution of the 1-dimensional procedure takes $O(\log^2 n)$ steps, which implies that its generic simulation requires $O(\log^3 n)$ time. The total time spent in resolving the sign of π at $\mathbf{x}^*$ is therefore $O(\log^3 n)$. Hence, the total running time of the 2-dimensional algorithm is $O(\log^4 n)$.

THEOREM 8.1. *The intersection of a set of congruent balls in $\mathbb{R}^3$ can be maintained dynamically, by a data structure of size $O(n^{1+\varepsilon})$, so that each insertion or deletion of a ball takes $O(n^\varepsilon)$ time and the following queries can be answered:* (a) *For any query point p, we can determine in $O(\log n)$ time whether p lies in the current intersection, and* (b) *after performing each update, we can determine in $O(\log^4 n)$ time whether the current intersection is nonempty.*

Remark 8.2. (i) The same data structure can be used to answer other queries, such as determining whether a line intersects $K(S)$, computing the highest (or the lowest) vertex of $K(S)$, etc.

(ii) The same technique can also be used to maintain the intersection of other simply-shaped, convex objects in $\mathbb{R}^3$. The technique will be most effective in cases where the complexity of such an intersection can be shown to be small.

(iii) The problem studied in this section arises in the 3-dimensional 2-*center* problem, where we are given a set S of n points in $\mathbb{R}^3$ and wish to cover them by the union of two congruent balls whose radius is as small as possible. Extending to three dimensions the standard approach to this problem [29], we face a main subproblem in which we need to maintain dynamically the intersection of a set of congruent balls and to determine after each update whether this intersection is nonempty. The main difference, though, is that in the 2-center problem the sequence of updates is known in advance, which makes the problem easier to solve. Still, using the method of this section, we obtain an $O(n^{3+\varepsilon})$-time algorithm for the 3-dimensional 2-center problem.

9. Smallest stabbing disk.

Let $\mathbf{C}$ be a (possibly infinite) family of simply shaped compact strictly-convex sets (called *objects*) in the plane. By "simply shaped" we mean that each object is described by a Boolean combination of a constant number of polynomial equalities and inequalities of constant maximum degree. Let $\mathcal{C} = \{c_1, \ldots, c_n\}$ be a finite subset of $\mathbf{C}$. We wish to update $\mathcal{C}$ dynamically, by inserting objects $c \in \mathbf{C}$ into $\mathcal{C}$ or by deleting such objects from $\mathcal{C}$, and maintain a smallest disk or, more generally, a smallest homothetic copy of some given simply shaped compact convex set P that intersects all sets of $\mathcal{C}$. This study extends recent work by Agarwal and Matoušek [6], who have obtained an algorithm that takes $O(n^\varepsilon)$ time per update operation for the case where $\mathcal{C}$ is a set of points and P is a disk.

9.1. Farthest-neighbor Voronoi diagrams.

The set P induces a *convex distance function* defined by

$$d_P(x, y) = \min \{\lambda \mid y \in x + \lambda P\}.$$

We assume here that P contains the origin in its interior. The function d_P is a metric if and only if P is centrally symmetric with respect to the origin. We define the farthest-neighbor Voronoi diagram $\mathit{Vor}_P(\mathcal{C})$ of $\mathcal{C}$, under the distance function d_P, in a standard manner (see [48, 56, 63] for details). In what follows, we assume that P is strictly convex; the results can be extended to more general sets with some extra care. We first prove the following theorem, which is of independent interest. (We are not aware of any previous proof of this result.)

THEOREM 9.1. *Let $\mathcal{C}$ be a set of n (possibly intersecting) simply shaped compact convex objects in the plane. Then the complexity of the farthest-neighbor Voronoi*

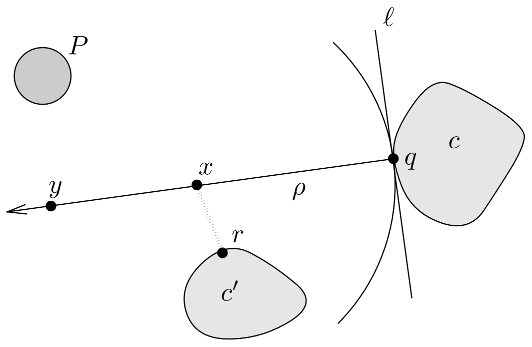

FIG. 9.1. *Anti-star-shape property of Voronoi cells.*

diagram of $\mathcal{C}$, under a convex distance function d_P induced by any simply shaped compact strictly convex set P, is $O(\lambda_s(n))$. Here s is a constant depending on the shape of P and of the objects in $\mathcal{C}$. If $\mathcal{C}$ is a set of n line segments and d_P is the Euclidean distance function (i.e., P is a disk), the complexity of the farthest-neighbor Voronoi diagram is $O(n)$.

Proof. Let R be one of the Voronoi cells of $Vor_P(\mathcal{C})$, and let $c \in \mathcal{C}$ be the farthest neighbor of all points of R. We show that R has the following "anti-star-shape" property: Let $x \in R$, and let $q \in c$ be the nearest point to x (i.e., $d_P(x,q) = d_P(x,c)$); the convexity of c and the strict convexity of P imply that q is unique. Let ρ be the ray emanating from q towards x, and let y be any point on ρ past x (i.e., x lies in the segment qy). We claim that c is the farthest neighbor of y; see Figure 9.1. Indeed, suppose to the contrary that the farthest neighbor of y in $\mathcal{C}$ is $c' \neq c$ (so that $d_P(y,c') > d_P(y,c)$), and let $r \in c'$ be the nearest point to x. Let ℓ be the (unique) line passing through q and tangent to $x + d_P(x,c)P$ there. The convexity of c implies that c is contained in the (closed) halfplane bounded by ℓ and not containing x. Since ℓ is also tangent to $y + d_P(y,q)P$, it easily follows that $d_P(y,c) = d_P(y,q)$. Now, by the triangle inequality we have

$$\begin{aligned} d_P(y,c') &\leq d_P(y,r) \\ &\leq d_P(y,x) + d_P(x,r) \\ &= d_P(y,x) + d_P(x,c') \\ &\leq d_P(y,x) + d_P(x,c) \\ &= d_P(y,x) + d_P(x,q) \\ &= d_P(y,q) \\ &= d_P(y,c), \end{aligned}$$

a contradiction that establishes the claim.

This implies that R is unbounded, and so $Vor_P(\mathcal{C})$ is an outerplanar map. It is easy to verify that every vertex of $Vor_P(\mathcal{C})$ has degree at least three. Hence, by Euler's formula for planar graphs, the complexity of $Vor_P(\mathcal{C})$ is proportional to the number of its faces. We bound the number of faces in $Vor_P(\mathcal{C})$, as follows. By a compactness argument, there exists a sufficiently large r such that the circle σ_r of radius r about the origin cuts the cells of $Vor_P(\mathcal{C})$ in the same sequence as does the circle at infinity. For each $c \in \mathcal{C}$, let $f_c(\theta) = d_P((r,\theta),c)$, and let $F(\theta) = \max_{c\in\mathcal{C}} f_c(\theta)$. Clearly, the number of edges of $Vor_P(\mathcal{C})$ crossed by σ_r, which is an upper bound on the number of faces

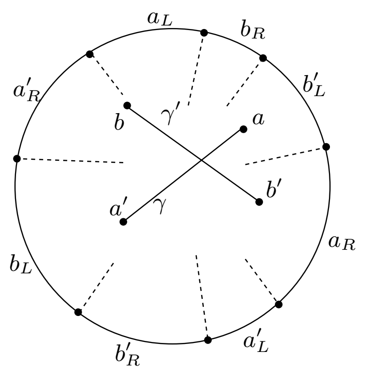

FIG. 9.2. *Partition of the circle σ_r into maximal arcs.*

in $Vor_P(\mathcal{C})$, is equal to the number of breakpoints in the upper envelope F. Since we have assumed P and each set $c \in \mathcal{C}$ to be simply shaped, it follows that for each pair $c, c' \in \mathcal{C}$, the functions f_c and $f_{c'}$ have at most some constant number, s, of intersection points. Hence, the number of breakpoints of F is, by standard Davenport–Schinzel theory [39, 66], at most $\lambda_s(n)$. This establishes the first part of the claim.

For the case of line segments and Euclidean distance, the bound improves to $O(n)$. To see this, let $\mathcal{C}$ be a set of n line segments in the plane. Traverse the circle σ_r, as defined above, and decompose it into maximal arcs so that the following conditions are satisfied for each arc ζ:

(i) The farthest segment from all points $q \in \zeta$ is the same segment e,
(ii) the nearest endpoint of e from q is fixed, and
(iii) ζ lies fully in one of the halfplanes bounded by the line containing e.

We label each arc ζ by the endpoint of the corresponding segment e, but we use different labels for arcs that lie on different "sides" of e (as in (iii) above); see Figure 9.1. We call an arc ζ, labeled by endpoint a, a *left arc* (and label it by a_L) if it lies on the left side of the segment incident to a when this segment is directed towards a; otherwise, ζ is a *right arc* (and we label it a_R). Let S (resp., S_R, S_L) denote the cyclic sequence consisting of the labels of all (resp., all the right, all the left) arcs in the clockwise order along σ_r. Note that S is obtained by merging S_L and S_R and it does not contain any pair of equal adjacent elements (S_L and S_R may contain such pairs). Each of S_L and S_R is composed of at most $2n$ symbols. We claim that S_L cannot contain an alternating subcycle of the form $\langle a_L \cdots b_L \cdots a_L \cdots b_L \rangle$, where a and b are two segment endpoints.

In order to prove this claim, it suffices to rule out the existence of such a subcycle in the partition of σ_r induced by the one or two segments incident to a and b. First, such a subcycle is impossible if a and b are endpoints of the same segment e because all arcs labeled by a are separated from all arcs labeled by b by the perpendicular bisector of e.

Suppose then that a and b are endpoints of two distinct respective segments e_1, e_2. Let a' be the other endpoint of e_1, and let b' be the other endpoint of e_2. Since r is sufficiently large, the perpendicular bisector of any two endpoints of segments in $\mathcal{C}$ partitions σ_r into two arcs, each of which is larger than, say, $3\pi r/4$. Both appearances of a (resp., of b) in the assumed subcycle occur within an arc γ_1 (resp., γ_2), bounded by the perpendicular bisector e_1 (resp., e_2) and by the line containing e_1 (resp., e_2). See Figure 9.3. An easy calculation shows that the lengths of γ_1, γ_2 are both less than

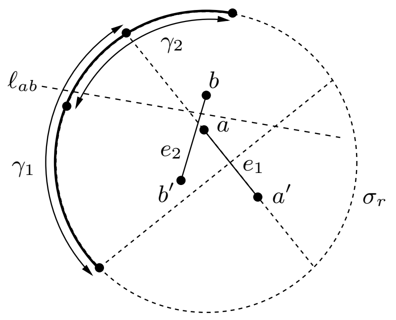

FIG. 9.3. *Segments e_1, e_2 and arcs γ_1, γ_2.*

$3\pi r/4$ (each of the arcs is approximately a quarter circle, so the above property will hold if r is chosen sufficiently large), and, by definition, a is the nearest endpoint of e_1 within γ_1 and b is the nearest endpoint of e_2 within γ_2. By assumption, γ_1 contains three disjoint subarcs labeled a_L, b_L, a_L in the clockwise order.

This, however,+ implies that the perpendicular bisector, ℓ_{ab}, of a and b intersects γ_1 twice, which is impossible because the length of γ_1 is less than $3\pi r/4$ and the length of each of the two arcs into which σ_r is partitioned by ℓ_{ab} is more than $3\pi r/4$. This completes the proof of the claim.

A symmetric argument shows that S_R too cannot contain such a subcycle. Hence, if we erase from S_L and from S_R every element equal to its predecessor, we obtain two (cyclic) Davenport–Schinzel sequences of order 2, each composed of at most $2n$ symbols, which are thus of length at most $4n-2$ each. It is now a fairly standard exercise to show that the total length of S is also linear in n (see, e.g., [66]). This completes the proof. $\square$

For each object $c_i \in \mathcal{C}$, define a bivariate function

$$f_i(\mathbf{x}) = -\min_{q \in c_i} d_P(\mathbf{x}, q)$$

for $\mathbf{x} \in \mathbb{R}^2$. Let $\mathcal{F} = \{f_i \mid 1 \le i \le n\}$. The minimization diagram of $\mathcal{F}$ is the farthest-neighbor Voronoi diagram of $\mathcal{C}$ under the distance function d_P. Following the same argument as in Theorem 6.1 and using Theorem 9.1, we obtain the following corollary.

COROLLARY 9.2. *Let $\mathcal{C}$ be a set of n (possibly intersecting) simply shaped compact convex sets in the plane and d_P be a convex distance function as above. $\mathcal{C}$ can be preprocessed into a farthest-neighbor-searching data structure of size $O(n^{1+\varepsilon})$ so that a query can be answered in $O(\log n)$ time and an object (of the same form) can be inserted into or deleted from $\mathcal{C}$ in $O(n^\varepsilon)$ time.*

9.2. Maintaining the smallest stabbing disk. Returning to the smallest stabbing disk problem, we need to compute the highest point w^* on the lower envelope $E_{\mathcal{F}}$ of $\mathcal{F}$. In view of Corollary 9.2 and the easily established fact that the cell of $\mathcal{A}(\mathcal{F})$ lying below $E_{\mathcal{F}}$ is convex, a natural approach to computing w^* is to use the multidimensional parametric-searching technique of Toledo [69] in a manner similar to that described in the preceding section. Omitting further details, which can be worked out by the reader, we have the next theorem.

THEOREM 9.3. *A set $\mathcal{C}$ of n (possibly intersecting) simply shaped compact convex sets in the plane can be stored in a data structure of size $O(n^{1+\varepsilon})$ so that a smallest* *homothetic placement of some given simply shaped compact strictly convex set P that intersects all objects of $\mathcal{C}$ can be computed in $O(n^{\varepsilon})$ time, after each insertion or deletion of a set into/from $\mathcal{C}$.*

Remark 9.4. A related problem is that of maintaining the smallest disk (or homothetic copy of some given P) *enclosing* all but at most k objects of a dynamically changing collection $\mathcal{C}$. The same technique as above can be used, except that now we need to replace $Vor_P(\mathcal{C})$ by a different farthest-neighbor diagram, where the d_P-distance to an object c is the maximum distance to a point of c. See [68] for a recent study of such Voronoi diagrams.

10. Other applications.

In this section, we list some other applications of the techniques developed in this paper. To keep the length of the paper under control, we omit most of the details concerning these applications; some of these details are fairly routine, but some are more technical and problem-specific. Some of the details can be found in [32]. We are confident that the new techniques will also find many additional applications.

10.1. Smallest stabbing disk with at most *k* violations.

Let $\mathcal{C}$ and P be as in section 9, and let $1 \leq k \leq n$ be an integer parameter. We consider the problem of finding a smallest homothetic placement of P that stabs at least $n-k$ of the objects of $\mathcal{C}$. This problem extends the problem studied by Matoušek [51], in which one seeks the smallest disk stabbing all but at most k points of a given set of points in the plane.

Let $\mathcal{F} = \{f_i \mid 1 \leq i \leq n\}$ be the set of bivariate functions as defined in section 9. As easily seen, our goal is to find a point in $\mathcal{A}_{\leq k}(\mathcal{F})$ with the maximum z-coordinate. In view of Corollary 9.2, this can be done in time $O(n^{1+\varepsilon}k^2)$ by explicitly computing $\mathcal{A}_{\leq k}(\mathcal{F})$, as in Theorem 5.1. However, one can do much better. Note that the problem

$$\max \quad z \quad \text{subject to}$$
$$z \leq f_i(x,y), \qquad i = 1,\ldots,n,$$

is an LP-type problem (see [54, 67]). Matoušek [51, Theorem 2.2] showed that the number of local maxima in the first k levels of $\mathcal{A}(\mathcal{F})$ is $O((k+1)^3)$. Note that each local maxima w of the jth level lies on at most three function graphs and is the unique maximum of the lower envelope of a subcollection $\mathcal{F}'$ of $n-j$ functions of $\mathcal{F}$. Moreover, there exists a local maximum w' of the $(j-1)$st level that "hides" w in the sense that w' is the unique maximum of the lower envelope of $\mathcal{F}' \cup \{f\}$, where f is one of the functions whose graph contains w'.

Matoušek also proposed a method for computing all these maxima, which proceeds in a depth-first-search fashion, starting from the unique maximum p in $\mathcal{A}_{\leq 0}(\mathcal{F})$ (i.e., the lower envelope of $\mathcal{F}$). Suppose the algorithm is currently at a local maxima q of the jth level for some $j \leq k$; q is the unique maximum of the lower envelope of a subset $\mathcal{F}' \subseteq \mathcal{F}$ of $n-j$ functions. If $j < k$, the algorithm removes one of the (at most) three constraints defining q, say, f, and finds the maximum q' of the LP-type problem defined by the constraints in $\mathcal{F}' \setminus \{f\}$, using an appropriate dynamic data structure. Applying this step repeatedly, we find all local maxima violating at most k constraints. The cost of this algorithm is proportional to the preprocessing cost for constructing the data structure plus the number of maxima (i.e., $O((k+1)^3)$) times the cost of a query and an update of the structure.

In our setting, a point q in $\mathbb{R}^3$ represents a homothetic copy of P that misses exactly k objects of $\mathcal{C}$ if and only if it lies at the kth level of $\mathcal{A}(\mathcal{F})$. Hence, to implement Matoušek's technique for our problem, we first construct the data structure of Theorem 9.3 in time $O(n^{1+\varepsilon})$. This also yields a smallest homothetic copy of P that stabs all the objects of $\mathcal{C}$. Then we compute each of the $O((k+1)^3)$ maxima of $\mathcal{A}_{\le k}(\mathcal{F})$, using the above technique. Each step of the algorithm starts at some local minimum q on one of the first k levels so that the data structure currently represents all the objects of $\mathcal{C}$ not violating q. It then deletes one of the (at most 3) objects defining q and queries the structure to obtain the minimum for the resulting set of remaining constraints (as in Theorem 9.3). The cost of such a query is $O(n^{\varepsilon})$. We thus obtain the following theorem.

THEOREM 10.1. *Let $\mathcal{C}$ be a family of n (possibly intersecting) simply shaped compact convex sets in the plane, and let $0 \le k \le n$ be a parameter. We can find a smallest homothetic placement of some given simply shaped, compact, strictly convex set P, which stabs all except at most k of the sets of $\mathcal{C}$, in time $O(n^{1+\varepsilon} + k^3 n^{\varepsilon})$.*

Remark 10.2. Note that this approach can be generalized to many other optimization problems, where the optimizing object has three degrees of freedom and we seek an optimum solution that violates at most k of the given constraints. The machinery developed in this paper is powerful enough to allow such extensions, requiring only that the lower envelope of any subcollection of objects is a convex surface and that the relevant constraints satisfy some rather mild conditions.

10.2. Segment center with at most k violations. Let S be a set of n points in the plane, and let e be a fixed-length segment. A placement e^* of e is called a *segment center* of S if the maximum distance between the points of S and e^* is minimized. We call e^* a *segment center* of S *with k violations* if the $(k+1)$st largest distance between e^* and the points of S is minimized. The problem of computing the segment center (without violations) has been studied in [3, 34, 42]; the best algorithm, given in [34], computes the segment center in $O(n^{1+\varepsilon})$ time.

Applying the machinery developed in section 5 and extending the result of [34], one can obtain the following result.

THEOREM 10.3. *The segment center with k violations of a set S of n points in the plane can be computed in time $O(n^{1+\varepsilon}k^2)$.*

Here is a brief sketch of the proof. We first solve the *fixed-size problem*: Given a real $d > 0$, determine whether there exists a placement of e for which the $(k+1)$st largest distance to the points of S is $\le d$. As follows from the analysis of [34], this is equivalent to the problem of determining whether there exists a (translated and rotated) placement Z of the *hippodrome* $H(e,d)$, defined as the Minkowski sum of e and a (closed) disk of radius d, that contains all but at most k points of S.

Extending the technique of [34], one can reduce this latter problem to the following one: We are given two collections $\mathcal{F}$ and $\mathcal{G}$ of n partially defined fixed-degree algebraic bivariate functions, and we wish to determine whether there exists an intersection between the first k lower levels of $\mathcal{A}(\mathcal{F})$ and the first k upper levels of $\mathcal{A}(\mathcal{G})$ so that the sum of the levels of such an intersection does not exceed k. This can be solved efficiently using the machinery developed in section 5. As shown in [34], we have $\psi(n) = O(n \log n)$ for the collections $\mathcal{F}$ and $\mathcal{G}$, which then implies that the asymptotic running time of the algorithm is $O(n^{1+\varepsilon}k^2)$.

Once the fixed-size problem is solved, the segment center problem can be solved by parallelizing the decision algorithm under Valiant's model [71] and by applying the parametric searching technique of [55]. The bound on the running time remains asymptotically the same.

11. Conclusions. In this paper we have extended known range-searching techniques to arrangements of low-degree algebraic bivariate functions in $\mathbb{R}^3$. By establishing sharp bounds on the vertical decomposition of the first k levels of such an arrangement, we were able to extend the construction of [52] of shallow cuttings to such arrangements. This in turn has yielded a collection of static and dynamic range-searching techniques for problems that involve such arrangements, from which we have obtained new and efficient solutions to several geometric optimization problems, including minimum weight Euclidean bipartite matching.

The main open problem that the paper raises is to extend our results to higher dimensions. The first obstacle that we face here is the lack of really sharp bounds on the complexity of vertical decompositions in arrangements of surfaces, even for the whole arrangement, which prevents our technique from "taking off" at all. Recently Schwarzkopf and Sharir [62] have shown that the complexity of the vertical decomposition of a single cell in an arrangement of surfaces in $\mathbb{R}^3$ is $O(n^{2+\varepsilon})$. It is an open problem whether these techniques can be extended to bound the complexity of the vertical decomposition of the lower envelope of trivariate functions.

Another open problem is to extend our results to other cases involving shallow levels in 3-dimensional arrangements. For example, we may want to maintain dynamically a single cell in an arrangement of surfaces in $\mathbb{R}^3$ or the union or intersection of a collection of 3-dimensional objects, etc. Extending the analysis of section 2 to these situations seems considerably more difficult.

A $2\frac{1}{2}$-APPROXIMATION ALGORITHM FOR SHORTEST SUPERSTRING*

Z. SWEEDYK†

Abstract. Given a set of strings $S = \{s_1, s_2, \ldots, s_n\}$ over a finite alphabet Σ, a *superstring* of S is a string that contains each s_i as a contiguous substring. The *shortest superstring* (SS) problem is to find a superstring of minimum length.

This problem has important applications in computational biology and in data compression (see, respectively, [A. Lesk, ed., *Computational Molecular Biology, Sources and Methods for Sequence Analysis*, Oxford University Press, Oxford, 1988]; [J. Storer, *Data Compression: Methods and Theory*, Computer Science Press, Rockville, MD, 1988]). SS is MAX SNP-hard [A. Blum et al., *Proc.* 23*rd Annual ACM Symposium on Theory of Computing*, ACM, New York, 1991, pp. 328–336] so it is unlikely that the length of a shortest superstring can be approximated to within an arbitrary constant. Several heuristics have been suggested and it is conjectured that GREEDY achieves an approximation factor of 2. This, unfortunately, remains an open question.

Several linear approximation algorithms for SS have been proposed. The first, by Blum et al. [*Proc.* 23*rd Annual ACM Symposium on Theory of Computing*, ACM, New York, 1991, pp. 328–336], guarantees a performance factor of 3. The factor has been successively improved to $2\frac{8}{9}$, $2\frac{5}{6}$, $2\frac{50}{63}$, $2\frac{3}{4}$, $2\frac{2}{3}$, and 2.596 (see, respectively, [S. Teng and F. Yao, *Proc.* 34*th Annual IEEE Symposium on Foundations of Computer Science*, IEEE Computer Society Press, Piscataway, NJ, 1993, pp. 158–165]; [A. Czumaj et al., *Proc. First Scandinavian Workshop on Algorithm Theory*, Lecture Notes in Comput. Sci. 824, Springer-Verlag, Berlin, 1994, pp. 95–106]; [R. Kosaraju, J. Park, and C. Stein, *Proc.* 35*th Annual IEEE Symposium on Foundations of Computer Science*, IEEE Computer Society Press, Piscataway, NJ, 1994, pp. 166–177]; [C. Armen and C. Stein, *Proc.* 5*th Internat. Workshop on Algorithms and Data Structures*, Lecture Notes in Comput. Sci. 955, Springer-Verlag, Berlin, 1995, pp. 494–505]; [C. Armen and C. Stein, *Proc. Combinatorial Pattern Matching*, Lecture Notes in Comput. Sci. 1075, Springer-Verlag, Berlin, 1996, pp. 87–101]; and [D. Breslauer, T. Jiang, and Z. Jiang, *J. Algorithms*, 24 (1997), pp. 340–353]). In this paper we give an algorithm that guarantees a $2\frac{1}{2}$-approximation factor.

1. Introduction.

Let $S = \{s_1, \ldots, s_n\}$ be a set of strings. A *superstring* of S is a string containing each $s_i \in S$ as a contiguous substring. The *shortest superstring* (SS) problem is to find a minimum length superstring of the input set S. We use OPT_S to denote a shortest superstring of S and $|OPT_S|$ to denote the string's length.

SS has important applications in computational biology [6], [8]. For example, DNA is a (double-stranded) sequence of four types of nucleotides: adenine, cytosine, guanine, and thymine. The sequence has an orientation and can be viewed as a string over the alphabet $\{A, C, G, T\}$. The *sequencing* problem in molecular biology is to "read" a string of DNA. There are laboratory methods to read fairly short pieces of DNA. To read a longer piece, many copies are made that are then cut into smaller, overlapping pieces that can be read. A typical approach to reassembling them is finding a short superstring; intuitively, short superstrings preserve important

biological structure and are good models of the original DNA sequence. SS also has applications in data compression [9], as data may be stored efficiently as a superstring.

In practice, biologists tend to use heuristics to find short superstrings. Probably the most widely used heuristic is GREEDY. It merges two strings in the input set with largest overlap, repeating until only one string remains. There are examples in which GREEDY produces a string of length $(2 - o(1))|OPT_S|$ and it is conjectured that this bound is tight.

SS is MAX SNP-hard [3], so it is unlikely that $|OPT_S|$ can be approximated to within an arbitrary constant. A p-approximation algorithm for SS produces a superstring of length at most $p \cdot |OPT_S|$; p is called the approximation factor of the algorithm. Blum et al. [3] gave the first linear approximation bound for SS; they showed that GREEDY is a 4-approximation algorithm and also gave a GREEDY variant that gives a 3-approximation. The 3-approximation factor was improved in a series of papers yielding approximation ratios of $2\frac{8}{9}$ by Teng and Yao [11]; $2\frac{5}{6}$ by Czumaj et al. [5]; $2\frac{50}{63}$ by Kosaraju, Park, and Stein [7]; $2\frac{3}{4}$ by Armen and Stein [1]; $2\frac{2}{3}$ by Armen and Stein [2]; and 2.596 by Breslauer, Jiang, and Jiang [4]. Here we give a $2\frac{1}{2}$-approximation algorithm.

The general approach of these algorithms is a two-stage process. They first partition the input set S into sets $S_1, S_2, \ldots, S_k$ and construct a superstring α_i for each S_i. In the second stage they construct a superstring α on the set $S' = \{\alpha_1, \alpha_2, \ldots, \alpha_k\}$; α is also a superstring of S. The strings in S' enjoy some nice properties that generally don't hold for S; Blum et al. are able to show that $|\alpha| \leq |OPT_{S'}| + |OPT_S|$. The 3-approximation proof is completed by showing that $|OPT_{S'}| \leq 2|OPT_S|$.

The partition of S described above is defined by a *cycle cover* on the *distance/overlap graph*. This graph, denoted G_S, is a complete digraph with vertex set S; each edge of the graph is assigned a positive *length*. A *cycle cover* of G_S is a set of simple cycles that partition the vertices of the graph. A minimum-length cycle cover of G_S, denoted ${\mathcal{C}_S}^*$, can be found in polynomial time, and the length of such a cover is no more than $|OPT_S|$. Each set S_i described above corresponds to a distinct cycle $c \in {\mathcal{C}_S}^*$.

Subsequent improvements in the approximation factor for SS have been achieved primarily by improving the $|\alpha| \leq |OPT_{S'}| + |OPT_S|$ bound; by more careful construction of the superstrings α_i in S', [2] and [4] show that $|\alpha| \leq |OPT_{S'}| + \frac{2}{3}|OPT_S|$. This general approach has obvious limitations: one needs to give an optimal superstring algorithm for the set S' in order to achieve a 2-approximation for the input set S, and the superstring problem remains MAX-SNP hard when restricted to input sets with the properties of S'.[1]

Our algorithm begins by constructing ${\mathcal{C}_S}^*$; then it *merges* cycles in ${\mathcal{C}_S}^*$ to produce a new cycle cover $\mathcal{C}$, and finally it *opens* each cycle of $\mathcal{C}$ to produce a set of strings. The concatenation of these strings yields a superstring of S; we denote this approximately optimal superstring as $AOPT_S$. Unlike the superstrings produced by the previous algorithms, $AOPT_S$ is not necessarily a superstring over some S' as described earlier. As a consequence we are able to avoid the problematic bound; there is no obvious reason our approach can't be improved to give a 2-approximation.

To analyze the length of $AOPT_S$ we define a generalized distance/overlap multigraph, $\mathcal{G}_S$. We also define an integer-valued function f. Our result is given in the following theorem; we call $\mathcal{C}_L$ the *lower bound cycle cover* and $\mathcal{C}_U$ the *upper bound cycle cover*.

[1]The property is that the self-loops of $G_{S'}$ are a minimum-length cycle cover of the graph.

Theorem 1.1. *Let S be a set of strings. There exist cycle covers $\mathcal{C}_U$ and $\mathcal{C}_L$ of $\mathcal{G}_S$ such that*

$$|AOPT_S| \leq |\mathcal{C}_U| \leq \frac{5}{2} f(\mathcal{C}_L) \leq \frac{5}{2}|OPT_S|.$$

Our algorithm runs in time $O(n^3 + L_S)$, where $L_S = \sum_{s \in S}|s|$, which is the same as the other approximation algorithms for this problem. We conjecture that our algorithm can be modified slightly and the analysis improved to show a $2\frac{1}{3}$ or better approximation bound. In addition, our techniques seem to shed light on GREEDY and may lead to better bounds for that algorithm.

In section 2 we give some basic definitions and lemmas related to strings. We also define the distance/overlap graph and give an algorithm that finds a minimum-length cycle cover of the graph. In section 3 we define the generalized distance/overlap multigraph and discuss properties of its cycles and cycle covers. In section 4 we describe our approximation algorithm and prove Theorem 1.1, subject to two lemmas which are proved in sections 5 and 6.

2. Background. In this section we give some basic definitions and well-known lemmas relating string overlap to periodic structure. We also define the distance/overlap graph and describe some properties of its cycles and cycle covers. In the following, s, t, u, v, and w refer to strings and S refers to a set of strings.

The string s^q (where $q|s|$ is integral) is defined recursively as the prefix of s of length $q|s|$ when $q < 1$ and the string ss^{q-1} otherwise. For example, $(ba)^0$ is the empty string, which we denote as ϵ, $(ba)^{1/2} = b$, $(ba)^{3/2} = bab$, and $(ba)^2 = baba$.

We say the string v is an *overlap of s with respect to t* if v is a proper suffix of s and a proper prefix of t. $OV(s,t)$ is the set of overlaps of s with respect to t, and $ov_\ell(s,t)$ denotes the string in $OV(s,t)$ of length ℓ, provided such a string exists. $OV(s,t)$ always contains the empty string ϵ and thus is nonempty for any s, t. When $ov_\ell(s,t)$ exists we denote the strings u and w, where $s = u \cdot ov_\ell(s,t)$ and $t = ov_\ell(s,t) \cdot w$, as $pref_\ell(s,t)$ and $suff_\ell(s,t)$. We use $ov(s,t)$ to denote the longest string in $OV(s,t)$; $pref(s,t)$ and $suff(s,t)$ denote the corresponding prefix of s and suffix of t. Finally, we define $ov_{max}(s,t) = \max(|ov(s,t)|, |ov(t,s)|)$.

Example 2.1. *Consider the strings $u_1 = c(ab)^j$ and $u_2 = (ba)^k$ for integers $j, k \geq 1$. Then $OV(u_1,u_2) = \{\epsilon, (ba)^{i-\frac{1}{2}}, i = 1, \ldots, \min(j,k)\}$, $OV(u_2,u_1) = \{\epsilon\}$, $OV(u_1,u_1) = \{\epsilon\}$, and $OV(u_2,u_2) = \{(ba)^i, i = 0, \ldots, k-1\}$.*

Note that in this example u_i, $i = 1, 2$, is not in $OV(u_i,u_i)$ since the self-overlap of u_i must be a proper prefix and proper suffix of u_i. Lemma 2.2 is due to [12] and [13]. The proof follows from Figure 1. Lemma 2.3 follows by a similar argument.

Lemma 2.2. *Let s, t, u, and v be strings. If $ov_k(s,t)$, $ov_\ell(s,u)$, and $ov_j(v,t)$ exist for $k \geq \max(j,\ell)$, then $ov_m(v,u)$ exists for $m = \max(0, j + \ell - k)$.*

Lemma 2.3. *Let s, t, and u be strings. If $ov_k(s,t)$ and $ov_j(t,u)$ exist, then so does $ov_\ell(s,u)$, where $\ell = \max(0, j + k - |t|)$.*

If $s = uv$, then vu is a *cyclic rotation* of s. If all the cyclic rotations of s are distinct, then s is *irreducible*. If not, then s is *reducible*. We say that $s \equiv t$ if s is a cyclic rotation of t; $\equiv$ is an equivalence relation and $[s]$ denotes the equivalence class of cyclic rotations of s. Thus s is irreducible if and only if $||[s]|| = |s|$. We say that s is *periodic* in t if $s = t^q$ for some q. We also say that s is periodic in $[t]$ to mean that s is periodic in some cyclic rotation of t. Any string s is periodic in $pref(s,s)$. We call $pref(s,s)$ the *period of s* and use the shorthand δ_s to denote this string. It is easy

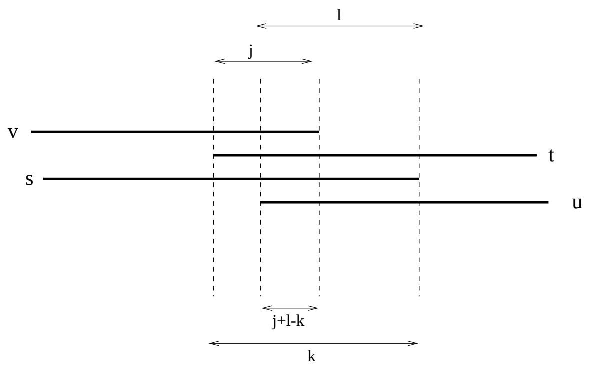

FIG. 1. *Overlap relationships.*

to see that δ_s is irreducible. In Example 2.1 $\delta_{u_1} = u_1$ and $\delta_{u_2} = ba$. The following lemmas and corollary are explicit or implicit in [3].

LEMMA 2.4. *For any string s, δ_s is the shortest string in which s is periodic. Furthermore, for $v \in OV(s,s)$, either $|v| \equiv |s| \bmod |\delta_s|$ or $|v| < |\delta_s|$.*

LEMMA 2.5. *Let δ_1 and δ_2 be irreducible strings such that $[\delta_1] \neq [\delta_2]$. If s is periodic in $[\delta_1]$ and in $[\delta_2]$, then $|s| < |\delta_1| + |\delta_2|$.*

Since $ov(s,t)$ is a substring of s and t and thus periodic in $[\delta_s]$ and $[\delta_t]$, we get the following corollary.

COROLLARY 2.6. *If s and t are strings such that $[\delta_s] \neq [\delta_t]$, then $|ov(s,t)| < |\delta_s| + |\delta_t|$.*

We say the set of strings $S = \{u_0, \dots, u_{n-1}\}$ is *substring free* if s is not a substring of t for any distinct strings $s,t \in S$. We assume, without loss of generality, that our input set S is substring free. Then for some permutation π of $[0, n-1]$, the string

$$pref(u_{\pi_0}, u_{\pi_1}) \cdot pref(u_{\pi_1}, u_{\pi_2}) \cdots pref(u_{\pi_{n-2}}, u_{\pi_{n-1}}) \cdot u_{\pi_{n-1}}$$

is a shortest superstring in S. We let π^*_S denote some such permutation for a substring-free set of strings S.

The *distance/overlap graph for S* is a digraph with vertex set S, and for every $s,t \in S$ an edge e from s to t with *length* $|e| = |pref(s,t)|$ and *overlap* $ov(e) = |ov(s,t)|$. As is standard in weighted graphs, the weight, in this case either length or overlap, of a cycle or cycle cover in G_S is the sum of the weights of its edges. Any permutation π of $[0, n-1]$ defines a Hamiltonian cycle c_π in G_S, $c_\pi = (u_{\pi_0}, u_{\pi_1}, \dots, u_{\pi_{n-1}}, u_{\pi_0})$. The following theorem given by Blum et al. [3] follows from the facts that $c_{\pi^*_S}$ is a cycle cover of G_S and that $|c_{\pi^*_S}| \leq |OPT_S|$.

THEOREM 2.7. *Let $\mathcal{C}$ be a minimum-length cycle cover of G_S. Then $|\mathcal{C}| \leq |OPT_S|$.*

Note that a minimum-length cycle cover of G_S is also a maximum-overlap cover. Blum et al. [3] show that the following algorithm constructs a maximum-overlap cover of G_S.

```
GREEDY-COVER($G_S$)
 Let $\mathcal{C}_S{}^* = \phi$. Order the edges of $G_S$ as $e_1, \dots, e_{n^2}$ so that $ov(e_i) \geq ov(e_{i+1})$.
 For $i = 1, \dots, n^2$
         Add $e_i = \langle s,t \rangle$ to $\mathcal{C}_S{}^*$ if $s$ does not have an out-edge and $t$ does not have an
             in-edge in $\mathcal{C}_S{}^*$.
```

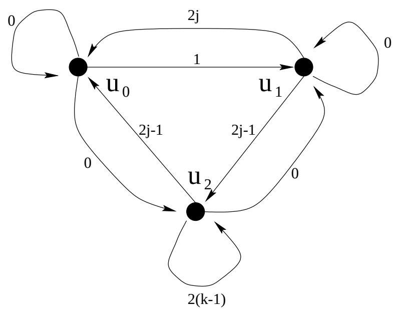

FIG. 2. $G_{S_{j,k}}$ *for* $1 \leq j \leq k$ *with edge overlaps shown.*

EXAMPLE 2.8. *Consider the class of sets*

$$S_{j,k} = \{u_0 = (ab)^j c, u_1 = c(ab)^j, u_2 = (ba)^k\}$$

for integers $k \geq j \geq 1$*. The graph* $G_{S_{j,k}}$ *is shown in Figure* 2*. For this example*

1. $OPT_S = c(ab)^{k+1}c$*,* $|OPT_S| = 2k + 4$*,*
2. $c_{\pi_S^*} = (u_0, u_1, u_2, u_0)$*,* $|c_{\pi_S^*}| = 2k + 3$*,*
3. $\mathcal{C}_S{}^* = \{c_1 = (u_0, u_1, u_0), c_2 = (u_2, u_2)\}$*,* $|\mathcal{C}_S{}^*| = 2j + 3$*.*

As the previous example illustrates, $|\mathcal{C}_S{}^*|$ may be a very good lower bound for $|OPT_S|$ or an arbitrarily bad lower bound; e.g., set $j = k$ or fix j and let k be arbitrarily large.

Throughout this paper we describe various features of the simple cycles of G_S (and later describe simple cycles of the generalized graph $\mathcal{G}_S$); we use *cycle* synonymously with *simple cycle*. Let $c = (s_0, s_1, \ldots, s_{j-1}, s_0)$ be a cycle of G_S. The *periods* of c, denoted $[c]$, are the equivalence class of cyclic rotations of the string

$$pref(s_0, s_1), \ldots, pref(s_{j-2}, s_{j-1}), pref(s_{j-1}, s_0).$$

For any ℓ, the string

$$x = pref(s_\ell, s_{\ell+1}) \cdot pref(s_{\ell+1}, s_{\ell+2}) \cdots pref(s_{\ell+j-2}, s_{\ell+j-1}) \cdot s_{\ell+j-1},$$

where the indices are taken modulo j, is called an *open* of c. The vertices s_ℓ and $s_{\ell+j-1}$ are called, respectively, x_{first} and x_{last}. The edge $\langle x_{last}, x_{first}\rangle$ is called the *opening edge* of x. We use $op(c)$ to denote a shortest open of c.

FACT 2.9. *Let c be a cycle in G_S and let x be an open of c with opening edge e. Then* $|x| = |c| + ov(e)$*.*

For $c \in \mathcal{C}_S{}^*$, we define $OP(c)$ to be the set of opens of c and $U_S^* = \cup_{c \in \mathcal{C}_S^*} OP(c)$. For $x \in U_S^*$, we use c_x to denote the cycle for which x is an open and e_x to denote the opening edge of x in c_x. Thus $\mathcal{C}_S{}^*$ consists of the edges $\{e_x \mid x \in U_S^*\}$. For $x, y \in U^*$, $c_x \neq c_y$, we define $e_{max}(x, y)$ to be the maximum-overlap edge in $\{\langle x_{last}, y_{first}\rangle, \langle y_{last}, x_{first}\rangle\}$.

EXAMPLE 2.8 (continued).

1. *The set* U_S^* *for this example is*

$$U_S^* = \{x_0 = (ab)^j c(ab)^j, x_1 = c(ab)^j c, x_2 = (ba)^k\}.$$

2. *The opening edges for* $x \in U_S^*$ *are* $e_{x_0} = \langle u_1, u_0\rangle, e_{x_1} = \langle u_0, u_1\rangle$*, and* $e_{x_2} = \langle u_2, u_2\rangle$*.*

3. *The shortest opens of the cycles in* ${\mathcal{C}_S}^*$ *are* $op(c_1) = x_1$, $op(c_2) = x_2$.

Blum et al. [3] proved the following lemmas. The second of these lemmas, together with Theorem 2.7, provides the bound described in the introduction, $OPT_{S'} \leq 2OPT_S$, when S' contains an open for each $c \in {\mathcal{C}_S}^*$.

LEMMA 2.10. *Let* c_x *and* c_y *be distinct cycles in* ${\mathcal{C}_S}^*$ *with opens, respectively,* x *and* y. *Then*

1. $[\delta_x] = [c_x] \neq [c_y] = [\delta_y]$,
2. $OV(x, x) = OV(x_{last}, x_{first})$ *and* $OV(x, y) = OV(x_{last}, y_{first})$,
3. $ov(e_{max}(x, y)) = ov_{max}(x, y) < |c_x| + |c_y|$.

LEMMA 2.11. *Let* X *be a subset of the cycles in* ${\mathcal{C}_S}^*$, *let* $T \subseteq S$ *be the strings corresponding to* $c \in X$, *and let* V *contain exactly one* $x \in OP(c)$ *for each* $c \in X$. *Then*

$$OPT_{S-T\cup V} \leq OPT_S + \sum_{c \in X} |c|.$$

Sweedyk [10] proved the following lemma. Since finding a shortest open of a cycle in G_S is easy, we can assume that ${\mathcal{C}_S}^*$ consists of more than one cycle.

LEMMA 2.12. *If* ${\mathcal{C}_S}^*$ *consists of a single cycle* c, *then* $op(c)$ *is a shortest superstring of* S.

We now define the edge exchange, which is a general purpose tool used throughout our proof.

DEFINITION 2.13. *Let* $\mathcal{C}$ *be a cycle cover and let* $e = \langle s, t\rangle$ *be an edge of* G_S. *Assume* $e_1 = \langle s, u\rangle$ *and* $e_2 = \langle v, t\rangle$ *are, respectively, the out-edge of* s *and the in-edge of* t *in* $\mathcal{C}$. *The edge exchange of* e *in* $\mathcal{C}$, *denoted* $\mathcal{X}(\mathcal{C}, e)$, *is the cycle cover* $\mathcal{C} - \{e_1, e_2\} \cup \{e, e_3\}$, *where* $e_3 = \langle v, u\rangle$.

Note that the in- and out-degrees of each vertex are unchanged by the edge exchange, so if $\mathcal{C}$ is a cycle cover and e an edge of G_S, then $\mathcal{X}(\mathcal{C}, e)$ is in fact a cycle cover of G_S. Also, we make no assumptions about distinctness of the strings u, v, s, and t in this definition.

DEFINITION 2.14. *Let* $\mathcal{C}$ *be a cycle cover and let* $e = \langle s, t\rangle$ *be an edge of* G_S. *Assume* $e_1 = \langle s, u\rangle$ *and* $e_2 = \langle v, t\rangle$ *are, respectively, the out-edge of* s *and the in-edge of* t *in* $\mathcal{C}$. *We say that* $e = \langle s, t\rangle$ *is a* winning edge *for* $\mathcal{C}$ *if* $ov(e) \geq \max(ov(e_1), ov(e_2))$.

LEMMA 2.15. *Let* $\mathcal{C}$ *be a cycle cover of* G_S *and let* e *be a winning edge for* $\mathcal{C}$. *Then* $|\mathcal{X}(\mathcal{C}, e)| \leq |\mathcal{C}|$.

This follows directly from Lemmas 2.2 and 2.10. In Example 2.8 the edge $e = \langle u_1, u_0\rangle$ is a winning edge for $c_{\pi_S^*} = (u_0, u_1, u_2, u_0)$ and $\mathcal{X}(\{c_{\pi_S^*}\}, e) = {\mathcal{C}_S}^*$. If $k > j$, then $\langle u_2, u_2\rangle$ is also a winning edge and the corresponding edge exchange also produces ${\mathcal{C}_S}^*$. The next fact follows from the construction in GREEDY-COVER.

FACT 2.16. *Let* $\langle s, t\rangle$ *be any edge in* G_S *and let* $\langle s, u\rangle$ *and* $\langle v, t\rangle$ *be, respectively, the out-edge of* s *and the in-edge of* t *in* ${\mathcal{C}_S}^*$. *Then* $\max(ov(s, u), ov(v, t)) \geq ov(s, t)$.

Lemma 2.15 and Fact 2.16 form the basis of the following optimality proof of ${\mathcal{C}_S}^*$. We generalize this proof in section 6.

1. Color the edges of ${\mathcal{C}_S}^*$ *white* and the remaining edges of G_S *black*. Let $\mathcal{C}_0$ be any cycle cover of G_S and set $i = 0$.
2. While $\mathcal{C}_i$ contains a *black* edge, choose the maximum overlap *white* edge e that is not in $\mathcal{C}_i$ and set $\mathcal{C}_{i+1} = \mathcal{X}(\mathcal{C}_i, e)$ and $i = i + 1$.

The construction produces a series of covers $\mathcal{C}_0, \mathcal{C}_1, \ldots, \mathcal{C}_m$. By Fact 2.16 each edge selected as the basis of an edge exchange is a winning edge for the current cover so $|\mathcal{C}_{i+1}| \leq |\mathcal{C}_i|$. The final cover consists entirely of *white* edges and thus is ${\mathcal{C}_S}^*$.

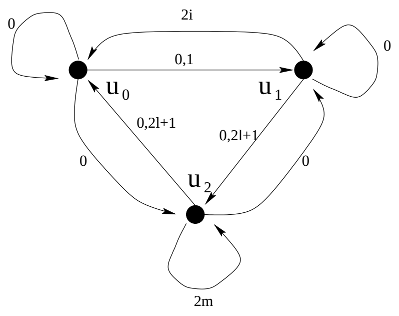

FIG. 3. $\mathcal{G}_{S_{j,k}}$ *with edge overlaps shown, where* $i \in [0, j]$, $\ell \in [0, j-1]$, *and* $m \in [0, k-1]$. *(Recall* $u_0 = (ab)^j c$, $u_1 = c(ab)^j$, $u_2 = (ba)^k$.*)*

3. The string functions and lemmas.

In this section we introduce several definitions that capture some of the structure of the overlaps of strings in U_S^*. To analyze this structure we generalize the distance/overlap graph as follows.

DEFINITION 3.1. *The distance/overlap multigraph* $\mathcal{G}_S$ *for a set of strings* S *is a digraph with vertex set* S *and, for every* $s, t \in S$, *and every* $v \in OV(s, t)$, *an edge* $\langle s, t, |v|\rangle$ *from* s *to* t *with length* $|s| - |v|$ *and overlap* $|v|$.

Figure 3 shows $\mathcal{G}_S$ for the set of strings in Example 2.8. An edge $\langle s, t, k\rangle$ of $\mathcal{G}_S$ is *tight* if $k = |ov(s, t)|$ and *loose* otherwise. The tight edge $\langle s, t, |ov(s, t)|\rangle$ may be denoted simply as $\langle s, t\rangle$. Edge $e = \langle s, t, k\rangle$ and $e' = \langle s, t, k'\rangle$ are *versions* of each other and if $|e| \geq |e'|$ we say that e is an expansion of e'. These definitions extend to cycles (as before, we mean *simple cycles*) and to cycle covers in the natural way; e.g., c is an expansion of c' if every edge of c is an expansion of an edge of c'. Any edge of a maximum-overlap cover of $\mathcal{G}_S$ must be tight, so $\mathcal{C}_S{}^*$ is an optimal cover of $\mathcal{G}_S$.

We call a cycle $\hat{c}$ of $\mathcal{G}_S$ a 1-*expansion* of $c \in \mathcal{C}_S{}^*$ if $\hat{c}$ is an expansion of c; furthermore, it has at most one loose edge. When we refer to a 1-expansion of c_x for $x \in U_S^*$ we mean that the only possible loose edge in the 1-expansion is from x_{last} to x_{first}. There is a 1-expansion of c_x for each expansion of e_x in $\mathcal{G}_S$. We could define 1-expansions for arbitrary cycles in G_S, but we never need this broader definition, so by 1-expansion we implicitly mean a 1-expansion of some cycle $c \in \mathcal{C}_S{}^*$. (We will use the more general notion of expansion for arbitrary simple cycles of $\mathcal{G}_S$.)

The definitions of period and open extend in the natural way for cycles in $\mathcal{G}_S$. For a cycle

$$c = \langle s_0, s_1, k_0\rangle, \langle s_1, s_2, k_1\rangle, \ldots, \langle s_{j-1}, s_0, k_{j-1}\rangle$$

in $\mathcal{G}_S$ $[c] = [\mathit{pref}_{k_0}(s_0, s_1) \cdot \mathit{pref}_{k_1}(s_1, s_2) \cdots \mathit{pref}_{k_{j-1}}(s_{j-1}, s_0)]$, and for any ℓ,

$$x = \mathit{pref}_{k_\ell}(s_\ell, s_{\ell+1}) \cdot \mathit{pref}_{k_{\ell+1}}(s_{\ell+1}, s_{\ell+2}) \cdots \mathit{pref}_{k_{\ell+j-2}}(s_{\ell+j-2}, s_{\ell+j-1}) \cdot s_{\ell+j-1}$$

is an open of c, where the indices are taken modulo j. Furthermore, $|x| = |c| + ov(e)$, where $e = \langle s_{\ell+j-1}, s_\ell, k_{\ell+j-1}\rangle$ is the opening edge of x. It follows that if a cycle c is an expansion of c' in $\mathcal{G}_S$, then $|op(c)| \geq |op(c')|$. Also, for $x \in U_S^*$, x is an open of any 1-expansion $\hat{c}_x$ of c_x and its opening edge in $\hat{c}_x$ is an expansion of e_x.

Definition 2.14 for a winning edge does not change for covers in $\mathcal{G}_S$; an edge $e = \langle s, t, k\rangle$ of $\mathcal{G}_S$ is a winning edge for a cycle cover $\mathcal{C}$ of $\mathcal{G}_S$ if k is at least as large as the overlap of the out-edge of s and the in-edge of t in $\mathcal{C}$. We continue to use the

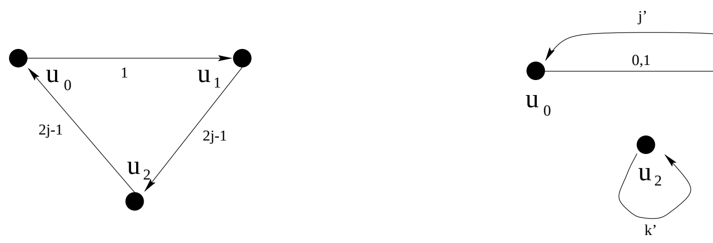

FIG. 4. *The cycle $c_{\pi_S^*}$ is shown on the left and the cycle cover $\tilde{\mathcal{X}}(c_{\pi_S^*}, e)$ on the right. If $e = e_{x_0}$, then $j' = 2j$ and $k' = 2j - 2$. If $e = \langle u_2, u_2, 2m\rangle$ for some $2k > 2m > 2j - 1$, then $j' = \max(0, 2(2j - 1 - m))$ and $k' = 2m$.*

edge exchange function $\mathcal{X}$ from Definition 2.13, which uses tight edges, but we define another edge exchange function, $\tilde{\mathcal{X}}$, which exploits the loose edges of $\mathcal{G}_S$.

DEFINITION 3.2. *Let $\mathcal{C}$ be a cycle cover and $e = \langle s, t, k\rangle$ be an edge of $\mathcal{G}_S$. Assume $e_1 = \langle s, u, j\rangle$ and $e_2 = \langle v, t, \ell\rangle$ are, respectively, the out-edge of s and the in-edge of t in $\mathcal{C}$. The* parsimonious *edge exchange of e in $\mathcal{C}$, denoted $\tilde{\mathcal{X}}(\mathcal{C}, e)$, is the cycle cover $\mathcal{C} - \{e_1, e_2\} \cup \{e, e_3\}$, where if $k \geq \max(j, \ell)$, then $e_3 = \langle v, u, \max(0, j + \ell - k)\rangle$; otherwise $e_3 = \langle v, u\rangle$.*

The existence of the edge e_3 in this definition is guaranteed by Lemma 2.2 when $k \geq j, \ell$. We call e_3 the *losing edge* of the edge exchange.

LEMMA 3.3. *Let $\mathcal{C}$ be a cycle cover of $\mathcal{G}_S$ and let e be a winning edge for $\mathcal{C}$. Then $|\tilde{\mathcal{X}}(\mathcal{C}, e)| \leq |\mathcal{C}|$. Also, the overlap of the losing edge of the exchange is no more than the minimum overlap of the edges eliminated by the exchange. Finally, if $|\tilde{\mathcal{X}}(\mathcal{C}, e)| < |\mathcal{C}|$, then the losing edge of the exchange has zero overlap.*

EXAMPLE 2.8 (continued). *The edge $e_{x_0} = \langle u_1, u_0\rangle$ is a winning edge for $c_{\pi_S^*}$. When $k > j$ and $2k > 2m \geq 2j - 1$, the edge $e_m = \langle u_2, u_2, 2m\rangle$ is also a winning edge for $c_{\pi_S^*}$. Figure 4 shows $c_{\pi_S^*}$ and $\tilde{\mathcal{X}}(\{c_{\pi_S^*}\}, e)$ for this example.*

To motivate the remaining definitions in this section we describe the general strategy of our proof relative to Example 2.8. We focus on two specific cases: case 1, where $j = 1$ and $k >> j$; and case 2, where $j = k > 1$. Our first objective is to establish the existence of a cover $\mathcal{C}_L$ whose length gives a *good* lower bound for $|OPT_S|$; for the moment *good* means that $|OPT_S|/|\mathcal{C}_L|$ is bounded. In case 2, setting $\mathcal{C}_L = \mathcal{C}_S{}^*$ suffices since $|\mathcal{C}_S{}^*| = |OPT_S| - 1$. In case 1, however, $|OPT_S|/|\mathcal{C}_S{}^*|$ is unbounded and the cover $\mathcal{C}_L$ must be a strict expansion of $\mathcal{C}_S{}^*$. We argue that, since $c_{\pi_S^*}$ is a Hamiltonian cycle, it does not contain $\langle u_2, u_2\rangle$ and thus must include either the edges $\langle u_1, u_2\rangle$ and $\langle u_2, u_0\rangle$ or the edges $\langle u_0, u_2\rangle$ and $\langle u_2, u_1\rangle$. In either case, $e = \langle u_2, u_2, 2\rangle$ is a winning edge for $c_{\pi_S^*}$. The cover $\mathcal{C}_L = \tilde{\mathcal{X}}(c_{\pi_S^*}, e)$ includes the 1-expansion $\hat{c}_1$ of c_1 containing the loose edge $\langle u_1, u_0, 0\rangle$ and the 1-expansion $\hat{c}_2$ of c_2 containing the loose edge $\langle u2, u_2, 2\rangle$. The length of $\mathcal{C}_L$ is exactly $|c_{\pi_S^*}| = |OPT_S| - 1$.

Our general argument is complicated by the fact that $\mathcal{C}_S{}^*$ typically contains more than two cycles, and the cycles may have many different opens. Nevertheless, our argument hinges on the fact that, for any $c \in \mathcal{C}_S{}^*$, there are vertices s and t in c whose in-edge and out-edge connect to vertices not in c; by analyzing the possibilities we can, when necessary, get a better bound for $|OPT_S|$ than that provided by $|\mathcal{C}_S{}^*|$. To this end we want to identify for x and y in U_S^*, $c_x \neq c_y$, the expansions of e_x and e_y that are winning edges for the cycle $c_{x,y} = \mathcal{X}(\{c_x, c_y\}, e_{max}(x, y))$; by this somewhat abusive notation we mean that $c_{x,y}$ is the tight cycle created by the edge exchange to the cover $\{c_x, c_y\}$ on the vertex-induced subgraph of $\mathcal{G}_S$ containing the vertices of c_x

and c_y. We are also interested in the forms of the 1-expansions resulting from edge exchanges to $c_{x,y}$.

Our second objective is to establish an appropriate upper bound on $AOPT_S$. In case 1 our algorithm would set $AOPT_S = x_1 \cdot x_2$. The cover $\mathcal{C}_L$ for this case has the *shallow* property—by that we mean[2] $|op(\hat{c}_i)| \leq 2|\hat{c}_i|$, $i = 1, 2$. Thus we get the following bound:

$$|AOPT_S| = |x_1| + |x_2| \leq |x_0| + |x_2| = \sum_{i=1,2} |op(\hat{c}_i)| \leq 2 \sum_{i=1,2} |\hat{c}_i| = 2|\mathcal{C}_L| \leq 2|OPT_S|.$$

The construction of $\mathcal{C}_U$ for this case is trivial and we omit the details. In case 2, however, the cover $\mathcal{C}_L$ does not have the shallow property and our bound is more complicated. For this case our algorithm would output the shortest open of the cycle $\mathcal{X}(\mathcal{C}_S^*, e_{max}(x_0, x_2))$, which just happens to be the string OPT_S. We cannot argue that strict expansions of e_{x_0} and e_{x_2} are winning edges for $c_{\pi_S^*}$ because of the relatively large overlap of $e_{max}(x, y)$. However, we can argue that there is an expansion $\mathcal{C}_U$ of of $\mathcal{C}_L$ such that $|\mathcal{C}_U| \leq \frac{5}{2}|\mathcal{C}_L|$, $e_{max}(x_0, x_2)$ is a winning edge for $\mathcal{C}_U$, and the cover $\tilde{\mathcal{X}}(\mathcal{C}_U, e_{max}(x_0, x_2))$ has a zero overlap edge. Because $\mathcal{C}_U$ is an expansion of $\mathcal{C}_L$ and thus of ${\mathcal{C}_S}^*$, $\tilde{\mathcal{X}}(\mathcal{C}_U, e_{max}(x_0, x_2))$ is an expansion of $\mathcal{X}({\mathcal{C}_S}^*, e_{max}(x_0, x_2))$ so we get

$$|op(\mathcal{X}({\mathcal{C}_S}^*, e_{max}(x_0, x_2)))| \leq |op(\tilde{\mathcal{X}}(\mathcal{C}_U, e_{max}(x_0, x_2)))| \leq \frac{5}{2}|\mathcal{C}_L| \leq \frac{5}{2}|OPT_S|.$$

To establish upper bounds for $AOPT_S$ we are interested in pairs $x, y \in U_S^*$, $c_x \neq c_y$, and the expansions of c_x and c_y for which the edge $e_{max}(x, y)$ is a winning edge.

For the remainder of this section let x and y be strings in U_S^*, $c_x \neq c_y$. Throughout this section we will use Lemma 2.10, which relates the self-overlaps and overlaps of x and y to the edges between $x_{first}, x_{last}, y_{first}, y_{last}$ in $\mathcal{G}_S$; i.e., $OV(x, x) = OV(x_{last}, x_{first})$ and $OV(x, y) = OV(x_{last}, y_{first})$. Next we develop some notation for describing the 1-expansion in $\mathcal{G}_S$.

DEFINITION 3.4. *Let x be a string in U_S^* and let $\hat{e}_x$ be an expansion of e_x. We denote the* 1*-expansion of c_x corresponding to $\hat{e}_x$ as c_x^d, where*

$$d = \frac{|x| - ov(\hat{e}_x)}{|c_x|}.$$

The quantity $d|c_x|$ is called the pseudolength *of the edge $\hat{e}$ and d is called the* normalized pseudolength *of the edge.*

FACT 3.5. *Let x be a string in U_S^*.*

1. *The* 1*-expansion c_x^d exists for some d if and only if there is an expansion of e_x with pseudo-length $d|c_x|$*
2. *If $\hat{e}_x$ is an expansion of e_x with pseudolength $d|c_x|$, then $d \geq 1$ with equality if and only if $\hat{e}_c = e_x$.*

Throughout our analysis we make the assertion that certain 1-expansions of c_x exist based on the definitions, lemmas, and corollaries of this section. In particular we define the *string functions* on U_S^* and $U_S^* \times U_S^*$ as *shallow*, *trade-off*, *stop*, and *squeeze.* We also prove various properties of the strings in U_S^* and their overlaps based on these functions: Lemmas 3.7, 3.10, 3.12, and 3.15. We call these the *string lemmas.*

DEFINITION 3.6. *Let x be a string in U_S^*. The* shallow *of x, denoted $sh(x)$, is the quantity $(|x| - |v|)/|\delta_x|$, where v is the longest string in $OV(x, x)$ such that $|v| \leq |\delta_x|$.*

[2]Note that the opens of $\hat{c}_1$ are x_0 and $c(ab)^{2j}c$.

Note that $sh(x)$ is well defined since $\epsilon \in OV(x,x)$ and $|\epsilon| = 0 < |\delta_x|$. The next lemma follows directly from Lemma 2.10.

LEMMA 3.7. *Let x be a string in U_S^*. Then $c_x^{sh(x)}$ exists and $|x| \leq (sh(x)+1)|c_x|$.*

By Lemma 2.4, the structure of the 1-expansions of c_x ordered by increasing length is

$$c_x = c_x^1, c_x^2, \ldots, c_x^k, c^{sh(x)}, c_x^{q_1}, c_x^{q_2}, \ldots, c_x^{q_j}, c_x^{|x|/|c_x|}$$

for some integer $k \geq 1, j \geq 0$ and some values $q_1 < q_2, \ldots, < q_{j-1} < q_j < |x|/|c_x|$, where possibly $c_x = c_x^{sh(x)}$ and/or $c_x^{sh(x)} = c_x^{|x|/|c_x|}$. Thus we get the following corollary to Lemma 2.4.

COROLLARY 3.8. *Let x be a string in U_S^*. Then c_x^k exists for any integer $1 \leq k \leq |x|/|c_x|$. If c_x^q exists for some nonintegral q, then $sh(x) \leq q \leq |x|/|c_x| \leq sh(x)+1$.*

The *trade-off* function allows us to identify the expansions of e_x and e_y that are winning edges for $c_{x,y}$.

DEFINITION 3.9. *Let x and y be strings in U_S^*, $c_x \neq c_y$. The* trade-off *of x with respect to y, denoted $tr(x,y)$, is defined as*

$$tr(x,y) = \frac{1}{|\delta_x|}(|x| - ov_{max}(x,y)).$$

LEMMA 3.10. *Let x and y be strings in U_S^*, $c_x \neq c_y$. Then*
1. *c_x^k exists for $k = \max(\lfloor tr(x,y) \rfloor, 1)$,*
2. *$|x| < (tr(x,y)+1)|c_x| + |c_y|$,*
3. *either $tr(x,y) \geq 1$ or $tr(y,x) \geq 1$,*
4. *any expansion of e_x with pseudolength at most $tr(x,y)|c_x|$ has overlap at least $ov(e_{max}(x,y))$, and*
5. *$e_{max}(x,y)$ is a winning edge for any 1-expansions c_x^q and c_y^r that exist, where $q \geq tr(x,y)$ and $r \geq tr(y,x)$.*

In the last point of the lemma, c_x^q and c_y^r exist for $q = |x|/|c_x| \geq tr(x,y)$ and $r = |y|/|c_y| \geq tr(y,x)$, so the claim is never vacuous. The proof of this lemma follows directly from point 3 of Lemma 2.10 and from Fact 2.16. If $tr(y,x) < 1$, then no expansion of e_y is a winning edge for $c_{x,y}$. In this case, by point 4 of Lemma 3.10, e_x is a winning edge for $c_{x,y}$. The following definition identifies the largest expansion of e_x that is guaranteed to be a winning edge for $c_{x,z}$ for any z, $c_z \neq c_x$, such that $tr(z,x) < 1$.

DEFINITION 3.11. *Let x be a string in U_S^*. The* stop *of x, denoted $st(x)$, is defined as*

$$st(x) = \min\{\lfloor tr(x,y) \rfloor \ : \ y \in U_S^*, c_y \neq c_x, tr(y,x) < 1\},$$

where min *over an empty set is ∞. When $st(x)$ is finite, $ST(x)$ denotes an arbitrary $y \in U_S^*$ that determines $st(x)$. If $st(x) = \infty$, then $ST(x)$ is undefined.*

LEMMA 3.12. *Let x be a string in U_S^* such that $st(x)$ is finite. Then $c_x^{st(x)}$ exists and, for $y = ST(x)$,*
1. *$|y| < 2|c_y| + |c_x|$,*
2. *$|x| < (st(x)+2)|c_x| + |c_y|$, and*
3. *$e_{max}(x,y)$ is a winning edge between the 1-expansions $c_x^{\min(st(x)+1, |x|/|c_x|)}$ and c_y.*

The proof follows from Lemma 3.10. If $tr(y,x) \geq 1$, then e_y is a winning edge for $c_{x,y}$, and $\tilde{\mathcal{X}}(\{c_{x,y}\}, e_y)$ consists of c_y and some 1-expansion of c_x. The following definition identifies the smallest 1-expansion of c_x that can be produced by such an edge exchange over all z, $c_z \neq c_x$, where $tr(z,x) \geq 1$.

Definition 3.13. *Let x be a string in U_S^*. The* squeeze *of x, denoted $sq(x)$, is defined to be*

$$sq(x) = \frac{1}{|\delta_x|} \min\{|c_{x,y}| - |c_y| \quad : \quad y \in U_S^*, c_y \neq c_x, |ov(y,y)| \geq ov_{max}(y,x)\},$$

where min *over an empty set is ∞. When $sq(x)$ is finite, $SQ(x)$ denotes an arbitrary $y \in U_S^*$ that determines $sq(x)$. If $sq(x) = \infty$, then $SQ(x)$ is undefined.*

Before we give the string lemma for the squeeze function, we give a technical lemma that will be useful here and later.

Lemma 3.14. *Let x and y be strings in U_S^* such that $c_x \neq c_y$. If $ov_k(y,y)$ exists for some $ov_{max}(x,y) \leq k < |ov(x,y)| + |ov(y,x)| - |\delta_x|$, then $ov_k(y,y)$ is periodic in $[\delta_x]$. Furthermore, $ov_{max}(x,y) > k - \min(|\delta_x|, |\delta_y|)$.*

Proof of Lemma 3.14. To see the proof of the first point refer to Figure 1 and let $s = t = y$, $u = v = x$, $j = |ov(y,x)|$, $\ell = |ov(x,y)|$, and let k be the self-overlap of y as defined in the lemma. Then $k \geq \max(j,\ell)$, so $ov_m(x,x)$ exists for $m = |ov(y,x)| + |ov(x,y)| - k$. By the upper bound on k in the lemma, $m > |\delta_x|$ and by Lemma 2.4 $pref_m(x,x) \cdot x$ is periodic in δ_x. Referring again to Figure 1, $ov_k(y,y)$ is a substring of $pref_m(x,x) \cdot x$ and thus periodic in $[\delta_x]$.

Now consider the second point of the lemma and suppose that $|\delta_x| \leq |\delta_y|$. By the previous point and the fact that x is periodic in $[\delta_x]$, if $ov_{\ell'}(x,y)$ exists for some $\ell' \leq k - |\delta_x|$, then $ov_{\ell'+|\delta_x|}(x,y)$ also exists. Thus $ov_{max}(x,y) \geq |ov(x,y)| > k - |\delta_x|$.

Now suppose that $|\delta_y| < |\delta_x|$ and $ov_{max}(x,y) \leq k - |\delta_y|$. Then, using Lemma 2.2, $ov_{m'}(x,x)$ exists for $m' = |ov(y,x)| + |ov(x,y)| - k + |\delta_y| = m + |\delta_y|$, where m is obtained from the proof of the first point of the lemma. By the upper bound assumption of the lemma, $m > |\delta_x|$ so by Lemma 2.4 $m' - m \equiv 0 \bmod |\delta_x|$. However, $m - m' = |\delta_y| < |\delta_x|$, which is a contradiction. ∎

The next lemma follows from Lemmas 3.10 and 3.14; to use Lemma 3.14 let $k = |ov(y,y)|$ and notice that $|c_{x,y}| = |x| + |y| - |ov(x,y)| - |ov(y,x)|$ and $|c_y| = |y| - |ov(y,y)|$.

Lemma 3.15. *Let x be a string in U_S^* such that $sq(x)$ is finite. Then $c_x^{sq(x)}$ exists and $|x| < (sq(x)+1)|c_x| + |c_{SQ(x)}|$. Furthermore, if $sq(x) < sh(x)$, then for $y = SQ(x)$*

1. *$ov(y,y)$ is periodic in $[\delta_x]$,*
2. *$|y| < 2|c_y| + |c_x|$,*
3. *the edge $e_{max}(x,y)$ is a winning edge between the 1-expansions $c_x^{sq(x)}$ and c_y^q, where $q = 1 + \frac{\min(|c_x|,|c_y|)}{|c_y|}$.*

We are primarily concerned with $sq(x)$ when $sq(x) < sh(x)$ because of the properties guaranteed by the previous lemma for $SQ(x)$.

Example 2.8 (continued). *The 1-expansions in this example are $c_{x_0}^{1+\frac{2\ell}{2j+1}}$, $\ell = 0,1,\ldots,j$, c_{x_1}, $c_{x_1}^{|x_1|/|c_{x_1}|}$, and $c_{x_2}^{\ell}$, $\ell = 1,2,\ldots,k$. The string functions are*

1. *shallow: $sh(x_0) = 1$, $sh(x_1) = 1$, and $sh(x_2) = k-1$;*
2. *trade-off: $tr(x_0,x_2) = 1$, $tr(x_2,x_0) = k-j$, $tr(x_1,x_2) = 1$, $tr(x_2,x_1) = 1$;*
3. *stop: $st(x_1) = st(x_2) = \infty$; if $j = k$, then $st(x_0) = 1$ and $ST(x_0) = x_2$; if $j > k$, then $st(x_0) = \infty$;*

```
1. Construct $G_S$ and find ${\mathcal{C}_S}^*$. Compute $U_S^*$ and the string functions.
2. Build the set of merging edges $W$.
3. Let $\mathcal{C} = {\mathcal{C}_S}^*$.
     While $W$ is nonempty do
          Let $e = \langle s, t \rangle$ be a minimum-overlap edge in $W$.
          If $s$ and $t$ are in different cycles of $\mathcal{C}$, then $\mathcal{C} = \mathcal{X}(\mathcal{C}, e)$.
          $W = W \setminus \{e\}$
4. Set $AOPT_S$ to the concatenation of $op(c)$, $c \in \mathcal{C}$.
```

FIG. 5. *The approximation algorithm.*

4. *squeeze:* $sq(x_0) \geq sh(x_0)$, $sq(x_1) \geq sh(x_1)$, *and either* $sq(x_2) \geq sh(x)$ *or* $sq(x) = 2(k - j - 1) \geq 1$ *and* $SQ(x_2) = x_0$.

4. The approximation algorithm. The approximation algorithm is given in Figure 5. In step 2 the algorithm builds a set of *merging edges* W; these are a subset of the tight edges of $\mathcal{G}_S$. In step 3 the algorithm merges cycles of ${\mathcal{C}_S}^*$ by edge exchanges in G_S based on the edges in W. The cycles of the resulting cover are opened and concatenated to produce the string $AOPT_S$.

During the course of step 2, the algorithm constructs an *expansion value function* and, implicitly, the lower bound cover $\mathcal{C}_L$.

DEFINITION 4.1. *A function* $\mathcal{V}_S : U_S^* \to \mathcal{Q}$ *is an* expansion value function *if for any* $x \in U_S^*$ *there is an expansion of* e_x *with pseudolength* $\mathcal{V}_S(x)|c_x|$. *Furthermore, we say that* $\mathcal{V}_S$ *is* valid *if it satisfies the following conditions:*

1. *For any* $x \in U_S^*$, $\mathcal{V}_S(x) \leq \min(sh(x), sq(x), st(x))$.
2. *For any* $x, y \in U_S^*$, $c_x \neq c_y$, *either* $\mathcal{V}_S(x) \leq tr(x, y)$ *or* $\mathcal{V}_S(y) \leq tr(y, x)$.

FACT 4.2. *Let* $\mathcal{V}_S$ *be an expansion value function. Then the edges*

$$\{\hat{e}_x \mid x \in U_S^* \text{ and } \hat{e}_x \text{ is an expansion of } e_x \text{ with pseudolength } \mathcal{V}_S(x)|c_x|\}$$

form a cycle cover that is an expansion of ${\mathcal{C}_S}^*$.

During step 2, the algorithm also assigns each cycle in ${\mathcal{C}_S}^*$ to a color class in $\{$*blue*, *red*, *yellow*$\}$, and for each *red* and *yellow* cycle c selects an $x \in OP(c)$ as *representative*, denoted *rep*(c). The *red* and *yellow* cycles are the ones for which we need a better bound in $\mathcal{C}_L$. The cover $\mathcal{C}_L$ will include each *blue* cycle and a 1-expansion of $c_{rep(c)}$ for each *red* and *yellow* cycle c. In section 6 we prove that $|\mathcal{C}_L| \leq |OPT_{S'}|$, where S' is constructed from S by replacing the strings associated with each *red* cycle c by *rep*(c). This reduces the constraints that $\mathcal{C}_L$ must satisfy, but at a price, since the best bound we have for $OPT_{S'}$ is, by Lemma 2.11, $|OPT_{S'}| \leq |OPT_S| + \sum_{c \in \mathcal{R}} |c|$, where $\mathcal{R}$ denotes the set of *red* cycles. The function f in Theorem 1.1 is $f(\mathcal{C}_L) = |\mathcal{C}_L| - \sum_{c \in \mathcal{R}} |c|$. We begin by discussing $\mathcal{V}_S$, the coloring, and the representatives. Then we define the cover $\mathcal{C}_L$. Finally, we discuss the selection of edges for W.

Step 2 is broken down into two parts. Part 1 is shown in Figure 6. Let N be the number of cycles in ${\mathcal{C}_S}^*$. The algorithm begins by ordering the cycles of ${\mathcal{C}_S}^*$ by increasing length. We use $c < c'$ (resp., $c > c'$) to denote the fact that c precedes (resp., follows) c' in the order. Throughout our discussion of part 1 of step 2, c_i, $1 \leq i \leq N$, refers to the ith cycle in the algorithm's order. The algorithm initializes $\mathcal{V}_S(x) = 1$ for every $x \in U_S^*$. The algorithm then proceeds in rounds (j, i), $j = 1, 2$ and $i = 1, \ldots, N$; in each round it selects zero or more cycles to color. For notational purposes, each $x \in U_S^*$ adopts the color of c_x and is uncolored while c_x is uncolored.

```
Order the cycles of $\mathcal{C}_S{}^*$ so $|c_1| \le |c_2| \le \cdots \le |c_N|$. Each cycle is initially uncolored.
For each $x \in U_S^*$, $\mathcal{V}_S(x) = 1$.
For $j = 1, 2$ {
        For $i = 1, \dots N$ {
            If $c_i$ is uncolored, then
                For each $x$ in $OP(c_i)$ compute $fo(x)$ and set

                        $g(x) = \min(sh(x), sq(x), st(x), of(x))$.

                Color $c_i$ by the first rule, if any, that holds for some $w \in OP(c_i)$.

                    Rule 1: $g(w) \le \frac{3}{2}$ and stopping condition 1 holds:
                      Color $c_i$ blue.
                      If $G(w)$ is defined and $G(w)$ is uncolored, then color $c_{G(w)}$ blue .
                      If $G(w)$ is defined, then add $e_{max}(w, G(w))$ to $W$.

                    Rule 2: $g(w) > \frac{3}{2}$ and some uncolored $u > w$ conflicts with
                    $w$ and stopping conditions 2 holds and if $G(w)$ is defined, then
                    $c_u \ne c_{G(w)}$:
                      Color $c_i$ red, $\mathcal{V}_S(w) = g(w)$, and $rep(c_i) = w$.
                      Color $c_u$ blue and add $e_{max}(w, u)$ to $W$.
                      *If $G(w)$ is defined and $G(w)$ is colored and $c_i$ is unmatched,
                        then add $e_{max}(w, G(w))$ to $W$.
                      If $G(w)$ is defined and $G(w)$ is uncolored, then color $c_{G(w)}$
                        blue and add $e_{max}(w, G(w))$ to $W$.

                    Rule 3: $g(w) > \frac{3}{2}$ and $G(w)$ is defined and $G(w)$ is uncolored
                    and $G(w) > w$ and stopping condition 3 holds:
                      Color $c_i$ red, $\mathcal{V}_S(w) = g(w)$, and $rep(c_i) = w$.
                      Color $c_{G(w)}$ blue and add $e_{max}(w, G(w))$ to $W$.

                    Rule 4: $j = 2$:
                      Color $c_i$ yellow.
                      For each $x \in OP(c_i)$ {
                          $\mathcal{V}_S(x) = g(x)$.
                          *If $x = rep(c_i)$ and $c_i$ is unmatched and $G(x)$ is defined and
                            $G(x)$ is colored non-yellow, then add $e_{max}(x, G(x))$ to $W$.
                          If $ST(x)$ is defined and $ST(x)$ is uncolored, then color $c_{ST(x)}$
                            blue and add $e_{max}(rep(c_i), ST(x))$ to $W$.
                      }
                }
```

FIG. 6. *Construction of the merging set W, part* 1.

Also for $x, y \in U_S^*$, we use $x < y$ to denote the fact that $c_x < c_y$. Similarly $x > y$ denotes $c_x > c_y$.

Let c_i be a cycle in $\mathcal{C}_S{}^*$. If c_i is colored when round (j, i) begins, the algorithm takes no action during the round. If c_i is uncolored when the round begins, the algorithm computes two functions $fo(x)$ and $g(x) = \min(sh(x), sq(x), st(x), fo(x))$ for each $x \in OP(c_i)$.

DEFINITION 4.3. *Let x be a string in U_S^*. The* force of x *during round (j,i) of the algorithm is defined as*

$$fo(x) = \min\{\max(\lfloor tr(x,y)\rfloor, 1) \mid y \in U_S^* \text{ is colored, } c_y \neq c_x, \text{ and } \mathcal{V}_S(y) \geq tr(y,x)\},$$

where min *over an empty set is ∞. If $fo(x)$ is finite in some round, then $FO(x)$ is set to $ST(x)$ if $st(x) = fo(x)$ and to an arbitrary $y \in U_S^*$ that determines the value of $fo(x)$ otherwise.*

LEMMA 4.4. *Let x be a string in U_S^*. Suppose the algorithm computes $g(x)$ during some round. Then $g(x) \geq 1$ and there is an expansion of e_x with pseudolength $g(x)|c_x|$.*

The proof follows from the string functions and lemmas. Hereafter we include $fo(\cdot)$ when we refer to the "string functions." After computing $fo(x)$ and $g(x)$ for $x \in OP(c_i)$ the algorithm may choose to color c_i *blue*, *red*, or *yellow*. If the algorithm colors c_i it may take additional action as well; it may select additional uncolored cycles and color them *blue*, it may set $\mathcal{V}_S(x) = g(x)$ for some strings $x \in OP(c_i)$, it may add edges incident to vertices of c_i to W, and it may choose an $x \in OP(c_i)$ as the representative of c_i. The next fact follows from the construction.

FACT 4.5. *Let x be a string in $OP(c_i)$ for some $c_i \in \mathcal{C}_S{}^*$. If $\mathcal{V}_S(x) \neq 1$ at the end of some round of the algorithm, then c_i is colored. Furthermore, c_i was colored in round (j,i), where j is either* 1 *or* 2, *and $\mathcal{V}_S(x)$ is set to $g(x)$ as computed at the beginning of round (j,i).*

LEMMA 4.6. *At every point of the algorithm after initialization, $\mathcal{V}_S$ is a valid expansion value function.*

Proof. Let x be a string in U_S^*. We first show that there is an expansion of e_x with pseudolength $\mathcal{V}_S(x)|c_x|$. By Fact 4.5, $\mathcal{V}_S(x)$ is either 1 or is set to $g(x)$ as computed in the round when x is colored. In the first case e_x satisfies the claim. The claim follows in the second case by Lemma 4.4.

Consider the first condition for validity. By the definition of the string functions and lemmas, $1 \leq \min(sh(x), q(x), st(x), fo(x))$. Then the claim follows from Fact 4.5.

Finally, we show that the second condition for validity holds. Let y be a string in U_S^* such that $c_x \neq c_y$. First consider the case where $\mathcal{V}_S(x) = 1$. If $tr(x,y) \geq 1$, we are done, so assume $tr(x,y) < 1$. Then $st(y) \leq tr(y,x)$ and since $\mathcal{V}_S$ is an expansion value function, $\mathcal{V}_S(y) \leq st(y)$. A symmetric argument holds if $\mathcal{V}_S(y) = 1$. Thus we need only consider the case where $\mathcal{V}_S(x) > 1$ and $\mathcal{V}_S(y) > 1$. By Fact 4.5 and the fact that $c_x \neq c_y$, x and y are colored in different rounds. Assume, without loss of generality, that y is colored before x. Then in the round when x is colored, $\mathcal{V}_S(x)$ is set to $g(x)$, where $1 < g(x) \leq fo(x) \leq \max(\lfloor tr(x,y)\rfloor, 1) = \lfloor tr(x,y)\rfloor$, and the condition is satisfied. ☐

DEFINITION 4.7. *Let x be a string in $OP(c_i)$, $c_i \in \mathcal{C}_S{}^*$, and let y be a string in U_S^*, $c_y \neq c_i$. Suppose c_i is uncolored when round (j,i) begins. Then we say that y conflicts with x during the round if $tr(x,y) \leq g(x)$ and $tr(y,x) \leq 2$.*

LEMMA 4.8. *Let x be a string in U_S^* such that in some round the algorithm computes $fo(x) = 1$. Assume $c_{FO(x)} = c_k$. If $FO(x)$ is uncolored when round (j,k) begins, then x conflicts with $FO(x)$ during round (j,k).*

Proof. When the algorithm computes $fo(x) = 1$, $FO(x)$ is colored, $\mathcal{V}_S(FO(x)) \geq tr(FO(x),x)$, and $tr(x, FO(x)) \leq fo(x) + 1 = 2$. Assume $\mathcal{V}_S(FO(x)) = q$. Then in round (j,k), $g(FO(x)) \geq q \geq tr(FO(x),x)$ and $tr(x, FO(x)) \leq 2$, so x conflicts with $FO(x)$. ☐

The algorithm is complicated by the possible presence of strings $x \in U_S^*$ such that $st(x) = 1$ or 2; we handle these cases carefully and are not always able to do so seamlessly. These cases necessitate the *stopping conditions* in the first three rules of the algorithm.

DEFINITION 4.9. *Let c_i be a cycle in ${\mathcal{C}_S}^*$ and let x be a string in $OP(c_i)$. If c_i is uncolored when round (j,i) begins, we say that $g(x)$* is set by f *during the round, where $f = sh, sq, fo$, or st, according to the following rules:*

1. *If $j = 2$, $g(x) = st(x) = 2$, and $ST(x) > x$ is uncolored, then $g(x)$ is set by st.*
2. *Otherwise, f is the highest priority function such that $g(x) = f(x)$, where the functions are prioritized as sh, sq, fo, and st with sh having highest priority.*

We also may say that $g(x)$ is set by $f(x) = q$ to mean that $g(x)$ is set by f and $f(x) = q$.

In Figure 5 $G(w)$ should be read by replacing G with SH, SQ, FO, or ST where $g(w)$ is set by sh, sq, fo, or st. We include SH for convenience of notation but leave $SH(x)$ undefined. Any action on $G(w)$ by the algorithm is explicitly conditioned by the fact that $G(w)$ is defined.

DEFINITION 4.10. *The statement "*stopping condition *i holds" is logically equivalent to the following statements:*

1. *Stopping condition 1 holds $\leftrightarrow$ If $g(w)$ is set by $st(w) = 1$, then $ST(w) > w$.*
2. *Stopping condition 2 holds $\leftrightarrow$ If $g(w)$ is set by $st(w) = 2$, then $ST(w) > w$.*
3. *Stopping condition 3 holds $\leftrightarrow$ $g(w)$ is not set by $st(w) = 2$.*

The two lines of the algorithm marked by * rely on the definition of unmatched and on the choice of representative of *yellow* cycles; these lines affect only the choice of edges of W. We delay discussion until later and assume, for the moment, that the algorithm ignores these lines when it is executed. Under this assumption the algorithm clearly concludes. The next fact follows from the construction of Rule 4.

FACT 4.11. *Let c_i be a cycle of ${\mathcal{C}_S}^*$. Then c_i is colored by the algorithm no later than round $(2,i)$ of Rule 4.*

The next three lemmas describe important features of the coloring and $\mathcal{V}_S$. Proof of the last two are given in the appendix.

LEMMA 4.12. *Let x be a string in $OP(c_i)$ for some $c_i \in OP(c_i)$. Suppose c_i is uncolored when round (j,i) begins. If $g(x)$ is nonintegral, then $g(x)$ is set by $sh(x)$.*

Suppose c_i is uncolored when round $(2,i)$ begins. If $g(x)$ is set by $sh(x) = q$ (resp., $sq(x) = k$, $st(x) = k$) in round $(1,i)$, then $g(x)$ is set by $sh(x) = q$ (resp., $sq(x) = k$, $st(x) = k$) or $fo(x) < q$ (resp., $fo(x) < k$, $fo(x) \leq k$) in round $(2,i)$. If $g(x)$ is set by $sh(x) = q$ (resp., $sq(x) = k$, $st(x) = k$) in round $(2,i)$, then $g(x)$ is set by $sh(x) = q$ (resp., $sq(x) = k$, $st(x) = k$) in round $(1,i)$.

Proof. The first point follows from Corollary 3.8, Lemma 4.6, and our priority rule. The remaining points follow from our priority rule and the fact that for any $x \in U_S^*$ the functions $sh(x)$, $sq(x)$, and $st(x)$ are constant over the course of the algorithm. □

LEMMA 4.13. *Let c_i be a cycle in ${\mathcal{C}_S}^*$. Suppose c_i is colored in round (j,i). Let x be a string in $OP(c_i)$ where, if c_i is colored by Rules 1, 2, or 3, then x is the string by which the rule is chosen.*

1. *If $g(x)$ is set by sq, then $SQ(x)$ is colored no later than round (j,i). Furthermore, if $j = 2$, then $SQ(x)$ is colored before the round begins.*
2. *If $g(x)$ is set by fo, then $FO(x)$ is colored before round (j,i) begins.*
3. *If $g(x)$ is set by st, then $ST(x)$ is colored during round (j,i).*

LEMMA 4.14. *Let c_i be a cycle of ${\mathcal{C}_S}^*$. Suppose that c_i is colored in round $(2,i)$. Let x be a string in $OP(c_i)$ where, if c_i is colored by Rules 1, 2, or 3, then x is the string by which the rule is chosen.*

```
Construct the graph $\mathcal{G}(\mathcal{V}_S)$ and find a minimum-weight matching $M^*$.
    1. For each yellow $c$ set $rep(c)$ to $w \in OP(c)$ that determines the edge incident
       to $c$ in $M^*$. Add $e_{max}(rep(c), G(rep(c)))$ as required by part 1, to $W$.
    2. For each matched pair $(c, c')$ add $e_{max}(rep(c), rep(c'))$ to $W$.
```

FIG. 7. *Construction of the merging set W, part 2.*

1. *If c_i is colored by Rule 1, then $g(x)$ is set by $fo(x) = 1$ and $FO(x)$ is colored nonyellow (in a previous round).*
2. *If c_i is colored by Rule 2, then $g(x)$ is set by $fo(x) = 2$ and $FO(x) = ST(x)$.*
3. *If c_i is colored by Rule 3 we get a contradiction. This case cannot occur.*
4. *If c_i is colored by Rule 4, then $g(x) > \frac{3}{2}$. If $g(x)$ is set by sq or fo and $G(x)$ is yellow , then $|x| \leq \frac{5}{2}g(x)|c_i|$. If $ST(x)$ is defined and colored during the round, then $g(x)$ is set by $sh(x) < 2$ or by $st(x) = 2$.*

After constructing $\mathcal{V}_S$ the algorithm builds the graph $\mathcal{G}(\mathcal{V}_S)$ and finds a minimum-weight matching M^*; see part 2 in Figure 7. The purpose of this step is to select representatives for the *yellow* cycles and to identify *red* and *yellow* cycles that have large overlap edges between them. As described earlier $\mathcal{R}$ is the set of cycles colored *red* by the algorithm. Let $\mathcal{R}_1$ be the *red* cycles such that $\mathcal{V}_S(rep(c)) \leq 2$ and let $\mathcal{R}_2$ be the *red* cycles such that $\mathcal{V}_S(rep(c)) > 2$. Let $\mathcal{Y}$ be the set of cycles colored *yellow.* (Note that we drop the convention used in the discussion of part 1 that c_i refers to the ith cycle in the algorithm's order.)

DEFINITION 4.15. *Let c_1 and c_2 be distinct cycles of ${\mathcal{C}_S}^*$ in $\mathcal{R}_2 \cup \mathcal{Y}$. For $i = 1, 2$, let $X_i = \{rep(c_i)\}$ if $c_i \in \mathcal{R}_2$ and let $X_i = OP(c_i)$ otherwise. For $i = 1, 2$, let x_i be a string in X_i. Then $pair(x_1, x_2)$ is a cycle in $\mathcal{G}_S$ constructed as follows:*

1. *Set $pair(x_1, x_2)$ to the tight cycle $\mathcal{X}(\{c_1, c_2\}, e_{max}(x_1, x_2))$. Assume that e_i is the out-edge of $x_{i,last}$ in $pair(x_1, x_2)$.*
2. *For $i = 1, 2$, if c_i is red and $ov(e_i) > 0$, then replace e_i in $pair(x_1, x_2)$ by its maximum-overlap expansion $\hat{e}_i$ such that $ov(\hat{e}_i) < ov(e_i)$.*

Notice that if the edge e_i in the above definition has positive overlap, then the zero-overlap edge of e_i has overlap strictly less than e_i. Thus the replacement edge $\hat{e}_i$ always exists. Also, notice that $pair(\cdot, \cdot)$ is a symmetric function.

DEFINITION 4.16. *$\mathcal{G}(\mathcal{V}_S)$ is an undirected, weighted graph with vertex set ${\mathcal{C}_S}^*$. Each vertex c of the graph has a self-loop with weight $|c|$ if c is blue, $\max(\mathcal{V}_S(rep(c)), 2)|c|$ if c is red, and $\min_{x \in OP(c)} \mathcal{V}_S(x)|c|$ if c is yellow. Each pair $c_1 \neq c_2$, $c_i \in \mathcal{R}_2 \cup \mathcal{Y}$, $i = 1, 2$, shares an edge with weight $\min_{x_i \in X_i} |pair(x_1, x_2)|$, where $X_i = \{rep(c_i)\}$ if c_i is red and $X_i = OP(c_i)$ if c_i is yellow.*

After constructing $\mathcal{G}(\mathcal{V}_S)$ the algorithm finds a minimum-weight matching M^*. For vertices $c_1 \neq c_2$ in $\mathcal{G}(\mathcal{V}_S)$, the matching algorithm chooses the self-loops of c_1 and c_2 over the edge (c_1, c_2) in the event of a tie. Because of the self-loops each vertex c is incident to some edge in M^*; if the edge incident to c is a self-loop we say that c is *unmatched*; otherwise we say that c is *matched.* For each *yellow* cycle c the algorithm sets $rep(c)$ to an $x \in OP(c)$ that determines the weight of the edge incident to the vertex c in M^* subject to the following:

1. Suppose that c is *yellow*, unmatched; the self-loop incident to c in M^* has weight $2|c|$; and some $c' \neq c$ is colored in the same round as c in part 1. Then $c' = c_{ST(x)}$ for some $x \in OP(c)$. In this case the algorithm sets $rep(c_i)$ to such an x. (Note that by Lemma 4.14 $st(x) = 2$, so this is purely a tie-breaking rule.)

2. If (c, c') is in M^*, $c' \neq c$, then $rep(c)$ is chosen consistently with $rep(c')$ in the sense that the weight of the edge (c, c') in $\mathcal{G}(\mathcal{V}_S)$ is $|pair(rep(c_1), rep(c_2))|$.

The following fact is obvious from the construction. We will use this fact frequently in the next section.

FACT 4.17. *Let c be a matched cycle of ${\mathcal{C}_S}^*$. Then c is red or yellow. In the first case $\mathcal{V}_S(rep(c)) > 2$ and in the latter case $\mathcal{V}_S(rep(c)) > \frac{3}{2}$.*

Let (c_1, c_2) be an edge of M^*, $c_1 \neq c_2$. We call c_1 the max-*overlap cycle of the pair* if $|rep(c_1)| - \mathcal{V}_S(rep(c_1))|c_1| \geq |rep(c_2)| - \mathcal{V}_S(rep(c_2))|c_2|$, i.e., if the expansion of $e_{rep(c_1)}$ corresponding to $\mathcal{V}_S(rep(c_1))$ has overlap at least as large as the expansion of $e_{rep(c_2)}$ corresponding to $\mathcal{V}_S(rep(c_2))$. Otherwise we call c_2 the max-overlap cycle of the matched pair.

LEMMA 4.18. *Let M^* be a minimum-weight matching of $\mathcal{G}(\mathcal{V}_S)$. Suppose (c_1, c_2) is an edge of M^*, $c_1 \neq c_2$, where c_1 is the* max-*overlap cycle of the pair. Then $c_{x_2}^k$ exists for the integer $k = |pair(rep(c_1), rep(c_2))| - \mathcal{V}_S(rep(c_1))|c_1|$. Furthermore, if c_{x_2} is red , then $k \geq 2$.*

Proof. Assume that $rep(c_i) = x_i$, $i = 1, 2$. Since $\mathcal{V}_S$ is an expansion value function there exists an expansion of e_{x_i}, $i = 1, 2$, with pseudolength $\mathcal{V}_S(x_i)|c_i|$. Let $\hat{e}_i$, $i = 1, 2$, denote the expanded edge. Cycle c_1 is the max-overlap cycle of the pair, so $ov(\hat{e}_1) \geq ov(\hat{e}_2)$. Since $\mathcal{V}_S$ is a valid expansion value function, $\hat{e}_1$ is a winning edge for the cycle $pair(x_1, x_2)$. Then $\mathcal{X}(\{pair(x_1, x_2)\}, \hat{e}_1)$ consists of $c_{x_1}^{\mathcal{V}_S(x_1)}$ and a 1-expansion $\hat{c}_{x_2}$ of c_{x_2} of length at most $|pair(x_1, x_2)| - \mathcal{V}_S(x_1)|c_1|$. Next we show that equality holds. Suppose that $|\hat{c}_{x_2}| < |pair(x_1, x_2)| - \mathcal{V}_S(x_1)|c_1|$. By Lemma 3.3, the expansion of e_{x_2} in $\hat{c}_{x_2}$ has zero-overlap and thus $|\hat{c}_{x_2}| = |x_2|$. Since c_1 and c_2 are in $\mathcal{R}_2 \cup \mathcal{Y}$, the self-loops of c_1 and c_2 in $\mathcal{G}(\mathcal{V}_S)$ have total weight no more than

$$\mathcal{V}_S(x_1)|c_1| + \mathcal{V}_S(x_1)|c_2| \leq \mathcal{V}_S(x_1)|c_1| + sh(x_2)|c_2| \leq \mathcal{V}_S(x_1)|c_1| + |x_2| \leq |pair(x_1, x_2)|$$

which contradicts the matching algorithm's tie-breaking rule; i.e., self-loops are chosen over nonloop edges. Thus equality must hold. By the same argument, $|\hat{c}_{x_2}| < sh(x_2)|c_{x_2}|$ so by Corollary 3.8 $\hat{c}_{x_2} = c_{x_2}^k$ for some integer k.

Now suppose that c_{x_2} is *red*. By construction the out-edge of $x_{2,last}$ in $pair(x_1, x_2)$ has either zero-overlap or overlap strictly less than $ov(e_{x_2})$. In the first case the matching algorithm would choose the self-loops of c_1 and c_2. Thus $\hat{c}_{x_2} = c_{x_2}^k$ for some integer $k > 1$. ☐

DEFINITION 4.19. *The cover $\mathcal{C}_L$ consists of the following cycles:*

1. *If c is blue , then $c \in \mathcal{C}_L$.*
2. *If c is red and unmatched, then $c_{rep(c)}^q$ is in $\mathcal{C}_L$ where*

$$q = \min(|rep(c)|/|c|, \max(\mathcal{V}_S(rep(c)), 2)).$$

3. *If c is yellow and unmatched, then $c_{rep(c)}^{\mathcal{V}_S(rep(c)}$ is in $\mathcal{C}_L$.*
4. *If $c_1 \neq c_2$ are matched, where (c_1, c_2) is an edge in M^* and c_1 is the* max-*overlap cycle of the pair, then $c_{rep(c_1)}^{\mathcal{V}_S(rep(c_1))}$ and the 1-expansion of $c_{rep(c_2)}$ with length $|pair(rep(c_1), rep(c_2))| - \mathcal{V}_S(rep(c_1))|c_1|$ are in $\mathcal{C}_L$.*

The existence of these cycles is guaranteed by Lemma 4.6, Corollary 3.8, and Lemma 4.18. In section 6 we prove the following lemma.

LEMMA 4.20. $|\mathcal{C}_L| - \sum_{c \in \mathcal{R}} |c| \leq |OPT_S|$.

The selection of the edges W is shown in Figures 6 and 7. Several choices in part 1 (i.e., the lines marked by *) depend on the outcome of the matching and on representatives selected in part 2. We assume that the algorithm records the current

TABLE 1
Summary of alloc(c).

Color of c	c Matched ?	Allocation
blue	N/A	$\frac{5}{2}\|c\|$
red	Yes	$\|m(c)\| - \frac{1}{2}\|c\|$
	No	$\frac{5}{2}(\max(\mathcal{V}_S(rep(c)), 2) - 1)\|c\|$
yellow	Yes	$\|m(c)\|$
	No	$\frac{5}{2}\mathcal{V}_S(rep(c))\|c\|$

status when these lines are invoked and then in part 2 goes back and adds the necessary edges to W. In part 2 the algorithm also adds edges for matched cycles to W.

The proof of Theorem 1.1 follows from Lemma 4.20 and the next lemma which we prove in section 5.

LEMMA 4.21. *There exists a cover $\mathcal{C}_U$ of $\mathcal{G}_S$ such that $|AOPT_S| \leq |\mathcal{C}_U| \leq \frac{5}{2}(|\mathcal{C}_L| - \sum_{c\in\mathcal{R}} |c|)$.*

5. The upper bound cover $\mathcal{C}_U$.

To prove Lemma 4.21, we explicitly construct $\mathcal{C}_U$. We begin with $\mathcal{C}_U$ and W empty and simulate the construction of W by the algorithm. In a round of part 1, where the algorithm colors a cycle $c \in \mathcal{C}_S{}^*$, we add an expansion of c, denoted $m(c)$, to $\mathcal{C}_U$. We may also *expand* an existing cycle in $\mathcal{C}_U$, i.e., replace some edge of the cycle by one of its expansions.

LEMMA 5.1. *At each point of the construction, $\mathcal{C}_U$ and W satisfy the following invariants:*

1. *$\mathcal{C}_U$ is a cycle cover of the graph $G_{S'}$, where $S' = \{s \in S \mid s$ is a vertex of a colored $c \in \mathcal{C}_S{}^*\}$. Furthermore, for any colored $c \in \mathcal{C}_S{}^*$, $\mathcal{C}_U$ contains an expansion of $m(c)$.*
2. *Every weakly connected component of the subgraph $\mathcal{C}_U \cup W$ of $\mathcal{G}_S$, that is, every connected component where the edges are considered in an undirected sense, contains a zero-overlap edge or an expansion of $m(c)$, $c \in \mathcal{C}_S{}^*$, such that c is matched.*
3. *Every edge of W is a winning edge for $\mathcal{C}_U$.*
4. *$|\mathcal{C}_U| \leq \sum_{\text{colored } c} alloc(c)$, where $alloc(\cdot)$ is defined in Table 1.*

For any $(c, c') \in M^*$, $c \neq c'$, the algorithm adds $e_{max}(rep(c), rep(c'))$ to W in part 2. Thus, the next fact and invariant 2 imply that when the construction concludes, every weakly connected component of $\mathcal{C}_U \cup W$ has a zero-overlap edge.

FACT 5.2. *Suppose (c, c') is an edge of M^*, where $c \neq c'$. Then either $m(c)$ or $m(c')$ has a zero-overlap edge.*

Thus Lemma 5.1 together with the next lemma implies that $|AOPT_S| \leq |\mathcal{C}_U|$.

LEMMA 5.3. *Let $\tilde{\mathcal{C}}$ be an expansion of $\mathcal{C}_S{}^*$ and let W be the set of merging edges constructed by the algorithm. If every edge of W is a winning edge for $\tilde{\mathcal{C}}$ and every weakly connected component of the subgraph $\tilde{\mathcal{C}} \cup W$ has a zero-overlap edge, then $|AOPT_S| \leq |\tilde{\mathcal{C}}|$.*

When the construction concludes, invariant 4 implies that $|\mathcal{C}_U| \leq \sum_{c\in\mathcal{C}_S{}^*} alloc(c)$. By the next lemma, the length of $\mathcal{C}_U$ satisfies the bound of Lemma 4.21.

LEMMA 5.4. *For $alloc(c), c \in \mathcal{C}_S{}^*$, defined in Table 1,*

$$\sum_{c\in\mathcal{C}_S{}^*} alloc(c) \leq \frac{5}{2}\left(|\mathcal{C}_L| - \sum_{c\in\mathcal{R}} |c|\right).$$

Table 2

	$\mathcal{V}_S(x) \geq 3$	$c_x^{\mathcal{V}_S(x)+1}$	

Thus, to complete the proof of Lemma 4.21 it suffices to demonstrate Fact 5.2 and prove Lemmas 5.1, 5.3, and 5.4. The proofs of Lemmas 5.1 and 5.4 are very technical; they are given in the appendix. The proof of Lemma 5.3 is given at the end of this section.

Next we describe the construction in detail. The construction of $m(c)$ is given in Table 2, with reference to Table 3. For ease of notation throughout this section, we use c_x^q to mean $c_x^{\min(q,|x|/|c_x|)}$ for $x \in U_S^*$. With some abuse of notation in these tables we also let x, $x \in U_S^*$, denote the 1-expansion of c_x with length $|x|$, i.e., the 1-expansion of c_x that includes the zero-overlap version of e_x. We refer to this policy as our naming convention. Fact 5.2 is obvious from Table 3. NC and NA in Table 2 mean *no change* and *not applicable* .

We now describe the construction in round (j,i). If c_i is not colored in the round we do not change $\mathcal{C}_U$. So assume c_i is colored in round (j,i). If c_i is colored by Rule 1, 2, or 3, let w be the string by which the rule is chosen. If c_i is colored by Rule 4, let $w = rep(c_i)$. Thus $c_i = c_w$. If c_w is colored by Rule 2 then c_u, where u conflicts with w, is also colored in the round. If $G(w)$ is defined, then for convenience of notation we let z denote $G(w)$. If c_w is colored by Rule 4 and a cycle c, $c \neq c_w$ and $c \neq c_z$, and is also colored in round (j,i), then $j = 2$ and $c = c_{ST(x)}$ for some $x \in OP(c_w), x \neq w$. Let v denote such a string $ST(x)$. There may be several such

v in a round corresponding to different $x \in OP(c_w)$; the construction is identical for each.

We first describe the construction of $m(c_w)$. Suppose $g(w)$ is set by sh. The construction of $m(c_w)$, as shown in Table 2, depends on whether c_w is unmatched or matched. If c_w is unmatched then $m(c) = w$, where w denotes the 1-expansion of c_w of length $|w|$ as described earlier. If c_w is matched, the construction of $m(c_w)$ is given in Table 3. It depends on whether or not c_w is the winning cycle of the matched pair, on the color of c_w, and on the value of $\mathcal{V}_S(w)$.

Now suppose that $g(w)$ is set by sq, fo, or st. Then z is defined. In this case $m(c_w)$ depends on whether c_w is unmatched or matched, whether c_z is colored in the current round, and whether $e_{max}(w, z)$ is added to W. (Note that by Lemma 4.13 c_z is colored in either round (j, i) or in an earlier round.) Thus there are eight possible cases, but not all of them can occur. Specifically, if c_z is colored in round (j, i), then the algorithm always adds $e_{max}(w, z)$ to W. Also, if c_w is matched, and thus colored in Rules 2–4, and c_z is colored in a previous round, $e_{max}(w, z)$ is never added to W. The remaining five cases can occur when $g(w)$ is set by sq, and Table 2 handles each possibility. If $g(w)$ is set by fo, then by Lemma 4.13 c_z is colored in a previous round so there are only three possible cases. If $g(w)$ is set by st, then by Lemma 4.13 c_z is colored in the current round and so there are only two possible cases. Table 2 handles every possibility, with reference to Table 3 when c_w is matched.

When u is defined, Table 2 gives the construction of $m(c_u)$. When z is defined, the column labeled $m(c_z)$ gives the new construction for $m(c_z)$ for the cases where c_z is colored in round (j, i). If c_z is colored in a previous round, then $\mathcal{C}_U$ already contains an expansion of $m(c_z)$ and the table describes any necessary modifications to this cycle; expanding this cycle by $|c_w|$ should be interpreted as replacing the version $\hat{e}_z$ of e_z in the cycle by its expansion with overlap $\max(ov(\hat{e}_z) - |c_w|, 0)$. Finally, if v is defined, the column labeled $m(c_v)$ gives the appropriate construction.

Proof of Lemma 5.3. Let the edge of W ordered by increasing overlap be $e_1, \ldots, e_k$. We define a sequence of cycle covers $\mathcal{C}_0, \mathcal{C}_1, \mathcal{C}_2, \ldots, \mathcal{C}_k$ of $\mathcal{G}_S$ as follows. $\mathcal{C}_0 = \tilde{\mathcal{C}}$. Assume $e_i = \langle s, t \rangle$. If s and t are in the same cycle of $\mathcal{C}_{i-1}$, then $\mathcal{C}_i = \mathcal{C}_{i-1}$ and otherwise $\mathcal{C}_i = \tilde{\mathcal{X}}(\mathcal{C}_{i-1}, e_i)$. We claim that $|\mathcal{C}_i| \leq |\mathcal{C}_{i+1}|$, every edge in $\{e_{i+1}, \ldots, e_k\}$ is a winning edge for $\mathcal{C}_i$, and every weakly connected component of $\mathcal{C}_i \cup \{e_{i+1}, \ldots, e_k\}$ has a zero-overlap edge.

The claim is true by assumption when the construction begins. Suppose it is true for $\mathcal{C}_{i-1}$, $i \geq 1$, and assume $e_i = \langle s, t \rangle$. If s and t are in the same cycle in $\mathcal{C}_{i-1}$, then $\mathcal{C}_i = \mathcal{C}_{i-1}$ and the claim holds. Now suppose s and t are in different cycles. Assume these cycles are, respectively, c_s and c_t. Then $\mathcal{C}_i = \tilde{\mathcal{X}}(\mathcal{C}_{i-1}, e_i) = \mathcal{C}_i - \{c_s, c_t\} \cup \tilde{\mathcal{X}}(\{c_s, c_t\}, e_i)$. Since e_i is a winning edge for $\mathcal{C}_{i-1}$, $|\mathcal{C}_i| \leq |\mathcal{C}_{i-1}|$. If e_j, $j > i$, is a winning edge for $\mathcal{C}_{i-1}$ but not for $\mathcal{C}_i$, then by Lemma 3.3 e_j must be an out-edge of s or an in-edge of t. However, $ov(e_j) < ov(e_i)$, which contradicts the fact that the edges are ordered by increasing overlap. Thus each edge of $\{e_{i+1}, \ldots, e_k\}$ is a winning edge for $\mathcal{C}_i$. Finally, consider the last point. The only edges of $\mathcal{C}_{i-1} \cup \{e_i, \ldots, e_k\}$ that are not in $\mathcal{C}_i \cup \{e_{i+1}, \ldots, e_k\}$ are the edges removed by the edge exchange. If either of these edges has zero-overlap, then by Lemma 3.3 the losing edge of the exchange does as well. Thus the component of $\mathcal{C}_i$ containing the cycle $\tilde{\mathcal{X}}(\{c_s, c_t\}, e_i)$ includes a zero-overlap edge. The remaining components satisfy the claim by the inductive hypothesis. The final cover $\mathcal{C}_k$ has the property that $|\mathcal{C}_k| \leq |\tilde{\mathcal{C}}|$ and furthermore, each cycle c of $\mathcal{C}_k$ has a zero-overlap edge so $|op(c)| = |c|$.

Notice that our construction simulates step 4 of the algorithm (see Figure 5) but

```
Construction Protocol
1. Color the edges of $\mathcal{C}_S{}^*$ *white* and the remaining edges of $\mathcal{G}_S$ *black*.
2. Initialize $\mathcal{C}_0$ to a Hamiltonian cycle of $\mathcal{G}_s$ and set $i = 0$.
3. Each cycle of $c \in \mathcal{C}_S{}^*$ is initially *unmarked*.
4. While $\mathcal{C}_i$ contains a mixed cycle.
    (i) **Mark:** If $c$ is unmarked and represented in a mixed cycle in $\mathcal{C}_i$, then
        mark $c$ "represented." Recolor the missing edge $e_x$ *black* and its expansion
            $\tilde{e}_x$ with pseudolength $\mathcal{V}_S(x)|c_x|$ *white*.
    (ii) **Edge exchange:** Let $e_W$ be the maximum overlap *white* edge of $\mathcal{G}_S$ such
        that (1) $e_W$ is not in $\mathcal{C}_i$, and (2) $\mathcal{C}_i$ is not uniform for $c(e_W)$.
            Set $\mathcal{C}_{i+1} = \tilde{\mathcal{X}}(\mathcal{C}_i, e_W)$ and $i = i + 1$.
    (iii) **Eliminate-uniform-cycle:** While $\mathcal{C}_i$ includes a mixed cycle $\hat{c}_{mixed}$ with
        a vertex $s$ and a uniform cycle $\hat{c}_{uniform}$ with the vertex $next(s)$ such that
        $|join(\hat{c}_{uniform}, \hat{c}_{mixed}, s)| \leq |\hat{c}_{uniform}| + |\hat{c}_{mixed}|$
        Set $\mathcal{C}_{i+1} = \mathcal{C}_i - \{\hat{c}_{uniform}, \hat{c}_{mixed}\} \cup \{join(\hat{c}_{uniform}, \hat{c}_{mixed}, s)\}$ and $i = i+1$.
    (iv) **Reorder-path:** While $\mathcal{C}_i$ includes a mixed cycle $\hat{c}_{mixed}$ such that for some
        $c \in \mathcal{C}_S{}^*$, the vertices of $c$ comprise a path in $\hat{c}_{mixed}$, $c$ is not represented in
        $\hat{c}_{mixed}$, and $|represent(\hat{c}_{mixed}, c)| \leq |\hat{c}_{mixed}|$
            Set $\mathcal{C}_{i+1} = \mathcal{C}_i - \{\hat{c}_{mixed}\} \cup \{represent(\hat{c}_{mixed}, c)\}$ and $i = i + 1$.
```

FIG. 8.

beginning with an expansion of $\mathcal{C}_S{}^*$, i.e., $\tilde{\mathcal{C}}$, and using parsimonious edge exchanges. At each point our current cover $\mathcal{C}_i$ is an expansion of the algorithm's current cover $\mathcal{C}$. When the construction concludes,

$$|AOPT_S| = \sum_{c \in \mathcal{C}} op(c) \leq \sum_{c \in \mathcal{C}_k} op(c) = \sum_{c \in \mathcal{C}_k} |c| = |\mathcal{C}_k| \leq |\tilde{\mathcal{C}}|. \qquad \square$$

6. The lower bound cover.

In this section we prove Lemma 4.20. Our strategy is similar to the proof of Theorem 2.7 given at the end of section 2. The construction protocol for the proof of Lemma 4.20 is given in Figure 6. We construct a series of covers of $\mathcal{G}_S$ that are nonincreasing in length beginning with a Hamiltonian cycle $\mathcal{C}_0$. After we've described the general construction, we choose $\mathcal{C}_0$ so as to get the desired bound of Lemma 4.20.

We begin by coloring the edges of $\mathcal{C}_S{}^*$ *white* and the remaining edges of $\mathcal{G}_S$ *black*. At each point in the protocol, $\mathcal{C}_W$ denotes the set of white edges of $\mathcal{G}_S$. We may recolor edges during the protocol but we'll see that the construction satisfies the following invariant.

FACT 6.1. *$\mathcal{C}_W$ is always an expansion of $\mathcal{C}_S{}^*$. For any $\mathcal{C}_i$ and $\mathcal{C}_{i+1}$ constructed by the protocol,*

1. *if e is a* white *edge in $\mathcal{C}_i$, then e is a* white *edge of $\mathcal{C}_{i+1}$, and*
2. *$\mathcal{C}_{i+1}$ has strictly more* white *edges than $\mathcal{C}_i$.*

At any point in the protocol the *current cover* is the cover $\mathcal{C}_i$ for the current value of i. The protocol continues as long as the current cover includes a *mixed* cycle. A cycle $\hat{c}$ of $\mathcal{G}_S$ is *mixed* if it includes vertices s and t such that $c_s \neq c_t$, where c_v denotes the cycle of $\mathcal{C}_S$ containing the vertex v. A cycle $\hat{c}$ of $\mathcal{G}_S$ that is not mixed is *uniform*. If $\hat{c}$ is uniform, then for some $c \in \mathcal{C}_s$ every vertex of $\hat{c}$ is also a vertex of c and we may also say that $\hat{c}$ is uniform for c. The cycle $\hat{c}$ need not include every vertex of c and need not include any edges of c. A cycle cover $\mathcal{C}$ of $\mathcal{G}_S$ is uniform for $c \in \mathcal{C}_S{}^*$ if every vertex of c is in a cycle uniform for c in $\mathcal{C}$. By our earlier assumption $\mathcal{C}_S{}^*$ consists of more than one cycle so the Hamiltonian cycle $\mathcal{C}_0$ is mixed. Fact 6.1 guarantees that the protocol concludes. The final cover of the protocol, which we denote as $\mathcal{C}_{final}$, is uniform for every $c \in \mathcal{C}_S{}^*$.

Step (i) of the protocol marks cycles of $\mathcal{C}_S{}^*$ that are *represented* in a mixed cycle of the current cover. We say that a cycle $\hat{c}$ of $\mathcal{G}_S$ *represents* $x \in U_S^*$ if $order(c_x, x_{first})$ is a tight path of $\hat{c}$; here $order(c, s)$, for a cycle $c \in \mathcal{C}_S{}^*$ and a vertex $s \in c$, is a list of the vertices of c in the order they occur in c beginning at vertex s. If a cycle $\hat{c}$ of $\mathcal{G}_S$ represents $x \in U_S^*$ we also say it represents c_x. Note that if a cycle $\hat{c}$ of $\mathcal{G}_S$ represents $c \in \mathcal{C}_S{}^*$ and $\hat{c} \neq c$, then $\hat{c}$ represents a unique $x \in OP(c)$.

Let c be a cycle of $\mathcal{C}_S{}^*$. Initially c is unmarked. In step (i) we mark c "represented" if c is still unmarked and some mixed cycle of the current cover represents c. The protocol maintains the following invariant.

FACT 6.2. *Let c be a cycle of $\mathcal{C}_S{}^*$. If c is unmarked at some point in the protocol, then $c \in \mathcal{C}_W$. If c is marked "represented," then $c_x^{\mathcal{V}_S(x)} \in \mathcal{C}_W$ for some $x \in OP(c)$.*

Suppose we mark c in some round. Let $\hat{c}$ be the cycle of the current cover that represents c. Since $\hat{c}$ is mixed (and hence $\hat{c} \neq c$), $\hat{c}$ represents a unique $x \in OP(c)$. Since $c \in \mathcal{C}_W$ when the step begins, by Fact 6.2 e_x is *white*. When we mark c in step (i) we also recolor e_x *black* and recolor the expansion of e_x with pseudolength $\mathcal{V}_S(x)|c|$ *white*. Since $\hat{c}$ is a mixed cycle and represents c, the current cover does not contain e_x or any of its expansions. Thus the recoloring has no effect on the current cover. After the recoloring, $c_x^{\mathcal{V}_S(x)} \in \mathcal{C}_W$. By Facts 6.1 and 6.2 if $\mathcal{C}_i$ represents $x \in U_S^*$, then $\mathcal{C}_{i+1}$ represents x.

In step (ii) the protocol performs an edge exchange based on a maximum overlap *white* edge e_W that satisfies two conditions. The first condition is that e_W is not in the current cover. By Fact 6.1 e_W is an expansion of an edge of some $c \in \mathcal{C}_S{}^*$; we use $c(e_W)$ to denote the cycle c. The second condition is that the current cover is not uniform for $c(e_W)$.

LEMMA 6.3. *Suppose the protocol constructs $\mathcal{C}_{i+1} = \tilde{\mathcal{X}}(\mathcal{C}_i, e_W)$ in some round. Then e_W is a winning edge for $\mathcal{C}_i$.*

Proof. Assume that $e_W = \langle s, t, k\rangle$, the out-edge of s in the current cover is $e = \langle s, u, j\rangle$, and the *white* in-edge of u is $e' = \langle v, u, \ell\rangle$. Suppose that $c_s = c_u$, where c_v is the cycle of $\mathcal{C}_S{}^*$ containing the vertex v. Since $\langle s, u\rangle$ is not an edge of $\mathcal{C}_S{}^*$, c_s is not represented in the current cover, c_s is not marked "represented," and e_W and e' are tight edges. Since $k \geq \ell$, by Fact 2.16 $k \geq j$. Now suppose that $c_s \neq c_u$. Then s and u are x_{last} and y_{first} for some $x, y \in U_S^*$, $c_x \neq c_y$. The edge e_W is either tight or has pseudolength $\mathcal{V}_S(x)|c_x|$; in either case $k \geq |x| - \mathcal{V}_S(x)|c_x|$. By a symmetric argument $\ell \geq |y| - \mathcal{V}_S(y)|c_y|$. Since $k \geq \ell$, $k \geq \max(|x| - \mathcal{V}_S(x)|c_x|, |y| - \mathcal{V}_S(y)|c_y|)$. By Lemma 4.6 $\mathcal{V}_S$ is a valid expansion value function so $k \geq \max(|x| - \mathcal{V}_S(x)|c_x|, |y| - \mathcal{V}_S(y)|c_y|) \geq ov_{max}(x, y) \geq ov(s, t') = j$.

By a symmetric argument k is at least as large as the overlap of the in-edge of t in the current cover. Thus e_W is a winning edge for the current cover. □

The previous proof relies on the fact that if the edge $e_W = \langle s, t, k\rangle$ is loose, then for some $x \in OP(c_s)$, $s = x_{last}$, $t = x_{first}$, the out-edge of s in the current cover is to some u such that $c_u \neq c_s$, and a symmetric statement holds for the in-edge of t.

These conditions hold when $c(e_W)$ is represented in a mixed cycle. In steps (iii) and (iv) we attempt to force the representation of each $c \in \mathcal{C}_S{}^*$ in a mixed cycle at some point in the protocol. We can guarantee this only for cycles in $\mathcal{C}_S{}^*$ with *depth* at least 3; the depth of c of $\mathcal{G}_S$, denoted d_c, is defined as $d_c = |op(c)|/|c|$. We'll see, however, that this is enough. In the next lemma, $len_{final}(c)$ is the total length of the cycles uniform for $c \in \mathcal{C}_S{}^*$ in the final cover $\mathcal{C}_{final}$.

LEMMA 6.4. *Let c be a cycle of $\mathcal{C}_S{}^*$. If c is not marked "represented" when the protocol concludes, then $d_c < 3$ and $len_{final}(c) \geq sh(x)|c|$ for some $x \in OP(c)$.*

The proof of this lemma is given in the appendix. Next we describe steps (iii) and (iv). Let c be a cycle of $\mathcal{C}_S{}^*$ and suppose that when step (iii) begins, the current cover $\mathcal{C}_i$ contains a cycle uniform for c and a mixed cycle containing a vertex of c. In this case there must be vertices s and t of c such that $\langle s, t\rangle$ is an edge of c, s is in a mixed cycle of $\mathcal{C}_i$, and t is in a cycle uniform for c in $\mathcal{C}_i$. In step (iii) we insert the vertices of the uniform cycle into the mixed cycle provided we can do so without increasing cover length. We use $next(s)$, $s \in S$, to denote the vertex t (possibly $s = t$) such that $\langle s, t\rangle$ is in $\mathcal{C}_S{}^*$.

DEFINITION 6.5. *Let c be a cycle of $\mathcal{C}_S{}^*$, let*

$$c_{uniform} = \langle t_0, t_1, k_0\rangle, \ldots, \langle t_j, t_0, k_j\rangle$$

be a cycle of $\mathcal{G}_S$ that is uniform for c, and let

$$c_{mixed} = \langle s_0, s_1, \ell_0\rangle, \ldots, \langle s_m, s_0, \ell_m\rangle$$

be a mixed cycle of $\mathcal{G}_S$ that includes a vertex s such that $next(s)$ is in $c_{uniform}$. Assume $s = s_0$ and $next(s) = t_0$. The cycle $join(c_{uniform}, c_{mixed}, s)$ is defined as

$$\langle s_0, t_0\rangle, \langle t_0, t_{i_1}\rangle, \ldots, \langle t_{i_{m-1}, t_{i_m}}\rangle, \langle t_{i_m}, s_1, \ell'\rangle, \langle s_1, s_2, \ell_2\rangle, \ldots, \langle s_m, s_0, \ell_m\rangle,$$

where the vertices of $c_{uniform}$ occur in c in order $t_0, t_{i_1}, \ldots, t_{i_j}$ and ℓ' is the maximum overlap of any edge from t_{i_m} to s_1 such that $\ell' \leq \ell_0$.

Let c be a cycle of $\mathcal{C}_S{}^*$. Suppose at the beginning of step (iv) the vertices of c comprise a path in some mixed cycle of the current cover. If c is not represented by $\hat{c}$, then the vertices of c may be out of order or the path may include some loose edges. If so, we reorganize the path so that c is represented provided we can do so without increasing cover length.

DEFINITION 6.6. *Let c be a cycle of $\mathcal{C}_S{}^*$ and let*

$$c_{mixed} = \langle s_0, s_1, k_0\rangle, \langle s_1, s_2, k_1\rangle, \ldots, \langle s_j, t_0, k_j\rangle\langle t_0, t_1, \ell_0\rangle, \ldots, \langle t_m, s_0, \ell_m\rangle$$

be a mixed cycle such that $s_0, \ldots, s_j$ are the vertices of c. Assume that $order(c, s_0) = s_0, s_{i_1}, s_{i_2}, \ldots, s_{i_j}$. The cycle represent$(c_{mixed}, c)$ *is defined as*

$$\langle s_0, s_{i_1}\rangle, \langle s_{i_1}, s_{i_2}\rangle, \ldots, \langle s_{i_{j-1}}, s_{i_j}\rangle, \langle s_{i_j}, t_0, k'\rangle, \langle t_0, t_1, \ell_1\rangle, \ldots, \langle t_m, s_0, \ell_m\rangle,$$

where k' is the maximum overlap of any edge from s_{i_j} to t_0 such that $k' \leq k_j$.

We can assume, without loss of generality, that if some $c \in \mathcal{C}_0$ satisfies the conditions of step (iv), then c is represented in $\mathcal{C}_0$.

LEMMA 6.7. *Let c be a nonblue cycle of $\mathcal{C}_S{}^*$ such that $len_{final}(c) < \mathcal{V}_S(x)|c|$ for every $x \in OP(c)$. Then for some covers $\mathcal{C}_i$ and $\mathcal{C}_{i+1}$ constructed by the protocol*

$$\mathcal{C}_{i+1} = \tilde{\mathcal{X}}(\mathcal{C}_i, \hat{e}_y) = \mathcal{C}_i - \{\hat{c}\} \cup \{c_x^q, c_y^{\mathcal{V}_S(y)}\},$$

where $x \in OP(c)$, $y \in U_S^*$, $c_y \neq c$, $\hat{e}_y$ is a strict expansion of e_y with pseudolength $\mathcal{V}_S(y)|c_y|$, $\hat{c}$ is some expansion of $\mathcal{X}(\{c_x, c_y\}, e_{max}(x,y))$, and $q|c| = len_{final}(c)$.

Proof. Let $\mathcal{C}_i$ be the first cover that is uniform for c. By Lemma 6.4 $d_c \geq 3$ and c is represented in a mixed cycle $\hat{c}$ in $\mathcal{C}_{i-1}$. Assume $\hat{c}$ represents $x \in OP(c)$. The only step that can create a uniform cycle is the edge exchange so

$$\mathcal{C}_i = \tilde{\mathcal{X}}(\mathcal{C}_{i-1}, e) = \mathcal{C}_{i-1} - \{\hat{c}\} \cup \{c_1, c_2\},$$

where c_2 is a 1-expansion c_x^q with length $len_{final}(c)$. If e is the expansion of e_x with length $\mathcal{V}_S(x)|c|$, then $c_2 = c_x^{\mathcal{V}_S(x)}$, which is a contradiction. Thus e is an edge from y_{last} to y_{first} for some $y \in U_S^*$, $c_y \neq c$ and the losing edge of the exchange $\hat{e}_x$ is an expansion of e_x. If $ov(\hat{e}_x) < |x| - sh(x)|c|$, then $|c_2| \geq sh(x)|c| \geq \mathcal{V}_S(x)|c|$, which is a contradiction. So assume that $ov(\hat{e}_x) \geq |x| - sh(x)|c|$. If e is tight, then $ov(\hat{e}_x) \leq |x| - sq(x)|c|$ so $|\hat{c}_x| \geq sq(x)|c| \geq \mathcal{V}_S(x)|c|$, which is a contradiction. Thus e is a loose edge. By Fact 6.2 $\hat{c}$ also represents y. Since $\hat{c}$ must also include edges from x_{last} to y_{first} and from y_{last} to x_{first}, $\hat{c}$ is an expansion of $\mathcal{X}(\{c_x, c_y\}, e_{max}(x,y))$. □

Proof of Lemma 4.20. To prove this theorem we construct a cover $\tilde{\mathcal{C}}_L$ such that

$$|\mathcal{C}_L| \leq |\tilde{\mathcal{C}}_L| \leq OPT_S + \sum_{c \in \mathcal{R}} |c|.$$

First consider the case where $\mathcal{R}$ is empty. Set $\mathcal{C}_0 = \{c_{\pi_S^*}\}$ and construct $\mathcal{C}_{final}$ by the construction protocol. By construction and Lemma 6.3 $|\mathcal{C}_{final}| \leq |c_{\pi_S^*}| \leq OPT_S$. For each $c \in \mathcal{C}_S{}^*$ such that $\mathcal{C}_{final}$ does not include a 1-expansion of c, replace the cycles uniform for c by the 1-expansion $c_x^{sh(x)}$ for the x defined by Lemma 6.4; these modifications do not increase the length of $\mathcal{C}_{final}$. Let $\tilde{\mathcal{C}}_L = \mathcal{C}_{final}$. Lemma 6.7 implies a matching between *yellow* cycles c_x and c_y such that $len_{final}(c_x) < \mathcal{V}_S(x)|c_x|$ and $len_{final}(c_x) + len_{final}(c_y) \geq pair(x,y)$. For any remaining cycle c, $len_f(c) \geq \mathcal{V}_S(x)|c|$ for some $x \in OP(c)$. Thus $\tilde{\mathcal{C}}_L$ corresponds to a matching of $\mathcal{G}(\mathcal{V}_S)$ with length at most $|\tilde{\mathcal{C}}_L| \leq |OPT_S|$. Our claim then follows since $|\mathcal{C}_L|$ is the weight of a minimum-weight matching M^* of $\mathcal{G}(\mathcal{V}_S)$.

Now consider the case where $\mathcal{R}_1$ is empty. We begin by setting $\mathcal{C}_0 = c_{\pi_S^*}$. For each $c \in \mathcal{R}_2$ do the following. Delete the vertices of c, except for $rep(c)_{first}$, from $\mathcal{C}_0$ using Lemma 2.3. Duplicate the vertex $rep(c)_{first}$ and insert the deleted vertices between the two copies in the order the vertices occur in c using tight edges. Delete the second copy of $rep(c)_{first}$. When the construction concludes, $|\mathcal{C}_0| \leq |OPT_S| + \sum_{c \in \mathcal{R}_2} |c|$. Also by the construction, for any $c \in \mathcal{R}_2$, the out-edge of $rep(c)_{last}$ in $\mathcal{C}_0$ is either zero or strictly less than $ov(rep(c)_{last}, rep(c)_{first})$. Construct $\mathcal{C}_{final}$ as above. The same arguments hold for this case except for matched pairs where one or both of c_x and c_y are *red*. To prove this case it is sufficient to show that the cycle $\hat{c}_{mixed}$ which represents x and y in the proof of Lemma 6.7 is an expansion of $pair(x,y)$. By Lemma 3.3 and the construction of steps (iii) and (iv) the overlap of the out-edge of x_{last} (resp., y_{last}) is nonincreasing over the construction, so the claim holds.

Now suppose that $\mathcal{R}_1$ is nonempty. Construct $\mathcal{C}_0$ as in the last case. We will treat $c \in \mathcal{R}_1$ as a *blue* cycle in the construction, i.e., set $\mathcal{V}_S(x) = 1$ for every $x \in OP(c)$. Construct $\tilde{\mathcal{C}}_L$ as in the previous case. Then for each $c \in \mathcal{R}_1$, replace the expansion of c in $\tilde{\mathcal{C}}_L$ by the cycle c_x^2 where $x = rep(c)$. Then $|\tilde{\mathcal{C}}_L| \leq |OPT_S| + \sum_{c \in \mathcal{R}} |c|$ and, as above, $\tilde{\mathcal{C}}_L$ corresponds to a matching of $\mathcal{G}(\mathcal{V}_S)$. □

7. Conclusions. Probably the most interesting open question in superstring study is whether GREEDY yields a 2-approximation. GREEDY has an (almost) obvious interpretation relative to the protocol we described in section 6. At each point in its operation, the strings in GREEDY's current set defines a collection of simple, disjoint paths in G_S. When GREEDY merges x and y (i.e., replaces them by $pref(x, y) \cdot y$) we perform an edge exchange based on the edge from the end of x's path to the beginning of y's path. The difficulty with analyzing GREEDY in this way is that these edges are not always winning edges and thus we must account for the cost increases along the way. The construction protocol in section 6 may be useful in analyzing these increases. In addition, the *stop* and *squeeze* functions seem important for the study of GREEDY. If for every $x \in U^*$, $st(x) > sh(x)$, there is a simple algorithm that gives a $2\frac{1}{3}$-approximation bound (see [10]).

Of course the other important question in this area is whether OPT_S can be approximated within a factor of 2 by any algorithm. We conjecture that our algorithm can be modified slightly and the analysis improved to prove a $2\frac{1}{3}$ bound. Unfortunately the analysis is even more complicated and, perhaps worse, the algorithm becomes extremely complex.

Appendix. Proofs of Lemmas 4.13, 4.14, 5.1, 5.3, 5.4, and 6.4.

Proof of Lemma 4.13. 1. Suppose $g(x)$ is set by sq. Consider the case where c_i is colored by Rules 1, 2, or 3. By Lemma 4.12 c_i is colored in round $(1, i)$. In every rule $G(x) = SQ(x)$ is colored during the round if it is not already colored. Now suppose that c_i is colored by Rule 4. In this case $j = 2$. Since Rule 1 is not used in round $(1, i)$, $sq(x) > \frac{3}{2}$. Then since Rule 3 is not used in round $(1, i)$, $SQ(x) < x$. However, by Fact 4.11, $SQ(x)$ is colored when round $(2, i)$ begins.

2. The second point follows by the definition of force.

3. Now suppose that c_i is set by st. In any rule by which c_i can be colored, $ST(x)$ is also colored during the round if it isn't already colored when the round begins. Thus it suffices to show that $ST(x)$ is uncolored when the round begins. Suppose $ST(x)$ is colored in an earlier round. Referring to the definition of *set by*, since $ST(x)$ is colored the first rule does not apply. Thus the second must. By definition of stop $tr(ST(x), x) < 1$, and by Lemma 3.10, $tr(x, ST(x)) \geq 1$. Then since $\mathcal{V}_S(ST(x)) \geq 1$, $fo(x) \leq \max(\lfloor tr(x, ST(x)) \rfloor, 1) = st(x)$. However, this contradicts our priority rule. ☐

Proof of Lemma 4.14. 1. If $g(x)$ is set by sh, sq, or st, then by Lemma 4.12 the same conditions hold in round $(1, i)$, which is a contradiction. Thus $g(x)$ is set by fo in round $(2, i)$. Also by this lemma $fo(x)$ is integral, and since Rule 1 applies, $fo(x) < \frac{3}{2}$ so $fo(x) = 1$.

Assume that $c_{FO(x)} = c_k$. By Lemma 4.13, $FO(x)$ is colored when round $(2, i)$ begins. Suppose $FO(x)$ is *yellow*. Then $FO(x)$ is colored in round $(2, k)$ of Rule 4. Since $FO(x)$ is colored before round $(2, i)$ begins, $k < i$ and $FO(x) < x$. By Lemma 4.8 x conflicts with $FO(x)$ in round $(2, k)$. Since Rule 2 is not chosen, one of the following three conditions holds:

(a) $g(FO(x)) \leq \frac{3}{2}$. However, $FO(x)$ is colored *blue* in Rule 1, which is a contradiction.

(b) Stopping condition 2 fails to hold. Then $g(FO(x))$ is set by $st(FO(x)) = 2$ and $ST(FO(x)) < FO(x)$. This contradicts either Fact 4.11 or Lemma 4.13.

(c) $G(FO(x))$ is defined and $G(FO(x)) \in OP(c_i)$. Then by Lemma 4.13 c_i is colored no later than round $(2, k)$, which is a contradiction.

2. Suppose c_i is colored by Rule 2 in round $(2,i)$. Since $g(x) > \frac{3}{2}$ in round $(2,i)$ and since $g(x)$ in nonincreasing, $g(x) > \frac{3}{2}$ and $u > x$ is uncolored and conflicts with x in round $(1,i)$. Since x is not colored by Rule 2 in round $(1,i)$, one of the following conditions holds in round $(1,i)$:

(a) Stopping condition 2 fails to hold. Then $g(x)$ is set by $st(x) = 2$ and $ST(x) < x$. By Lemma 4.12 $g(x)$ is set by $st(x) = 2$ or by $fo(x) \leq 2$ in round $(2,i)$. In the first case we get a contradiction to either Fact 4.11 or Lemma 4.13. Thus $g(x)$ is set by $\frac{3}{2} < fo(x) \leq 2$; by Lemma 4.12 $fo(x) = 2$. Furthermore, since $st(x) = 2$ and $ST(x)$ is colored (by Fact 4.11), $FO(x) = ST(x)$.

(b) $G(x)$ is defined and $c_u = c_{G(x)}$. Since $G(x)$ is uncolored in round $(2,i)$, by Lemma 4.13 $g(x)$ is set by sq or st in round $(1,i)$. Since $G(x) \in c_u$ and $c_u > c_i$ but Rule 3 is not used in round $(1,i)$, $g(x)$ is set by $st(x) = 2$ in that round. By Lemma 4.12 $g(x) = 2$ in round $(2,i)$, and since $ST(x) > x$, this is the special case of *set by*. Thus $g(x)$ is set by st. However, stopping condition 2 fails to hold in round $(2,i)$, which is a contradiction.

3. Suppose c_i is colored by Rule 3 in round $(2,i)$. By Lemma 4.12 the same conditions hold in round $(1,i)$, which is a contradiction.

4. Suppose that for some $x \in OP(c_i)$ $g(x) \leq \frac{3}{2}$. Since Rule 1 is not used, $g(x)$ is set by $st(x) = 1$ and $ST(x) < x$. Then we get a contradiction to either Fact 4.11 or Lemma 4.13.

Now suppose that $g(x)$ is set by sq or fo in the round. By Lemma 4.12 and the fact that $g(x) > \frac{3}{2}$, $g(x) \geq 2$. Let $y = G(x)$ and assume $c_y = c_k$. By Lemma 3.10 $|x| \leq (tr(x,y)+1)|c_i| + |c_k|$. By Lemma 4.13 y is colored when the round begins. Suppose it is colored *yellow*. Then y is colored in round $(2,k)$ by Rule 4, and since it is colored when round $(2,i)$ begins, $k < i$, $|c_k| \leq |c_i|$. Hence $|x| \leq (tr(x,y)+2)|c_x|$. If $g(x)$ is set by sq, then by definition of squeeze $tr(x,y) \leq sq(x)$. If $g(x)$ is set by fo, then by the definition of force $tr(x,y) \leq fo(x)+1$. Thus $|x| \leq (g(x)+3)|c_x|$. Then since $g(x) \geq 2$, $|x| \leq \frac{5}{2}g(x)|c_x|$.

Now suppose that $ST(x)$ is defined and colored during the round. Since $st(x) \geq g(x) > \frac{3}{2}$, by Lemma 4.12, $st(x) \geq 2$. By Fact 4.11, $ST(x) > x$. If $st(x) \geq 3$, then c_i is colored no later than round $(1,i)$ of Rule 3, which is a contradiction, so $st(x) = 2$. If $g(x) = 2$, then this is the special case of *set by* and $g(x)$ is set by st. If $g(x) < 2$, then by Lemma 4.12 $g(x)$ is set by sh. $\square$

Proof of Lemma 5.1. The invariant holds when the construction begins. Suppose it holds at the beginning of round (j,i). If c_i is not colored in the round, the algorithm takes no action during the round and $\mathcal{C}_U$ is unchanged. So assume c_i is colored in round (j,i). Let w, u, z, and v be defined as above (conditioned on the various cases).

Invariant 1. To show that invariant 1 holds we need to show that the construction is correct in the sense that the newly created cycles and modified cycles exist in $\mathcal{G}_S$. Each new $m(c)$ construction in Table 2 exists by the string lemmas, Lemma 4.6, Corollary 3.8, and our naming convention. Now consider the case where an existing cycle of $\mathcal{C}_U$ is modified in the round. The only possibility is that $g(w)$ is set by sq, c_z is colored in an earlier round, and $e_{max}(w,z)$ is added to W. Since $g(w)$ is set by sq, $sq(w) < sh(w)$. Thus by Lemma 3.15, $ov(z,z)$ is periodic in $[c_w]$. Then if $ov_k(z,z)$ exists, so does $ov_{\max(k-|c_w|,0)}(z,z)$. The correctness of the modification to $\mathcal{C}_U$ then follows from Lemma 2.10.

Now suppose that c_w is matched. Each construction in Table 3 exists by Lemma 4.6, Corollary 3.8, and our naming convention, except the case when c_w is the winning cycle of the matched pair, c_w is *red*, and $\mathcal{V}_S(w) < 3$. We now prove the correctness of this last case. Assume (c_w, c_y) is an edge of M^*, where $y = rep(c_y)$. Consider the cycle $pair(w, y)$ that determines the weight of the edge (c_w, c_y). Let e be the version of e_w with pseudolength $\mathcal{V}_S(w)|c_w|$ and assume its overlap is k. Since c_w is the winning cycle of the pair, e is a winning edge for the cycle $pair(w, c)$. Furthermore, $\tilde{\mathcal{X}}(\{pair(w, y)\}, e)$ consists of the 1-expansion $c_w^{\mathcal{V}_S(w)}$ and the 1-expansion $\hat{c}_y$ of c_y with length $|pair(w, y)| - \mathcal{V}_S(w)|c_w|$. Since the self-loops of c_w and c_y are chosen by the matching algorithm over the edge (c_w, c_y) in the event of a tie in weight, it must be the case that $|\hat{c}_y| = |pair(w, y)| - \mathcal{V}_S(w)|c_w| < \mathcal{V}_S(y)|c_y|$. By Lemma 4.6 $\mathcal{V}_S(y) \leq sh(y)$. Thus the expansion of e_y in $\hat{c}_y$ has overlap more than $|y| - sh(y)|c_y|$. Then by Lemma 3.14 $ov_k(w, w)$ is periodic in $[\delta_y]$. Of course, it is also the case that $ov_k(w, w)$ is periodic in $[\delta_w]$. Then by Lemma 4.6 $c_w^{\mathcal{V}_S(w)}$ exists, so using Lemma 2.10 $c_w^{\mathcal{V}_S(w)+\min(|c_w|+|c_y|)/|c_w|}$ exists as well.

Invariant 2. Now consider invariant 2. Our modifications to existing cycles of $\mathcal{C}_U$ never eliminate a zero-overlap edge, so any weakly connected component of $\mathcal{C}_U \cup W$ that satisfies the invariant at the beginning of round (j, i) also satisfies the invariant at the end of the round. Thus we need only be concerned with the new cycles added to $\mathcal{C}_U$ during round (j, i). If $m(c)$ is created in round (j, i) for some $c \neq c_w$, then $e_{max}(w, y)$ is added to W for some $y \in OP(c)$. Thus it suffices to show that at the end of round (j, i) the weakly connected component of $\mathcal{C}_U \cup W$ containing $m(c_w)$ satisfies the invariant. If c_w is matched we are done, so assume c_w is unmatched. Referring to Table 2, the only cases in which one of the created cycles does not explicitly have a zero-overlap edge is when $g(w)$ is set by sq or fo, c_z is colored in a previous round, and $e_{max}(w, z)$ is added to W. However, in these cases, $m(c_w)$ is attached via $e_{max}(w, z)$ to the existing weakly connected component of $\mathcal{C}_U$ containing the expansion of $m(c_z)$; this component satisfies the invariant by our induction hypothesis.

Invariant 3. Now consider invariant 3. We point out that our naming convention does not affect our arguments in the proof of this invariant; i.e., in the case of a 1-expansion c_x^q where $q > |c_x|/|x|$, the edge from x_{last} to x_{first} has zero-overlap and any out-edge of x_{last} or in-edge of x_{first} has at least as much overlap. In proving that this invariant holds we will repeatedly use the fact that if c_x is non-*yellow* , then $m(c_x)$ is an expansion of $c_x^{\mathcal{V}_S(x)}$, which obviously holds if $\mathcal{V}_S(x) = 1$ and when $\mathcal{V}_S(x) > 1$ holds by construction since x must in fact be $rep(c_x)$. Also for the string w, $m(c_w)$ is an expansion of $c_w^{g(w)}$.

Suppose e is added to W during round (j, i). Then $e = e_{max}(w, u)$ or $e = e_{max}(w, z)$ or $e = e_{max}(w, v)$.

1. $e = e_{max}(w, u)$: In this case c_w is colored by Rule 2. As pointed out above, $m(c_w)$ is an expansion of $c_w^{g(w)}$ and, referring to Table 2, $m(c_u) = c_u^2$. By the definition of conflict, $tr(w, u) \leq g(w)$ and $tr(u, w) \leq 2$. Thus by Lemma 3.10, e is a winning edge for $\mathcal{C}_U$.

2. $e = e_{max}(w, z)$: Since z is defined, $g(w)$ is not set by sh. Suppose $g(w)$ is set by sq. Then $\mathcal{V}_S(w) = sq(w)$. Referring to Tables 2 and 3 for the three cases where $e_{max(w,z)}$ is added to W, $m(c_w)$ is an expansion of $c_w^{sq(w)}$ and the version of $m(c_z)$ in $\mathcal{C}_U$ is always an expansion of $c_z^{1+\min(|c_w|,|c_z|)/|c_z|}$. By Lemma 3.15 e is a winning edge for $\mathcal{C}_U$.

Suppose $g(w)$ is set by fo. In the only case where $e_{max}(w, z)$ is added to W, $m(c_w) = c_w^{fo(w)+1}$. By definition $fo(w) + 1 > tr(w, z)$. Since z is colored in an earlier round, $\mathcal{C}_U$ includes an expansion of c_z and we claim that it is in fact an expansion of c_z^q where $q \geq tr(z, w)$, so e is a winning edge by Lemma 3.10. If z is non-*yellow*, then let $q = \mathcal{V}_S(z)$ and the claim holds; note that earlier we argued that $m(c_z)$ is an expansion of $c_z^{\mathcal{V}_S(z)}$ if z is non-*yellow*. Now suppose that z is *yellow*. If c_w is colored by Rules 1–3, then by Lemma 4.14 c_w is colored by Rule 2, $z = ST(w)$, and so $q = 1$ satisfies the claim. If c_w is colored in Rule 4, then since c_z is *yellow* the algorithm does not add $e_{max}(w, z)$ to W.

Finally, suppose that $g(w)$ is set by st. When c_w is unmatched $m(c_w) = w$. Now suppose c_w is matched. If c_w is *yellow*, then $st(w) \geq 2$ and if c_w is *red*, then c_w is in $\mathcal{R}_2$ and $st(w) \geq 3$. In each case $m(c_w)$ is an expansion of $c_w^{st(w)+1}$. Also, $m(c_z) = c_z$. By the definition of stop, $1 > tr(z, w)$ and $st(w) + 1 > tr(w, z)$. By Lemma 3.10 e is a winning edge for $\mathcal{C}_U$.

3. $e = e_{max}(w, v)$: Now c_w is *yellow*, the round is $(2, i)$, $w = rep(c_w)$, $\frac{3}{2} < \mathcal{V}_S(w) \leq 2$, and $v = ST(x)$ for some $x \in OP(c_w)$ such that $st(x) = 2$. By Lemma 2.10 $\delta_w \in [\delta_x]$. Since c_v is uncolored when round $(2, i)$ begins, by Lemma 4.13 $|c_v| \geq |c_w|$. Thus $tr(v, w) < tr(v, x) + 1$. By definition of stop $tr(v, x) < 1$ so $tr(v, w) < 2$. In every case $m(c_v) = c_v^2$. Similarly, $tr(w, v) \leq tr(x, v) + |c_w|/|c_v| \leq tr(x, v) + 1$. By definition of stop $tr(x, v) < st(x) + 1$. Thus $tr(w, v) < st(x) + 2 = 4$. Referring to Table 2 for the cases where c_w is unmatched, $m(c) = w$. If c_w is matched, then $m(c_w)$ is either w or $c_w^{\mathcal{V}_S(w)+2}$, where $\mathcal{V}_S(w) \geq 2$. By Lemma 3.10 e is a winning edge for $\mathcal{C}_U$.

Invariant 4. Finally, consider Invariant 4. We analyze the lengths and allocations depending on the rule by which c_w is colored. The analysis is summarized in Table 4.

1. Suppose that c_w is colored by Rule 1. Then c_w is *blue* and, by Fact 4.17, it is unmatched. Also, $1 \leq g(w) < \frac{3}{2}$ and if $g(w)$ is not set by sh, then by Lemma 4.12 $g(w) = 1$. Furthermore, if z is defined then $e_{max}(w, z)$ is added to W in the round. If in addition c_z is colored during the round, then c_z is *blue*. The possible cases are shown in Table 4 for Rule 1. This table also gives the construction of $m(c_w)$ and, when applicable, the column *length bound* gives an upper bound on the increase in $|\mathcal{C}_U|$ during the round. The length increase is due to the newly created cycles and any expansions to existing cycles. The bound in each case is obvious from the construction and the length bounds given by the string lemmas. The column *allocation* gives the total allocation to c_w and, if c_z is colored in the round, to c_z. In each case the total allocation is at least as large as the total length increase. In the first case, by Lemma 3.7, $|w| \leq (sh(w)+1)|c_w|$. Since c_w is *blue*, its allocation is $alloc(c_w) = \frac{5}{2}|c_w|$. Since $sh(w) \leq \frac{3}{2}$, $|w| \leq alloc(c)$. In the second case $|c_w^{sq(w)}| = sq(w)|c_w|$ (by definition) and c_z is expanded by up to $|c_w|$. Thus the total length increase is no more than $(sq(w)+1)|c_w|$. This is no more than $alloc(c_w) = \frac{5}{2}|c_w|$ since $sq(w) = 1$. In the third case $|c_w^{sq(w)}| = sq(w)|c_w|$, and by Lemma 3.15 $|z| \leq 2|c_z| + |c_w|$ for a total length increase of no more than $(sq(w) + 1)|c_w| + 2|c_z|$, which is no more than the total allocation. The fourth case follows in a similar way using Lemma 3.10. The last case also uses Lemma 3.10 for its length bound, which is no more than the total allocation since $|c_z| \geq |c_w|$; this last fact holds because stopping condition 1 holds.

2. Suppose c_w is colored by Rule 2. Then c_w is *red*, $\mathcal{V}_S(w) = g(w)$ as computed at the beginning of the round, and $g(w) > \frac{3}{2}$. If c_w is matched, then by Fact 4.17 $g(w) > 2$. As before, by Lemma 4.12 $g(x)$ is integral if set by something other than sh. The *no*/*no*/*no* cases of Table 2 are not applicable under this rule since $e_{max}(z, w)$ is added to W provided z is defined and c_i is unmatched. The table gives the construction for $m(c_w)$ and, if z is defined, for $m(c_z)$. For this rule u is defined, colored *blue* in the round, and $m(c_u) = c_u^2$. If z is defined and colored in the round it is also *blue*.

TABLE 4
Cost accounting.

Case from Table 2		Construction		Analysis

	yes/no/no	$m(c_w)$	NC	$\|m(c_w)\|$	$\|m(c_w)\|$
$st(w) \geq 2$	no/yes/yes	w	c_z	$(st(w)+2)\|c_w\|+2\|c_z\|$	$\frac{5}{2}(st(w)\|c_w\|+\|c_z\|)$
	yes/yes/yes	$m(c_w)$	c_z	$\|m(c_w)\|+\|c_z\|$	$\|m(c_w)\|+\frac{5}{2}\|c_z\|$

In every case the length bound is obvious using the case and the string lemmas. In every case the allocation is clearly as large as the length bound, using the fact that $|c_u| \geq |c_w|$ and the range for $g(w)$, except the case $st(w) \geq 2$ *no/yes/yes*. We prove this case next. Using the definition of stop we get the bound $|w| \leq (st(w)+2)|c_w| + |c_z|$ from Lemma 3.10. This gives a total length increase of no more than $(st(w)+2)|c_w| + 2|c_z| + 2|c_u|$, which is no more than the allocation when $st(w) \geq 3$. Now suppose $st(w) = 2$. Since stopping condition 2 holds, $c_z > c_w$. Using the length bound of Lemma 3.10 with the definitions of stop and conflict we get

$$\begin{aligned} |w| &\leq \frac{1}{2}((st(w)+2)|c_w| + |c_z| + (st(w)+1)|c_w| + |c_u|) \\ &\leq \left(st(w) + \frac{3}{2}\right)|c_w| + \frac{1}{2}|c_z| + \frac{1}{2}|c_u|. \end{aligned}$$

Then the total length increase is no more than

$$\left(st(w) + \frac{3}{2}\right)|c_w| + \frac{3}{2}|c_z| + \frac{5}{2}|c_u|,$$

which is no more than the allocation since $|c_z| \geq |c_w|$, $|c_u| \geq |c_w|$, and $st(w) = 2$.

3. Suppose c_w is colored by Rule 3. In this case $g(w)$ is set by sq or st, z is defined, $c_z > c_w$, c_z is colored in the round, and $e_{max}(w,z)$ is added to W. If $g(w)$ is set by st, then $st(w) \geq 3$. If $g(w)$ is set by sq, then $sq(w) \geq 2$ with equality only if $c_z \in \mathcal{R}_1$, in which case c_w is unmatched. The table handles all the possibilities. The bound and allocation arguments follow as before.

4. Suppose c_w is colored by Rule 4. In this case c_w is *yellow*, $w = rep(c_w)$, and $g(w) > \frac{3}{2}$ subject to the integrality constraints of Lemma 4.12. By Lemma 4.13, if $g(w)$ is set by sq, then $SQ(w)$ is colored in an earlier round so the $*/yes/*$ cases do not apply. Furthermore, by our choice of representative, if $g(w)$ is set by $st(w)$, then $ST(w) > w$ and is colored during the round. The analysis follows as described for the previous rules except for the *no/no/no* cases; these follow from Lemma 4.14. Finally, for every v that is defined, $|m(c_v)| = 2|c_v| \leq \frac{5}{2}|c_v|$. ◻

Proof of Lemma 5.4. Let c be a cycle of $\mathcal{C}_S{}^*$ and let $\hat{c}$ be the 1-expansion of c in $\mathcal{C}_L$. In each of the first three cases of Definition 4.19, the allocation in Table 1 satisfies the following:

$$alloc(c) = \frac{5}{2}(|\hat{c}| - 1_{c \in \mathcal{R}} \cdot |c|),$$

where $1_{c\in\mathcal{R}}$ is 1 if $c \in \mathcal{R}$ and 0 otherwise. Thus it suffices to show that for matched pairs $(c_1, c_2) \in M^*$,

$$\sum_{i=1,2} |m(c_i)| - \frac{1}{2} \cdot 1_{c\in\mathcal{R}_2} \cdot |c| \leq \frac{5}{2} \sum_{i=1,2} (|\hat{c}_i| - 1_{c_i\in\mathcal{R}_2} \cdot |c_i|).$$

Note that by construction of $\mathcal{G}(\mathcal{V}_S)$ if $c \in \mathcal{R}_1$, then c is unmatched.

Let c_1 and c_2 be a matched pair in M^*. Assume for $i = 1, 2$ that $x_i = rep(c_i)$, $\hat{c}_i$ is the 1-expansion of c_i in $\mathcal{C}_L$, $\hat{e}_i$ is the expansion of $e_{rep(c_i)}$ in $\hat{c}_i$, and $k_i = ov(\hat{e}_i)$. Also assume that c_1 is the max-overlap cycle of the pair. Next we assemble the following facts about these cycles:

1. $k_2 > |c_2|$: This was argued in the proof of invariant 1 for Lemma 5.1 when c_w is *red*, but the proof doesn't rely on the coloring.

2. $ov_{k_1}(x_1, x_1)$ is periodic in $[\delta_{x_1}]$: This also was in the proof cited above.
3. $k_1 \leq |c_1| + |c_2|$: This follows from the previous fact by Lemma 2.10.
4. If $\mathcal{V}_S(x_1)$ is nonintegral, then $k_1 < |c_1|$. This holds by Corollary 3.8 and Lemma 4.6.
5. $k_2 \leq k_1$: This holds by Lemma 3.3.
6. If c_2 is *red*, then $|\hat{c}_2| = \ell|c_2|$ for some $\ell \geq 2$: This holds by Lemma 4.18.
7. $\hat{c}_1 = c_{x_1}^{\mathcal{V}_S(x_1)}$: This holds by Definition 4.19.

We now consider the four possible constructions in Table 3.

1. c_1 is *yellow* and $\frac{3}{2} < \mathcal{V}_S(x_1) < 2$: In this case $1_{c_1 \in \mathcal{R}_2} = 0$, $m(c_i) = x_i$, and by points 4 and 5 above $|x_i| \leq |\hat{c}_i| + |c_1|$. These facts give the first inequality below. By this case and point 7 above, $\frac{3}{2}|c_1| < |\hat{c}_1| < 2|c_1|$, and by point 6 $|\hat{c}_2| - 1_{c_2 \in \mathcal{R}_2} \cdot |c_2| = k|c_2|$ for some $k \geq 1$. These facts yield the second inequality, where we again use $1_{c_1 \in \mathcal{R}_2} = 0$:

$$\begin{aligned}|m(c_1)| + |m(c_2)| - \tfrac{1}{2} \cdot 1_{c_2 \in \mathcal{R}_2} \cdot |c_2| &= |x_1| + |x_2| - \tfrac{1}{2} \cdot 1_{c_2 \in \mathcal{R}_2} \cdot |c_2| \\ &\leq |\hat{c}_1| + |\hat{c}_2| + 2|c_1| - \tfrac{1}{2} \cdot 1_{c_2 \in \mathcal{R}_2} \cdot |c_2| \\ &\leq \tfrac{5}{2} \textstyle\sum_{i=1,2}(|\hat{c}_i| - 1_{c_i \in \mathcal{R}_i} \cdot |c_i|).\end{aligned}$$

2. c_1 is *yellow* and $\mathcal{V}_S(x_1) \geq 2$: In this case $1_{c_1 \in \mathcal{R}_2} = 0$, $m(c_1) = c_{x_1}^{\mathcal{V}_S(x_1)+2}$, and $m(c_2) = x_2$, so by point 7 we get the equality below. By points 3 and 5 above, $|x_2| \leq |\hat{c}_2| + |c_1| + |c_2|$ so we get the following first inequality. By this case and point 7 above $|\hat{c}_1| \geq 2|c_1|$, and by point 6 $|\hat{c}_2| - 1_{c_2 \in \mathcal{R}_2} \cdot |c_2| = k|c_2|$ for some $k \geq 1$. These facts yield the second inequality, where we again use $1_{c_1 \in \mathcal{R}_2} = 0$:

$$\begin{aligned}|m(c_1)| + |m(c_2)| - \tfrac{1}{2} \cdot 1_{c_2 \in \mathcal{R}_2} \cdot |c_2| &= |\hat{c}_1| + 2|c_1| + |x_2| - \tfrac{1}{2} \cdot 1_{c_2 \in \mathcal{R}_2} \cdot |c_2| \\ &\leq |\hat{c}_1| + 3|c_2| + |\hat{c}_2| + |c_2| - \tfrac{1}{2} \cdot 1_{c_2 \in \mathcal{R}_2} \cdot |c_2| \\ &\leq \tfrac{5}{2} \textstyle\sum_{i=1,2}(|\hat{c}_i| - 1_{c_i \in \mathcal{R}_i} \cdot |c_i|).\end{aligned}$$

3. c_1 is *red* and $2 < \mathcal{V}_S(x_1) < 3$: In this case $1_{c_1 \in \mathcal{R}_2} = 1$, $m(c_1) = c_{x_1}^{\mathcal{V}_S(x_1)+\frac{|c_2|}{|c_1|}}$, and $m(c_2) = x_2$. These facts plus point 7 yield the equality below. By points 4 and 5 $|x_2| \leq |\hat{c}_2| + |c_1|$, giving us the first inequality below. By point 7, $2|c_1| \leq |\hat{c}_1| \leq 3|c_1|$, and by point 6, $|\hat{c}_2| - 1_{c_2 \in \mathcal{R}_2} \cdot |c_2| = k|c_2|$ for some $k \geq 1$. These facts yield the second inequality:

$$\begin{aligned}|m(c_1)| - \tfrac{1}{2}|c_1| + |m(c_2)| - \tfrac{1}{2} \cdot 1_{c_2 \in \mathcal{R}_2} \cdot |c_2| &= |\hat{c}_1| + |c_2| - \tfrac{1}{2}|c_1| + |x_2| - \tfrac{1}{2} \cdot 1_{c_2 \in \mathcal{R}_2} \cdot |c_2| \\ &\leq |\hat{c}_1| + \tfrac{1}{2}|c_1| + |\hat{c}_2| + |c_2| - \tfrac{1}{2} \cdot 1_{c_2 \in \mathcal{R}_2} \cdot |c_2| \\ &\leq \tfrac{5}{2} \textstyle\sum_{i=1,2}(|\hat{c}_i| - 1_{c_i \in \mathcal{R}_i} \cdot |c_i|).\end{aligned}$$

4. c_1 is *red* and $\mathcal{V}_S(x_1) \geq 3$: In this case $1_{c_1 \in \mathcal{R}_2} = 1$, $m(c_1) = c_{x_1}^{\mathcal{V}_S(x_1)+1}$, and $m(c_2) = x_2$. These facts plus point 7 yield the equality below. By points 3 and 5 $|x_2| \leq |\hat{c}_2| + |c_1| + |c_2|$, giving us the first inequality below. By point 7, $|\hat{c}_1| \geq 3|c_1|$, and by point 6, $|\hat{c}_2| - 1_{c_2 \in \mathcal{R}_2} \cdot |c_2| = k|c_2|$ for some $k \geq 1$. These facts yield the second inequality:

$$\begin{aligned}|m(c_1)| - \tfrac{1}{2}|c_1| + |m(c_2)| - \tfrac{1}{2} \cdot 1_{c_2 \in \mathcal{R}_2} \cdot |c_2| &= |\hat{c}_1| + \tfrac{1}{2}|c_1| + |x_2| - \tfrac{1}{2} \cdot 1_{c_2 \in \mathcal{R}_2} \cdot |c_2| \\ &\leq |\hat{c}_1| + \tfrac{3}{2}|c_1| + |\hat{c}_2| + |c_2| - \tfrac{1}{2} \cdot 1_{c_2 \in \mathcal{R}_2} \cdot |c_2| \\ &\leq \tfrac{5}{2} \textstyle\sum_{i=1,2}(|\hat{c}_i| - 1_{c_i \in \mathcal{R}_i} \cdot |c_i|). \qquad \square\end{aligned}$$

To prove Lemma 6.4 we need the following lemma and corollaries.

LEMMA A.1. *If c is a cycle of $\mathcal{C}_S{}^*$ such that $d_c \geq 3$, then for any vertex s of c, $[\delta_s] = [c]$.*

Proof. Suppose $[\delta_s] \neq [c]$. By definition, δ_s is irreducible. By Lemma 2.10, every $\alpha \in [c]$ is irreducible. Furthermore, s is periodic in $[\delta_s]$ and $[c]$ so, using Lemma 2.5, $|s| < |\delta_s| + |c|$. Let x be the open of c such that $x_{first} = s$. Then $|x| < |s| + |c| < |\delta_s| + 2|c|$. Since s is periodic in $[c]$, $|\delta_s| < |c|$. Thus $|x| < 3|c|$ and $d_c < 3$. □

COROLLARY A.2. *Let c be a cycle in $\mathcal{C}_S{}^*$ and let $\hat{c}$ be a cycle of $\mathcal{G}_S$ that is uniform for c. If $d_c \geq 3$, then $|\hat{c}| \geq |c|$.*

Proof. This follows from the fact that any cycle including a vertex s must have length at least $|\delta_s|$. □

The length of a path in $\mathcal{G}_S$ is the sum of the edge lengths of the path.

COROLLARY A.3. *Let c be a cycle in $\mathcal{C}^*$ containing an edge $\langle s, t\rangle$, $s \neq t$. Let p be any simple path in $\mathcal{G}_S$ from t to s. If $d_c \geq 3$, then $|p| \geq |c| - |pref(s,t)|$.*

Proof. Consider the tight cycle on the vertices s and t; this cycle has length $|pref(s,t)| + |pref(t,s)|$. By the previous corollary the length of this cycle is at least $|c|$. Thus $|pref(t,s)| \geq |c| - |pref(s,t)|$. The tight edges of G_S satisfy the triangle inequality so any path from t to s has length at least $|c| - |pref(s,t)|$. □

Proof of Lemma 6.4. Let c be a cycle of $\mathcal{C}_S{}^*$ such that $d_c \geq 3$. Since $\mathcal{C}_{final}$ is uniform for c and $\mathcal{C}_0$ is not, there is some smallest $i > 0$ such that $\mathcal{C}_i$ is uniform for c. Steps (i), (iii), and (iv) cannot create a uniform cycle, so it must be the case that $\mathcal{C}_i = \tilde{\mathcal{X}}(\mathcal{C}_{i-1}, e)$ for some edge e in $\mathcal{G}_S$. Since $\mathcal{C}_{i-1}$ is not uniform for c, some vertex s of c is in a mixed cycle in $\mathcal{C}_{i-1}$. Furthermore, an edge exchange can increase the number of cycles uniform for some c by at most 1. Thus if $i = 1$, by our assumptions on $\mathcal{C}_0$, c is represented in $\mathcal{C}_0$ and marked in the first step. Suppose $i > 1$. Then $\mathcal{C}_{i-1}$ is produced during the previous round. By step (iii) we can assume that $\mathcal{C}_{i-1}$ does not contain any cycles uniform for c. Thus $\mathcal{C}_i$ contains exactly one cycle uniform for c. It must be the case that the vertices of c comprise a path in a mixed cycle of $\mathcal{C}_{i-1}$. By step (iv) c is represented in the mixed cycle. Thus c is marked in step (i) of the current round.

Let c be a cycle of $\mathcal{C}_S{}^*$ such that $d_c < 3$. Suppose that $c \in \mathcal{C}_{final}$. As argued above there are covers $\mathcal{C}_{i-1}$ and $\mathcal{C}_i$, where $\mathcal{C}_i$ is uniform for c, $\mathcal{C}_{i-1}$ is not, and $\mathcal{C}_i = \tilde{\mathcal{X}}(\mathcal{C}_{i-1}, e)$ for some e of $\mathcal{G}_S$. By construction, no subsequent steps modify the cycles uniform for c, so since $c \in \mathcal{C}_{final}$, $c \in \mathcal{C}_i$. Then it is easy to see that the edge exchange must replace a mixed cycle in $\mathcal{C}_{i-1}$ by two cycles, one of which is c. However, it must be the case that c is represented in the mixed cycle in $\mathcal{C}_{i-1}$ and thus is marked in step (i).

Now suppose that $c \notin \mathcal{C}_{final}$. Then $\mathcal{C}_{final}$ includes cycles $\hat{c}_1, \ldots, \hat{c}_k$ that are uniform for c and partition its vertices. Suppose ($k = 1$ and) $\hat{c}_1$ is a 1-expansion c_x^q of c. If q is nonintegral, then by Corollary 3.8 $q \geq sh(x)$. Now suppose q is integral. Since $c_x^q \neq c$, by Corollary 3.8, $q \geq 2$. Since $d_c < 3$, there is some open y of c such that $|y| < 3|c|$ and so $sh(y) \leq 2$.

If the above case does not hold, we can perform edge exchanges based on the edges of c (in order by increasing overlap) until we reach some final exchange producing a 1-expansion of c. If this 1-expansion is different from c, the proof follows as above. Otherwise c is produced by an edge exchange $\tilde{\mathcal{X}}(\{\tilde{c}_1, \tilde{c}_2\}, e)$, where $\tilde{c}_1$ and $\tilde{c}_2$ partition the vertices of c, $|\tilde{c}_1| + |\tilde{c}_2| = |c|$, and $e = \langle s, t\rangle$ for some s in $\tilde{c}_1$ and t in $\tilde{c}_2$. If $[\tilde{c}_1] = [\tilde{c}_2]$, then every vertex in c is periodic in $[\tilde{c}_1]$ and there is a cycle on these vertices with length $|\tilde{c}_1|$; this contradicts the optimality of $\mathcal{C}_S{}^*$. Thus $[\tilde{c}_1] \neq [\tilde{c}_2]$. Then by Corollary 2.6 $ov(e) < |\tilde{c}_1| + |\tilde{c}_2| = |c|$. The edge e is e_x for some $x \in OP(c)$ and $|x| = |c| + ov(e) < 2|c|$ so $sh(x) = 1$. □

Acknowledgment. We'd like to thank Sampath Kannan for his careful checking of our proof and suggestions on improving the exposition.

ON THE STRUCTURE OF LOGSPACE PROBABILISTIC COMPLEXITY CLASSES[*]

IOAN I. MACARIE[†]

Abstract. We investigate hierarchical properties and logspace reductions of languages recognized by logspace probabilistic Turing machines, Arthur–Merlin games, and games against nature with logspace probabilistic verifiers. Each logspace complexity class is decomposed into a hierarchy based on corresponding two-way multihead finite-state automata and we (eventually) prove the separation of the hierarchy levels (even for languages over a single-letter alphabet); furthermore, we show efficient reductions of each logspace complexity class to, or between, low levels of its corresponding hierarchy.

We find probabilistic and probabilistic-plus-nondeterministic variants of Savitch's maze threading problem which are logspace complete for **PL** (the class of languages recognized by logspace probabilistic Turing machines) and, respectively, **P** (the class of languages recognized by polynomial-time deterministic Turing machines), and which can be recognized by one-way non-sensing two-head (or one-way one-head one-counter) finite-state automata with probabilistic and both probabilistic and nondeterministic states, respectively.

Key words. multihead finite automata, heads hierarchy, probabilistic computation, probabilistic Turing machines, Arthur–Merlin games, games against nature, logspace reductions

1. Introduction.

Deterministic and nondeterministic multihead finite(-state) automata were studied primarily in the 1970s. Several results were published, including characterizations of hierarchies of multihead finite automata, their connections with logspace Turing machines, and transformations of languages recognized by one type of devices to languages recognized by the same or different types of devices [16, 18, 44, 30, 39, 40, 46, 31]. More specifically, some of these results show that the classes recognized by deterministic and nondeterministic logspace Turing machines (i.e., **L** and **NL**, respectively) can be represented as proper hierarchies defined by deterministic and, respectively, nondeterministic two-way multihead finite automata [30, 31]. Other results provide variants of Savitch's maze threading problem that are logspace complete for **NL** and can be solved by simple nondeterministic automata (more exactly, by one-way non-sensing two-head or one-way one-head one-counter nondeterministic finite automata [44]). The corresponding relations hold for alternating computation as well [24]. In the probabilistic settings only some of the analogous results have been reported so far. All that is currently known are characterizations of logspace probabilistic complexity classes in terms of hierarchies defined by the corresponding two-way multihead finite automata and separations of head hierarchies for two-way multihead unbounded-error and one-sided-error probabilistic finite automata [29].

One goal of this paper is to further investigate properties of logspace probabilistic Turing machines, focusing on their connection with multihead *one*-way probabilistic finite automata. We show that the languages recognized by polynomial-time logarithmic-space (bounded-error and one-sided-error) probabilistic Turing machines are logspace reducible to languages recognized by the corresponding one-way non-sensing four-head probabilistic finite automata that move at least one head at each computation step. In the setting of *un*bounded-error probabilistic computation we obtain the even stronger reductions to languages recognized by one-way non-sensing two-head probabilistic finite automata (or one-way one-head one-counter probabilistic finite automata) that move at least one head at each computation step. (See section 4.) These last reductions parallel the reductions of Sudborough for nondeterministic computation [44]. They imply immediately Jung's well-known result which states the equivalence, with respect to the language recognition, of logspace probabilistic Turing machines and polynomial-time logspace probabilistic Turing machines [20]. As a consequence of these reductions it follows that **PL** (the class of languages recognized by logspace probabilistic Turing machines) can be characterized as the class of languages logspace reducible to languages recognized by these simple one-way probabilistic finite-state automata. These reductions are quite surprising to hold in the setting of probabilistic computation. For instance, it is known that several versions of matrix inversion are logspace complete for **PL** [2, 20, 28]. The above-mentioned reductions show that **PL** is efficiently reducible to classes of languages recognized by one-way one-head one-counter or one-way non-sensing two-head probabilistic finite automata although these devices do not seem to have enough computational power to invert matrices.

Another goal of this paper is to generalize these separations and reductions obtained for traditional probabilistic devices to the settings of Arthur–Merlin games (AM-games) and games against nature having as verifiers logspace probabilistic Turing machines or two-way and one-way multihead probabilistic finite automata (see sections 3 and 4). We obtain that **P** (the class of languages recognized by polynomial-time deterministic Turing machines) is logspace reducible to the class of languages recognized by one-way one-head one-counter or one-way non-sensing two-head finite automata with both probabilistic and nondeterministic states.

The structure of the paper is as follows.

In section 2 we give some definitions and notations, and we state the new results in terms of these notations. Table 2.1 contains a summary of these results and shows some of the remaining open problems.

In section 3 we notice the equalities between the classes of languages recognized by AM-games (and games against nature) with logspace probabilistic Turing machines as verifiers and the classes of languages recognized by the same games with two-way multihead probabilistic finite-state verifiers. Next we show that for several AM-games (and games against nature) with two-way non-sensing multihead probabilistic finite-state verifiers, some of the corresponding head hierarchies are proper.

In section 4 we present efficient reductions of logspace probabilistic complexity classes to classes of languages recognized by simple probabilistic finite automata. Also, we generalize these results and show similar reductions in the settings of AM-games and games against nature. To prove some of these results, we design probabilistic and, respectively, probabilistic-plus-nondeterministic variants of Savitch's maze threading problem that are logspace complete for the corresponding logspace complexity classes. These problems can be solved by one-way non-sensing two-head or one-way one-

head one-counter finite-state automata with probabilistic and both probabilistic and nondeterministic states, respectively.

2. Background. This section presents the definitions and notations used in this article. In its final part we summarize our results in terms of these notations. Also see Table 2.1.

A *two-way (non-sensing)*[1] *k-head probabilistic finite (-state) automaton* is a probabilistic finite automaton having k heads on the input string, which is delimited by two distinct endmarkers. A configuration of the probabilistic automaton is defined by its state and the positions of the k heads on the input string. From each configuration the automaton executes transitions to next configurations with probabilities from the set $\{0, 1/2, 1\}$.[2] The transition probability to another configuration depends on the present state and the symbols scanned by the k heads (and not on the fact that some heads do or do not have the same position). The acceptance probability of a probabilistic finite automaton for an input w is the probability of eventually reaching the accepting states when processing w. The automaton accepts the input string if this probability is larger than 1/2.

Formally, the definition for two-way (non-sensing) multihead probabilistic automata is as follows.

DEFINITION 2.1. *A two-way (non-sensing) k-head probabilistic finite automaton is a structure*

$$S = (Q, \Sigma, \delta, q_0, Q_{acc}, Q_{rej}),$$

where

- *Q is a finite, nonempty set of states;*
- *$q_0 \in Q$ is the initial state;*

[1]All the multihead finite automata used in this paper have non-sensing heads, i.e., heads that do not detect each other's position. Sometimes we drop the word "non-sensing," but this should not create misunderstanding.

[2]See [29] for results concerning probabilistic automata with transition probabilities from more general sets.

- *Q_{acc} and Q_{rej} are disjoint sets of accepting and rejecting states ($Q_{acc}, Q_{rej} \subset Q$);*
- *Σ is a nonempty input alphabet that does not contain the symbols (left and right endmarkers) $\cancel{c}$ and $\$$;*
- *$\delta : Q \times (\Sigma \cup \{\cancel{c}, \$\})^k \times Q \times (\{-1, 0, 1\})^k \to \{0, 1/2, 1\}$ is the transition function that, depending on the current state and the symbols scanned by the k heads, may change the automaton state and increment, decrement, or leave unchanged its head positions with probabilities from the set $\{0, 1/2, 1\}$. More precisely, the meaning of $\delta(q, s_1, \ldots, s_k, q', d_1, \ldots, d_k)$ is as follows: if the automaton is in state q scanning the symbols $s_1, \ldots, s_k$, then with probability $\delta(q, s_1, \ldots, s_k, q', d_1, \ldots, d_k)$ it enters state q' and moves each input head $i \in \{1, \ldots, k\}$ one symbol in direction d_i (left if $d_i = -1$, right if $d_i = 1$, stationary if $d_i = 0$). There are the following restrictions on δ:*
  - *$\forall (q, s_1, \ldots, s_k) \in Q \times (\Sigma \cup \{\cancel{c}, \$\})^k$, it holds that*

$$\sum_{q', d_1, \ldots, d_k} \delta(q, s_1, \ldots, s_k, q', d_1, \ldots, d_k) = 1$$

    (i.e., δ is a probability function).
  - *$\delta(q, s_1, \ldots, s_{j-1}, \cancel{c}, s_{j+1}, \ldots, s_k, q', d_1, \ldots, d_{j-1}, -1, d_{j+1}, \ldots, d_k) = 0$ (i.e., no head can move to the left of the left endmarker $\cancel{c}$) and $\delta(q, s_1, \ldots, s_{j-1}, \$, s_{j+1}, \ldots, s_k, q', d_1, \ldots, d_{j-1}, 1, d_{j+1}, \ldots, d_k) = 0$ (i.e., no head can move to the right of the right endmarker $\$$).*

Without loss of generality, we can assume that the accepting (Q_{acc}) and rejecting (Q_{rej}) states are halting states (i.e., the automaton stops when it enters them). For an input string x, the acceptance probability of a k-head probabilistic finite automaton is the probability to reach the accepting state when processing x. The input x is accepted, if its acceptance probability is larger than $1/2$.

The definition of probabilistic Turing machine is standard [13].

We recall a classification of probabilistic automata depending on the type of acceptance. If there is an interval around $1/2$ such that for every input string the acceptance probability never falls inside, then the automaton is called (*two-sided*) *bounded-error*. If this is not the case, it is called *unbounded-error*. If for every input string the acceptance probability is either 0 or above $1/2$, the automaton is called *one-sided error* (or *randomized*).

Several equivalent definitions of AM-games or interactive proof systems with public coins have been published in the literature [1, 15]. See [4] for an extensive survey. For our purpose, the most appropriate is the definition based on automata with guess (i.e., nondeterministic) states and random (i.e., probabilistic) states [15]. Such an automaton A accepts an input string x if there is a strategy such that if the nondeterministic transitions are decided according to this strategy, then the acceptance probability of x by A is larger than $1-\epsilon$, for some $\epsilon < 1/2$. A rejects x if for any strategy (used to "decide" the nondeterministic transitions) the acceptance probability of x by A is less than $1/2$. If $\epsilon = 1/2$, we obtain an unbounded-error variant of AM-games (UAM-games) called games against nature [33]. In this paper, we focus on cases where the machine A is a multihead finite automaton or a logspace Turing machine with both nondeterministic and probabilistic states that recognizes with bounded-error or unbounded-error.[3] We call these devices either probabilistic-plus-nondeterministic automata or automata with both probabilistic and nondeterministic states.

The formal definition of a two-way multihead finite automaton with both nondeterministic and probabilistic states and of its (nondeterministic) strategy is a straightforward generalization of the definition for the corresponding two-way one-head finite automaton [6].

DEFINITION 2.2. *A two-way (non-sensing) k-head finite automaton with nondeterministic and probabilistic states is a structure* $S = (Q, \Sigma, \delta, q_0, N, R, Q_{acc}, Q_{rej})$, *where*

- Q *is a finite, nonempty set of states partitioned into the (disjoint) sets* N, R, Q_{acc}, Q_{rej};
- Σ *is the input alphabet and does not contain the symbols (left and right endmarkers)* $\cancel{c}$ *and* \$;
- $q_0 \in Q$ *is the initial state;*
- N *is the subset of nondeterministic states;*
- R *is the subset of probabilistic states;*
- Q_{acc} *and* Q_{rej} *are the sets of accepting and rejecting states;*
- $\delta : Q \times (\Sigma \cup \{\cancel{c}, \$\})^k \times Q \times (\{-1, 0, 1\})^k \to \{0, 1/2, 1\}$ *is the transition function; the meaning of* $\delta(q, s_1, \ldots, s_k, q', d_1, \ldots, d_k)$ *is as follows: if* $q \in R$ *and the automaton is in state* q *reading the symbols* $s_1, \ldots, s_k$, *then with probability* $\delta(q, s_1, \ldots, s_k, q', d_1, \ldots, d_k)$ *the automaton enters state* q' *and moves each head* $j \in \{1, \ldots, k\}$ *one symbol in direction* d_j *(left if* $d_j = -1$, *right if* $d_j = 1$, *stationary if* $d_j = 0$*); if the current state is* $q \in N$ *and the symbols read are* $s_1, \ldots, s_k$, *then the automaton nondeterministically chooses some* q' *and* $d_1, \ldots, d_k$ *such that* $\delta(q, s_1, \ldots, s_k, q', d_1, \ldots, d_k) = 1$, *enters state* q', *and moves each head* $j \in \{1, \ldots, k\}$ *one symbol in direction* d_j. *There are the following restrictions on* δ:
  - $\forall q \in R, \forall (s_1, \ldots, s_k) \in (\Sigma \cup \{\cancel{c}, \$\})^k$, *it holds that*
  $$\sum_{q', d_1, \ldots, d_k} \delta(q, s_1, \ldots, s_k, q', d_1, \ldots, d_k) = 1$$
  (i.e., δ *is a transition probability function);*
  - $\forall q \in N, \forall (s_1, \ldots, s_k) \in (\Sigma \cup \{\cancel{c}, \$\})^k, \forall (q', d_1, \ldots, d_k) \in Q \times (\Sigma \cup \{\cancel{c}, \$\})^k$ *it holds that* $\delta(q, s_1, \ldots, s_k, q', d_1, \ldots, d_k) \in \{0, 1\}$ *(i.e.,* δ *is a nondeterministic transition);*
  - $\delta(q, s_1, \ldots, s_{j-1}, \cancel{c}, s_{j+1}, \ldots, s_k, q', d_1, \ldots, d_{j-1}, -1, d_{j+1}, \ldots, d_k) = 0$ *(i.e., no head can move to the left of the left endmarker* $\cancel{c}$*) and* $\delta(q, s_1, \ldots, s_{j-1}, \$, s_{j+1}, \ldots, s_k, q', d_1, \ldots, d_{j-1}, 1, d_{j+1}, \ldots, d_k) = 0$ *(i.e., no head can move to the right of the right endmarker* \$*).*

DEFINITION 2.3. *For any input string* $x = x_0 x_1 \ldots x_{n+1}$ *(where* $x_0 = \cancel{c}$ *and* $x_{n+1} = \$$ *are the endmarkers) a (nondeterministic) strategy on* x *is a function*

$$S_x : N \times (\{0, \ldots, n+1\})^k \to Q \times (\{-1, 0, 1\})^k$$

such that $\delta(q, s_1, \ldots, \ldots, s_k, q', d_1, \ldots, d_k) = 1$ *whenever* $S_x(q, p_1, \ldots, p_k) = (q', d_1, \ldots, d_k)$ *and* $x_{p_l} = s_l, \forall l \in \{1, \ldots, k\}$. (*Discussions on other possible definitions for (nondeterministic) strategy and their equivalence can be found in* [3].)

[3]Using a different terminology, we investigate properties of interactive proofs with public coins and multihead probabilistic finite automata or logspace probabilistic Turing machines as verifiers that recognize with bounded-error or unbounded-error.

We recall that an automaton A with nondeterministic and probabilistic states accepts an input string x if there is a strategy by which the nondeterministic transitions are decided such that the acceptance probability of x by A is larger than $1-\epsilon$, where $\epsilon < 1/2$ for **AM**-games and $\epsilon = 1/2$ for **UAM**-games. A rejects x if for any strategy (used to "decide" the nondeterministic transitions) the acceptance probability of x by A is less than $1/2$. Without loss of generality, we can assume that Q_{acc} and Q_{rej} contain only halting states.

A multihead automaton has *sweeping* heads if it may reverse the direction of motion of any head only when that head is scanning the right or left endmarker of the input string. A multihead automaton has non-sensing heads if they cannot detect each other's position. We recall that all the multihead automata used in this article have non-sensing heads and that we sometimes omit the word "non-sensing."

Our notations are as follows:

- 2pfa(k) and 2bpfa(k) (1pfa(k) and 1bpfa(k)) denote two-way (one-way) k-head unbounded-error and respectively bounded-error probabilistic finite automata.
- **2PFA**(k), **2BPFA**(k), and **2RPFA**(k) (**1PFA**(k), **1BPFA**(k), and **1RPFA**(k)) denote the classes of languages recognized by the corresponding two-way (one-way) unbounded-error, bounded-error, and one-sided-error probabilistic finite automata, respectively.
- **1PCM**(1) is the class of languages recognized by one-way one-head one-counter unbounded-error probabilistic finite automata.
- **2DFA**(k) and **2NFA**(k) denote the classes of languages recognized by two-way k-head deterministic and nondeterministic finite automata, respectively.
- **DSPACE**(S) is the class of languages recognized by $O(S)$-space-bounded deterministic Turing machines.
- **DTIME**(t) is the class of languages recognized by $O(t)$-time bounded deterministic Turing machines.
- **L**, **NL**, and **AL** are the classes of languages recognized by logspace deterministic, nondeterministic, and alternating Turing machines, respectively.
- **PL**, **BPL**, and **RL** are the classes of languages recognized by unbounded-error, bounded-error, and one-sided-error probabilistic Turing machines, respectively.
- 2pnfa(k) denotes two-way k-head (unbounded-error) finite automata with both probabilistic and nondeterministic states (or, equivalently, **UAM**-games with a two-way k-head probabilistic finite automaton as verifier).
- (P+N)TM denotes Turing machines with both probabilistic and nondeterministic states.
- **AM**($2pfa(k)$) and **AM**($1pfa(k)$) (**UAM**($2pfa(k)$) and **UAM**($1pfa(k)$)) are the classes of languages recognized by **AM**-games (**UAM**-games) with two-way and one-way k-head probabilistic finite automaton, respectively, as verifier.
- **UAM**($1pcm(1)$) is the class of languages recognized by **UAM**-games with one-way one-head one-counter probabilistic finite automaton as verifier.
- **AML** and **UAML** denote the classes of languages recognized by **AM**-games (**UAM**-games) with logspace probabilistic Turing machines as verifiers.
- $\mathbf{C}_{poly}$ is the subclass of languages recognized by the machines that define the class **C** but are restricted to work in polynomial time.
- For any complexity class **C**, $\overbrace{\mathbf{C}}$ is the subclass of unary languages defined

by $\widehat{\mathbf{C}} = \{L_1 \mid L_1 \subseteq \{1^{2^n} \mid n \in \mathbf{N}\}, L_1 \in \mathbf{C}\}$.

- $\subset$ and $\subsetneqq$ denote inclusion (possible not proper) and proper inclusion, respectively.
- $|x|$ is the length of the string x.
- $\mathbf{N}$ is the set of natural numbers (note that we use N to denote the set of nondeterministic states of an automaton).
- By probabilistic-plus-nondeterministic automata we mean automata with both probabilistic and nondeterministic states.

Using the notations introduced above, the results presented in this article are as follows.

- The "equivalence" between the exact space (as opposed to big "O" only) of logspace Turing machines with probabilistic and nondeterministic states, and the number of heads of multihead finite automata with the same kind of states:
  $\mathbf{AML} = \bigcup_{k=1}^{\infty} \mathbf{AM}(2pfa(k))$, $\mathbf{UAML} = \bigcup_{k=1}^{\infty} \mathbf{UAM}(2pfa(k))$,
  $\mathbf{AML}_{poly} = \bigcup_{k=1}^{\infty} \mathbf{AM}_{poly}(2pfa(k))$, and
  $\mathbf{UAML}_{poly} = \bigcup_{k=1}^{\infty} \mathbf{UAM}_{poly}(2pfa(k))$ (Theorem 3.1).
  These relations parallel those recently noticed in the setting of probabilistic computation [29]. The proofs of these decompositions are straightforward adaptations of the proofs of their corresponding deterministic and nondeterministic results [16].
- For $\mathbf{AM}$-games and $\mathbf{UAM}$-games with two-way multihead probabilistic finite-state verifiers the head hierarchy is proper (even for languages over a single-letter alphabet), i.e., for $k \geq 2$,
  $\mathbf{AM}(2pfa(k)) \subsetneqq \mathbf{AM}(2pfa(k+1))$, $\mathbf{UAM}(2pfa(k)) \subsetneqq \mathbf{UAM}(2pfa(k+1))$,
  $\mathbf{UAM}_{poly}(2pfa(k)) \subsetneqq \mathbf{UAM}_{poly}(2pfa(k+1))$ (Theorems 3.2 and 3.7).
  The proofs of these separations are less straightforward adaptations of their deterministic and nondeterministic variants obtained by Monien [30, 31]. Similar separations hold for multihead unbounded-error and one-sided-error probabilistic finite automata [29].
- Using various techniques, we show logspace reductions ($\leq_{log}$) among probabilistic (probabilistic-plus-nondeterministic) complexity classes, as follows:
  - Logspace (bounded-error and one-sided-error) complexity classes are reducible to classes of languages recognized by the corresponding two-way (non-sensing and sweeping) two-head finite automata:
    $\mathbf{BPL} \leq_{log} \mathbf{2BPFA}(2)$, $\mathbf{BPL}_{poly} \leq_{log} \mathbf{2BPFA}_{poly}(2)$,
    $\mathbf{RL} \leq_{log} \mathbf{2RPFA}(2)$, $\mathbf{RL}_{poly} \leq_{log} \mathbf{2RPFA}_{poly}(2)$ (Theorem 4.1), and
    $\mathbf{P} = \mathbf{AML} \leq_{log} \mathbf{AM}(2pfa(2))$ (Theorem 4.9).
  - Polynomial-time logspace (bounded-error and one-sided-error) complexity classes are reducible to languages recognized by the corresponding one-way non-sensing multihead finite automata that additionally move at least one head at each computation step:
    $\mathbf{BPL}_{poly} \leq_{log} \mathbf{1BPFA}(4)$, $\mathbf{RL}_{poly} \leq_{log} \mathbf{1RPFA}(4)$ (Theorem 4.3) and
    $\mathbf{AML}_{poly} \leq_{log} \mathbf{AM}(1pfa(4))$ (Theorem 4.9).
  - Logspace unbounded-error complexity classes are reducible to classes of languages recognized by the corresponding one-way non-sensing two-head finite automata and one-way one-head one-counter finite automata that additionally move at least one head at each computation step:
    $\mathbf{PL} \leq_{log} \mathbf{1PFA}(2)$, $\mathbf{PL} \leq_{log} \mathbf{1PCM}(1)$ (Theorem 4.4) and

$\mathbf{P} = \mathbf{UAML} \leq_{log} \mathbf{UAM}(1pfa(2))$, $\mathbf{P} \leq_{log} \mathbf{UAM}(1pcm(1))$ (Theorem 4.9).

It follows that **PL** (and **P**) can be defined as the classes of languages logspace reducible to languages recognized by one-way two-head or one-way one-head one-counter finite automata that recognize with unbounded-error and have probabilistic (probabilistic and nondeterministic, respectively) states.

Some of these results parallel reductions proven by Hartmanis [16] and Sudborough [44] for the nondeterministic setting. However, our proofs are more complex and require a number of innovations.

- To prove the logspace reductions of **PL** we design probabilistic variants of Savitch's maze threading problem that are logspace complete for **PL**, and can be recognized by simple one-way automata. Surprisingly, these natural variants have not been noticed so far, despite the lack of natural problems known to be complete for **PL**. (Note that several nondeterministic variants of maze threading problems were already known in the early 1970s.) Similarly, to prove logspace reductions of **P**, we present probabilistic-plus-nondeterministic variants of the maze threading problem that are logspace complete for **P**. Each of these complete problems can be recognized by some corresponding one-way non-sensing two-head or one-way one-head one-counter finite automata. These one-way machines use a new recognition technique: during their computation on an input string the automata simulate nondeterministic guesses by "probabilistic guesses" (in a standard way); however, this method alone may change the acceptance probability of the input string and, consequently, can change the recognized languages; fortunately, the automata have an elegant way to compensate for the acceptance probability changes, using only a small amount of additional randomness.

We conclude this section with some additional comments on the results we have listed.

- We show that translational methods used in the 1960s and the 1970s for separating complexity classes [34, 30, 31] can be adapted to the settings of probabilistic and probabilistic-plus-nondeterministic computations. Here is a further example of the strength of these methods: Dwork and Stockmeyer proved that the set of palindromes, i.e., $\{x \in \Sigma^* | x = x^R\}$, separates $\mathbf{AM}(2pfa(1))$ from $\mathbf{AML} = \mathbf{P}$ [8]; we prove that there are entire natural hierarchies between $\mathbf{AM}(2pfa(1))$ and **P**, which can be separated even by languages over a one-letter alphabet.
- Our reductions $\mathbf{BPL}_{poly} \leq_{log} \mathbf{1BPFA}(4)$, $\mathbf{RL}_{poly} \leq_{log} \mathbf{1RPFA}(4)$, and $\mathbf{AML}_{poly} \leq_{log} \mathbf{AM}(1pfa(4))$ are somewhat surprising because the reduction of two-way bounded-error probabilistic computation to one-way probabilistic computation does not naturally preserve the separation from 1/2 of the error-bound (see [22], for example).
- Our reduction $\mathbf{PL} \leq_{log} \mathbf{1PFA}(2)$ is stronger than the well-known result $\mathbf{PL} = \mathbf{PL}_{poly}$ [21]. Note that **PL** contains several matrix inversion problems whose solutions seem to require rather complex computations. It is surprising that these problems can be reduced to languages recognized by one-way non-sensing two-head or one-way one-head one-counter probabilistic finite automata, which do not seem to have strong computational capabilities.

- Using our result $\mathbf{P} = \mathbf{UAML} \leq_{log} \mathbf{UAM}(1pfa(2))$, we can reason that

$$\begin{aligned}\mathbf{P} \subset \mathbf{DSPACE}(\log^k n) &\Leftrightarrow \mathbf{AM}(2pfa(2)) \subset \mathbf{DSPACE}(\log^k n)\\ &\Leftrightarrow \mathbf{UAM}(1pfa(2)) \subset \mathbf{DSPACE}(\log^k n)\\ &\Leftrightarrow \mathbf{UAM}(1pcm(1)) \subset \mathbf{DSPACE}(\log^k n).\end{aligned}$$

  This apparent simplification might eventually lead to the possible inclusion of $\mathbf{P}$ in a small-space-bounded complexity class, and to its separation from $\mathbf{PSPACE}$.

3. Heads hierarchy.

This section presents analogues, in the setting of probabilistic-plus-nondeterministic computation, of results presented in [29] for probabilistic computation.

First, we notice the equality of the class of languages recognized by **AM**-games and **UAM**-games with two-way multihead probabilistic finite-state verifiers and the class of languages recognized by the same games with logspace probabilistic Turing machines as verifiers. Next, we separate head hierarchies for **AM**-games and **UAM**-games with two-way multihead probabilistic finite-state verifiers.

THEOREM 3.1. *$\mathbf{AML}_{poly} = \bigcup_{k=1}^{\infty} \mathbf{AM}_{poly}(2pfa(k))$, $\mathbf{UAML}_{poly} = \bigcup_{k=1}^{\infty} \mathbf{UAM}_{poly}(2pfa(k))$, $\mathbf{AML} = \bigcup_{k=1}^{\infty} \mathbf{AM}(2pfa(k))$, $\mathbf{UAML} = \bigcup_{k=1}^{\infty} \mathbf{UAM}(2pfa(k))$.*

Proof. Adapt the proof for the nondeterministic case [16]. See the appendix, section 6. ☐

In what follows we show separations of head hierarchies. The main result is the following theorem.

THEOREM 3.2. *$\forall\, k \in \mathbf{N}$, $k \geq 2$, $\mathbf{AM}(2pfa(k)) \subsetneq \mathbf{AM}(2pfa(k+1))$, $\mathbf{UAM}(2pfa(k)) \subsetneq \mathbf{UAM}(2pfa(k+1))$, $\mathbf{UAM}_{poly}(2pfa(k)) \subsetneq \mathbf{UAM}_{poly}(2pfa(k+1))$.*

This theorem follows trivially from Theorem 3.7, i.e., from its stronger version over a single-letter alphabet. To prove Theorem 3.7 we follow the same outline as in Monien's proof for the deterministic and nondeterministic automata [31]. We prove first a coarse separation (Theorem 3.3) and then we refine this separation using Lemmas 3.4–3.6.

The proofs of Lemmas 3.4–3.6 are only sketched since they are adaptations of Monien's proofs in the deterministic and nondeterministic settings. In these proofs we use languages $X \subseteq \{1^{2^n} \mid n \in \mathbf{N}\}$ and the family of padding functions

$$f_k : \{1^{2^n} \mid n \in \mathbf{N}\} \to \{1^{2^n} \mid n \in \mathbf{N}\} \text{defined by} f_k(1^{2^n}) = 1^{2^{kn}}.$$

The advantage of using these particular languages is in simplifying the unpadding, encoding, and decoding procedures. Note that checking whether a string is of the form 1^{2^n} can be done deterministically with finite control and only two non-sensing heads. (Repeatedly moving one head twice as fast as the other, in the opposite direction, we can achieve division of the input string length by 2, 2^2, 2^3, etc. Each result of this division is trivially encoded by the position of one head on the input string.)

We recall that, for every class of languages C, $\overbrace{C}$ denotes the languages of type X contained in C.

We show only $\overbrace{\mathbf{AM}(2pfa(k))} \subsetneq \overbrace{\mathbf{AM}(2pfa(k+1))}$ $\forall k \geq 2$ since the proofs for the relations $\overbrace{\mathbf{UAM}(2pfa(k))} \subsetneq \overbrace{\mathbf{UAM}(2pfa(k+1))}$ and $\overbrace{\mathbf{UAM}_{poly}(2pfa(k))} \subsetneq \overbrace{\mathbf{UAM}_{poly}(2pfa(k+1))}$ are similar.

Theorem 3.3 (coarse separation). *For every natural number k,*

$$\overbrace{\mathbf{AM}(2pfa(k))} \subsetneq \overbrace{\mathbf{AML}}\,.$$

Proof. We show that $\exists\alpha > 0$ such that for any $k \in \mathbf{N}$ it holds $\mathbf{AM}(2pfa(k)) \subseteq \mathbf{DTIME}(n^{k\alpha})$. From $\overbrace{\mathbf{DTIME}(n^{k\alpha})} \subsetneq \overbrace{\mathbf{P}} = \overbrace{\mathbf{AML}}$, we obtain the coarse separation.

In what follows we present more details. Let $L \in \mathbf{AM}(2pfa(k))$. Deciding whether a length-n input string x belongs to L is equivalent to solving a linear programming problem with $O(n^k)$ variables. (A detailed proof for the similar case $\mathbf{AML} \subset \mathbf{P}$ can be found in [3].) Using the result of Khachiyan [23], this can be deterministically done in time $O((n^k)^\alpha)$, for some constant α. It follows $L \in \mathbf{DTIME}(n^{k\alpha})$. We obtain $\mathbf{AM}(2pfa(k)) \subset \mathbf{DTIME}(n^{k\alpha})$. As a corollary, we have $\overbrace{\mathbf{AM}(2pfa(k))} \subset \overbrace{\mathbf{DTIME}(n^{k\alpha})}$. To prove $\overbrace{\mathbf{DTIME}(n^{k\alpha})} \subsetneq \overbrace{\mathbf{P}}$, we use a universal deterministic Turing machine that stops its computation after $n^{2k\alpha+1}$ steps and diagonalizes over all one-tape deterministic Turing machines that run in time less than $n^{2k\alpha+1}$. (We recall that any multitape deterministic Turing machine that runs in time $O(n^{k\alpha})$ can be simulated by a one-tape deterministic Turing machine that runs in time $O(n^{2k\alpha})$.) The witness language consists of all the strings of the form 1^{2^m}, where m is a valid encoding of a one-tape deterministic Turing machine M_m, and 1^{2^m} is not accepted by M_m in time $(2^m)^{2k\alpha+1}$. ∎

Lemma 3.4. *For all languages $X \in \overbrace{\mathbf{AML}}$ there is a natural number u such that*

$$f_u(X) \in \overbrace{\mathbf{AM}(2pfa(3))}\,.$$

Proof (sketch). For every language $X \in \overbrace{\mathbf{AML}}$ we modify the Turing machine with probabilistic and nondeterministic states (i.e., a (P+N)TM) that recognizes it in the following way: The worktape of the new (P+N)TM has four tracks that store the binary representation of the input string, the position of the input-tape head, the content of the worktape of the original (P+N)TM, and the position of the worktape head on the original work tape. (Without loss of generality we suppose that the original Turing machine has only one head on its worktape.) All this information can be represented in binary using space $c\log n$, where c is a computable constant. After the deterministic computation of the binary representation of the input string, the new (P+N)TM uses only the worktape head in simulating the original (P+N)TM. This new (P+N)TM can be simulated by a three-counter machine with both probabilistic and nondeterministic states that uses two counters to encode the worktape contents from the left and right, respectively, of the work head and another counter to implement divisions and multiplication by 2 and to increment and decrement of the first two counters. The only problem is the capacity requirement of the three counters. We notice that these counters can be simulated by three heads that move on a "stretched" version of the input. If we choose $u = c$, then the padding function f_u can perform the needed "stretch" operation. ∎

Lemma 3.5. *For all languages $X \in \overbrace{\mathbf{AML}}$ and for $u, v \geq 1$,*

$$f_u(X) \in \overbrace{\mathbf{AM}(2pfa(v))} \Rightarrow X \in \overbrace{\mathbf{AM}(2pfa(u \cdot v))}\,.$$

Proof (sketch). A natural number in the interval $[0, 2^{u\cdot n})$ can be represented in base 2^n by u integers from the interval $[0, 2^n)$. Therefore, the position on the "stretched" input of each head of a 2pnfa(v) that recognizes a language of the form $f_u(X)$ can be encoded by the positions on a normal ("unstretched") input of u heads of a 2pnfa($u \cdot v$). The simulation is straightforward. □

LEMMA 3.6. *For all languages $X \in \overbrace{\mathbf{AML}}$ and for $u > v > 1$,*

$$f_{u+1}(X) \in \overbrace{\mathbf{AM}(2pfa(v))} \Rightarrow f_u(X) \in \overbrace{\mathbf{AM}(2pfa(v+1))}.$$

Proof (sketch). Let A be a 2pnfa(v) that recognizes $f_{u+1}(X)$. We build a 2pnfa(v+1) (called B) that recognizes $f_u(X)$. In order to simulate A's moves, B encodes each head position h_i of A ($h_i \in [0, 2^{(u+1)n}+1]$) by the position of a corresponding head g_i ($g_i \in [0, 2^{u\cdot n}+1]$) and by an additional number $x_i \in [0, 2^n)$ such that $h_i = g_i + x_i \cdot 2^{u\cdot n}$ ($\forall\ i = 1, \ldots, v$). All the numbers $x_i, i = 1, \ldots, v$ are stored as the coefficients of the representation in base 2^n of a number encoded by the $(v + 1)$st head of V. The condition $u > v$ guarantees that the $(v+1)$th head of V can represent a number that is large enough to make that representation possible. The details of this simulation are similar to those from Monien's simulation for the deterministic case [31]. □

Using the relations $\mathbf{P} = \mathbf{AML} = \mathbf{UAML} = \mathbf{UAML}_{poly}$ [3], we can prove that Theorem 3.3 and Lemmas 3.4–3.6 hold for **UAM**-games as well. Furthermore, by adapting the technique of Monien [31], we obtain the following theorem.

THEOREM 3.7. $\forall\ k \in \mathbf{N}$, $k \geq 2$,

$\overbrace{\mathbf{AM}(2pfa(k))} \subsetneq \overbrace{\mathbf{AM}(2pfa(k+1))}$, $\overbrace{\mathbf{UAM}(2pfa(k))} \subsetneq \overbrace{\mathbf{UAM}(2pfa(k+1))}$,
$\overbrace{\mathbf{UAM}_{poly}(2pfa(k))} \subsetneq \overbrace{\mathbf{UAM}_{poly}(2pfa(k+1))}$.

Proof (sketch). We prove the first claim, the other proofs being similar. Suppose that for some $h \geq 2$ we have $\overbrace{\mathbf{AM}(2pfa(h))} = \overbrace{\mathbf{AM}(2pfa(h+1))}$. We prove that this assumption implies $\overbrace{\mathbf{AM}(2pfa(h(h+1)))} = \overbrace{\mathbf{AML}}$, which contradicts Theorem 3.3.

Let $H \in \overbrace{\mathbf{AML}}$. There is $p \in \mathbf{N}$ such that $f_p(H) \in \overbrace{\mathbf{AM}(2pfa(3))}$ (by Lemma 3.4). As a result $f_p(H) \in \overbrace{\mathbf{AM}(2pfa(h))}$. If $p > h + 1$, then, by Lemma 3.6, $f_{p-1}(H) \in \overbrace{\mathbf{AM}(2pfa(h+1))} = \overbrace{\mathbf{AM}(2pfa(h))}$, and so on, until $p = h + 1$. If $p \leq h + 1$, by Lemma 3.5 it follows that $H \in \overbrace{\mathbf{AM}(2pfa(h(h+1)))}$. □

4. Efficient reductions of logspace probabilistic complexity classes. In this section we present logspace reductions of logspace probabilistic (probabilistic-plus-nondeterministic) complexity classes to classes of languages recognized by one-way or two-way multihead probabilistic (probabilistic-plus-nondeterministic) automata. Our simulations could also help to investigate space upper bounds for deterministic space simulation of probabilistic (probabilistic-plus-nondeterministic) automata. Some of our results parallel reductions obtained in the nondeterministic setting by Hartmanis [16] and Sudborough [44] and in the alternating setting by King [24].

The main steps in proving our reductions are as follows. The classes of languages recognized by polynomial-time logspace Turing machines can be recognized by the corresponding two-way multihead finite-state automata; these languages are logspace reducible to languages recognized by $O(n^2)$-time-bounded two-way non-sensing and sweeping two-head finite-state automata that move at least one head at each computation step, which languages, in turn, are reducible to languages recognized by one-way non-sensing multihead finite-state automata that have only a small number of heads and move at least one head at each computation step.

First we state a general theorem that relates the classes of languages recognized by logspace Turing machines to the classes of languages recognized by the corresponding two-way two-head finite-state automata.

THEOREM 4.1. *For any of the computation modes nondeterministic, probabilistic, alternating, and probabilistic-plus-nondeterministic, the languages recognized by logspace Turing machines are logspace reducible to languages recognized, with only a multiplicative polynomial-time loss, by the corresponding two-way two-head non-sensing and sweeping finite-state automata that move at least one head at each computation step.*

Proof. We use the following transformation defined by Monien [30].

Let Σ be an alphabet and $\vdash$ and $\dashv$ be (pseudo-endmarker) symbols not in Σ. For any $h \geq 1$, the transformation $g_{\Sigma,h} : \Sigma^* \longrightarrow ((\Sigma \cup \{\vdash, \dashv\})^h)^*$ is defined as follows: For any positive integer m and any length-m string $a_1 \dots a_m \in \Sigma^m$,

$$g_{\Sigma,h}(a_1 \dots a_m) = b_0 b_1 \dots b_{n^h-1},$$

where $n = m+2$, $a_0 = \vdash$, $a_{n-1} = \dashv$, and $b_j = (a_{i_1}, \dots, a_{i_h})$ for any $j = i_1 + i_2 n + \cdots + i_h n^{h-1}$ with $0 \leq i_p \leq n-1$, $\forall p \in \{1, \dots, k\}$.

First we recall that, for all the computation modes mentioned above, a language L recognized by a logspace Turing machine can be recognized by a corresponding two-way non-sensing multihead finite automaton with only polynomial-time loss [16, 24, 29]. It remains to show that for any $h \in \mathbf{N}$ and any language L over Σ^*, recognized in $O(f(n))$-time by a two-way non-sensing h-head finite automaton, the language $g_{\Sigma,h}(L)$ is recognized in $O(f(n)n^h)$-time by a two-way non-sensing and sweeping two-head finite automaton that moves at least one head at each computation step.

More precisely, we prove that any two-way non-sensing h-head finite automaton processing a string $a_1 \dots a_m \in L$ can be simulated (with a multiplicative $O(n^h)$-time loss) by a two-way non-sensing and sweeping two-head finite automaton processing the string $g_{\Sigma,h}(a_1 \dots a_m)$.

First, at the beginning of its computation, the simulating automaton checks whether the length-u input string $b_0 b_1 \dots b_{u-1}$ is of the form $g_{\Sigma,k}(a_1 \dots a_m)$. This check can be done deterministically in $O(u)$ time with two sweeping heads. If the input string is not of the right form the automaton rejects it. Otherwise it starts the simulation. Note that in this case $u = (m+2)^h$.

In the transformation $g_{\Sigma,h}(a_1 \dots a_m) = b_0 b_1 \dots b_{n^h-1}$ each symbol b_j encodes h ordered symbols $a_{i_1}, \dots, a_{i_h}$. Thus, one head scanning the string $b_0 b_1 \dots b_{n^h-1}$ (called the "encoding head") keeps track of the symbols scanned by h heads on the string $a_0 \dots a_n$. Incrementing (decrementing) the position of the ith head on the string $a_0 \dots a_n$ is equivalent to moving the encoding head n^{i-1} symbols right (left) on the string $b_0 b_1 \dots b_{n^h-1}$. To perform these operations, the encoding head deterministically cooperates with an auxiliary head, whose normal position is at one end of the input string. Note that the auxiliary head can easily count n^{i-1} steps using the particular form of $g_{\Sigma,k}(a_1 \dots a_m)$ and then move to the other end of the input string. The number of computation steps required to perform such an operation is $O(n^h)$. When the encoding head needs to change direction inside the input string, it switches roles with the auxiliary head coming from the opposite direction. To perform this operation the auxiliary head moves first at the end of the input string currently headed toward by the encoding head. Next both heads move toward each other with the same speed until the encoding head reaches the end of the string. At that moment the auxiliary head is in the position where the encoding head had to change direction and it becomes the new encoding head.

It follows that both the encoding and auxiliary heads can be non-sensing and sweeping. Also, we can pad the computation so that at least one head moves at each computation step. To achieve this, it suffices to move the auxiliary head from one end of the input string to the other end for each computation step when the encoding head does not move. The time required to perform this operation is $O(n^h)$.

Overall, the running time of the simulation is $O(n^h)$ times the running time of the simulated automaton. □

OBSERVATION 1. *Theorem* 4.1 *can be stated in the following, more precise, form: For any $h \in \mathbf{N}$ and any of the computation modes nondeterministic, probabilistic, alternating, and probabilistic-plus-nondeterministic, the languages recognized by two-way non-sensing h-head finite automata are logspace reducible (by a transformation that converts a length-n string into a length-n^h string) to languages recognized, with only a multiplicative $O(n^h)$-time loss, by the corresponding two-way non-sensing and sweeping two-head finite-state automata that move at least one head at each computation step.*

For our purpose this form is more useful. These reductions to languages recognized by automata having at least one moving head at each computation step are used in the proof of Proposition 4.2.

As in the nondeterministic setting, we can ask whether **PL**, **BPL**, **RL** are logspace reducible to classes of languages recognized by the corresponding *one-way* multihead probabilistic finite automata. Sudborough proved $\mathbf{NL} \leq_{log} \mathbf{1NFA}(2)$. Unfortunately, his technique uses properties of nondeterministic computation (like particular forms of some logspace complete problems for **NL**) that are not known to hold for probabilistic computation. However, by adding to his proofs ([44], Theorem 1) the idea to "reuse one-way heads," we obtain the following proposition.

PROPOSITION 4.2. *For any integer k, $k > 1$, and any language L recognized in $O(n^k)$-time by a two-way non-sensing and sweeping two-head finite automaton that moves at least one head at each computation step, there is a logspace transformation f such that $f(L)$ is recognized by a one-way non-sensing $(k+2)$-head finite automaton that moves at least one head at each computation step.*

Proof. Without loss of generality we consider a language L recognized in time less than n^k by a two-way (sweeping, non-sensing) two-head finite automaton A, for some $k \in \mathbf{N}$. We chose the transformation f defined by $f(x) = u = (axbbx^Ra)^{n^k}$, where a, b are symbols not contained in the alphabet of L and x^R is the reverse of the length-n string x.

We show that $f(L)$ is recognized by a one-way $(k+2)$-head automaton. First, notice that the form of each input string u can be deterministically checked using only $k+1$ one-way heads as follows:

- Two one-way heads check whether u is of the form $ax_1bbx_2aax_3bbx_4aa\dots bx_{2m}a$ and whether $x_1 = x_3 = \cdots = x_{2m-1}$ and $x_2 = x_4 = \cdots = x_{2m}$. (All they have to do is to keep a constant distance of $|x_1| + |x_2| + 4$ between them.) The head from behind is also used for the next check.
- Two one-way heads check that $|x_1| = |x_2|$ (assuming that the previous check is done this is equivalent to $|x_{2i-1}| = |x_{2i}|$, $\forall\ i \in \{1, \cdots, m\}$). (In what follows, n denotes $|x_1|$.) Then, the same heads check whether x_{2i} is the reverse of x_{2i+1}, $\forall\ i \in \{1, \cdots, m\}$. Assuming that $x_1 = x_3 = \cdots = x_{2m-1}$

and $x_2 = x_4 = \cdots = x_{2m}$, this is equivalent to checking whether the symbol from position i of x_{2i} is equal to the symbol from position $n - i + 1$ of x_{2i+1}, for $i = 1, \ldots, n$. To do this check, for each $i = 1, \ldots, n$ one head scans the ith symbol from the beginning of the string x_{2i} and compares it with the ith symbol from the end of the string x_{2i+1} (which is scanned by the second head), as follows: When the two heads sweep the substring $bx_{2i}aax_{2i+1}b$, they maintain a constant distance between them equal to $2n + 3 - i$; when the left head scans the b before x_{2i} then the right head scans the symbol from position i from the end of x_{2i+1}; when the right head scans the first b after x_{2i+1} then the left head scans the symbol from position i of x_{2i}. Note that using more finite control it is possible to check the equality of many pairs of symbols during one sweeping of the substring $bx_{2i}aax_{2i+1}b$. The front head used in this check is the same as the head from behind used in the previous check. After sweeping $x_i, i = 1, \ldots, 2n+1$ the two heads are available for the next check.

- k one-way heads can check whether $m = n^k$; each head i counts the number of blocks x_j scanned by head $i - 1$, for $i = 2, \ldots, k$. The first head just scans the symbols of each block x_j. Two heads become available from the check described above (in fact after sweeping $x_i, i = 1, \cdots, 2n + 1$, but this is an insignificant inconvenience) so we need only $k - 2$ extra heads for this check.

If during one of the above checks B discovers that u is not of the right form (i.e., $u \notin f(L)$), then B rejects the string. While checking whether u is of the right form (i.e., whether $u = f(x)$ for some $x \in L$), with two one-way heads scanning u, B tries to simulate the computation of A on x. Also, the head from behind used for the last check can be used as one head simulating one of the two heads of A. In fact, the moves of this head trigger the moves of the heads performing the check of the input string, so we have to make sure that, in case of acceptance, this head will move up to the end of the input string. To finish the proof, one other detail remains to be clarified: When the two one-way heads of B "simulate" the sweeping heads of A, the automaton B does not know yet whether $u = f(x)$. In fact if $u \neq f(x)$, B does not even simulate A on x. However, in this case B is going to reject u since it knows whether both its heads, used to simulate the heads of A, stop moving before reaching the end of u. In this case, if B has reached a state corresponding to an accepting state of A and if the check whether $u = f(x)$ is not yet done, B continues the check, by moving its heads up to the end of the input string and accepting u only if $u = f(x)$. At this moment it becomes obvious why in Theorem 4.1 we use reductions to languages recognized by two-way two-head finite automata having at least one moving head at each computation step. □

Using this proposition we obtain the next relations.

THEOREM 4.3. $\mathbf{BPL}_{poly} \leq_{log} \mathbf{1BPFA}(4)$, $\mathbf{RL}_{poly} \leq_{log} \mathbf{1RPFA}(4)$.

Proof. We prove only the first relation, since the proof of the second relation is similar. It is enough to show that $\mathbf{BPL}_{poly}$ is logspace reducible to languages recognized by (non-sensing, sweeping) 2bpfa(2) that run in *subquadratic* time and move at least one head at each computation step. Using the proof of Proposition 4.2 with $k = 2$ it follows our claim.

For any language $L \in \mathbf{BPL}_{poly}$ over the alphabet Σ, we consider a 2bpfa(h) A that recognizes any length-n input string from L in time less than n^p, for some constants p and h. As in the proof of Theorem 4.1, we choose a transformation $g_{\Sigma,l}$, where l is much larger than $\max(p, h)$. We denote by B the corresponding (sweeping, non-sensing) 2bpfa(2) that recognizes $g_{\Sigma,l}(L)$. The computation time of B on a length-m input string w is $O(m)$ if $w \neq g_{\Sigma,l}(x)$ for any $x \in \Sigma^*$, and is $O(n^p m)$ if $w = g_{\Sigma,l}(x)$ for some string x of length n. In the latter case $|w| = n^l$ and n^l is much larger than n^p and thus it follows that the computation time of B is $o(m^2)$. ∎

THEOREM 4.4. $\mathbf{PL} \leq_{log} \mathbf{1PFA}(2)$, $\mathbf{PL} \leq_{log} \mathbf{1PCM}(1)$.

Proof. The proof follows from Lemmas 4.7 and 4.8 stated after the following definitions. ∎

We define two languages that are logspace complete for **PL** and can be recognized by "simple" probabilistic finite automata, i.e., by one-way two-head and respectively one-way one-head one-counter unbounded-error probabilistic finite automata. These languages may be seen as probabilistic versions of the Savitch's Maze threading problem [38] and of the languages L_P and L_Q of Sudborough [44]. There are several interesting aspects involved in the design of these languages since they have to be quite complex in order to be complete for **PL**, but they also have to be relatively simple in order to be recognized by simple one-way devices.

DEFINITION 4.5. *PMT_1 is the language over the alphabet $\{[,],a,\#\}$ containing the strings of the following form, denoted by (*):*

$$[a^{p_1}\#a^{m_1(1)}\#a^{m_2(1)}]\cdots[a^{p_t}\#a^{m_1(t)}\#a^{m_2(t)}]a^{v_1}\#\ldots\#a^{v_{h_1}}\#\#a^{r_1}\#\ldots\#a^{r_{h_2}}\#$$

with the properties

$$\sum_{(q,i_1,\ldots,i_q)\in A_{cc}} 1/2^{q-1} > \sum_{(r,i_1,\ldots,i_r)\in R_{ej}} 1/2^{r-1},$$

where $m_i : \mathbf{N} \to \mathbf{N}, i \in \{1,2\}$, and A_{cc} and R_{ej} are sets satisfying the relations

$$(q,i_1,\ldots,i_q) \in A_{cc} \Leftrightarrow \begin{cases} q,i_1,\ldots,i_q \in \mathbf{N}, \\ i_1 = 1, i_2 > 1, \text{and } i_k > i_{k-2} \text{ for } 3 \leq k \leq q, \\ \forall k \in \{2,\ldots,q\}, \exists l \in \{1,2\} \text{ such that } p_{i_k} = m_l(i_{k-1}), \\ \exists l \in \{1,2\} \text{ such that } m_l(i_q) \in \{v_1,\ldots,v_{h_1}\}, \end{cases}$$

$$(r,i_1,\ldots,i_r) \in R_{ej} \Leftrightarrow \begin{cases} r,i_1,\ldots,i_r \in \mathbf{N}, \\ i_1 = 1, i_2 > 1, \text{and } i_k > i_{k-2} \text{ for } 3 \leq k \leq r, \\ \forall k \in \{2,\ldots,r\}, \exists l \in \{1,2\} \text{ such that } p_{i_k} = m_l(i_{k-1}), \\ \exists l \in \{1,2\} \text{ such that } m_l(i_r) \in \{r_1,\ldots,r_{h_2}\}. \end{cases}$$

For each string of the form (*), p_1 is the initial index, $v_i, i \in \{1,\ldots,h_1\}$ and $r_i, i \in \{1,\ldots,h_2\}$ are the accepting and respectively rejecting indices, and A_{cc} and R_{ej} are all the "almost one-way" paths that connect the index p_1 to the accepting and respectively rejecting indices. A string belongs to PMT_1 if the weight of all the "almost one-way" paths connecting the initial index to accepting indices is larger than the weight of all the almost one-way paths connecting the initial index to rejecting indices. ∎

DEFINITION 4.6. *PMT_2 is the language over the alphabet $\{[,],a,\#\}$ defined in a similar way as PMT_1 with the following difference: In the definitions of A_{cc} and R_{ej} the conditions "$i_k > i_{k-2}$ for $3 \leq k \leq q$" and "$i_k > i_{k-2}$ for $3 \leq k \leq r$" are replaced by "$i_k > i_{k-1}$ for $2 \leq k \leq q$"and "$i_k > i_{k-1}$ for $2 \leq k \leq r$," respectively. In this case, A_{cc} and R_{ej} contain all the "one-way" paths that connect the index p_1 to the accepting and respectively rejecting indices.* ∎

To summarize, PMT_1 and PMT_2 are the encodings of the languages recognized by probabilistic devices whose computation successive steps can be encoded in "almost" increasing order and increasing order, respectively. Also note that PMT_1 and PMT_2 are incomparable.

LEMMA 4.7. **PL** $\leq_{log}$ *PMT_1,* **PL** $\leq_{log}$ *PMT_2.*

Proof. Using Proposition 4.2 and some standard techniques from probabilistic computation [36], it can be easily shown that each language in **PL** is logspace reducible to a language recognized by a one-way multihead probabilistic finite automaton which reaches halting (i.e., accepting or rejecting) configurations with probability 1, moves at least one head at every computation step, and from each nonhalting (i.e., nonaccepting or nonrejecting) configuration goes with probability 1/2 to the next two configurations.

Let Σ be a finite alphabet and $L \in \Sigma^*$ be an arbitrary language recognized by such a multihead probabilistic finite automaton A. We show how to reduce (in logspace) L to PMT_1 and PMT_2.

For each input string x, the configurations of a one-way multihead finite automaton A can be indexed in lexicographically increasing order of input heads positions. (Note that during the computation of A on x, the sequence of indices assigned to consecutive configurations is strictly increasing.) For each configuration we build a "configuration transition block" containing the configuration and its successors. The logspace transformation f we are looking for maps each string x to the string consisting of the sequence of "configuration transition blocks" (corresponding to all the configurations of A on x, enumerated in increasing order of their indices) concatenated with the sequences of accepting and rejecting configurations of A on x. It can be checked that $f(x) \in PMT_1$ iff $f(x) \in PMT_2$ iff A accepts x.

More exactly, the transformation $f_A : \Sigma^* \longrightarrow \{[,], a, \#\}^*$ is

$$f_A(x) = [a^{p_1}\#a^{m_1(1)}\#a^{m_2(1)}]\cdots[a^{p_t}\#a^{m_1(t)}\#a^{m_2(t)}]a^{v_1}\#\ldots\#a^{v_{h_1}}\#\#a^{r_1}\#\ldots\#a^{r_{h_2}}\#\#,$$

where

- t is the number of nonhalting configurations of A, h_1 and h_2 are the number of accepting and, respectively, rejecting configurations of A;
- p_1 is the index of the initial configuration of A;
- $\forall\ i \in [1, t]$, from the configuration with index p_i, A moves with probability 1/2 in one of the configurations with indices $m_1(i)$ and $m_1(i)$;
- if $i < j$ then $p_i < p_j$;
- $v_i, i = 1, \ldots, h_1$ and $r_i, i = 1, \ldots, h_2$ are the indices assigned to the accepting and rejecting configurations, respectively.

The transformation f_A can be easily obtained in logarithmic space by writing all the configurations of A (enumerated in increasing order of the input heads positions) followed by their successors. From the fact that during the computation of A on any input x the sequence of indices assigned to consecutive configurations is strictly increasing, it follows that in $f_A(L)$, all the "paths" connecting the initial index to the accepting and rejecting indices are one-way. Additionally, using the fact that the computation of A on x stops with probability 1, it follows that $x \in L \Leftrightarrow$ "the probability that A accepts x is larger than the probability that A rejects x" $\Leftrightarrow f_A(x) \in PMT_1 \Leftrightarrow f_A(x) \in PMT_2$. □

LEMMA 4.8. *$PMT_1 \in$* **1PFA**(2)*, $PMT_2 \in$* **1PCM**(1)*.*

Proof. We describe an 1pfa(2) B that recognizes PMT_1. In parallel to its main computation (described next), B checks whether the input string u is of the form (*)

from the definition of PMT_1. If not, B rejects u. Consequently, in what follows we suppose that u is of the form (*).

By block-i we mean $[a^{p_i}\#a^{m_1(i)}\#a^{m_2(i)}]$ if $i \leq t$, or $a^{v(i-t)}$ if $t < i \leq t + h_1$, or $a^{r(i-t-h_1)}$ if $t + h_1 < i \leq t + h_1 + h_2$.

Suppose that B has one head ($H1$) on the substring $a^{m_l(i)}$ (inside block $i = [a^{p_i}\#a^{m_1(i)}\#a^{m_2(i)}]$) which is the "current" index, and the second head ($H2$) at the end of some block j. B "probabilistically guesses" a block $q > j$ moving head H_2 right and tossing a fair coin for each encountered block. q is the first block for which the outcome of the coin toss is "tails". If H_2 reaches the right end of u without "guessing" any block, then B accepts and rejects with the same probability 1/2. If H_2 guesses a block q, then B deterministically compares a^{p_q} with $a^{m_l(i)}$ moving both heads right over these substrings.

If $p_q \neq m_l(i)$ (i.e., the probabilistic guess is wrong), then B accepts and rejects with probability 1/2.

If $p_q = m_l(i)$ and $q \leq t$ (i.e., B has found the block describing the transitions from the "current index" $m_l(i)$), then B tosses a coin to select the next index. If the outcome is tails, it moves H_2 at the beginning of $a^{m_1(q)}$. Otherwise, it moves H_2 at the beginning of $a^{m_2(q)}$. Next, it continues the operation with H_1 and H_2 interchanged.

If $p_q = m_l(i)$ and $t < q \leq t + h_1$ (or $t + h_1 < q \leq t + h_1 + h_2$) (i.e., B has found an accepting (or rejecting) path), then B performs a procedure that "equalizes" the probability modifications produced by "probabilistic guesses." It keeps both heads moving to the right end of u, one head at a time, and it tosses a fair coin each time when a head encounters a block. If the outcome in all these tosses is all tails, then B accepts (rejects, respectively) u. If not, B accepts and rejects with the same probability 1/2. In this way, B makes sure that the probabilities of all accepting and rejecting almost one-way paths in PMT are multiplied by the same number, independent of the length and the structure of the path.

Using a similar technique, it follows that each language $L \in PMT_2$ can be recognized by a one-way one-counter probabilistic finite automaton B. In this case, the second head is replaced by a counter as follows: B stores into the counter the "current index" $m_l(i)$ and moves its head forward to probabilistically guess the block q describing the transitions from $m_l(i)$. For comparing $m_l(i)$ with p_q, B decrements the counter. If $p_q = m_l(i)$ (so B guessed the right block), then B selects the next index and stores its value into the counter. □

In the settings of **AM**-games and **UAM**-games we have the reductions as follows.

THEOREM 4.9.
$\mathbf{AML}_{poly} \leq_{log} \mathbf{AM}(1pfa(4))$, $\mathbf{AML} \leq_{log} \mathbf{AM}(2pfa(2))$,
$\mathbf{AML} \leq_{log} \mathbf{UAM}(1pfa(2))$, $\mathbf{AML} \leq_{log} \mathbf{UAM}(1pcm(1))$.

Proof (sketch). The proof for the first reduction is similar to that of Theorem 4.3. The second reduction is a corollary of Theorem 4.1. The last two reductions follow from $\mathbf{AML} = \mathbf{P} = \mathbf{UAML}_{poly}$ [3], $\mathbf{UAML}_{poly} \leq_{log} \mathbf{UAM}(1pfa(4))$ (similar to the proof of Theorem 4.3), $\mathbf{UAM}(1pfa(4)) \leq_{log} \mathbf{UAM}(1pfa(2))$, and $\mathbf{UAM}(1pfa(4)) \leq_{log} \mathbf{UAM}(1pcm(1))$. To prove these last two claims, we design probabilistic-plus-nondeterministic variants of Savitch's maze-threading problem ($PNMT_1$, $PNMT_2$) that are logspace complete for **P** and can be solved by **UAM**-games with simple probabilistic finite-state verifiers. The claims follow from Lemmas 4.12 and 4.13. □

DEFINITION 4.10. *$PNMT_1$ is a language over the alphabet $\{[,], a, \#\}$ that has a structure similar to PMT_1 but the "transition" blocks have the form* $[a^{p_i}\#a^k\#a^{m_1(i)}$

$\#a^{m_2(i)}]$, where $k = 1$ if p_i is a "nondeterministic" index and $k = 2$ if p_i is a "probabilistic" index. A nondeterministic strategy for such a string is a function that, for each nondeterministic index, selects its successor from the two indices from its transition block. For each nondeterministic strategy K we define the sets $A_{cc}(K)$ and $R_{ej}(K)$ that contain all almost one-way paths that, according to the strategy, connect the (initial) index p_1 to the accepting and rejecting indices, respectively. Note that, given a strategy K, $A_{cc}(K)$ and $R_{ej}(K)$ are identical to A_{cc} and, respectively, R_{ej} from the definition of PMT_1. A string is in $PNMT_1$ if there is a strategy K such that

$$\sum_{(q,i_1,\ldots,i_q)\in A_{cc}(K)} 1/2^{q-1} > \sum_{(r,i_1,\ldots,i_r)\in R_{ej}(K)} 1/2^{r-1}. \qquad \square$$

DEFINITION 4.11. *$PNMT_2$ is a language over the alphabet $\{[,],a,\#\}$ that has a structure similar to $PNMT_1$, but for each nondeterministic strategy K the sets $A_{cc}(K)$ and $R_{ej}(K)$ contain all one-way paths connecting the initial index p_1 to the accepting or rejecting indices. For a fixed K, $A_{cc}(K)$ and $R_{ej}(K)$ are similar to the sets A_{cc} and R_{ej} used in the definition of PMT_2.* $\square$

LEMMA 4.12. $\mathbf{UAM}(1pfa(4)) \leq_{log} PNMT_1$, $\mathbf{UAM}(1pfa(4)) \leq_{log} PNMT_2$.

Proof. The proof is similar to the proof of the probabilistic case (Lemma 4.7). $\square$

LEMMA 4.13. $PNMT_1 \in \mathbf{UAM}(1pfa(2))$, $PNMT_2 \in \mathbf{UAM}(1pcm(1))$.

Proof. The proof is similar to the proof of the probabilistic case (Lemma 4.8). $\square$

5. Discussion. In this paper, we obtain results for logspace Turing machines and multihead finite automata with probabilistic and both probabilistic and nondeterministic states that parallel well-known relations proven for their nondeterministic counterparts [16, 44, 30, 31].

Each logspace complexity class is decomposed into a hierarchy based on corresponding two-way multihead finite automata. To obtain the properness of several of these head hierarchies, in section 3 we adapt translational methods to the setting of probabilistic-plus-nondeterministic computation. However, we could not prove the corresponding separation for **AM**-games with two-way multihead probabilistic finite-state verifiers that run in polynomial time. We leave it as an open problem. The main difficulty is in the fact that the class $\mathbf{AML}_{poly}$ is not known to be equal to **P** and, consequently, it does not seem large enough to solve linear programming problems. (We used this property of **P** when we proved the "coarse separation" for **AM**-games.)

In section 4 we obtain several reductions of logspace complexity classes to the second or lower level of their corresponding hierarchies. The most interesting ones are the reductions of **PL** (and **P**) to languages recognized by one-way non-sensing two-head or one-way one-head one-counter finite automata with probabilistic (probabilistic and nondeterministic) states. We define probabilistic (probabilistic-plus-nondeterministic) variants of the Savitch's maze threading problem that parallel the languages L_Q and L_P of Sudborough. Part of our proofs make use of Sudborough's techniques to prove the corresponding results for nondeterministic automata. However our proofs are much more complex for the following reason: Whereas in the setting of nondeterministic computation the number of additional guesses required during a simulation does not matter, in the probabilistic setting we can use only probabilistic guesses that unbalance the acceptance probability of the simulating machine; consequently we need additional resources and additional ideas to correct this "unbalance." Using a simple technique, we show that the one-way automata that recognize our probabilistic versions of the maze threading problem are powerful enough to correct the unbalance. These reductions give us characterizations for **PL** (and **P**) as the classes of languages logspace reducible to languages recognized by one-way non-sensing two-head or one-way one-head one-counter finite automata with probabilistic (probabilistic and nondeterministic) states. In the cases of polynomial-time logspace bounded-error probabilistic (probabilistic-plus-nondeterministic) computation we have obtained only reductions to languages recognized by one-way non-sensing four-head finite automata. Our technique to correct the unbalance successfully applied for unbounded-error computation does not seem to work anymore since it does not preserve the error-bounds. We ask whether it is possible to do better in these cases.

6. Appendix.

Proof of Theorem 3.1. We show only $\bigcup_{k=1}^{\infty} \mathbf{UAM}(2pfa(k)) = \mathbf{UAML}$. The other proofs are similar.

($\subset$). Straightforwardly, the multihead automaton's head positions may be stored in $O(\log n)$ work space.

($\supset$). Let B be a Turing machine with probabilistic and nondeterministic states with work space less than $c(\lfloor \log n \rfloor - 1)$, $c \in \mathbf{N}$, and let x be an input string of length n. Without loss of generality, we consider that B writes only 0's and 1's. We show how to simulate B using a multihead finite automaton with probabilistic and nondeterministic states (called A). We considered the work tape of B parsed into c segments of $\lfloor \log n \rfloor - 1$ bits each. A is designed with $c + 3$ heads scanning the input tape, of which one head (we call it the "input head") simulates the input head of B, $c - 1$ heads encode the contents of the segments not currently scanned by B's work head, 2 heads encode the right-of-head and left-of-head contents of the segment currently scanned by B's work head (we call U and V the numbers encoded by these two heads), and one auxiliary head implements some operations required by the simulation. In the encoding of any segment (or of the left or right side of the currently scanned segment) we use the next conventions: the closest bit to the current position of the work head of B is the least significant bit; the most significant bit of a tape segment of B is always 1 (so the segments are "ended" by an imaginary bit); the left and right side of the currently scanned segment do not contain the bit scanned by the work head of B; the value of the scanned bit is stored in the finite control. Using this encoding, the event when the work head of B moves from one segment to another coincides with the moment when U or V get value 1. A move of B's input head is simulated by a move of the input head of A; a move of the working head of B or a modification of the work tape content of B is simulated by modifications of the types $U \to \lfloor U/2 \rfloor$, $U \to 2U$ and $U \to 2U + 1$ (and similar modifications for V). To implement these operations we use the auxiliary head. The overall simulation is as follows. Corresponding to each of the nondeterministic (probabilistic) transitions of B, A nondeterministically (probabilistically) chooses the transition to simulate (with the same probability as B does) and then deterministically executes the corresponding sequence of operations. That sequence of operations is finite, so it can be stored in a finite control. $\square$

APPROXIMATION ALGORITHMS FOR THE ORTHOGONAL Z-ORIENTED THREE-DIMENSIONAL PACKING PROBLEM*

F. K. MIYAZAWA† AND Y. WAKABAYASHI‡

Abstract. We present approximation algorithms for the *orthogonal z-oriented three-dimensional packing problem* (TPP^z) and analyze their asymptotic performance bound. This problem consists in packing a list of rectangular boxes $L = (b_1, b_2, \ldots, b_n)$ into a rectangular box $B = (l, w, \infty)$, orthogonally and oriented in the z-axis, in such a way that the height of the packing is minimized. We say that a packing is oriented in the z-axis when the boxes in L are allowed to be rotated (by ninety degrees) around the z-axis. This problem has some nice applications but has been less investigated than the well-known variant of it—denoted by TPP (three-dimensional orthogonal packing problem)—in which rotations of the boxes are not allowed. The problem TPP can be reduced to TPP^z. Given an algorithm for TPP^z, we can obtain an algorithm for TPP with the same asymptotic bound. We present an algorithm for TPP^z, called R, and three other algorithms, called LS, BS, and SS, for special cases of this problem in which the instances are more restricted. The algorithm LS is for the case in which all boxes in L have square bottoms; BS is for the case in which the box B has a square bottom, and SS is for the case in which the box B and all boxes in L have square bottoms. For an algorithm $\mathcal{A}$, we denote by $r(\mathcal{A})$ the asymptotic performance bound of $\mathcal{A}$. We show that $2.5 \le r(R) < 2.67$, $2.5 \le r(LS) \le 2.528$, $2.5 \le r(BS) \le 2.543$, and $2.333 \le r(SS) \le 2.361$. The algorithms presented here have the same complexity $\mathcal{O}(n \log n)$ as the other known algorithms for these problems, but they have better asymptotic performance bounds.

Key words. approximation algorithms, three-dimensional packing, asymptotic performance bound

1. Introduction.

We present approximation algorithms for the orthogonal z-oriented three-dimensional packing problem and show results concerning their asymptotic performance bound. All algorithms described here have time complexity $\mathcal{O}(n \log n)$, where n is the number of boxes in the input list.

Let $L = (b_1, b_2, \ldots, b_n)$ be a list of rectangular boxes $b_i = (x_i, y_i, z_i)$, where x_i, y_i, and z_i is the *length*, *width*, and *height* of b_i, respectively. The *orthogonal z-oriented three-dimensional packing problem* (TPP^z), can be defined as follows. Given a box $B = (l, w, \infty)$ and a list of boxes $L = (b_1, b_2, \ldots, b_n)$, find an orthogonal z-oriented packing of L into B that minimizes the total height. In the next section we define the concept of *orthogonal z-oriented packing.* For the moment, let us informally say that it is an orthogonal packing in which the boxes may be rotated around the z-axis (but may not be turned down).

A variant of TPP^z, in which the boxes may not be rotated around the z-axis, has been more investigated and is known as the *three-dimensional orthogonal packing*

problem [3, 5, 6]. We denote it by TPP. Since all packings to be mentioned here are orthogonal we omit this term. Here we show that TPP can be reduced to TPP^z. Since the unidimensional packing problem [2] can be reduced to TPP, it follows that both TPP and TPP^z are $\mathcal{NP}$-hard.

If $\mathcal{A}$ is an algorithm for TPP^z or TPP and L is a list of boxes, then $\mathcal{A}(L)$ denotes the height of the packing generated by algorithm $\mathcal{A}$ when applied to a list L; and $\mathrm{OPT}(L)$ denotes the height of an optimal packing of L. We say that α is *an asymptotic performance bound* of an algorithm $\mathcal{A}$ if there exists a constant β such that for all lists L, in which all boxes have a height bounded by a constant Z, the following holds: $\mathcal{A}(L) \leq \alpha \cdot \mathrm{OPT}(L) + \beta \cdot Z$. Furthermore, if for any small ϵ and any large M, both positive, there is an instance L such that $\mathcal{A}(L) > (\alpha - \epsilon)\mathrm{OPT}(L)$ and $\mathrm{OPT}(L) > M$, then we say that α is *the asymptotic performance bound* of algorithm $\mathcal{A}$. We denote by $r(\mathcal{A})$ the asymptotic performance bound of $\mathcal{A}$.

In 1990, Li and Cheng [4] presented TPP^z as a model for a *job scheduling problem in partitionable mesh connected systems*. In this problem a set of jobs $J_1, J_2, \ldots, J_n$ is to be processed in a partitionable mesh connected system that consists of $l \times w$ processing elements connected as a rectangular mesh. Each job J_i is specified by a triplet $J_i = (x_i, y_i, t_i)$ indicating that a submesh of size either (x_i, y_i) or (y_i, x_i) is required by job J_i, and t_i is its processing time. The objective is to assign the jobs to the submeshes so as to minimize the total processing time. The algorithm for TPP^z described in [4] has asymptotic performance bound $4\frac{4}{7}$.

In [3] Li and Cheng describe several algorithms for TPP: for the general case, an algorithm whose asymptotic performance bound is 3.25, and for the special case in which all boxes have square bottom, an algorithm whose asymptotic performance bound is 2.6875. In 1992, these authors [5] also presented an on-line algorithm with an asymptotic performance bound that can be made as close to 2.89 as desired.

In [6] we present an algorithm for TPP whose asymptotic performance bound is less than 2.67. In this paper we describe an algorithm for TPP^z that has a similar asymptotic performance bound. We also describe an algorithm for the special case of TPP^z in which the box B has a square bottom and show that its asymptotic performance bound is less than 2.528. For the case in which all boxes of L have square bottoms, we present an algorithm with an asymptotic performance bound less than 2.543. Moreover, for the case in which all boxes have square bottoms, we present an algorithm whose asymptotic performance is less than 2.361. The algorithms we describe here for special instances of TPP^z are not straightforward simplifications of the algorithm for the general case. Each one resulted from a careful analysis of the instances under consideration.

There is a fundamental aspect in which the algorithms we have developed differ from those of Li and Cheng. Their strategy is to divide the input list into sublists and apply appropriate algorithms for each sublist, returning a packing that is a concatenation of these individual packings. The strategy we use also makes subdivisions (different ones) of the input list, but generates not only packings of each sublist but also those that are obtained by appropriate combinations of different sublists. In fact, we may say that the key idea behind our algorithms is to consider sublists which can be combined to generate better packings.

This paper is organized as follows. In section 2 we define some basic concepts, establish the notation, and discuss relations between TPP and TPP^z. In section 3 we describe the main algorithm (for TPP^z) and analyze its asymptotic performance bound. In each of the next three sections we describe an algorithm for a special instance of TPP^z and prove results on its asymptotic performance bound.

2. Notation and basic results. Given a list of boxes $L = (b_1, \dots, b_n)$ to be packed into a box $B = (l, w, \infty)$, we assume that each box b_i is of the form $b_i = (x_i, y_i, z_i)$, with $x_i \leq l$ and $y_i \leq w$ or $x_i \leq w$ and $y_i \leq l$ (that is, each box b_i can be packed into B in some orientation). We also assume throughout this paper that the list L consists of boxes with height bounded by a constant Z. In all algorithms mentioned here, unless otherwise stated, the input box B is assumed to be of the form $B = (l, w, \infty)$.

Given a triplet $t = (a, b, c)$, we also refer to each of its elements a, b, and c as $x(t)$, $y(t)$, and $z(t)$, respectively. For each box $b_i = (x_i, y_i, z_i)$, we denote by $\rho(b_i)$ the box consisting of the triplet (y_i, x_i, z_i) and we set $\Gamma(L) = \{(c_1, c_2, \dots, c_n) : c_i \in \{b_i, \rho(b_i)\}\}$. Given a real function $f : C \to \mathbb{R}$ and a subset $C' \subseteq C$, we denote by $f(C')$ the sum $\sum_{e \in C'} f(e)$.

Although a list is given as an ordered n-tuple of boxes, when the order of the boxes is irrelevant, the corresponding list may be viewed as a set.

Note that, by using a three-dimensional coordinate system, the box $B = (l, w, \infty)$ can be seen as the region $[0, l) \times [0, w) \times [0, \infty)$; and we may define a *$z$-oriented packing* $\mathcal{P}$ of a list of boxes L into B as a mapping $\mathcal{P} : L' = (b_1, \dots, b_n) \to [0, l) \times [0, w) \times [0, \infty)$, such that

$$L' \in \Gamma(L), \qquad \mathcal{P}^x(b_i) + x_i \leq l \text{ and } \mathcal{P}^y(b_i) + y_i \leq w \ ,$$

where $\mathcal{P}(b_i) = (\mathcal{P}^x(b_i), \mathcal{P}^y(b_i), \mathcal{P}^z(b_i))$, $i = 1, \dots, n$.

Furthermore, if $\mathcal{R}(b_i)$ is defined as

$$\mathcal{R}(b_i) = [\mathcal{P}^x(b_i), \mathcal{P}^x(b_i) + x_i) \times [\mathcal{P}^y(b_i), \mathcal{P}^y(b_i) + y_i) \times [\mathcal{P}^z(b_i), \mathcal{P}^z(b_i) + z_i),$$

then the following must hold:

$$\mathcal{R}(b_i) \cap \mathcal{R}(b_j) = \emptyset \quad \forall i, j,\ 1 \leq i \neq j \leq n \ .$$

If in the above definition we replace $L' \in \Gamma(L)$ by $L' = L$, then we have the concept of *oriented packing* (note that the condition $L' = L$ means that the boxes in L may not be rotated around the z-axis).

In what follows, we may use the term *packing* to refer to both the z-oriented and the oriented packing. To be precise, sometimes we should refer to a *z-oriented packing* (when some boxes are being rotated), but we simply say *packing* as this will be clear from the context. When this may cause confusion we specify which packing we are referring to.

Given a packing $\mathcal{P}$ of L, we denote by $H(\mathcal{P})$ the *height* of the packing $\mathcal{P}$, i.e., $H(\mathcal{P}) := \max\{\mathcal{P}^z(b) + z(b) :\ b \in L\}$.

If $\mathcal{P}_1, \mathcal{P}_2, \dots, \mathcal{P}_v$ are packings of disjoint lists $L_1, L_2, \dots, L_v$, respectively, we define the *concatenation* of these packings as a packing $\mathcal{P} = \mathcal{P}_1 \| \mathcal{P}_2 \| \cdots \| \mathcal{P}_v$ of $L = L_1 \cup L_2 \cup \cdots \cup L_v$, where $\mathcal{P}(b) = (\mathcal{P}_i^x(b), \mathcal{P}_i^y(b), \sum_{j=1}^{i-1} H(\mathcal{P}_j) + \mathcal{P}_i^z(b))$, for all $b \in L_i$, $1 \leq i \leq v$. If each list $L_i = (b_1^i, b_2^i, \dots, b_{n_i}^i)$, $i = 1, \dots, v$, then the *concatenation* of these lists, denoted by $L_1 \| L_2 \| \cdots \| L_v$, is the list $(b_1^1, \dots, b_{n_1}^1, b_1^2, \dots, b_{n_2}^2, \dots, b_1^v, \dots, b_{n_v}^v)$.

The following notation is used to consider sublists of the list L.

- $\mathcal{C} := \{b_i = (x_i, y_i, z_i) : 0 \leq x_i \leq l, \quad 0 \leq y_i \leq w, \quad z_i > 0\}$;
- $\mathcal{C}[p'', p' \ ;\ q'', q'] := \{b_i = (x_i, y_i, z_i) :\ p'' \cdot l < x_i \leq p' \cdot l,\ q'' \cdot w < y_i \leq q' \cdot w\}$, for $0 \leq p'' < p' \leq 1, \quad 0 \leq q'' < q' \leq 1$;

- $\mathcal{Q}[p'', p' \ ; \ q'', q'] := \{b_i = (x_i, y_i, z_i) : \ b_i \in \mathcal{C}[p'', p' \ ; \ q'', q'] \ \text{ and } \ x_i = y_i\}$;
- $\mathcal{X} := \{b_i = (x_i, y_i, z_i) : \ y_i < x_i\}$, $\mathcal{Y} := \{b_i = (x_i, y_i, z_i) : \ y_i \geq x_i\}$;
- $\mathcal{C}_m := \mathcal{C}[0, \frac{1}{m} \ ; \ 0, \frac{1}{m}]$, $\quad \mathcal{Q}_m := \mathcal{Q}[0, \frac{1}{m} \ ; \ 0, \frac{1}{m}]$, for $m > 0$;
- $\mathcal{R}_1 := \mathcal{C}[0, \frac{1}{2} \ ; \ 0, \frac{1}{2}]$, $\mathcal{R}_2 := \mathcal{C}[0, \frac{1}{2} \ ; \ \frac{1}{2}, 1]$, $\mathcal{R}_3 := \mathcal{C}[\frac{1}{2}, 1 \ ; \ 0, \frac{1}{2}]$, $\mathcal{R}_4 := \mathcal{C}[\frac{1}{2}, 1 \ ; \ \frac{1}{2}, 1]$.

If $\mathcal{R}$ is a set of boxes, then we say that a box b is of *type* $\mathcal{R}$ if $b \in \mathcal{R}$ or $\rho(b) \in \mathcal{R}$.

We denote by $S(b)$ and $V(b)$ the *bottom area* (i.e., $S(b) := x(b)y(b)$) and the *volume* of the box b, respectively.

A *level* N in a packing $\mathcal{P}$ is a region $[0, l) \times [0, w) \times [Z_1, Z_2)$ in which there is a set L' of boxes such that for all $b \in L'$, $\mathcal{P}^z(b) = Z_1$ and $Z_2 - Z_1 = \max\{z(b) : \ b \in L'\}$. Sometimes we shall consider the level N as a packing of the list L'; we denote by $S(N)$ the sum $\sum_{b \in L'} S(b)$.

A *layer* (in the x-axis direction) in a level is a region $[0, l) \times [Y_1, Y_2) \times [Z_1, Z_2)$ in which there is a set L' of boxes such that, for all $b \in L'$, $\mathcal{P}^y(b) = Y_1$ and $\mathcal{P}^z(b) = Z_1$; and moreover, $Y_2 - Y_1 = \max\{y(b) : \ b \in L'\}$ and $Z_2 - Z_1 = \max\{z(b) : \ b \in L'\}$.

Relations between TPP and TPP$^{\boldsymbol{z}}$. One way to solve TPP^z is to adapt algorithms for TPP. A simple approach is to generate for each instance $L = (b_1, b_2, \ldots, b_n)$ a new instance $\phi(L) \in \Gamma(L)$, such that $\phi(L) = (d_1, d_2, \ldots, d_n)$, where

$$d_i = \begin{cases} b_i & \text{if } \ x_i \leq l \ \text{ and } \ y_i \leq w, \\ \rho(b_i) & \text{otherwise,} \end{cases}$$

and then apply an algorithm for TPP on the list $\phi(L)$.

For each algorithm $\mathcal{A}$ for TPP, let us denote by $\widehat{\mathcal{A}}$ the corresponding algorithm for TPP^z, as described above. That is, for every instance L of TPP^z, algorithm $\widehat{\mathcal{A}}$ applies algorithm $\mathcal{A}$ on the list $\phi(L)$. It is easy to see that the algorithm $\widehat{\mathcal{A}}$ may not preserve the asymptotic performance of the original algorithm $\mathcal{A}$.

The next result shows that there is no algorithm $\widehat{\mathcal{A}}$ for TPP^z, obtained from an algorithm $\mathcal{A}$ for TPP, as described previously, that has an asymptotic performance bound less than 3.

PROPOSITION 2.1. *If $\widehat{\mathcal{A}}$ is an algorithm for* TPP^z *obtained from an algorithm $\mathcal{A}$ for* TPP, *as described above, then the asymptotic performance bound of $\widehat{\mathcal{A}}$ is at least* 3.

Proof. Let $L = (b_1, b_2, \ldots, b_{3k})$ and $B = (3 + 3\epsilon, 2, \infty)$ be an instance of of TPP^z, where $b_1 = b_2 = \cdots = b_{3k} = (2, 1 + \epsilon, 1)$, k is a positive integer, and ϵ is a positive small number.

First, observe that it is possible to pack L in k levels, that is, $\mathrm{OPT}(L) \leq k$. For that, initially rotate each box in L and generate a packing putting three boxes per level. Now it suffices to note that, since $L = \phi(L)$, any algorithm $\mathcal{A}$ for TPP is such that $\widehat{\mathcal{A}}(L) \geq 3k$ (as the algorithm $\widehat{\mathcal{A}}$ packs only one box per level). ∎

Now suppose we have an algorithm $\mathcal{A}$ for TPP^z. There is a natural way to adapt it to an algorithm, say $\mathcal{A}'$, for TPP. The question is what can we say about the performance of $\mathcal{A}'$. The next result gives the answer.

THEOREM 2.2. *There is a polynomial reduction of* TPP *to* TPP^z *that preserves the approximability. Moreover, this reduction also preserves the additive constant β. That is, if $\mathcal{A}$ is a polynomial algorithm for* TPP^z, *such that $\mathcal{A}(L) \leq \alpha \cdot \mathrm{OPT}(L) + \beta \cdot Z$ then there exists a polynomial algorithm $\mathcal{A}'$ for* TPP *such that $\mathcal{A}'(L) \leq \alpha \cdot \mathrm{OPT}'(L) + \beta \cdot Z$, where* $\mathrm{OPT}'(L)$ *is the height of an optimum oriented packing of L.*

Proof. Let L, as described, and $B = (l, w, \infty)$ be an instance of TPP. Consider the following algorithm $\mathcal{A}'$. First scale B to $B' = (l', w', \infty)$ and L to L' in the same proportion in such a way that $\min\{x(b) : b \in L'\} > w$; then apply algorithm $\mathcal{A}$ to pack L' into the box B', obtaining a packing $\mathcal{P}'$. Finally, rescale $\mathcal{P}'$ back, obtaining a packing of the original list L (into B). It is clear that $\mathcal{A}'(L) \leq \alpha \cdot \mathrm{OPT}'(L) + \beta Z$. ∎

For all algorithms presented in the next sections, we consider, without loss of generality, that $L = \phi(L)$. That is, we may assume that the boxes in L need not be rotated to fit in the box B.

Before we present the algorithms for TPP^z, let us mention some algorithms used as subroutines and also the related results that are needed.

We denote by NFDH the next fit decreasing height algorithm for TPP, presented by Li and Cheng in [3]. For the description of this algorithm the reader may refer to [3] or [6]. This algorithm has two variants: NFDH^x and NFDH^y. The notation NFDH is used to refer to any of these variants.

Li and Cheng [3] proved the following result.

LEMMA 2.3. *If* $L \subset \mathcal{C}[\frac{1}{m+1}, \frac{1}{m} \;;\; 0, \frac{1}{m}]$, *then* $\mathrm{NFDH}^y(L) \leq (\frac{m+1}{m-1})\frac{V(L)}{l \cdot w} + Z$. *The same result also holds for the algorithm* NFDH^x *when applied to a list* $L \subset \mathcal{C}[0, \frac{1}{m} \;;\; \frac{1}{m+1}, \frac{1}{m}]$.

The following result is more general and gives as a corollary the result above [6].

LEMMA 2.4. *Let L be an instance of* TPP *and $\mathcal{P}$ be a packing of L consisting of levels $N_1, \ldots, N_v$ such that* $\min\{z(b) : b \in N_i\} \geq \max\{z(b) : b \in N_{i+1}\}$, *and* $S(N_i) \geq s \cdot l \cdot w$ *for a given constant $s > 0$, $i = 1, \ldots, v-1$. Then* $H(\mathcal{P}) \leq \frac{1}{s}\frac{V(L)}{l \cdot w} + Z$.

The constant s mentioned in the above lemma is called an *area guarantee* of the packing $\mathcal{P}$.

Li and Cheng presented in [4] an algorithm called LL for instances $L \subset \mathcal{C}_m$, $m \geq 3$. We write $\mathrm{LL}(L, m)$ to indicate that we are applying the algorithm LL to a list $L \subset \mathcal{C}_m$. They proved that the following result holds for this algorithm.

LEMMA 2.5. *Let* $L \subset \mathcal{C}[0, \frac{1}{m} \;;\; 0, \frac{1}{m}]$ *be an instance of* TPP *and $\mathcal{P}$ be a packing of L obtained by applying the algorithm* LL. *Then* $H(\mathcal{P}) \leq (\frac{m}{m-2})\frac{V(L)}{l \cdot w} + Z$.

We give an idea of the algorithm $\mathrm{LL}(L, m)$, as we need to refer to it in the proof of Lemma 2.6. Initially, it sorts the boxes in L in nonincreasing order of their height. Then it divides L into sublists $L_1, \ldots, L_v$, such that $L = L_1 \| L_2 \| \cdots \| L_v$, each sublist preserving the (nonincreasing) order of the boxes, and

$$\begin{aligned} &S(L_i) \leq \left[\left(\tfrac{m-2}{m}\right) + \left(\tfrac{1}{m}\right)^2\right] lw && \text{for } i = 1, \ldots, v\ , \\ &S(L_i) + S(first(L_{i+1})) > \left[\left(\tfrac{m-2}{m}\right) + \left(\tfrac{1}{m}\right)^2\right] lw && \text{for } i = 1, \ldots, v-1\ , \end{aligned}$$

where *first*(L') is the first box in L'. Then, the algorithm LL uses a two-dimensional packing algorithm to pack each list L_i in only one level, say, N_i. The final packing is the concatenation of each of these levels.

The next lemma is used to prove lower bounds for the asymptotic performance bound of some algorithms shown here.

LEMMA 2.6. *Let $\mathcal{A}$ be an algorithm for* TPP (TPP^z) *that partitions the input list L into two sublists $L_1 \subset \mathcal{R}_4$ and $L_2 \subset \mathcal{Q}_m$, $m \geq 3$, and generates a packing $\mathcal{P} = \mathcal{P}_1 || \mathcal{P}_2$, where $\mathcal{P}_1$ is any packing of L_1 and $\mathcal{P}_2$ is a packing of L_2 using the algorithm* LL. *Then the asymptotic performance bound $r(\mathcal{A})$ of $\mathcal{A}$ is such that* $r(\mathcal{A}) \geq \frac{7m-8}{4m-8}$.

Proof. Consider a box $B = (1, 1, \infty)$. Let L be a list of boxes, $L = L_1 \cup L_2$, with $L_1 \subset \mathcal{R}_4$ and $L_2 \subset \mathcal{Q}_m$, $m \geq 3$. Let $L_1 = (b'_1, \ldots, b'_{N'})$ and $L_2 = (b''_1, \ldots, b''_{M \cdot N''})$, where

$$b'_i = \left(\frac{1}{2}+\frac{1}{k}, \frac{1}{2}+\frac{1}{k}, 1\right) \quad \text{and} \quad b''_i = \begin{cases} \left(\frac{1}{m}, \frac{1}{m}, 1-(i-1)\xi\right) & \text{if } i \bmod M = 1, \\ \left(\frac{1}{k}, \frac{1}{k}, 1-(i-1)\xi\right) & \text{otherwise.} \end{cases}$$

Recall that the algorithm LL groups the first boxes with total bottom area no greater than $\left(\frac{m-2}{m}\right)+\left(\frac{1}{m}\right)^2$. This instance was chosen in such a way that, in the packing generated by the algorithm LL, each level has M boxes whose bottom area is $\left(\frac{m-2}{m}\right)+\left(\frac{1}{k}\right)^2$.

Note that the algorithm LL divides the list L_2 into N'' sublists, each sublist consisting of one box of the form $\left(\frac{1}{m}, \frac{1}{m}, 1-(i-1)\xi\right)$ and $M-1$ boxes of the form $\left(\frac{1}{k}, \frac{1}{k}, 1-(i-1)\xi\right)$.

The strategy is to take the instance $L = L_1 \cup L_2$ in such a way that the optimum packing consists of N' levels, each level containing one box of L_1 and the remaining space (in each level) almost filled with boxes of L_2. Taking N' and k as very large integers, with $N'' = \lceil \frac{3}{4} N' \frac{m}{m-2} \rceil$ and k a multiple of $2m$, we may choose M appropriately so that $r(\mathcal{A})$ can be made as close to $\frac{7m-8}{4m-8}$ as desired. $\square$

Another algorithm that plays an important role for the algorithms presented here is the algorithm COMBINE. This algorithm is a slightly modified version of the algorithm COLUMN presented in [6]. This algorithm generates a partial packing of a list L. The packing consists of several stacks of boxes, referred to as *columns*. Each column is built by putting one box on top of the other, and each column consists only of boxes of type either $\mathcal{T}^1$ or $\mathcal{T}^2$.

The algorithm COMBINE is called with the parameters $(L, \mathcal{T}^1, p^1, \mathcal{T}^2, p^2)$, where $p^1 = [p^1_1, p^1_2, \dots, p^1_{n_1}]$ consists of the positions in the bottom of box B where the columns of boxes of type $\mathcal{T}^1$ should start and $p^2 = [p^2_1, p^2_2, \dots, p^2_{n_2}]$ consists of the positions in the bottom of box B where the columns of boxes of type $\mathcal{T}^2$ should start. Each point $p^i_j = (x^i_j, y^i_j)$ represents the x-axis and the y-axis coordinates where the first box (if any) of each column of the respective type must be packed. Note that the z-axis coordinate need not be specified since it may always be assumed to be 0 (corresponding to the bottom of box B). Here we are assuming that the positions p^1, p^2 and the types $\mathcal{T}^1$, $\mathcal{T}^2$ are chosen in such a way that the defined packing can always be performed.

We call *height of a column* the sum of the height of all boxes in that column.

Initially, all $n_1 + n_2$ columns are empty, starting at the bottom of box B. At each iteration, the algorithm chooses a column with the smallest height, say a column given by the position p^i_j, and packs the next box b of type $\mathcal{T}^i$, updating the list L after each iteration. If there is no such box b, then the algorithm halts returning the partial packing $\mathcal{P}$ of L. We also say that $\mathcal{P}$ *combines* the lists of types $\mathcal{T}^1$ and $\mathcal{T}^2$.

If each box of type $\mathcal{T}^i$ has bottom area at least $s_i \cdot l \cdot w$, then $(n_1 s_1 + n_2 s_2) \cdot l \cdot w$ is called the *combined area* of the packing generated by the algorithm COMBINE.

The following result about this algorithm holds. The proof is analogous to the one given in [6] for the algorithm COLUMN.

LEMMA 2.7. *Let $\mathcal{P}$ be the packing of $L' \subseteq L$ generated by the algorithm* COMBINE *when applied to lists of types $\mathcal{T}^1$ and $\mathcal{T}^2$ and list of positions $p^i_1, p^i_2, \dots, p^i_{n_i}$, $i = 1, 2$. If $S(b) \geq s_i \cdot l \cdot w$ for all boxes b in $\mathcal{T}^i$ $(i = 1, 2)$, then*

$$H(\mathcal{P}) \leq \frac{1}{s_1 n_1 + s_2 n_2} \frac{V(L')}{l \cdot w} + Z.$$

To simplify the notation, given two lists L_1 and L_2, we denote by COLUMN(L_1, p_1, L_2, p_2) the algorithm COMBINE called with parameters $(L_1||L_2, L_1, p_1, L_2, p_2)$ and assume that it returns a pair $(\mathcal{P}', L')$ where $\mathcal{P}'$ is the partial packing of $L_1||L_2$ and L' is the set of boxes packed in $\mathcal{P}'$.

Another simple algorithm that we use is the algorithm OC (one column). Given a list of boxes, say $L = (b_1, \ldots, b_n)$, this algorithm packs each box b_{i+1} on top of the box b_i for $i = 1, \ldots, n-1$. It is easy to verify the following results.

Lemma 2.8. *If $\mathcal{P}$ is the packing generated by the algorithm* OC *when applied to a list L and s is a constant such that $S(b) \geq s \cdot l \cdot w$ for all boxes b in L, then $H(\mathcal{P}) \leq \frac{V(L)}{s \cdot l \cdot w}$.*

Lemma 2.9. *If $\mathcal{P}$ is the packing generated by the algorithm* OC *when applied to a list L of boxes b such that $b \in \mathcal{R}_4$ and ($\rho(b) \in \mathcal{R}_4$ or $\rho(b) \notin \mathcal{C}$), then $H(\mathcal{P}) = \mathrm{OPT}(L)$.*

We use two other algorithms, UD^x and UD^y, described in [6]. These algorithms are based on the algorithm UD, developed by Baker, Brown, and Kattseff [1] for the strip packing problem. The following results hold for these algorithms [6].

Lemma 2.10. *Let L be an instance for* TPP *such that $b \in \mathcal{C}[\frac{1}{2}, 1\ ;\ 0, 1]$ (resp., $b \in \mathcal{C}[0, 1\ ;\ \frac{1}{2}, 1]$) for all boxes b in L. Then the packing $\mathcal{P}$ generated by the algorithm* UD^x *(resp.,* UD^y*) is such that $H(\mathcal{P}) \leq \frac{5}{4}\mathrm{OPT}(L) + \frac{53}{8}Z$.*

Lemma 2.11. *Let L be an instance for* TPP^z *consisting of boxes b such that $b \in \mathcal{C}[\frac{1}{2}, 1\ ;\ 0, 1]$ (resp., $b \in \mathcal{C}[0, 1\ ;\ \frac{1}{2}, 1]$), and whenever $x(b) > y(b)$ (resp., $y(b) > x(b)$) then $\rho(b) \notin \mathcal{C}$. That is, no two boxes of L can be packed side by side in the x-direction (resp., y-direction). Then the packing $\mathcal{P}$ generated by the algorithm* UD^x *(resp.,* UD^y*) is such that $H(\mathcal{P}) \leq \frac{5}{4}\mathrm{OPT}(L) + \frac{53}{8}Z$.*

Proof. This result follows directly from the previous lemma and the fact that no two boxes can be packed side by side in the x-direction (resp., y-direction), even if rotations are allowed. □

3. The algorithm $\mathbf{R}_k$.

In [6] we presented an algorithm for TPP, called $\mathcal{A}_k$, that has an asymptotic performance bound less than 2.67. In this section we present an algorithm for TPP^z, called R_k, that is based on the algorithm $\mathcal{A}_k$. The algorithm depends on a parameter k, an integer that is assumed to be greater than 5.

Before we give the description of the algorithm we define some numbers which are used to define sublists, called critical sets.

Definition 3.1. *Let $r_1^{(k)}, r_2^{(k)}, \ldots, r_{k+15}^{(k)}$ and $s_1^{(k)}, s_2^{(k)}, \ldots, s_{k+14}^{(k)}$ be real numbers defined as follows:*

- *$r_1^{(k)}, r_2^{(k)}, \ldots, r_k^{(k)}$ are such that* $r_1^{(k)}\frac{1}{2} = r_2^{(k)}(1 - r_1^{(k)}) = r_3^{(k)}(1 - r_2^{(k)}) = \cdots = r_k^{(k)}(1 - r_{k-1}^{(k)}) = \frac{1}{3}(1 - r_k^{(k)})$ *and* $r_1^{(k)} < \frac{4}{9}$*;*
- $r_{k+1}^{(k)} = \frac{1}{3},\ r_{k+2}^{(k)} = \frac{1}{4},\ \ldots,\ r_{k+15}^{(k)} = \frac{1}{17}$*;*
- $s_i^{(k)} = 1 - r_i^{(k)}$ *for* $i = 1, \ldots, k$*;*
- $s_{k+i}^{(k)} = 1 - (\frac{2i+4-\lfloor\frac{i+2}{3}\rfloor}{4i+10})$ *for* $i = 1, \ldots, 14$.

The following result can be proved using a continuity argument.

Claim 3.1. *The numbers $r_1^{(k)}, r_2^{(k)}, \ldots, r_k^{(k)}$ are such that $r_1^{(k)} > r_2^{(k)} > \cdots > r_k^{(k)} > \frac{1}{3}$ and $r_1^{(k)} \to \frac{4}{9}$ as $k \to \infty$.*

For simplicity we omit the superscripts $^{(k)}$ of the notation $r_i^{(k)}, s_i^{(k)}$ when k is clear from the context.

Using the numbers in Definition 3.1, we define the following critical sets.

$$\mathcal{C}_i^A = \mathcal{C}[r_{i+1}, r_i \ ; \ \frac{1}{2}, s_i], \quad \mathcal{C}_i^B = \mathcal{C}[\frac{1}{2}, s_i \ ; \ r_{i+1}, r_i],$$

$$\mathcal{C}^A = \bigcup_{i=1}^{k+14} \mathcal{C}_i^A, \quad \mathcal{C}^B = \bigcup_{i=1}^{k+14} \mathcal{C}_i^B, \quad \mathcal{C}_{[1-k]}^A = \bigcup_{i=1}^{k} \mathcal{C}_i^A, \quad \mathcal{C}_{[1-k]}^B = \bigcup_{i=1}^{k} \mathcal{C}_i^B.$$

The next result refers to a list of positions $p_{i,j}, q_{i,j}, p'_j, q'_j, p''_j$ and q''_j to be considered when applying the algorithm COMBINE. In [6] we give such a list of positions, defined for a box $B = (1, 1, \infty)$. To use in this context, we have to consider a proportional reparameterization for a box $B = (l, w, \infty)$. For completeness, we define here these positions (only for $i < j$, since the case $i > j$ is symmetric). See Figure 3.1(a).

Positions to combine sublists of $\mathcal{C}_i^A$ and $\mathcal{C}_j^B$. For simplicity, we denote by A_i the list of boxes of type $\mathcal{C}_i^A$, and by B_j the list of boxes of type $\mathcal{C}_j^B$.

- To combine the lists A_i $(1 \le i \le k)$ and B_j $(i \le j \le k)$, take
  $p_{i,j} = \left[(0,0), \left(\frac{1}{2}, 0\right)\right]$ and $q_{i,j} = [(0, s_i)]$.
  In this case we have an area guarantee of at least $\frac{1}{2}$.
- To combine the list $A_{[1-k]} = A_1 \cup \cdots \cup A_k$ with B_j $(k+1 \le j \le k+14)$, we consider two phases. We divide $A_{[1-k]}$ into A' and A'', taking $A' = \{b \in A_{[1-k]} : \ x(b) \le 1 - s_j\}$ and $A'' = A_{[1-k]} \setminus A'$.
  - ⋆ To combine A' with B_j, take
    $p'_j = [(s_j, 0)]$ and
    $q'_j = \left[(0,0), \left(0, \frac{1}{j-k+2}\right), \left(0, \frac{2}{j-k+2}\right), \ldots, \left(0, \frac{j-k+1}{j-k+2}\right)\right]$.
    In this case we have an area guarantee of at least $\frac{13}{24}$. This minimum is attained when $j = k+1$.
  - ⋆ To combine A'' with B_j, take
    $p''_j = \left[(0,0), \left(\frac{1}{2}, 0\right)\right]$ and
    $q''_j = \left[\left(0, \frac{2}{3}\right), \left(0, \frac{2}{3} + \frac{1}{j-k+2}\right), \left(0, \frac{2}{3} + \frac{2}{j-k+2}\right), \ldots, \left(0, \frac{2}{3} + \left(\lfloor \frac{j-k+2}{3} \rfloor - 1\right) \frac{1}{j-k+2}\right)\right]$.
    Here we obtain an area guarantee of at least $\frac{27}{56}$.
- To combine the lists A_i $(k+1 \le i \le k+14)$ and B_j $(i \le j \le k+14)$, take
  $p_{i,j} = \left[(s_j, 0), \left(s_j + \frac{1}{i-k+2}, 0\right), \left(s_j + \frac{2}{i-k+2}, 0\right), \ldots, \left(s_j + (\lfloor (1-s_j) \cdot (i-k+2) \rfloor - 1) \frac{1}{i-k+2}, 0\right)\right]$ and
  $q_{i,j} = \left[(0,0), \left(0, \frac{1}{j-k+2}\right), \left(0, \frac{2}{j-k+2}\right), \ldots, \left(0, \frac{j-k+1}{j-k+2}\right)\right]$.
  In this case we also obtain an area guarantee of at least $\frac{27}{56}$.

LEMMA 3.2. *The following statements are valid for the list of positions $p_{i,j}$, $q_{i,j}$, p'_j, q'_j, p''_j, and q''_j:*

(a) *If $\mathcal{P}$ is a packing generated by the algorithm COMBINE with parameters $(L, \mathcal{C}_i^A, p_{i,j}, \mathcal{C}_j^B, q_{i,j})$, $1 \le i, j \le k$ or $k+1 \le i, j \le k+14$, then we have that $H(\mathcal{P}) \le \frac{56}{27} \frac{V(\mathcal{P})}{l \cdot w} + Z$.*

(b) *There is a partition of $\mathcal{C}_{[1-k]}^A$ into sets $\mathcal{C}'_{A,j}$ and $\mathcal{C}''_{A,j}$ such that a packing $\mathcal{P}'$ generated by the algorithm* COMBINE *with parameters $(L, \mathcal{C}'_{A,j}, p'_j, \mathcal{C}_j^B, q'_j)$, $k+1 \le j \le k+14$, is such that $H(\mathcal{P}') \le \frac{56}{27} \frac{V(\mathcal{P}'')}{l \cdot w} + Z$ and a packing $\mathcal{P}''$*

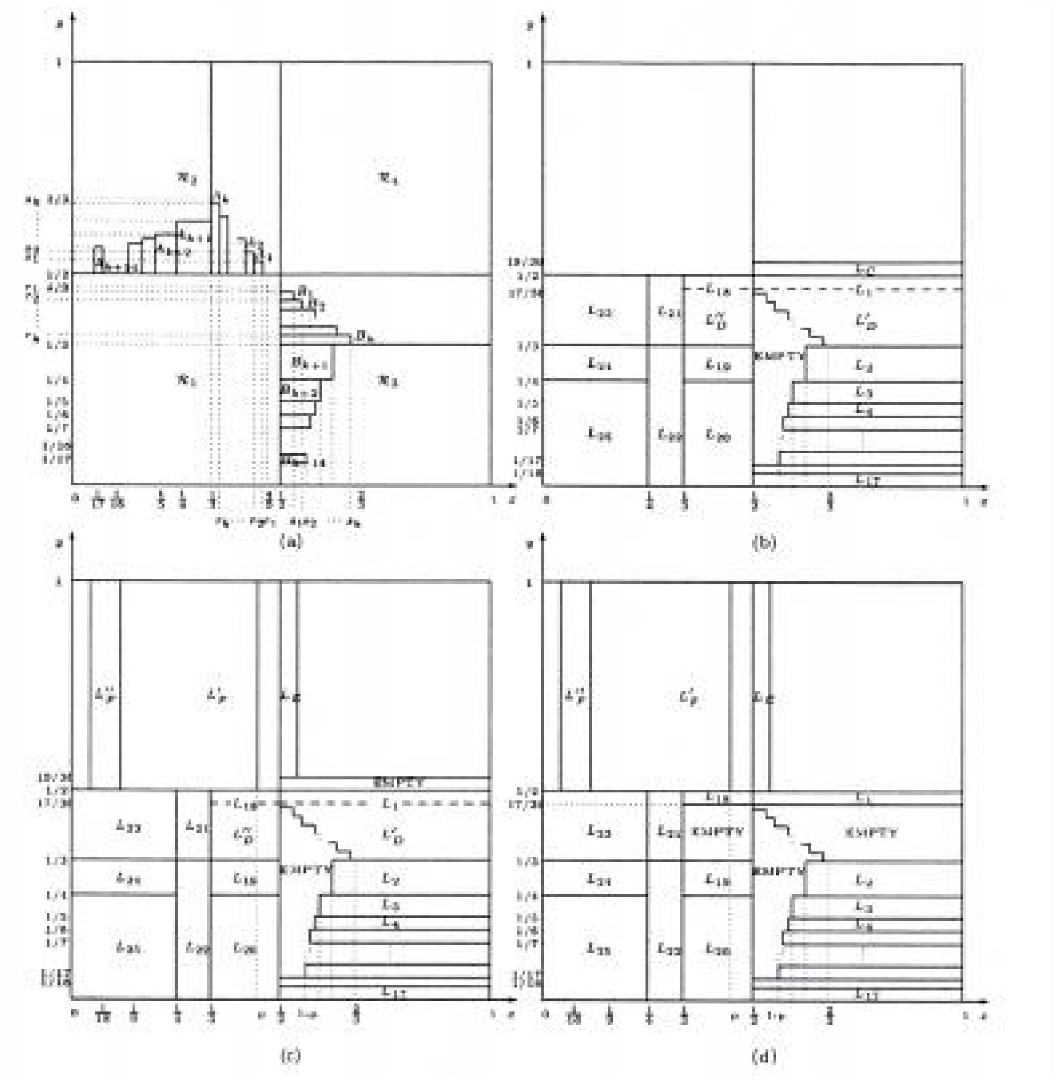

FIG. 3.1. *Partition of list L for algorithm R_k. The sets A_i and B_i in* (a) *correspond to the sets $\mathcal{C}_i^A$ and $\mathcal{C}_i^B$, resp.*

generated by the algorithm COMBINE *with parameters* $(L, \mathcal{C}''_{A,j}, p''_j, \mathcal{C}^B_j, q''_j)$, $k+1 \leq j \leq k+14$, *is such that* $H(\mathcal{P}'') \leq \frac{56}{27}\frac{V(\mathcal{P}'')}{l \cdot w} + Z$.

(c) *Defining positions symmetric to* $p_{i,j}, q_{i,j}, p'_j, q'_j, p''_j$ *and* q''_j, *analogous results hold when the letter A and B are exchanged in the items above.*

The algorithm R_k is inspired by the algorithm $\mathcal{A}_k$ presented in [6]. The reader may compare both algorithms to see where they differ; it should be noted that now there are steps where rotations are performed. This is done because otherwise we may not obtain valid inequalities with respect to the optimum packing.

ALGORITHM R_k

Input: List of boxes L.

```
    Output: Packing $\mathcal{P}$ of $L$ into $B = (l, w, \infty)$.
1 Rotate all boxes $b$ that are in $\mathcal{R}_4$ such that $\rho(b) \in \mathcal{R}_2 \cup \mathcal{R}_3$.
        /* i.e., Let $T \leftarrow \{b \in L \cap \mathcal{R}_4 : \rho(b) \in \mathcal{R}_2 \cup \mathcal{R}_3\}$. $L \leftarrow (L \setminus T) \bigcup \rho(T)$. */
2 Rotate all boxes $b$ of $L$ that are in $\mathcal{R}_2 \cup \mathcal{R}_3$ such that $\rho(b) \in \mathcal{R}_1$.
3 Let $p_{i,j}, q_{i,j}$, $1 \leq i, j \leq k+14$, and $p'_j, p''_j, q'_j, q''_j$, $k+1 \leq j \leq k+14$, be as defined
    above.
4 Combine boxes of types $\mathcal{C}^A$ and $\mathcal{C}^B$ of $L$ as follows (see Figure 3.1(a)).
    4.1 $i \leftarrow 1$; $j \leftarrow 1$; $\mathcal{P}_{AB} \leftarrow \emptyset$.
    4.2 While ($i \leq k$ and $j \leq k$) do
        $\mathcal{P}_{i,j} \leftarrow$ COMBINE($L, \mathcal{C}_i^A, p_{i,j}, \mathcal{C}_j^B, q_{i,j}$) .
        $\mathcal{P}_{AB} \leftarrow \mathcal{P}_{AB} \| \mathcal{P}_{i,j}$ .
        Update the list $L$ removing the packed boxes.
        If all boxes of type $\mathcal{C}_i^A$ have been packed, then increment $i$; else incre-
            ment $j$.
    4.3 If all boxes of type $\mathcal{C}^B_{[1-k]}$ have been packed
        4.3.1 Then
            While ($j \leq k+14$ and there is a box of type $\mathcal{C}^A_[1-k]$) do
                Let $\mathcal{C}'_{A,j}$ and $\mathcal{C}''_{A,j}$ be a partition of $\mathcal{C}^A_{[1-k]}$, as in Lemma 3.2.
                $\tilde{\mathcal{P}}'_j \leftarrow$ COMBINE($L, \mathcal{C}'_{A,j}, p'_j, \mathcal{C}_j^B, q'_j$). Update $L$ removing the
                    packed boxes.
                $\tilde{\mathcal{P}}''_j \leftarrow$ COMBINE($L, \mathcal{C}'_{A,j}, p'_j, \mathcal{C}_j^B, q'_j$). Update $L$ removing the
                    packed boxes.
                $\mathcal{P}_{AB} \leftarrow \mathcal{P}_{AB} \| \tilde{\mathcal{P}}'_j \| \tilde{\mathcal{P}}''_j$.
                if $B_j = \emptyset$, then $j \leftarrow j+1$.
            $i \leftarrow k+1$
        4.3.2 Else /* All boxes of types $\mathcal{C}^A_{[1-k]}$ have been packed */
            Perform steps symmetric to the ones given in the case 4.3.1.
    4.4 While ($i \leq k+14$ and $j \leq k+14$) do
        $\mathcal{P}_{i,j} \leftarrow$ COMBINE($L, \mathcal{C}_i^A, p_{i,j}, \mathcal{C}_j^B, q_{i,j}$). Update $L$ removing the packed
            boxes.
        $\mathcal{P}_{AB} \leftarrow \mathcal{P}_{AB} \| \mathcal{P}_{i,j}$ .
        If all boxes of type $\mathcal{C}_i^A$ have being packed, then increment $i$; else incre-
            ment $j$.
5 If all boxes of type $\mathcal{C}^B$ have been packed, then
    5.1 Rotate the boxes of $L \cap \mathcal{R}_2$ that fit in $\mathcal{R}_3$.
    5.2 Rotate the boxes of $L \cap (\mathcal{R}_2 \cup \mathcal{R}_4)$ such that if $b \in L \cap (\mathcal{R}_2 \cup \mathcal{R}_4)$, then
        $x(b) \leq y(b)$ or $\rho(b) \notin \mathcal{C}$.
    5.3 Subdivide the list $L$ into sublists $L_1, \ldots, L_{25}$ as follows (see Figure 3.1(b)).
```

$$
\begin{array}{ll}
L_i = L \bigcap \mathcal{C}[\frac{1}{2}, 1 \ ; \ \frac{1}{i+2}, \frac{1}{i+1}], \text{ for } i = 1, \ldots, 16 & L_{17} = L \bigcap \mathcal{C}[\frac{1}{2}, 1 \ ; \ 0, \frac{1}{18}], \\
L_{18} = L \bigcap \mathcal{C}[\frac{1}{3}, \frac{1}{2} \ ; \ \frac{1}{3}, \frac{1}{2}], & L_{19} = L \bigcap \mathcal{C}[\frac{1}{3}, \frac{1}{2} \ ; \ \frac{1}{4}, \frac{1}{3}], \\
L_{20} = L \bigcap \mathcal{C}[\frac{1}{3}, \frac{1}{2} \ ; \ 0, \frac{1}{4}], & L_{21} = L \bigcap \mathcal{C}[\frac{1}{4}, \frac{1}{3} \ ; \ \frac{1}{3}, \frac{1}{2}], \\
L_{22} = L \bigcap \mathcal{C}[\frac{1}{4}, \frac{1}{3} \ ; \ 0, \frac{1}{3}], & L_{23} = L \bigcap \mathcal{C}[0, \frac{1}{4} \ ; \ \frac{1}{3}, \frac{1}{2}], \\
L_{24} = L \bigcap \mathcal{C}[0, \frac{1}{4} \ ; \ \frac{1}{4}, \frac{1}{3}], & L_{25} = L \bigcap \mathcal{C}_4, \\
L_C = L \bigcap \mathcal{C}[\frac{1}{2}, 1 \ ; \ \frac{1}{2}, \frac{19}{36}] & L'_D = L_1 \bigcap \mathcal{C}[0, \frac{17}{36} \ ; \ 0, 1], \\
L''_D = L_{18} \bigcap \mathcal{C}[0, \frac{17}{36} \ ; \ 0, 1] & L_D = L'_D \bigcup L''_D.
\end{array}
$$

```
    5.4 Generate packing $\mathcal{P}_{CD}$ as follows.
```

```
          $(\mathcal{P}_{CD'}, L_{CD'}) \leftarrow$ COLUMN$(L_C, [(0,0)], L'_D, [(0, \frac{19}{36})])$.
          $(\mathcal{P}_{CD''}, L_{CD''}) \leftarrow$ COLUMN$(L_C \setminus L_{CD'}, [(0,0)], L''_D, [(0, \frac{19}{36}), (\frac{1}{2}, \frac{19}{36})])$.
          $\mathcal{P}_{CD} \leftarrow \mathcal{P}_{CD'} \| \mathcal{P}_{CD''}$.
          $L_{CD} \leftarrow L_{CD'} \bigcup L_{CD''}$.  $L_1 \leftarrow L_1 \setminus L_{CD}$.  $L_{18} \leftarrow L_{18} \setminus L_{CD}$.
     5.5 Generate packings $\mathcal{P}_1, \ldots, \mathcal{P}_{25}$ as follows.
          $\mathcal{P}_i \leftarrow$ NFDH$^y(L_i)$ for $i = 1, \ldots, 22$.
          $\mathcal{P}_i \leftarrow$ NFDH$^x(L_i)$ for $i = 23, 24$.
          $\mathcal{P}_{25} \leftarrow$ LL$(L_{25}, 4)$.
     5.6 Update $L$ removing the packed boxes. Note that $L \subseteq \mathcal{R}_2 \cup \mathcal{R}_4$.
     5.7 If $L_C \subseteq L_{CD}$
          then /* (Case 1) */
               $p \leftarrow \frac{\sqrt{199145}-195}{570} = 0.440\ldots$.  /* $L_C$ is totally packed (see Figure
                  3.1(c)) */
          else /* (Case 2) $L_D \subseteq L_{CD}$ */
               $p \leftarrow \frac{\sqrt{23401}-71}{180} = 0.455\ldots$.  /* $L_D$ is totally packed (see Figure
                  3.1(d)) */
     5.8  $L_E \leftarrow L \cap \mathcal{C}[\frac{1}{2}, 1-p\ ;\ \frac{1}{2}, 1]$.   $L'_F \leftarrow L \cap \mathcal{C}[\frac{1}{9}, p\ ;\ \frac{1}{2}, 1]$.
          $L''_F \leftarrow L \cap \mathcal{C}[\frac{1}{18}, \frac{1}{9}\ ;\ \frac{1}{2}, 1]$.        $L_F \leftarrow L'_F \cup L''_F$.
     5.9  $(\mathcal{P}_{EF'}, L_{EF'}) \leftarrow$ COLUMN$(L_E, [(0,0)], L'_F, [(1-p, 0)])$.
          $(\mathcal{P}_{EF''}, L_{EF''}) \leftarrow$  COLUMN$(L_E \setminus L_{EF'}, [(0,0)], L''_F, [(0, 1-p),$
                                $(0, 1-p+\frac{1}{9}), \ldots, (0, 1-p+(\lfloor 9p \rfloor - 1)\frac{1}{9})])$.
          $\mathcal{P}_{EF} \leftarrow \mathcal{P}_{EF'} \| \mathcal{P}_{EF''}$.
          $L_{EF} \leftarrow L_{EF'} \cup L_{EF''}$.
     5.10 If $L_E \subseteq L_{EF}$ /* (Subcase 1) $L_E$ is totally packed */
          then
               $\mathcal{P}_{\mathrm{UD}} \leftarrow$ UD$^x(L)$.

               $\mathcal{P}_{2e} \leftarrow$ NFDH$^x((L \setminus L_{EF}) \cap \mathcal{C}[0, \frac{1}{3}\ ;\ 0, 1])$.
               $\mathcal{P}_{2d} \leftarrow$ NFDH$^x((L \setminus L_{EF}) \cap \mathcal{C}[p, \frac{1}{2}\ ;\ 0, 1])$.
               $\mathcal{P}' \leftarrow \mathcal{P}_{OC} \| \mathcal{P}_{2e} \| \mathcal{P}_{2d} \| \mathcal{P}_{EF}$.
               $\mathcal{P}'' \leftarrow \{\mathcal{P} \in \{\mathcal{P}_{\mathrm{UD}}, \mathcal{P}'\} :\ H(\mathcal{P})$ is minimum $\}$.
               $\mathcal{P}_{aux} \leftarrow \mathcal{P}_{AB} \| \mathcal{P}_{CD} \| \mathcal{P}_1 \| \ldots \| \mathcal{P}_{25}$.
               Let $L''$ and $L_{aux}$ be the lists of boxes packed in $\mathcal{P}''$ and $\mathcal{P}_{aux}$, resp.
               $\mathcal{P} \leftarrow \mathcal{P}_{aux} \| \mathcal{P}''$.
     5.11 If $L_F \subseteq L_{EF}$ /* (Subcase 2) $L_F$ is totally packed */
          then
               $\mathcal{P}_{OC} \leftarrow$ OC$((L \setminus L_{EF}) \cap \mathcal{R}_4)$.
               $\mathcal{P}_{2e} \leftarrow$ NFDH$^x((L \setminus L_{EF}) \cap \mathcal{C}[0, \frac{1}{18}\ ;\ \frac{1}{2}, 1])$.
               $\mathcal{P}_{2d} \leftarrow$ NFDH$^x((L \setminus L_{EF}) \cap \mathcal{C}[p, 1\ ;\ \frac{1}{2}, 1])$.
               $\mathcal{P}' \leftarrow \mathcal{P}_{OC} \| \mathcal{P}_{EF}$.
               $\mathcal{P}_{aux} \leftarrow \mathcal{P}_{AB} \| \mathcal{P}_{CD} \| \mathcal{P}_{2e} \| \mathcal{P}_{2d} \| \mathcal{P}_1 \| \ldots \| \mathcal{P}_{25}$.
               Let $L'$ and $L_{aux}$ be the lists of boxes packed in $\mathcal{P}'$ and $\mathcal{P}_{aux}$, resp.
               $\mathcal{P} \leftarrow \mathcal{P}_{aux} \| \mathcal{P}'$.
6 If all boxes of type $\mathcal{C}^A$ have been packed then generate a packing $\mathcal{P}$ of $L$ as in step
     5 (in a symmetric way).
7 Return $\mathcal{P}$.
end algorithm.
```

The next theorem gives an asymptotic performance bound of the algorithm R_k when $k \to \infty$.

THEOREM 3.3. *For any instance L of* TPP^z *we have*

$$R_k(L) \leq \alpha_k \cdot \mathrm{OPT}(L) + \left(2k + \frac{597}{8}\right) Z,$$

where $\alpha_k \to \frac{579+\sqrt{199145}}{384} = 2.669\ldots$ *as* $k \to \infty$.

Proof. We present the proof for the case all boxes of type $\mathcal{C}^{\mathcal{B}}$ have been packed (see step 5). The proof of the other case (step 6) is analogous. We consider 4 cases, according to step 5.7 ($L_C \subseteq L_{CD}$), step 5.10 ($L_E \subseteq L_{EF}$), and step 5.11 ($L_F \subseteq L_{EF}$).

As many steps of the algorithm R_k are similar to the ones of the algorithm $\mathcal{A}_k$ for TPP, many of the inequalities obtained in the analysis of $\mathcal{A}_k$ are valid in these cases. We only mention them in the four claims A, B, C, and D below (see [6]).

Case 1.1. ($L_C \subseteq L_{CD}$) and ($L_E \subseteq L_{EF}$).

CLAIM A.

$$H(\mathcal{P}'') \leq \frac{1}{(1-p)\frac{19}{36}} \frac{V(L'')}{l \cdot w} + 4Z \quad \text{and} \quad H(\mathcal{P}_{aux}) \leq \frac{1}{r_1} \frac{V(L_{aux})}{l \cdot w} + (2k+68)Z.$$

Let $\mathcal{H}_1 := H(\mathcal{P}'') - \frac{53}{8}Z$ and $\mathcal{H}_2 := H(\mathcal{P}_{aux}) - (2k+68)Z$.

Using the definition of $\mathcal{H}_1$ and $\mathcal{H}_2$ in the two inequalities above we obtain

$$\mathrm{OPT}(L) \geq \frac{V(L)}{l \cdot w} = \frac{V(L'')}{l \cdot w} + \frac{V(L_{aux})}{l \cdot w} \geq \frac{(1-p)19}{36}\mathcal{H}_1 + r_1\mathcal{H}_2,$$

that is,

$$\mathrm{OPT}(L) \geq \frac{(1-p)19}{36}\mathcal{H}_1 + r_1\mathcal{H}_2 \ . \tag{3.1}$$

Note that from steps 1, 2, 4, 5.1, and 5.2 the list L'' satisfies the condition of Lemma 2.11. Hence, we have

$$H(\mathcal{P}'') \leq \mathrm{UD}^x(L'') \leq \frac{5}{4}\mathrm{OPT}(L'') + \frac{53}{8}Z \leq \frac{5}{4}\mathrm{OPT}(L) + \frac{53}{8}Z \ ,$$

that is,

$$\mathrm{OPT}(L) \geq \frac{4}{5}\mathcal{H}_1 \ . \tag{3.2}$$

Combining inequalities (3.1) and (3.2), we have

$$\mathrm{OPT}(L) \geq \max\left\{\frac{4}{5}\mathcal{H}_1, (1-p)\frac{19}{36}\mathcal{H}_1 + r_1\mathcal{H}_2\right\}.$$

From the definition of $\mathcal{H}_1$ and $\mathcal{H}_2$, we obtain

$$H(\mathcal{P}) = H(\mathcal{P}'') + H(\mathcal{P}_{aux}) = \mathcal{H}_1 + \mathcal{H}_2 + \left(2k + \frac{597}{8}\right) Z.$$

Using the last inequality in the above equation, we have

$$H(\mathcal{P}) \leq \left(\frac{\mathcal{H}_1 + \mathcal{H}_2}{\max\{\frac{4}{5}\mathcal{H}_1, (1-p)\frac{19}{36}\mathcal{H}_1 + r_1\mathcal{H}_2\}}\right) \mathrm{OPT}(L) + \left(2k + \frac{597}{8}\right) Z.$$

Analyzing the two possibilities for the maximum, we can prove (see [6]) that

$$\alpha'_k(r_1) := \frac{49+95p+180r_1}{144r_1} \geq \frac{\mathcal{H}_1+\mathcal{H}_2}{\max\{\frac{4}{5}\mathcal{H}_1, (1-p)\frac{19}{36}\mathcal{H}_1 + r_1\mathcal{H}_2\}}.$$

Thus,

$$H(\mathcal{P}) \leq \alpha'_k(r_1)\cdot \mathrm{OPT}(L) + \left(2k+\frac{597}{8}\right)Z.$$

Since $r_1 \to \frac{4}{9}$ as $k\to\infty$, we can conclude that $\alpha'_k(r_1) \to \frac{579+\sqrt{199145}}{384}$ as $k\to\infty$.

Case 1.2. $(L_C \subseteq L_{CD})$ and $(L_F \subseteq L_{EF})$.

Claim B.

$$H(\mathcal{P}'') \leq \frac{72}{19}\frac{V(P')}{l\cdot w} + 2Z, \quad \text{and} \quad H(\mathcal{P}_{aux}) \leq \frac{1}{p}\frac{V(L_{aux})}{l\cdot w} + (2k+70)Z.$$

Let $\mathcal{H}_1 := H(\mathcal{P}') - 2Z$ and $\mathcal{H}_2 := H(\mathcal{P}_{aux}) - (2k+70)Z$.

Then we have

$$\mathrm{OPT}(L) \geq \frac{V(L')}{l\cdot w} + \frac{V(L_{aux})}{l\cdot w} \geq \frac{19}{72}\mathcal{H}_1 + p\mathcal{H}_2. \tag{3.3}$$

Note that each box in $L'\cap\mathcal{R}_4$ considered in step 5.11 cannot be rotated, or if it can be rotated, then it fits in $\mathcal{R}_4$ again. So we can conclude that

$$\mathrm{OPT}(L) \geq \mathrm{OPT}(L') \geq \frac{19}{72}\mathcal{H}_1. \tag{3.4}$$

Proceeding as in Case 1.1, using inequalities (3.3) and (3.4), we have

$$H(\mathcal{P}) \leq \alpha''_k\cdot \mathrm{OPT}(L) + (2k+72)Z,$$

where $\alpha''_k = \frac{53+72p}{72p}$.

Thus, from the analysis of subcases 1.1 and 1.2, we can conclude that

$$\mathcal{A}_k(L) \leq \alpha_k\cdot\mathrm{OPT}(L) + \left(2k+\frac{597}{8}\right)Z,$$

where $\alpha_k \to \alpha'_k(\frac{4}{9}) = \alpha''_k = \frac{\sqrt{199145}+579}{384} = 2.669\ldots$ as $k\to\infty$.

Case 2.1. $(L_D \subseteq L_{CD})$ and $(L_E \subseteq L_{EF})$.

Claim C.

$$H(\mathcal{P}'') \leq \frac{1}{(1-p)\frac{1}{2}}\frac{V(L'')}{l\cdot w} + \frac{53}{8}Z \quad \text{and} \quad H(\mathcal{P}_{aux}) \leq \frac{1}{\frac{1}{4}+\frac{r_1}{2}}\frac{V(L_{aux})}{l\cdot w} + (2k+68)Z.$$

Let $\mathcal{H}_1 := H(\mathcal{P}'') - \frac{53}{8}Z$ and $\mathcal{H}_2 := H(\mathcal{P}_{aux}) - (2k+68)Z$.

Then we have $\mathrm{OPT}(L) \geq \frac{V(L'')}{l\cdot w} + \frac{V(L_{aux})}{l\cdot w} \geq \frac{1-p}{2}\mathcal{H}_1 + \left(\frac{1}{4}+\frac{r_1}{2}\right)\mathcal{H}_2$.

Using the same idea used in Case 1.1, we have $\mathrm{OPT}(L) \geq \mathrm{OPT}(L'') \geq \frac{4}{5}\mathcal{H}_1$ and thus we obtain $H(\mathcal{P}) \leq \beta'_k(r_1)\mathrm{OPT}(L) + \left(2k+\frac{597}{8}\right)Z$, where $\beta'_k(r_1) = \frac{11+10p+10r_1}{4+8r_1}$.

Case 2.2. $(L_D \subseteq L_{CD})$ and $(L_F \subseteq L_{EF})$.

Claim D.

$$H(\mathcal{P}') \leq 4\frac{V(P')}{l\cdot w} + 2Z, \quad \text{and} \quad H(\mathcal{P}_{aux}) \leq \frac{1}{p}\frac{V(L_{aux})}{l\cdot w} + (2k+70)Z.$$

Let $\mathcal{H}_1 := H(\mathcal{P}') - 2Z$ and $\mathcal{H}_2 := H(\mathcal{P}_{aux}) - (2k + 70)Z$.

In this case we have $\mathrm{OPT}(L) \geq \frac{V(L')}{l\cdot w} + \frac{V(L_{aux})}{l\cdot w} \geq \frac{1}{4}\mathcal{H}_1 + p\mathcal{H}_2$ and $\mathrm{OPT}(L) \geq \mathcal{H}_1$. Thus, $H(\mathcal{P}) \leq \beta''_k \cdot \mathrm{OPT}(L) + (2k + 72)Z$, where $\beta''_k = \frac{3+4p}{4p}$.

Furthermore, for the given value of p, as in the previous cases, we can conclude that

$$H(\mathcal{P}) \leq \beta_k \cdot \mathrm{OPT}(L) + \left(2k + \frac{597}{8}\right) Z,$$

where $\beta_k \to \beta'_k(\frac{4}{9}) = \beta''_k = \frac{\sqrt{23401}+207}{136} = 2.64\ldots$ as $k \to \infty$.

The theorem follows from the conclusions obtained in all cases analyzed. $\square$

The following result proved in [6] is also valid for this algorithm and can be proved analogously. It shows that for relatively small value of k ($k = 13$) the algorithm R_k has already an asymptotic performance bound that is very close to the value shown for $k \to \infty$.

COROLLARY 3.4. *For any instance L of* TPP^z *and $k \geq 13$ we have*

$$R_k(L) \leq \gamma_k \cdot \mathrm{OPT}(L) + \left(2k + \frac{597}{8}\right) Z,$$

where $\gamma_k = \frac{99+1080r_1^{(k)}+\sqrt{199145}}{864r_1^{(k)}} < 2.67$.

PROPOSITION 3.5. *The asymptotic performance bound of the algorithm R_k, $k \geq 13$, is between* 2.5 *and* 2.67.

Proof. The proof follows directly from Corollary 3.4 and Lemma 2.6 (using $m = 4$). $\square$

4. The Algorithm LS: Boxes in L have square bottoms.

In this section and in the following sections we apply the idea used in algorithm R_k to generate algorithms for particular instances of TPP^z. Here we consider the case in which the list L consists of boxes with square bottoms.

Without loss of generality, we consider that the box B has dimensions $(1, w, \infty)$, $w \geq 1$.

Given a list of boxes $L = (b_1, \ldots, b_n)$, consider the list of points given by the set $\{(x_1, y_1), \ldots, (x_n, y_n)\}$. Note that all points lay down in a line on the xy-plane that goes through $(0, 0)$ and $(1, 1)$. We call it a *box-line* (see Figure 4.1). The algorithm consider two cases, according to the position in the x-axis, where the box-line crosses the line $y = \frac{1}{2}$ (that is, in the position $xw = \left(\frac{1}{2w}\right) w$).

ALGORITHM LS.

Input: List of boxes $L \subset \mathcal{Q}[0, 1\ ;\ 0, 1]$.

Output: Packing $\mathcal{P}$ of L into $B = (1, w, \infty)$.

```
1 Take $p := 0.4791964$ and subdivide the list $L$ into sublists $L_1, \ldots, L_7, L_A, L_B, L_C$
      as follows (see Figures 4.1 and 4.2).
```

$$\begin{aligned}
&L_1 = L \bigcap \mathcal{C}[\tfrac{1}{2}, 1\ ;\ \tfrac{1}{2}, 1], \quad &&L_2 = L \bigcap \mathcal{C}[\tfrac{1}{3}, \tfrac{1}{2}\ ;\ \tfrac{1}{2}, 1], \quad &&L_3 = L \bigcap \mathcal{C}[0, \tfrac{1}{3}\ ;\ \tfrac{1}{2}, 1],\\
&L_4 = L \bigcap \mathcal{C}[\tfrac{1}{3}, \tfrac{1}{2}\ ;\ \tfrac{1}{3}, \tfrac{1}{2}], &&L_5 = L \bigcap \mathcal{C}[\tfrac{1}{4}, \tfrac{1}{3}\ ;\ \tfrac{1}{3}, \tfrac{1}{2}], &&L_6 = L \bigcap \mathcal{C}[0, \tfrac{1}{4}\ ;\ \tfrac{1}{3}, \tfrac{1}{2}],\\
&L_7 = L \bigcap \mathcal{C}[0, \tfrac{1}{3}\ ;\ \tfrac{1}{4}, \tfrac{1}{3}], &&L_8 = L \bigcap \mathcal{C}[0, \tfrac{1}{4}\ ;\ 0, \tfrac{1}{4}], &&L_A = L_2 \bigcap \mathcal{C}[0, 1\ ;\ 0, \tfrac{5}{8}],\\
&L_B = L_3 \bigcap \mathcal{C}[0, 1\ ;\ 0, \tfrac{3}{8}], &&L_C = L_1 \bigcap \mathcal{C}[0, 1\ ;\ 0, \tfrac{5}{8}].
\end{aligned}$$

```
2 Let $x \leftarrow \frac{1}{2w}$.
3 if $x \leq \frac{2}{5}$
```

            $\mathcal{P}_{aux} \leftarrow \mathcal{P}_{AB}\|\mathrm{NFDH}^x(L_2)\|\dots\|\mathrm{NFDH}^x(L_7)\|\mathrm{LL}(L_8,4)$.
            Let $L'$ and $L_{aux}$ be the lists of boxes packed in $\mathcal{P}'$ and $\mathcal{P}_{aux}$, resp.
            $\mathcal{P} \leftarrow \mathcal{P}'\|\mathcal{P}_{aux}$.
        **(Subcase 2.2.2)** if $L_E \subseteq L_{DE}$ then
            $\mathcal{P}'_{1,2} \leftarrow \mathrm{OC}(L_1)\|\mathrm{NFDH}^x(L_2)\|\mathcal{P}_{DE}$.
            $\mathcal{P}''_{1,2} \leftarrow \mathrm{UD}(L_1 \cup L_2 \cup L_{DE})$.
            $\mathcal{P}'' \leftarrow \left(\mathcal{P} \in \{\mathcal{P}'_{1,2}, \mathcal{P}''_{1,2}\} :\ H(\mathcal{P}) \text{ is minimum}\right)$.
            $\mathcal{P}_{aux} \leftarrow \mathcal{P}_{AB}\|\mathrm{NFDH}^x(L_4)\|\dots\|\mathrm{NFDH}^x(L_7)\|\mathrm{LL}(L_8,4)$.
            Let $L''$ and $L_{aux}$ be the lists of boxes packed in $\mathcal{P}''$ and $\mathcal{P}_{aux}$, resp.
            $\mathcal{P} \leftarrow \mathcal{P}''\|\mathcal{P}_{aux}$.
8 Return $\mathcal{P}$.
**end algorithm.**
```

THEOREM 4.1. *For any instance of* TPP^z *consisting of a list L of boxes with square bottoms, we have*

$$\mathrm{LS}(L) \leq 2.543 \cdot \mathrm{OPT}(L) + \frac{101}{8}Z.$$

Proof. As the proof technique is analogous to the previous one, we only give the inequalities that are valid in each case. We suggest that the reader follow the analysis of each case, together with the corresponding case in the description of the algorithm. Throughout this proof $l = 1$, as we are considering that $B = (1, w, \infty)$.

Case 1. In this case we obtain the following inequalities:

$$H(\mathcal{P}'') \leq \frac{16}{5}\frac{V(L'')}{l \cdot w} + \frac{53}{8}Z,$$
$$H(\mathcal{P}'') \leq \frac{5}{4}\mathrm{OPT}(L) + \frac{53}{8},$$
$$H(\mathcal{P}_{aux}) \leq 2\frac{V(L_{aux})}{l \cdot w} + 5Z.$$

Defining $\mathcal{H}_1 := H(\mathcal{P}'') - \frac{53}{8}Z$ and $\mathcal{H}_2 := H(\mathcal{P}_{aux}) - 4Z$, we have $\mathrm{OPT}(L) \geq \max\{\frac{4}{5}\mathcal{H}_1, \frac{5}{16}\mathcal{H}_1 + \frac{1}{2}\mathcal{H}_2\}$ and therefore, proceeding as before, we obtain

$$H(\mathcal{P}) \leq \alpha_1 \cdot \mathrm{OPT}(L) + \frac{53}{8}Z,$$

where $\alpha_1 \le \frac{\mathcal{H}_1+\mathcal{H}_2}{\max\{\frac{4}{5}\mathcal{H}_1, \frac{5}{16}\mathcal{H}_1+\frac{1}{2}\mathcal{H}_2\}} \le 2.5$.

Note that for the remaing cases, the lists L_3 and $L_2 \setminus L_A$ are empty and the box-line crosses the region L_C.

Subcase 2.1.1. Note that in this case, $L_A \cup L_B$ is totally packed in $\mathcal{P}_{AB} \| \mathcal{P}_{BC}$. Note also that the boxes of L_C in $\mathcal{P}_{BC}$ are of type $\mathcal{R}_4$ and therefore we obtain the following inequality:

$$H(\mathcal{P}') \le 4\frac{V(L')}{l\cdot w} + Z.$$

Since

$$H(\mathcal{P}_{aux}) \le 2\frac{V(L_{aux})}{l\cdot w} + 7Z,$$
$$H(\mathcal{P}') \le \mathrm{OPT}(L) + Z,$$

using the above inequalities and defining $\mathcal{H}_1 := H(\mathcal{P}') - Z$ and $\mathcal{H}_2 := H(\mathcal{P}_{aux}) - 7Z$, we have

$$H(\mathcal{P}) \le \alpha_{2,1,1} \cdot \mathrm{OPT}(L) + 8Z,$$

where $\alpha_{2,1,1} \le \frac{\mathcal{H}_1+\mathcal{H}_2}{\max\{\mathcal{H}_1, \frac{1}{4}\mathcal{H}_1+\frac{1}{2}\mathcal{H}_2\}} \le 2.5$.

Subcase 2.1.2. In this case the boxes of $L_A \cup L_C$ are totally packed in $\mathcal{P}_{AB} \| \mathcal{P}_{BC}$. Furthermore, we have $x = \frac{1}{2w}$ and $x \in (\frac{2}{5}, \frac{1}{2}]$ (note that $x \cdot w$ is the position in the x-axis where the box-line crosses the line $y = \frac{1}{2}$). In this case we have the following inequalities with respect to x:

$$H(\mathcal{P}') \le \frac{32}{25x}\frac{V(L')}{l\cdot w} + Z,$$
$$H(\mathcal{P}_{aux}) \le \frac{1}{\min\{\frac{2}{9x}, \frac{1}{2}\}}\frac{V(L_{aux})}{l\cdot w} + 8Z,$$
$$H(\mathcal{P}') \le \mathrm{OPT}(L) + Z,$$

and therefore,

$$H(\mathcal{P}) \le \alpha_{2,1,2} \cdot \mathrm{OPT}(L) + 9Z \ ,$$

where $\alpha_{2,1,2} \le \frac{\mathcal{H}_1+\mathcal{H}_2}{\max\{\mathcal{H}_1, \frac{25x}{32}\mathcal{H}_1+\min\{\frac{2}{9x}, \frac{1}{2}\}\mathcal{H}_2\}}$. Evaluating the value of $\alpha_{2,1,2}$, when $x \ge \frac{4}{9}$ and when $x < \frac{4}{9}$, we obtain that $\alpha_{2,1,2} \le 2.5$.

Subcase 2.2.1. In this case $L_B \cup L_D$ is totally packed in $\mathcal{P}_{AB} \| \mathcal{P}_{DE}$. Recall that $x = \frac{1}{2w}$. We divide the analysis in two cases. We consider first $x \in (p, \frac{1}{2}]$. Here we have

$$H(\mathcal{P}') \le 8x\frac{V(L')}{l\cdot w} + Z,$$
$$H(\mathcal{P}_{aux}) \le \frac{1}{x}\frac{V(L_{aux})}{l\cdot w} + 7Z,$$
$$H(\mathcal{P}') \le \mathrm{OPT}(L) + Z,$$

and therefore,

$$H(\mathcal{P}) \le \alpha_{2,2,1} \cdot \mathrm{OPT}(L) + 8Z \ ,$$

where $\alpha_{2,2,1} \leq \frac{\mathcal{H}_1+\mathcal{H}_2}{\max\{\mathcal{H}_1, \frac{1}{8x}\mathcal{H}_1+x\mathcal{H}_2\}} \leq \frac{\mathcal{H}_1+\mathcal{H}_2}{\max\{\mathcal{H}_1, \frac{1}{8p}\mathcal{H}_1+p\mathcal{H}_2\}} \leq 2.543$.

If $x \in (\frac{2}{5}, p]$, the analysis is similar and is omitted.

Subcase 2.2.2. Here $L_B \cup L_E$ is totally packed in $\mathcal{P}_{AB} \| \mathcal{P}_{DE}$. Let $x = \frac{1}{2w}$, $x \in (\frac{2}{5}, p]$. In this case,

$$H(\mathcal{P}'') \leq \frac{2x}{(1-p)^2}\frac{V(L')}{l \cdot w} + \frac{53}{8}Z,$$
$$H(\mathcal{P}_{aux}) \leq 2\frac{V(L_{aux})}{l \cdot w} + 5Z,$$
$$H(\mathcal{P}'') \leq \frac{7}{5}4\mathrm{OPT}(L) + \frac{53}{8}Z,$$

and so,

$$H(\mathcal{P}) \leq \alpha_{2,2,2} \cdot \mathrm{OPT}(L) + \frac{93}{8}Z,$$

where $\alpha_{2,2,2} \leq \frac{\mathcal{H}_1+\mathcal{H}_2}{\max\{\frac{4}{5}\mathcal{H}_1, \frac{(1-p)^2}{2x}\mathcal{H}_1+\frac{1}{2}\mathcal{H}_2\}} \leq \frac{\mathcal{H}_1+\mathcal{H}_2}{\max\{\frac{4}{5}\mathcal{H}_1, \frac{(1-p)^2}{2p}\mathcal{H}_1+\frac{1}{2}\mathcal{H}_2\}} \leq 2.543$.

In fact, the value of p was taken in such a manner that the two subcases above (2.2.1 and 2.2.2) lead to the same bound.

The theorem follows considering the cases analyzed above. □

PROPOSITION 4.2. *The asymptotic performance bound of the algorithm LS is between* 2.5 *and* 2.5425.

Proof. The proof follows directly from Theorem 4.1 and Lemma 2.6 (when we use $m = 4$). □

5. The Algorithm BS: Box *B* has a square bottom.

We now consider the special case of TPP^z where B has a square bottom. Without loss of generality, we consider $B = (1, 1, \infty)$.

First, we present an algorithm called NFDH$_p^{xy}$, $0 < p < 1$, that is used as a subroutine. This algorithm packs the boxes of a list L in the following way. Initially, it sorts L in a nonincreasing order of height, then generates a packing divided into levels. Each level is divided into two parts; the boxes are packed first in the region $[0, 1) \times [0, p)$ and then in the region $[0, 1) \times [1 - p, 1)$. The boxes are packed in the region $[0, 1) \times [0, p)$ using the algorithm NFDH^x until a box b_i cannot be packed in the same level; then NFDH$_p^{xy}$ uses the algorithm NFDH^y to pack boxes $\rho(b_i), \rho(b_{i+1}), \ldots$ in the region $[0, 1) \times [1 - p, 1)$ until a box b_k cannot be packed in the same level. At this point, the algorithm NFDH$_p^{xy}$ considers the two parts as only one level and continues to pack the box b_k in a new level. The process continues until all boxes in L have been packed.

Another variant of the above algorithm is called NFDH$_p^{yx}$. This algorithm is similar to the NFDH$_p^{xy}$ algorithm, except that NFDH$_p^{yx}$ first packs boxes b with $x(b) \leq p$, in the y-axis direction, and then packs the next boxes in the x-axis direction.

The following notation is used in the description of the algorithm:

$$\mathcal{X}' := \{b_i = (x_i, y_i, z_i) : \ y_i \leq 1 - x_i\}.$$

ALGORITHM BS.

Input: List of boxes L.

Output: Packing $\mathcal{P}$ of L into $B = (1, 1, \infty)$.

```
1 Rotate the boxes of $L$ in such a way that for each box $b$, $x(b) \leq y(b)$.
```

```
   Take $p = 0.43322958$ and $q = 1 - p$.
2  Divide $L$ into sublists $L'_1, L'_2, L'_3, L_A, L_B, L_C, L_4, \dots, L_{14}$ as follows (see Figure 5.1).
```

$$
\begin{array}{lll}
L'_1 = L \bigcap \mathcal{C}[q, 1\ ;\ q, 1], & L_A = L \bigcap \mathcal{C}[\tfrac{1}{2}, q\ ;\ \tfrac{1}{2}, 1], & L'_2 = L \bigcap \mathcal{C}[p, \tfrac{1}{2}\ ;\ \tfrac{1}{2}, 1] \backslash \mathcal{X}', \\
L_B = L \bigcap \mathcal{C}[\tfrac{1}{3}, p\ ;\ \tfrac{1}{2}, 1] \backslash \mathcal{X}', & L'_3 = L \bigcap \mathcal{C}[p, \tfrac{1}{2}\ ;\ \tfrac{1}{3}, \tfrac{1}{2}], & L_C = L \bigcap \mathcal{C}[\tfrac{1}{3}, p\ ;\ \tfrac{1}{3}, \tfrac{1}{2}], \\
L_4 = L \bigcap \mathcal{C}[\tfrac{1}{4}, \tfrac{1}{3}\ ;\ \tfrac{2}{3}, 1], & L_5 = L \bigcap \mathcal{C}[\tfrac{1}{5}, \tfrac{1}{4}\ ;\ \tfrac{2}{3}, 1], & L_6 = L \bigcap \mathcal{C}[0, \tfrac{1}{5}\ ;\ \tfrac{8}{13}, 1], \\
L_7 = L \bigcap \mathcal{C}[\tfrac{1}{3}, \tfrac{1}{2}\ ;\ \tfrac{1}{2}, \tfrac{2}{3}] \bigcap \mathcal{X}', & L_8 = L \bigcap \mathcal{C}[\tfrac{1}{4}, \tfrac{1}{3}\ ;\ \tfrac{1}{2}, \tfrac{2}{3}], & L_9 = L \bigcap \mathcal{C}[\tfrac{1}{5}, \tfrac{1}{4}\ ;\ \tfrac{1}{2}, \tfrac{2}{3}], \\
L_{10} = L \bigcap \mathcal{C}[0, \tfrac{1}{5}\ ;\ \tfrac{1}{2}, \tfrac{8}{13}], & L_{11} = L \bigcap \mathcal{C}[\tfrac{1}{4}, \tfrac{1}{3}\ ;\ \tfrac{1}{3}, \tfrac{1}{2}], & L_{12} = L \bigcap \mathcal{C}[0, \tfrac{1}{4}\ ;\ \tfrac{1}{3}, \tfrac{1}{2}], \\
L_{13} = L \bigcap \mathcal{C}[0, \tfrac{1}{3}\ ;\ \tfrac{1}{4}, \tfrac{1}{3}], & L_{14} = L \bigcap \mathcal{C}[0, \tfrac{1}{4}\ ;\ 0, \tfrac{1}{4}] &
\end{array}
$$

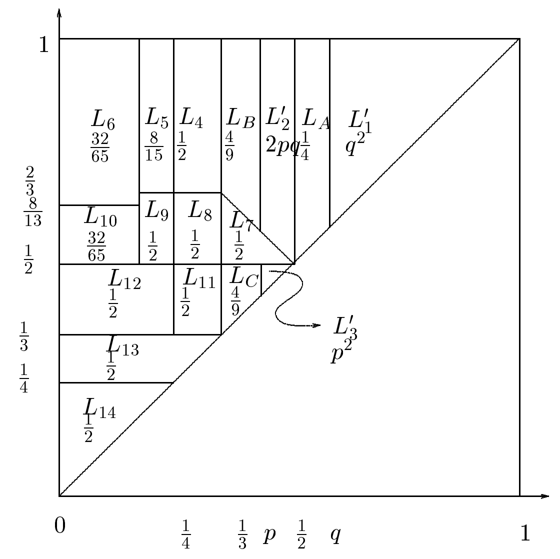

FIG. 5.1. *Partition of list L done by algorithm* BS.

```
3  $(\mathcal{P}_{AB}, L_{AB}) \leftarrow$ COLUMN$(L_A, [(0,0)], L_B, [(q,0)])$.
4  $(\mathcal{P}_{AC}, L_{AC}) \leftarrow$ COLUMN$(L_A \setminus L_{AB}, [(0,0)], L_C, [(q,0), (q, \frac{1}{2})])$.
5  $L_1 \leftarrow (L'_1 \cup L_A) \setminus (L_{AB} \cup L_{AC})$.  $L_2 \leftarrow (L'_2 \cup L_B) \setminus L_{AB}$.  $L_3 \leftarrow (L'_3 \cup L_C) \setminus L_{AC}$.
6  Let $\mathcal{P}_7$ be a packing of $L_7$ obtained as follows.
       6.1  Sort $L_7$ in a nonincreasing order of height.
       6.2  Construct a partition of $L_7$ given by $L_7^1, L_7^2, \dots, L_7^{n_7}$ such that
```

$$
\begin{cases}
L_7 & = L_7^1 \| L_7^2 \| \dots \| L_7^{n_7}, \\
|L_7^i| & = 3, \quad i = 1, \dots, n_7 - 1, \\
|L_7^{n_7}| & \leq 3.
\end{cases}
$$

```
       6.3  Generate a packing $\mathcal{P}_7^i$ of $L_7^i$, $i = 1, \dots, n_7$ as follows.
            6.3.1  Choose $b \in L_7^i$, such that $x(b)$ is minimum.
            6.3.2  Pack $\rho(b)$ in the position $(0, 1 - x(b))$ and the boxes in $L_7^i \setminus \{b\}$
                   in the positions $(0,0)$ and $(\frac{1}{2}, 0)$.
       6.4  $\mathcal{P} \leftarrow \mathcal{P}_7^1 \| \dots \| \mathcal{P}_7^{n_7}$.
7  $\mathcal{P}' \leftarrow$ OC$(L_1) \| \mathcal{P}_{AB} \| \mathcal{P}_{AC}$.
```

```
8  $\mathcal{P}_{aux} \leftarrow \mathrm{NFDH}^x(L_2)\| \dots \|\mathrm{NFDH}^x(L_6)\|\mathcal{P}_7\|\mathrm{NFDH}^{xy}_{\frac{2}{3}}(L_8)\|\mathrm{NFDH}^{xy}_{\frac{2}{3}}(L_9)\|$
       $\mathrm{NFDH}^{xy}_{\frac{8}{13}}(L_{10})\|\mathrm{NFDH}^x(L_{11})\| \dots \|\mathrm{NFDH}^x(L_{13})\|\mathrm{LL}(L_{14})$.
9  $\mathcal{P} \leftarrow \mathcal{P}'\|\mathcal{P}_{aux}$.
10 Return $\mathcal{P}$.
end algorithm.
```

THEOREM 5.1. *For any list L for the* TPP^z*, where B has a square bottom,*

$$\mathrm{BS}(L) \leq 2.528 \cdot \mathrm{OPT}(L) + 15Z\ .$$

Proof. From steps 3 and 4, we can conclude that either L_A is totally packed or $L_B \cup L_C$ is totally packed in $\mathcal{P}_{AB}\|\mathcal{P}_{BC}$. So we divide the proof into these two subcases.

Case 1. L_A is totally packed in $\mathcal{P}_{AB}\|\mathcal{P}_{BC}$.

Here we have

$$H(\mathcal{P}') \leq \frac{1}{q^2}V(L') + 2Z,$$
$$H(\mathcal{P}_{aux}) \leq \frac{9}{4}V(L_{aux}) + 13Z,$$
$$H(\mathcal{P}') \leq \mathrm{OPT}(L) + 2Z.$$

As before, we have $H(\mathcal{P}) \leq \alpha_1 \cdot \mathrm{OPT}(L) + 15Z$, where $\alpha_1 \leq \frac{\mathcal{H}_1+\mathcal{H}_2}{\max\{\mathcal{H}_1, q^2\mathcal{H}_1+\frac{4}{9}\mathcal{H}_2\}} \leq 2.528$.

Case 2. $(L_B \cup L_C)$ is totally packed in $\mathcal{P}_{AB}\|\mathcal{P}_{BC}$.

Here we have

$$H(\mathcal{P}') \leq 4V(L') + 2Z,$$
$$H(\mathcal{P}_{aux}) \leq \frac{1}{2pq}V(L_{aux}) + 13Z,$$
$$H(\mathcal{P}') \leq \mathrm{OPT}(L) + 2Z.$$

Analogously, we have $H(\mathcal{P}) \leq \alpha_2 \cdot \mathrm{OPT}(L) + 15Z$, where $\alpha_2 \leq \frac{\mathcal{H}_1+\mathcal{H}_2}{\max\{\mathcal{H}_1, \frac{1}{4}\mathcal{H}_1+2pq\mathcal{H}_2\}} \leq 2.528$.

From the two cases above, the theorem follows. □

PROPOSITION 5.2. *The asymptotic performance bound of the algorithm* BS *is between* 2.5 *and* 2.528.

Proof. It follows directly from Theorem 5.1 and Lemma 2.6 (using $m = 4$). □

6. The Algorithm SS: Boxes in L and box B have square bottoms.

Now we consider the special case of TPP^z, where all boxes in L and box B have square bottoms. Without loss of generality, we take $B = (1, 1, \infty)$.

In 1990, Li and Cheng [3] presented an algorithm for this problem with asymptotic performance bound 2.6875. The algorithm we present here, called SS, has an asymptotic performance bound of 2.361.

Here we need an algorithm, called GQ$_m$, described in [3], to pack boxes in $\mathcal{Q}_m$.

The algorithm GQ$_m$ works in the same way as algorithm LL. It sorts the boxes in $L \subset \mathcal{Q}_m$ in nonincreasing order of their height, divides L into sublists $L_1, \dots, L_v$, and uses the same two-dimensional packing algorithm to pack each sublist L_i in a level. The only place where algorithm GQ$_m$ differs from LL is the bottom area size used to subdivide L into sublists L_i. This is because the two-dimensional packing algorithm used by algorithm LL can guarantee a better area if all boxes have square bottoms. In this case the sublists L_i satisfy the following inequalities:

$$S(L_i) \le \left[\left(\tfrac{m-1}{m}\right)^2 + \left(\tfrac{1}{m}\right)^2\right] lw \qquad \text{for } i = 1, \dots, v,$$
$$S(L_i) + S(first(L_{i+1})) > \left[\left(\tfrac{m-1}{m}\right)^2 + \left(\tfrac{1}{m}\right)^2\right] lw \qquad \text{for } i = 1, \dots, v-1.$$

The following result is proved in [3].

LEMMA 6.1. *Let $L \subset \mathcal{Q}_m$, $m \ge 2$. Then, $GQ_m(L) \le (\frac{m}{m-1})^2 \frac{V(L)}{lw} + Z$.*

Analogously to Lemma 2.6 with algorithm LL, we can show that the following result holds for algorithm GQ$_m$.

LEMMA 6.2. *Let $\mathcal{A}$ be an algorithm for* TPP^z *to pack a list $L \subset \mathcal{Q}[0,1\ ;\ 0,1]$ into a box $B = (1,1,\infty)$. If $\mathcal{A}$ subdivides the input list L into two sublists $L_1 \subset \mathcal{R}_4$ and $L_2 \subset \mathcal{Q}_m$, $m \ge 2$, and applies algorithm* GQ$_m$ *to pack L_2, then the asymptotic performance bound of $\mathcal{A}$ is at least $\frac{4(m-1)^2+3m^2}{4(m-1)^2}$.*

Proof. The proof is similar to the proof of Lemma 2.6, now using the value $\left(\frac{m-1}{m}\right)^2$ instead of $\left(\frac{m-2}{m}\right)$. ∎

```
ALGORITHM SS.
  Input: List of boxes $L \subset \mathcal{Q}[0,1\ ;\ 0,1]$.
  Output: Packing $\mathcal{P}$ of $L$ into $B = (1,1,\infty)$.
1 Take $p = 0.37123918$ and $q = 1 - p$.
  Divide $L$ into sublists, $L_1', L_A, L_2', L_B, L_3$, and $L_4$ (see Figure 6.1),
      $L_1' = L \bigcap \mathcal{Q}[\frac{1}{2},1\ ;\ \frac{1}{2},1]$,   $L_A = L \bigcap \mathcal{Q}[\frac{1}{2},q\ ;\ \frac{1}{2},q]$,
      $L_2' = L \bigcap \mathcal{Q}[\frac{1}{3},\frac{1}{2}\ ;\ \frac{1}{3},\frac{1}{2}]$,   $L_B = L \bigcap \mathcal{Q}[\frac{1}{3},p\ ;\ \frac{1}{3},p]$,
      $L_3 = L \bigcap \mathcal{Q}[\frac{1}{4},\frac{1}{3}\ ;\ \frac{1}{4},\frac{1}{3}]$,   $L_4 = L \bigcap \mathcal{Q}[0,\frac{1}{4}\ ;\ 0,\frac{1}{4}]$.
2 $(\mathcal{P}_{AB}, L_{AB}) \leftarrow$ COLUMN$(L_A, [(0,0)], L_B, [(0,q),(q,q),(q,0)])$.
3 $L_i \leftarrow L_i' \setminus L_{AB}$ for $i = 1,2$.
4 $\mathcal{P}_1 \leftarrow$ OC$(L_1) \| \mathcal{P}_{AB}$.
5 $\mathcal{P}_{aux} \leftarrow$ NFDH$^x(L_2) \|$NFDH$^x(L_3) \| GQ_4(L_4)$.
6 $\mathcal{P} = \mathcal{P}_1 \| \mathcal{P}_{aux}$.
7 Return $\mathcal{P}$.
end algorithm.
```

THEOREM 6.3. *For any list L for* TPP^z*, where all boxes have square bottoms,*

$$\text{SS}(L) \le 2.361 \cdot \text{OPT}^z(L) + 4Z\ .$$

Proof. Again we analyze two cases, considering the packing generated in step 2.

Case 1. L_A is totally packed in $\mathcal{P}_{AB}$.

$$H(\mathcal{P}_1) \le \frac{1}{q^2} V(L') + Z,$$
$$H(\mathcal{P}_{aux}) \le \frac{9}{4} V(L_{aux}) + 3Z,$$
$$H(\mathcal{P}_1) \le \text{OPT}(L) + Z.$$

Proceeding as before, we have $H(\mathcal{P}) \le \alpha_1 \cdot \text{OPT}(L) + 4Z$, where

$$\alpha_1 \le \frac{\mathcal{H}_1 + \mathcal{H}_2}{\max\{\mathcal{H}_1, q^2\mathcal{H}_1 + \frac{4}{9}\mathcal{H}_2\}} \le 2.361.$$

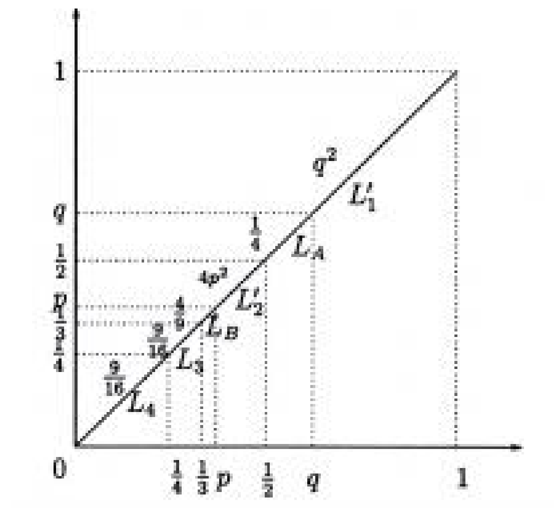

FIG. 6.1. *Partition of list L done by Algorithm* SS.

Case 2. L_B is totally packed in $\mathcal{P}_{AB}$.

Here we have

$$H(\mathcal{P}_1) \leq 4V(L') + Z,$$
$$H(\mathcal{P}_{aux}) \leq \frac{1}{4p^2}V(L_{aux}) + 3Z,$$
$$H(\mathcal{P}_1) \leq \mathrm{OPT}(L) + Z.$$

Thus, $H(\mathcal{P}) \leq \alpha_2 \cdot \mathrm{OPT}(L) + 4Z$, where $\alpha_2 \leq \frac{\mathcal{H}_1+\mathcal{H}_2}{\max\{\mathcal{H}_1, \frac{1}{4}\mathcal{H}_1+4p^2\mathcal{H}_2\}} \leq 2.361$.

From the two cases above, the theorem follows. □

PROPOSITION 6.4. *The asymptotic performance bound of Algorithm* SS *is between* 2.333 *and* 2.361.

Proof. It follows directly from Theorem 6.3 and Lemma 6.2 (with $m = 4$). □

EXAMINING COMPUTATIONAL GEOMETRY, VAN EMDE BOAS TREES, AND HASHING FROM THE PERSPECTIVE OF THE FUSION TREE*

DAN E. WILLARD†

Abstract. This article illustrates several examples of computer science problems whose performance can be improved with the use of either the fusion trees [Fredman and Willard, *J. Comput. System Sci.*, 47 (1993), pp. 424–436; Fredman and Willard, *J. Comput. System Sci.*, 48 (1994), pp. 533–551] or one of several recent improvements to this data structure. It is likely that many other data structures can also have their performance improved with fusion trees. The examples here are only illustrative.

1. Introduction.

The fusion tree [25] and its several variants [1, 2, 3, 4, 5, 6, 7, 8, 9, 11, 15, 26, 36, 37, 38, 40, 41, 43, 44, 45, 46] are data structures that perform sorting operations in better than $O(N \ \log N)$ worst-case time and execute dynamic search operations in faster than $O(\log N)$ time in a very natural model of complexity. Since many classic algorithms were designed under the assumption that further improvements for sorting and searching were impossible, one would intuitively anticipate many of the classic search procedures to permit $O(\log\log N)$ or better time improvements when their use of conventional dynamic search trees is simply replaced by the faster underlying data structures made theoretically possible by new advances in data structure theory.

This article will illustrate several examples of such improvements. Most of these improvements will use a data structure, called the q-heap, as an intermediate device to speed up the search methodology. Q-heaps were introduced in [26] as a vehicle for solving the minimum spanning tree problem in linear time. However, they also have many other applications. Q-heaps will be shown in this article to improve many other classic searching problems.

The particular examples and new results we establish are listed at the bottom of this paragraph. None of the so-called improvements in this list are practical improvements because the coefficients associated with their asymptotic changes are undesirably large. However, item 1 below (dynamic universal hashing) is a foundational problem in computer science. All the other topics already appear (in some form) in volumes 1 and 3 of Mehlhorn's textbook [33, 34] as well as in many other textbooks [23, 27, 39]. Thus our improvements are very germane to a two-semester course on general algorithms and computational geometry. The six topics below are only intended as a representative sample to illustrate what can be done theoretically (albeit

*Received by the editors June 9, 1997; accepted for publication (in revised form) March 24, 1998; published electronically January 11, 2000. A preliminary version of this paper [53] appeared as *Applications of the fusion tree method to computational geometry and searching*, in Proceedings of the 3rd ACM-SIAM Symposium on Discrete Algorithms, SIAM, Philadelphia, PA, 1992, pp. 386–395. This work was partially supported by NSF grants CCR 9302920 and CCR 9902726.

not practically) when fusion trees and q-heaps are applied to several problems:

1. A variant of dynamic hashing where each lookup, insertion, and deletion respects an $O(1)$ time bound with a probability exceeding $1 - o(N^{-(\log N)^K})$, for any arbitrary constant $K > 0$. (This result is a significant improvement over Dietzfelbinger and Meyer auf der Heide's universal hash scheme [22]. It will probably be the most noteworthy result of this paper because hashing is one of the basic operations studied in computer science. The improvement is based on combining the fusion-tree formalism with some of Siegel's theorems [42] about universal hashing.)
2. An improved version of McCreight's priority-search trees [35] that reduces the worst-case dynamic time performance to $O(\log N / \log \log)$ can search a set of N rectangles and output all K intersections among this set in time $O(K + N \log N / \log \log N)$. See Mehlhorn's textbook [34] for a concise description of priority-search trees.)
3. A related $\log \log N$ improvement of Chazelle's $O(N \log^{d-1} N / \log \log N)$ space data structure [16] that performs the reporting version of d-dimensional orthogonal range queries in time $O(\log^{d-1} N / \log \log N + K)$, where K is the number of elements outputted.
4. For any dimension $d \geq 2$ and any $p \geq d-1$, it will be possible to construct an $O(N \log^p N)$ space structure that supports an $O\{ (\log N / \log \log N)^{d-1} \}$ time for executing the aggregate version of orthogonal range queries. (Section 6 will explain how there are at least certain perspectives where this combination of time and space can be viewed as optimal.)
5. An improved variant of Van Emde Boas trees [48, 47, 28] that has a somewhat improved memory space.
6. A $\log \log N$ speedup of the Bentley–Shamos linear space method [10, 14] that calculates a set of N d-dimensional ECDF statistics in a time asymptote of $O(N \log^{d-1} N / \log \log N)$. (The acronym ECDF is an often-used abbreviation for "empirical cumulative distribution function.")

Each of the results above will employ the q-heap data structure from [26]. Section 9 will briefly illustrate several further examples of algorithmic problems whose performance can be improved with merely a faster sorting algorithm. In particular, such problems can have their runtimes improved by either the Fredman–Willard sorting procedure or by the further subsequent improvements of this procedure that have been proposed by Andersson [4], Andersson et al. [5], and Thorup [44, 46].

We do not believe that any of the six sample topics mentioned in the preceding paragraph are the main point. Rather the key question is how many other well-known results in computer science can undergo a similar theoretical (albeit perhaps impractical) asymptotic improvement when some type of application of fusion trees, q-heaps and their generalizations are employed [25, 26]? For instance, Thorup recently discovered a worst-case linear-time algorithm for solving Dijkstra's single source shortest path (SSSP) problem with a method that uses some of the constructs of [26] in one of its main interim steps. In the present article, we focus mostly on a moderately narrow bandwidth of problems, drawn from computational geometry and information retrieval theory, simply because such problems reflect the author's particular expertise and knowledge. However, it will become apparent to the reader who examines our six sample problems in the context of the expanding literature [1, 2, 3, 4, 5, 6, 7, 8, 9, 11, 15, 25, 26, 36, 37, 40, 41, 43, 44, 45, 46] that there are surely many other problems that can undergo theoretical (although often not practical) improvements when some type of variant of fusion tree is present.

Thus our goal in this article will not be exclusively to address the six sample problems mentioned. Sections 2, 3, and 4 are written so that they can be understood by a reader who is unacquainted with both fusion trees and computational geometry. Their goal will be to provide such a reader with an intuitive feel for this subject, ending with a very curious example about hashing. Our more specialized discussion appears in sections 4 through 9. They focus mostly around computational geometry and Van Emde Boas trees.

2. Literature survey. We will use largely the same notation and computational model that appeared in the articles [1, 2, 3, 4, 5, 6, 7, 8, 9, 11, 15, 25, 26, 36, 37, 40, 41, 43, 44, 45, 46]. A word is assumed to consist of b bits, and each key shall be assumed to be a fixed point integer fitting into one word. The instruction set available to the computer will be arithmetic, bitwise logical, and comparison operations on b-bit words. The integer N will denote the size of the database we search. It will be assumed that $b \geq \log_2 N$ since otherwise our main memory search structures would not even have a sufficiently large word length to store the addresses of the N objects that are stored in the computer's main memory bank. The runtime of our algorithm will be viewed as a quantity $F(b, N)$. Usually it has not been done, but most of the algorithms of [1, 2, 3, 4, 5, 6, 7, 8, 9, 11, 15, 25, 26, 36, 37, 40, 41, 43, 44, 45, 46] can be trivially generalized to common floating point representations of real numbers.

The first surprising article about fast dynamic tree operations was Van Emde Boas's data structure [48], which had an $O(\log\log U)$ worst-case retrieval, insertion, and deletion time for a data structure using $O(\ U \ \log\log\ U\ )$ space to represent a set of elements from the universe $0, 1, 2, \ldots, U$. The space was further compressed by Van Emde Boas to $O(\mathrm{U})$ in [47]. (One can also find a further discussion of the implications of Van Emde Boas trees and their variants in, for instance, [28, 29, 30, 31, 49, 50].) Since $b = \log U$, one can think of Van Emde Boas's algorithm as having an $O(\ \log\ b\ )$ time. Unless b is a very large number, this time is better than the conventional $O(\log N)$ balance tree time.

The first contribution of Fredman and Willard's fusion trees [25] was that they established a sorting time $F(b, N)$ with a worst-case bound $O(N \log N/ \log\log N)$ for an $O(N)$ data space structure (regardless of b's and N's values). This was the first method to obtain an $o(N \log N)$ time for sorting using what Andersson et al. [5] later called a "conservative method" for measuring computing costs. Fusion trees also provided an $O(\log N/ \log\log N)$ worst-case and $O(\sqrt{\log\ N})$ randomized time cost for performing standard balance-tree and search-and-update operations in an $O(N)$ space structure. A cousin of the fusion tree, called the q-heap, can bring dynamic balance-tree search, insert, and delete worst-case times down to an $O(1)$ asymptote provided the relevant set has a PolyLog(N) size and one has access to an $o(N)$-sized lookup table. Q-heaps were introduced in [26] as a vehicle for devising a worst-case linear time algorithm for the minimum spanning tree problem.

One open question raised by Fredman and Willard's original paper [25] was whether or not one could achieve an $O(\sqrt{\log\ N})$ worst-case time cost for performing standard balance-tree search-and-update operations in an $O(N)$ space structure. Such a question was naturally pressing because Fredman and Willard had indeed achieved an $O(\sqrt{\log\ N})$ worst-case time in the three cases where a static data structure had access to $O(N)$ space, a dynamic data structure was allowed more space, or where the environment was dynamic, the space was $O(N)$ but the time was now *randomized.* The final design of this revised and more idealized version of a fusion tree was done recently by Andersson [4]. He showed that $O(\sqrt{\log\ N})$ amortized and also that implicitly[1] worst-case times for performing standard balance-tree search-and-update operations were possible for strictly $O(N)$ space structures. His article explicitly uses all the functionality of the original fusion trees and adds to these a new memory compression method to achieve the $O(N)$ space.

Another open question raised by the discussion on fusion trees in [25] was whether the cost of sorting could be improved beyond the $O(N \log N/ \log\log N)$ worst-case and $O(N\sqrt{\log\ N})$ randomized times. This problem has been studied extensively by [1, 4, 5, 40, 44, 46], and the best combined results from this evolving literature are roughly that $O(N)$ space supports either a randomized time $O(N \log\log N)$ or a worst-case time $O[N(\log\log N)^2\ ]$ for sorting. In particular, the randomized problem was resolved by Andersson et al. [5] and Thorup [44], and the best worst-case sorting is due to Thorup [46].

Another recent direction of research has been the study of Dijkstra's SSSP problem. Thorup showed in [45] that it was possible to devise a fully $O(N)$ worst-case algorithm for constructing the SSSP. Most of Thorup's algorithm is unrelated to the prior Fredman–Willard fusion tree research, but he does use a q-heap data structure as one important subcomponent of his final data structure.

There are simply too many new ideas in the rapidly expanding literature [1, 2, 3, 4, 5, 6, 7, 8, 9, 11, 15, 36, 37, 40, 41, 43, 44, 45, 46] for us to describe all these results in full detail. Albers and Hagerup [1] have discussed parallel analogues of fusion tree sorting. (An important aspect of their work is that some of its ideas are essential for implementing the *nonparallel sorting* algorithms of [5].) Many lower bounds relevant to fusion-like data structures have been developed by Andersson et al. [6], Brodnik, Mitlersen, and Munro [15], Beame and Fich [9], Ben-Amram and Galil [11], Miltersen [36, 37]. Andersson [3], and Andersson, Miltersen, and Thorup showed in [7] that the Fredman–Willard fusion tree results could be extended to a data model using exclusively AC^0 instructions. Raman [40] and Thorup [43] have developed some interesting new priority queue data structures, which ultimately led Thorup to announce a linear algorithm [45] for Dijkstra's SSSP problem and a worst-case $O[N(\log\log N)^2]$ algorithm [46] for sorting.

It should be noted that while many of these articles improve upon the prior Fredman–Willard results with better upper bounds, a large number of these papers (such as, for example, [4, 45]) mention using particular parts of the Fredman–Willard data structure as working subroutines of their yet more refined algorithms. In essence what we will do in sections 4 through 8 of this paper is also employ such subcomponents of fusion trees to examine six other algorithmic paradigms.

It also should be mentioned that it is not entirely true that all aspects of research related to fusion trees are fully divorced from practical application. For instance, the discussion of AC^0 circuits by Andersson [3] and Andersson, Miltersen, and Thorup [7] could result in practical hard-wired algorithms. Also some of the engineering-grade sorting algorithms of Bentley and McIlroy [13] and P. McIlroy, Bostic, and M. McIlroy [32] are partly related to fusion tree research in that one part of their procedures breaks a larger problem into locally smaller problems with tiny constants.

[1]The relevant "worst-case" cost algorithm did not actually appear in Andersson's paper [4], but we think it should be fairly credited to Andersson because it is an easy extension of his amortization techniques combined with standard methods for converting an amortized optimizing algorithm into a worst-case control procedure. For instance, one could use techniques roughly similar to either our proof of Lemma 3.3 (see section 10) or methodologies of [52, 53] to easily transform Andersson's amortized optimizing algorithm into a worst-case controlling procedure.

It also should be mentioned that some of the older subcomponent data structures employed by the original fusion trees, such as perfect hashing, Van Emde Boas tree and fast tries [22, 24, 42, 47, 48, 49, 50] can be potentially pragmatic when used in a context *perhaps different from* that utilized by the fusion tree.

As we noted in section 1, our goal in the present article will be to consider six sample problems, which illustrate some types of theoretically feasible (although not necessarily practical) improvements that can result when the Fredman–Willard q-heap data structures are applied in various settings. In order to simplify the presentation, we will not require the reader to examine [26] or any other article that was mentioned in the preceding paragraphs of this literature survey. All the reader is required to know is that there is a *black box software package,* called the q-heap, that was proven in [26] to have the following characteristics.

THEOREM 2.1. *Suppose S is a subset of cardinality $M < \sqrt[5]{\log N}$ lying in a larger database consisting of N elements. Then there exists a q-heap data structure for representing S such that the q-heap uses $O(M)$ space and enables insertions, deletions, member, and predecessor queries into the subset S to run in constant worst-case time, provided access is available to a precomputed lookup table of size $o(N)$.*

The lookup table for q-heaps can be constructed in $O(N^c)$ time (for some small constant $c < 1$). The $o(N)$ space and preprocessing costs accrued to such lookup tables are an acceptably small and minor expense in most computing applications because they will have a large number of different q-heaps share access to one common search table. In other words, a large number of different minisets $S_1, S_2, \ldots, S_j$ will typically each have different q-heap data structures $Q(S_1)$, $Q(S_2), \ldots, Q(S_j)$, but they will share use of the very expensive common lookup table. This notion of sharing an expensive lookup table, jointly developed by Fredman and us in the context of two slightly different lookup schemes [25, 26], is perhaps the main intuitive reason one can improve the performance of such a large number of different computing tasks (using either the fusion trees or much of the subsequent literature).

We emphasize that this article has been organized so that the reader does not need to know what algorithm is actually contained in the "black box" of software of Theorem 2.1. It will matter not whether the software inside this curious black box is manufactured by some corporate giant, such as IBM, Microsoft, or NetScape, or by some financially stumbling computer company, called perhaps the NanoSoft Corporation$^{\text{TM}}$. Regardless of such details, our improvements over the prior literature's six sample problems will be easily comprehensible to the reader, as a theoretical family of algorithms, without knowledge of what lies inside the curious black box, inserted by the engineering staff of NanoSoft.

Indeed if I may drop the mild humor from the preceding paragraph, it makes a serious point. It is that one does not need to understand the details of the fusion procedures of [25, 26] to grasp the nature of our six sample problems. Thus, it is sufficient to view Theorem 2.1 as a black box of software. Our six sample problems are intended to motivate curiosity into the subject matter of [1, 2, 3, 4, 5, 6, 7, 8, 9, 11, 15, 25, 26, 36, 37, 40, 41, 43, 44, 45, 46] by illustrating the breadth of the improvements they make feasible.

Moreover, despite the perhaps impractical coefficients associated with most fusion-like algorithms, one enticing aspect of this subject is the long list of potential problems which can have some facet of their capacity undergo at least a theoretical mathematical improvement. The six sample problems examined in sections 4 through 9 of this paper and Thorup's recently announced linear solution to Dijkstra's SSSP problem

[45] are probably only a small sample of what can actually be done. For instance, the entire literature on fusion trees [1, 2, 3, 4, 5, 6, 7, 8, 9, 11, 15, 25, 26, 36, 37, 40, 41, 43, 44, 45, 46] seems to be relevant to lower bound theory because it shows that certain conjectured mathematical lower bounds, that had once looked very plausible, are in fact theoretically fallacious under some quite natural models of computation.

3. Corollaries to Theorem 2.1. This section will discuss two simple corollaries to Theorem 2.1, which will illustrate the main format in which we will apply Theorem 2.1. First we will introduce one useful lemma.

Lemma 3.1. *For simplicity, let us assume that $B > 16$. Consider a B-tree whose internal nodes have arity between $B/8$ and B, whose root has arity between 2 and B, and whose leaves store the data and each have the same depth. Suppose that searches, insertions, and deletions in such a tree of height h will have an $O(h)$ cost when no splits or merges occur, and the costs of splitting a node or merging two nodes is bounded by $O(B)$. Then regardless of the details of the structure of the node v, it is possible to devise an insertion and deletion algorithm for this tree that runs in amortized time $O(h)$, with the $O(h)$ asymptote using a constant that is independent of B.*

Our main interest in Lemma 3.1 will be when the q-heaps of Theorem 2.1 are the main organizing method for v's internal structure.

Proof. We will only briefly sketch the proof of Lemma 3.1. Consider the natural B-tree insertion/deletion algorithm that merges a nonroot internal node v with its sibling w if v's arity is less than $B/8$, that splits a node into two equal halves whenever its arity exceeds B, and that makes the child of a tree root into the new root if the preceding operations caused the old root to have only one child. (Sometimes a merge will immediately trigger a split into two equal-size halves because a node becomes too large after the merge operation.) It is easy to devise an accounting function that shows there will be only an amortized number of $O(1/\mathrm{B})$ splits and merges in a tree of height h. (This is essentially because nodes of height j will have an amortized frequency of $O[\ (8/B)^{j+1}\ ]$ of splitting and merging.) Hence the splits and merges will have an $O(1)$ amortized cost. This shows that the total cost of insertions and deletions is $O(h)$, since splitting and merging are the only costly operations outside a general $O(h)$ searching cost. □

Lemma 3.1 also holds if splits and merges have a cost proportional to the number of leaf descendants of a node. (Multibranching B-trees with such properties were presented in [51].) However, such trees are not relevant to our present discussion.

We will frequently employ versions of the B-tree structure of Lemma 3.1 where the branching factor $B = \sqrt[5]{\log N}$ and where a q-heap is used to format the structure of the individual internal nodes. This tree will have a height, search time, and update time proportional to $1 + \log M / \log\log N$ when it stores M elements. The term q*-heap will refer to such a modified B-tree form of q-heap. From the combination of Lemma 3.1 and Theorem 2.1, we thus have the following corollary.

Corollary 3.2. *Assume that in a database of N elements, we have available the use of precomputed tables of size $o(N)$. Then for sets of arbitrary cardinality $M \leq N$, it is possible to have available variants of q*-heaps using $O(M)$ space that have a worst-case time $O\{\ 1 + \log M\ /\ \log\log N\}$ for doing member, predecessor, and rank searches, and that support an amortized time $O\{\ 1 + \log M\ /\ \log\log N\}$ for insertions and deletions.*

The proof of Corollary 3.2 is an immediate consequence of Lemma 3.1 and Theorem 2.1 because the data structure of Corollary 3.2 simply consists of a B-tree storing M records whose internal nodes are q-heaps, and which has a branching factor

$B = \sqrt[5]{\log N}$.

LEMMA 3.3. *Consider again a B-tree data structure that satisfies the hypothesis of Lemma* 3.1. *Then it is possible to develop a more elaborate version of the insertion and deletion algorithms of Lemma* 3.1 *so that the insertion or deletion of a leaf-record has an $O(h)$ worst-case (rather than amortized) cost.*

The previous literature has illustrated many examples of amortized optimization algorithms which can also guarantee worst-case time, if their procedures are made somewhat more elaborate. A similar type of proof of Lemma 3.3 is sketched in the appendix (section 10). The reason we postpone the proof of Lemma 3.3 until the appendix is that its worst-case control procedure has a poor coefficient, and the techniques needed to transform the amortized time-optimizing algorithm of Lemma 3.1 into a worst-case controlled procedure is very similar to what often appears in the previous literature.

COROLLARY 3.4. *The data structure in Corollary* 3.2 *can be improved so that its predecessor-query, member-query, insertion, and deletion operations all have a worst-case complexity* $O\{ 1 + \log M / \log\log N\}$.

Once again, no proof is needed to verify Corollary 3.4. It is an immediate consequence of Lemma 3.3 and Theorem 2.1 because its data structure simply consists of a B-tree storing M records whose internal nodes are q-heaps and which has a branching factor $B = \sqrt[5]{\log N}$. We will use the term q*-heap to refer to the data structure of either Corollaries 3.2 or 3.4 because they are essentially the same concept, except that one uses an amortized-optimizing algorithm and the other employs a slightly more elaborate worst-case control. We close this section by emphasizing that the q*-heaps of Corollaries 3.2 and 3.4 are related to q-heaps and AF-heaps in [26]. The latter data structures, originating in our joint paper with Fredman, stimulated Corollaries 3.2 and 3.4.

Finally, we point out that there are roughly two types of applications of q*-heaps that are explored in this paper and the previous literature. One type of application is based on using the q*-heap to speed up an algorithm by essentially reducing the height of a tree. This method is feasible because the q*-heap can often allow us to traverse in $O(1)$ time tree nodes which have roughly PolyLog(N) arity. An alternate approach is to forgo making any use of the q*-heap until one has essentially reduced an initial problem of size N to one of roughly size $(\log N)^c$ for some fixed constant $c > 0$, at which time the final processing step can be made to run in $O(1)$ time. In essence, the first method is used by us in sections 5 through 7 of this paper, while the second was used by Fredman and Willard [26] and Thorup [45] and will be again used by us in section 4 of this paper.

4. Hashing.

Most of the sample problems discussed in this article come from computational geometry. However, this article will begin by considering universal hashing because our proposed improvement has a short description that contains one very pretty idea. It will be unnecessary for the reader to examine the prior literature on hashing before examining this section. Our discussion, although only an abbreviated outline, should be sufficiently self-contained for the reader inexperienced with universal hashing to still appreciate the gist.

Dietzfelbinger and Meyer auf der Heide [22] have developed a universal hashing scheme where each insertion, deletion, and lookup will always have a probability exceeding $1 - o(N^{-k})$ of running in constant time (for an arbitrary $k > 0$). This section will illustrate how q*-heaps enable us to develop a quite different alternate structure that provides a better probability $1 - o(N^{-(\log N)^k})$ for these three operations to run in constant time (where $k > 0$ is again an arbitrary constant, and it is assumed again that the universe size $U <$ Polynomial(N)).

The data structure for achieving this functionality rests on two concepts. First, it was noted by Corollary 3.4 that the q*-heap provides a formalism to perform constant time insertions, deletions, and retrievals on any set of PolyLog(N) cardinality. Now, consider a hash table, with N addressable buckets for representing a time-varying set of cardinality $\leq N$, which has no overflow mechanism, and which simply stores in a q*-heap all the records that are mapped into a common bucket address. This hash table will thus assure that a bucket can be searched in $O(1)$ time provided it stores no more than PolyLog(N) elements.

The pleasing point is that the Poisson probability distribution will assign each bucket a probability less than $o(N^{-(\log N)^{k+1}})$ for containing more than $(\log N)^{k+2}$ elements. Thus, there will be only this tiny probability that a single one of our N buckets will store no more than $(\log N)^{k+2}$ elements. Thus for an arbitrary constant k, there is the same probability greater than $1 - o(N^{-(\log N)^k})$ that a constant time bound on searches, insertions, and deletions will hold *within all N buckets simultaneously!*

Another pleasing point is that by applying some theorems of Siegel [42], we can strengthen in a straightforward manner the Poisson probability analysis (above) into a formal theorem about classes of universal hash functions. To do so, we assume that there is a prespecified constant N bounding the maximal size of the time-varying set stored in the hash table and that the universe size satisfies $U \leq$ Polynomial(N). Then Siegel's universal hash functions [42] will require only N^ϵ words to form a class satisfying his $(\log N)^k$-wise independence property, for any constant k. This fact immediately implies that the Poisson distribution is a sufficiently accurate probability predictor for this *universal hash class* to imply the same claimed $1 - o(N^{-\text{PolyLog}(N)})$ probability that each search and update operation will run in constant time. (We omit the further details because they are basically a routine hybridized application of Siegel's quite sophisticated formalism [42] in the context of the data structure outlined in the prior paragraph of this section. The basic point is thus that *universal hash classes* are assured by Siegel's analysis to operate in the same manner as the simpler analysis of randomized Poisson probability distributions from the prior paragraph of our discussion.)

The three-paragraph passage above is obviously more complicated than it appears because it cannot be fully formalized without duplicating both Siegel's full formalism [42] and the full proof [26] that a q-heap data structure satisfies the black box properties of Theorem 2.1. The reason the preceding discussion is significant is that it uses essentially the same computing model as Dietzfelbinger and Meyer auf der Heide [22] had used for their universal hashing scheme. Our probability of constant time operations is an $1 - o(N^{-\text{PolyLog}(N)})$ magnitude, which is better than the probability of the form found in [22] $1 - o(N^{-k})$.

5. Priority-search trees. This section will examine McCreight's priority-search tree in considerable detail. This search problem will offer an excellent case study illustrating how a data structure can undergo theoretical (although possibly impractical) improvements when q-heaps are used to streamline it. McCreight's priority-search trees are described by both his journal article [35] and by Mehlhorn's textbook [34]. We will assume that the reader has examined at least one of these sources when we present our $\log\log N$ improvements. The second half of this section will also explain how to produce similar theoretical (but again not practical) improvements upon one of Chazelle's orthogonal range query structures in [16].

Given a set S of N points on the xy-plane, define Query (a, b, c) to be a request for the subset of S that satisfies

$$a < x < b \;\wedge\; y > c. \tag{5.1}$$

The McCreight priority-search trees can perform this operation in $O(\log N + K)$ time (where K is the size of the output). It supports $\log N$ insert and delete operations and uses $O(N)$ space.

The fusion priority-search tree described here will be a variant of the B-tree, with a branching factor B essentially storing information about some subset of points whose x-value lies in some line segment $[A_v,\ B_v)$, whose "range" is implicitly defined by the B-tree's stored keys. This line segment will be denoted as Range(v), and Set(v) will denote the subset of points from S whose x-coordinate lies in this interval. (This notation thus implies that if $w_1, w_2, \ldots, w_n$ are the children of v then the union of Range(w_1), Range$(w_2), \ldots,$Range(w_n) will equal Range(v), and similarly the union of Set(w_1), Set$(w_2), \ldots,$Set(w_n) will equal Set(v).)

Following McCreight's example [35], each node v will store the particular ordered pair (x, y) from SET(v) which has maximal y-value but is not stored in any ancestor of v. This ordered pair is denoted as MAX(v). The unique aspect of the fusion priority-search tree is that it will contain the following three additional fields:

1. KEYS(v): This will be a q*-heap describing the keys separating the ranges of v's children.
2. TOPS(v): This will be a second q*-heap that stores the y-coordinates of the MAX elements belonging to v's children.
3. FUSEDTOPS(v): Let $y_1,\ y_2, \ldots, y_B$ denote the distinct y-values stored in TOPS(v) and r_i denote the rank of y_i in this subset. Then FUSEDTOPS(v) is the ordered tuple $(r_1,\ r_2, \ldots, r_B)$. Since FUSEDTOPS(v) can be encoded in $B\ \log\ B\ \leq\ O(\sqrt{\log\ N}\cdot\ \log\ \log\ N)$ bits, it can fit into one word of memory. (Recall that section 2 indicated that we always employ words which have a bit length $\geq \log N$.)

Some notation is helpful to describe the search algorithm for the fusion priority-search tree. Given the ordered triple (a, b, c) associated with the query (5.1), we say a node v is a

(i) *left borderline* node if Range(v) intersects a but not b.
(ii) *right borderline* node if Range(v) intersects b but not a.
(iii) *double borderline* node if Range(v) intersects both a and b.
(iv) *subsumed* node if Range(v) is contained within the interval (a, b)
(v) *pivotal* node if v is both subsumed and a child of a double borderline node.

Since a fusion priority-search tree will have a $O(\log\ N/\log\ \log\ N)$ height and a $\sqrt{\log\ N}$ branching factor, it will have no more than $O(\log\ N/\log\ \log\ N)$ borderline and pivotal nodes. (This is because there can never be more than $\sqrt{\log\ N}$ pivotal nodes in a tree with $\sqrt{\log\ N}$ branching factor.) All these pivotal and borderline nodes can be found in $O(\log\ N/\log\ \log\ N)$ time by a trivial application of the "q*-heap" search procedure of Corollary 3.2 (see footnote[2] for the formal details). The first step of our retrieval algorithm will consist of such a search for the borderline and pivotal nodes. The second step of the algorithm of query (5.1) will examine the MAX(v) elements of the nodes just visited to check whether they satisfy the query. It will output those elements which do.

Each remaining element in S that satisfies query (5.1) will be a MAX(v) element for some subsumed node v. Since we desire to make our algorithm run in time $O(\ \log N\ /\ \log\log N\ \ + K)$ (where K is the size of the output), it is necessary to make the last step of our search find these elements in time proportional to $O(\ \log N\ /\ \log\log N\ + K)$. (This is quite a tight constraint that we are required to satisfy. It will require some care to achieve this objective.)

To obtain this run time, the third step of our search will repeatedly invoke a subroutine called LOOKAHEAD. Upon visiting a node v, this procedure will determine in constant time precisely which of v's children w are *subsumed* nodes that *simultaneously* store an element in their MAX(w) fields that satisfies the query (5.1) *before it actually visits these elements!* (It is *extremely* delicate and tricky to do this search in precisely $O(1)$ time because query (5.1) is a query with three inequality constraints rather than the usual two inequalities associated with a conventional one-dimensional range query condition. Since the tree node v will have $\sqrt{\log\ N}$ children, the procedure LOOKAHEAD must make strong use of the q*-heap property to determine *in constant time* which of these $\sqrt{\log\ N}$ children contain data of interest *before they are even visited.)* The LOOKAHEAD procedure is easiest to describe if we let

(i) J_1 denote an integer indicating how many of v's children are subsumed,

(ii) J_2 denote an integer indicating how many y-values in TOPS(v) are greater than c,

(iii) J_3 denote an integer that equals zero if v is a left borderline node, one if it is a right borderline node, and two if it is subsumed.

Each of these three integers can be calculated in constant time, since J_1 can be discovered during a q*-heap search of the KEYS(v) field, J_2 discovered by a similar search through TOPS(v), and J_3's value will be known by the algorithm as soon as it enters the node v.

Now consider the 4-tuple $J^*\ =\ (J_1,\ J_2,\ J_3,\ \text{FUSEDTOPS}(v))$. This tuple can be encoded in $O\ (\sqrt{\log\ N}\ \cdot\ \log\ \log\ N)$ bits. Consequently, we can store all the possible values for this tuple in a precomputed lookup table of size $o(N)$, where each table entry shall essentially encode a list of which subsumed children w of v have MAX(w) data elements satisfying query (5.1). (More precisely, the particular entry in our table that is indexed by the 4-tuple $J^*\ =\ (J_1,\ J_2,\ J_3,\ \text{FUSEDTOPS}(v))$ can be thought of as containing a list of integers, $I_1,\ I_2,\ldots,I_t$, such that the next nodes that should be visited by our top-down search are v's I_1th, I_2th$,\ldots,I_t$th children.) Since the lookup table can be built in $o(N)$ preprocessing time and occupies $o(N)$ space, its presence does not increase the data structure's overall memory space and

[2]The key idea behind this fast search procedure is that the q*-heap property allows us to trivially organize a node v's data structure so that only $O(1)$ time is needed to find the children of v that are borderline when v is a borderline node. Therefore by a trivial repeated iteration of this functionality over the $O(\log N/\log\log N)$ different height levels, we can trivially find all the $O(\log N/\log\log N)$ borderline nodes in $O(\log N/\log\log N)$ time. Moreover, since the fusion priority-search tree has a $\sqrt{\log\ N}$ branching factor and since all its pivotal nodes will be the children of that particular double-borderline node which has the greatest depth, the same procedure will obviously only need $\sqrt{\log\ N}$ time to find the $\sqrt{\log\ N}$ or fewer pivotal nodes that exist. Hence, we have displayed an $O(\log N/\log\log N)$ time procedure for finding all the pivotal and borderline nodes.

preprocessing time. But yet it enables LOOKAHEAD to determine in $O(1)$ time which of v's $O(\sqrt{\log N})$ children are subsumed nodes having MAX-values satisfying the query even before the time these elements are actually visited!

The key point about the preceding paragraph's lookup table is that its $o(N)$ space and preprocessing costs are insignificant quantities because all the nodes in the fusion priority-search tree will *use one common lookup table,* rendering its cost an acceptably small and trivial burden.

Define EXPLORE(p) to be a three-part procedure that first visits the node p, then invokes LOOKAHEAD to discover which children q of p are subsumed nodes with Max(q) satisfying (5.1), and finally recursively calls itself to explore these children. The final step of the search algorithm of query (5.1) will invoke EXPLORE to probe the subtrees descending from the pivotal and the left and right borderline nodes. Each subsumed node whose MAX(v) element satisfies (5.1) will lie in one such subtree, and all its ancestors in this subtree will also have their Max elements satisfy (5.1). These two conditions guarantee that EXPLORE will correctly find all the nodes whose Max elements satisfy (5.1). Moreover, EXPLORE requires only $O(\log N/\log\log N + K)$ time to process the K subsumed nodes it finds because of LOOKAHEAD's $O(1)$ search property, combined with the fact that there are only $O(\log N/\log\log N)$ borderline and $O(\sqrt{\log N})$ pivotal nodes generated by the query (5.1). Hence, we have shown that all three steps of the retrieval algorithm of query (5.1) run in time $O(\log N/\log\log N + K)$.

Finally, we will show how to execute insertions and deletions in the preceding data structure in amortized time $O(\log N/\log\log N)$. We assume $B = \sqrt{\log N}$ and employ a fusion priority-search tree where each node has arity between $B/8$ and B. We will use the algorithm of Lemma 3.1 for rebalancing the B-tree. It is immediate that constant time insertion and deletion operations are feasible in the KEYS(v) and TOPS(v) fields because they are q*-heaps with $O(1)$ height. The similar $O(1)$ algorithm to update FUSEDTOPS(v) consists of a two-step procedure that first searches TOPS(v) to determine in $O(1)$ time the rank of the particular element y_i (that is to be inserted or deleted) and then uses this rank, the integer i, and the old value of FUSEDTOPS(v) to determine FUSEDTOPS(v)'s new value via table lookup. (Once again, we note that the storage and preprocessing costs of the lookup tables are negligible expenses throughout this paper, since they are $o(N)$ costs.)

The natural algorithm for modifying a fusion priority-search tree of height h will perform $O(h)$ search and update operations into the KEYS(v), TOPS(v), and FUSEDTOPS(v) fields (plus some minor bookkeeping work) when an insertion or deletion does not trigger a node split or merge. It will thus consume $O(h)$ time when a split or merge does not occur. Each split and merge will consume $O(B)$ time. This data structure thus satisfies requirements of Lemma 3.1. Since $h < O(\log N/\log\log N)$, its amortized cost for insertions and deletions is thus $O(\log N/\log\log N)$, by Lemma 3.1. (Once again by Lemma 3.3, a strengthened version of this algorithm can also guarantee worst-case insertion and deletion time.)

This paragraph will explain how to use the fusion trees to improve one of Chazelle's data structures. His article [16] devised a data structure that occupies $O(N \log^{d-1} N/\log\log N)$ space and allows d-dimensional orthogonal reporting queries to run in time $O(\log^{d-1} N+K)$, where K is the number of elements reported [16]. The new fusion priority-search trees allow us to revise Chazelle's orthogonal range query data structure so that a theoretically faster (but impractical) $O(\log^{d-1} N/\log\log N+K)$ reporting time prevails in the same memory space. For the case of the dimension

$d = 2$, the new data structure and algorithm will be the same as Chazelle's except for the following four changes:

1. Wherever Chazelle's data structure had employed McCreight's priority-search trees, the new data structure will obviously utilize the new $\log \log N$ faster fusion priority-search trees.
2. The branching factor of the base tree nodes of [16] will be changed from $\log N$ to $\log N/\log\log N$, thereby enabling one to traverse the set of children of a particular node in $\log \log N$ faster time.
3. Wherever an $O(\log N)$ time fractional cascade was previously employed, the new data structure will use a revised fractional cascade that has a fusion tree rather than a binary search tree as its index, thereby speeding up the index search by a $\log \log N$ factor.
4. The $O(\log N)$ time top-down tree walk in the base tree of [16] will be speeded up by a $\log \log N$ factor by having a q*-heap index the $\log N/\log\log N$ children of each node in this tree. (This is possible to do because the base tree has height $O(\log N/\log\log N)$ and every node has an arity $\log N/\log\log N$. Thus, using the q*-heap data structure of Corollary 3.2, each such node can then be traversed in constant time. Therefore, the top-down tree walk will run in time $O(\log N/\log\log N)$.)

It is immediate that this revision of Chazelle's data structure supports two-dimensional orthogonal reporting queries in time $O(\log N/\log\log N \ + \ K)$. The d-dimensional reporting time of $O(\log^{d-1} N/\log\log N \ + \ K)$ in space $O(N \ \log^{d-1} N \ / \ \log \ \log \ N)$ follows from Bentley's method of reducing d-dimensional queries to two-dimensional ones [10]. (All these results are obviously theoretical but not practical modifications of the procedure of [16].)

The McCreight and Chazelle versions of priority-search trees have many uses in computer science [35]. The fusion priority-search trees pertain to all such problems. For example, one can search a set of N rectangles and output all the K intersections among this set in time $O(K \ + N \ \log N/\log \ \log \ N)$.

6. Aggregation queries. Let S denote a set of points in d-dimensional space. Each point-record r shall contain a special field denoted as VALUE(r). Then a d-dimensional aggregation query is defined as a d-tuple $(A_1,\, A_2, \ldots, A_d)$, representing a request to calculate $\sum$ VALUE(r) for those elements satisfying

$$KEY \cdot 1 \ < \ A_1 \ \wedge \ KEY \cdot 2 \ < \ A_2 \ \wedge \ \cdots \ \wedge \ KEY \cdot d \ < \ A_d. \tag{6.1}$$

This section will explain how to perform query (6.1) in time $O\,\{\,(\log \ N/\log \ \log \ N)^{d-1}\,\}$ when the data structure uses space $O(N \ \log^p N)$ with $p \ > \ d-1$. The last paragraph of this section will define a certain sense in which our proposed algorithm can be regarded as optimal.

Our data structure will be a hybridization of fusion trees with the overlapping K-ranges of [12] and fractional cascading [19]. For simplicity, we will restrict our attention to the case of the dimension $d = 2$. The data structure will be a variant of the range tree whose "base" section T will be a tree with $O(\log \ N/\log \ \log \ N)$ height, PolyLog (N) branching factor and which stores the elements of S at the tree's leaf level in order of increasing KEY·1 value. Each internal node v of T will contain B auxiliary fields, denoted as AUX$(v,1)$, AUX$(v,2),\ldots,$AUX(v,B). The field AUX(v,i) will describe the leaves descending from v's left-most i sons arranged in order by increasing KEY·2 value. Let $r_1 \ r_2 \ r_3 \ldots$ be the elements in AUX(v,i), so arranged in order *of increasing* KEY·2 value. Then AUX(v,i) will also store the aggregate quantities SUBTOTAL$(v,i,j) = \sum_{k=1}^{j}$ VALUE(r_k), for each $j \leq$ CARDINALITY(AUX(v,i)).

A two-dimensional orthogonal wedge query (a,b) is a request to retrieve $\sum$ VALUE(r) for the subset of elements from S satisfying

$$(6.2) \qquad KEY \cdot 1 < a \ \wedge \ KEY \cdot 2 < b.$$

It was implicit from the prior literature that the data structure from the previous paragraph could answer such a query by retrieving $O(\log N/\log \log N)$ subtotal counters. However, the difficulty was that there was no previously apparent computation method to find these counters in time $O(\log N/\log \log N)$.

This difficulty will be resolved by assigning a q*-heap to each node v in the base tree. The q*-heaps will enable a search algorithm to traverse each base tree node in constant time and locate in $O(\log N/\log \log N)$ time the $O(\log N/\log\log N)$ auxiliary fields that will need to be probed. The root's auxiliary field will be searched next in $O(\log N/\log \log N)$ time by using a fusion tree to index it. The remaining AUX-fields can be searched in constant time per field if we employ fractional cascading [19] to interconnect these fields. This algorithm easily generalizes to all dimensions d $O\{(\log N/\log\log N)^{d-1}\}$ search algorithm for doing query (6.1) in $O(N \cdot \log^p N)$ space, for any $p > d-1$.

Finally, we wish to define a partial sense in which the algorithms proposed in this section can be regarded as optimal. Let the notational symbol $L_d(N)$ denote the mathematical quantity of $(\log N/\log \log N)^{d-1}$. Chazelle and Yao have studied time-space tradeoffs for aggregate queries using what is called the semigroup model of computation. Their goal has been to determine how many semigroup addition operations are needed to perform a query similar to (6.1) or (6.2). If a d-dimensional data structure occupies $O(N \cdot \log^p N)$ space for any $p > d-1$, they have determined that the asymptote $L_d(N)$ constitutes both an upper and lower bound for the number of required semigroup addition operations. (Essentially, Yao published this result for the dimension $d = 2$ in 1985 [55], and a more recent 1990 *Journal of the ACM* article by Chazelle generalized Yao's result for higher dimensions [17].)

Our computational model for doing the queries (6.1) or (6.2) is similar to that used by Chazelle and Yao, *except that we wish to be more conservative* by charging one unit cost for *both* each semigroup addition operation *as well as* for each other type of standard machine-language computer operation *that is needed to locate these semigroup* aggregate counters. From the earlier work of Chazelle and Yao, we know that this model of computation certainly cannot calculate aggregates in a time better than their lower bound asymptotes of the form $L_d(N)$. The pleasing aspect of the algorithm outlined in this section is that the upper bound on its runtime will match the Chazelle and Yao lower bounds up to a constant factor when we assume the computer's machine language commands include the standard machine-language operations recognized by the literature on fusion trees.

7. Compressed Van Emde Boas trees. Van Emde Boas trees provide a facility to dynamically perform predecessor queries among a set S of N keys chosen from the universe $0, 1, 2, \ldots, U-1$ in worst-case time $O(\log \log U)$. The early variants of this data structure [48] had used $O(U)$ space, and Johnson [28] showed how the same result could also hold in $O(N \cdot U^{\epsilon})$ space. The y-fast tries [49] with their modifications implied by Dietzfelbinger et al. [21] establishes a $\log\log U$ time in $O(N)$ space, but they establish this speedup in an amortized expected rather than a strict worst-case model of time. This section will show that a $\log\log U$ combination of worst-case retrieval, insertion, and deletion times are possible in $O(N)$ space provided that $N \geq U/(\log\ U)^{c\cdot\log\ \log\ U} = U\cdot 2^{-c(\log\ \log\ U)^2}$, for any fixed constant c. Without the use of the q-heap, the same $O(\log\log U)$ time in $O(N)$ space would only be possible when $N \geq U/\text{PolyLog}(U))$.

Let us begin by explaining how Van Emde Boas would derive the result in the sentence above. There are two published variants of Van Emde Boas trees [48, 47]. The first variant [48] provides dynamic worst-case times $O(\log\log U)$ in space $O(U\log\log U)$. For some fixed constant K, the second variant of Van Emde Boas trees [47] divides the initial set S into U/K subsets. Each subset S_i of the larger set S is associated with an integer $i \leq U/K$, and S_i describes the subset of S whose key values lie between $(i-1)K$ and $iK-1$. Let Z denote the set of integers i whose S_i sets are nonempty. Van Emde Boas's second data structure [47] was a two-part structure whose upper fragment uses his earlier data structure to index the set Z and whose lower fragment is a forest of conventional balanced trees, where there is one tree representing each set S_i. Van Emde Boas [47] noted this structure would have $O(\log\log U + \log K)$ worst-case search, insertion, and deletion times, and it would use space $O[\ N + (U\log\log U)/K\ ]$ (where N is the cardinality of the set S). Such constraints allow one to obtain $O[\ \log\log U\ ]$ worst-case times for the basic retrieval and update operations over an $O(N)$ space structure when N satisfies $N \geq U/\text{PolyLog}(U))$ (assuming we set $K = U/N$).

Q*-heaps allow us to improve the result above. In particular the above retrieval and update times can be reduced to $O(\ \log\log U + \log K\ /\ \log\log N)$ balance trees in the preceding data structure. Then the revised Van Emde Boas tree will allow an $O[\ \log\log U\ ]$ worst-case time for the basic retrieval and update operations over an $O(N)$ space structure when N satisfies the much weaker constraint $N^{-c(\log\ \log\ U)^2}$ for any arbitrarily chosen constant c (assuming we again set $K = U/N$).

8. The ECDF calculation. The section will describe a new algorithm to calculate a set of N d-dimensional ECDF statistics [10, 14] in linear space and time $O(N\log^{d-1}N/\log\log N)$. This result is a $\log\log N$ improvement over the Bentley [10] and Bentley–Shamos ECDF algorithm [14]. The last paragraph of this brief section will explain why we conjecture our algorithm is optimal at least for the dimension $d = 2$.

Since our solution to the ECDF problem of [10, 14] will employ a data structure that naturally combines fusion trees with an earlier data structure devised by Dietz [20], we will provide only an abbreviated description of the new ECDF algorithm. Dietz developed an O(U) space data structure for representing any subset of the integers $0, 1, 2, \ldots, U$ which supports $\log U/\log\log U$ time for dynamic rank queries.

Consider a set S of N points in the plane. Let $x(p)$ and $y(p)$ denote the x and y coordinates of a point $p \in S$. Let $r(p)$ denote the rank of $x(p)$ among the set of x-coordinates. The first two steps of the new 2-dimensional ECDF algorithm will sort the set S twice (by x and y coordinate) and calculate the value of $r(p)$ for each $p \in S$. The third step will employ Dietz's data structure, where we now set the universe size $U = N$. It will take the sorted list that enumerates the elements of S *by increasing y-value* and insert the $r(p)$ attributes of these elements *one by one in order by their increasing y-value* into a Dietz data structure (whose search keys are its r-elements). Just before the insertion of $r(p)$, the algorithm will calculate the quantity $e(p)$ that indicates $r(p)$'s rank *relative to the previously inserted* r-elements. The three steps of this algorithm run in $O(N)$ space and $O(N\log N/\log\log N)$ time. The derived quantities $e(p)$ correspond to the 2-dimensional ECDF statistics of [10, 14].

For the case of the higher dimensions $d > 2$, essentially we will use Bentley's multidimensional divide-and-conquer method [10], adapted to Dietz's data structure and fusion trees, in a manner analogous to the preceding algorithm. That is, we will use Bentley's reduction method to reduce a d-dimensional search to a 2-dimensional ECDF search and then apply the faster 2-dimensional ECDF algorithm outlined in the preceding paragraph.

It is unknown whether the preceding algorithm is in *any sense* optimal for the dimension $d \geq 3$. Our algorithmic upper bounds *almost matches* one of Chazelle's lower bounds [18] when the dimension $d = 2$. The preceding sentence used the phrase "almost matches" because the computational model in [18] for batch-oriented lower bounds is similar but not identical to our model of computation for upper bounds. An interesting open question is whether or not Chazelle's lower bound model could be extended to show that the 2-dimensional ECDF algorithm in this section is optimal.

9. Further results and open questions. There are many examples of algorithms which have linear costs except for their use of sorting and searching. Fusion trees and/or the yet faster, more recent, and more refined sorting and searching algorithms of especially Andersson [4], Andersson et al. [5], and Thorup [44, 46] immediately imply speedups for such tasks. Some examples of these speedups include the construction of a convex hull, the testing for the equality, disjointedness, and containment relationships between two sets, the determination of the chromatic number of a permutation graph, etc. In particular, the algorithm of [5, 44] provides an $O(N \log\log N)$ randomized sorting time and the algorithm in [46] achieves a strict $O[N(\log\log N)^2]$ worst-case sorting time applicable for each of the four paradigm applications mentioned in this paragraph.

The main point is not the particular examples explored in the paragraph (above), or indeed any of the examples discussed in this article. Rather it is that there are so many other similar examples and problems that can somehow be theoretically improved with one of the methodologies of [1, 2, 3, 4, 5, 6, 7, 8, 9, 11, 15, 25, 26, 36, 37, 40, 41, 43, 44, 45, 46]. It should be stressed that we have focused mostly on a moderately narrow bandwidth of problems, drawn from computational geometry and information retrieval theory because such problems reflect the author's particular expertise and knowledge. If one merely examines Thorup's linear time algorithm for resolving Dijkstra's SSSP problem [45], it is apparent that there will be many other problems which theoretically can be improved with the use of q-heaps and their many modifications.

One interesting open question is whether or not it is feasible to construct a Vornoi diagram in faster than $N \log N$ time. Since a convex hull can be constructed in faster time using especially the new faster variants of the fusion tree sorting algorithm [4, 5, 44, 46], it is natural to inquire whether the same may be somehow true for Vornoi diagram construction. Another interesting question is whether or not the original q-heaps of [26] can somehow have their $O(1)$ performance time characteristics extended beyond the minisets of PolyLlog(N) size, described by Corollaries 3.2 and 3.4.

It is best to close this article by reviewing what we have accomplished, as well as what has certainly *not been done.* Section 1 had deliberately used the phrase "so-called improvements" to stress the fact that our theoretical asymptotic improvements are not accompanied with coefficients of practically small size. On the other hand, for the sheer delight of intellectual exploration, it is curious that so many different problems in theoretical computer science can undergo asymptotic improvements after the application of fusion trees and q-heaps. (There are obviously many more of these counterintuitive upper bounds one can establish when investigating this subject further. Even *when their coefficients are poor*, such upper bounds are helpful in clarifying what types of conjectured lower bounds can or cannot feasibly hold under various different possible models of computation.) Moreover, although not practical, our even-theoretical discussion of universal hashing is significant because dynamic universal hashing is a foundational problem.

10. Appendix. The proof of Lemma 3.3.

The previous literature has illustrated many examples of amortized optimization algorithms which can also guarantee worst-case time, if their procedures are made somewhat more elaborate and complicated. We will use a similar approach here to transform the amortize-optimizing procedure of Lemma 3.1 into an algorithm that also controls its worst-case running time, as required by Lemma 3.3. Our algorithm in many respects will be analogous to [54]. The discussion in this appendix will therefore be brief. It may be helpful if the reader examines [54] at some juncture, if he wishes to see how one should fill in the precise details for the ideas that are intuitively sketched below.

Our B-tree will be quite conventional, in that all the data will be stored at the leaf level of the B-trees and all leaves will have the same depth. Say an internal node v is "safe" if its arity lies between $B/4$ and $3B/4$, and it is "legal" if its arity lies between $B/8$ and B. (Let us remember that Lemmas 3.1 and 3.3 assume that $B > 16$, and that the tree root is allowed to "legally" contain between 2 and B children.) Our insertion/deletion algorithms will then guarantee that each node has legal arity at all times, and it will attempt to make the arity safe as often as possible.

The following notation will help us describe the insertion and deletion algorithms of Lemma 3.3.

1. An insertion (or deletion) operation will be said to *involve* a node v if it either inserts or deletes a leaf-record L that is either a descendent of v or a descendent of one of the two "adjacent" siblings of v (that lie to its immediate left or right).
2. An *evolutionary merge process* will be a procedure that gradually merges two adjacent B-tree sibling nodes, v and w, into one new node x. We will not allow the merge process to merge the two nodes, v and w, during one single unified action because such an operation would require $O(B)$ time and possibly cause our algorithm to lose its desired worst-case running time $O(h)$. Rather, for some fixed prespecified constant K, each *action* of our merge process will take K new pointers from v's and w's set of children and put copies of these pointers into the new node x that is gradually being constructed. Once the command to "merge" v and w is initiated, one such "action" will be performed by our insertion-deletion algorithm during each insertion and deletion command that "involves" either v or w. Once the new node x is fully constructed, our merge algorithm will deallocate the nodes v and w and make x a new child of the former parent of v and w.
3. An *evolutionary split process* will be the exact reverse of an evolutionary merge process. It will be a procedure that gradually splits one node x into two equal-sized nodes v and w by doing $O(K)$ units of work for each insertion-deletion command that "involves" x. That is, each operation will take K pointers from x and put copies of them into the new evolving nodes v and w.

Our algorithm for inserting and deleting new leaf-records into the B-tree will employ the above three constructs. It will be called Alg(K). It will initiate an evolutionary split process whenever a node's arity becomes unsafely large by exceeding the arity $3B/4$. If a deletion causes a node v's arity to fall below $B/4$ then Alg(K) will do roughly the reverse action of the preceding sentence by essentially activating an evolutionary merge process.[3] Also, all conventional B-tree algorithms, including Alg(K), must be prepared for the possibility that the root r might possibly contain only one child s at the end of some deletion (or insertion) command. In this case, Alg(K) will simply make s the new root of the B-tree and deallocate the node r (similar to conventional B-tree algorithms).

For the sake of brevity, the preceding paragraph's description of Alg(K) was kept very short. The two natural questions a reader will ask about Alg(K) are

1. What is its runtime?
2. Is Alg(K) correct in the sense that it assures the B-tree is always legally balanced?

The punchline will be that it will be trivial to show that Alg(K) always satisfies its claimed $O(h)$ worst-case time bound in a tree of height h, but its correctness will depend on one further delicate observation.

In particular, the answer to question 1 is easy because each insertion or deletion of a leaf-record L in a tree of height h will "involve" no more than $3h$ nodes in the B-tree. (This is because only the ancestors y of L and y's two adjacent siblings will be "involved.") Thus the evolutionary split processes of Alg(K) will execute no more than $3h$ "actions," each of which requires approximately K units of work. Hence, it will consume no more than worst-case time $O(h)$, where the coefficient hidden within the O-notation is proportional to $3K$.

Now let us turn to question 2. Its full answer is complex because Alg(K) will certainly not have the power to assure a B-tree is legally balanced if the prespecified constant K has too small an initial value. However, it is basically trivial to verify that if the prespecified constant K is sufficiently large (i.e., say $K > 100$), then the evolutionary processes used by Alg(K) will be quick enough to repair a temporarily "unsafe" node v and its adjacent siblings (when necessary) to assure that the tree's balance never becomes so much worse as to be "illegal." The latter is all we need to prove Lemma 3.3.

We will not delve into further details or describe the tedious formal encoding of the procedure Alg(K) because many other papers have appeared in the prior literature about how an amortized-optimizing algorithm can be transformed into a worst-case controlling procedure when one manipulates the algorithm's constant coefficient factor K with prudence (see, for example, [54, 52]). Our goal in this abbreviated appendix was only to sketch the intuition behind Lemma 3.3 very briefly. The reader can find much more sophisticated and interesting examples of amortized-to-worst-case transformations in [54].

[3]Deletions are conceptually similar to insertions, but their formal algorithm is painfully more complicated because there are several different subcases. The problem is that one might wish a tiny node v to merge with its sibling w but the latter cannot be done immediately because either w is currently too large or w is in the midst of another evolutionary split or merge that was previously invoked. If w is too large (say its arity is of size larger than $5B/8$), then v will initiate an evolutionary split to break w into two equal-size halves (before v merges with one of the newly produced halves of w). Similarly, if w is previously in the midst of another evolutionary split or merge when v wishes to merge with it, then v's merge must wait until the latter is completed. (The reason our definition of "involvement" made mention of the "adjacent siblings" of v is that a process where an unsafe node v cannot repair itself until its sibling is fixed will work correctly only if we make certain that every insertion or deletion among the leaves descending from v causes K units of evolutionary repair to be done for *both* v and its two adjacent siblings.)

Acknowledgments. I thank both referees for their very helpful comments.

NEAR-OPTIMAL PARALLEL PREFETCHING AND CACHING*

TRACY KIMBREL† AND ANNA R. KARLIN‡

Abstract. Recently there has been a great deal of interest in the operating systems research community in prefetching and caching data from parallel disks, as a technique for enabling serial applications to improve input–output (I/O) performance. In this paper, algorithms are considered for integrated prefetching and caching in a model with a fixed-size cache and any number of backing storage devices (disks). The integration of caching and prefetching with a single disk was previously considered by Cao, Felten, Karlin, and Li. Here, it is shown that the natural extension of their *aggressive* algorithm to the parallel disk case is suboptimal by a factor near the number of disks in the worst case. The main result is a new algorithm, *reverse aggressive*, with near-optimal performance for integrated prefetching and caching in the presence of multiple disks.

1. Introduction.

Recent advances in technology have made magnetic disks both cheaper and smaller. As a result, parallel disk arrays have become an attractive means for achieving high performance from storage devices at low cost. Multiple disks offer the advantages of both increased bandwidth and reduced contention. Nonetheless, there are many applications which do not benefit from this I/O parallelism as much as they could, and end up stalling for I/O a significant fraction of the time.

At the same time, it has been observed that many of these applications have largely predictable access patterns. This has enabled the use of prefetching and informed cache replacement (e.g., [11, 21, 28, 29]) as techniques for reducing I/O overhead in such systems. The two techniques are not independent, however, and can interact poorly if their interaction is not considered carefully [6, 28].

In this paper, we consider a theoretical model that captures the important characteristics of a system for prefetching and caching with multiple disks. We study the offline problem of constructing an optimal prefetching and caching schedule in this model for a given stream of requests for blocks of data residing on the disks. An optimal schedule minimizes the elapsed time required to serve the given request stream. Although complete information about future requests is usually not available, partial information *is* often available in the form of limited or even significant lookahead into the request stream. Empirically we have found that a limited-lookahead version of our algorithm outperforms other approaches in practice [17]. In addition, the design and analysis of the optimal offline algorithm is an important step towards understanding and evaluating more practical limited-lookahead algorithms. We can perhaps draw

an analogy with the impact of the optimal offline paging algorithm [3] on the design, implementation, and evaluation of online paging algorithms.

Surprisingly, even in the offline, single-disk situation, this is a challenging combinatorial problem. Recently, a polynomial-time exact solution for the single-disk case was found via a linear programming relaxation [2]. The difficulty comes from the fact that prefetching too soon can cause additional cache misses by replacing blocks that would remain in the cache if prefetching were done later or not at all: new and possibly better eviction opportunities arise as a program proceeds. Cao et al. [6] were able to show that a simple, practical algorithm called *aggressive*, which prefetches as early as is reasonable, has performance that is provably close to optimal in the single-disk case.

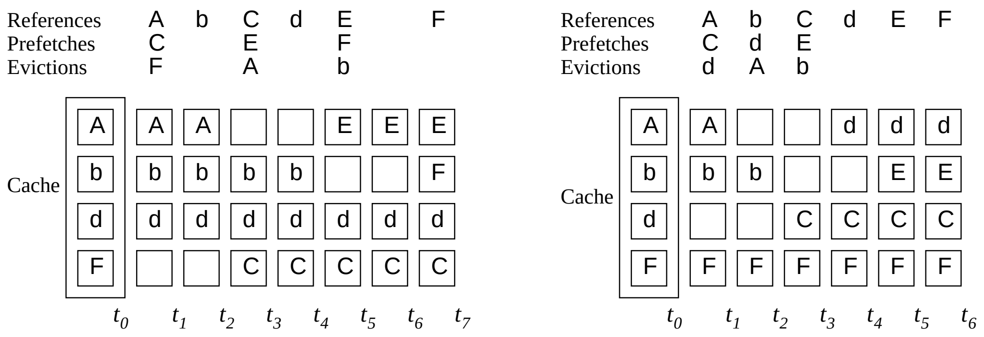
We show, however, that the natural extension of this algorithm to the multiple disk case has performance that is suboptimal by a factor nearly equal to the number of disks. The interaction between caching and prefetching is significantly more complicated in a system with multiple disks because a set of blocks can be prefetched in parallel only if they reside on different disks: each disk can serve only one prefetch at a time. The prefetching schedule and choice of cache evictions impact the potential for subsequent parallel prefetching in a complex way. Our main result is a new algorithm, *reverse aggressive*, with near-optimal performance for this problem.

1.1. An example. An example will serve to introduce our model and illustrate the challenge posed by the multidisk problem. An application program references one block per time unit. If the application wants to reference a block that is not present in the cache, the application must wait or *stall* until the block is present. Each disk can perform only one fetch at a time. If the cache is full, every fetch requires the eviction of some block from the cache. In a real system, it is not known in advance exactly how long a fetch will take (though in our theoretical model, the fetch time is constant); because of this, we assume the evicted block becomes unavailable at the moment the fetch starts. The goal is to minimize the total time spent by the application, or equivalently to minimize the stall time. In the following example, the cache holds four blocks, and it takes two time units to fetch a block from disk.

Suppose the application references blocks according to the sequence (A, b, C, d, E, F), and the cache initially holds blocks A, b, d, and F. Blocks A, C, E, and F reside on one disk, blocks b and d on a different disk. A straightforward approach is to use the *aggressive* algorithm [6]: always fetch the missing block that will be referenced soonest and evict the block whose next reference is furthest in the future, but do not fetch if the evicted block will be referenced before the fetched block.

Figure 1(a) shows the schedule of prefetches, evictions, and block service times produced by this algorithm. For example, initially the first missing block is C, and the block whose next reference is furthest in the future is F. Moreover, the reference to F is after the reference to C. Therefore, the *aggressive* algorithm immediately initiates a fetch for C, evicting F. Notice that this fetch is entirely overlapped with computation (the references to A and b). The schedule produced using this algorithm results in one unit of stall time (the sixth time unit). The entire sequence is served in seven time units.

Figure 1(b) shows another schedule that is faster by one time unit. On the first fetch, d is evicted rather than F, even though d is referenced earlier than F. This has the advantage of offloading one fetch from the heavily loaded disk to the otherwise idle disk. This change allows the fetches of C and d and of d and E to proceed in parallel, thus saving one time unit.



(a) A prefetching and caching schedule. (b) A better schedule.

FIG. 1. *An example of prefetching and caching with two disks. One disk holds blocks A, C, E, and F, and another disk holds blocks b and d. The cache size is $K = 4$ and the fetch time is $F = 2$.*

The example shows that it is helpful to take disk load into account when making fetching and eviction decisions. This is the factor that makes the multidisk problem more difficult than the single-disk problem.

1.2. Overview of results. Our model generalizes the previous example in the obvious way.

- Let D be the number of disks.
- Let B be a set of blocks. We will refer to the disk on which a block $b \in B$ resides as the *color* of b.
- There is a cache that contains at most K blocks in B at any time.
- A *reference sequence*, or *request sequence*, is an ordered sequence of references $R = r_1, r_2, \dots r_{|R|}$, where each $r_i \in B$.
- Fetching a block from a disk into the cache takes F time units.

We imagine that there is a *cursor* which, at any time during the servicing of the request sequence, points to the next request to be served. If this request is for a block that is in the cache, the cursor advances by one during the next time unit. If this request is for a block that is not in the cache, the cursor *stalls* until that block arrives in the cache (i.e., until the fetch for that block completes). Note that to the extent that the cursor is advancing, a prefetch can overlap the serving of requests. Also, prefetches can overlap each other provided that the prefetched blocks reside on different disks. We assume that each block resides on only a single disk.

The goal is to determine a schedule of prefetches and evictions such that the time required to serve the entire sequence is minimized. Since it requires one unit of time to serve each request, the elapsed time is equal to the length of the request sequence plus the total number of steps during which the cursor stalls.

We consider three algorithms for parallel prefetching in this paper: *conservative*, *aggressive*, and *reverse aggressive*. The first two are natural extensions of the two single-disk prefetching strategies described in [6]. They lie at opposite ends of the spectrum in terms of the total number of fetches performed: *conservative* performs the minimum possible number of fetches, at the expense of a worse elapsed time in the worst case; *aggressive* prefetches as aggressively as possible without being foolish.

We give nearly tight bounds on the performance of both of these algorithms. Unfortunately, for both of these algorithms there are reference patterns on which their performance is suboptimal by a factor of nearly D, for values of D, F, and K

that are typical in practice.

THEOREM 1. *On any reference string R, the elapsed time of* conservative *with D disks on R is at most $D+1$ times the elapsed time of the optimal prefetching strategy on R.*

This bound is nearly tight for $D \ll F \ll K$: There are arbitrarily long strings on which conservative *requires time $1 + D\frac{K-F}{K}\frac{F}{F+D}$ times the optimal elapsed time.*

THEOREM 2. *On any reference string R, the elapsed time of* aggressive *with D disks on R is at most $D(1+\frac{F+1}{K})$ times the elapsed time of the optimal prefetching strategy on R.*

This bound is nearly tight for $D \ll \sqrt{F}$: There are arbitrarily long strings on which aggressive *requires time $D - \frac{3D(D-1)}{F+3(D-1)}$ times the optimal elapsed time (within an additive constant that depends only on F and K).*

Our main result is the development and analysis of a new algorithm, called *reverse aggressive*, whose performance is provably close to optimal. Interestingly, it achieves this by constructing a prefetching schedule backwards, i.e., by considering the reference sequence in reverse order. For reasons that will be made clear, this causes it to avoid problems encountered by the (forward) *aggressive* algorithm. *Aggressive* suffers from load imbalance and an inability to keep lightly loaded disks from outpacing (prefetching far ahead of) heavily loaded disks. On real systems, DF/K is small,[1] so that the factor $1 + DF/K$ in the following theorem is not much greater than one (hence our claim of "near-optimality").

THEOREM 3. Reverse aggressive *requires at most $1 + DF/K$ times the optimal elapsed time to service any request sequence, plus an additive term DF independent of the length of the sequence.*

This bound is nearly tight for small D: There are arbitrarily long strings on which reverse aggressive *requires $(1 + (F-1)/K)$ times the elapsed time of the optimal prefetching strategy on R.*

1.3. Related work. Our problem is a generalization of (but significantly more complicated than) the classical paging problem. Indeed, one principle for prefetching (the *optimal eviction* rule described in section 2.1) is derived from Belady's optimal *longest forward distance* [3] paging algorithm. As we will see, however, the application of this rule alone is insufficient to guarantee good prefetching performance; the natural algorithm based on it is suboptimal by a factor of nearly $D+1$. (See Theorem 1.)

On the theoretical side, we know of no prior work on the integration of parallel prefetching and caching. There have been some interesting results on the use of data compression for the design of optimal prefetching strategies [20, 33] and work on prefetching strategies for external merging under a probabilistic model of request sequences [25]. However, these studies concentrated only on the problem of determining which blocks to fetch, and did not address the problem of determining which blocks to replace.

Our work builds on recent studies of the sequential (single-disk) version of this problem which showed [6, 5] that it is important to integrate prefetching, caching, and disk scheduling and that a properly integrated strategy can perform much better than a naive strategy, both theoretically and in practice.

In the systems community, caching and prefetching have been known techniques to improve the performance of storage hierarchies for many years [3, 12]. The breadth

[1] F/K is typically less than 0.02, and typical disk-arrays have at most 5 disks. Moreover, technological trends are such that F/K will only get smaller with time.

of application of these techniques has ranged from architecture [31] to database systems [9, 26, 10] to file systems [12, 22, 15, 24, 32, 4, 14, 7, 29] and beyond. A recent trend in this research is to use applications' knowledge about their access patterns to perform more effective caching and prefetching [4, 7, 28, 29].

Our practical motivation for this problem comes from file systems. In this domain, the most common prefetching approach is to perform sequential read-ahead, i.e., to detect when an application accesses a file sequentially and to prefetch the blocks of the files that are so used [12, 22, 23]. The obvious limitation of this approach is that it benefits only applications that make sequential references to large files. Another body of work has been on predicting future access patterns (without hints from the application) even when access patterns are more complicated [11, 32, 26, 10, 14].

Much research on parallel I/O has concentrated on techniques for "striping" and distributing error-correction codes among redundant disk arrays or other devices. These techniques are used to achieve high bandwidth by exploiting parallelism and to tolerate failures [16, 30, 8, 27, 13].

Our work complements these previous efforts. File access prediction (with or without application hints) can be used to provide the inputs to the algorithm described in this paper. Once future accesses are known, our algorithm determines a near-optimal prefetching schedule. Our algorithm achieves near-optimal performance for any given layout of disk blocks (such as striping). Its performance will only improve when a near-optimal layout is used.

Recently, caching and prefetching have also been empirically studied for parallel file systems [11, 21, 28, 29].

Finally, we have performed simulation studies of the performance of the algorithms described in this paper. Companion papers [17, 19] report on this empirical evaluation. A brief summary of the results is given in section 6 of this paper.

1.4. Organization of the paper.

In section 2, we describe several properties that can be assumed of optimal prefetching algorithms. These constrain the problem and by adhering to them, we can ensure that an algorithm's performance is not far from optimal. Also in section 2, we describe the algorithms in greater detail and give intuition on their performance. In section 3, we give overviews of the proofs of the results claimed in section 1.2. Detailed proofs are contained in section 4. In section 5 we consider the time required by the algorithms to determine prefetching and caching schedules. In section 6, we briefly describe our empirical studies of the performance of these algorithms. We conclude with open problems for further research.

2. Properties of optimal prefetching and caching schedules.

After the following definition, we describe several properties that can be assumed of optimal prefetching algorithms.

DEFINITION 4. *At any point in processing the sequence (i.e., for any given cache state and cursor position), a* hole *is a block that is not present in the cache. We will refer to the operation of fetching a disk block as "filling a hole." We will use the term "hole" to refer to both the missing block and its next occurrence in the request sequence; which of these is meant will be clear from the context. If the cache is full, there are K out of $|B|$ blocks in the cache and thus $|B| - K$ holes. After a block is requested for the last time, we consider the corresponding hole in the request sequence to be at position $|R| + 1$, i.e., greater than the index of any request, where R is the request sequence.*

2.1. Prefetching and caching with a single disk. Before proceeding, we review the results of Cao et al. [6] for prefetching and caching in the single-disk case. They described four properties that can be assumed of any optimal strategy in the single-disk case:

1. *optimal fetching*: when fetching, always fetch the missing block that will be referenced soonest;
2. *optimal eviction*: when fetching, always evict the block in the cache whose next reference is furthest in the future;
3. *do no harm*: never evict block A to fetch block B when A's next reference is before B's next reference;
4. *first opportunity*: never evict A to fetch B when the same thing could have been done one time unit earlier.

It is easy to show that any schedule for serving requests and performing fetch-and-evict operations that does not follow these rules can be transformed into one that does, with performance at least as good. The first two rules specify what to fetch and what to evict, once a decision to fetch has been made. The last two rules constrain the times at which a fetch can be initiated. However, these rules do not uniquely determine a prefetching schedule. In particular, they do not specify how to choose between an earlier prefetch with a correspondingly earlier eviction and a later prefetch with a correspondingly later eviction. The former helps prevent stalling on earlier holes, whereas the latter may help prevent the introduction of holes, and hence stalling at a later time.

Nonetheless, these rules do provide a fair amount of guidance in the design of a prefetching algorithm. Cao et al. considered two natural algorithms, *aggressive* and *conservative*, that follow these rules and lie at opposite ends of the spectrum of possibilities. *Aggressive* is the algorithm that initiates a prefetch whenever its disk is ready (i.e., is not in the middle of a prefetch) and the *do no harm* rule allows it. *Conservative* is the algorithm that refuses to fetch until it can evict the same block that would be evicted by the optimal *longest forward distance* [3] algorithm in the classical paging model. That is, *conservative* applies the rule *optimal eviction* as though the prefetch were to be initiated immediately before serving the request to the missing block, then applies the rule *first opportunity* to swap the chosen fetch/eviction pair as early as possible. *Conservative* makes the minimum number of total fetches, but it often declines opportunities to prefetch blocks.

Cao et al. showed that in the single-disk case, *conservative*'s elapsed time on any sequence is at most twice the optimal time, and that *aggressive*'s worst-case elapsed time is at most $\min(1+F/K,\ 2)$ times optimal, where F is the time required to fetch a block and K is the cache size measured in blocks. (They also showed that these bounds are tight.) On real systems, F/K is typically small, so *aggressive* is close to optimal.

2.2. The multidisk case. There is an obvious and natural extension of each of these algorithms to the multidisk case. For *aggressive*, it is the following: Whenever a disk is free, prefetch the first missing block of that disk's color, replacing the block (of any color) whose next reference is furthest in the future among all cached blocks. However, a fetch should be started only if the next access to the evicted block is after that of the block being fetched.

Unfortunately, as we shall see, this algorithm does not enjoy the same performance guarantee in the multidisk case as it achieved in the single-disk case. In fact, the four properties on which it was based in the single-disk case do not hold for optimal strategies in the multidisk case. As a result, it suffers from two problems in the multidisk case that did not exist in the single-disk case:

- The eviction decisions it makes are "color blind": It chooses evictions to make without consideration of the load on the disks. These choices can result in a situation where many of the holes at any time are of the same color, and therefore cannot subsequently be prefetched in parallel. (See Figure 1 for an example of this.)
- *Aggressive* is too aggressive. The result is that it can cause some disks to fetch too far ahead with respect to other disks. These fetches increase the share of the cache occupied by blocks belonging to the lightly loaded disk(s), creating even more holes for the heavily loaded disk(s) to fill.

Therefore, we are motivated to approach the multidisk prefetching problem in a way that will constrain the space of possibilities for the prefetching schedule in the same way that the four rules described above constrain the schedule in the single-disk case.

2.3. Properties of optimal parallel prefetching and caching. It is not hard to show that out of the four rules for optimal prefetching with one disk, only the last (*first opportunity*) holds when there are multiple disks. Finding a rule to replace *optimal fetching* is not much of a problem, however. The "colored" version of the rule can be used, i.e., for each disk *col*, the next block to fetch from *col* is the next missing block in the sequence that is colored *col*. Thus, as in the single-disk case, the question of which block to fetch reduces to the question of when to initiate a prefetch operation; this question needs to be answered for each disk, of course.

Optimal eviction is more troublesome. Suppose there are two disks, colored red and blue. If there are many red blocks missing in the sequence, then it may be that the best choice for eviction is a blue block even though the block whose next request is furthest in the future is red. This is because the relatively lightly-loaded blue disk can better handle the increased burden of another missing block than the red disk can. (See Figure 1.) Given that a blue block is to be evicted, it is true that the best choice is the blue block that is not requested for the longest time. That is, the colored version of this rule holds, but it does not tell us which color block to evict.

Even the seemingly obvious *do no harm* rule can be violated by the optimal prefetching strategy. This is because the loads on the disks can be imbalanced. If there are many red blocks missing from the sequence, say, but no blue blocks missing, it may be advantageous to buy time by evicting a blue block (and completing a fetch of a red block sooner than would be possible otherwise), and then bringing the blue block back into the cache after a request to some red block has been served (so that a new eviction opportunity has arisen).

2.4. Using the reverse sequence. An interesting twist allows us to convert multiple-disk prefetching to a more constrained, and hence easier to solve, problem. In particular, we consider the request sequence in reverse, in a sense we will describe momentarily. We will be able to show that of the four rules, all but one (*optimal eviction*) hold for optimal schedules serving the reverse sequence. Moreover, we will be able to replace this rule by a simple colored variant as we did with the *optimal fetching* rule for the forward sequence; this will be shown in section 4.1.

First, we return to the single-disk case, and observe that any prefetching schedule that serves the reverse sequence $reverse(R)$ in time T can be used to derive a schedule to serve R in time T as follows. If the schedule for serving $reverse(R)$ serves request r_i between times t and $t+1$, the derived schedule for R serves r_i between times $T-t-1$

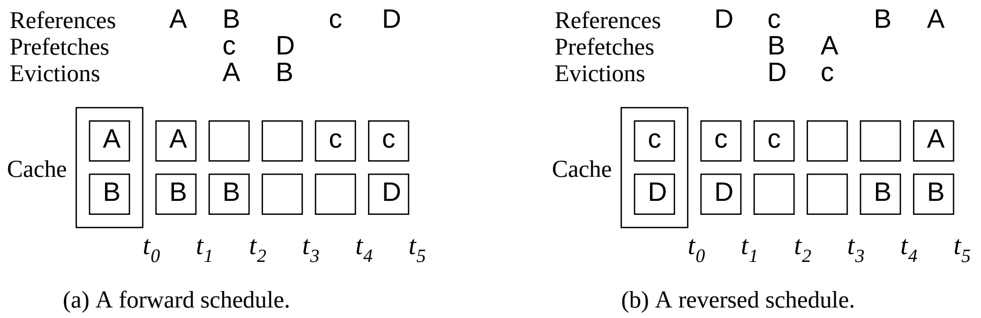


FIG. 2. *An example of reversing a schedule of prefetching and caching with two disks: a disk holding blocks A, B, and D, and another disk holding block c. The cache size is $K = 2$ and the fetch time is $F = 2$.*

and $T - t$. If the reverse schedule replaces a with b between times t and $t + F$, the derived schedule replaces b with a between times $T - t - F$ and $T - t$.[2] Applying this logic twice, we see that the optimal elapsed time for the reverse sequence is the same as the optimal elapsed time for the original sequence.

Reversal of the sequence is more complicated when multiple disks are considered. In the forward direction, the prefetching schedule is constrained to fetch at most one block at a time from each disk; eviction choices may be blocks of either color. Switching between the forward sequence and the reverse sequence, fetches become evictions and vice versa. To derive a useful schedule from a schedule serving the reverse sequence, then, requires that the schedule for the reverse sequence be constrained to *evict* at most one block of each color at a time. This is illustrated in the following example (see Figure 2):

Consider the request sequence "ABcD," where upper case letters denote red blocks and lower case letters denote blue blocks. Let $F = 2$ and $K = 2$. By assumption, at time 0, blocks A and B reside in the cache (for the execution of the sequence in the forward direction). At time 1, a fetch is initiated to bring c into the cache from the blue disk, evicting A. At time 2, a fetch of D from the red disk is initiated, evicting B from the cache. The schedule serves the request sequence in five units of time. See part (a) of Figure 2.

In the schedule for the reverse sequence, at time 1, D is evicted in order to start fetching B. Since c is blue and D is red, a fetch of A (evicting c) can be started at time 2, even though A and B are both red. See part (b) of Figure 2. This schedule can be transformed as described in the previous paragraphs into the valid schedule for the forward sequence of part (a), which is its mirror image.

As previously mentioned, all of the rules presented in section 2.1 except *optimal eviction* can be assumed of optimal prefetching schedules for the reverse sequence. *This fact makes it easier to find a schedule for the reverse sequence, then transform it into one for the original sequence, than to find a schedule for the original sequence directly.* The reason for this is that in the forward direction, any time a block is prefetched a decision must be made as to which color block to evict. In the reverse direction, this decision is made for us: the block to evict is the one not needed for the

[2]We assume that all schedules start with the cache containing the first K distinct requests in the sequence. Alternatively, all our results hold within an additive constant that accounts for differences in algorithms' transient cold-cache startup behaviors. We can assume without loss of generality that all schedules end with the last K distinct requests in the cache.

longest time whose color matches the color of the free disk (i.e., the colored version of the *optimal eviction* rule can be used). One might expect that fetch decisions are harder, but this is not the case. In the forward direction, the missing block to fetch is the one of the right color that is needed soonest. (This is the colored version of *optimal fetching* described earlier.) In the reverse direction, it is the one needed soonest, regardless of color.

2.5. The *reverse aggressive* algorithm. *Reverse aggressive* is a prefetching algorithm that performs aggressive prefetching on the reverse of its input sequence, then derives a schedule to serve the forward sequence as described in section 2.4. That is, on the reverse sequence, it behaves as follows. Whenever a disk is not in the middle of a prefetch, it determines which block in the cache is not needed for the longest time among those with the same color as the disk. If the index of the next request to that block is greater than the index of the first hole (of any color), the block identified for eviction is evicted, and the first hole is prefetched.

An intuitive explanation of *reverse aggressive*'s advantage over (forward) *aggressive* is the following:

- Whereas *aggressive* chooses evictions without considering the relative loads on the disks, *reverse aggressive* greedily evicts to as many disks as possible on the reverse sequence. In the forward direction, this translates to performing a maximal set of fetches in parallel. The fact that these are fetches in the forward direction means that at some point earlier in the sequence, corresponding blocks were evicted. Thus the eviction decisions of *reverse aggressive* on the forward sequence are based on the ability to prefetch the evicted blocks later on in parallel.
- Whereas *aggressive* can wastefully prefetch ahead on some of its disks, *reverse aggressive* is greedy in the reverse direction. Consequently, it is fetching pages in the forward direction just in time (to the extent possible) for them to be used. This results in performing close to the best evictions possible for those fetches, and exploiting parallelism as much as possible without creating load imbalance.

3. Results. In this section we give high-level descriptions of the main ideas used to derive our results. Full details are given in section 4.

3.1. Performance of *conservative* and *aggressive*. The key concept in the upper bound of Theorem 2 is the notion of *domination* from the work on prefetching in the single-disk case [6]. This allows us to bound the cost of *aggressive*'s prefetching schedule in terms of the progress of the optimal schedule at intermediate points during the processing of the request sequence.

DEFINITION 5. *Given two sets A and B of holes with $|A| \leq |B|$, A is said to* dominate *B if for all i, $1 \leq i \leq |A|$, the index of A's ith hole (ordered by increasing index) is no less than the index of B's ith hole. We will say that the ith hole in A is* matched *to the ith hole of B. Notice that domination is transitive.*

Let *opt* denote an optimal algorithm. For intuition, consider the following. If *aggressive*'s cursor is ahead of *opt*'s cursor, *aggressive*'s holes dominate *opt*'s holes, and both are initiating prefetches at the same times, then *opt*'s cursor cannot pass *aggressive*'s: while *aggressive* stalls on a hole, *opt*'s cursor cannot pass its matching hole. We show that *aggressive* is able to continually regain and maintain such an advantage (having its cursor ahead and its holes dominate) over *opt* at regular intervals, without losing too much time to *opt* in the process. *Aggressive* can lose its advantage,

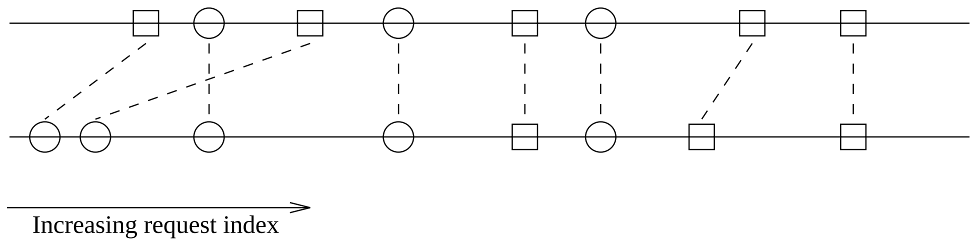

FIG. 3. *Strong domination example: the upper set of holes strongly dominates the lower one. Mismatched shapes represent excess holes. Edges show how strong domination implies ordinary domination. (See Lemma* 11 *and the discussion following.)*

and lose time to *opt*, by prefetching more aggressively than *opt*; this will become clear as the details are presented.

The lower bounds of nearly D in Theorems 1 and 2 come from the fact that an adversary can construct request sequences that cause both *conservative* and *aggressive* to always fetch blocks from only one disk (because they make poor eviction choices). The optimal algorithm *opt* can serve these same sequences at nearly D times the rate because of the parallelism of prefetching on D disks. The additive term of one for *conservative* (in both the upper and lower bounds) comes from *opt*'s ability to overlap prefetches with the serving of requests. In contrast, *conservative* may not be able to do so.

The factor of D in the upper bounds comes from the fact that D is also a limit to the parallelism available to *opt*. As in the single-disk case, the additive term $\frac{(D+1)F}{K}$ in the upper bound for *aggressive* comes from the fact that *aggressive*'s newly created holes are always at least K steps from the cursor. From this, it follows that *aggressive* prefetches too soon (creating extra holes) at most once every K requests.

3.2. Performance of reverse aggressive. The proof of Theorem 3 required several new ideas. The notion of domination from the proof of Theorem 2 is replaced by a stronger notion that we call *strong domination.*

DEFINITION 6. *Let A and B be sets of holes, possibly with different numbers of holes of each color, such that $|A| \leq |B|$. For each color col, let $N_{col}(A)$ (respectively, $N_{col}(B)$) be the number of holes of color col in A (respectively, B). Let $N_{col} = \min(N_{col}(A), N_{col}(B))$. If $N_{col}(A) > N_{col}(B)$, we say that col is an* excess color *of A; if $N_{col}(A) < N_{col}(B)$, col is an excess color of B; if $N_{col}(A) = N_{col}(B)$, col is not an excess color. Let $E_{col} = |N_{col}(A) - N_{col}(B)|$. If col is an excess color of A, we refer to A's first E_{col} holes of color col following the cursor as* excess *holes; excess holes of B are defined similarly. We say the set of holes A* strongly dominates *the set of holes B if*

- *for each col, A's last N_{col} holes of color col dominate B's last N_{col} holes of color col (i.e., A's nonexcess holes of color col dominate B's nonexcess holes of color col, whether col is an excess color of A or B or col is not an excess color), and*
- *all of B's excess holes precede the first hole in A of any color.*

This idea is illustrated in Figure 3, in which holes of different colors are depicted by different shapes.

DEFINITION 7. *For two sets A and B of holes, we say that A strongly dominates B up to index y, if the subset of holes in A that occur at or before index y in the request sequence strongly dominates the subset of holes in B that occur at or before*

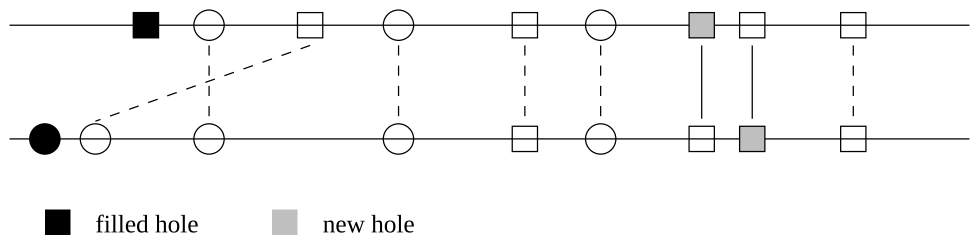

FIG. 4. *Domination lemma: the upper set of holes continues to strongly dominate the lower one.*

index y. When y is the end of the request sequence, we will simply use "strongly dominates" rather than "strongly dominates up to the end of the sequence."

DEFINITION 8. *Let $New(H,(cur,col))$ denote the new set of holes should a prefetch be initiated, if possible (i.e., if allowed by the* do no harm *principle), evicting a block of color col, when the cursor position is cur and the current set of holes is H. Note that $New(H,(cur,col))$ is uniquely determined by the optimal prefetching principles* optimal fetching *and* colored optimal eviction *described in section* 2.4*. If the* do no harm *principle prevents a prefetch, define $New(H,(cur,col)) = H$.*

The following crucial lemma is used to show that if *reverse aggressive* strongly dominates *opt*, and both have the opportunity to initiate a fetch replacing blocks of the same color, then *reverse aggressive* strongly dominates *opt* after the corresponding fetches complete.[3] For purposes of analysis, we consider any blocks that are currently being fetched to be in the cache, i.e., there is no corresponding hole in A or B, even though the corresponding request cannot be served until the F steps are over.

LEMMA 9 (strong domination lemma). *Let A and B be two sets of holes in a request sequence R, and let y, $cur_A < y$, and $cur_B < y$ be indices in R. If A strongly dominates B up to index y, then*

1. *for each color col, if $cur_A \geq cur_B$, $New(A,(cur_A,col))$ strongly dominates $New(B,(cur_B,col))$ up to y;*
2. *for each color col, $New(A,(cur_A,col))$ strongly dominates B up to y;*
3. *for each color col, if $cur_A \geq cur_B$ and every block of color col that is* not *a hole in A is requested after cur_A and before the first hole in A so that $New(A,(cur_A,col)) = A$ (i.e.,* do no harm *prevents a prefetch), A strongly dominates $New(B,(cur_B,col))$ up to y;*
4. *for each pair col_A and col_B of colors, if the best eviction choice of color col_A given the set of holes A and the cursor position cur_A is a block that is not requested between cur_A and y, $New(A,(cur_A,col_A))$ strongly dominates $New(B,(cur_B,col_B))$ up to y.*

Part 1 of Lemma 9 is illustrated in Figure 4.

Note that part 3 of Lemma 9 is a special case of part 1. We prove it separately because it is an important case and because it will aid understanding later, where the lemma is used.

It is not possible to show that *reverse aggressive* strongly dominates *opt* throughout the sequence. Instead, we show that by giving *reverse aggressive* a little more time to serve every subsequence of K requests, it will strongly dominate *opt* at these

[3]We are speaking here of the performance of *reverse aggressive* on the reverse sequence, compared to an optimal schedule for the reverse sequence. However, as described in section 2.4, the optimal elapsed time is the same in both directions, and from *reverse aggressive*'s schedule, we are able to derive a prefetching schedule for the forward sequence with the same elapsed time.

regular intervals. That is, *reverse aggressive* loses about DF steps by prefetching too soon, thereby generating extra holes to fill, only every K requests or so.

The difficulty in showing this is that, in fact, *reverse aggressive* may prefetch prematurely very often, *but with at most $D-1$ disks.* We show that it is able to compensate by consistently making good (distant from the cursor) evictions with the other ("good") disk. While *reverse aggressive* spends an extra F steps relative to *opt* filling the first extra hole created by one of the "bad" disks, the good disk fills one hole. This gives *reverse aggressive* a "one-hole lead" over *opt* with respect to the filling of holes. (Remember, each disk can fetch blocks of any color.) This provides a buffer against stalling on the (further) extra holes created by the bad disks, at least until an extra hole created by the good disk is reached. (The strong domination lemma is used to show that this invariant is maintained.) The good disk creates extra holes only once every K requests.

Formalizing these arguments is difficult; the details are presented in section 4.

4. Proofs.

The following definitions will be useful. Further definitions, specific to the particular proofs in which they are used, will be introduced later.

We divide the request sequence (or, when appropriate, its reverse) into *phases*, maximal-length subsequences of requests to K distinct blocks, as follows. The first phase begins with the first request. Each phase ends immediately before the first request to the $(K+1)$st distinct block since the beginning of the phase, and the next phase begins with that request.

If algorithm *alg* has fetches in progress at any time t, we denote *alg*'s holes before initiating those fetches by $H^-_{alg}(t)$ (i.e., $H^-_{alg}(t)$ contains the holes being filled, but not the ones being created), and *alg*'s holes after those fetches are complete (but ignoring any fetches that haven't begun by time t) by $H^+_{alg}(t)$.

In this section and the next, we assume all algorithms are working with the reverse sequence and denote the optimal algorithm for serving the reverse sequence by *opt*.

Under any algorithm that works on the forward sequence and follows the *optimal eviction* rule, no new holes will be created in a phase once the cursor enters the phase. For every hole in the phase, there is at least one block in the cache that is not requested for the remainder of the phase (since there are only K blocks requested in the phase, by definition, and the cache holds K blocks). In contrast, it is possible that *reverse aggressive* (and *opt* working on the reverse sequence, in fact) will create a new hole within a phase even after its cursor has entered the phase. Although it is true that for every hole in the phase there is a block in the cache that is not requested until after the end of the phase, it may be that all those blocks are the same color and that the best eviction choice of another color is a block that will be requested before the end of the phase. However, if *reverse aggressive* does create new holes in the phase containing the cursor, it will create such holes of at most $D-1$ colors. We refer to the other disk as the *busy* disk for the phase. (If there are two or more such disks, an arbitrary one is chosen.) As long as there are holes remaining in the phase, the busy disk will initiate a fetch to fill one of them every F steps, and will create new holes beyond the end of the current phase.

A fetch using the busy disk (and evicting a block of the same color as the busy disk; the block fetched may be any color) is referred to as a *busy-disk fetch*; fetches using other disks are referred to as *non-busy-disk fetches.*

4.1. Reverse aggressive: Upper bound.

We first give some preliminaries, proving the claims of section 2.4 and a simple lemma on combining subsets of dominating and dominated sets of holes. We next prove the strong domination lemma (Lemma 9).

The strong domination lemma is then used to bound *reverse aggressive*'s elapsed time for a single phase relative to *opt*'s elapsed time. Roughly speaking, if *reverse aggressive*'s holes dominate *opt*'s, *opt* cannot get ahead of *reverse aggressive* since *opt*'s first hole is at least as early in the request sequence as *reverse aggressive*'s. By allowing *reverse aggressive* a small amount of time to correct for mistakes it makes by prefetching sooner than *opt*, strong domination up to the end of the phase is maintained as an invariant until both algorithms reach the end of the phase. This step of the proof is complicated by the fact that the algorithms may fetch blocks using their respective disks in different orders. We must permute one sequence of fetches in order to make direct comparisons between the two algorithms' operations.

Finally, we show that by using a different permutation (and a correspondingly different matching of one algorithm's prefetch operations to the other's), the strong domination lemma implies that strong domination up to the end of the request sequence holds as an invariant as we compare the algorithms' progress from one phase to the next.

LEMMA 10. *Any prefetching schedule for the reverse sequence that does not satisfy the four rules described in section* 2.4 *can be transformed into one that does, with no increase in elapsed time.*

Proof.

1. *Optimal fetching* (fill the first hole): Suppose that at time t_1, a fetch is initiated to fill some hole h_2 other than the first hole h_1. h_1 must be filled before it can be served; say it is filled by a fetch initiated at time $t_2 > t_1$. Since the (later) reference to h_2 cannot be served until after the reference to h_1 is served, the schedule remains valid if h_1 is filled at time t_1 and h_2 at time t_2, and all other operations (prefetches, evictions, and cursor movements) are unchanged. Since we are working with the reverse sequence, this change can be made regardless of the colors of h_1 and h_2. If filling h_1 at time t_1 allows the cursor to advance sooner than it can if h_2 is filled at time t_1, then the eviction opportunities under this schedule are at least as good as those under the original schedule; i.e., the set of holes obtained strongly dominates that obtained under the original schedule. Thus the transformed schedule can be completed to derive a schedule with elapsed time no greater than that of the original.
2. *Colored optimal eviction* (evict the block not needed for the longest time among those colored the same as the free disk): Suppose that at time t_1, block b_1 is evicted, and block b_2 of the same color as b_1 is in the cache and is first referenced after the next reference to b_1. If b_2 is subsequently evicted before the next reference to b_1 is served, the effect is the same if b_2 is evicted first, then b_1. Otherwise, b_1 must be fetched back at some time $t_2 > t_1$ before the reference to it can be served. If b_2 is evicted at time t_1 instead of b_1, it can be fetched back at time t_2. By assumption, there are no intervening references of b_2 on which to stall; thus the transformed schedule stalls no more than the original.
3. *Do no harm* (do not evict b_1 to fetch b_2 if b_1 is needed sooner): Suppose b_1 is evicted to fetch b_2. b_1 must be fetched back before the reference to it can be served; this fetch evicts some other block b_3. Since fetches on any disk can be of any color, the fetch of b_1 can be replaced by a fetch of b_2 (evicting b_3). By

assumption, there are no intervening references of b_2 on which to stall; thus the transformed schedule stalls no more than the original.

4. *First opportunity* (perform each fetch/eviction pair as soon as possible): Suppose that the disk colored *col* is left idle at time t, a fetch of block b_1 is initiated at $t+1$ evicting block b_2 of color *col*, and that the block served at time t is not b_2. Then by initiating the fetch at time t rather than $t+1$, the hole (b_1) is filled one step sooner; certainly, no additional stall is incurred by this change. ∎

We assume without loss of generality that *opt* obeys these rules.

LEMMA 11. *Given two sets of holes $A = A_1 \cup A_2$ and $B = B_1 \cup B_2$ with $|A_1| \leq |B_1|$, $|A_2| \leq |B_2|$, $A_1 \cap A_2 = \emptyset$, and $B_1 \cap B_2 = \emptyset$, if A_1 dominates B_1 and A_2 dominates B_2, then A dominates B.*

Proof. Suppose the contrary. Let i be such that the ith member of A (ordered, as usual, by increasing index in the request sequence) has an index less than the ith member of B. Then A contains i holes with indices less than or equal to that of A's ith hole, and B contains only $i-1$ such holes. But because A_1 dominates B_1 and A_2 dominates B_2, for each member of A there is a distinct member of B with lesser or equal index. Thus we have a contradiction. ∎

Note that Lemma 11 extends to pairs of sets composed of more than two disjoint subsets each. Notice also that by Lemma 11, strong domination implies ordinary, color-blind domination. (Match nonexcess holes according to colors, and all of one set's excess holes to all of the other set's excess holes. See Figure 3 for an example illustrating this.)

LEMMA 12. *Strong domination is transitive.*

Proof. Suppose A strongly dominates B and B strongly dominates C. We show that A strongly dominates C. Fix a color *col*; for convenience (so it can be used as an adjective), suppose *col* is red. Define $N_{col}(\cdot)$ as before. For a collection S of sets of holes, let $N_{col}(S) = \min_{s \in S}(N_{col}(s))$. (We will drop the brackets when listing the members of S.) Let $N_{col} = N_{col}(A, B, C)$. We consider three cases, illustrated in Figure 5.

1. $N_{red} = N_{red}(A)$. A has N_{red} red holes, and these dominate the last N_{red} red holes in B. B's last $N_{red}(B, C)$ red holes dominate C's last $N_{red}(B, C)$ red holes, so B's last N_{red} red holes must dominate C's last N_{red} red holes. Since domination is transitive, A's N_{red} red holes dominate C's last N_{red} red holes. Suppose h is a red hole in C that is excess with respect to A. If h is matched to a red hole h' of B, h' is excess with respect to A and thus precedes A's first hole, so h must precede A's first hole as well. If h is excess with respect to B, it precedes B's first hole, which precedes or is the same as A's first hole, since strong domination implies ordinary domination.
2. $N_{red} = N_{red}(B)$. A's last N_{red} red holes dominate B's N_{red} red holes, which dominate C's last N_{red} red holes. Suppose h is a red hole in C that is excess with respect to B. h must precede B's first hole. h precedes A's first hole as well, since B's first hole precedes or is the same as A's first hole; again, this is because strong domination implies ordinary domination. If h is excess with respect to A, we are done. If h matches some hole h' of A, h surely does not occur after h'.
3. $N_{red} = N_{red}(C)$. A's last $N_{red}(A, B)$ red holes dominate B's last $N_{red}(A, B)$ red holes, so A's last N_{red} red holes must dominate B's last N_{red} red holes, which dominate C's N_{red} red holes. C has no excess red holes with respect

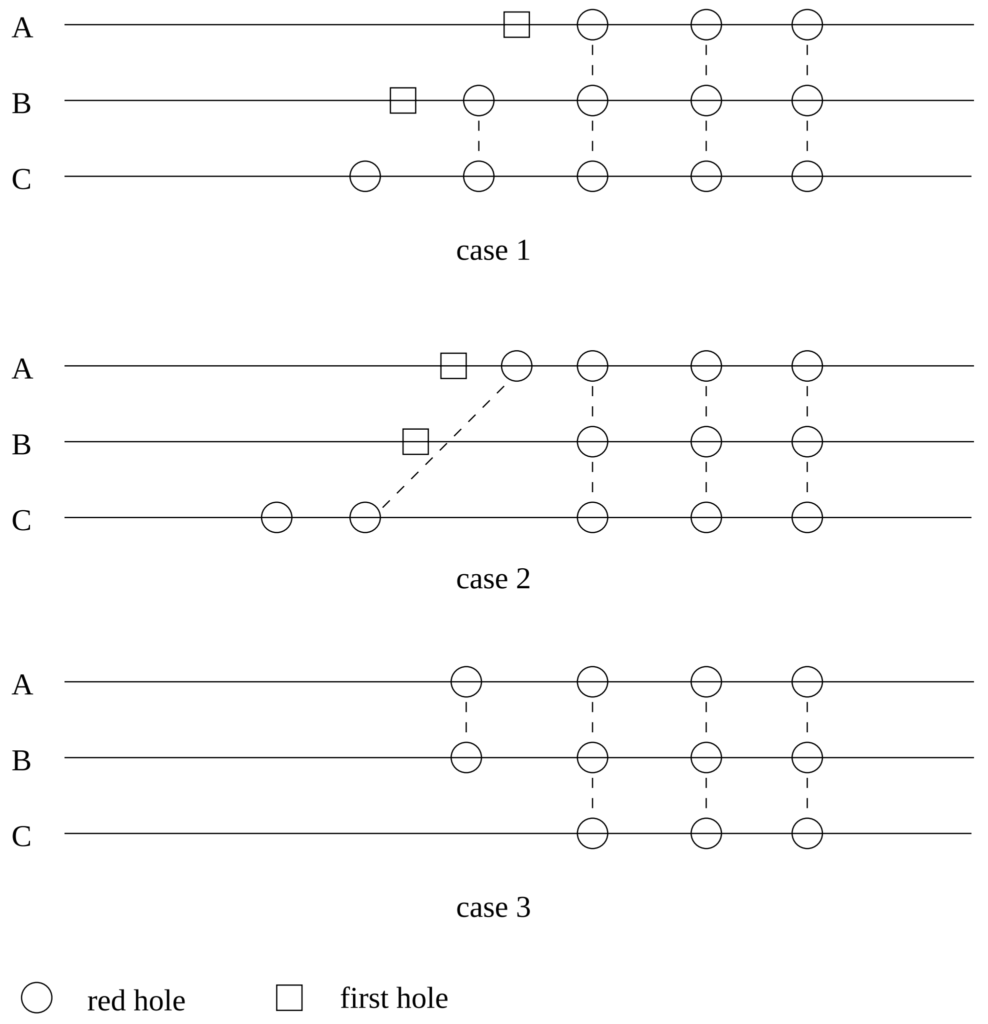

FIG. 5. *Strong domination is transitive.*

to B or A. ▯

We now prove Lemma 9 (the strong domination lemma).

Proof. Define $N_{col}(A)$, $N_{col}(B)$, and N_{col} as before.

We consider the individual changes to A and B in three steps:

1. A's first hole is removed (if necessary, i.e., if $New(A, (cur_A, col)) \neq A$).
2. B's new hole is added to B (if necessary) and A's new hole is added to A (if necessary).
3. B's first hole is removed (if necessary).

We will show that after each step, strong domination of A over B up to y is preserved.

For convenience, we will say that (a hole at) index i is "left" of (a hole at) index j, and (the hole at) j is "right" of (the hole at) i, if $i < j$.

First we prove part 1.

Step 1. *A's first hole is filled.*

Let *col* be the hole's color. First, since A's new first hole is to the right of its old first hole (the one being filled), B's excess holes all are still to the left of A's first hole. If *col* was an excess color of A, we are done. Otherwise, B's hole that was matched to A's filled hole becomes an excess hole, and since it occurred no later than the hole it matched, it is to the left of A's new first hole. Notice that $|A| < |B|$ at this point, in addition to the fact that A strongly dominates B.

Step 2. *Eviction.*

If $cur_A > y$, A's new hole does not affect strong domination up to y, and the addition of a new hole to B (whether left of, right of, or at y) cannot affect strong domination. If $cur_A \leq y$, let A's last N_{col} holes of the same color *col* as the block evicted occur at indices $a_1 < a_2 < \cdots < a_{N_{col}}$, and let B's occur at $b_1 < b_2 < \cdots < b_{N_{col}}$. Since A strongly dominates B, we know that $a_i \geq b_i$ for each i. Let B's new hole be its jth nonexcess hole of color *col*, i.e., the new hole occurs between b_{j-1} and b_j, or at an index greater than $b_{N_{col}}$ in which case $j = N_{col} + 1$, or before b_1 in which case $j = 1$. (As a special case, if *col* is an excess color of B, and the new hole is left of B's last excess hole of color *col*, the new hole becomes an excess hole and the last excess hole takes its place in the following argument.) Let A's new hole be its r^{th} hole of color *col*, with a special case similar to that in the definition of j. Let $a'_1 < a'_2 < \cdots < a'_{N_{col}+1}$ be the indices of A's last $N_{col} + 1$ holes of color *col* after the eviction, and let $b'_1 < b'_2 < \cdots < b'_{N_{col}+1}$ be the indices of B's last $N_{col} + 1$ holes of color *col* after the eviction. Then for $i < r$, $a'_i = a_i$ and for $i > r$, $a'_i = a_{i-1}$; for $i < j$, $b'_i = b_i$ and for $i > j$, $b'_i = b_{i-1}$. To show that domination is preserved, we need to show that $a'_i \geq b'_i$ for each i, $1 \leq i \leq N_{col} + 1$. For $i < \min(r, j)$ and $i > \max(r, j)$ it is immediate that $a'_i \geq b'_i$. If $r > j$, then we have

$$\begin{aligned} a'_r &> a_{r-1} \geq b_{r-1} = b'_r, \\ a'_{r-1} &= a_{r-1} \geq b_{r-1} > b'_{r-1}, \\ &\cdots \\ a'_j &= a_j \geq b_j > b'_j \end{aligned}$$

and we are done. If $r \leq j$, then we must show

$$\begin{aligned} a'_j &\geq b'_j, \\ a'_{j-1} &\geq b'_{j-1}, \\ &\cdots \\ a'_{r+1} &\geq b'_{r+1}, \\ a'_r &\geq b'_r. \end{aligned}$$

Suppose that one or more of these inequalities does not hold, and let i be the largest index for which $a'_i < b'_i$. Then either $i = j = N_{col} + 1$ and $a'_i < b'_i$, or

$$a'_i < b'_i < b'_{i+1} \leq a'_{i+1},$$

where A's new hole at a'_r satisfies $a'_r \leq a'_i$. In either case, there is a block that is not requested until index b'_i that is not a hole in A, and the new hole in A is a block requested earlier at index a'_r instead. But the definition of *New* states that the best possible eviction choice is made, i.e., that the block evicted is the block whose next occurrence is at the greatest index among all blocks of color *col* in the cache. Thus we have a contradiction.

Since the holes of color other than *col* are unaffected by this change, and domination of holes of color *col* is preserved, strong domination is preserved. Also, we still have that $|A| < |B|$.

Step 3. *B's first hole is filled.*

Let *col* be the hole's color. If *col* is an excess color of B, then B will have one fewer excess hole of color *col*; the remaining ones are unchanged, and thus are still to the left of A's first hole. Otherwise, the hole was matched to some hole of A, which becomes an excess hole. The newly excess hole's position is relevant in the definition of strong domination only if it is A's first hole; in this case, since neither A's first hole nor B's excess holes are changed, strong domination is preserved. Because $|A| < |B|$ before this step, we have that $|A| \leq |B|$ afterwards, as needed for strong domination.

The proof of part 1 is complete.

For part 2, step 1 is the same as in the proof of part 1. For step 2, first note that A's new hole is to the right of A's (old) first hole (by the *do no harm* rule), so that B's excess holes still precede all of A's holes. Let *col* be the color of A's new hole. If *col* is an excess color of B, an argument similar to the one above for part 1 shows that A's holes of color *col* will dominate B's nonexcess holes of the same color. If *col* is not an excess color of B, the new hole or some previous hole of A will become an excess hole. In the former case, A's last N_{col} holes are unchanged. In the latter case, the index of A's ith nonexcess hole of color *col* is the same as or greater than before, for each $i \leq N_{col}$. No changes are made in step 3.

For part 3 nothing happens in step 1. Let *col* be the color of B's new hole. Again, for step 2, an argument similar to that for part 1 shows that A's nonexcess holes of color *col* dominate B's nonexcess holes of color *col*; if not, A would contain a hole to the left of the next request for some block that is not a hole. If *col* is not an excess color of B, we are done with step 2. Otherwise, we need to show that all of B's excess holes of color *col* precede A's first hole. Suppose that B has $N_{col} + 1$ holes of color *col* at or to the right of A's first hole. A has only N_{col} holes of color *col*, so B has some hole h of color *col* that is not a hole of A and is to the right of A's first hole. Again, A would then contain a hole to the left of the next request for some block that is not a hole. Step 3 is the same as for part 1.

The proof of part 4 is an easy simplification of part 1, since A's new hole is beyond y and need not be considered. (B's new hole may be beyond y as well.) ∎

A particular case in which part 3 of Lemma 9 applies deserves mention. It may be that all blocks of some color *col* are holes in A, i.e., there are no blocks of color *col* in the cache, and that a fetch is not possible since there is no block of color *col* in the cache to evict, but that there are blocks of color *col* that are not holes in B. It may seem that a schedule with B as its set of holes has an advantage since it can make use of its disk *col* while a schedule with A as its set of holes cannot. But there is no advantage, provided that the conditions of strong domination are met. A is a superior state, and the schedule filling one of the holes in B by evicting a block of color *col* is merely "catching up" to the other schedule by eliminating one of its excess holes.

Here is our main result, the upper bound of Theorem 3.

Reverse aggressive *requires less than* $1 + DF/K$ *times the optimal elapsed time to service any request sequence, plus an additive term* DF *independent of the length of the sequence.*

Proof. For $D = 1$, the theorem follows directly from the result of [6]. Thus we may assume $D \geq 2$.

We show that for each $i \geq 0$ (numbering the phases starting with 0), there are times T_i and T'_i, such that

- T'_i is the time *opt*'s cursor reaches the ith phase;
- *reverse aggressive*'s cursor position at time T_i is at least as great as *opt*'s

cursor position at time T'_i;
- for $i > 0$, $T_i - T_{i-1} \leq T'_i - T'_{i-1} + DF - 1$;
- $H^+_{rev}(T_i)$ strongly dominates $H^+_{opt}(T'_i)$;
- if *reverse aggressive*'s busy disk for phase i will become free (i.e., complete any fetch in progress) in $z \leq F - 1$ steps after T_i, then *opt*'s corresponding disk will not become free until $z' \geq z$ steps after T'_i.

If there are p phases, we take T_p (respectively, T'_p) to be the time at which *reverse aggressive* (respectively, *opt*) finishes serving the request sequence.

The theorem will follow from the first three conditions as follows. For each phase i, *reverse aggressive*'s elapsed time $e_{rev}(i) = T_{i+1} - T_i$ and *opt*'s elapsed time $e_{opt}(i) = T'_{i+1} - T'_i$ satisfy

$$e_{rev}(i) \leq e_{opt}(i) + DF - 1$$

so that

$$\frac{e_{rev}(i)}{e_{opt}(i)} \leq 1 + \frac{DF - 1}{e_{opt}(i)}.$$

Each phase, except possibly the last, is of length at least K, so that $e_{opt}(i) \geq K$. Putting these together, we have that for all phases but the last,

$$\frac{e_{rev}(i)}{e_{opt}(i)} \leq 1 + \frac{DF - 1}{K}.$$

The last phase may be incomplete, i.e., may contain requests for fewer than K distinct blocks. *Reverse aggressive* requires at most $DF - 1$ steps more than *opt* to serve the last phase.

We prove the claims about T_i and T'_i by induction. For the base case ($i = 0$), we take $T_0 = T'_0 = 0$. The fact that the claims hold at this time is trivial. For the inductive step, assume the claims hold for the ith phase. We show that they hold for the $(i + 1)$st phase via a two-step process.
- We first show in Lemma 13 that in phase i, *reverse aggressive* (starting at time T_i) loses at most $(D - 1)F$ steps to *opt* (starting at time T'_i).
- We then use this fact to show that at the end of the phase, by giving *reverse aggressive* an extra $DF - 1$ steps relative to *opt* (from the start of the phase), the invariants are restored.

We begin with a formal statement of the first of these steps.

LEMMA 13. *Suppose that at time T_i,* reverse aggressive*'s cursor is at position p_i in the sequence. Let $T'_i + t_O(j)$ (respectively, $T_i + t_R(j)$) denote the time at which* opt *(respectively,* reverse aggressive*) serves the request at cursor position $j \geq p_i$, for any j such that r_j is in phase i. Then for all j in the phase, $t_R(j) \leq t_O(j) + (D - 1)F$.*

Proof. For the sake of contradiction, suppose the contrary, and consider the least index ℓ such that $t_R(\ell) > t_O(\ell) + (D - 1)F$.

First, consider the case in which ℓ precedes the first hole in $H^+_{rev}(T_i)$. Each of *reverse aggressive*'s fetches in progress at time T_i completes by time $T_i + F - 1$, so that *reverse aggressive*'s cursor cannot stall more than $F - 1$ steps before reaching the first hole in $H^+_{rev}(T_i)$. Recall we have assumed $D \geq 2$; thus we have a contradiction.

The remainder of the proof of Lemma 13 (and the bulk of that of the upper bound of Theorem 3) consists of the remaining case, in which ℓ is at or beyond the first hole in $H^+_{rev}(T_i)$. By the minimality of ℓ, $t_R(\ell - 1) \leq t_O(\ell - 1) + (D - 1)F$, and *reverse* *aggressive* stalls at least one step more than *opt* on request r_ℓ. In particular, *reverse aggressive* stalls at time $T_i + t_R(\ell) - 1$, and *opt* does not stall at time $T'_i + t_O(\ell)$. *Reverse aggressive* initiates a prefetch for the block requested at index ℓ at time $T_i + t_R(\ell) - 1 - x$ for some $0 \leq x \leq F - 1$; at this time, r_ℓ is *reverse aggressive*'s first hole. We will show that *opt* must have a hole that it has not yet begun to fill at an index no greater than ℓ at time $T'_i + t_O(\ell) - x$, and thus cannot serve r_ℓ before time $T'_i + t_O(\ell) - x + F > T'_i + t_O(\ell)$. Recall that *reverse aggressive*'s busy disk will be free in $x \leq F - 1$ steps after T_i, and *opt*'s corresponding disk will be free in $z' \geq z$ steps after T'_i.

Reverse aggressive will perform busy-disk fetches continuously, initiating a fetch at time $T_i + z + bF$ for each $b \geq 0$, at least until such a time as there are no holes left in the phase. Once there are no holes left in the phase, *reverse aggressive* will not stall at least until the end of the phase is reached. Let b and δ be such that $t_R(\ell) - 1 - x - z = bF + \delta$ and $0 \leq \delta < F$. Then *reverse aggressive* has filled b holes by busy-disk fetches by time $T_i + t_R(\ell) - 1 - x$, and *opt* has filled at most $b - D + 1$ holes by busy-disk fetches by time $T'_i + t_O(\ell) - x$, since

$$\begin{aligned} t_O(\ell) - x - z' &< t_R(\ell) - x - z - (D-1)F \\ &= bF + \delta + 1 - (D-1)F \\ &\leq (b - D + 2)F. \end{aligned}$$

Let n be the number of non-busy-disk fetches initiated by *opt* by time $T'_i + t_O(\ell) - x$. Consider the sequence $S = ((cur_1, col_1), \ldots, (cur_{n+b-D+1}, col_{n+b-D+1}))$ of fetches *opt* initiates after time T'_i and at or before time $T'_i + t_O(\ell) - x - F$, where the pair (cur, col) denotes that a fetch evicting a block of color col is initiated at cursor position cur. For each fetch (cur', col') of *opt*, we define a *matching fetch opportunity* of *reverse aggressive*. A matching fetch opportunity is a pair (cur, col) such that *reverse aggressive* has the opportunity to initiate a fetch of color col at a cursor position at least as great as cur. Each matching fetch opportunity to a fetch in S allows *reverse aggressive* to initiate a fetch (if allowed by the *do no harm* principle) by time $T_i + t_R(\ell) - 1 - x - F$. They are defined as follows:

- Let *opt*'s jth non-busy-disk fetch be initiated at time $T'_i + t'_j$. This fetch is matched to the fetch on the same disk that *reverse aggressive* initiates (if any) in the time interval

$$[T_i + t'_j + (D-1)F, T_i + t'_j + DF - 1].$$

Note that by the minimality of ℓ, at time $T_i + t'_j + (D-1)F$ *reverse aggressive*'s cursor is already at or beyond the cursor position at which *opt* initiates its jth non-busy-disk fetch, and its disk of the same color becomes free (finishes any fetch already in progress) within another $F - 1$ steps. Therefore, such a fetch opportunity exists. The fact that *reverse aggressive*'s cursor position at the time of this matching fetch opportunity is at least as great as *opt*'s at the time of its fetch will allow us to apply part 1 or part 3 of the strong domination lemma (Lemma 9) to this pair.

If *opt* initiates a total of n non-busy-disk fetches by time $T'_i + t_O(\ell) - x$, then each fetch except (possibly) the last one on each non-busy-disk (i.e., at least $n - (D-1)$ of the n non-busy-disk fetches) is initiated at a time less than or equal to $T'_i + t_O(\ell) - x - F$. Therefore, *reverse aggressive* can initiate a matching fetch if needed at a time strictly less than

$$T_i + t_O(\ell) - x + (D-1)F < T_i + t_R(\ell) - x.$$

- *opt*'s jth busy-disk fetch is matched to the jth busy-disk fetch *reverse aggressive* performs in the phase. Since *reverse aggressive* prefetches continuously using its busy disk, we know that each of these fetch opportunities corresponds to an actual fetch. Part 4 of the strong domination lemma will be applied to this pair of fetches.
- Finally, each non-busy-disk fetch initiated by *opt* between times $T_i' + t_O(\ell) - x - F + 1$ and $T_i' + t_O(\ell) - x$ is matched to one of the last $D - 1$ busy-disk fetches initiated by *reverse aggressive*. Note that there can be only one such fetch of each color. Part 4 of the strong domination lemma will be applied to this pair of fetches.

We claim that *reverse aggressive*'s holes after these $n + b - D + 1$ matching fetch opportunities strongly dominate *opt*'s holes up to the end of the phase after *opt* initiates its sequence S of n non-busy-disk fetches and at most $b - D + 1$ busy-disk fetches. Let R_0 be *reverse aggressive*'s set of holes $H^+_{rev}(T_i)$ at time T_i. Let O_0 be *opt*'s set of holes $H^+_{opt}(T_i')$ at time T_i'. Define O_j, $j \geq 1$, inductively as the set of holes resulting from initiating *opt*'s jth fetch (cur_j, col_j) with the set of holes O_{j-1}; i.e., $O_j = New(O_{j-1}, (cur_j, col_j))$. Similarly, define R_j, $j \geq 1$, inductively by $R_j = New(R_{j-1}, (cur_j, col_j))$. $R_{n+b-D+1}$ is the state that would be reached by starting in *reverse aggressive*'s state R_0, but then initiating fetches (when allowed by *do no harm*) according to *opt*'s prefetching schedule. By a sequence of applications of part 1 and part 3, as appropriate, of the strong domination lemma (Lemma 9), we have that $R_{n+b-D+1}$ strongly dominates $O_{n+b-D+1}$ up to the end of the phase.

We now show that *reverse aggressive*'s holes after its matching fetch opportunities pass strongly dominate $R_{n+b-D+1}$ up to the end of the phase. Because strong domination is transitive (Lemma 12), we will obtain that *reverse aggressive*'s holes strongly dominate *opt*'s up to the end of the phase. Since *opt* and *reverse aggressive* may perform fetches on different disks at different times and in different orders, we need to somehow permute *opt*'s schedule of fetches into *reverse aggressive*'s; then we will be able to make pairwise comparisons between the two sequences of fetches and apply the strong domination lemma. Toward this end, we define the following.

DEFINITION 14. *Consider a fetch sequence, defined by a sequence of triples of the form* (t_j, cur_j, col_j), *where for each* j, $t_j \leq t_{j+1}$ *and* $cur_j \leq cur_{j+1}$. (t_j, cur_j, col_j) *denotes a fetch, or an opportunity to fetch, beginning at time* t_j *with the cursor at position* cur_j, *where the color of the evicted block is* col_j. *A fetch opportunity denotes an opportunity to fetch in the sense that the disk is free, but no fetch may be possible under the optimal prefetching rules.*

DEFINITION 15. *A fetch sequence* S *is obtained from a fetch sequence* S' *by a* busy-early swap *if* S' *and* S *are the same except that a pair* (t_j', cur_j', col_j), $(t_{j+1}', cur_{j+1}', col_{j+1})$ *in* S' *is replaced by* (t_j, cur_j, col_{j+1}), $(t_{j+1}, cur_{j+1}, col_j)$ *in* S, *where* $cur_j \geq p_i$ *(recall that* p_i *is* reverse aggressive*'s cursor position at time* T_i*),* $cur_{j+1} \geq cur_j'$, *and* col_{j+1} *is the color of* reverse aggressive*'s busy disk for the phase.* $cur_j \geq p_i$ *will be enough to ensure that* reverse aggressive *is able to complete a fetch with the busy disk and that the new hole is beyond the end of phase* i, *which is enough to maintain strong domination up to the end of the phase, regardless of the fetch/eviction pair of* opt *to which this fetch of* reverse aggressive *is matched.*

DEFINITION 16. *A fetch sequence* S *is obtained from a fetch sequence* S' *by an* overlapping swap *if* S *and* S' *are the same except that a pair* (t_j', cur_j', col_j), $(t_{j+1}', cur_{j+1}', col_{j+1})$ *in* S' *is replaced by* (t_j, cur_j, col_{j+1}), $(t_{j+1}, cur_{j+1}, col_j)$ *in* S, *where* $t_{j+1}' < t_j' + F$, $t_{j+1} < t_j + F$, $cur_j \geq cur_{j+1}'$, *and* $cur_{j+1} \geq cur_j'$. *(Note* *that $cur_{j+1} \geq cur'_j$ is implied by $cur_j \geq cur'_{j+1}$, since cursor positions increase with time.)*

We extend the notation $New(A, (cur, col))$ to allow a series of fetches or fetch opportunities, with or without the time indices (which have no effect on the resulting set of holes), in the obvious way: $New(A, S) = New(New(A, f_1), f_2, \ldots, f_{|S|})$, where $S = f_1, \ldots, f_{|S|}$ is a sequence of fetches or fetch opportunities.

Before we can complete the proof of Lemma 13, we need the following three lemmas.

LEMMA 17. *Suppose that fetch sequence S within phase i is obtained from fetch sequence S' by a busy-early swap. Then $New(R_0, S)$ strongly dominates $New(R_0, S')$ up to the end of the phase.*

Proof. Let blue denote the color of *reverse aggressive*'s busy disk, and let red denote the color of the first disk to fetch under S' in the swapped pair. We refer to fetches using the blue disk as blue fetches, even though blue is the color of the evicted block; the block fetched may be any color. We refer to fetches using the red disk as red fetches, even though red is the color of the evicted item. The sets of holes of the two sequences immediately before initiating the swapped pair of fetches are the same. In both cases, a blue fetch can be initiated, since by hypothesis there are still holes in the phase. This blue fetch will not require an eviction that creates a new hole within the phase.

Unless the first hole filled is a red block, the set of red blocks in the cache at the time the red fetch is initiated is the same under S' and S. If the first hole is red, then under S', this red block is brought into the cache by the red fetch, and under S, by the blue fetch. Thus, the best eviction opportunity at the time of the red fetch under S is at least as good as that under S', since under S the red fetch occurs at a cursor position cur_{j+1} at least as great as that under S', which is cur_j.

Let the first hole occur at index h_1 and the second at h_2; let the new hole created by the red fetch under S' occur at index h_r. There are two possibilities:

- $h_2 < h_r$. Under S', the red fetch fills h_1 and the blue fetch fills h_2; under S, the blue fetch fills h_1 and the red fetch fills h_2. The red hole created under S is at a position in the request sequence at least as great as h_r, since the cursor position of the red fetch is at least as great as under S'. Under neither sequence does the blue eviction create a new hole in phase i. Thus, the sets of holes remaining in phase i after completing S' and S are the same, or after S one red hole has a greater index than after S'.
- $h_1 < h_r < h_2$. Under S', the red fetch fills h_1 and creates a hole at h_r. This new hole is the first hole at the time of the blue fetch, and thus the blue fetch fills it (leaving h_2 unfilled). Under S, however, the red fetch may be unable to proceed. The blue fetch fills the hole at h_1; after this, the first hole is at h_2. The red eviction of h_r would violate the rule *do no harm*. But the end result is the same as it is under S' (ignoring holes beyond the end of the phase): the next hole is at h_2, and a new blue hole has been created beyond the end of the phase. The red block requested at h_r does not get evicted and then fetched back, as it does under S'. (Again, under S it may be possible to create a red hole with greater index; in this case, h_2 gets filled, and the holes dominate those after S' up to the end of the phase by part 2 of the strong domination lemma.) ∎

LEMMA 18. *Suppose that fetch sequence S is obtained from fetch sequence S' by an overlapping swap. Then for any set A of holes, $New(A, S)$ strongly domi-*

nates $New(A, S')$ up to the end of the entire sequence and thus up to the end of the phase.

Proof. Neither fetch affects the eviction opportunities of the other, since they overlap and evict to different disks. Because they overlap, the first does not bring a block into the cache in time for it to be served before the second fetch starts. An easy consequence of the rules described in section 2.4 is that each block fetched is served at least once before it is subsequently evicted. Because they evict to different disks, the first does not evict a block that could otherwise be evicted by the second.

For each of the two fetches under S', the fetch of the same color under S is initiated at a cursor position at least as great. An argument similar to the proof of Lemma 17 finishes the proof. ∎

LEMMA 19. Reverse aggressive*'s sequence of fetch opportunities can be obtained from the sequence leading to $R_{n+b-D+1}$ (i.e.,* opt*'s sequence of fetches) via a sequence of busy-early swaps, overlapping swaps that do not involve fetches performed by the busy disk, substitutions of busy-disk fetches for non-busy-disk fetches, and insertions of extra fetches not matched to any fetch of* opt.

Proof. The definition of matching fetch opportunities identifies a sufficient set of fetch opportunities. We will show that no operations other than those described are necessary to transform *opt*'s sequence of fetches to *reverse aggressive*'s sequence of matching fetch opportunities.

First we show that for each disk other than the busy disk, any inversion of fetches on that disk and the busy disk is in the "right direction" (i.e., corresponds to a busy-early swap). Let blue denote the color of the busy disk, and let red denote the color of some other disk. For $1 \leq j \leq b$, let $T_i + t_{B_j}$ be the time at which *reverse aggressive*'s jth blue fetch is initiated, and for $1 \leq j \leq b - D + 1$, let $T'_i + t'_{B_j}$ be the time at which *opt*'s jth blue fetch is initiated. For $1 \leq j \leq r$, let t'_{R_j} be the time at which *opt*'s jth red fetch is initiated, and for $1 \leq j \leq r - 1$, let t_{R_j} be the time at which *reverse aggressive*'s matching fetch is initiated, where r is the number of red fetches initiated by *opt* at or before $T'_i + T_O(\ell)$.

First, consider all of *reverse aggressive*'s blue and red fetches except its last $D-1$ blue fetches, and all of *opt*'s blue and red fetches except its last red fetch (which is matched to one of *reverse aggressive*'s last $D - 1$ blue fetches). We have that for all $j \leq b-D+1$, $t_{B_j} \leq t'_{B_j}$ (i.e., *reverse aggressive*'s jth blue fetch is no later than *opt*'s, by the definition of matching fetch opportunities) and for all $j \leq r - 1$, $t_{R_j} \geq t'_{R_j}$ (i.e., *reverse aggressive*'s jth red fetch is no earlier than *opt*'s). Suppose that there is an inversion in the "wrong direction," i.e., that for some j and some k, $t'_{B_j} < t'_{R_k}$ and $t_{R_k} < t_{B_j}$. Then

$$t'_{B_j} < t'_{R_k} \leq t_{R_k} < t_{B_j} \leq t'_{B_j},$$

which contains the contradiction $t'_{B_j} < t'_{B_j}$.

Next, consider *opt*'s last (rth) red fetch. Recall that this fetch is matched to one of *reverse aggressive*'s last $D - 1$ blue fetches. This requires the substitution of a blue fetch for a red fetch, and possibly some number of busy-early swaps to move the blue fetch forward to its place in *reverse aggressive*'s sequence of fetches; no other red fetches in the sequence are affected by this.

For fetches other than blue fetches (i.e., non-busy-disk fetches), let $T'_i + t'_1$ and $T'_i + t'_2$ be the times of two fetches of *opt*, where $t'_1 \leq t'_2$, and let $T_i + t_1$ and $T_i + t_2$ be the times of *reverse aggressive*'s matching fetch opportunities. If *opt*'s fetches do not overlap, then $t'_1 \leq t'_2 - F$. By the definition of matching fetch opportunites, we have

$t_1 \leq t'_1 + DF - 1$ and $t_2 \geq t'_2 + (D-1)F$. Putting these together, we have $t_1 < t_2$, i.e., *reverse aggressive*'s matching fetch opportunities occur in the same order as *opt*'s fetches.

That the cursor positions of the swapped pairs satisfy the inequalities in the definitions of busy-early-swaps and overlapping swaps, respectively, can be seen from the definition of matching fetch opportunities. □

We now complete the proof of Lemma 13 using Lemmas 17, 18, and 19. We show that *reverse aggressive*'s holes at time $T_i + t_R(\ell) - 1 - x$ strongly dominate *opt*'s holes at time $T'_i + t_O(\ell) - x$ up to the end of the phase, as follows. Let $S_{opt} = S_1, S_2, \ldots, S_m = S_{rev}$ be the series of fetch sequences obtained in the transformation of *opt*'s fetch sequence into *reverse aggressive*'s that was shown to exist by Lemma 19. Recall that we have already shown that $New(R_0, S_{opt}) = R_{n+b-D+1}$ strongly dominates *opt*'s set of holes $New(O_0, S') = O_{n+b-D+1}$ up to the end of the phase. For each $1 < i \leq m$, $New(R_0, S_i)$ strongly dominates $New(R_0, S_{i-1})$ by Lemma 17, if S_i is derived from S_{i-1} by a busy-early swap, by Lemma 18, if S_i is derived from S_{i-1} by an overlapping swap, by part 2 of the strong domination lemma (Lemma 9), if S_i is derived from S_{i-1} by an insertion; or by part 4 of the strong domination lemma (Lemma 9), if S_i is derived from S_{i-1} by the substitution of a busy-disk fetch for a non-busy-disk fetch. By transitivity of strong domination (Lemma 12), $New(R_0, S_{rev})$ strongly dominates $New(O_0, S_{opt})$ up to the end of the phase.

Thus we have the following corollary.

COROLLARY 20. Reverse aggressive*'s first hole at time $T_i + t_R(\ell) - 1 - x$ is at a cursor position at least as great as* opt*'s first hole at time $T'_i + t_O(\ell) - x$.*

This contradicts the hypothesis that *reverse aggressive* stalls at time $T_i + t_R(\ell) - 1$ and *opt* does not stall at time $T'_i + t_O(\ell)$, and completes the proof of Lemma 13. □

We now use Lemma 13 to complete the inductive step of the proof of the upper bound of Theorem 3.

Let T'_{i+1} be the time at which *opt*'s cursor first reaches phase $i+1$ (i.e., one greater than the time at which *opt* serves the last request in phase i). Let f'_j be the jth fetch *opt* initiates after time T'_i and at or before time T'_{i+1}, and suppose it begins at time $T'_i + t'_j$. Define the jth *dominating fetch opportunity* to be the fetch opportunity (possibly an actual fetch) that *reverse aggressive* has on the same disk as f'_j in the time interval

$$[T_i + t'_j + (D-1)F, T_i + t'_j + DF - 1],$$

say, at time $T_i + t_j$. (Notice this is a different matching than that used in Lemma 13. In this matching, fetches of all colors are matched in the same way non-busy-disk fetches were matched in Lemma 13.) By Lemma 13, we know that *reverse aggressive*'s cursor position at time $T_i + t_j$ is at least as great as *opt*'s cursor position at time $T'_i + t'_j$.

By the same argument as in the proof of Lemma 19, *reverse aggressive*'s sequence of dominating fetch opportunities can be obtained from *opt*'s sequence of fetches by a series of overlapping swaps and insertions. Applying the strong domination lemma (Lemma 9), Lemma 18, and transitivity of strong domination (Lemma 12) as needed, we obtain that *reverse aggressive*'s holes after its dominating fetch opportunities have passed strongly dominate *opt*'s holes after completing its sequence of fetches. This is the same argument as in the proof of Lemma 13, but without the complication of busy-early swaps.

By Lemma 13, *reverse aggressive*'s cursor reaches phase $i+1$ by time $T_i + (T'_{i+1} - T'_i) + (D-1)F$. Within another $F-1$ steps, *reverse aggressive* initiates its dominating fetches matching the ones *opt* has in progress at time T'_{i+1}. A fetch of *opt* started at time $T'_{i+1} - x$ is matched (if needed) by *reverse aggressive* by time $T_i + (T'_{i+1} - T'_i) + DF - 1 - x$; in particular, if *opt* has a fetch in progress on *reverse aggressive*'s busy disk for phase $i+1$ at time T'_{i+1}, that fetch has at least as many steps remaining at time T'_{i+1} as *reverse aggressive*'s fetch (if any) has remaining at time $T_i + (T'_{i+1} - T'_i) + DF - 1$. Thus if we take time T_{i+1} to be $T_i + (T'_{i+1} - T'_i) + DF - 1$, the invariants are restored. $\square$

4.2. Reverse aggressive: Lower bound. We have been unable to strengthen the lower bound of Cao et al. [6], which showed that *aggressive* can perform $(1 + (F - 1)/K)$ times worse than optimal in the single-disk case. This bound applies directly to *reverse aggressive*, since there is no asymmetry between the reverse and forward problems in the single-disk case. It applies to the multiple-disk case as well, since a request sequence that contains only blocks that reside on a single disk is a special case.

4.3. Conservative: Lower bound. The following example shows that for $D < F \leq K$, there are arbitrarily long strings on which *conservative* requires time $1 + D\frac{K-F}{K}\frac{F}{F+D}$ times the optimal elapsed time.

Suppose that F divides K, and also that D divides K, and consider a repeated cycle on $K + (\frac{K}{F} - 1)D$ blocks. *Conservative* always evicts the page just referenced whenever it fills a hole, since that is the page that will not be needed again for the longest time. Thus *conservative* will never be able to overlap prefetches with each other or with references. Since there are at least $(\frac{K}{F} - 1)D$ holes on each pass through the cycle, *conservative* will spend at least $K + (\frac{K}{F} - 1)D + (\frac{K}{F} - 1)DF$ steps on each pass through the cycle. Suppose that the blocks are colored such that each contiguous sequence of D blocks in the cycle contains one block from each of the D disks. It is not hard to see that *opt* is able to maintain its holes in groups of D, one of each color, spaced F steps apart. Thus *opt* can service the entire sequence without stalling, and requires only $K + (\frac{K}{F} - 1)D$ steps on each pass through the cycle. The ratio of these two expressions (after a little manipulation) turns out to be at least as great as the stated bound.

4.4. Conservative: Upper bound. We now show that on any reference string R, the elapsed time of *conservative* with D disks on R is at most $D + 1$ times the elapsed time of the optimal prefetching strategy on R.

Let m be the minimum number of fetches (which is exactly how many fetches *conservative* performs) on request sequence R. *Conservative*'s elapsed time is at most $|R| + mF$, even if it never overlaps prefetches with each other or with the servicing of requests. Since the optimal algorithm *opt* must perform at least as many fetches as *conservative* and also must service the request sequence R, *opt*'s elapsed time is at least $\max(|R|, mF/D)$. The ratio of these is maximized with $|R| = mF/D$, and has the value $D + 1$.

4.5. Aggressive: Lower bound. The following example shows that for two disks, there are arbitrarily long strings on which *aggressive* requires time $2 - \frac{4}{F+2}$ times the optimal elapsed time (within an additive constant that depends only on F and K). In general, our bound is a little weaker: for D disks, there are arbitrarily long strings on which *aggressive* requires time $D - \frac{3D(D-1)}{F+3(D-1)}$ times the optimal elapsed time (within an additive constant that depends only on F and K). Consider the sequence

$$b_1 b_2 r_1 \cdots r_F b_3 b_4 r_F \cdots r_1 b_2 b_1 r_1 \cdots r_F b_4 b_3 \cdots,$$

where all r_i are red and all b_i are blue. Let $K = F + 2$. The initial cache contents are b_1, b_2, and $r_1 \cdots r_F$; there are holes at the first references to b_3 and b_4. Both algorithms service the initial request of b_1 during the first unit of time. *Aggressive* then evicts the block in its cache not referenced for the longest time, b_1, in order to fetch b_3; the optimal algorithm *opt* does the same. At the completion of this fetch, the next hole for both algorithms is at b_4, and the cursor is at the first request of r_F. *Aggressive* immediately evicts the block among those in the cache not used for the longest time, which is now b_2; *opt* evicts r_1 instead. Both algorithms stall for $F - 2$ steps on the hole at b_4. However, *opt* is able to initiate a fetch of its next hole, r_1, evicting b_3, since the hole is red and the fetch in progress is fetching a blue block; *aggressive* is unable to perform a second fetch in parallel because its next hole (b_2) is also blue. Notice that *aggressive* still has no red holes, and thus can complete only one fetch every F steps. From this point on, *opt* is able to create one red and one blue hole in each subsequence of $F + 2$ requests, and can always fill them without stalling, whereas *aggressive* will always create a pair of blue holes, and will require time $2F$ to serve each subsequence of $F + 2$ requests, since it takes this long to complete two fetches. Thus from this point on, the ratio of *aggressive*'s elapsed time to that of *opt* is $\frac{2F}{F+2} = 2 - \frac{4}{F+2}$.

We have illustrated the case $K = F + 2$, $D = 2$ for simplicity. It is easily generalized to larger values of $\frac{K}{F}$ (which are the cases of interest in practice) as follows: let $K = iF + 2$, and interleave i distinct subsequences of F distinct red blocks each with $i + 1$ distinct pairs of blue blocks in round-robin fashion, reversing each subsequence of red blocks and each pair of blue blocks on alternate occurrences. It is not hard to see that *aggressive* will behave similarly to the illustrated case, and that *opt* is able to service the sequence without stalling (after an initial startup period).

The generalization to $D > 2$ is also straightforward. Consider the sequence

$$b_1 \cdots b_D b_1 \cdots b_{D-2} x_1 \cdots x_{D-1} r_1 \cdots r_{F-D+1} x'_1 \cdots x'_{D-1} \cdots$$

$$\cdots b_{D+1} \cdots b_{2D} b_{D+1} \cdots b_{2D-2} \cdots,$$

where $F > D$ and $K = F + 2D - 1$, the colors of the b_i are all the same, the colors of the x_i are distinct from each other and the color of the b_i, and the color of x'_i is the same as that of x_i. We omit the details of the startup period, and note that if *aggressive* has holes at $b_1 \cdots b_D$, it will fill them by evicting $b_{D+1} \cdots b_{2D}$ and thus requires time at least DF to serve the sequence up to b_{D+1}. Its state is then similar to the state in which it started, and thus the process can repeat indefinitely. *opt*, on the other hand, is able to maintain D holes of D distinct colors, and can serve the sequence without stalling. Each sequence of $3(D - 1) + F$ requests requires time $3(D - 1) + F$ for *opt*, and DF for *aggressive*, for a ratio of

$$\frac{DF}{3(D-1)+F} = D - \frac{3D(D-1)}{F+3(D-1)}.$$

Again, generalizing to arbitrary K/F is easy.

4.6. Aggressive: Upper bound. First we state a very simple lemma, leaving the proof to the reader.

LEMMA 21. *If a set A of holes dominates a set B of holes, and some hole in A is filled and some hole at a larger index added to A, the resulting holes A' dominate B.*

We now show that on any reference string R, the elapsed time of *aggressive* with D disks on R is at most $D(1+\frac{F+1}{K})$ times the elapsed time of the optimal prefetching strategy on R.

Proof. In the analysis of aggressive prefetching with one disk, it was shown that if A's holes dominate B's holes, and A's cursor position is at least as great as B's, and each algorithm initiates a fetch, A's holes will continue to dominate B's when the fetch is completed. This result was referred to as the *domination lemma* [6]. The proof of this is similar to but simpler than that of Lemma 9 for algorithms working with the reverse sequence.

In order to apply this lemma to more than one disk, we must be sure that when we are comparing a fetch A initiates to a fetch B initiates that the hole being filled by A is *the first hole*. If not, the domination lemma does not hold.

In general, we cannot ensure that D parallel prefetches *aggressive* initiates will fill the first D holes, since some of these holes may be of the same color. However, we do know that by the time *aggressive* completes D prefetches on the same disk, the first D holes that were present (and perhaps others) have been filled. Thus our proof strategy is to run *opt* at $1/D$ times the speed of *aggressive*, so that during each subsequence of time in which *aggressive* fills *at least* its first D holes, *opt* can fill *at most* its first D holes. We will show inductively that at the end of each of these subsequences, *aggressive*'s holes dominate *opt*'s holes. This will imply that *aggressive* can take only about D times as long as *opt* to complete a phase.

Notice that as long as there are holes in the phase containing the cursor, there are blocks in the cache which are not requested before the end of the phase (since the cache holds K blocks and there are only K distinct requests in a phase). Since *aggressive* always evicts the block that is not requested for the longest time, once its cursor enters a phase, *aggressive* will not create any new holes within the phase. Also, once *aggressive* enters a phase, each disk will initiate a fetch every F steps as long as there are holes of that disk's color remaining in the phase.

We show that for each i such that $0 \le i < p-1$ where p is the number of phases (numbering the phases starting with 0), there are times T_i and T'_i, such that

- $T_i \le DT'_i + i(D+1)F$;
- *aggressive*'s cursor is in the ith phase of the request sequence at time T_i;
- *opt*'s cursor at time T'_i is not past the first request of phase i;
- $H^-_{agg}(T_i)$ dominates $H^+_{opt}(T'_i)$, so that each of *aggressive*'s disks is either ready to initiate a prefetch or is already filling a hole in phase i, for which *opt* has not yet started filling its matching hole.

The theorem will follow from the first three conditions, as follows. For each phase i, *aggressive*'s elapsed time $e_{agg}(i)$ and *opt*'s elapsed time $e_{opt}(i)$ satisfy

$$e_{agg}(i) \le De_{opt}(i) + (D+1)F$$

so that

$$\frac{e_{agg}(i)}{e_{opt}(i)} \le D + \frac{(D+1)F}{e_{opt}(i)}.$$

Each phase except possibly the last is of length at least K, so that $e_{opt}(i) \ge K$. Putting these together, we have that for all phases but the last,

$$\frac{e_{agg}(i)}{e_{opt}(i)} \le D + \frac{(D+1)F}{K}.$$

The last phase may be incomplete, i.e., may contain requests for fewer than K distinct blocks. *Aggressive* requires at most D times as many steps as *opt* to serve the last phase, as shown below.

This claim is proven by induction on i. The basis ($i = 0$) is trivial, since both algorithms start at the beginning of the first phase in the same state, with all disks idle.

For the induction, assume that the claim is true for i.

We first show that for each index j in phase i, *aggressive*'s cursor passes j after at most D times as many steps as *opt*'s cursor takes to pass j. Let $T_i + t_A(j)$ be the time *aggressive* serves request j, and let $T'_i + t_O(j)$ be the time *opt* serves j. Assume by way of contradiction that *aggressive*'s cursor falls behind *opt*'s (relative to the start of the phase) by more than a factor of D, and let ℓ be the least index for which this happens, i.e., $t_A(\ell) > Dt_O(\ell)$. It must be true that *aggressive* has a hole at ℓ (or equivalently stalls on the ℓth request in the phase) at time $T_i + t_A(\ell) - 1$, and that the ℓth request in the phase is in *opt*'s cache before time $T'_i + t_O(\ell)$, since $T_i + t_A(\ell)$ is the *first* time *aggressive*'s cursor falls behind *opt*'s by more than a factor of D. As noted previously, each disk of *aggressive*'s fills a hole every F steps as long as there are holes of that disk's color in the phase. Let h be the number of holes in $H^-_{agg}(T_i)$ that are the same color as the one at ℓ, up to and including the one at ℓ. Then $t_A(\ell) \leq hF$, since the hole at ℓ is filled at a time no later than $T_i + hF$. $H^+_{opt}(T'_i)$ contains at least h holes at or before ℓ, since $H^-_{agg}(T_i)$ dominates $H^+_{opt}(T'_i)$. Thus the earliest time *opt* could finish filling all its holes up to index ℓ is $T'_i + \lceil h/D \rceil F$, even if it fills a hole every F steps with each disk. Thus we have a contradiction: $hF \geq t_A(\ell) > Dt_O(\ell) \geq D(\lceil h/D \rceil F) \geq hF$.

To show that *aggressive*'s holes after finishing phase i dominate *opt*'s holes, we need another induction. Let I'_j denote the F-step interval $[T'_i + jF, T'_i + (j+1)F)$, $j \geq 0$, and let cur_j be *opt*'s cursor position at time $T'_i + jF$, for each j such that *opt*'s cursor is still in phase i at time $T'_i + jF$. Let $I_j = [T_i + jDF, T_i + (j+1)DF)$. Consider the set of at most D fetches that *opt* initiates during I'_j. We match these to the set of fetches *aggressive* initiates during I_{j+1}. We prove by induction on j that $H^+_{opt}(T'_i + jF)$ is dominated by $H^+_{agg}(T_i + D(j+1)F)$. The base case follows from the hypothesis that $H^-_{agg}(T_i)$ dominates $H^+_{opt}(T'_i)$. Any fetches completed or initiated by *aggressive* during I_0 do not affect this, by Lemma 21. For the inductive step (on j), note that each fetch *opt* initiates during I'_j is initiated at a cursor position at most cur_{j+1}, and that *aggressive*'s cursor position is at least cur_{j+1} during the interval I_{j+1}. Thus *aggressive*'s fetches can be matched to *opt*'s and the domination lemma implies that *aggressive*'s resulting holes $H^+_{agg}(T_i + (j+2)DF)$ dominate *opt*'s resulting holes $H^+_{opt}(T'_i + (j+1)F)$. Any extra fetches of *aggressive* (there may actually be as many as D^2 by *aggressive* and as few as zero by *opt* during their respective time intervals) do not affect this, by Lemma 21. As a special case, if *aggressive* should stop fetching altogether at some time and thus have fewer than D fetches to match to *opt*'s, *aggressive* has reached the optimal cache configuration: its cache contains the next K distinct requests, and its holes are as far from the cursor as possible. These holes certainly dominate *opt*'s holes at any earlier cursor position.

Consider the value j^* such that *opt*'s cursor reaches phase $i+1$ during I'_{j^*}. Then by the preceding arguments, *aggressive*'s cursor reaches phase $i+1$ by time $T_i+(j^*+1)DF$ and *aggressive*'s holes $H^+_{agg}(T_i+(j^*+1)DF) = H^-_{agg}((j^*+1)DF+F)$ after completing all fetches initiated in I_{j^*} dominate *opt*'s holes $H^+_{opt}(T'_i + j^*F)$ after completing all fetches initiated in I'_{j^*-1}. Let $T_{i+1} = T_i + (j^*+1)DF + F$ and let $T'_{i+1} = T'_i + j^*F$, and the conditions for the induction step on the phase index i are met. ∎

5. The algorithms' running times. In this section we consider the time required to determine a prefetching and caching schedule in the uniform-cost RAM model (see, for example, [1]). This is distinct from the time required to serve the sequence in the model described in section 1.2, which is the primary measure we are trying to optimize.

First, consider the single-disk case. We assume that the ith member of the set B of blocks is identified by the integer i. We will need per-block lists of requests (indices in the request sequence R); let $Next(b)$ refer to the head of the list of references to block b. Initially, $Next(b)$ points to the first request of block b; after that request is served, $Next(b)$ will be updated to point to the next occurrence of b in R, and so on. We will also need a vector $InCache$ indexed by the set B indicating for each block whether it is present in the cache, and a pointer $NextHole$ indicating the index of the first hole in the request sequence. Finally, we will need a priority queue $Cache$ containing the identifiers of all blocks present in the cache and keyed on the index in the request sequence of the next request to that block. $Cache$ will need to be augmented by an operation to update the key of an item (which could be implemented as a deletion and a reinsertion), as well as to the usual operations to insert items and delete the item with maximum key. Note that $Cache$ will never contain more than K keys. Each operation on $Cache$ thus requires $O(\log K)$ time (see, for example, [1]). Note that the maximum element in $Cache$, the value of $NextHole$, and the position of the cursor provide the information needed by *aggressive* and *reverse aggressive* to decide when and what to prefetch, and what to evict.

A preprocessing step to initialize these data structures requires time linear in $|B| + |R|$; we assume $K \leq |B|$, since the scheduling problem is trivial otherwise. To maintain these structures when serving a request of block b, we need to update the pointer $Next(b)$ and update b's entry in the priority queue $Cache$. Thus scheduling the servicing of a request requires $O(\log K)$ time. To maintain these structures when evicting a block b_1 and fetching b_2, we delete the maximum element (which is b_1) from $Cache$, insert b_2 in $Cache$, update the vector $InCache$ appropriately, and scan forward in R from $NextHole$ until a request is found that is missing from the cache (by referring to $InCache$); this index becomes the new $NextHole$. These operations require time $O(\log K)$ with the exception of the scan of the request sequence to find the new $NextHole$. The scans require $O(|R|)$ time, amortized over the entire sequence. $|R|$ is an upper bound on the total number of fetches. The reversal of R and of *reverse aggressive*'s reverse schedule can be done in time linear in $|R|$. Thus, each of the algorithms *aggressive* and *reverse aggressive* can be implemented to run in time $O(|B| + |R| \log K)$ in the uniform-cost RAM model.

A simple implementation of *conservative* is to run Belady's paging algorithm, recording each fetch/eviction pair along with a "release index," i.e., the index of the last request of the evicted block (before it is fetched back into the cache later in the schedule, if ever). A similar analysis to that above shows the same bound of $O(|B| + |R| \log K)$ for the construction of this list of fetches and evictions. The list can then be "played back" to construct a schedule for the fetches and the serving of the sequence, issuing each fetch as soon as the cursor has passed the release index and the disk is free. Thus, we have the same bound on *conservative*'s running time as on that of the other algorithms.

In the case of $D > 1$ disks, we assume a constant-time operation yields the disk a block resides on, given the block's identifier. The changes required in the analysis of *conservative* are trivial. For the other algorithms, data structures are maintained on a per-disk basis as needed. $NextHole$ becomes a vector of D entries for *aggressive*. A linear time preprocessing step can be used to produce per-disk request sequences; these are needed to update $NextHole$. In the case of *reverse aggressive*, it is the priority queue $Cache$ that needs to be split into D separate structures, one for each disk; none will ever contain more than K keys. Thus, the running time bound given above applies to the multidisk case as well as the single-disk case.

6. Empirical results.

Reverse aggressive is not a practical algorithm. However, it serves as a benchmark against which to compare practical algorithms such as *aggressive* and the algorithms mentioned below. Perhaps more important, an understanding of the reasons for *reverse aggressive*'s performance guarantee led to the design of the practical algorithm *forestall* with performance matching that of *reverse aggressive* in empirical studies.

As mentioned, in joint work with A. Tomkins, R. H. Patterson, B. Bershad, P. Cao, E. Felten, G. A. Gibson, and K. Li, we have performed simulation studies of the performance of prefetching and caching algorithms. These results are reported in companion papers [17, 19]. We implemented the *aggressive* and *reverse aggressive* algorithms and tested them on reference streams taken from real file systems. We also implemented two other algorithms, *fixed horizon* and *forestall*.

Fixed horizon. For a fixed value H, whenever there is a missing block at most H references in the future, *fixed horizon* issues a fetch for that block, replacing the cached block whose next reference is furthest in the future, provided that reference is further than H accesses in the future.

Forestall. For each disk, for each i, $i \geq 1$, let d_i denote the distance from the cursor to the ith missing block in the request sequence that resides on the disk. For any $i \geq 1$, if $iF > d_i$, processing will surely stall on the ith missing block or some earlier missing block. It will take iF time units to fetch the first i missing blocks, and at most the next d_i requests can be served concurrently. *Forestall* initiates a prefetch according to the (forward) *optimal fetching* and *optimal replacement* rules whenever $iF \geq d_i$ is true for some i and the *do no harm* rule allows it.

See [19] for intuition and more details on these algorithms. *Forestall* and *fixed horizon* have worst-case performance similar to *aggressive*'s. All three of these algorithms perform much better than the worst case in practice.

Our experimental work models many details of real systems not captured by the theoretical model. These are as follows:

- Disk response times and CPU times between I/O requests are not constant. We use average values for each and expect that variation in event times does not substantially invalidate the algorithm's decisions. In our experimentation, this does not appear to be a major effect. (The systematic effects of disk scheduling on disk response time are considered separately.)
- Disk response time is sensitive to the order in which requests are serviced. In particular, disk scheduling reduces average disk response time as more accesses are presented and allowed to be reordered by the I/O driver. Although *fixed horizon* implicitly allows multiple outstanding requests at each disk, the other algorithms were defined to submit only one request at a time, since in the theoretical model there is no advantage to batching. Because of the significance of the disk scheduling effect, we modify the definitions of the other algorithms to submit disk requests in batches. We have found that the performance of all four algorithms benefits from the CSCAN disk

scheduling algorithm.

- Access patterns exhibit locality of reference, and loads are balanced across the multiple disks when data is laid out well. In practice, this allows the other algorithms to effectively utilize multiple disks, and to achieve elapsed times comparable to the theoretically superior *reverse aggressive*.
- Disk accesses require significant CPU overhead to form the request, communicate with the disk, and service the resulting interrupt(s). Thus, avoidable data fetches may add elapsed time even if they do not cause stalls. Because the theory assumes that fetches entail no CPU overhead, this penalty punishes overly aggressive fetching. In practice, this effect favors the *fixed horizon* algorithm since its late replacement decisions tend to lead to the fewest fetches.

The following is a summary of our empirical findings:

- All four algorithms significantly outperform demand fetching, even when advance knowledge of the access sequence is used to make optimal replacement decisions in conjunction with demand fetching.
- In compute-bound situations, *fixed horizon* and *forestall* have the best performance (which is usually matched by *reverse aggressive*'s).
- In I/O-bound situations, *aggressive* and *forestall* have the best performance (which is usually matched by *reverse aggressive*'s).
- In any given situation, one of *fixed horizon* or *aggressive* performs close to the theoretically near-optimal *reverse aggressive*.
- In all situations, *forestall* performs close to *reverse aggressive*.
- When data is well laid out on the disks, disk loads are balanced even without careful replacement choices. For this reason, *reverse aggressive* does not significantly outperform the other algorithms.
- *Fixed horizon* places the least I/O load on the disks, due to its conservative fetching and near-optimal replacement choices; *aggressive* places the greatest load on the disks. *Reverse aggressive* and *forestall* are intermediate between *aggressive* and *fixed horizon*.
- *Forestall* is a promising new approach that combines the best features of the other three algorithms: good performance regardless of I/O- or compute-boundedness, simplicity, and practicality.

For further details, see [19].

7. Summary and open problems.

In this paper, we have considered algorithms for prefetching and caching of data from multiple backing stores. Previous algorithms, designed for the case of a single backing store, were found to be suboptimal by a factor near the number of backing stores. Our main result is a new algorithm, *reverse aggressive*, that is provably near optimal. Although *reverse aggressive* is not a practical algorithm, this paper lays theoretical groundwork for the parallel prefetching and caching problem and exposes its structure. Also, as described in section 6, *reverse aggressive* serves as an important benchmark against which to compare more practical algorithms.

We know of no polynomial-time algorithm for optimal prefetching for multiple disks. It is a difficult problem to find either such an algorithm or a proof of hardness. Another very interesting direction is to extend these results to the case in which only probabilistic information is available about the request sequence.

Acknowledgments. We thank Richard Anderson for helpful discussions of this work and for commenting on a draft of this paper.

Pei Cao, Ed Felten, and Kai Li introduced us to this problem, helped us to formalize the model, and collaborated with us on the empirical evaluation. Their contribution to this work has been enormous.

Last, but not least, Martin Tompa's unfailing patience and encouragement have been indispensable to the first author. Both authors are extremely grateful to Martin for lending his insightful suggestions and constructive criticism to this work at every step of the way.

COMPLEXITY RESULTS FOR FIRST-ORDER TWO-VARIABLE LOGIC WITH COUNTING*

LESZEK PACHOLSKI[†], WIESŁAW SZWAST[‡], AND LIDIA TENDERA[‡]

Abstract. Let C_p^2 denote the class of first-order sentences with two variables and with additional quantifiers "there exists exactly (at most, at least) i" for $i \leq p$, and let C^2 be the union of C_p^2 taken over all integers p. We prove that the satisfiability problem for C_1^2 sentences is NEXPTIME-complete. This strengthens the results by [E. Grädel, Ph. Kolaitis, and M. Vardi, Bull. Symbolic Logic, 3 (1997), pp. 53–69], who showed that the satisfiability problem for the first-order two-variable logic L^2 is NEXPTIME-complete and by [E. Grädel, M. Otto, and E. Rosen, *12th Annual IEEE Symposium on Logic in Computer Science*, 1997, pp. 306–317], who proved the decidability of C^2. Our result easily implies that the satisfiability problem for C^2 is in nondeterministic, doubly exponential time. It is interesting that C_1^2 is in NEXPTIME in spite of the fact that there are sentences whose minimal (and only) models are of doubly exponential size.

It is worth noticing that by a recent result of [E. Grädel, M. Otto, and E. Rosen, *Proceedings of 14th Annual Symposium on Theoretical Aspects of Computer Science*, Lecture Notes in Comput. Sci. 1200, Springer-Verlag, Berlin, 1997], extensions of two-variable logic L^2 by a weak access to cardinalities through the Härtig (or equicardinality) quantifier is undecidable. The same is true for extensions of L^2 by very weak forms of recursion.

The satisfiability problem for logics with a bounded number of variables has applications in artificial intelligence, notably in modal logics (see, e.g., [W. van der Hoek and M. De Rijke, *J. Logic Comput.*, 5 (1995), pp. 325–345]), where counting comes in the context of graded modalities and in description logics, where counting can be used to express so-called number restrictions (see, e.g., [A. Borgida, *Artificial Intelligence*, 82 (1996), pp. 353–367]).

1. Introduction.

Let L^2 denote the class of first order sentences with two variables over a relational vocabulary, and let C_p^2 denote L^2 extended with additional quantifiers "there exists exactly (at most, at least) i" for $i \leq p$. Finally, let C^2 be the union of C_p^2 taken over all integers p. We prove that the problem of satisfiability of sentences of C_1^2 is NEXPTIME-complete.

Problems concerning decidability of restricted classes of quantificational formulas have been studied since the second decade of this century by many logicians, including Ackermann, Bernays, Gödel, Kalmár, Schönfinkel, Skolem, Wang [1, 2, 5, 11, 12, 24, 33, 34, 35, 37], and many others. In the late twenties and in the thirties (see [7] and [19] for more information) the study of classification of solvable classes of prenex formulas was one of the most active areas of logic. Now, after the works of Gurevich [18], Rabin [30], Shelah [32], and Goldfarb [14], the classification of prenex classes has been completed. Accounts of the classical results in this area can be found in several books [3, 7, 9, 25]. More recent results have been obtained by Lewis and Goldfarb

[13, 14, 26]. A short survey of the research in this area can be found in [19] (see also the introduction to [15]).

In 1962, in a short note, D. Scott [31] proved that the satisfiability problem for L^2 was decidable. His proof was based on a reduction of this problem to the problem of satisfiability of sentences in the Gödel class with equality. Later, in 1975, Mortimer gave another proof of decidability by proving that L^2 has a finite model property. When in 1984 Goldfarb [14] found a counterexample to the claim, that the Gödel class with equality had a decidable satisfiability problem, the very short and elegant proof by Scott lost its validity. In 1980 Lewis [27] proved that the satisfiability problem for L^2 was NEXPTIME-hard. The complexity of an algorithm which could be extracted from Mortimer's work was doubly exponential. Recently, Grädel, Kolaitis, and Vardi [15] have closed the gap by providing a very elegant proof that the satisfiability problem for L^2 was in NEXPTIME. Later we found another proof [36] of the same result. Our proof was not as nice as the one in [15], but we hoped it could be extended to get the complexity bounds for C^2.

In [16], Grädel, Otto, and Rosen established decidability of the satisfiability problem for C^2. They proved that the set of sentences which have infinite models was recursive, which implied the above mentioned result. No complexity estimates could be obtained from their proof.

In this paper we prove that the satisfiability problem for C^2_1 is in NEXPTIME, so by the result of Lewis [27] it is NEXPTIME-complete. By the reduction of C^2 to C^2_1 given in [16] this implies that C^2 is in 2-NEXPTIME. Although our strict upper bound applies only to C^2_1 we believe that we have developed techniques that can be used to close the gap for the entire class C^2.

Our approach is in a very remote way based on the ideas of Mortimer. A very simple cardinality argument shows that Mortimer's notion of a *star* could not be used to give a NEXPTIME decision procedure. This led to a weakening of this notion to the notion of a *constellation.* As the first application of this notion we gave in [36] another proof of the result of Grädel, Kolaitis, and Vardi [15]. There we have also used a stronger notion of a normal form—going further than Grädel, Otto, and Rosen in [16]—a *constellation form*, in which, additionally, constant symbols do not appear. The proof in [36] is "syntactic"; however, in the case of L^2, the "syntactic" structure coding a model is almost equivalent to a model. This changes dramatically when we move to C^2 and allows for a concise description of models that can be even infinite.

In contrast to [16] our basic notions are almost entirely syntactic. We like the feudal terminology of [16] and we treat *kings* of [16] with proper care and respect. However, *kings* in our sense have other virtues besides belonging to a finite set. Population of our kings is always at most doubly exponential in the size of the language. On the other hand, it is easy to give examples of models whose sets of kings in the sense of [16] have, for a language of bounded size, arbitrary large cardinality. This seems to suggest that the method of [16] could not easily be adapted to give complexity bounds.

To get our result we analyze the structure of the feudal court. We have a few kings and kings are characterized by the fact that they are connected between themselves using only *counting types.* Instead of a more or less uniform court we have a hierarchy V_i for $i < 2^{n^2}$ of vassals, each of which may be a sovereign of perhaps several vassals in V_{i+1}. The union V of all V_i for $i < 2^{n^2}$ is included in the set of *kings* in the sense of [16] and provides information sufficient to reconstruct a model and thus gives rise to a 2-NEXPTIME algorithm for C^2_1 and a 3-NEXPTIME algorithm for C^2. Of course, we cannot easily improve the above bounds, since we can provide a sentence (see Proposition 4.18) of C^2_1 of size n whose unique model coincides with V and has cardinality $O(2^{2^n})$.

To push the lower bound down we had to provide a finer analysis. We have noticed that although the number of vassals in a model can be large (doubly exponential), the number of vassals that are different from the point of view of relations between themselves is smaller (exponential). In more technical terms a potential model is described by a set of indexed constellations and numbers of elements that realize these constellations. Roughly speaking, an indexed constellation—in addition to information on 2-types realized by pairs containing a given element—carries, for certain 2-types, *requests* for partner constellations, that is, constellations that should realize, together with the given constellation, these 2-types. Moreover, we show that the model is composed of some number of parts (only one of them can be infinite), which can be treated separately and independently during construction of the model. To check if the parts can be constructed we use several graph-theoretical results concerning the existence of Hamiltonian cycles, matchings, and bipartition.

It is worth noticing that by a recent result of Grädel, Otto, and Rosen [17], extensions of two-variable logic L^2 by a weak access to cardinalities through the Härtig (or equicardinality) quantifier is undecidable. The same is true for extensions of L^2 by very weak forms of recursion.

The satisfiability problem for logics with a bounded number of variables has applications in artificial intelligence, notably in modal logics (see, e.g., [22]) where counting comes in the context of graded modalities and in description logics, where counting can be used to express so-called number restrictions (see, e.g., [8]). More information on applications and relation of two-variables logics to modal logics is given in [15].

2. Preliminaries.

Throughout the paper we are concerned mainly with signatures that consist of unary and binary predicate letters without Boolean predicates, function symbols, and constants. This restriction allows us to simplify definitions and technical proofs. We would, however, like to emphasize that it is easy to adapt all notions used in this paper and to modify the proofs in order to obtain the same results also for the full first-order two-variable logic with counting, including predicate letters of higher arity and constants (see, e.g., [15] for a proof that predicate letters of higher arity can be eliminated).

We assume that the reader is familiar with standard notions of logic and with basic concepts of computational complexity theory. In this paper, $\mathcal{L}$-structures are denoted by Gothic capital letters and their universes are denoted by corresponding Latin capitals. Furthermore, if a structure $\mathfrak{A}$ is fixed, then its substructure with the universe denoted by a Latin capital is denoted by the corresponding Gothic capital.

By L^2 we denote the class of first-order sentences with two variables over a relational vocabulary, and by C^2_p we denote L^2 extended by additional quantifiers of the form $\exists^{=i}$, $\exists^{\leq i}$, or $\exists^{\geq i}$ (respectively, there exists exactly, at most, at least i) for $i \leq p$. Finally, C^2 is the union of C^2_p taken over all integers p.

Let $\mathcal{L}$ be a relational vocabulary with unary and binary predicate letters only. A 1-*type* $t(x)$ is a maximal consistent set of atomic and negated atomic formulas of the language $\mathcal{L}$ in the variable x. A 2-*type* $t(x, y)$ is a maximal consistent set of atomic and negated atomic formulas of the language $\mathcal{L}$ in the variables x, y, such that $(x \neq y) \in t(x, y)$. A type t is often identified with the conjunction of formulas in t. For a 2-type $t(x, y)$ we denote by $t(x, y)\restriction\{x\}$ the unique 1-type $t(x)$ included in

$t(x, y)$ and we denote by t^* the type dual to t; that is, the type obtained from t by replacing each occurrence of the variable x by y and each occurrence of y by x. If $\mathfrak{A}$ is an $\mathcal{L}$-structure with the universe A, and if $a, b \in A$, then we denote by $tp^{\mathfrak{A}}(a, b)$ the unique type realized by the pair $\langle a, b\rangle$ in $\mathfrak{A}$.

Recall that for any integer function $t(n)$, NTIME$(t(n))$ is the class of all decision problems that can be solved by a nondeterministic Turing machine in time $t(n)$, where n is the length of the input. We put

$$\text{NEXPTIME} = \bigcup\nolimits_p \text{NTIME } (2^{p(n)}),$$

$$\text{2-NEXPTIME} = \bigcup\nolimits_p \text{NTIME } (2^{2^{p(n)}}),$$

where p is a polynomial.

3. On the L^2case. In this section we consider the satisfiability problem for L^2, the first-order logic with two variables and without counting quantifiers. We give an algorithm solving this problem which runs in nondeterministic exponential time. As we have mentioned in the introduction, it follows from the paper of Mortimer [28] that the satisfiability problem for L^2 can be solved by a nondeterministic algorithm in doubly exponential time. An algorithm whose complexity matches the NEXPTIME lower bound given by Lewis [27] was presented in a very nice paper by Grädel, Kolaitis, and Vardi [15]. This algorithm and the bound that follow from Mortimer's work depend on the bounds on the cardinality of a minimal model of an L^2 sentence. Our algorithm, in contrast to the above, does not exploit the bounded model property of L^2.

This section is a modification of [36] and it is included here following a suggestion of one of the referees in order to introduce and explain the techniques used later for logic with counting.

Our approach in a remote way is based on Mortimer's notion of a *star* [28], a *star* being an arbitrary set of 2-types with a consistent *center*. The notion of a star was a very convenient technical tool to describe a finite structure and to check, with the help of Ehrenfeucht games of depth two [10], that this structure is a model of an L^2 sentence. Unfortunately, Mortimer's notion of a star cannot be directly used to give a NEXPTIME decision procedure since the cardinality of a star is exponential and the number of possible stars is doubly exponential in the number of predicate letters in the signature.

We weaken the notion of a star to a notion of a *small constellation* that we introduce after a close analysis of L^2 sentences from the point of view of their satisfiability. As in other related papers [31, 15] we use a variant of a notion of a normal form of first-order sentences. Our notion is called a *constellation form* and it allows to introduce the notion of a small constellation in a very natural way. Unlike a star, a small constellation is of linear size and it contains only these 2-types that describe a relation of a given point to a witness that must exist in a model of an L^2 sentence.

We also introduce a notion of a *small galaxy* as a set of small constellations that can be modeled in a first-order structure and we prove that an L^2-sentence is satisfiable if and only if there exists a small galaxy (Theorem 3.5). A small galaxy has only exponential size.

As the next step we give necessary and sufficient conditions for a set of small constellations to form a small galaxy (Definition 3.12, Theorem 3.13). In the proof of Theorem 3.13 we use notions of special and replicable constellations which are analogous to Mortimer's notions of asymmetric and symmetric stars. These notions are crucial for our analysis of models for L^2-sentences. As a result we get a nondeterministic exponential upper bound for the satisfiability problem for L^2-sentences (Corollary 3.14).

3.1. Small constellations, small galaxies, and satisfiability. Let $\mathcal{R} \subseteq \mathcal{L}$ be a set of binary predicate letters, $\mathcal{R} = \{R_1, \ldots, R_m\}$.

DEFINITION 3.1. *An $\mathcal{L}$-sentence Φ is in constellation form if*

$$\Phi = \forall x \forall y \phi(x,y) \wedge \bigwedge_{1 \le i \le m} \forall x \exists y R_i(x,y),$$

where ϕ is quantifier-free.

This definition may seem too strong. The second part of the formula seems to suggest that all elements are similar from the point of view of $\mathcal{R}$. Note, however, that we do not require that $x \neq y$; therefore, for an element x, by $R_i(x,x)$ we can code those relations R_i, for which the existential quantifier of the second part of Φ does not apply.

Let $\mathcal{A}$ be a set of 2-types closed under operation * and let $\mathcal{A}^+ = \{t \in \mathcal{A} : R_i(x,y) \in t, \text{ for some } i \le m\}$.

DEFINITION 3.2. *Let $S = \{s_0, s_1, \ldots, s_k\}$, where $0 \le k \le m$, s_0 is a* 1*-type and, if $k > 0$, then $s_1, \ldots, s_k \in \mathcal{A}^+$. Define center$(S) = \bigwedge_{0 \le i \le k} s_i \restriction \{x\}$. The set S is a small $\mathcal{A}$-$\mathcal{R}$-constellation if the following conditions hold:*

(1) *center$(S) = s_0$;*

(2) *for every $R_i \in \mathcal{R}$, if $R_i(x,x) \notin$ center(S), then there exists j, $1 \le j \le k$, such that $R_i(x,y) \in s_j$.*

Notice that the notion of a small $\mathcal{A}$-$\mathcal{R}$-constellation depends on a set $\mathcal{A}$ of 2-types and a set $\mathcal{R}$ of binary predicate symbols.

DEFINITION 3.3. *Let $\mathfrak{A}$ be an $\mathcal{L}$-structure. An element $a \in A$ realizes a small $\mathcal{A}$-$\mathcal{R}$-constellation $S = \{s_0, \ldots, s_k\}$ if $tp^{\mathfrak{A}}(a,a) = s_0$, for each $b \in A$, $tp^{\mathfrak{A}}(a,b) \in \mathcal{A}$, and there exists a sequence $b_1, \ldots, b_k$ of elements of A such that $tp^{\mathfrak{A}}(a,b_i) = s_i$, $0 < i \le k$.*

A small $\mathcal{A}$-$\mathcal{R}$-constellation S is realized *in $\mathfrak{A}$ if there exists $a \in A$ which realizes S.*

Note that if an element $a \in \mathfrak{A}$ realizes a small $\mathcal{A}$-$\mathcal{R}$-constellation, then $\mathfrak{A} \models \bigwedge_{1 \le i \le m} \exists y R_i(a,y)$.

DEFINITION 3.4. *Let $\mathcal{S}$ be a set of small $\mathcal{A}$-$\mathcal{R}$-constellations. A structure $\mathfrak{A}$ realizes $\mathcal{S}$ if every element $a \in A$ realizes a small $\mathcal{A}$-$\mathcal{R}$-constellation $S \in \mathcal{S}$, and every small $\mathcal{A}$-$\mathcal{R}$-constellation $S \in \mathcal{S}$ is realized by an element $a \in A$.*

The set $\mathcal{S}$ is a small galaxy if there is a structure $\mathfrak{A}$ such that card$(A) > 1$, and $\mathfrak{A}$ realizes $\mathcal{S}$.

The following theorem gives a necessary and sufficient condition for satisfiability of sentences in constellation form,

THEOREM 3.5. *Let $\mathcal{R} = \{R_1, \ldots, R_m\} \subseteq \mathcal{L}$ and let Φ be an $\mathcal{L}$-sentence in constellation form,*

$$\Phi = \forall x \forall y \phi(x,y) \wedge \bigwedge_{1 \le i \le m} \forall x \exists y R_i(x,y).$$

Put $\mathcal{A} = \{t : t(x,y)$ is a 2*-type over $\mathcal{L}$ and $t(x,y) \to \phi(x,y)\}$.*

Then Φ has a model with at least two-element universe if and only if there exists a set $\mathcal{S}$ of small $\mathcal{A}$-$\mathcal{R}$-constellations which is a small galaxy.

Proof. ($\Rightarrow$) Let $\mathfrak{A} \models \Phi$ and $card(A) > 1$. Since $\mathfrak{A} \models \forall x \forall y \phi(x, y)$, the set $\mathcal{A}$ is closed under the operation *. Moreover, $\mathfrak{A} \models \bigwedge_{1 \le i \le m} \forall x \exists y R_i(x, y)$ implies that every element of A realizes at least one small $\mathcal{A}$-$\mathcal{R}$-constellation. Let $\mathcal{S} = \{S : S$ is a small $\mathcal{A}$-$\mathcal{R}$-constellation and S is realized in $\mathfrak{A}\}$. By Definitions 3.4, $\mathfrak{A}$ realizes $\mathcal{S}$.

($\Leftarrow$) Let $\mathcal{S}$ be a small galaxy and assume $\mathfrak{A} \models \mathcal{S}$. Let $a \in A$. By Definition 3.4, a realizes a small $\mathcal{A}$-$\mathcal{R}$-constellation $S \in \mathcal{S}$, $S = \{s_0, \dots, s_k\}$. This implies that $tp^{\mathfrak{A}}(a, a) = s_0$, and there exists a sequence $b_1, \dots, b_k$ of distinct elements of A such that $b_i \neq a$ for $i = 1, \dots, k$ and

(1) $tp^{\mathfrak{A}}(a, b_i) = s_i$ for $i = 1, \dots, k$,

(2) $tp^{\mathfrak{A}}(a, b) \in \mathcal{A}$ for $b \in \mathcal{A}$.

Therefore, by Definition 3.2, the elements $b_1, \dots, b_k$ are witnesses of a for the part $\bigwedge_{1 \le i \le m} \exists y R_i(x, y)$ of Φ. Moreover, for every $b \in A, b \neq a$, $tp^{\mathfrak{A}}(a, b) \in \mathcal{A}$, and so $\mathfrak{A} \models \phi(a, b)$. Therefore $\mathfrak{A} \models \Phi$. $\Box$

3.2. The reduction. The following reduction theorem is essentially due to Scott [31]. It has been also used in [28] and [15]. We present a slightly modified version of the theorem given in [15].

THEOREM 3.6. *There exists a polynomial time algorithm which, given an L^2 sentence Ψ over an arbitrary relational vocabulary, constructs a sentence Φ in constellation form with the following properties:*

(1) *Ψ is satisfiable if and only if Φ is satisfiable.*

(2) *Every predicate letter occurring in Φ has arity at most 2.*

(3) *If n is the length of Ψ, then Φ contains $O(n)$ different predicate letters and has length $O(n \log n)$.*

3.3. The small galaxy theorem. In this section we fix $\mathcal{R} = \{R_1, \dots, R_m\} \subseteq \mathcal{L}$, and a set $\mathcal{A}$ of 2-types closed under the operation *.

To simplify terminology in this subsection we write "constellation" instead of "small $\mathcal{A}$-$\mathcal{R}$-constellation" and "galaxy" instead of "small galaxy."

By Theorem 3.6 and Theorem 3.5 the satisfiability problem for L^2 sentences can be reduced to the problem of finding an appropriate galaxy. In this subsection we shall give syntactic conditions that are necessary and sufficient for a set of constellations to be a galaxy.

DEFINITION 3.7. *Let S, T be constellations and let $t(x, y) \in \mathcal{A}$. S* is connectable to *T* by *$t(x, y)$ if $center(S) \subseteq t(x, y)$ and $center(T) \subseteq t^*(x, y)$.*

We say that S is connectable to *T if there is a type $t(x, y) \in \mathcal{A}$ such that S is connectable to T by $t(x, y)$.*

PROPOSITION 3.8. *Let $\mathcal{S}$ be a galaxy and $S \in \mathcal{S}$. Then the following conditions are equivalent.*

(1) *There is a structure $\mathfrak{A}$ which realizes $\mathcal{S}$, and S is realized in $\mathfrak{A}$ by at least two elements.*

(2) *S is connectable to S.*

Proof. Let $\mathcal{S}$ be a galaxy, $S \in \mathcal{S}$, and let $\mathfrak{B}$ be a structure such that $\mathfrak{B} \models \mathcal{S}$. To prove the implication (1) $\Rightarrow$ (2), assume that S is realized in $\mathfrak{A}$ by two elements a and b. Let $t(x, y) = tp^{\mathfrak{A}}(a, b)$. Since $\mathfrak{A} \models \mathcal{S}$, we have $t(x, y) \in \mathcal{A}$. Of course, $center(S) \subseteq t(x, y)$ and $center(S) \subseteq t^*(x, y)$.

Now we shall prove that (2) $\Rightarrow$ (1). Let $t \in \mathcal{A}$ be such that $center(S) \subseteq t(x, y)$ and $center(S) \subseteq t^*(x, y)$. Let $b \in B$ realize S in $\mathfrak{B}$. We claim that there exists an extension $\mathfrak{A}$ of $\mathfrak{B}$ such that $A = B \cup \{a\}$, where $a \notin B$ and a realizes S. Indeed, $\mathfrak{A}$ can be obtained from $\mathfrak{B}$ by putting $A = B \cup \{a\}$, $tp^{\mathfrak{A}}(a, b) = t(x, y)$, and $tp^{\mathfrak{A}}(a, c) = tp^{\mathfrak{A}}(b, c)$, for every $c \in B$. $\Box$

The proposition above motivates the following definition.

DEFINITION 3.9. *A constellation S is* replicable *if S is connectable to S. Otherwise, the constellation S is* special.

Let $\mathcal{S}$ be a galaxy, and let $\mathfrak{A}$ satisfy $\mathcal{S}$. In the universe A of $\mathfrak{A}$ we can distinguish the set $K \subseteq A$ consisting of all elements which realize special constellations. Elements of the set K are called *kings*. A *noble* is an element of the set $N = \bigcup_{a\in K}\{b_1, \ldots, b_k \in A : k \leq m \text{ and } \{tp^{\mathfrak{A}}(a), tp^{\mathfrak{A}}(a, b_1), \ldots, tp^{\mathfrak{A}}(a, b_k)\} \in \mathcal{S}\}$. Nobles are those elements of the universe that are necessary for the existence of kings. Define the *court* $C = K \cup N$. Note that $card(C) \leq (m+1)card(K)$. There may also be *plebeians*—elements outside the court; they are not necessary for the kings but perhaps some nobles may need them. Plebeians may also depend on kings to survive.

Remark. The notion of a king in a structure has been used in many places. For example, Gurevich and Shelah have used this notion in [20] to show that their proof of the solvability of the Gödel class without equality could not be generalized to the case with equality. Grädel, Kolaitis, and Vardi have also used this notion in [15]. We would like to point out that although in this paper the kings are defined in terms of constellations, they have the same meaning as in [15].

DEFINITION 3.10. *Denote by $Sp(\mathcal{S})$ the subset of $\mathcal{S}$ consisting of all special constellations and by $Rp(\mathcal{S})$ the set $\mathcal{S} \setminus Sp(\mathcal{S})$.*

The following simple observation establishes relations between the notions defined above.

PROPOSITION 3.11. *Let $\mathcal{S}$ be a galaxy, and let $\mathfrak{A}$ realize $\mathcal{S}$. Then there exist sets K and C such that the following conditions hold.*

(1) *$K \subseteq C \subseteq A$, $card(K) \leq card(Sp(\mathcal{S}))$, and $card(C) \leq (m + 1)card(K)$.*
(2) *Every element $a \in K$ realizes a constellation $S \in Sp(\mathcal{S})$ in $\mathfrak{A}{\restriction}C$.*
(3) *Every constellation $S \in Sp(\mathcal{S})$ is realized by an element $a \in K$ in $\mathfrak{A} \restriction C$.*
(4) *For every S, $T \in Rp(\mathcal{S})$, S is connectable to T.*

Proof. The proof is immediate. □

One can easily check that the converse to the above proposition does not hold. For example, let

$$\begin{aligned}
\mathcal{L} &= \mathcal{R} = \{R_1, R_2\},\\
\mathcal{A} &= \{t_1, t_1^*, t_2, t_2^*, t_3\},\\
s_0(x) &= R_1(x, x) \wedge R_2(x, x),\\
t_0(x) &= \neg R_1(x, x) \wedge \neg R_2(x, x),\\
t_1 &= t_0(x) \wedge R_1(x, y) \wedge \neg R_2(x, y) \wedge R_1(y, x) \wedge R_2(y, x) \wedge s_0(y),\\
t_2 &= t_0(x) \wedge \neg R_1(x, y) \wedge R_2(x, y) \wedge R_1(y, x) \wedge R_2(y, x) \wedge s_0(y),\\
t_3 &= t_0(x) \wedge \neg R_1(x, y) \wedge \neg R_2(x, y) \wedge \neg R_1(y, x) \wedge \neg R_2(y, x) \wedge t_0(y),\\
\mathcal{S} &= \{S, T\}, \text{ where } S = \{s_0\} \text{ and } T = \{t_0, t_1, t_2\}.
\end{aligned}$$

It is easy to see that the constellation S is special and T is replicable. One can check that if we define $K = \{a\}$, $C = K$, $tp^{\mathfrak{A}}(a) = s_0$, then conditions (1)–(3) of Proposition 3.11 hold and, since T is connectable to T by t_3, condition (4) holds too. Unfortunately, the constellation T cannot be realized in any structure, since to realize T we need two elements, b_1 and b_2, such that $tp^{\mathfrak{A}}(b_1) = s_0$, $tp^{\mathfrak{A}}(b_2) = s_0$, and $tp^{\mathfrak{A}}(b_1, b_2) \in \mathcal{A}$, which is not possible. Therefore, $\mathcal{S}$ is not a galaxy.

Now we shall extend the set of conditions given in Proposition 3.11 to a set of conditions that will imply that a set $\mathcal{S}$ of constellations is a galaxy.

DEFINITION 3.12. *Let $\mathcal{S}$ be a set of constellations. A* small representation *of $\mathcal{S}$ is a system*

$$\langle K, C, I, F, G\rangle,$$

where K and C are sets, I, F, G are functions such that $I : C \to \mathcal{S}$, $F : C \times C \to \mathcal{A}$, $G : Rp(\mathcal{S}) \times K \to \mathcal{A}$, and the following conditions hold.

(s1) *$K \subseteq C$, $card(K) \leq card(Sp(\mathcal{S}))$, and $card(C) \leq (m+1)card(K)$.*

(s2) *$I(K) = Sp(\mathcal{S}), I(C \setminus K) \subseteq Rp(\mathcal{S})$, $F(a,a) = F(a,b)\restriction\{x\}$, and for every $a \neq b$ $F(a,b) = F(b,a)^*$.*

(s3) *For every $a \in K$ and every $t \in I(a)$, there is an element $c \in C$ such that $t = F(a,c)$.*

(s4) *For every $b \in C \setminus K$ and every $t \in I(b)$, if there is no $c \in C$ such that $t = F(b,c)$, then there is a constellation $T \in Rp(\mathcal{S})$ such that $I(b)$ is connectable to T by t.*

(s5) *For every S, $T \in Rp(\mathcal{S})$, S is connectable to T.*

(s6) *For every $S \in Rp(\mathcal{S})$ and every $a \in K$, S is connectable to $I(a)$ by $G(S,a)$.*

(s7) *For every $S \in Rp(\mathcal{S})$ and every type $t(x,y) \in S$, if there is no $a \in K$ such that $G(S,a) = t(x,y)$, then there is a constellation $T \in Rp(\mathcal{S})$ such that S is connectable to T by t.*

Conditions (s1), (s2), and (s3) say that the set C is a universe of a structure in which all special constellations are realized. In other words, kings are provided with all they need to survive. Condition (s4) ensures that every noble can find enough plebeians around him. Condition (s5) says that plebeians can live together in one society and, by condition (s6), the society is ruled by kings. Condition (s7) states that plebeians can get what they need—if not from kings, then from somewhere else.

THEOREM 3.13 (small galaxy theorem). *A set of constellations $\mathcal{S}$ is a galaxy if and only if there exists a small representation of $\mathcal{S}$.*

Proof. ($\Rightarrow$) Assume that $\mathcal{S}$ is a galaxy and $\mathfrak{A}$ realizes $\mathcal{S}$. Let K be the set of kings in $\mathfrak{A}$, and let C be the court in $\mathfrak{A}$. For every $a \in C$ choose a constellation $S \in \mathcal{S}$ which is realized by a, and put $I(a) = S$. For every $a, b \in C$, put $F(a,b) = tp^{\mathfrak{A}}(a,b)$. For every constellation $S \in Rp(\mathcal{S})$ find an element $b \in A$ which realizes S, and for every $a \in K$ put $G(S,a) = tp^{\mathfrak{A}}(b,a)$.

It is easy to check that the system $\langle K, C, I, F, G\rangle$ is a small representation of $\mathcal{S}$.

($\Leftarrow$) Let $\mathcal{S}$ be a set of constellations, and let $\langle K, C, I, F, G\rangle$ be a small representation of $\mathcal{S}$.

We shall construct a structure $\mathfrak{A}$ realizing $\mathcal{S}$ such that the universe A of $\mathfrak{A}$ contains C, every $a \in K$ realizes $I(a)$ in $\mathfrak{A}\restriction C$, and $tp^{\mathfrak{A}}(a,b) = F(a,b)$, for each pair $\langle a, b\rangle$ of elements of C.

The construction proceeds in steps. The number of steps can be infinite. In each step new elements are added to the universe. A new element is added when there is a request to satisfy a constellation, say, S. Whenever an element a is added to satisfy S, I is extended by putting $I(a) = S$. An element a such that $I(a) = S$ is *inactivated* after adding enough elements to witness that a realizes S. An unordered pair of elements will be *reserved*, when a type to be realized by this pair has been designated.

In every step of the construction the universe of the part of the structure $\mathfrak{A}$ defined so far is finite. We also assume that there is a fixed linear ordering $<$ of the universe, and each new element added to the universe is greater than all old elements.

Let $\mathcal{S} = \{S_1, \ldots, S_k\}$.

Stage 1.

(1) Let $A = C$.
(2) For every $a, b \in C$, put $tp^{\mathfrak{A}}(a, b) = F(a, b)$ (cf. (s2)).
(3) For every $a \in K$, inactivate a.
(4) For every $a, b \in C$, reserve $\{a, b\}$.
(5) For every $S \in Rp(\mathcal{S})$ such that $I(b) \neq S$, for each $b \in C$, add a new element d to A and put $I(d) = S$.

Stage 2.

(6) Let b be the first active (i.e., yet not inactivated) element of A.
Note that $I(b) \in Rp(\mathcal{S})$. Indeed, $b \notin K$, so either $b \in C \setminus K$, and so $I(b) \in Rp(\mathcal{S})$, by (s2), or b has been added to A in steps 5, 7(a)(ii), or 9(b), and whenever we add a new element b to the universe we always put $I(b) \in Rp(\mathcal{S})$.
(7) If $b \in C \setminus K$, then
  (a) for every $t \in I(b)$ if there is no element $c \in C$ such that $t = F(b, c)$, do
    (i) using (s4) find $T \in Rp(\mathcal{S})$ such that $I(b)$ is connectable to T by t;
    (ii) add a new element d to A;
    (iii) put $I(d) = T$, and $tp^{\mathfrak{A}}(b, d) = t$, reserve $\{b, d\}$;
  (b) inactivate b and go to 6.
(8) Using (s6), for every $a \in K$, put $tp^{\mathfrak{A}}(b, a) = G(I(b), a)$.
Note that, $b \notin C$, so no pair $\{a, b\}$, with $a \in K$, has been reserved earlier.
(9) For every $t \in I(b)$, if there is no $c \in A$ such that $\{c, b\}$ is reserved and $tp^{\mathfrak{A}}(c, b) = t^*$, do
  (a) by (s7) find $T \in Rp(\mathcal{S})$ such that $I(b)$ is connectable to T by t.
  Note that, by step 8, there is no element $a \in K$; such that $t = G(I(b), a)$.
  (b) add a new element d to A;
  (c) put $I(d) = T$, $tp^{\mathfrak{A}}(b, d) = t$, and reserve $\{b, d\}$;
  (d) for every $a < b$, if $\{a, b\}$ is not reserved, then using (s5) find $t \in \mathcal{A}$ such that $I(b)$ is connectable to $I(a)$ by t, put $tp^{\mathfrak{A}}(b, a) = t$ and reserve $\{b, a\}$.
(10) Inactivate b and go to 6.

We shall now show that $\mathfrak{A}$ realizes $\mathcal{S}$. First, let us note that every pair of distinct elements of A realizes in $\mathfrak{A}$ a 2-type of $\mathcal{A}$ (see steps 2, 7(a)(iii), 8, 9(c), 9(d)).

New elements are added at the end of the fixed ordering, and in step 6 we always consider the first active element; therefore every element $a \in A$ will eventually be inactivated. We claim that when an element a is inactivated, then a realizes a constellation of $\mathcal{S}$ in $\mathfrak{A}$. In fact an element inactivated in step 3, by (s2) and (s3) of Definition 3.12, realizes a special constellation of $\mathcal{S}$. Before an element b is inactivated in step 7(b), in step 7(a) every type of $I(b)$ has been realized by a pair $\langle b, a \rangle$ for some $a \in A$. Similarly, step 9 ensures that the element inactivated in step 10 realizes its constellation.

Finally, by step 5 every constellation of $\mathcal{S}$ is realized in $\mathfrak{A}$. $\square$

Now let us consider the cardinality of the structure constructed by the algorithm described above. If $Rp(\mathcal{S}) = \emptyset$, then only the first stage of the algorithm is performed and we get a structure with the universe K. We also get a finite structure if no new elements are added in step 7(a)(i). In this case $I(C) = \mathcal{S}$, and the function F is defined in such a way that no noble element needs a plebeian. In other cases we get an infinite structure. The construction could be modified in such a way that it will stop after a bounded number of steps. However, we omit this modification, since the construction described above is better suited for generalization to logic with counting.

3.4. Complexity.

Corollary 3.14. *There is a nondeterministic algorithm with time complexity $O(2^{cn^2})$, for some constant c, which, given an L^2-sentence Φ, decides if Φ is satisfiable.*

Remark. In [36], using more complicated techniques, we gave a similar algorithm with time complexity $O(2^{cn})$. Here we provide a simplified version only, since it is easier to understand and better explains the methods used in the main part of this paper.

Proof. Let Φ be an L^2 sentence of length n. In the first step we use the polynomial time algorithm of Theorem 3.6 to get a sentence Ψ in constellation form,

$$\Psi = \forall x \forall y \phi(x, y) \wedge \bigwedge_{1 \le i \le m} \forall x \exists y R_i(x, y),$$

which is satisfiable if and only if Φ is satisfiable. Moreover, Ψ has at most $p = O(n)$ predicate letters and has length $O(n \log n)$.

Then we use Theorem 3.5. We build a set $\mathcal{A}$ in time $O(2^{O(p)})$, and, in time $O((2^{4p})^m) = O(2^{O(n^2)})$, we guess a set $\mathcal{S}$ of small $\mathcal{A}$-$\mathcal{R}$-constellations.

Next, we use Theorem 3.12 and we guess sets K and C and functions I, F, and G. Since $card(K) \le 2^{O(n^2)}$ and $card(C) \le (m+1)card(K)$ we can do this in time $O(2^{O(n^2)})$.

Finally, we accept Ψ after checking whether $\langle K, C, I, F, G\rangle$ is a small representation of $\mathcal{S}$. This can also be done in time $O(2^{O(n^2)})$. □

4. Double exponential algorithm.

4.1. Constellations, galaxies, and satisfiability.

Let $\mathcal{R} = \{R_1, \dots, R_m\} \subseteq \mathcal{L}$ be the set of binary predicate letters.

Definition 4.1. *An $\mathcal{L}$-sentence Φ is in* constellation form *if*

$$\Phi = \forall x \forall y \phi(x, y) \wedge \bigwedge_{1 \le i \le m} \forall x \exists^{=m_i} y R_i(x, y),$$

where ϕ is quantifier-free. Φ is in $\exists^{=1}$-constellation form *if $m_i = 1$ for each $i \le m$.*

As Definition 3.1, the definition above may seem too strong, since the second part of the formula seems to suggest that all elements are similar from the point of view of $\mathcal{R}$. However, as before, the fact whether $R_i(x, x)$ holds is used to code those relations R_i for which the counting quantifier does not apply.

Let $\mathcal{A}$ be a set of 2-types closed under operation *.

Definition 4.2.

$\mathcal{A} = \mathcal{A}^{\leftrightarrow} \dot\cup \mathcal{A}^{\leftarrow} \dot\cup \mathcal{A}^{\rightarrow} \dot\cup \mathcal{A}^{-}$, *where*

$\mathcal{A}^{\leftrightarrow} = \{t \in \mathcal{A} :$ *there are* $i, j \le m$ *such that* $R_i(x, y) \in t$ *and* $R_j(y, x) \in t\}$,

$\mathcal{A}^{\leftarrow} = \{t \in \mathcal{A} : t \notin \mathcal{A}^{\leftrightarrow}$ *and there exists* $i \le m$ *such that* $R_i(y, x) \in t\}$,

$\mathcal{A}^{\rightarrow} = \{t \in \mathcal{A} : t \notin \mathcal{A}^{\leftrightarrow}$ *and there exists* $i \le m$ *such that* $R_i(x, y) \in t\}$,

$\mathcal{A}^{-} = \{t \in \mathcal{A} :$ *for every* $i \le m, \neg R_i(x, y) \in t$ *and* $\neg R_i(y, x) \in t\}$.

In the definition above $\mathcal{A}^{\leftrightarrow}$, $\mathcal{A}^{\leftarrow}$, and $\mathcal{A}^{\rightarrow}$ represent *counting types.* Since R_i appears in the second part of the formula Φ in constellation form, it follows that $R_i(x, y) \in t$ implies that for (a, b) and (a, b') realizing t we always have $b = b'$.

Definition 4.3. *Let $S = \{s_0, s_1, \dots, s_k\}$, where $k \ge 0$, s_0 is a 1-type and, if $k > 0$, then $s_1, \dots, s_k \in \mathcal{A}^{\leftrightarrow} \cup \mathcal{A}^{\rightarrow}$. Define $center(S) = \bigwedge_{0 \le i \le k} s_i \restriction \{x\}$. The set S is an* $\mathcal{A}$-$\mathcal{R}$-constellation *if the following conditions hold:*

(1) *$center(S) = s_0$;*
(2) *for every $R_i \in \mathcal{R}$, if $R_i(x,x) \notin center(S)$, then there is exactly one j, $1 \leq j \leq k$, such that $R_i(x,y) \in s_j$;*
(3) *for every $R_i \in \mathcal{R}$, if $R_i(x,x) \in center(S)$, then for every j, $1 \leq j \leq k$, $R_i(x,y) \notin s_j$.*

Notice that the notion of an $\mathcal{A}$-$\mathcal{R}$-constellation depends on fixed sets $\mathcal{A}$ of 2-types and $\mathcal{R}$ of binary predicate symbols. Moreover, the number of 2-types in a constellation does not exceed $card(\mathcal{R})$. It does not follow from Definition 4.3 that each constellation contains a counting type. There may be constellations S such that $center(S) = \{R_i(x,x) : R_i \in \mathcal{R}\}$. In fact $center(S)$ codes the relations in $\mathcal{R}$ which are not used in S in the context of counting.

DEFINITION 4.4. *Let $\mathfrak{A}$ be an $\mathcal{L}$-structure. An element $a \in A$* realizes *an $\mathcal{A}$-$\mathcal{R}$-constellation $S = \{s_0, \ldots, s_k\}$ if $tp^{\mathfrak{A}}(a,a) = s_0$, and there exists a unique sequence $b_1, \ldots, b_k \in A$ that $tp^{\mathfrak{A}}(a,b_i) = s_i$, $1 \leq i \leq k$, and for every $b \in A$, $b \neq a$, $b \neq b_i$, $1 \leq i \leq k$, we have $tp^{\mathfrak{A}}(a,b) \in \mathcal{A}^{\leftarrow} \cup \mathcal{A}^{-}$. An $\mathcal{A}$-$\mathcal{R}$-constellation S is* realized *in $\mathfrak{A}$ if there exists an element $a \in A$ which realizes S.*

For $a \in A$, we write $C_a^{\mathfrak{A}}$ to denote the unique $\mathcal{A}$-$\mathcal{R}$-constellation realized by a.

DEFINITION 4.5. *Let $\mathcal{S}$ be a set of $\mathcal{A}$-$\mathcal{R}$-constellations. A structure $\mathfrak{A}$* realizes *$\mathcal{S}$ if every element in A realizes an $\mathcal{A}$-$\mathcal{R}$-constellation and every constellation in $\mathcal{S}$ is realized in $\mathfrak{A}$.*

A set $\mathcal{S}$ of $\mathcal{A}$-$\mathcal{R}$-constellations is a galaxy *if there is a structure $\mathfrak{A}$ such that $card(A) > 1$, and $\mathfrak{A}$ realizes $\mathcal{S}$.*

The following theorem gives a necessary and sufficient condition for satisfiability of sentences in $\exists^{=1}$-constellation form.

THEOREM 4.6. *Let $\mathcal{R} = \{R_1, \ldots, R_m\} \subseteq \mathcal{L}$, and let Φ be an $\mathcal{L}$-sentence in $\exists^{=1}$-constellation form,*

$$\Phi = \forall x \forall y \phi(x,y) \wedge \bigwedge_{1 \leq i \leq m} \forall x \exists^{=1} y R_i(x,y).$$

Put $\mathcal{A} = \{t : t(x,y)$ is a 2-type over $\mathcal{L}$ and $t(x,y) \rightarrow \phi(x,y)\}$.

Then Φ has a model with at least two-elements if and only if there exists a set of $\mathcal{A}$-$\mathcal{R}$-constellations which is a galaxy.

Proof. ($\Rightarrow$) Assume that $\mathfrak{A} \models \Phi$ and $card(A) > 1$. Since $\mathfrak{A} \models \forall x \forall y \phi(x,y)$, the set $\mathcal{A}$ is closed under *. Since $\mathfrak{A} \models \bigwedge_{1 \leq i \leq m} \forall x \exists^{=1} y R_i(x,y)$, every element of A realizes some $\mathcal{A}$-$\mathcal{R}$-constellation. Therefore $\mathcal{S} = \{C_a^{\mathfrak{A}} : a \in A\}$ is a galaxy.

($\Leftarrow$) Let $\mathcal{S}$ be a galaxy and assume that $\mathfrak{A}$ realizes $\mathcal{S}$. Let $a \in A$. By Definition 4.5, a realizes an $\mathcal{A}$-$\mathcal{R}$-constellation $S \in \mathcal{S}$, $S = \{s_0, \ldots, s_k\}$. This implies that $tp^{\mathfrak{A}}(a,a) = s_0$ and that there exists a sequence $b_1, \ldots, b_k$ of distinct elements of A such that $b_i \neq a$ for $i = 1, \ldots, k$, and

(1) $tp^{\mathfrak{A}}(a,b_i) = s_i$, for $i = 1, \ldots, k$,
(2) $tp^{\mathfrak{A}}(a,b) \in \mathcal{A}^{\leftarrow} \cup \mathcal{A}^{-} \subset \mathcal{A}$, for each $b \in \mathcal{A}$, such that $b \neq a$ and $b \neq b_i$, $i = 1, \ldots, k$.

Therefore, by Definition 4.3, the elements $b_1, \ldots, b_k$ are witnesses of a for the part

$$\bigwedge_{1 \leq i \leq m} \exists^{=1} y R_i(x,y).$$

Moreover, for every $b \in A, b \neq a$, $tp^{\mathfrak{A}}(a,b) \in \mathcal{A}$, and so $\mathfrak{A} \models \phi(a,b)$. Hence, $\mathfrak{A} \models \Phi$. ▯

4.2. The reduction. The following theorem has been shown in [16].

THEOREM 4.7. *There is a recursive reduction* NF *from C^2-sentences to C^2-sentences in normal form over an extended vocabulary, which is sound for satisfiability: Φ is satisfiable if and only if* $\mathrm{NF}(\Phi)$ *is satisfiable.*

In the above theorem the normal form is slightly weaker than our $\exists^{=1}$-constellation form. The difference is that in the $\exists^{=1}$-constellation form the quantifier free part of the sentences with prefix $\forall\exists^{=1}$ is atomic, whereas in the normal form in the sense of [16] it could be any quantifier free two-variable formula. This additional condition can be easily met by introducing new relation symbols for quantifier free formulas, and adding $\forall\forall$-sentences defining the newly introduced symbols.

From the proof of Theorem 4.7 given in [16] the following corollaries can be derived.

COROLLARY 4.8. *There exists a polynomial time algorithm which, given a C^2_1 sentence Ψ over a relational vocabulary, constructs a sentence Φ in $\exists^{=1}$-constellation form with the following properties:*

(1) *Ψ is satisfiable if and only if Φ is satisfiable.*
(2) *Every predicate letter occurring in Φ has arity at most* 2.
(3) *If n is the length of Ψ, then Φ contains $O(n)$ different predicate letters and has length $O(n \log n)$.*

The reduction for the full logic C^2 is more expensive.

COROLLARY 4.9. *There exists an exponential time algorithm which, given a C^2 sentence Ψ over a relational vocabulary, constructs a sentence Φ in $\exists^{=1}$-constellation form with the following properties:*

(1) *Ψ is satisfiable if and only if Φ is satisfiable.*
(2) *Every predicate letter occurring in Φ has arity at most* 2.
(3) *If n is the length of Ψ, then Φ contains $O(2^n)$ different predicate letters and has length $O(2^{O(n)})$.*

The exponential increase of the length of the sentence Φ given by the algorithm in Corollary 4.9 is caused by the necessity to introduce as many new predicate letters as the maximal integer which appear as an index of a counting quantifier. If integers are represented in binary we have to introduce $O(2^n)$ new predicate letters for a sentence of length n. We do not know any better reduction and this is the main reason why we cannot improve the upper complexity bound for the satisfiability problem for the full C^2 from double to single exponential.

4.3. The galaxy theorem. In this subsection we fix $\mathcal{R} = \{R_1, \ldots, R_m\} \subseteq \mathcal{L}$ and a set $\mathcal{A}$ of 2-types closed under *. Henceforth, whenever the sets $\mathcal{A}$ and $\mathcal{R}$ are fixed, we write "a constellation" instead of "an $\mathcal{A}$-$\mathcal{R}$-constellation."

So far we have shown that the satisfiability problem for C^2_1 sentences can be transformed to the problem of finding an appropriate galaxy. In this section we shall formulate syntactic conditions which are necessary and sufficient for a set of constellations to form a galaxy, but before doing that, in order to acquaint the reader with our basic technique and to provide a better background for the proof of the main result of this section, we shall state and prove some basic properties of constellations.

At the beginning we introduce a syntactic notion of *connectability* of two constellations. This definition says that two constellations are connectable by a 2-type t if t is a connective type for them; that is, t contains the centers of both constellations and either t is noncounting, or t and t^* are distributed between these two constellations. In other words, this notion provides a necessary condition for two constellations to be realizable in the same structure.

The notion of connectability, together with the notions of constellation and galaxy, plays a crucial role in this section and is basic in the whole paper. An easy observation (Proposition 4.13) shows that in a specific situation this notion suffices to formulate very simple conditions that allows to solve the satisfiability problem. This "specific" situation can be described in both semantic and syntactic terms. There is a structure in which every constellation is realized infinitely many times, or every two constellations are connectable by a noncounting type. Intuitively it means that there are no privileged elements in the structure.

Next, we consider the case when there are some privileged elements in a model. We prove that if a constellation S is realized in a structure sufficiently often, then we can build a structure in which S appears infinitely many times (Lemma 4.2). Constellations that can be realized infinitely often are easy to deal with, in contrast with those that always appear only finitely many times.

Lemma 4.3 plays a crucial role in the proof of the main result of this section—the galaxy theorem. It says that every galaxy can be partitioned into two sets: constellations which can be realized by at most r elements and constellations which can be realized by infinitely many elements. The integer r is bounded by an exponential function of the number of constellations in a given galaxy. To prove this lemma, for a structure $\mathfrak{A}$ realizing the given galaxy, we define a sequence of sets $V_1 \subset V_2 \subset \cdots \subset V_{p-1}$ of subsets of A. The set V_1 consists of lords, that is, of elements of A which realize constellations appearing in $\mathfrak{A}$ very rarely—less than $2m + 1$ times. Every set V_{i+1}, for $i > 1$, besides members of V_i, contains elements that are vassals of elements of V_i. They realize constellations appearing in $\mathfrak{A}$ not very often with respect to the cardinality of the set V_i of sovereigns of the elements of V_{i+1}. In this way we obtain a finite hierarchy of elements of A and therefore a hierarchy of elements of the galaxy—constellations realized by elements of appropriate V_i. This hierarchy does not necessarily include all constellations.

All the results mentioned above give several necessary conditions for a set of constellations to be a galaxy. As the next step we introduce the notion of a *finite representation of* a set of constellations (Definition 4.14), and we prove the galaxy theorem (Theorem 4.15) which says that the problem whether a set of constellations $\mathcal{S}$ is a galaxy can be reduced to the problem whether there exists a finite representation of $\mathcal{S}$.

Since the components of a finite representation are either finite sets of bounded cardinality or functions from such sets into some fixed finite sets, and since the conditions on the components are easily[1] computable, the galaxy theorem forms a basis for a decision procedure for the satisfiability problem for C_1^2 (Corollary 4.17 in 4.4).

We begin the technical part of this section with some additional definitions.

DEFINITION 4.10. *Let S, T be constellations, and let $t(x, y) \in \mathcal{A}$. S* is connectable *to T* by *$t(x, y)$ if $center(S) \subseteq t(x, y)$, $center(T) \subseteq t^*(x, y)$, and*

(1) *$t \in S$ and $t^* \in T$ if $t \in \mathcal{A}^{\leftrightarrow}$,*

(2) *$t \in S$ if $t \in \mathcal{A}^{\rightarrow}$,*

(3) *$t^* \in T$ if $t \in \mathcal{A}^{\leftarrow}$.*

DEFINITION 4.11. *Let $\mathcal{S}$ be a galaxy, and assume that $\mathfrak{A}$ realizes $\mathcal{S}$. Define a function* $\mathrm{rank}_{\mathfrak{A}} : \mathcal{S} \to \mathbb{N} \cup \{\infty\}$ *putting* $\mathrm{rank}_{\mathfrak{A}}(S) = card(\{a \in A : C_a^{\mathfrak{A}} = S\})$*.*

We write $\mathrm{rank}(\mathcal{S}) = \infty$ *if there is a structure $\mathfrak{B}$ realizing $\mathcal{S}$ such that*

$$\min_{S \in \mathcal{S}}(\mathrm{rank}_{\mathfrak{B}}(S)) > 2m + 1.$$

[1]In this section "easily" means in double exponential time.

LEMMA 4.1. *Assume that $\mathfrak{A}$ is a structure which realizes $\mathcal{S}$. Let $S, T \in \mathcal{S}$. If* $\mathrm{rank}_{\mathfrak{A}}(S) > 2m+1$, *and* $\mathrm{rank}_{\mathfrak{A}}(T) > 2m+1$, *then there exist $a, b \in A$ such that $C_a^{\mathfrak{A}} = S$, $C_b^{\mathfrak{A}} = T$, and $tp^{\mathfrak{A}}(a,b) \in \mathcal{A}^-$.*

Proof. Let $X = \{a \in A : C_a^{\mathfrak{A}} = S\}$, $Y = \{a \in A : C_a^{\mathfrak{A}} = T\}$, and assume that $card(X) \geq card(Y) > 2m+1$.

By Definition 4.4, for every $a \in X$ ($a \in Y$) there is at most m distinct elements b such that $tp^{\mathfrak{A}}(a,b) \in S$ ($tp^{\mathfrak{A}}(a,b) \in T$, respectively). Therefore, the number of pairs $\langle a, b\rangle$ such that $a \in X$, $b \in Y$, and $tp^{\mathfrak{A}}(a,b) \in S$ or $tp^{\mathfrak{A}}(b,a) \in T$ does not exceed $m \cdot card(X) + m \cdot card(Y) \leq 2m \cdot card(X)$. On the other hand, the number of pairs $\langle a, b\rangle$ such that $a \in X$ and $b \in Y$ is $card(X) \cdot card(Y) > (2m+1)card(X)$. ☐

COROLLARY 4.12. *Let $\mathcal{S}$ be a galaxy with* $\mathrm{rank}(\mathcal{S}) = \infty$. *Then there exists a structure $\mathfrak{B}$ realizing $\mathcal{S}$ such that* $\mathrm{rank}_{\mathfrak{B}}(S) = \infty$, *for each $S \in \mathcal{S}$.*

Proof. Assume that $\mathfrak{A}$ realizes $\mathcal{S}$, $S \in \mathcal{S}$, and $\mathrm{rank}_{\mathfrak{A}}(S) = n$. We claim that there is an extension $\mathfrak{B}$ of $\mathfrak{A}$, such that $\mathfrak{B}$ realizes $\mathcal{S}$, and $\mathrm{rank}_{\mathfrak{B}}(S) > n$. By Lemma 4.1, for all constellations $S, T \in \mathcal{S}$, there exists a type $t(x,y) \in \mathcal{A}^-$ such that S is connectable to T by $t(x,y)$. Let $\mathfrak{A}'$ be a structure isomorphic to $\mathfrak{A}$ such that $A \cap A' = \emptyset$. Define $B = A \cup A'$, and let $\mathfrak{B} \restriction A = \mathfrak{A}$, $\mathfrak{B} \restriction A' = \mathfrak{A}'$. Now, for every $a \in A$, and every $a' \in A'$, find $t(x,y) \in \mathcal{A}^-$ such that $C_a^{\mathfrak{A}}$ is connectable to $C_{a'}^{\mathfrak{A}'}$ by $t(x,y)$, and put $tp^{\mathfrak{B}}(a,a') = t(x,y)$. ☐

PROPOSITION 4.13. *The following conditions are equivalent:*

(1) $\mathrm{rank}(\mathcal{S}) = \infty$;

(2) (a) *for every $S \in \mathcal{S}$, and every $s(x,y) \in S$, there exists $T \in \mathcal{S}$ such that S is connectable to T by $s(x,y)$;*

(b) *for every $S, T \in \mathcal{S}$, S is connectable to T by some $t(x,y) \in \mathcal{A}^-$.*

Proof. (1) $\Rightarrow$ (2). Condition (a) follows from Definition 4.5 and condition (b) from Lemma 4.1.

(2) $\Rightarrow$ (1). We shall give an algorithm which constructs a structure $\mathfrak{A}$ realizing $\mathcal{S}$. In the process of construction new elements will be added to the universe; some elements of the universe will be inactivated and some unordered pairs of elements will be reserved. An element a will be inactivated when the constellation S that had been earlier assigned to a has been built, i.e., when elements which witness that a realizes S have been added. An unordered pair $\{a,b\}$ will be reserved, when the type realized by $\{a,b\}$ has been defined. Moreover, a function $I : A \mapsto \mathcal{S}$ will be defined in such a way that $I(a) = C_a^{\mathfrak{A}}$ for every $a \in A$.

In every step of the construction the part of the model defined so far $\mathfrak{A}$ will be finite. We assume that a linear ordering $<$ of the universe is given such that a new element added to the universe is always greater then the old elements.

Let $\mathcal{S} = \{S_1, \ldots, S_k\}$.

(1) Let $A = \{a_1, \ldots, a_k\}$. Put $I(a_i) = S_i$, $i = 1, \ldots, k$.
(2) Let $a \in A$ be the first active (not yet inactivated) element.
(3) For every $t_i \in I(a)$, if there is no element $b \in A$ such that $\{a,b\}$ is reserved, and $tp^{\mathfrak{A}}(a,b) = t_i$, then
    (a) add a new element b_i to A,
    (b) put $tp^{\mathfrak{A}}(a,b_i) = t_i$,
    (c) find a constellation $T \in \mathcal{S}$ such that S is connectable to T by t_i,
    (d) put $I(b_i) = T$, and reserve $\{a, b_i\}$.
(4) For every $c < a$ put $tp^{\mathfrak{A}}(a,c) = t \in \mathcal{A}^-$ such that $I(a)$ is connectable to $I(c)$ by t.
(5) Inactivate a.

(6) Go to 2.

If $\min_{S\in\mathcal{S}}(\mathrm{rank}_{\mathfrak{A}}(S)) \leq 2m+1$, perform the operations from the proof of Corollary 4.12. ◻

LEMMA 4.2. *Assume that $\mathfrak{A}$ realizes $\mathcal{S}$. Let V be a finite subset of A and let $\mathcal{S}' = \{C_a^{\mathfrak{A}} : a \in A\setminus V\}$. If $\mathcal{S}'\cap\{C_a^{\mathfrak{A}} : a\in V\} = \emptyset$, and for every $a \in A\setminus V$, $\mathrm{rank}_{\mathfrak{A}}(C_a^{\mathfrak{A}}) > \max(card(V)\cdot m, 2m+1)$, then there is a structure $\mathfrak{B}$ realizing $\mathcal{S}$, such that for every $S\in\mathcal{S}'$ $\mathrm{rank}_{\mathfrak{B}}(S)=\infty$, and $\mathrm{rank}_{\mathfrak{B}}(S) = \mathrm{rank}_{\mathfrak{A}}(S)$, for every $S\in\mathcal{S}\setminus\mathcal{S}'$.*

Proof. Let $\mathfrak{A}$ realize $\mathcal{S}$.

An iterative application of the following algorithm applied to every $S\in\mathcal{S}'$ yields a structure $\mathfrak{B}$ such that $\mathrm{rank}_{\mathfrak{B}}(S)=\infty$ for every $S\in\mathcal{S}'$ and $\mathrm{rank}_{\mathfrak{B}}(S)=\mathrm{rank}_{\mathfrak{A}}(S)$ for every $S\in\mathcal{S}\setminus\mathcal{S}'$ (inactivation, reserving elements, and the function I play the same role as in the proof of Proposition 4.13). At the beginning, put $\mathfrak{A}'=\mathfrak{A}$.

```
(1) Let $A'' = A'\cup\{x\}$.
(2) For every $a\in A'$ put $I(a) = C_a^{\mathfrak{A}'}$ and inactivate $a$.
(3) Put $I(x) = S$.
(4) Let $x$ be the first active element of $A''$.
(5) Find $a\in A\setminus V$ such that $C_a^{\mathfrak{A}} = I(x)$, and $tp^{\mathfrak{A}}(a,b)\in\mathcal{A}^{-}\cup\mathcal{A}^{\rightarrow}$, for every $b\in V$.
    Such an element $a$ exists, since there are at most $m\cdot card(V)$ elements $c\in A\setminus V$ such that $tp^{\mathfrak{A}}(c,b)\in\mathcal{A}^{\leftrightarrow}\cup\mathcal{A}^{\leftarrow}$.
(6) For every $t_i\in S$,
    (a) if there is $b\in V$ such that $tp^{\mathfrak{A}}(a,b)=t_i$, then put $tp^{\mathfrak{A}}(x,b)=t_i$, and reserve $\{x,b\}$
        else
    (b) if there is no element $d\in A''$ such that $\{x,d\}$ is reserved and $tp^{\mathfrak{A}''}(x,d)=t_i$, then
        add a new element $b_i$ to $A''$,
        put $tp^{\mathfrak{A}}(x,b_i)=t_i$, reserve $\{x,b_i\}$,
        find $a_i\in A\setminus V$ such that $tp^{\mathfrak{A}}(a,a_i)=t_i$, and put $I(b_i)=I(a_i)$.
    An element $a_i$ can be found since $C_a^{\mathfrak{A}}=S$ and therefore there is an element $c_i\in A$ such that $tp^{\mathfrak{A}}(a,c_i)=t_i$. Since $c_i\in A\setminus V$ and $\mathfrak{A}$ realizes $\mathcal{S}$ we have $I(c_i)=C_{c_i}^{\mathfrak{A}}\in\mathcal{S}'$.)
(7) For every $c<x$, if $\{c,x\}$ is not reserved, put $tp^{\mathfrak{A}''}(x,c)=t\in\mathcal{A}^{-}$ such that $I(x)$ is connectable to $I(c)$ in $\mathfrak{A}$ by $t$, and reserve $\{x,c\}$.
    (By Lemma 4.1, for every $S,T\in\mathcal{S}'$, $S$ is connectable to $T$ in $\mathfrak{A}$ by some $t\in\mathcal{A}^{-}$.)
(8) Inactivate $x$.
(9) Go to 4.
```

One application of the above algorithm to the constellation $S\in\mathcal{S}'$ and the structure $\mathfrak{A}'$ expands the structure $\mathfrak{A}'$ to a structure $\mathfrak{A}''$ such that $\mathrm{rank}_{\mathfrak{A}''}(S) > \mathrm{rank}_{\mathfrak{A}'}(S)$.

In step 6, when the types $tp^{\mathfrak{A}''}(x,b)$ are defined, where $b\in V$, the constellation realized by b does not change, since $tp^{\mathfrak{A}''}(x,b)\in\mathcal{A}^{\rightarrow}$. Also in step 7, the constellations realized by the elements $c<x$ are not changed since only types in $\mathcal{A}^{-}$ are used.

Every $x\in A''$ is eventually inactivated since new elements b_i are added at the end of the ordering. When an element x is inactivated it is ensured that for every $c<x$, $tp^{\mathfrak{A}''}(c,x)$ is defined, and $C_x^{\mathfrak{A}''}\in\mathcal{S}$. ◻

LEMMA 4.3. *Let $\mathcal{S}$ be a galaxy. There is a constant r, $r = O(m \cdot card(\mathcal{S}))^{card(\mathcal{S})}$, and there exists a structure $\mathfrak{B}$ realizing $\mathcal{S}$ such that* $\operatorname{rank}_{\mathfrak{B}}(S) < r$ *or* $\operatorname{rank}_{\mathfrak{B}}(S) = \infty$ *for every $S \in \mathcal{S}$.*

Proof. Let $\mathfrak{A}$ realize $\mathcal{S}$. It suffices to define $V \subseteq A$ of appropriate cardinality which satisfies the conditions of Lemma 4.2.

The set V will be constructed in stages.

STAGE 1. Let $V_1 = \{a \in A : \operatorname{rank}_{\mathfrak{A}}(C_a^{\mathfrak{A}}) \le 2m + 1\}$.

Note that if $V_1 = \emptyset$, then by Corollary 4.12, there is a structure $\mathfrak{B}$ such that for every $S \in \mathcal{S}$, $\operatorname{rank}_{\mathfrak{B}}(S) = \infty$. In this case only Stages 1 and 2 are performed.

STAGE i $(i > 1)$.

(1) If $\operatorname{rank}_{\mathfrak{A}}(C_a^{\mathfrak{A}}) > card(V_{i-1}) \cdot m$ for every $a \in A \setminus V_{i-1}$,
then put $V_i = V_{i-1}$ and `stop`.

(2) Put $V_i = V_{i-1} \cup \{a \in A \setminus V_{i-1} : \operatorname{rank}_{\mathfrak{A}}(C_a^{\mathfrak{A}}) \le card(V_{i-1}) \cdot m\}$.

(3) Go to Stage $i + 1$.

Note that there is a stage i such that $V_i = V_{i-1}$. Indeed, for every stage i, let $C(V_i) = \{S \in \mathcal{S} :$ there is $a \in V_i$ such that $C_a^{\mathfrak{A}} = S\}$. Hence, for every $i > 1$, if $V_i \ne V_{i-1}$, then $C(V_i) \supset C(V_{i-1})$. Therefore, since $\mathcal{S}$ is finite, the number p of stages performed is less than or equal to $card(\mathcal{S})$. Put $V = V_p$.

Now, we estimate $card(V)$. We have $card(V_1) \le (2m+1)\cdot card(\mathcal{S})$, and, for $i > 1$,

$$card(V_i) \le card(V_{i-1}) + m \cdot card(V_{i-1}) \cdot (1 + m \cdot card(\mathcal{S})).$$

If we put $q = 1 + m \cdot card(\mathcal{S})$, then we have $card(V_1) \le 3q^p$. Moreover, for every $a \in V$, $\operatorname{rank}_{\mathfrak{A}}(C_a^{\mathfrak{A}}) \le card(V)$, and for every $a \in A \setminus V, \operatorname{rank}_{\mathfrak{A}}(C_a^{\mathfrak{A}}) > card(V) \cdot m$. Put $r = 3 \cdot (1 + m \cdot card(\mathcal{S}))^{card(\mathcal{S})}$. This by Lemma 4.2 finishes the proof. □

Now we are ready to introduce the main definition of this section.

DEFINITION 4.14. *Let $\mathcal{S}$ be a set of constellations. A* finite representation *of $\mathcal{S}$ is a system*

$$\langle \mathcal{S}_1, V, C, I, F, G\rangle,$$

where $\mathcal{S}_1$ is a set of constellations , V and C are sets, I, F, G are functions such that

$$I : C \mapsto \mathcal{S}, \quad F : C \times C \to \mathcal{A}, \quad G : (\mathcal{S} \setminus \mathcal{S}_1) \times V \to \mathcal{A},$$

and the following conditions hold:

(f1) *$\mathcal{S}_1 \subseteq \mathcal{S}$, $V \subseteq C$, and $card(C) \le m \cdot (2m \cdot card(\mathcal{S}))^{card(\mathcal{S})}$;*

(f2) *$I(V) = \mathcal{S}_1$, $I(C \setminus V) \subseteq \mathcal{S} \setminus \mathcal{S}_1$,*
$F(a, a) = F(a, b)\lceil\{x\}$, and for every $a \ne b$, $F(a, b) = F(b, a)^*$,
$G : (\mathcal{S} \setminus \mathcal{S}_1) \times V \to \mathcal{A}^{\rightarrow} \cup \mathcal{A}^{-}$;

(f3) *For every $b \in C$ define $D(b) = \{F(b, c) : c \in C, c \ne b, F(b, c) \in \mathcal{A}^{\rightarrow} \cup \mathcal{A}^{\leftrightarrow}\}$. Then*

  (a) *for every $b \in C$ and every $t \in D(b)$, there is exactly one $c \in C, c \ne b$ such that $F(b, c) = t$,*

  (b) *$D(a) = I(a)$ for every $a \in V$,*

  (c) *for every $b \in C \setminus V$, we have $D(b) \subseteq I(b)$, and for every $t \in I(b) \setminus D(b)$ there is $T \in \mathcal{S} \setminus \mathcal{S}_1$ such that $I(b)$ is connectable to T by t;*

(f4) *for every $S, T \in \mathcal{S} \setminus \mathcal{S}_1$, S is connectable to T by some $t \in \mathcal{A}^{-}$;*

(f5) *for every $S \in \mathcal{S} \setminus \mathcal{S}_1$ we have $\{G(S, a) \in \mathcal{A}^{\rightarrow} : a \in V\} \subseteq S$, and for every $a \in V$, S is connectable to $I(a)$ by $G(S, a)$;*

(f6) *for every $S \in \mathcal{S} \setminus \mathcal{S}_1$ and every $t \in S$, if $t \in \mathcal{A}^{\rightarrow}$ and there is no $T \in \mathcal{S} \setminus \mathcal{S}_1$ such that S is connectable to T by t, then there is a unique $a \in V$ such that $G(S, a) = t$;*

(f7) *for every $S \in \mathcal{S} \setminus \mathcal{S}_1$ and every $t \in S$, if there is no $a \in V$ such that $G(S,a) = t$, then there is $T \in \mathcal{S} \setminus \mathcal{S}_1$ such that S is connectable to T by t.*

We say that $\mathcal{S}$ is finitely representable*, if there is a finite representation of $\mathcal{S}$.*

Let us note that the notion of a finite representation is almost identical with the notion of small representation (Definition 3.12). The role of replicable small constellations is taken here by constellations in $\mathcal{S} \setminus \mathcal{S}_1$.

THEOREM 4.15 (galaxy theorem). *A set of constellations $\mathcal{S}$ is a galaxy if and only if $\mathcal{S}$ is finitely representable.*

Proof. ($\Rightarrow$) Let $\mathcal{S}$ be a galaxy. Use Lemma 4.3 to get a structure $\mathfrak{A}$ and a constant r such that $\mathfrak{A}$ realizes $\mathcal{S}$, and for every $S \in \mathcal{S}$, $\mathrm{rank}_{\mathfrak{A}}(S) < r$ or $\mathrm{rank}_{\mathfrak{A}}(S) = \infty$. Put

$\mathcal{S}_1 = \{S \in \mathcal{S} : \mathrm{rank}_{\mathfrak{A}}(S) < r\}$,

$V = \{a \in A : \mathrm{rank}_{\mathfrak{A}}(C_a^{\mathfrak{A}}) < r\}$,

$C = V \cup \{a \in A : \text{there is } b \in V \text{ such that } tp^{\mathfrak{A}}(b,a) \in \mathcal{A}^{\rightarrow} \cup \mathcal{A}^{\leftrightarrow}\}$.

Note that if $S \in \mathcal{S} \setminus \mathcal{S}_1$, then $\mathrm{rank}_{\mathfrak{A}}(S) = \infty$. For every $a \in V$, put $I(a) = C_a^{\mathfrak{A}}$. For every $a, b \in C, a \neq b$, put $F(a,b) = tp^{\mathfrak{A}}(a,b)$. For every $S \in \mathcal{S} \setminus \mathcal{S}_1$ find $a \in A \setminus C$ such that $C_a^{\mathfrak{A}} = S$, and for every $c \in V$ put $G(S,c) = tp^{\mathfrak{A}}(a,c)$.

It is easy to check that conditions (f1)–(f7) of Definition 4.14 hold.

($\Leftarrow$) Let $\langle \mathcal{S}_1, V, C, I, F, G \rangle$ be a finite representation of $\mathcal{S}$.

Case 1. $\mathcal{S}_1 = \emptyset$. By condition (f2), $V = \emptyset$. Consequently conditions (f7) and (f4) are equivalent to conditions (a) and (b) of Proposition 4.13.

Case 2. $\mathcal{S}_1 = \mathcal{S}$. By condition (f2), $V = C$. Therefore, by conditions (f1)–(f3), we can define $\mathfrak{V}$ realizing $\mathcal{S}$ with universe V in which $tp^{\mathfrak{V}}(a,b) = F(a,b)$ for every $a, b \in V$.

Case 3. $\mathcal{S}_1 \neq \emptyset$ and $\mathcal{S}_1 \neq \mathcal{S}$. We shall construct a structure $\mathfrak{A}$ realizing $\mathcal{S}$ with the universe A ($A \supseteq C$). In our infinite construction, inactivation and reservation have the same role as in the previous algorithms. Additionally, function I will be extended to all elements of A in such a way that for every $b \in A$, $I(b) = C_b^{\mathfrak{A}}$. In each step of construction the universe of partially defined model $\mathfrak{A}$ will be finite, and we assume that there is a fixed linear ordering on the universe such that any new element added to the universe is greater than the old ones.

```
STAGE 1.
  (1) Let $A = C$.
  (2) For every $a, b \in C$, put $tp^{\mathfrak{A}}(a,b) = F(a,b)$ (cf. (f2)).
  (3) For every $a \in V$, inactivate $a$.
  (4) For every $a, b \in C$, reserve $\{a, b\}$.
  (5) For every $S \in \mathcal{S} \setminus \mathcal{S}_1$, if there is no $b \in C$ such that $I(b) = S$, then add
      a new element $d$ to $A$ and put $I(d) = S$.
STAGE 2.
  (6) Let $b$ be the first active element of $A$ (note that $I(b) \in \mathcal{S} \setminus \mathcal{S}_1$).
  (7) If $b \in C$, then
      (a) for every $t \in I(b) \setminus D(b)$ do
           (i) find $T \in \mathcal{S} \setminus \mathcal{S}_1$ such that $I(b)$ is connectable to $T$ by $t$ (use
               (f3-c)),
          (ii) add a new element $d$ to $A$ and put $I(d) = T$,
          (ii) put $tp^{\mathfrak{A}}(b,d) = t$ and reserve $\{b, d\}$,
      (b) inactivate $b$ and go to 6.
  (8) For every $a \in V$, put $tp^{\mathfrak{A}}(b,a) = G(I(b),a)$ (use (f5) and (f6)).
  (9) For every $t \in I(b)$, if there is no $c \in A$ such that $\{c, b\}$ is reserved, and
```

$tp^{\mathfrak{A}}(c,b) = t^*$, then
(a) find $T \in \mathcal{S} \setminus \mathcal{S}_1$ which is connectable to $I(b)$ by t^* (use (f7)),
(b) add a new element d to A, and put $I(d) = T$,
(c) put $tp^{\mathfrak{A}}(b,d) = t$, and reserve $\{b,d\}$.

(10) For every $a < b$, if $\{a,b\}$ is not reserved, then using (f4) find $t \in \mathcal{A}^-$ such that $I(b)$ is connectable to $I(a)$ by t, put $tp^{\mathfrak{A}}(b,a) = t$ and reserve $\{b,a\}$.

(11) Inactivate b and go to 6.

After performing Stage 1, every $a \in V$ realizes the constellation $I(a) \in \mathcal{S}$ in the partially defined structure $\mathfrak{A}$, by f(2) every constellation $S \in \mathcal{S}_1$ is realized by some $a \in V$, and only elements of V have been inactivated. Moreover, for every $S \in \mathcal{S}$, there is $b \in A$ such that $I(b) = S$.

The role of Stage 2 is to realize all constellations of $\mathcal{S} \setminus \mathcal{S}_1$ by elements of A. Step 7 is executed if, at Stage 1, some types between the chosen b and the other elements of A were defined using function F. For every type of $I(b)$ that has not been defined, a new element d is added to A, and some $T \in \mathcal{S} \setminus \mathcal{S}_1$ is put as $I(d)$. Therefore, only constellations of $\mathcal{S} \setminus \mathcal{S}_1$ have to be realized in the next steps. In step 10, when the types between an element b and smaller, already inactivated elements are defined, the constellation realized by the earlier elements are not changed because only types in $\mathcal{A}^-$ are used.

Every $b \in A$ is eventually inactivated since new elements are added at the end of the ordering. When an element b is inactivated it is ensured that $C_b^{\mathfrak{A}} \in \mathcal{S}$. ∎

COROLLARY 4.16. *If $\langle \mathcal{S}_1, V, C, I, F, G \rangle$ is a finite representation of $\mathcal{S}$, then there exists a structure $\mathfrak{A}$ realizing $\mathcal{S}$, such that $A = C \cup B$ for every $a \in B$, $\mathrm{rank}_{\mathfrak{A}}(C_b^{\mathfrak{A}}) = \infty$, and conditions* (f1)–(f7) *hold.*

Proof (sketch). Take $\mathfrak{A}$ given by part ($\Leftarrow$) of the proof of Theorem 4.15. ∎

4.4. Complexity. In this subsection, using the galaxy theorem proved in the previous subsection, we provide an algorithm solving the satisfiability problem for C_1^2. This algorithm works in nondeterministic, double exponential time. In the next section, using more sophisticated techniques, we will show that this bound can be improved.

COROLLARY 4.17. $\mathrm{SAT}(\mathcal{C}_1^2) \in$ 2-NEXPTIME.

Proof. We describe a nondeterministic algorithm which for every sentence $\Phi \in \mathcal{C}_1^2$ decides if Φ is satisfiable and works in time doubly exponential with respect to the length of Φ.

Let Φ be a $\mathcal{C}_1^2$-sentence of length n. In the first step we use the polynomial time algorithm from Corollary 4.8 to obtain a sentence Ψ in $\exists^{=1}$-constellation form

$$\Psi = \forall x \forall y \phi(x,y) \wedge \bigwedge_{1 \le i \le m} \forall x \exists^{=1} y R_i(x,y),$$

which is satisfiable if and only if Φ is satisfiable. Moreover Ψ has at most $p = O(n)$ predicate letters and has length $O(n \log n)$.

Then we use Theorem 4.6. We build the set $\mathcal{A}$ in time $O(2^{4p})$, and we guess a set $\mathcal{S}$ of $\mathcal{A}$-$\mathcal{R}$-constellations. Note that $card(\mathcal{A}) \le 2^{4p}$, and $card(\mathcal{S}) \le (2^{4p})^m$, where $m = card(\mathcal{R})$ is the number of existential quantifiers in Ψ. Therefore $\mathcal{S}$ can be guessed in time $(2^{4p})^m \cdot m \cdot 4p = O(2^{O(n^2)})$.

Next, we apply Theorem 4.15 and guess sets $\mathcal{S}_1$, V, and C, as well as functions I, F, and G as in Definition 4.14. Since $\mathcal{S}_1 \subseteq \mathcal{S}$, and $card(V) \le card(C) \le m \cdot (2m \cdot card(\mathcal{S}))^{card(\mathcal{S})}$ we can guess the components in time:

$$\begin{aligned}
\mathcal{S}_1 &\quad — \quad O(card(\mathcal{S})) = O\big(2^{O(n^2)}\big),\\
V \text{ and } C &\quad — \quad O(m(2m \cdot card(\mathcal{S}))^{card(\mathcal{S})}) = O\big(2^{2^{O(n^2)}}\big),\\
I, F &\quad — \quad O((card(C)^2) = O\big(2^{2^{O(n^2)}}\big),\\
G &\quad — \quad O(card(\mathcal{S} \setminus \mathcal{S}_1) \cdot card(V)) = O\big(2^{2^{O(n^2)}}\big).
\end{aligned}$$

Therefore, the time required for this step is bounded by $O(2^{2^{cn^2}})$ for some constant c.

Finally, we check whether the system $\langle \mathcal{S}, \mathcal{S}_1, V, C, I, F, G\rangle$ is a finite representation of $\mathcal{S}$. It is easy to see that this can also be done in time $O(2^{2^{cn^2}})$. □

4.5. An example. It is well known that the class $\mathcal{C}_1^2$ admits axioms of infinity, i.e., there are satisfiable sentences of $\mathcal{C}_1^2$ that have only infinite models. Using the notion of a finite representation, in the proof of Corollary 4.17 we have described an algorithm solving the satisfiability problem for sentences in constellation form, which did not depend on constructing a complete model.

The size of the finite representation $\langle \mathcal{S}_1, V, C, I, F, G\rangle$ of a set of constellations $\mathcal{S}$ depends mainly on the cardinality of the set C. It is bounded in Definition 4.14 by a number that is exponential with respect to the number of constellations in $\mathcal{S}$ and double exponential with respect to the number of predicate letters in the signature.

Below we give an example Φ of a sentence in $\mathcal{C}_1^2$ which has finite models, and is such that for every finite representation $\langle \mathcal{S}_1, V, C, I, F, G\rangle$ of the set of constellations realized in a model of Φ, the cardinality of C is doubly exponential. In this example, following the idea of Lewis's proof [27] that NEXPTIME is reducible to the monadic Gödel class, we use a concise representation of the successor relation between encodings of natural numbers that is reminiscent to that used by Jones and Selman in [23].

Let n be a positive integer.

Let $\mathcal{L} = \{B_1, \ldots, B_n, C_0, C_1, \ldots, C_n,$ *Root*, *Leaf*, *Left*, *Right*, *In*, $R\}$, where B_i, C_i, *Root*, *Leaf* are monadic predicate letters and *Left*, *Right*, *In*, R are binary predicate letters. The sentence Φ will describe the unique model (up to isomorphism) that is a full binary tree of height $2^n - 1$.

The sentence Φ is a conjunction of the following sentences.

$\forall x \exists^{=1} y\ R(x, y)$,
$\forall x \exists^{=1} y\ \mathit{Left}(x, y)$,
$\forall x \exists^{=1} y\ \mathit{Right}(x, y)$,
$\forall x \exists^{=1} y\ \mathit{In}(x, y)$,
$\forall x \forall y\ \mathit{Root}(x) \wedge \mathit{Root}(y) \to x = y$,
$\forall x \forall y\ R(x, y) \to \mathit{Root}(y)$,
$\forall x \forall y\ \neg[\mathit{Left}(x, y) \wedge \mathit{Right}(x, y)] \vee \mathit{Leaf}(x)$,
$\forall x\ \mathit{Leaf}(x) \to [\mathit{Left}(x, x) \wedge \mathit{Right}(x, x)]$,
$\forall x \forall y\ \mathit{In}(x, y) \to [\neg \mathit{Leaf}(y) \wedge (\mathit{Left}(y, x) \vee \mathit{Right}(y, x))$
$\qquad \vee \mathit{Root}(x) \wedge \mathit{Root}(y)]$,
$\forall x\ \mathit{Root}(x) \leftrightarrow \bigwedge_{0 \le i < n} \neg B_i(x)$,
$\forall x\ \mathit{Leaf}(x) \leftrightarrow \bigwedge_{0 \le i < n} B_i(x)$,
$\forall x\ C_0(x) \wedge [\bigwedge_{0 \le i < n} (C_i(x) \leftrightarrow (C_{i-1}(x) \wedge B_i(x)))]$,
$\forall x \forall y\ [\neg \mathit{Leaf}(x) \wedge (\mathit{Left}(x, y) \vee \mathit{Right}(x, y))] \to$
$\qquad \bigwedge_{0 \le i < n} [B_i(y) \leftrightarrow \neg(B_i(x) \leftrightarrow C_{i-1}(x))]$.

The sentence Φ is a slight modification of the example given in [29]. A similar example can also be found in [16]. It is worth noticing that Φ is in $\exists^{=1}$-constellation form. We have here $\mathcal{R} = \{\mathit{In}, \mathit{Left}, \mathit{Right}, R\}$.

PROPOSITION 4.18. *The sentence Φ is satisfiable, and if $\mathfrak{A}$ realizes Φ, then $card(\mathfrak{A}) = 2^{2^n} - 1$.*

Proof. Let, for every d, $0 \leq d \leq 2^n - 1$, $Level_d$ denote the unique 1-type over the set $\{B_1, \ldots, B_n\}$ such that $B_i(x) \in Level_d$ if and only if the ith bit of d in the binary notation is 1.

It is easy to see that a full binary tree $\mathfrak{T}$ (see Figure 1) is the unique model of Φ with the interpretations for the predicate letters such that for every $a, b \in \mathfrak{T}$

$Root(a)$	iff	a is the root of $\mathfrak{T}$,
$Leaf(a)$	iff	a is a leaf of $\mathfrak{T}$,
$Left(a, b)$	iff	b is the immediate left successor of a or $a = b$ is a leaf of $\mathfrak{T}$,
$Right(a, b)$	iff	b is the immediate right successor of a or $a = b$ is a leaf of $\mathfrak{T}$,
$In(a, b)$	iff	b is the immediate predecessor of a or $a = b$ is the root of $\mathfrak{T}$,
$Level_d(a)$	iff	the distance from the root to a is equal to d.

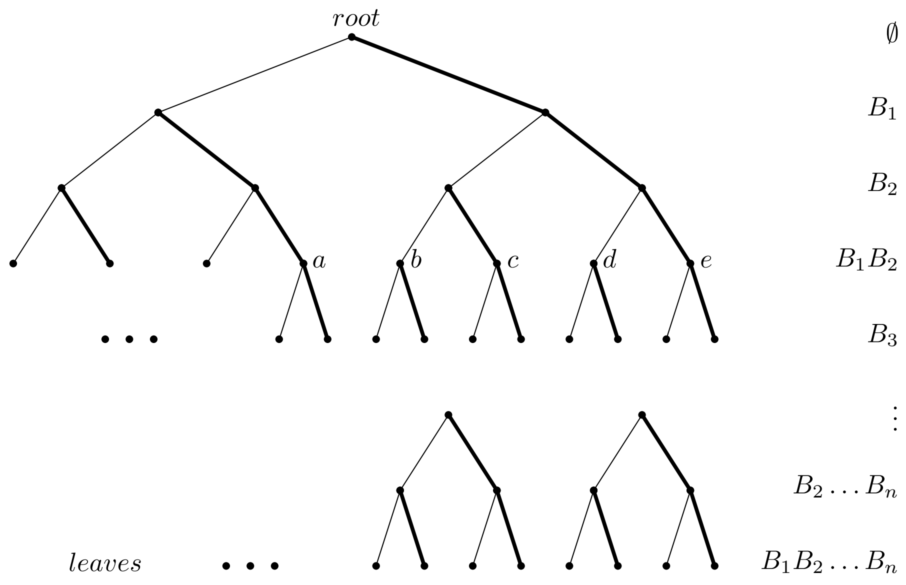

FIG. 1. *The model for Φ.*

Since the remaining predicates are explicitly defined by Φ, their interpretations can be derived from the interpretations above.

Note that for every d, $0 \leq d \leq 2^n - 1$, there is $a \in T$ such that $Level_d(a)$, and for every $a \in T$, $Leaf(a)$ if and only if $Level_{2^n-1}(a)$. $\square$

5. The main result.

5. The main result. The main result of this paper is the following theorem.

THEOREM 5.1. SAT($\mathcal{C}_1^2$) $\in$ NEXPTIME.

We begin this section by providing some intuition arising from a close analysis of the example given in section 4.5. Then we define a notion of a *concise representation* of a set of constellations which will play a similar role to the notion of finite representation but will require less space. Finally, we show how to use this notion to get a nondeterministic decision procedure working in exponential time, and solving the satisfiability problem for C_1^2. In the last step we use graph-theoretical notions and results given in the appendix.

5.1. Example continued. In this subsection we want to provide some intuition on how to improve the double exponential upper complexity bound for C^2_1. This will be done by discussing in greater detail the example from section 4.5 of the sentence Φ that describes a binary tree of exponential height.

Let us first examine the types and constellations realized in the model of Φ (see Figure 1). For every pair of elements x and y such that y is an immediate successor of x, x and y are joined with a thin or a thick line depending on whether $\mathit{Left}(x,y)$ or $\mathit{Right}(x,y)$ holds and then also, $\mathit{In}(y,x)$ holds. Moreover, every element x of the tree should in the picture be joined to the root by a line representing $R(x,\text{root})$.

For every element x, the unique 1-type realized by x contains positive formulas of the form $B_i(x)$ for those and only those B_i-s which are listed on the right margin. The values of C_i-s on x are determined by the values of B_i-s. If an element x is neither the root nor a leaf then the 1-type realized by x does not contain any positive appearance of other predicate letters.

Below, when describing types, we list only atomic formulas with both x and y, omitting the remaining two-variable conjuncts which are negations of atomic formulas that are not listed. The elements on the same level $d > 0$ of the tree realize constellations of two kinds with the same center. For $d = 2, 3, \dots, 2^n - 3$ we have the following constellations, each containing exactly four 2-types:

$S = \{\mathit{Left}(y,x) \wedge \mathit{In}(x,y), \mathit{Left}(x,y) \wedge \mathit{In}(y,x), \mathit{Right}(x,y) \wedge \mathit{In}(y,x), R(x,y)\}$,

$T = \{\mathit{Right}(y,x) \wedge \mathit{In}(x,y), \mathit{Left}(x,y) \wedge \mathit{In}(y,x), \mathit{Right}(x,y) \wedge \mathit{In}(y,x), R(x,y)\}$.

Therefore, elements denoted by a, c, and e realize the constellation T, and the constellation S is realized by b and d.

The constellations realized on the first level include exactly three 2-types:

$S = \{\mathit{Left}(y,x) \wedge \mathit{In}(x,y) \wedge R(x,y), \mathit{Left}(x,y) \wedge \mathit{In}(y,x), \mathit{Right}(x,y) \wedge \mathit{In}(y,x)\}$,

$T = \{\mathit{Right}(y,x) \wedge \mathit{In}(x,y) \wedge R(x,y), \mathit{Left}(x,y) \wedge \mathit{In}(y,x), \mathit{Right}(x,y) \wedge \mathit{In}(y,x)\}$.

The root and the leaves realize constellations containing exactly two 2-types. The root realizes the constellation

$S = \{\mathit{Left}(x,y) \wedge \mathit{In}(y,x) \wedge R(y,x), \mathit{Right}(x,y) \wedge \mathit{In}(y,x) \wedge R(y,x)\}$

and $\{\mathit{In}(x,x), R(x,x)\} \subset \mathit{center}(S)$.

If x is a leaf, then

$S = \{\mathit{Left}(y,x) \wedge \mathit{In}(x,y), R(x,y)\}$,

$T = \{\mathit{Right}(y,x) \wedge \mathit{In}(x,y), R(x,y)\}$,

and $\{\mathit{Left}(x,x), \mathit{Right}(x,x)\} \subset \mathit{center}(S) = \mathit{center}(T)$.

Note that since elements on different levels of the tree realize distinct constellations, the number of constellations realized in $\mathfrak{T}$ is exponential with respect to the number of predicate letters in $\mathcal{L}$. Moreover, the number of vassals, $\mathit{card}(V)$, is exponential with respect to the number of constellations realized in $\mathfrak{T}$. Therefore, the number of elements that are indistinguishable from the point of view of constellation they realize can be double exponential.

One could imagine that in order to check whether a sentence in $\exists^{=1}$-constellation form is satisfiable it is not necessary to have the complete submodel with the universe C defined by the finite representation, but it should be sufficient to know which constellations are realized in the submodel and in which number. It is, however, hard to adapt this idea directly.

Note that some elements that realize the same constellation in a given model can be distinguished by taking into account constellations that are realized by partners of the constellations—elements connected to them with a counting type. For example, elements a and c of the tree shown in Figure 1 realize the same constellation but they can be distinguished, since the predecessor of a realizes a constellation of kind T, whereas the predecessor of c realizes a constellation of kind S. Elements a and e, however, remain indistinguishable even if we take into account the additional information.

The above remarks suggest that in order to push the complexity down, a potential model can be described by a set of *indexed* constellations and numbers of elements that realize these constellations. Roughly speaking, an indexed constellation in addition to the information on 2-types realized by an element, carries requests for partner constellations that should realize, together with the host, the 2-types of the host constellation.

5.2. Concise representation. At the end of section 4.3, using the galaxy theorem, which allows us to transform the problem whether a set of constellations is a galaxy into the problem whether the same set is finitely representable, we gave an algorithm solving the satisfiability problem for C^2_1. As it was shown in the previous subsection, the size of a finite representation can be exponential with respect to the number of constellations.

In this section we shall define the notion of a concise representation of a set of constellations which will play a similar role to finite representation but will use only polynomial space with respect to the number of constellations.

We need several additional notions, the most important of which are the notion of an *indexed constellation* (Definition 5.5) and of a *$\mathcal{X}$-rnk-model* (Definition 5.9). An indexed constellation is a pair $\langle S, f\rangle$, where S is a constellation and f is a function that associates a constellation T to each 2-type of S. This definition allows to control not only which constellation S is realized by an element a but also which constellations are realized in the neighborhood of a, that is, by elements that together with a realize 2-types of S.

Definition 5.9 describes a model very precisely. It says which indexed constellations are realized and in which amount. Additionally, it allows to partition a model into parts, each part containing elements realizing the same indexed constellation, and it specifies 2-types that can be realized by elements from these parts.

The first easy fact proved here (Proposition 5.10) gives several necessary conditions for a set of constellations to be a galaxy. These conditions are described in terms of new notions introduced below. We hope that through studying this easy proposition the reader will get familiar with the complex terminology and notation use here. It should also provide a good background for the most important notion of concise representation.

Lemma 5.1 is an analogue of the galaxy theorem, and one could think that it could form a basis to formulate another algorithm for the satisfiability problem for C^2_1, as in section 4.3. However, although the space needed to write a concise representation is small, and most of the conditions of the definition of concise representation are easily[2] computable, condition (c5), however, seems to require still double exponential time since it requires checking whether there exists a model of double exponential cardinality, which in addition satisfies some conditions. As a first step towards removing this difficulty we prove the decomposition theorem (Lemma 5.2) that shows that such a model is composed of a certain number of parts which can be treated separately and independently. Unfortunately, to check if the parts can be constructed we need several technical lemmas.

[2]Here, "easily" means in exponential time.

Let $\mathcal{R} \subseteq \mathcal{L}$ be a fixed set of predicate letters with $card(\mathcal{R}) = m$. Let $\mathcal{A}$ be a fixed set of 2-types closed under the operation *, and let $\mathcal{S}$ be a set of constellations $\mathcal{S} = \{S_1, \ldots, S_w\}$.

Definition 5.2. *Let $S \in \mathcal{S}$. A set S' of types is a* subconstellation of S *if $S' \subseteq S$ and $center(S) \in S'$.*

Note that a subconstellation S' of S is a constellation (cf. Definition 4.3) only if $S' = S$.

Definition 5.3. *Let $\mathfrak{A}$ be an $\mathcal{L}$-structure, and let $S' = \{s_0, s_1, \ldots, s_l\}$ be a subconstellation of S for some $S \in \mathcal{S}$. An element $a \in A$* realizes S' *if $tp^{\mathfrak{A}}(a, a) = s_0$, and there exists a unique sequence $b_1, \ldots, b_l \in A$ such that $tp^{\mathfrak{A}}(a, b_i) = s_i$, $0 < i \leq l$, and $tp^{\mathfrak{A}}(a, b) \in \mathcal{A}^{\leftarrow} \cup \mathcal{A}^{-}$, for each $b \in A$, $b \neq a$, $b \neq b_i$, $0 < i \leq l$. A subconstellation S' is* realized *in $\mathfrak{A}$ if there exists $a \in A$ which realizes S'.*

Definition 5.4. *Let $\mathcal{S}'$ be a set of subconstellations. A structure $\mathfrak{A}$ realizes $\mathcal{S}'$, if every subconstellation $S' \in \mathcal{S}'$ is realized in $\mathfrak{A}$, and every element $a \in A$ realizes a subconstellation of $\mathcal{S}'$.*

Definition 5.5. *Let $S \in \mathcal{S}$. An* indexed constellation *S^f is a pair $\langle S, f \rangle$, where $S \in \mathcal{S}$, and $f : S \setminus \{center(S)\} \to \mathcal{S}$ is a function such that, for every $s \in S$, S is connectable to $f(s)$ by s.*

We denote by $\mathcal{S}_{ind}$ the set of all indexed constellations of $\mathcal{S}$.

Definition 5.6. *Let $\mathfrak{A}$ be an $\mathcal{L}$-structure, and let $a \in A$ realize a constellation of $\mathcal{S}$. Assume that for every $b \in A$, $b \neq a$, if $tp^{\mathfrak{A}}(a, b) \in C_a^{\mathfrak{A}}$, then b realizes a constellation of $\mathcal{S}$.*

We denote by $ind_a^{\mathfrak{A}}$ the function $ind_a^{\mathfrak{A}} : C_a^{\mathfrak{A}} \setminus center(C_a^{\mathfrak{A}}) \to \mathcal{S}$ such that for every $b \in A$, $b \neq a$, if $tp^{\mathfrak{A}}(a, b) \in C_a^{\mathfrak{A}}$, then $ind(tp^{\mathfrak{A}}(a, b)) = C_b^{\mathfrak{A}}$.

An element a of $\mathfrak{A}$ realizes an indexed constellation *S^f if $C_a^{\mathfrak{A}} = S$, and $ind_a^{\mathfrak{A}} = f$.*

Some explanation of Definitions 5.5 and 5.6 was already given in the previous section. Consider again the example of section 4.5. The elements a, c, and e (see Figure 1) realize the same constellation; however, a and c realize different indexed constellations, whereas a and e realize the same indexed constellation.

Definition 5.7. *Let $\mathcal{T}, \mathcal{U} \subseteq \mathcal{S}$. A set $\mathcal{X}$, $\mathcal{X} \subseteq \mathcal{S}_{ind}$, is an* indexing of $\mathcal{T}$ restricted to $\mathcal{U}$ *if for every $S \in \mathcal{T}$ there is a function f such that $S^f \in \mathcal{X}$, and for every $S^f \in \mathcal{X}$ we have $S \in \mathcal{T}$, and $f : S \setminus \{center(S)\} \to \mathcal{U}$.*

We say that a set $\mathcal{X}$, $\mathcal{X} \subseteq \mathcal{S}_{ind}$ is an indexing of $\mathcal{T}$ *if $\mathcal{X}$ is an indexing of $\mathcal{T}$ restricted to $\mathcal{S}$.*

A pair $\langle \mathcal{X}, rnk \rangle$ is a rnk-indexing *of $\mathcal{T}$ if $\mathcal{X}$ is an indexing of $\mathcal{T}$ and rnk is a function such that $rnk : \mathcal{X} \to \mathbb{N}^+$.*

Note that if $\langle \mathcal{X}, rnk \rangle$ is a rnk-indexing of $\mathcal{T}$, $\mathcal{U} \subseteq \mathcal{T}$, $\mathcal{X}' = \{U^f : U^f \in \mathcal{X}$ and $U \in \mathcal{U}\}$ and $rnk' = rnk \restriction \mathcal{X}'$, then $\langle \mathcal{X}', rnk' \rangle$ is a rnk'-indexing of $\mathcal{U}$.

Let $\mathcal{X} \subseteq \mathcal{S}_{ind}$, $\mathcal{U} \subseteq \mathcal{S}$, and $T^f \in \mathcal{X}$. Denote by $T^f \restriction \mathcal{U}$ the subconstellation $= \{s \in T : f(s) \in \mathcal{U}\} \cup \{center(T)\}$ of T.

Definition 5.8. *Let $\langle \mathcal{X}, rnk \rangle$ be a rnk-indexing of $\mathcal{T}$, and let A be a finite set. A function $lab : A \overset{onto}{\longrightarrow} \mathcal{X}$ is called a* rnk-labeling of A *if for every $T^f \in \mathcal{X}$, $card(\{a \in A : lab(a) = T^f\}) = rnk(T^f)$.*

Let $\langle \mathcal{X}, rnk \rangle$ be a rnk-indexing of $\mathcal{T}$, and let A be a finite set. If lab is a rnk-labeling of A, then, for every $T_i \in \mathcal{T}$, we put $A_i^{lab} = \{a \in A : lab(a) = T_i^f$ for some f such that $T_i^f \in \mathcal{X}\}$.

Definition 5.9. *Let $\mathcal{X} \subseteq \mathcal{S}_{ind}$ and let $\langle \mathcal{X}, rnk \rangle$ be a rnk-indexing of $\mathcal{T}$. An $\mathcal{L}$-structure $\mathfrak{A}$ is a* $\mathcal{X}$-rnk-model for $\mathcal{T}$ *($\mathfrak{A} \models_{\mathcal{X}}^{rnk} \mathcal{T}$) if and only if there exists a rnk-labeling lab of A such that for every A_i^{lab}, A_j^{lab}, and every $a \in A_i^{lab}$, a realizes the* *subconstellation* $lab(a)\restriction\{T_j\}$ *in the substructure of* $\mathfrak{A}$ *restricted to* $\{a\} \cup A_j^{lab}$.

The notions of an indexed constellation and of a $\mathcal{X}$-rnk-model are fundamental in our proof of the single exponential upper bound on the complexity of SAT($\mathcal{C}_1^2$). The intuitions behind the above definitions are explained by the next proposition.

Proposition 5.10. *If* $\mathcal{S}$ *is a galaxy then there exist a structure* $\mathfrak{A}$*, a set* $C \subseteq A$*, subsets* $\mathcal{S}_1, \mathcal{S}_2$ *of* $\mathcal{S}$*,* $\mathcal{X} \subseteq \mathcal{S}_{ind}$*, and a function* $rnk : \mathcal{X} \to \{1, \ldots, card(C)\}$*, such that* $\mathfrak{A}$ *realizes* $\mathcal{S}$*,* $card(C) \leq m(2m \cdot card(\mathcal{S}))^{card(\mathcal{S})}$*, and the following conditions hold:*

(1) $\mathcal{S}_1 \cap \mathcal{S}_2 = \emptyset$*,* $\mathcal{X} = \mathcal{X}_1 \cup \mathcal{X}_2$*, where* $\mathcal{X}_1$ *is an indexing of* $\mathcal{S}_1$ *restricted to* $\mathcal{S}_1 \cup \mathcal{S}_2$ *and* $\mathcal{X}_2$ *is an indexing of* $\mathcal{S}_2$ *restricted to* $\mathcal{S}$*,* $\langle \mathcal{X}, rnk\rangle$ *is an rnk-indexing of* $\mathcal{S}_1 \cup \mathcal{S}_2$*,*

(2) *for every* $a \in C$*,* $C_a^{\mathfrak{A}} \in \mathcal{S}_1 \cup \mathcal{S}_2$*,*

(3) *for every* $a \in A$*, if* $C_a^{\mathfrak{A}} \in \mathcal{S}_1$*, then* $a \in C$ *and, for every* $a \in A$ *and every* $S \in \mathcal{S}_1$*, if* $C_a^{\mathfrak{A}} = S$*, then* $C_a^{\mathfrak{C}} = S$*,*

(4) $\mathfrak{C} \models_{\mathcal{X}}^{rnk} \mathcal{S}_1 \cup \mathcal{S}_2$*,*

(5) *for every* $S \in \mathcal{S} \setminus \mathcal{S}_1$*,* $\mathrm{rank}_{\mathfrak{A}}(S) = \infty$.

Proof. Let $\mathcal{S}$ be a galaxy, and let $\langle \mathcal{S}_1, V, C, I, F, G\rangle$ be a finite representation of $\mathcal{S}$ which exists by Theorem 4.15. Let $\mathfrak{A}$ be a structure realizing $\mathcal{S}$ whose existence follows from Corollary 4.16. The domain of the structure $\mathfrak{A}$ is divided into two parts: B and C with $B = A \setminus C$, and $V \subset C$.

Let $\mathcal{S}_1 = \{S \in \mathcal{S} : S = C_a^{\mathfrak{A}}$, for some $a \in V\}$,

$\mathcal{S}_2 = \{S \in \mathcal{S} : S = C_a^{\mathfrak{A}}$, for some $a \in C \setminus V\}$,

$\mathcal{X}_1 = \{C_a^{\mathfrak{A},f} : a \in V, f = ind_a^{\mathfrak{A}}\}$,

$\mathcal{X}_2 = \{C_a^{\mathfrak{A},f} : a \in C \setminus V, f = ind_a^{\mathfrak{A}}\}$, $\mathcal{X} = \mathcal{X}_1 \cup \mathcal{X}_2$,

and for every $S^f \in \mathcal{X}$, let $rnk(S^f) = card(\{a \in C : S = C_a^{\mathfrak{A}}$ and $f = ind_a^{\mathfrak{A}}\}$.

Assume that $\mathcal{S}_1 = \{S_1, \ldots, S_x\}$, $\mathcal{S}_2 = \{S_{x+1}, \ldots, S_y\}$, and $\mathcal{X} = \{\langle S_1, f_{11}\rangle, \ldots, \langle S_1, f_{1,v_1}\rangle, \langle S_2, f_{21}\rangle, \ldots, \langle S_2, f_{2,v_2}\rangle, \ldots, \langle S_y, f_{y1}\rangle, \ldots, \langle S_y, f_{y,v_y}\rangle\}$, where $v_i = card(\{f_{ij} : S_i^{f_{ij}} \in \mathcal{X}\})$, $1 \leq i \leq y$.

We have partitioned the set C into sets $C_1, \ldots, C_y$ in such a way that for every $a \in C$, if $a \in C_i$, then $C_a^{\mathfrak{A}} = S_i$ (see Figure 2). Furthermore, every set C_i is partitioned into classes of elements realizing the same indexed constellations $\langle S_i, f_{ij}\rangle$. Moreover, for every $a \in C_i$, if $C_i \subseteq V$, then $C_a^{\mathfrak{C}} = S_i$. This means that for every $a \in V$, for every $b \in B$, $tp^{\mathfrak{A}}(a, b) \in \mathcal{A}^{\leftarrow} \cup \mathcal{A}^{-}$ ($\notin \mathcal{A}^{\rightarrow} \cup \mathcal{A}^{\leftrightarrow}$) which is denoted in Figure 2 by the slashed arrows.

Define a rnk-labeling lab of C letting $lab(c) = S^f$, where $S = C_c^{\mathfrak{A}}$ and $f = ind_c^{\mathfrak{A}}$.

It is easy to check that conditions (1)–(5) hold. ◻

The main idea of the proof of Theorem 5.1 is to replace in Proposition 5.10 the condition *there exists a structure* $\mathfrak{A}$ with something easier to verify and to substitute the implication by an equivalence. To do this we add several additional conditions, which are easily computable.

Definition 5.11. *A* concise representation of $\mathcal{S}$ *is a system*

$$\langle \mathcal{S}_1, \mathcal{S}_2, \mathcal{X}, rnk, \mathcal{Y}\rangle,$$

where $\mathcal{S}_1, \mathcal{S}_2$ *are sets of constellations,* $\langle \mathcal{X}, rnk\rangle$ *is a rnk-indexing of* $\mathcal{S}_1 \cup \mathcal{S}_2$*,* $\mathcal{Y}$ *is an indexing of* $\mathcal{S} \setminus \mathcal{S}_1$*, and the following conditions hold:*

(c1) $\mathcal{S}_1, \mathcal{S}_2 \subseteq \mathcal{S}$*,* $\mathcal{S}_1 \cap \mathcal{S}_2 = \emptyset$*,*

(c2) $\mathcal{X} = \mathcal{X}_1 \cup \mathcal{X}_2$*, where* $\mathcal{X}_1$ *is an indexing of* $\mathcal{S}_1$ *restricted to* $\mathcal{S}_1 \cup \mathcal{S}_2$ *and* $\mathcal{X}_2$ *is an indexing of* $\mathcal{S}_2$ *restricted to* $\mathcal{S}$*,*

(c3) *for every* $\langle S, f_1\rangle, \langle S, f_2\rangle \in \mathcal{Y}$*,* $f_1 = f_2$*,*

(c4) $\sum_{S^f \in \mathcal{X}} rnk(S^f) \leq m(2m \cdot card(\mathcal{S}))^{card(\mathcal{S})}$*,*

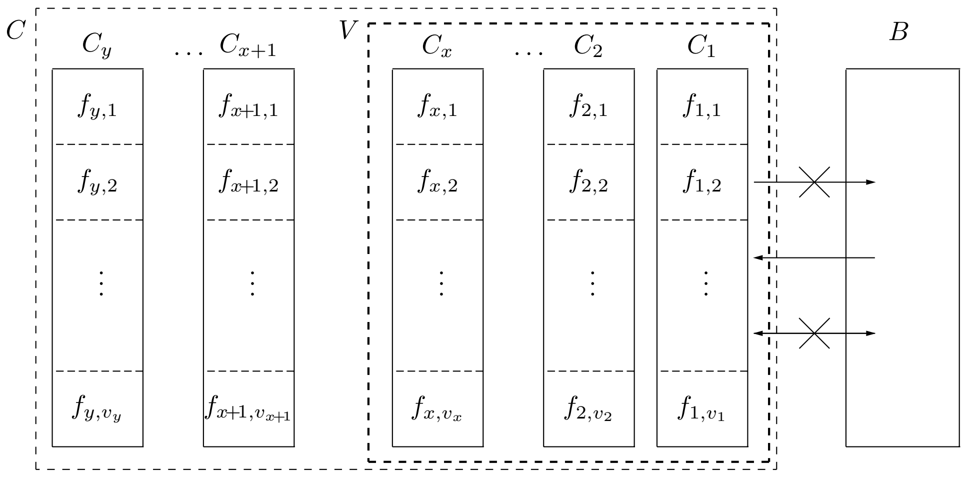

FIG. 2. *Partition of the universe according to the rnk-labeling.*

(c5) *there is a structure $\mathfrak{C}$ such that $\mathfrak{C} \models^{rnk}_{\mathcal{X}} \mathcal{S}_1 \cup \mathcal{S}_2$,*

(c6) *for every $S^f \in \mathcal{Y}$ and every $s \in S$, if $f(s) \in \mathcal{S}_1$, then $s \in \mathcal{A}^{\rightarrow}$,*

(c7) *for every $S^f \in \mathcal{Y}$ and every $T \in \mathcal{S}_1$, $card(\{s \in S\colon f(s) = T\}) \leq \sum_{T^f \in \mathcal{X}_1} rnk(T^f)$ and if $card(\{s \in S\colon f(s) = T\}) < \sum_{T^f \in \mathcal{X}_1} rnk(T^f)$, then there exist $t \in \mathcal{A}^-$ such that S is connectable to T by t,*

(c8) *for every $S, T \in \mathcal{S} \setminus \mathcal{S}_1$, S is connectable to T by some $t \in \mathcal{A}^-$.*

Some comments are in order here. Conditions (c1)–(c8) of the above definition precisely describe the situation illustrated in Figure 2.

(c1) Three subsets of $\mathcal{S}$ are distinguished: $\mathcal{S}_1$, constellations realized by elements of V; $\mathcal{S}_2$, constellations realized by elements of $C \setminus V$; and $\mathcal{S} \setminus \mathcal{S}_1$, constellations realized by elements of B.

(c2) $\mathcal{X}_1$ is an indexing of $\mathcal{S}_1$ and it defines partitions of set $C_i \subseteq V$ into appropriate classes. The indexing guarantee that the elements of V realize constellations of $\mathcal{S}_1$ in the substructure restricted to C. Similarly, $\mathcal{X}_2$ defines partitions of $C_i \subseteq C \setminus V$.

(c3) The indexing $\mathcal{Y}$ defines 2-types which are realized by pairs of elements $\langle a, b \rangle$, where $a \in B$, and $b \in V$. Note that if B is nonempty, then the constellations realized in B or in $C \setminus V$ are expected to appear infinitely many times.

(c4) The function *rnk* defines the cardinality of every class of C_i and thus the cardinality of V and C.

(c5) This condition takes care of definability of $\mathfrak{C}$. In particular, it specifies which elements in C_i are connected with elements in C_j by counting types and which counting types are used to realize the connections.

(c6) An element $a \in B$ can be connected to an element $b \in V$ only by a type from $\mathcal{A}^{\rightarrow} \cup \mathcal{A}^-$. These types do not change the constellation realized by elements in V.

(c7) If an element $a \in B$ realizes S such that $S^f \in \mathcal{Y}$, then the number of elements in V is sufficient to realize types of S. Moreover, it is possible to define noncounting types between a and elements of V, if necessary.

(c8) Every two constellations which are realized infinitely many times are connectable by a noncounting type in $\mathcal{A}^-$.

Lemma 5.1. *A set of constellations $\mathcal{S}$ is a galaxy if and only if there exists a concise representation of $\mathcal{S}$.*

Proof. ($\Rightarrow$) Let $\mathcal{S}$ be a galaxy. Take a structure $\mathfrak{A}$, a set $C \subseteq A$, $\mathcal{S}_1, \mathcal{S}_2 \subseteq \mathcal{S}$, $\mathcal{X}$, and a function *rnk* given by Proposition 5.10. For every constellation $S \in \mathcal{S} \setminus \mathcal{S}_1$ find an element $b \in A \setminus C$ such that b realizes S (if it exists) and add the indexed constellation realized by b to $\mathcal{Y}$. Note that if $\mathcal{S} = \mathcal{S}_1$, then $\mathcal{Y} = \emptyset$.

It is obvious that $\langle \mathcal{S}_1, \mathcal{S}_2, \mathcal{X}, rnk, \mathcal{Y}\rangle$ satisfies conditions (c1)–(c8).

($\Leftarrow$) Let $\langle \mathcal{S}_1, \mathcal{S}_2, \mathcal{X}, rnk, \mathcal{Y}\rangle$ be a concise representation of $\mathcal{S}$. By Theorem 4.15 it suffices to show that there exists a finite representation of $\mathcal{S}$. Let $\mathfrak{C}$ be the structure given by (c5), and let *lab* be the *rnk*-labeling of C. Let $V = \{a \in C : lab(a) \in \mathcal{S}_1\}$. We will define functions I, F, G so that the system $\langle \mathcal{S}_1, V, C, I, F, G\rangle$ is a finite representation of $\mathcal{S}$. To define I, for every $a \in C$, put $I(a) = S$, where $lab(a) = \langle S, f\rangle$. In order to define F, for every $a, b \in C$, put $F(a, b) = tp^{\mathfrak{C}}(a, b)$. Now, let $S \in (\mathcal{S} \setminus \mathcal{S}_1)$, $S = \{s_0, s_1, \ldots, s_k\}$. By (c3), there exists $\langle S, f\rangle \in \mathcal{Y}$. By condition (c8), find k distinct elements $a_1, \ldots, a_k \in V$ such that for every i, $1 \leq i \leq k$, $f(s_i) = lab(a_i)$. For every a_i, $1 \leq i \leq k$, define $G(S, a_i) = s_i$. If there is an element $b \in V$ such that $G(S, b)$ has not been defined yet, then, by (c8), find a type $s \in \mathcal{A}^-$ such that S is connectable to $lab(b)$ by s, and put $G(S, b) = s$. It is easy to check that conditions (f1)–(f7) of Definition 4.14 hold. $\square$

5.3. Complexity.

Proof of Theorem 5.1. The proof proceeds in the same way as the proof of Corollary 4.17.

Let Φ be a $\mathcal{C}^2_1$-sentence of length n. By Corollary 4.8 we obtain a sentence Ψ in $\exists^{=1}$-constellation form which is satisfiable if and only if Φ is satisfiable. After defining the set $\mathcal{A}$, we guess a set $\mathcal{S}$ of $\mathcal{A}$-$\mathcal{R}$-constellations, as in Theorem 4.6.

Then, we guess sets $\mathcal{S}_1$ and $\mathcal{S}_2$ of constellations, an *rnk*-indexing $\langle \mathcal{X}, rnk\rangle$ of $\mathcal{S}_1 \cup \mathcal{S}_2$, and an indexing $\mathcal{Y}$ of $\mathcal{S} \setminus \mathcal{S}_1$, as in Definition 5.11.

In contrast to the proof of Corollary 4.17, this step can be performed in time $O(2^{n^3})$ since $card(\mathcal{S}_{ind}) \leq 2^{n^3}$, and the length of a maximal value of the function *rnk* is bounded by $\log(m(2m \cdot card(\mathcal{S}))^{card(\mathcal{S})}) = O(2^{dn^2})$ for some constant d.

Finally, we check in time $O(2^{dn^3})$ whether $\langle \mathcal{S}_1, \mathcal{S}_2, \mathcal{X}, rnk, \mathcal{Y}\rangle$ is a concise representation of $\mathcal{S}$. $\square$

Remark. It can be easily seen that all the conditions of Definition 5.11 except (c5) can be verified in time $O(2^{dn^3})$ for some constant d. It is less obvious that the same holds for (c5). We devote the next subsection to the problem how to verify (c5) in exponential time.

As a consequence of Theorem 5.1, by Corollary 4.9, we get the following corollary.

Corollary 5.12. SAT($\mathcal{C}^2$) $\in$ 2-NEXPTIME.

There are at least two reasons why it is difficult to improve the above result. One has been already discussed at the end of section 4.2. Another one is that it is difficult to generalize the notion of a constellation to count an arbitrary number of witnesses without increasing the number of possible constellations to double exponential. In spite of this we conjecture that the satisfiability problem for the full C^2 has only exponential complexity.

5.4. Verification of (c5). The following definition will be used in the decomposition theorem (Lemma 5.2).

DEFINITION 5.13. *Let $\mathcal{T} \subseteq \mathcal{S}$, and let $\langle \mathcal{X}, rnk\rangle$ be an rnk-indexing of $\mathcal{T}$. For $S_i, S_j \in T$ we define $\mathcal{X}_{ij} = \{S^f \in \mathcal{X} : S = S_i \text{ or } S = S_j\}$, and $rnk_{ij} = rnk{\restriction}\mathcal{X}_{ij}$.*

The following lemma gives a condition which is equivalent to condition (c5) of Definition 5.11 but is more tractable.

LEMMA 5.2 (decomposition theorem). *Let $\mathcal{T} \subseteq \mathcal{S}$, and let $\langle \mathcal{X}, rnk\rangle$ be an rnk-indexing of $\mathcal{T}$. Then the following conditions are equivalent:*

(1) *There is a structure $\mathfrak{C}$ such that $\mathfrak{C} \models^{rnk}_{\mathcal{X}} \mathcal{T}$.*

(2) *For every $S_i, S_j \in \mathcal{T}$ there exists a structure $\mathfrak{C}_{ij}$ such that $\mathfrak{C}_{ij} \models^{rnk_{ij}}_{\mathcal{X}_{ij}} \{S_i, S_j\}$.*

Remark. Condition 1 coincides with condition (c5).

Proof. (1) $\Rightarrow$ (2) is obvious.

(2) $\Rightarrow$ (1). Assume that Condition (2) holds. Let $\mathcal{X} = \{\langle S_1, f_{1,1}\rangle, \dots, \langle S_1, f_{1,v_1}\rangle, \langle S_2, f_{2,1}\rangle, \dots, \langle S_2, f_{2,v_2}\rangle, \dots, \langle S_y, f_{y,1}\rangle, \dots, \langle S_y, f_{y,v_y}\rangle\}$. For every i, j, $1 \le i \le j \le y$, let $\mathfrak{C}_{ij}$ be a structure such that $\mathfrak{C}_{ij} \models^{rnk_{ij}}_{\mathcal{X}_{ij}} \{S_i, S_j\}$, and let lab_{ij} be the rnk_{ij}-labeling of (the universe of) $\mathfrak{C}_{ij}$.[3] Note that

$$card\Big(\Big\{a \in C_{ij} : lab_{ij}(a) = S_i^f \text{ and } S_i^f \in \mathcal{X}_{ij}\Big\}\Big) = \sum_{S_i^f \in \mathcal{X}_{ij}} rnk_{ij}(S_i^f) = card(C_{ii}).$$

We are going to define a structure $\mathfrak{C}$. Let C, the universe of $\mathfrak{C}$, be a set such that there exists a rnk-labeling of C, and let lab be such a labeling. It is easy to notice that C could also be defined as a union of disjoint copies of C_{ii}. In fact, define $C_i = \{a \in C : lab(c) = S_i^f$, for some function $f\}$ for every i, $1 \le i \le y$. Then $C = \bigcup_{i \le y} C_i$, and $card(C_i) = card(C_{ii})$.

Now we shall define types realized by pairs of elements in $\mathfrak{C}$. For every i, j such that $1 \le i \le j \le y$, choose a function g_{ij} such that $g_{ij} : C_{ij} \xrightarrow[onto]{1-1} C_i \cup C_j$, and for every $a \in C_{ij}$, $lab_{ij}(a) = lab(g_{ij}(a))$. For every a, b such that $a \in C_i$, $b \in C_j$, and $i \le j$, put $tp^{\mathfrak{C}}(a, b) = tp^{\mathfrak{C}_{ij}}(g_{ij}^{-1}(a), g_{ij}^{-1}(b))$.

To show that the structure $\mathfrak{C}$ satisfies condition 1, let $S_i, S_j \in \mathcal{T}$, and $a \in C_i$ (cf. Definition 5.9). Set $B = \{tp^{\mathfrak{C}}(a, b) : b \in C_j\} \cap (\mathcal{A}^{\rightarrow} \cup \mathcal{A}^{\leftrightarrow})$. By construction, $B = \{tp^{\mathfrak{C}_{ij}}(g_{ij}^{-1}(a), g_{ij}^{-1}(b)) : b \in C_j\} \cap (\mathcal{A}^{\rightarrow} \cup \mathcal{A}^{\leftrightarrow})$ and $B \cup \{tp^{\mathfrak{C}_{ij}}(a, a)\} = lab_{ij}(g_{ij}^{-1}(a)){\restriction}\{S_j\} = lab(a){\restriction}\{S_j\}$. $\square$

Now we present three technical lemmas, each of them showing how to check condition 2 of Lemma 5.2. Lemma 5.3 deals with the case $i = j$, Lemma 5.4 with the case when $i \ne j$ and both S_i and S_j are realized by many elements, and Lemma 5.5 with the case when $i \ne j$, but only one of S_i and S_j is realized by many elements.

We are very sorry that in spite of the suggestions of the referees, many requests of our friends, and our best intentions we have not been able to make the proofs more readable.

We have tried to write a reader-friendly paper, but we have been only partially successful in this attempt. We did not find a way to avoid yet another technical definition below.

We will use the following notation.

[3]The notation $\mathcal{X}_{ii}, C_{ii}$, and $\mathfrak{C}_{ii}$ can be misleading—the notation $\mathcal{X}_i, C_i$, and $\mathfrak{C}_i$ would be more intuitive, but we keep the less intuitive notation since it is more uniform.

Definition 5.14. *Assume that $\mathcal{T} \subseteq \mathcal{S}$, and $\langle \mathcal{X}, rnk\rangle$ is a rnk-indexing of $\mathcal{T}$. Let q be a positive integer. For $S_i, S_j \in \mathcal{T}$ and every $s \in S_i$, define*

$$\begin{aligned}
c_i &= \sum_{S_i^f \in \mathcal{X}} rnk\big(S_i^f\big),\\
u_{ij}(s) &= \sum_{S_i^f \in \mathcal{X}, f(s)=S_j} rnk\big(S_i^f\big) \qquad \text{for } s \in S_i,\\
S_{ij}^q &= \{s \in S_i \cap \mathcal{A}^{\leftrightarrow} : u_{ij}(s) \le q\},\\
\mathcal{X}_{ij}^q &= \big\{S_i^f \in \mathcal{X}_{ij} : \text{ for some } s \in S_{ij}^q, f(s) = S_j\big\}\\
&\quad \cup \big\{S_j^f \in \mathcal{X}_{ij} : \text{ for some } s \in S_{ij}^q, f(s^*) = S_i\big\},\\
rnk_{ij}^q &= rnk_{ij}{\restriction}\mathcal{X}_{ij}^q.
\end{aligned}$$

Observe that the notions defined by Definition 5.14 have the following meaning in the context of $\mathfrak{C}_{ij}$.

c_i	is the cardinality of $\mathfrak{C}_{ii}$;
$u_{ij}(s)$	is the number of all elements a which realize $S_i^f{\restriction}\{S_j\}$, and for which there is a b, $b \neq a$, such that $\langle a, b\rangle$ realizes s, and b realizes $S_j^f{\restriction}\{S_i\}$;
S_{ij}^q	is the set of 2-types of S_i which are realized in $\mathfrak{C}_{ij}$ by at most q pairs $\langle a, b\rangle$ such that a realizes $S_i^f{\restriction}\{S_j\}$, and b realizes $S_j^f{\restriction}\{S_i\}$;
$\mathcal{X}_{ij}^q$	is the restriction of $\mathcal{X}_{ij}$ to the constellations including types of S_{ij}^q;
rnk_{ij}^q	is the restriction of rnk_{ij} to $\mathcal{X}_{ij}^q$.

Note that $u_{ij}(s)$, c_i, S_{ij}^q, $\mathcal{X}_{ij}^q$, and rnk_{ij}^q are easily computable from $\mathcal{X}$ and rnk in time $O(2^{n^3} \cdot 2^{dn^2}) = O(2^{en^3})$ for some constant e.

Definition 5.15. *Let $\mathcal{X} \subseteq \mathcal{S}_{ind}$, let $\langle \mathcal{X}, rnk\rangle$ be an rnk-indexing of $\mathcal{T}$, and let $\mathcal{B} \subseteq \mathcal{A}$. Given a $\mathcal{L}$-structure $\mathfrak{A}$ we write $\mathfrak{A} \models_{\mathcal{B},\mathcal{X}}^{rnk} \mathcal{T}$ if and only if there exists an rnk-labeling lab of the universe A of $\mathfrak{A}$ such that for every $S_i, S_j \in \mathcal{T}$ and every $a \in A_i^{lab}$,*

$$tp^{\mathfrak{A}}(a, a) = center(lab(a){\restriction}\{S_i\}),$$

$$\{tp^{\mathfrak{A}}(a, b) : b \in A_j^{lab}\} \cap (\mathcal{A}^{\rightarrow} \cup \mathcal{A}^{\leftrightarrow}) = lab(a){\restriction}\{S_j\} \cap \mathcal{B},$$

and for every 2-type $t \in lab(a){\restriction}\{S_j\} \cap \mathcal{B}$ there exists a unique $b \in A_j^{lab}$ such that $tp^{\mathfrak{A}}(a, b) = t(x, y)$.

The above definition says that $\mathfrak{A} \models_{\mathcal{B},\mathcal{X}}^{rnk} \mathcal{T}$ if and only if there exists a rnk-labeling lab of A such that for every A_i^{lab}, A_j^{lab}, and every $a \in A_i^{lab}$, a realizes the subconstellation $lab(a){\restriction}\{S_j\} \cap \mathcal{B}$ in the substructure of $\mathfrak{A}$ with the universe $\{a\} \cup A_j^{lab}$. Note that in case $\mathcal{B} = \mathcal{A}$ the above definition is equivalent to Definition 5.9.

Lemma 5.3. *Let $S_i \in \mathcal{T}$, and assume that $c_i > 2^m$. There is a structure $\mathfrak{C}_{ii}$ such that $\mathfrak{C}_{ii} \models_{\mathcal{X}_{ii}}^{rnk_{ii}} \{S_i, S_i\}$ if and only if the following conditions hold:*

(i) *for every $s \in S_i \cap \mathcal{A}^{\leftrightarrow}$, $u_{ii}(s) = u_{ii}(s^*)$ and $u_{ii}(s)$ is even if $s = s^*$;*

(ii) *S_i is connectable to S_i by some $t \in \mathcal{A}^{-}$;*

(iii) *there exists a structure $\mathfrak{C}'$ such that $\mathfrak{C}' \models_{S_{ii}^q, \mathcal{X}_{ii}'}^{rnk_{ii}'} \{S_i\}$, where $q = 14m$.*

Proof. ($\Rightarrow$) This follows directly from the definition of $u_{ii}(s)$, Lemma 4.1, and Definitions 5.9, 5.15, and 5.14.

($\Leftarrow$) Assume that (i)–(iii) hold. Assume that $\{s_1,\ldots,s_v\} = \{s \in S_i \cap \mathcal{A}^{\leftrightarrow} : u_{ii}(s) > 0\} \cup \{s \in S_i \cap \mathcal{A}^{\rightarrow} : u_{ii}(s) > 0\}$, where $v < card(S_i)$ and $\{s_1,\ldots,s_p\} = S_{ii}^{14m}$. Let lab' be the rnk'_{ii}-labeling of C' given by (iii) and Definition 5.15.

Let C_{ii} be a set of cardinality $\sum_{S_i^f \in \mathcal{X}_{ii}} rnk(S_i^f)$, and let lab be a rnk_{ii}-labeling of C_{ii}. We shall build a structure $\mathfrak{C}_{ii}$ with the universe C_{ii} such that, for every $a \in C_{ii}$, a realizes $lab(a)\restriction\{S_i\}$ in C_{ii}. The structure $\mathfrak{C}_{ii}$ will be built in several steps.

First we define an embedding h of $\mathfrak{C}'$ into $\mathfrak{C}_{ii}$ as follows.

Let $h : C' \xrightarrow[into]{1-1} C_{ii}$, be such that for every $a \in C'$, $lab'(a) = lab(h(a))$. For every $a, b \in h(C')$, such that $tp^{\mathfrak{C}'}(h^{-1}(a), h^{-1}(b)) \in \mathcal{A}^{\leftrightarrow} \cup \mathcal{A}^{\rightarrow}$, define $tp^{\mathfrak{C}_{ii}}(a,b) = tp^{\mathfrak{C}'}(h^{-1}(a), h^{-1}(b))$.

Now it remains to define, for each type $s_l \in \{s_{p+1},\ldots,s_v\}$, the set of pairs of elements of C_{ii} which realize s_l. To do this we shall use the graph-theoretical Lemmas A.2 and A.3 given in the appendix. We proceed by induction. Assume that, for some $l \geq p$, the sets of pairs satisfying types $s_1,\ldots,s_{l-1}$ have been defined. We shall now define set of pairs satisfying s_l.

Case 1. $s_l \in \mathcal{A}^{\leftrightarrow}$. Let $X, Y \subseteq C_{ii}$ be defined as follows:

$X = \{a \in C_{ii} : s_l \in lab(a)\restriction\{S_i\}\}$,

$Y = \{a \in C_{ii} : s_l^* \in lab(a)\restriction\{S_i\}\}$.

Observe that s_l can be realized only by pairs $\langle a, b\rangle$ such that $a \in X$, and $b \in Y$. Also, if $s_l = s_j^*$, for some $j < l$, then the type s_l has been considered. By condition (i), $card(X) = card(Y)$, and if $s_l = s_l^*$, then $card(X)$ is even. Moreover, since $card(X) = u_{ii}(s_l)$, we have $card(X) > 14m$.

Let $G^* = (X \cup Y, E^*)$ be the graph such that $E^* = \{\{a,b\} :$ either $\langle a,b\rangle$ or $\langle b,a\rangle$ realizes a type s_j, $j < l\}$. Then, $d(G^*) < l \leq m$. Let $G = (X \cup Y, E)$ be the graph complement of G^*, and let $n = card(X \cup Y)$. We have $d(G) > n - l + 1 \geq n - m$. Note that if $E(a,b)$, then the type of $\langle a,b\rangle$ has not been specified so far.

Case 1a. $s_l = s_l^*$. By the definition of X and Y, we have $X = Y$. By Lemma A.2, there exists a Hamiltonian cycle $\mu = [a_1,\ldots,a_n]$ in G, and by (i) n is even. For each odd j such that $1 \leq j \leq n$, put $tp^{\mathfrak{C}_{ii}}(a_j, a_{j+1}) = s_l$.

Case 1b. $s_l \in \mathcal{A}^{\leftrightarrow}$, and $s_l \neq s_l^*$. Let $X' = X \setminus Y$, $Y' = Y \setminus X$, $Z = X \cap Y$, $n' = card(X') = card(Y')$, and $n_Z = card(Z)$. We consider two subcases.

Subcase 1ba. $card(Z) \leq 2m$. (See Figure 3.)

Let $G_X = (Z, X', E_X)$, where $E_X = \{\{a,b\} \in E : a \in Z, b \in X'\}$. Then G_X is a bipartite graph such that for every $A \subseteq Z$, $card(\Gamma_{G_X}(A)) > n' - l + 1 > 3m > card(A)$. Therefore, by Lemma A.1, there is a matching E'_X of Z onto $X_Z \subset X'$. For every $a \in X_Z$, $b \in Z$ such that $\{a,b\} \in E'_X$, put $tp^{\mathfrak{C}_{ii}}(a,b) = s_l$.

Similarly, there exists a matching E'_Y from Z onto $Y_Z \subset Y'$ in the graph G_Y defined in the same way as G_X. For every $a \in Z$, $b \in Y_Z$ such that $\{a,b\} \in E'_Y$, put $tp^{\mathfrak{C}_{ii}}(a,b) = s_l$.

Finally, let $G' = (X' \setminus X_Z, Y' \setminus Y_Z, E')$ be the bipartite graph such that $E' = \{\{a,b\} \in E : a \in X' \setminus X_Z, b \in Y' \setminus Y_Z\}$. Put $n'' = card(X' \setminus X_Z) = card(Y' \setminus Y_Z)$. Then, $n'' > 2m$ and $d(G') > n'' - l + 1 > n'' - m$. By Lemma A.3, there exists a matching E_1 from $X' \setminus X_Z$ onto $Y' \setminus Y_Z$. For every $a \in X' \setminus X_Z$, $b \in Y' \setminus Y_Z$ such that $\{a,b\} \in E_1$, put $tp^{\mathfrak{C}_{ii}}(a,b) = s_l$.

Subcase 1bb. $card(X') \leq 2m$.

We have $X \cup Y = X' \dot\cup Z \dot\cup Y'$ and $d(G) \geq n - l + 1 > n - m$. By Lemma A.4, there exists a set $Z' \subset Z$ such that X' and Y' can be matched onto Z'. Let $E_{X'}$ be the matching of X' onto Z', and let $E_{Y'}$ be the matching of Y'

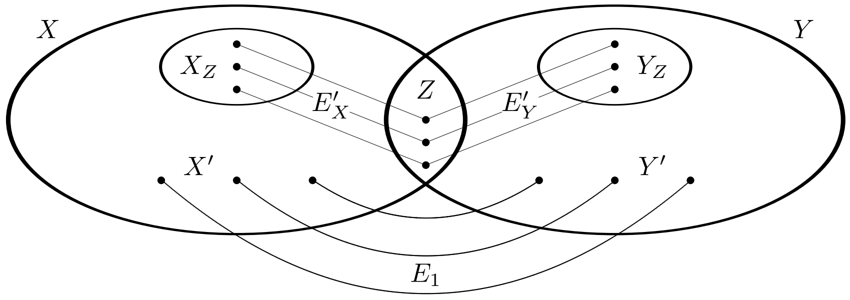

FIG. 3. *Subcase* 1BA.

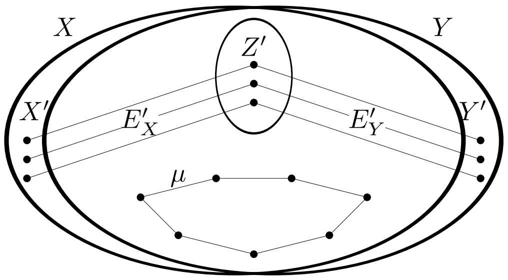

FIG. 4. *Subcase* 1BB.

onto Z'.

For every $a \in X'$, $b \in Z'$ such that $\{a, b\} \in E_{X'}$, put $tp^{\mathfrak{C}_{ii}}(a, b) = s_l$. For every $b \in Z'$, $c \in Y'$ such that $\{b, c\} \in E_{Y'}$, put $tp^{\mathfrak{C}_{ii}}(b, c) = s_l$.

Finally, let $G' = (Z \setminus Z', E')$, where $E' = \{\{a, b\} \subset Z \setminus Z' : \{a, b\} \in E\}$. Put $n'' = card(Z \setminus Z')$. Then, $n'' > 2m$, and $d(G') \geq n'' - l + 1 > n - m$. By Lemma A.2, there exists a Hamiltonian cycle $\mu = [a_1, \ldots, a_{n''}]$ in G'. For every j such that $1 \leq j < n''$, put $tp^{\mathfrak{C}_{ii}}(a_j, a_{j+1}) = s_l$, and put $tp^{\mathfrak{C}_{ii}}(a_{n''}, a_1) = s_l$.

CASE 2. $s_l \in \mathcal{A}^{\rightarrow}$. Let $X = \{a \in C_{ii} : s_l \in S_i^f \restriction \{S_i\}$, where f is a function such that $lab(a) = S_i^f\}$.

Let $G^* = (C_{ii}, E^*)$, where $E^* = \{\{a, b\} :$ either $\langle a, b\rangle$ or $\langle b, a\rangle$ realizes s_j, for some $j < l\}$. Then, $d(G^*) < l \leq m$. Let $G = (C_{ii}, E)$ be the graph complement of G^*, and let $n = card(C_{ii})$. We have $d(G) > n - l + 1 > n - m$, so by Lemma A.2, there exists a Hamiltonian cycle $\mu = [a_1, \ldots, a_n]$ in G. For every j such that $1 \leq j < n$ and $a_j \in X$, put $tp^{\mathfrak{C}_{ii}}(a_j, a_{j+1}) = s_l$, and put $tp^{\mathfrak{C}_{ii}}(a_n, a_1) = s_l$.

Notice that by condition (ii), there exists a type $t \in \mathcal{A}^-$ such that S_i is connectable to S_i by t. Therefore to finish the proof, it suffices to define $tp^{\mathfrak{C}_{ii}}(a, b) = t$, for any $a, b \in C_{ii}$, such that $tp^{\mathfrak{C}_{ii}}(a, b)$ has not been defined yet. □

LEMMA 5.4. *Let $S_i, S_j \in \mathcal{T}$, $i \neq j$, and assume that $c_i, c_j > 3m$. There is a structure $\mathfrak{C}_{ij}$ such that $\mathfrak{C}_{ij} \models^{rnk_{ij}}_{\mathcal{X}_{ij}} \{S_i, S_j\}$ if and only if the following conditions hold:*

(i) *there are structures $\mathfrak{C}_{ii}$, $\mathfrak{C}_{jj}$ such that $\mathfrak{C}_{ii} \models^{rnk_{ii}}_{\mathcal{X}_{ii}} \{S_i\}$, and $\mathfrak{C}_{jj} \models^{rnk_{jj}}_{\mathcal{X}_{jj}} \{S_j\}$;*

(ii) *$u_{ij}(s) = u_{ji}(s^*)$, for each $s \in S_i \cap \mathcal{A}^{\leftrightarrow}$, and $u_{ji}(s) = u_{ij}(s^*)$, for each $s \in S_j \cap \mathcal{A}^{\leftrightarrow}$;*

(iii) *there exists a structure $\mathfrak{C}'$ such that $\mathfrak{C}' \models^{rnk^q_{ij}}_{S^q_{ij}, \mathcal{X}^q_{ij}} \{S_i, S_j\}$, where $q = 2m$;*

(iv) *S_i is connectable to S_j by some $t \in \mathcal{A}^-$.*

Proof. ($\Rightarrow$) This part of the proof is obvious.

($\Leftarrow$) Assume that (i)–(iv) hold. Let $\{s_1, \ldots, s_v\} = \{s \in S_i \cap \mathcal{A}^{\leftrightarrow} : u_{ij} > 0\} \cup \{s \in (S_i \cup S_j) \cap \mathcal{A}^{\rightarrow} : u_{ij}(s) > 0\}$, where $v < card(S_i \cup S_j)$. Assume that $S^{2m}_{ij} = \{s_1, \ldots, s_p\}$, and $\{s_{r+1}, \ldots, s_v\} = \{s \in (S_i \cup S_j) \cap \mathcal{A}^{\rightarrow} : u_{ij}(s) > 2m\}$.

Let $\mathfrak{C}_{ii}$ and $\mathfrak{C}_{jj}$ be such that (i) holds, and assume that $\mathfrak{C}_{ii}$ and $\mathfrak{C}_{jj}$ are disjoint. Let $C_{ij} = C_{ii} \cup C_{jj}$. For every $a, b \in C_{ii}$, put $tp^{\mathfrak{C}_{ij}}(a, b) = tp^{\mathfrak{C}_{ii}}(a, b)$, and for every $a, b \in C_{jj}$, put $tp^{\mathfrak{C}_{ij}}(a, b) = tp^{\mathfrak{C}_{jj}}(a, b)$. Let lab_{ii} be the rnk_{ii}-labeling of C_{ii}, and lab_{jj} be the rnk_{jj}-labeling of C_{jj} as in Definition 5.9. To define the rnk_{ij}-labeling lab_{ij} of C_{ij}, we put $lab_{ij} = lab_{ii} \cup lab_{jj}$.

Now, for $a \in C_{ii}$ and $b \in C_{jj}$, we shall assign a type to $\langle a, b \rangle$, in such a way that for every $a \in C_{ii}$, a realizes in $\mathfrak{C}_{ij} \restriction C_{jj} \cup \{a\}$ the subconstellation $lab_{ij}(a) \restriction \{S_j\}$, and for every $b \in C_{jj}$, b realizes in $\mathfrak{C}_{ij} \restriction C_{ii} \cup \{b\}$ the subconstellation $lab(b)_{ij} \restriction \{S_i\}$.

As in the proof of Lemma 5.3, the construction proceeds in steps. First, we embed the structure $\mathfrak{C}'$ given by (iii) into $\mathfrak{C}_{ij}$, and then we consider types $s_l \in \{s_{p+1}, \ldots, s_v\}$.

Define

$X = \{a \in C_{ii} : s_l \in lab(a) \restriction \{S_j\}\}$,

$Y = \{a \in C_{jj} : s^*_l \in lab(a) \restriction \{S_i\}\}$.

Now, we deal with types in $\mathcal{A}^{\leftrightarrow}$. Let $s_l \in \mathcal{A}^{\leftrightarrow}$. By (ii) $card(X) = card(Y)$. Moreover, by the definition of u_{ij}, for every $s \in \mathcal{A}^{\leftrightarrow}$, $s \in S_i$ if and only if $s^* \in S_j$. Since $card(X) = u_{ij}(s_l) > 2m$, we can proceed as in Case 1b of the proof of Lemma 5.3 with $Z = \emptyset$.

Finally assume that we have already dealt with the types $s_1, \ldots, s_r$, and we want to realize types in $s_{r+1}, \ldots, s_v$.

Let $E = \{\{a, b\} : a \in C_{ii}, b \in C_{jj}$ and $\langle a, b \rangle$ realizes s_j, $j \leq r\}$, and $G = (C_{ii}, C_{jj}, E)$ be a bipartite graph. For every $a \in C_{ii}$, let $d'(a) = card(lab(a) \restriction \{S_j\})$.

Now, by Lemma A.5, G can be expanded to a bipartite graph $G' = (C_{ii}, C_{jj}, E')$ such that $E \subseteq E'$,

(a) for every $a \in C_{ii}$, $d_{G'}(a) = d'(a)$ and

(b) for every $b \in C_{jj}$, $d_{G'}(b) \leq c_i - m$.

By (a), for every $a \in C_{ii}$, we can find $card(lab(a) \restriction \{S_j\} \cap \mathcal{A}^{\rightarrow})$ elements $b \in C_{jj}$ such that $\langle a, b \rangle \in E' \setminus E$ and assign types in $lab(a) \restriction \{S_j\} \cap \mathcal{A}^{\rightarrow}$ to pairs $\langle a, b \rangle$. On the other hand, by (b), for every $b \in C_{jj}$, we can find $card(lab(b) \restriction \{S_i\} \cap \mathcal{A}^{\rightarrow})$ elements $a \in C_{ii}$ such that $\langle a, b \rangle \notin E'$ to realize the types of $lab(b) \restriction \{S_i\} \cap \mathcal{A}^{\rightarrow}$. ☐

Let

$$u = \sum_{s \in \mathcal{A}^{\leftrightarrow} \cup \mathcal{A}^{\leftarrow}} u_{ij}(s) + \sum_{s \in \mathcal{A}^{\rightarrow}} u_{ji}(s).$$

The integer u is the number of pairs of elements of $\mathfrak{C}_{ij}$ which realizes counting types.

LEMMA 5.5. *Let $S_i, S_j \in \mathcal{T}$, $i \neq j$, and assume that $c_i > 3m$ and $c_j \leq 3m$. There is a structure $\mathfrak{C}_{ij}$ such that $\mathfrak{C}_{ij} \models^{rnk_{ij}}_{\mathcal{X}_{ij}} \{S_i, S_j\}$ if and only if the following conditions hold:*

(i) *there are structures* $\mathfrak{C}_{ii}$, $\mathfrak{C}_{jj}$ *such that* $\mathfrak{C}_{ii} \models^{rnk_{ii}}_{\mathcal{X}_{ii}} \{S_i\}$, *and* $\mathfrak{C}_{jj} \models^{rnk_{jj}}_{\mathcal{X}_{jj}} \{S_j\}$;

(ii) *for every* $s \in S_i \cap \mathcal{A}^{\leftrightarrow}$, $u_{ij}(s) = u_{ji}(s^*)$, *and for every* $s \in S_j \cap \mathcal{A}^{\leftrightarrow}$, $u_{ji}(s) = u_{ij}(s^*)$;

(iii) *there exists a structure* $\mathfrak{D}$ *with the domain* $D = D_1 \dot{\cup} D_2$, *and there exists a* rnk'*-indexing* $\langle \mathcal{X}', rnk' \rangle$ *of* $\{S_i, S_j\}$ *such that* $card(D_1) \leq 3m^2$, $card(D_1) \leq c_i$, $card(D_2) = c_j$, $\mathcal{X}' \subseteq \mathcal{X}_{ij}$, *for every* $S_j^f \in \mathcal{X}_{ij}$, $S_j^f \in \mathcal{X}'$, *for every* $S_j^f \in \mathcal{X}'$, $rnk'(S_j^f) = rnk_{ij}(S_j^f)$, *for every* $S_i^f \in \mathcal{X}'$, $rnk'(S_i^f) \leq rnk_{ij}(S_i^f)$ *and*

$$\mathfrak{D} \models^{rnk'}_{\mathcal{X}'} \{S_i, S_j\};$$

(iv) *for every* $S_i^f \in \mathcal{X}_{ij}$, $card((S_i^f \restriction \{S_j\}) \setminus \{center(S_i)\}) \leq c_j$;

(v) *if* $u < c_i \cdot c_j$, *then* S_i *is connectable to* S_j *by some* $t \in \mathcal{A}^-$.

Proof. ($\Rightarrow$) This direction is obvious.

($\Leftarrow$) Assume that (i)–(v) hold. Assume the structures $\mathfrak{C}_{ii}$ and $\mathfrak{C}_{jj}$ given by (i) have disjoint universes. Put $C_{ij} = C_{ii} \dot{\cup} C_{jj}$, for every $a, b \in C_{ii}$, put $tp^{\mathfrak{C}_{ij}}(a,b) = tp^{\mathfrak{C}_{ii}}(a,b)$, and for every $a, b \in C_{jj}$, put $tp^{\mathfrak{C}_{ij}}(a,b) = tp^{\mathfrak{C}_{jj}}(a,b)$. Let lab_{ii} be the rnk_{ii}-labeling of C_{ii}, and lab_{jj} be the rnk_{jj}-labeling of C_{jj} as in the definition 5.9. Define the rnk_{ij}-labeling lab_{ij} of the set C_{ij} by putting $lab_{ij} = lab_{ii} \cup lab_{jj}$.

Now, by (iii), define an embedding h of $\mathfrak{D}$ into $\mathfrak{C}_{ij}$ as follows.

Let $h : D \xrightarrow[into]{1-1} C_{ij}$ be a mapping such that for every $a \in D$, $lab'(a) = lab(h(a))$. For every $a, b \in h(D)$ such that $a \in C_{ii}$, $b \in C_{jj}$ put $tp^{\mathfrak{C}_{ij}}(a,b) = tp^{\mathfrak{D}}(h^{-1}(a), h^{-1}(b))$.

Note that by Definition 5.15, for every $a \in C_{jj} \dot{\cup} h(D_1)$, $C_a^{\mathfrak{C}_{ij} \restriction h(D)} = lab(a) \restriction \{S_i, S_j\}$. Moreover, by (ii) and (iii), for every indexed constellation $S_i^f \in \mathcal{X}_{ij}$, if there is a type $s \in S_i \cap \mathcal{A}^{\leftrightarrow}$ such that $f(s) = S_j$, then $rnk'(S_i^f) = rnk(S_i^f)$. It follows that if $a \in C_{ii} \setminus h(D)$, then $s \notin \mathcal{A}^{\leftrightarrow}$ for each $s \in lab(a) \restriction \{S_j\}$. By (iv), for every $a \in C_{ii} \setminus h(D)$, for every $s \in lab(a) \restriction \{S_j\})$, find $b \in C_{jj}$ such that $tp^{\mathfrak{C}_{ij}}(a,b)$ has not been defined, and put $tp^{\mathfrak{C}_{ij}}(a,b) = s$. To finish the proof of Lemma 5.5, for every $a \in C_{ii}$, for every $b \in C_{jj}$, if $tp^{\mathfrak{C}_{ij}}(a,b)$ has not been defined, then put $tp^{\mathfrak{C}_{ij}}(a,b) = t$, where $t \in \mathcal{A}^-$ and S_i is connectable to S_j by t (cf. (v)). □

COROLLARY 5.16. (c5) *can be checked in exponential time.*

Proof. By decomposition theorem (Lemma 5.2), it suffices to check whether, for every $S_i, S_j \in \mathcal{S}_1 \cup \mathcal{S}_2$,

$$(*) \text{ there exists } \mathfrak{C}_{ij} \text{ such that } \mathfrak{C}_{ij} \models^{rnk_{ij}}_{\mathcal{X}_{ij}} \{S_i, S_j\}.$$

In the case $\boldsymbol{i = j}$, if $c_i \leq 2^m$, (*) can be checked by guessing the structure $\mathfrak{C}_{ii}$ of cardinality c_i and then verifying if $\mathfrak{C}_{ii} \models^{rnk_{ii}}_{\mathcal{X}_{ii}} \{S_i, S_i\}$. This will take no more than $O(2^{m^2}) = O(2^{n^2})$ steps. If $card(C_{ii}) > 2^m$, then by Lemma 5.3, it suffices to verify conditions (i)–(iii). This can be done in time $O(2^{dn^3})$ for some constant d.

In the case $\boldsymbol{i \neq j}$, if $c_i, c_j \leq 3m$, it suffices to guess a structure $\mathfrak{C}_{ij}$ of cardinality $c_i + c_j$ and verify if $\mathfrak{C}_{ij} \models^{rnk_{ij}}_{\mathcal{X}_{ij}} \{S_i, S_j\}$. This can be done in time polynomial with respect to m. To check whether (*) holds for $c_i > 3m$, it suffices to verify conditions (i)–(iv) of Lemma 5.4 or conditions (i)-(v) of Lemma 5.5. This also can be done in time $O(2^{dn^3})$ for some constant d.

In each of the cases above, checking whether (*) holds can be done in time $O(2^{dn^3})$, so it takes at most $O((2^{dn^3})^2) = O(2^{cn^3})$ steps to verify that (*) holds for every i, j. This finished the proof and completes the proof of Theorem 5.1. □

Appendix. We assume that the reader is familiar with the basic notions of graph theory. We use standard notation of graph theory (see, e.g., [4]).

In this paper a *graph* $G = (X, E)$ is a *finite* set X of nodes and a set E of edges, which are unordered pairs of nodes. For $x \in X$ we denote by $\Gamma_G(x)$ the set of neighbors of x, i.e., the set $\{y : \{x, y\} \in E\}$, and, for $A \subseteq X$, we put $\Gamma_G(A) = \bigcup_{a \in A} \Gamma_G(a)$. The degree of a node x, denoted by $d_G(x)$, is the number of neighbors of x. By $d(G)$ we denote the minimal value of $d_G(x)$. Given a graph $G = (X, E)$, a matching is defined as a set $E_0 \subseteq E$ such that, for each pair $\{u, v\}, \{u', v'\} \in E_0$ of edges, we have $\{u, v\} \cap \{u', v'\} = \emptyset$. A graph is *bipartite* if its nodes can be partitioned into two sets X_1, X_2 such that no two nodes in the same set are adjacent; such a bipartite graph is often denoted as $G = (X_1, X_2, E)$. Given a bipartite graph $G = (X, Y, E)$ and we say that X is matched into Y if there is a matching $E_0 \subseteq E$ such that for every $x \in X$ there exists $y \in Y$ such that $\{x, y\} \in E_0$.

Let m be a fixed nonnegative integer. The proof of the main result of this paper (Theorem 5.1) heavily depends on the following lemmas.

Lemma A.1 (König–Hall theorem (see [21]); cf. [4, p. 134]). *In a bipartite graph $G = (X, Y, E)$, X can be matched into Y if and only if $card(\Gamma_G(A)) \geq card(A)$ for every $A \subseteq X$.*

Lemma A.2. *Let G be a graph with n nodes and with $d(G) \geq n - m$. If $n > 2m$, then G has a Hamiltonian cycle.*

Proof. This is an easy consequence of the theorem by Bondy [6] (cf. [4, p. 212]) which says that *a graph G with $n \geq 3$ nodes, and with degrees $d_1 \leq \cdots \leq d_n$ has a Hamiltonian cycle if for every i, j such that $i \neq j$, $d_i \leq i$ and $d_j \leq j$, we have $d_i + d_j \geq n$.*

In fact, we have $d(G) \geq n - m$, so $d_i + d_j \geq n$ always holds for $n > 2m$. $\square$

Lemma A.3. *If $G = (X, Y, E)$ is a bipartite graph such that $card(X) = card(Y) = n$, $d(G) \geq n - m$ and $n > 2m$, then X can be matched into Y.*

Proof. We use Lemma A.1. Towards a contradiction, assume that there exists $A \subseteq X$ such that $card(\Gamma_G(A)) < card(A)$. Then $card(\Gamma_G(A)) < n$ and, since $d(G) \geq n - m$, $card(\Gamma_G(A)) \geq n - m$ and $card(A) > n - m$. Let $y \in Y \setminus \Gamma_G(A)$. For every $x \in X$, if $x \in \Gamma_G(y)$, then $x \notin A$. Moreover, $card(\Gamma_G(y)) \geq n - m$ and so, $card(A) < m$. This gives a contradiction if $n > 2m$. $\square$

Lemma A.4. *Let $G = (V, E)$ be a graph with n nodes such that $d(G) \geq n - m$, and assume that $V = X' \dot{\cup} Z \dot{\cup} Y'$, where $card(X') = card(Y') \leq 2m$. If $n > 14m$, then there exists $Z' \subseteq Z$ such that both X' and Y' can be matched onto Z'.*

Proof. Let $X' = \{a_1, \dots, a_k\}$, $Y' = \{b_1, \dots, b_k\}$, where $k \leq 2m$. Since $d(G) \geq n - m$, we have $card(\Gamma_G(a_1)) \geq n - m$. We claim that there is an element $c_1 \in \Gamma_G(a_1) \cap Z$ such that $c_1 \in \Gamma_G(b_1) \cap Z$. Indeed, $card(\Gamma_G(a_1) \cap Y) \geq n - m - 4m = n - 5m$, and $card(\Gamma_G(b_1) \cap Z) \geq n - 5m$. Therefore, $\Gamma_G(a_1) \cap \Gamma_G(b_1) \cap Z \neq \emptyset$, provided $n > 10m$. Similarly, $\Gamma_G(a_i) \cap \Gamma_G(b_i) \cap (Z \setminus \{c_1, \dots, c_{i-1}\}) \neq \emptyset$, provided $n > 10m + 2(i - 1)$. $\square$

Lemma A.5. *Let $G = (X, Y, E)$ be a bipartite graph such that for every $b \in Y$, $d_G(b) \leq card(X) - m$. Let $d' : X \mapsto \{0, \dots, m\}$ and for every $a \in X$, $d_G(a) \leq d'(a)$. If $card(X), card(Y) > 3m$, then there exists a bipartite graph $G' = (X, Y, E')$ such that $E \subseteq E'$, for every $a \in X$, $d_{G'}(a) = d'(a)$, and for every $b \in Y$, $d_{G'}(b) \leq card(X) - m$.*

Proof. Let $G = (X, Y, E)$ be a bipartite graph such that for every $b \in Y$, $d_G(b) \leq card(X) - m$, and let $d' : X \mapsto \{0, \dots, m\}$ be a function such that for every $a \in X$, $d_G(a) \leq d'(a)$.

To build the graph G' we will add new edges to the graph G repeating the following operation until we get a graph as needed.

(*) Let a be an element of X such that $d_G(a) < d'(a)$. Find an element $b \in Y$ such that $\{a,b\} \notin E$ and for every $c \in Y$ with $\{a,c\} \notin E$, $d_G(b) \leq d_G(c)$. Put $E = E \cup \{a,b\}$.

We will now show that an element b as above exists, and that the operation (*) preserves assumptions of the lemma.

Since $d_G(a) < m < card(Y)$, there exist at least $card(Y) - m$ elements c in Y such that $\{a,c\} \notin E$. We claim that among these elements there is an element b such that $d_G(b) < card(X) - m$. In fact, towards a contradiction, assume that $d_G(b) = card(X) - m$, for each $c \in Y$ such that $\{a,c\} \notin E$. Then

$$\sum_{c\in Y} d_G(c) = \sum_{c\in Y\setminus\Gamma_G(a)} d_G(c) + \sum_{c\in\Gamma_G(a)} d_G(c) \geq (card(Y) - m)(card(X) - m).$$

On the other hand, $d_G \leq m$, for every $e \in X$, which gives

$$\sum_{c\in Y} d_G(c) = \sum_{e\in X} d_G(e) < m \cdot card(X).$$

By the above inequalities,

$$m \cdot card(X) > (card(Y) - m)(card(X) - m)$$

and hence,

$$card(X)card(Y) - m(card(X) + card(Y)) - m(card(X) - m) < 0. \tag{A.1}$$

Assume $card(X) \geq card(Y)$. Then,

$$\begin{aligned} card(X)card(Y) - m(card(X) + card(Y)) - m(card(X) - m) \\ \geq card(X)card(Y) - 3m \cdot card(X) + m^2 \\ > card(X)(card(Y) - 3m) > 0, \text{provided } card(Y) > 3m. \end{aligned}$$

The last inequality contradicts (A.1). $\square$

Acknowledgments. We would like to thank the referees for their valuable comments that helped to improve the presentation.

MAKING NONDETERMINISM UNAMBIGUOUS[*]

KLAUS REINHARDT[†] AND ERIC ALLENDER[‡]

Abstract. We show that in the context of nonuniform complexity, nondeterministic logarithmic space bounded computation can be made unambiguous. An analogous result holds for the class of problems reducible to context-free languages. In terms of complexity classes, this can be stated as

$$\mathrm{NL/poly} = \mathrm{UL/poly},$$
$$\mathrm{LogCFL/poly} = \mathrm{UAuxPDA}(\log n, n^{O(1)})/\mathrm{poly}.$$

1. Introduction.

In this paper, we combine two very useful algorithmic techniques (the inductive counting technique of [Imm88, Sze88] and the isolation lemma of [MVV87]) to give a simple proof that two fundamental concepts in complexity theory coincide in the context of nonuniform computation: nondeterminism and unambiguity.

Unambiguous computation has been the focus of much attention over the past three decades. The notion of nondeterminism is a fundamental notion in many areas of computer science, and the version of nondeterminism where *at most one* nondeterministic path is accepting has proved to be one of the most meaningful restrictions of nondeterminism to study. For example,

- unambiguous context-free languages form one of the most important subclasses of the class of context-free languages;
- the complexity class UP (unambiguous polynomial time) was first defined and studied by Valiant [Val76], and a necessary precondition for the existence of one-way functions is for P to be properly contained in UP [GS88].

Although UP is one of the most intensely studied subclasses of nondeterministic polynomial time (NP), it is neither known nor widely believed that UP contains any sets that are hard for NP under any interesting notion of reducibility. (Recall that Valiant and Vazirani showed that "*Unique.Satisfiability*"—the set of all Boolean formulae with *exactly one* satisfying assignment—is hard for NP under probabilistic reductions [VV86]. However, the language *Unique.Satisfiability* is hard for coNP under $\leq_m^p$ reductions, and thus is not in UP unless NP = coNP.)

Nondeterministic and unambiguous space-bounded computation have also been the focus of much work in computer science. For instance, the question of whether every context-sensitive language has an unambiguous context-sensitive grammar is

[*]Received by the editors May 15, 1998; accepted for publication (in revised form) April 13, 1999; published electronically February 1, 2000. A preliminary version of this paper appeared in the Proceedings of the IEEE Symposium on Foundations of Computer Science (FOCS), 1997.

really a question about whether nondeterministic and unambiguous linear space coincide. This question remains open. In recent years, nondeterministic logspace (NL) has been the focus of much attention, in part because NL captures the complexity of many natural computational problems [Jon75]. The unambiguous version of NL, denoted UL, was first explicitly defined and studied in [BJLR91, AJ93]. A language A is in UL if and only if there is a nondeterministic logspace machine M accepting A such that, for every x, M has at most one accepting computation on input x.

Our results indicate that NL and UL are probably equal, but we cannot prove this equality. In order to state our theorem, we first need to discuss the issue of *uniformity.*

Complexity classes such as P, NP, and NL that are defined in terms of machines are known as "uniform" complexity classes, in contrast to "nonuniform" complexity classes, which are defined most naturally in terms of families of circuits $\{C_n\}$, with a circuit for each input length. In order to make a circuit complexity class "uniform," it is necessary to require that the function $n \mapsto C_n$ be "easy" to compute in some sense. (We will consider "logspace-uniform" circuits, where the function $n \mapsto C_n$ can be computed in space $\log n$.) P and NL (and many other uniform complexity classes) have natural definitions in terms of uniform circuits; for instance, NL can be characterized in terms of switching-and-rectifier networks (see, e.g. [Raz92, Raz90]) and skew circuits [Ven92]. Uniform complexity classes can be used to give characterizations of the nonuniform classes, too, using a formalism presented in [KL82]: Given any complexity class $\mathcal{C}$, $\mathcal{C}$/poly is the class of languages A for which there exists a sequence of "advice strings" $\{\alpha(n) \mid n \in \mathbf{N}\}$ and a language $B \in \mathcal{C}$ such that $x \in A$ if and only if $(x, \alpha(|x|)) \in B$.

Our main result is that NL/poly is equal to UL/poly.

(It is worth emphasizing that, in showing the equality UL/poly = NL/poly, we must show that for every B in NL/poly, there is a nondeterministic logspace machine M that never has more than one accepting path on any input, and there is an advice sequence $\alpha(n)$ such that $M(x, \alpha(|x|))$ accepts if and only if $x \in B$. This is stronger than merely saying that there is an advice sequence $\alpha(n)$ and a nondeterministic logspace machine such that $M(x, \alpha(|x|))$ never has more than one accepting path, and it accepts if and only if $x \in B$.)

Our work extends the earlier work of Wigderson and Gál. Motivated in part by the question of whether a space-bounded analogue of the result of [VV86] could be proved, Wigderson [Wig94, GW96] proved the inclusion NL/poly $\subseteq \oplus$L/poly. (An alternative proof of this inclusion is sketched in [Reg97, p. 284].) This is a weaker statement than NL $\subseteq \oplus$L, which is still not known to hold. $\oplus$L is the class of languages A for which there is a nondeterministic logspace bounded machine M such that $x \in A$ if and only if M has an odd number of accepting computation paths on input x.

In the proof of the main result of [Wig94, GW96], Wigderson observed that a simple modification of his construction produces graphs in which the shortest distance between every pair of nodes is achieved by a unique path. We will refer to such graphs in the following as *min-unique graphs.* Wigderson wrote: "We see no application of this observation." The proof of our main result is just such an application.

2. Nondeterministic logspace.

The s-t connectivity problem takes as input a directed graph with two distinguished vertices s and t and determines if there is a path in the graph from s to t. It is well known that this is a complete problem for NL [Jon75].

The following lemma is implicit in [Wig94, GW96], but for completeness we make it explicit here.

LEMMA 2.1. *There is a logspace-computable function f and a sequence of "advice strings" $\{\alpha(n) \mid n \in \mathbf{N}\}$ (where $|\alpha(n)|$ is bounded by a polynomial in n) with the following properties:*

- *For any directed acyclic graph G on n vertices, $f(G, \alpha(n)) = \langle G_1, \ldots, G_{n^2}\rangle$.*
- *For each i, the directed acyclic graph G_i has an s-t path if and only if G has an s-t path.*
- *There is some i such that G_i is a min-unique graph.*

Proof. We first observe that a standard application of the isolation lemma technique of [MVV87] shows that, if each edge in G is assigned a weight in the range $[1, 4n^4]$ uniformly and independently at random, then with probability at least $\frac{3}{4}$, for any two vertices x and y such that there is a path from x to y, there is only one path having minimum weight. (Sketch: The probability that there is more than one minimum weight path from x to y is bounded by the sum, over all edges e, of the probability of the event $\text{BAD}(e, x, y)$ ::= "e occurs on one minimum-weight path from x to y and not on another." Given any weight assignment w' to the edges in G other than e, there is at most one value z with the property that, if the weight of e is set to be z, then $\text{BAD}(e, x, y)$ occurs. Thus the probability that there are two minimum-weight paths between two vertices is bounded by $\sum_{x,y,e}\sum_{w'} \text{BAD}(e, x, y|w')\text{Prob}(w') \leq \sum_{x,y,e}\sum_{w'} 1/(4n^4)\text{Prob}(w') = \sum_{x,y,e} 1/(4n^4) \leq 1/4$.)

Our advice string α will consist of a sequence of n^2 weight functions, where each weight function assigns a weight in the range $[1, 4n^4]$ to each edge. (There are $A(n) = 2^{O(n^5)}$ such advice strings possible for each n.) Our logspace-computable function f takes as input a digraph G and a sequence of n^2 weight functions and produces as output a sequence of graphs $\langle G_1, \ldots, G_{n^2}\rangle$, where graph G_i is the result of replacing each directed edge $e = (x, y)$ in G by a directed path of length j from x to y, where j is the weight given to e by the ith weight function in the advice string. Note that, if the ith weight function satisfies the property that there is at most one minimum weight path between any two vertices, then G_i is a min-unique graph. To see this, it suffices to observe that, for any two vertices x and y of G_i, either (a) there exist vertices u and v such that x and y were both added in replacing the edge (u, v) (in which case there is exactly one path connecting u to v, or (b) there are vertices x' and y' such that

- x' and y' are vertices of the original graph G, and they lie on every path between x and y,
- there is only one path from x to x' and only one path from y' to y, and
- the minimum weight path from x' to y' is unique.

Let us call an advice string "bad for G" if none of the graphs G_i in the sequence $f(G)$ is a min-unique graph. For each G, the probability that a randomly-chosen advice string α is bad is bounded by (probability that G_i is not min-unique)$^{n^2} \leq (1/4)^{n^2} = 2^{-2n^2}$. Thus the total number of advice strings that are bad for some G is at most $2^{n^2}(2^{-2n^2}A(n)) < A(n)$. Thus there is some advice string $\alpha(n)$ that is not bad for *any* G. ∎

THEOREM 2.2. *NL⊆UL/poly.*

Proof. It suffices to present a UL/poly algorithm for the s-t connectivity problem.

We show that there is a nondeterministic logspace machine M that takes as input a sequence of digraphs $\langle G_1, \ldots, G_r\rangle$ and processes each G_i in sequence, with the following properties:

```
Input $(G, k, c_k, \Sigma_k, v)$
$count := 0$; $sum := 0$; $path.to.v :=$ false;
for each $x \in V$ do
    Guess nondeterministically if $d(x) \leq k$.
    if the guess is $d(x) \leq k$, then
        begin
         Guess a path of length $l \leq k$ from $s$ to $x$ (If this fails, then halt and reject).
         $count := count + 1$; $sum := sum + l$;
         if $x = v$, then $path.to.v :=$ true;
        end
endfor
if $count = c_k$ and $sum = \Sigma_k$,
    then return the Boolean value of $path.to.v$
    else halt and reject
end.procedure
```

FIG. 1. *An unambiguous routine to determine if $d(v) \leq k$.*

- If G_i is not min-unique, M has a unique path that determines this fact and goes on to process G_{i+1};[1] all other paths are rejecting.
- If G_i is a min-unique graph with an s-t path, then M has a unique accepting path.
- If G_i is a min-unique graph with no s-t path, then M has no accepting path.

Combining this routine with the construction of Lemma 2.1 yields the desired UL/poly algorithm.

Our algorithm is an enhancement of the inductive counting technique of [Imm88] and [Sze88]. We call this the *double counting* technique since in each stage we count not only the number of vertices having distance at most k from the start vertex, but also the sum of the lengths of the shortest path to each such vertex. In the following description of the algorithm, we denote these numbers by c_k and Σ_k, respectively.

Let us use the notation $d(v)$ to denote the length of the shortest path in a graph G from the start vertex to v. (If no such path exists, then $d(v) = n + 1$.) Thus, using this notation, $\Sigma_k = \sum_{\{x \mid d(x) \leq k\}} d(x)$.

A useful observation is that *if the subgraph of G induced by vertices having distance at most k from the start vertex is min-unique* (and if the correct values of c_k and Σ_k are provided), then an unambiguous logspace machine can, on input (G, k, c_k, Σ_k, v), compute the Boolean predicate "$d(v) \leq k$". This is achieved with the routine shown in Figure 1.

To see that this routine truly is unambiguous if the preconditions are met, note the following:

- If the routine ever guesses incorrectly for some vertex x that $d(x) > k$, then the variable *count* will never reach c_k and the routine will reject. Thus the only paths that run to completion guess correctly exactly the set $\{x \mid d(x) \leq k\}$.
- If the routine ever guesses incorrectly the length l of the shortest path to x, then if $d(x) > l$ no path of length l will be found, and if $d(x) < l$, then the

[1]More precisely, our routine will check if, for every vertex x, there is at most one minimal-length path from the start vertex to x. This is sufficient for our purposes. A straightforward modification of our routine would provide an unambiguous logspace routine that would determine if the entire graph G_i is a min-unique graph.

```
Input $(G, k, c_{k-1}, \Sigma_{k-1})$
Output $(c_k, \Sigma_k)$, and also the flag $BAD.GRAPH$

$c_k := c_{k-1}$; $\Sigma_k := \Sigma_{k-1}$;
for each vertex $v$ do
  if $\neg(d(v) \leq k-1)$, then
    for each $x$ such that $(x, v)$ is an edge do
      if $d(x) \leq k-1$, then
        begin
        $c_k := c_k + 1$; $\Sigma_k := \Sigma_k + k$;
        for $x' \neq x$ do
          if $(x', v)$ is an edge and $d(x') \leq k-1$, then $BAD.GRAPH :=$ true
        endfor
        end
    endfor
endfor
At this point, the values of $c_k$ and $\Sigma_k$ are correct.
```

FIG. 2. *Computing c_k and Σ_k.*

```
Input $(G)$
$BAD.GRAPH :=$ false; $c_0 := 1; \Sigma_0 := 0; k := 0$;
repeat
    $k := k + 1$;
    compute $c_k$ and $\Sigma_k$ from $(c_{k-1}, \Sigma_{k-1})$;
until $c_{k-1} = c_k$ or $BAD.GRAPH =$ true.
If $BAD.GRAPH =$ false, then there is an $s$-$t$ path in $G$ if and only if $d(t) \leq k$.
```

FIG. 3. *Finding an s-t path in a min-unique graph.*

variable *sum* will be increased by a value greater than $d(x)$. In the latter case, at the end of the routine, *sum* will be greater than Σ_k, and the routine will reject.

Clearly, the subgraph having distance at most 0 from the start vertex is min-unique, and $c_0 = 1$ and $\Sigma_0 = 0$. A key part of the construction involves computing c_k and Σ_k from c_{k-1} and Σ_{k-1}, at the same time checking that the subgraph having distance at most k from the start vertex is min-unique. It is easy to see that c_k is equal to c_{k-1} plus the number of vertices having $d(v) = k$. Note that $d(v) = k$ if and only if there is some edge (x, v) such that $d(x) \leq k-1$ and it is not the case that $d(v) \leq k-1$. (Note that both of these latter conditions can be determined in UL, as discussed above.) The subgraph having distance at most k from the start vertex *fails* to be a min-unique graph if and only if there exist some v and x as above, as well as some other $x' \neq x$ such that $d(x') \leq k-1$ and there is an edge (x', v). The code shown in Figure 2 formalizes these considerations.

Recall that we are building an algorithm that takes as input a sequence of graphs $\langle G_1, \dots, G_r \rangle$ and processes each graph G in the sequence in turn, as outlined at the start of this proof. Searching for an s-t path in a graph G in the sequence is now expressed by the routine shown in Figure 3.

We complete the proof by describing how our algorithm processes the sequence $\langle G_1, \dots, G_r \rangle$, as outlined at the start of the proof. Each G_i is processed in turn. If

G_i is not min-unique (or more precisely, if the subgraph of G_i that is reachable from the start vertex is not a min-unique graph), then one unique computation path of the routine returns the value *BAD.GRAPH* and goes on to process G_{i+1}; all other computation paths halt and reject. Otherwise, if G_i is min-unique, the routine has a unique accepting path if G_i has an s-t path, and if this is not the case, the routine halts with no accepting computation paths. ∎

COROLLARY 2.3. *NL/poly = UL/poly.*

Proof. Clearly UL/poly is contained in NL/poly. It suffices to show the converse inclusion. Let A be in NL/poly. By definition, there is a language $B \in$ NL and there is an advice sequence α_n such that x is in A if and only if $(x, \alpha_{|x|})$ is in B. By the preceding theorem, B is in UL/poly, and thus there is a C in UL and an advice sequence β_n such that (x, α_n) is in B if and only if $((x, \alpha_{|x|}), \beta_{|x|+|\alpha_{|x|}|})$ is in C. It is now obvious how to construct the desired advice sequence from α_n and $\beta_{n+|\alpha_n}$. ∎

3. LogCFL.

3. LogCFL. LogCFL is the class of problems logspace-reducible to a context-free language. Two important and useful characterizations of this class are summarized in the following proposition. (SAC^1 and AuxPDA$(\log n, n^{O(1)})$ are defined in the following paragraphs.)

PROPOSITION 3.1 (see [Sud78, Ven91]). *LogCFL* $=$ *AuxPDA*$(\log n, n^{O(1)})$ $=$ *SAC*^{1}.

An auxiliary pushdown automaton (AuxPDA) is a nondeterministic Turing machine with a read-only input tape, a space-bounded worktape, and a pushdown store that is not subject to the space-bound. The class of languages accepted by auxiliary pushdown automata in space $s(n)$ and time $t(n)$ is denoted by AuxPDA$(s(n), t(n))$. If an AuxPDA satisfies the property that, on every input x, there is at most one accepting computation, then the AuxPDA is said to be *unambiguous.* This gives rise to the class UAuxPDA$(s(n), t(n))$.

SAC^1 is the class of languages accepted by logspace-uniform semiunbounded circuits of depth $O(\log n)$; a circuit family is semiunbounded if the AND gates have fan-in 2 and the OR gates have unbounded fan-in.

Not long after NL was shown to be closed under complementation [Imm88, Sze88], LogCFL was also shown to be closed under complementation in a proof that also used the inductive counting technique [BCD$^+$89]. A similar history followed a few years later: not long after it was shown that NL is contained in $\oplus$L/poly [Wig94, GW96], the isolation lemma was again used to show that LogCFL is contained in $\oplus$SAC^1/poly [Gál95, GW96]. (As is noted in [GW96], this was independently shown by H. Venkateswaran.)

In this section, we show that the same techniques that were used in section 2 can be used to prove an analogous result about LogCFL. (In fact, it would also be possible to derive the result of section 2 from a modification of the proof of this section. Since some readers may be more interested in NL than LogCFL, we have chosen to present a direct proof of NL/poly = UL/poly.) The first step is to state the analogue to Lemma 2.1. Before we can do that, we need some definitions.

A *weighted circuit* is a semiunbounded circuit together with a *weighting function* that assigns a nonnegative integer weight to each wire connecting any two gates in the circuit.

Let C be a weighted circuit, and let g be a gate of C. A *certificate for* $g(x) = 1$ *(in* C*)* is a list of gates, corresponding to a depth-first search of the subcircuit of C rooted at g. The *weight of a certificate* is the sum of the weights of the edges traversed in the depth-first search. This informal definition is made precise by the following inductive definition. (It should be noted that this definition differs in some unimportant ways from the definition given in [Gál95, GW96].)

- If g is a constant 1 gate or an input gate evaluating to 1 on input x, then the only certificate for g is the string g. This certificate has weight 0.
- If g is an AND gate of C with inputs h_1 and h_2 (where h_1 lexicographically precedes h_2), then any string of the form gyz is a certificate for g, where y is any certificate for h_1, and z is any certificate for h_2. If w_i is the weight of the edge connecting h_i to g, then the weight of the certificate gyz is $w_1 + w_2$ plus the sum of the weights of certificates y and z.
- If g is an OR gate of C, then any string of the form gy is a certificate for g, where y is any certificate for a gate h that is an input to g in C. If w is the weight of the edge connecting h to g, then the weight of the certificate gy is w plus the weight of certificate y.

Note that if C has logarithmic depth d, then any certificate has length bounded by a polynomial in n and has weight bounded by 2^d times the maximum weight of any edge. Every gate that evaluates to 1 on input x has a certificate, and no gate that evaluates to 0 has a certificate.

We will say that a weighted circuit C *is min-unique on input* x if, for every gate g that evaluates to 1 on input x, the minimal-weight certificate for $g(x) = 1$ is unique.

LEMMA 3.2. *For any language A in LogCFL, there is a sequence of advice strings $\alpha(n)$ (having length polynomial in n) with the following properties:*

- *Each $\alpha(n)$ is a list of weighted circuits of logarithmic depth $\langle C_1, \dots, C_n\rangle$.*
- *For each input x and for each i, $x \in A$ if and only if $C_i(x) = 1$.*
- *For each input x, there is some i such that C_i is min-unique on input x.*

Lemma 3.2 is in some sense implicit in [Gál95, GW96]. We include a proof for completeness.

Proof. Let A be in LogCFL, and let C be the semiunbounded circuit of size n^l (i.e., having at most n^l gates) and depth $d = O(\log n)$ recognizing A on inputs of length n.

As in [Gál95, GW96], a modified application of the isolation lemma technique of [MVV87] shows that, for each input x, if each wire in C is assigned a weight in the range $[1, 4n^{3l}]$ uniformly and independently at random, then with probability at least $\frac{3}{4}$, C is min-unique on input x. (Sketch: The probability that there is more than one minimum weight certificate for $g(x) = 1$ is bounded by the sum, over all wires e, of the probability of the event $\text{BAD}(e, g)$ ::= "e occurs in one minimum-weight certificate for $g(x) = 1$ and not in another." Given any weight assignment w' to the edges in C other than e, there is at most one value z with the property that, if the weight of e is set to be z, then $\text{BAD}(e, g)$ occurs. Thus the probability that there are two minimum-weight certificates for any gate in C is bounded by $\sum_{g,e}\sum_{w'} \text{BAD}(e, g|w')\text{Prob}(w')$ $\le \sum_{g,e}\sum_{w'} 1/(4n^{3l})\text{Prob}(w') = \sum_{g,e} 1/(4n^{3l}) \le 1/4$.)

Now consider sequences β consisting of n weight functions $\langle w_1, \dots, w_n\rangle$, where each weight function assigns a weight in the range $[1, 4n^{3l}]$ to each edge of C. (There are $B(n) = 2^{n^{O(1)}}$ such sequences possible for each n.) There must exist a string β such that, for each input x of length n, there is some $i \le n$ such that the weighted circuit C_i that results by applying weight function w_i to C is min-unique on input x. (Sketch of proof: Let us call a sequence β "bad for x" if none of the circuits C_i in the sequence is min-unique on input x. For each x, the probability that a randomly chosen β is bad is bounded by (probability that C_i is not min-unique)^n $\le (1/4)^n = 2^{-2n}$. Thus the total number of sequences that are bad for some x is at

```
Input $(C, x, k, c_k, \Sigma_k, g)$
$count := 0$; $sum := 0$; $a := \infty$;
for each gate $h$ do
    Guess nondeterministically if $W(h) \leq k$.
    if the guess is $W(h) \leq k$, then
        begin
          Guess a certificate of size $l \leq k$ for $h$ (If this fails, then halt and reject).
          $count := count + 1$; $sum := sum + l$;
          if $h = g$, then $a := l$;
        end
endfor
if $count = c_k$ and $sum = \Sigma_k$,
    then return $a$
    else halt and reject
end.procedure
```

FIG. 4. *An unambiguous routine to calculate $W(g)$ if $W(g) \leq k$ and return ∞ otherwise.*

most $2^n(2^{-2n}B(n)) < B(n)$. Thus there is some sequence β that is not bad for *any* x.)

The desired advice sequence $\alpha(n) = \langle C_1, \ldots, C_n \rangle$ is formed by taking a good sequence $\beta = \langle w_1, \ldots, w_n \rangle$ and letting C_i be the result of applying weight function w_i to C. ∎

THEOREM 3.3. *LogCFL $\subseteq$ UAuxPDA$(\log n, n^{O(1)})$/poly.*

Proof. Let A be a language in LogCFL. Let x be a string of length n, and let $\langle C_1, \ldots, C_n \rangle$ be the advice sequence guaranteed by Lemma 3.2.

We show that there is an unambiguous auxiliary pushdown automaton M that runs in polynomial time and uses logarithmic space on its worktape that, given a sequence of circuits as input, processes each circuit in turn, and has the following properties:

- If C_i is not min-unique on input x, then M has a unique path that determines this fact and goes on to process C_{i+1}; all other paths are rejecting.
- If C_i is min-unique on input x and evaluates to 1 on input x, then M has a unique accepting path.
- If C_i is min-unique on input x but evaluates to zero on input x, then M has no accepting path.

Our construction is similar in many respects to that of section 2. Given a circuit C, let c_k denote the number of gates g that have a certificate for $g(x) = 1$ of weight at most k, and let Σ_k be the sum, over all gates g having a certificate for $g(x) = 1$ of weight at most k, of the minimum-weight certificate of g. (Let $W(g)$ denote the weight of the minimum-weight certificate of $g(x) = 1$, if such a certificate exists, and let this value be ∞ otherwise.)

A useful observation is that *if all gates of C having certificates of weight at most k have unique minimal-weight certificates* (and if the correct values of c_k and Σ_k are provided), then on input $(C, x, k, c_k, \Sigma_k, g)$, an unambiguous AuxPDA can determine if $W(g) > k$, and if $W(g) \leq k$, the AuxPDA can compute the value of $W(g)$. This is achieved with the routine shown in Figure 4.

To see that this routine truly is unambiguous if the preconditions are met, note the following:

- If the routine ever guesses incorrectly for some gate h that $W(h) > k$, then the variable *count* will never reach c_k and the routine will reject. Thus the only paths that run to completion guess correctly exactly the set $\{h \mid W(h) \leq k\}$.
- For each gate h such that $W(h) \leq k$, there is exactly one minimal-weight certificate that can be found. An UAuxPDA will find this certificate using its pushdown to execute a depth-first search (using nondeterminism at the OR gates and using its $O(\log n)$ workspace to compute the weight of the certificate), and only one path will find the minimal-weight certificate. If, for some gate h, a certificate of weight greater than $W(h)$ is guessed, then the variable *sum* will not be equal to Σ_k at the end of the routine, and the path will halt and reject.

Clearly, all gates at the input level have unique minimal-weight certificates (and the only gates g with $W(g) = 0$ are at the input level). Thus we can set $c_0 = n + 1$ (since each input bit and its negation are provided, along with the constant 1) and $\Sigma_0 = 0$. A key part of the construction involves computing c_k and Σ_k from (c_{k-1}, Σ_{k-1}), at the same time checking that no gate has two minimal-weight certificates of weight k. Consider each gate g in turn. If g is an AND gate with inputs h_1 and h_2 and weights w_1 and w_2 connecting g to these inputs, then $W(g) \leq k$ if and only if $(W(g) = l \leq k-1)$ or $((W(g) > k-1)$ and $(W(h_1) + W(h_2) + w_1 + w_2 = k))$. If g is an OR gate, then it suffices to check, for each gate h that is connected to g by an edge of weight w, if $(W(g) = l \leq k-1)$ or $((W(g) > k-1)$ and $(W(h)+w = k))$; if one such gate is found, then $W(g) = k$; if two such gates are found, then the circuit is not min-unique on input x. If no violations of this sort are found for any k, then C is min-unique on input x. The code shown in Figure 5 formalizes these considerations.

Evaluating a given circuit C_i is now expressed by the routine shown in Figure 6.

We complete the proof by describing how our algorithm processes the sequence $\langle C_1, \ldots, C_n\rangle$, as outlined at the start of the proof. Given the sequence $\langle C_1, \ldots, C_n\rangle$, the algorithm processes each C_i in turn. If C_i is not min-unique on input x, then one unique computation path of the routine returns the value *BAD.CIRCUIT* and goes on to process C_{i+1}; all other computation paths halt and reject. Otherwise, the routine has a unique accepting path if $C_i(x) = 1$, and if this is not the case the routine halts with no accepting computation paths. □

Corollary 3.4. *LogCFL/poly = UAuxPDA*$(\log n, n^{O(1)})$*/poly.*

4. Discussion and open problems.

Rytter [Ryt87] (see also [RR92]) showed that any unambiguous context-free language can be recognized in logarithmic time by a concurrent-read, exclusive-write parallel random access machine (CREW-PRAM). In contrast, no such CREW algorithm is known for any problem complete for NL, even in the nonuniform setting, although one might initially suspect that our results, combined with those of [Ryt87], would yield such algorithms, because of the following considerations:

- NL is the class of languages reducible to linear context-free languages [Sud75].
- The class of languages accepted by deterministic AuxPDAs in logarithmic space and polynomial time coincides with the class of languages logspace-reducible to deterministic context-free languages.
- LogCFL coincides with AuxPDA$(\log n, n^{O(1)})$.

```
Input $(C, x, k, c_{k-1}, \Sigma_{k-1})$
Output $(c_k, \Sigma_k)$, and also the flag $BAD.CIRCUIT$

$c_k := c_{k-1}; \Sigma_k := \Sigma_{k-1}$;
for each gate $g$ do
   if $W(g) > k-1$, then
      begin
      if $g$ is an AND gate with inputs $h_1, h_2$, connected
          to $g$ with edges weighted $w_1, w_2$ and
          $W(h_1) + W(h_2) + w_1 + w_2 = k$, then
        $c_k := c_k + 1$; $\Sigma_k := \Sigma_k + k$
      if $g$ is an OR gate, then
          for each $h$ connected to $g$ by an edge weighted $w$ do
              if $W(h) = k - w$, then
                  begin
                  $c_k := c_k + 1$; $\Sigma_k := \Sigma_k + k$
                  for $h' \neq h$ connected to $g$ by an edge of weight $w'$ do
                      if $W(h') = k - w'$,
                          then $BAD.CIRCUIT$ := true:
                  endfor
                  end
          endfor
      end
endfor
At this point, if $BAD.CIRCUIT$ = false, the values of $c_k$ and $\Sigma_k$ are correct.
```

FIG. 5. *Computing c_k and Σ_k.*

```
Input $(C_i)$
$BAD.CIRCUIT$ := false; $c_0 := n + 1; \Sigma_0 := 0$;
for $k = 1$ to $2^d 4n^{3l}$
     compute $(c_k, \Sigma_k)$ from $c_{k-1}, \Sigma_{k-1}$;
     if $BAD.CIRCUIT$ = true, then exit the for loop.
endfor
If $BAD.CIRCUIT$ = false, then the output gate $g$ evaluates to 1 if and only if $W(g) < \infty$.
```

FIG. 6. *Evaluating a circuit.*

That is, there is a close connection between deterministic and nondeterministic context-free languages, and related deterministic and nondeterministic complexity classes. Shouldn't similar relationships hold for the unambiguous classes? Unfortunately, it is *not* known that UAuxPDA$(\log n, n^{O(1)})$ or UL is reducible to unambiguous context-free languages. The work of Niedermeier and Rossmanith does an excellent job of explaining the subtleties and difficulties here [NR95]. CREW algorithms are closely associated with a version of unambiguity called *strong unambiguity.* In terms of Turing-machine based computation, strong unambiguity means that, not only is there at most one path from the start vertex to the accepting configuration, but in fact there is at most one path between *any two configurations of the machine.*

Strongly unambiguous classes have more efficient algorithms than are known for general NL or UL problems. It is shown in [AL98] that problems in strongly unambiguous logspace have deterministic algorithms using less than $\log^2 n$ space, and it is shown in [BJLR91] that this class is also in LogDCFL (and hence has logarithmic-time concurrent-read, owner-write parallel random access machine (CROW-PRAM) algorithms and is in SC^2). For more information on this connection to CROW-PRAM algorithms, see [FLR96].

The reader is encouraged to note that, in a min-unique graph, the shortest path between *any two vertices* is unique. This bears a superficial resemblance to the property of strong unambiguity. We see no application of this observation.

It is natural to ask if the randomized aspect of the construction can be eliminated using some sort of derandomization technique to obtain the equality UL = NL. In more recent work [ARZ], we observe that if DSPACE(n) contains a language with sufficiently high circuit complexity, then the techniques of [NW94] can be used to build pseudorandom generators of sufficiently high quality, so that the results of this paper would also hold in the uniform setting.

A corollary of our work is that UL/poly is closed under complement. It remains an open question if UL is closed under complement, although some of the unambiguous logspace classes that can be defined using strong unambiguity are known to be closed under complement [BJLR91]. Similarly, UL/poly has a complete set under the natural types of reducibility to consider (nonuniform logspace reductions or even nonuniform projections). In contrast, UL itself is not known to have any complete sets under logspace reducibility. In this regard, note that Lange has shown that one of the other unambiguous logspace classes does have complete sets [Lan97].

It is disappointing that the techniques used in this paper do not seem to provide any new information about complexity classes such as NSPACE(n) and NSPACE(2^n). It is straightforward to show that NSPACE($s(n)$) is contained in the advice class USPACE($s(n)$)/$2^{O(s(n))}$, but this is interesting only for sublinear $s(n)$. (In a personal communication, Fortnow [FOR] has pointed out that our argument does show that NSPACE(n) = USPACE(n) relative to a random oracle.)

There is a natural class of functions associated with NL, denoted FNL [AJ93]. This can be defined in several equivalent ways, such as

- the class of functions computable by NC^1 circuits with oracle gates for problems in NL,
- the class of functions f such that $\{(x, i, b) \mid \text{the } i\text{th bit of } f(x) \text{ is } b\}$ is in NL,
- the class of functions computable by logspace-bounded machines with oracles for NL.

Another important class of problems related to NL is the class #L, which counts the number of accepting paths of an NL machine. #L characterizes the complexity of computing the determinant [Vin91]. (See also [Tod, Dam, MV97, Val92, AO96].) It was observed in [AJ93] that if NL = UL, then FNL is contained in #L. Thus a corollary of the result in this paper is that FNL/poly $\subseteq$ #L/poly.

Many questions about #L remain unanswered. Two interesting complexity classes related to #L are PL (probabilistic logspace) and $\mathrm{C_=L}$ (which characterizes the complexity of singular matrices, as well as questions about computing the rank). It is known that some natural hierarchies defined using these complexity classes collapse:

- $\mathrm{AC}^0(\mathrm{C_=L}) = \mathrm{C_=L}^{\mathrm{C_=L}^{\cdot^{\cdot^{\mathrm{C_=L}}}}} = \mathrm{NC}^1(\mathrm{C_=L}) = \mathrm{L}^{\mathrm{C_=L}}$ [AO96, ABO96].
- $\mathrm{AC}^0(\mathrm{PL}) = \mathrm{PL}^{\mathrm{PL}^{\cdot^{\cdot^{\mathrm{PL}}}}} = \mathrm{NC}^1(\mathrm{PL}) = \mathrm{PL}$ [AO96, Ogi98, BF97].

In contrast, the corresponding #L hierarchy (equal to the class of problems AC^0 reducible to computing the determinant) $\mathrm{AC}^0(\#\mathrm{L}) = \mathrm{FL}^{\#\mathrm{L}^{\cdot^{\cdot^{\#\mathrm{L}}}}}$ is not known to collapse to any fixed level. Does the equality UL/poly = NL/poly provide any help in analyzing this hierarchy in the nonuniform setting?

It is instructive to view our results in terms of arithmetic circuits. An equivalent definition of the class of functions #L results by taking the Boolean circuit characterization of NL (see [Ven92]) and replacing each Boolean AND and OR gate by integer multiplication and addition, respectively. The class $\#\mathrm{SAC}^1$ can be defined similarly. This notion of arithmetic circuit complexity has been investigated in a series of papers including [Vin91, CMTV96, AAD97, All97]. Our results say that the zero-one valued characteristic function of any language in NL (or LogCFL) can be computed by the corresponding (nonuniform) class of arithmetic circuits. Note that, although the output gate is producing a value in {0,1}, some of the interior gates will be producing larger values. Are there equivalent arithmetic circuits where *all* gates take values in {0,1}? (This is essentially the notion of strong unambiguity.) Note that each such gate is itself defining a language in NL (or LogCFL), and thus there is a zero-one valued arithmetic circuit for it—but this circuit may itself have gates that produce large values.

Acknowledgments. We thank Klaus-Jörn Lange for helpful comments, for drawing our attention to min-unique graphs, and for arranging for the second author to spend some of his sabbatical time in Tübingen. We also thank V. Vinay and Lance Fortnow for insightful comments.

A COMBINATORIAL CONSISTENCY LEMMA WITH APPLICATION TO PROVING THE PCP THEOREM[*]

ODED GOLDREICH[†] AND SHMUEL SAFRA[‡]

Abstract. The current proof of the probabilistically checkable proofs (PCP) theorem (i.e., $\mathcal{NP} = \mathcal{PCP}(\log, O(1))$) is very complicated. One source of difficulty is the technically involved analysis of low-degree tests. Here, we refer to the difficulty of obtaining *strong* results regarding low-degree tests; namely, results of the type obtained and used by Arora and Safra [*J. ACM*, 45 (1998), pp. 70–122] and Arora et al. [*J. ACM*, 45 (1998), pp. 501–555].

In this paper, we eliminate the need to obtain such strong results on low-degree tests when proving the PCP theorem. Although we do not remove the need for low-degree tests altogether, using our results it is now possible to prove the PCP theorem using a simpler analysis of low-degree tests (which yields weaker bounds). In other words, we replace the strong algebraic analysis of low-degree tests presented by Arora and Safra and Arora et al. by a combinatorial lemma (which does not refer to low-degree tests or polynomials).

Key words. parallelization of probabilistic proof systems, probabilistically checkable proofs (PCP), NP, low-degree tests

AMS subject classifications. 68Q15

1. Introduction.

The characterization of $\mathcal{NP}$ in terms of probabilistically checkable proofs (PCP systems) [AS, ALMSS], hereafter referred to as the PCP characterization theorem, is one of the more fundamental achievements of complexity theory. Loosely speaking, this theorem states that membership in any NP-language can be verified probabilistically by a polynomial-time machine which inspects a constant number of bits (in random locations) in a "redundant" NP-witness. Unfortunately, the current proof of the PCP characterization theorem is very complicated and, consequently, has not been fully assimilated into complexity theory. Clearly, changing this state of affairs is highly desirable.

There are two aspects of the current proof (of the PCP characterization theorem) which are difficult. One difficult aspect is the complicated conceptual structure of the proof (most notably the acclaimed "proof composition" paradigm). Yet, with time, this part seems easier to understand and explain than when it was first introduced. Furthermore, the proof composition paradigm turned out to be very useful and played a central role in subsequent works in this area (cf. [BGLR, BS, BGS, H96]). The other difficult aspect is the technically involved analysis of low-degree tests. Here we refer to the difficulty of obtaining *strong* results regarding low-degree tests, namely, results of the type obtained and used in [AS] and [ALMSS].

In this paper, we eliminate the latter difficulty. Although we do not get rid of low-degree tests altogether, using our results it is now possible to prove the PCP characterization theorem using only the weaker and simpler analysis of low-degree

tests presented in [GLRSW, RS92, RS96]. In other words, we replace the complicated algebraic analysis of low-degree tests presented in [AS, ALMSS] by a combinatorial lemma (which does not refer to low-degree tests or even to polynomials). We believe that this combinatorial lemma is very intuitive and find its proof much simpler than the algebraic analysis of [AS, ALMSS]. (However, simplicity may be a matter of taste.)

Loosely speaking, our combinatorial lemma provides a method of generating sequences of pairwise independent random points so that any assignment of values to the sequences either induces essentially consistent values on the individual elements or is detected as inconsistent. This is achieved by a "consistency test" which samples a constant number of sequences (and obtains the values assigned to these sequences). We stress that the length of the sequences as well as the domain from which the elements are chosen are parameters, which may grow while the number of samples remains fixed.

1.1. Two combinatorial consistency lemmas. The following problem arises frequently when trying to design PCP systems, and in particular when proving the PCP characterization theorem. For some sets S and V, one has a procedure which, given (bounded) oracle access to any function $f : S \mapsto V$, tests whether f has some desired property. The procedure should always accept a function having the property and should reject with "noticeable" probability any function which is far from having the property (i.e., differs from any function having the property on a significant fraction of the domain). For example, the property may be that of being a proof-oracle in a basic PCP system which we want to utilize (as an ingredient in the composition of PCP systems). Our goal is to increase the detection probability (equivalently, to reduce the error probability) without increasing the number of queries, but rather allowing more informative queries. For example, we are willing to allow queries in which one supplies a sequence of elements in S and expects to obtain the corresponding sequence of values of f applied to these elements. The problem is that the sequences of values obtained may not be consistent with any function $f : S \mapsto V$.

We can now phrase a simple problem of testing consistency. One is given access to a function $F : S^\ell \mapsto V^\ell$ and is asked whether there exists a function $f : S \mapsto V$ so that for most sequences $(x_1, \ldots, x_\ell) \in S^\ell$,

$$F(x_1, \ldots, x_\ell) = (f(x_1), \ldots, f(x_\ell)).$$

Loosely speaking, we prove that querying F on a constant number of related random sequences suffices for testing a relaxation of the above.

LEMMA 1.1 (combinatorial consistency—simple case). *For every $\delta > 0$, there exist a constant $c = \mathrm{poly}(1/\delta)$ and a probabilistic oracle machine, T, which on input $(\ell, |S|)$ runs for $\mathrm{poly}(\ell \cdot \log |S|)$-time and makes at most c queries to an oracle $F : S^\ell \mapsto V^\ell$, such that*

- *If there exists a function $f : S \mapsto V$ such that $F(x_1, \ldots, x_\ell) = (f(x_1), \ldots, f(x_\ell))$, for all $(x_1, \ldots, x_\ell) \in S^\ell$, then T always accepts when given access to oracle F.*
- *If T accepts with probability at least $\frac{1}{2}$, when given access to oracle F, then there exists a function $f : S \mapsto V$ such that the sequences $F(x_1, \ldots, x_\ell)$ and $(f(x_1), \ldots, f(x_\ell))$ agree on at least $\ell - \sqrt{\ell}$ positions, for at least a $1-\delta$ fraction of all possible $(x_1, \ldots, x_\ell) \in S^\ell$.*

Specifically, the test examines the value of the function F on random pairs of sequences $((r_1, \ldots, r_\ell), (s_1, \ldots, s_\ell))$, where $r_i = s_i$ for $\sqrt{\ell}$ of the i's, and checks that the corresponding values (on these r_i's and s_i's) are indeed equal. For details, see section 4.

Unfortunately, this relatively simple consistency lemma does not suffice for the PCP applications. The reason being that, in that application, error reduction (see above) is done via randomness-efficient procedures such as pairwise-independent sequences (since we cannot afford to utilize $\ell \cdot \log_2 |S|$ random bits as above). Consequently, the function F is not defined on the entire set S^ℓ but rather on a very sparse subset, denoted $\mathbf{S}$. Thus, one is given access to a function $F : \mathbf{S} \mapsto V^\ell$ and is asked whether there exists a function $f : S \mapsto V$ so that for most sequences $(x_1, \ldots, x_\ell) \in \mathbf{S}$, the sequences $F(x_1, \ldots, x_\ell)$ and $(f(x_1), \ldots, f(x_\ell))$ agree on most (contiguous) subsequences of length $\sqrt{\ell}$. The main result of this paper is the following lemma.

Lemma 1.2 (combinatorial consistency—sparse case). *For every two of integers $s, \ell > 1$, there exists a set $\mathbf{S}_{s,\ell} \subset [s]^\ell$, where $[s] \overset{\text{def}}{=} \{1, \ldots, s\}$, so that the following holds:*

1. *For every $\delta > 0$, there exist a constant $c = \text{poly}(1/\delta)$ and a probabilistic oracle machine, T, which on input (ℓ, s) runs for $\text{poly}(\ell \cdot \log s)$-time and makes at most c queries to an oracle $F : \mathbf{S}_{s,\ell} \mapsto V^\ell$, such that*
   - *if there exists a function $f : [s] \mapsto V$ such that $F(x_1, \ldots, x_\ell) = (f(x_1), \ldots, f(x_\ell))$, for all $(x_1, \ldots, x_\ell) \in \mathbf{S}_{s,\ell}$, then T always accepts when given access to oracle F.*
   - *if T accepts with probability at least $\frac{1}{2}$, when given access to oracle F, then there exists a function $f : [s] \mapsto V$ such that for at least a $1 - \delta$ fraction of all possible $(x_1, \ldots, x_\ell) \in \mathbf{S}_{s,\ell}$ the sequences $F(x_1, \ldots, x_\ell)$ and $(f(x_1), \ldots, f(x_\ell))$ agree on at least a $1 - \delta$ fraction of the (contiguous) subsequences of length $\sqrt{\ell}$.*
2. *The individual elements in a uniformly selected sequence in $\mathbf{S}_{s,\ell}$ are uniformly distributed in $[s]$ and are pairwise-independent. Furthermore, the set $\mathbf{S}_{s,\ell}$ has cardinality $\text{poly}(s)$ and can be constructed in $\text{poly}(s, \ell)$-time.*

Specifically, the test examines the value of the function F on related random pairs of sequences $((r_1, \ldots, r_\ell), (s_1, \ldots, s_\ell)) \in \mathbf{S}_{s,\ell}$. These sequences are viewed as $\sqrt{\ell} \times \sqrt{\ell}$ matrices, and, loosely speaking, they are chosen to be random extensions of the same random row (or column). For details, see section 2.

In particular, the presentation in section 2 axiomatizes properties of the set of sequences, $\mathbf{S}_{s,\ell}$, for which the above tester works. Thus, we provide a "parallel repetition theorem" which holds for random but nonindependent instances (rather than for independent random instances as in other such results). However, our parallel repetition theorem applies only to the case where a single query is asked in the basic system (rather than a pair of related queries as in other results). Due to this limitation, we could not apply our parallel repetition theorem directly to the error-reduction of generic proof systems. Instead, as explained below, we applied our parallel repetition theorem to derive a relatively strong low-degree test from a weaker low-degree test.

We believe that the combinatorial consistency lemma of section 2 may play a role in subsequent developments in the area.

1.2. Application to the PCP characterization theorem. The currently known proof of the PCP characterization theorem [ALMSS] composes proof systems in which the verifier makes a constant number of multivalued queries. Such verifiers are constructed by "parallelization" of simpler verifiers, and thus the problem of "consistency" arises. This problem is solved by use of low-degree multivariant polynomials, which in turn requires "high-quality" low-degree testers. Specifically, given a function

$f : \mathrm{GF}(p)^n \mapsto \mathrm{GF}(p)$, where p is prime, one needs to test whether f is close to some low-degree polynomial (in n variables over the finite field $\mathrm{GF}(p)$). It is required that any function f which disagrees with every d-degree polynomial on at least, say, 1% of the inputs be rejected with, say, a probability of 99%. The test is allowed to use auxiliary proof oracles (in addition to f), but it may only make a *constant* number of queries and the answers must have length bounded by $\mathrm{poly}(n, d, \log p)$. Using a technical lemma due to Arora and Safra [AS], Arora et al. [ALMSS] proved such a result.[1] The full proof is quite complex and is algebraic in nature. A weaker result due to Gemmel et al. [GLRSW] (see [RS96]) asserts the existence of a d-degree test which, using $d+2$ queries, rejects such bad functions with probability at least $\Omega(1/d^2)$. Their proof is much simpler. Combining the result of Gemmel et al. [GLRSW, RS96] with our combinatorial consistency lemma (i.e., Lemma 1.2), we obtain an alternative proof of the following result.

LEMMA 1.3 (low-degree tester). *For every $\delta > 0$, there exist a constant c and a probabilistic oracle machine, T, which on input n, p, d runs for $\mathrm{poly}(n, d, \log p)$-time and makes at most c queries to both f and to an auxiliary oracle F, such that*

- *if f is a degree-d polynomial, then there exists a function F so that T always accepts.*
- *if T accepts with probability at least $\frac{1}{2}$, when given access to the oracles f and F, then f agrees with some degree-d polynomial on at least a $1 - O(1/d^2)$ fraction of the domain.*[2]

Furthermore, the test uses $O(n \log p)$ coin tosses, and makes queries of length $O(n \log p)$.

We stress that in contrast to [ALMSS] our proof of the above lemma is mainly combinatorial. Our only reference to algebra is in relying on the result of Gemmel et al. [GLRSW, RS96] (which is weaker and has a simpler proof than that of [ALMSS]). Our tester works by performing many (pairwise-independent) instances of the [GLRSW] test in parallel and by guaranteeing the consistency of the answers obtained in these tests via our combinatorial consistency test (i.e., of Lemma 1.2). In contrast, prior to our work the only way to guarantee the consistency of these answers resulted in the need to perform a low-degree test of the type asserted in Lemma 1.3 (and using [ALMSS], which was the only alternative known; this meant losing the advantage of utilizing a low-degree test with a simpler algebraic analysis).

1.3. Related work. We refrain from an attempt to provide an account of the developments which have culminated in the PCP characterization theorem. Works which should certainly be mentioned include [GMR, BGKW, FRS, LFKN, Sha, BFL, BFLS, FGLSS, AS, ALMSS] as well as [BF, BLR, LS, RS92]. For detailed accounts, see surveys by Babai [B94] and Goldreich [G97].

This paper reports work completed in the Spring of 1994 and announced at the *Weizmann Institute Workshop on Randomness and Computation* (January 1995). Hastad's recent work [H96] contains a combinatorial consistency lemma which is related to our Lemma 1.1 (i.e., the "simple case" lemma). However, Hastad's lemma (which is harder to establish) refers to the case where the test accepts with very low probability (i.e., a weaker hypothesis) and guarantees the existence of a small set of "piecewise-consistent" assignments (i.e., a weaker conclusion). Raz and Safra [RaSa] claim to have been inspired by our Lemma 1.2 (i.e., the "sparse case" lemma).

[1] An improved analysis was later obtained by Friedl and Sudan [FS].

[2] Actually, [ALMSS] only prove agreement on an (arbitrarily large) constant fraction of the domain.

1.4. Organization. The (basic) sparse case consistency lemma is presented in section 2. The application to the PCP characterization theorem is presented in section 3. Section 4 contains a proof of Lemma 1.1 (which refers to sequences of totally independent random points).

2. The consistency lemma (for the sparse case).

In this section we present our main result—a combinatorial consistency lemma which refers to sequences of bounded independence. Specifically, we considered k^2-long sequences viewed as k-by-k matrices. To emphasize the combinatorial nature of our lemma and its proof, we adopt an abstract presentation in which the properties required from the set of matrices are explicitly stated (as axioms). We comment that the set of all k-by-k matrices over S satisfies these axioms. A more important case is given in Construction 2.2— it is based on a standard construction of pairwise-independent sequences (i.e., the matrix is a pairwise-independent sequence of rows, where each row is a pairwise-independent sequence of elements).

General notation. For a positive integer k, let $[k] \stackrel{\text{def}}{=} \{1, \ldots, k\}$. For a finite set A, the notation $a \in_{\mathrm{R}} A$ means that a is uniformly selected in A. In case A is a multiset, each element is selected with probability proportional to its multiplicity.

2.1. The setting. Let S be some finite set, and let k be an integer. Though both S and k are parameters, they will be implicit in all subsequent notations.

Rows and columns. Let $\mathbf{R}$ be a multiset of sequences of length k over S so that every $e \in S$ appears in some sequence of $\mathbf{R}$. For the sake of simplicity, think of $\mathbf{R}$ as being a set (i.e., each sequence appears with multiplicity 1). Similarly, let $\mathbf{C}$ be another set of sequences (of length k over S). We neither assume $\mathbf{R} = \mathbf{C}$ nor $\mathbf{R} \neq \mathbf{C}$. We consider matrices having rows in $\mathbf{R}$ and columns in $\mathbf{C}$ (thus, we call the members of $\mathbf{R}$ row-sequences, and those in $\mathbf{C}$ column-sequences). We denote by $\mathbf{M}$ a multiset of k-by-k matrices with rows in $\mathbf{R}$ and columns in $\mathbf{C}$.

AXIOM 1. *For every $m \in \mathbf{M}$ and $i \in [k]$, the* ith *row of m is an element of $\mathbf{R}$ and the* ith *column of m is an element of $\mathbf{C}$.*

For every $i \in [k]$ and $\bar{r} \in \mathbf{R}$, we denote by $\mathbf{M}_i(\bar{r})$ the set of matrices (in $\mathbf{M}$) having $\bar{r}$ as the ith row. Similarly, for $j \in [k]$ and $\bar{c} \in \mathbf{C}$, we denote by $\mathbf{M}^j(\bar{c})$ the set of matrices (in $\mathbf{M}$) having $\bar{c}$ as the jth column. For every $\bar{r} = (r_1, \ldots, r_k) \in \mathbf{R}$ and every $\bar{c} = (c_1, \ldots, c_k) \in \mathbf{C}$, so that $r_j = c_i$, we denote by $\mathbf{M}_i^j(\bar{r}, \bar{c})$ the set of matrices having $\bar{r}$ as the ith row and $\bar{c}$ as the jth column (i.e., $\mathbf{M}_i^j(\bar{r}, \bar{c}) = \mathbf{M}_i(\bar{r}) \cap \mathbf{M}^j(\bar{c})$).

Shifts. We assume that $\mathbf{R}$ is "closed" under the shift operator.

AXIOM 2. *For every $\bar{r} = (r_1, \ldots, r_k) \in \mathbf{R}$ there exists a unique $\bar{s} = (s_1, \ldots, s_k) \in \mathbf{R}$ satisfying $s_i = r_{i-1}$, for every $2 \leq i \leq k$. We denote this right-shifted sequence by $\sigma(\bar{r})$. Similarly, we assume that there exists a unique $\bar{s} = (s_1, \ldots, s_k) \in \mathbf{R}$ satisfying $s_i = r_{i+1}$, for every $1 \leq i \leq k-1$. We denote this left-shifted sequence by $\sigma^{-1}(\bar{r})$. Furthermore,*[3] *we assume that shifting each of the rows of a matrix $m \in \mathbf{M}$ to the same direction yields a matrix m' that is also in $\mathbf{M}$.*

Axiom 2 implies that if $\bar{r}$ is uniformly distributed in $\mathbf{R}$, then so is $\sigma(\bar{r})$ (resp., $\sigma^{-1}(\bar{r})$). For every (nonnegative) integer i, the notations $\sigma^i(\bar{r})$ and $\sigma^{-i}(\bar{r})$ are defined in the natural way (e.g., $\sigma^i(\bar{r}) = \sigma^{i-1}(\sigma(\bar{r}))$ and $\sigma^0(\bar{r}) = \bar{r}$). Note that we do not assume that $\mathbf{C}$ is closed under shifts (in an analogous manner).

[3] The extra axiom is not really necessary; see the remark following the definition of the consistency test.

Distribution. We now turn to axioms concerning the distribution of rows and columns in a uniformly chosen matrix. We assume that the rows (and columns) of a uniformly chosen matrix are uniformly distributed in $\mathbf{R}$ (and $\mathbf{C}$, respectively).[4] In addition, we assume that the rows (but not necessarily the columns) are also pairwise-independent.

AXIOM 3. *Let m be uniformly selected in $\mathbf{M}$. Then,*

1. *For every $i \in [k]$, the* ith *column of m is uniformly distributed in $\mathbf{C}$.*
2. *For every $i \in [k]$, the* ith *row of m is uniformly distributed in $\mathbf{R}$.*
3. *Furthermore, for every $j \neq i$ and $\bar{r} \in \mathbf{R}$, conditioned that the* ith *row of m equals $\bar{r}$, the* jth *row of m is uniformly distributed over $\mathbf{R}$.*

Finally, we assume that the columns in a uniformly chosen matrix containing a specific row-sequence are distributed identically to uniformly selected columns with the corresponding entry.

AXIOM 4. *For every $i, j \in [k]$ and $\bar{r} = (r_1, \ldots, r_k) \in \mathbf{R}$, the* jth *column in a matrix that is uniformly selected among those having $\bar{r}$ as its* ith *row* (*i.e., $m \in_{\mathrm{R}} \mathbf{M}_i(\bar{r})$*) *is uniformly distributed among the column-sequences that have r_j as their* ith *element.*

Clearly, if the jth element of $\bar{r} = (r_1, \ldots, r_k)$ differs from the ith element of $\bar{c} = (c_1, \ldots, c_k)$, then $\mathbf{M}_i^j(\bar{r}, \bar{c})$ is empty. Otherwise (i.e., $r_j = c_i$), by the above axiom, $\mathbf{M}_i^j(\bar{r}, \bar{c})$ is not empty. Furthermore, the above axiom implies that (in case $r_j = c_i$) for a uniformly chosen $m \in \mathbf{M}$

$$\begin{aligned}\mathrm{Prob}(m \in \mathbf{M}_i^j(\bar{r}, \bar{c})) &= \mathrm{Prob}(m \in \mathbf{M}_i(\bar{r})) \cdot \mathrm{Prob}(m \in \mathbf{M}^j(\bar{c}) \mid m \in \mathbf{M}_i(\bar{r})) \\ &= \frac{1}{|\mathbf{R}|} \cdot \frac{1}{|C_i(r_j)|} > 0,\end{aligned}$$

where $C_i(e)$ denotes the set of column-sequences having e as their ith element, and the second equality is obtained by Axiom 4.

2.2. The test. Let Γ be a function assigning matrices in $\mathbf{M}$ (which may be a proper subset of all possible k-by-k matrices over S) values which are k-by-k matrices over some set of values V (i.e., $\Gamma : \mathbf{M} \mapsto V^{k \times k}$). The function Γ is *supposed* to be "consistent" (i.e., assign each element, e, of S the same value, independently of the matrix in which e appears). The purpose of the following test is to check that this property holds in some approximate sense.

CONSTRUCTION 2.1 (consistency test).

1. Column test. *Select a column-sequence $\bar{c}$ uniformly in $\mathbf{C}$, and $i, j \in_{\mathrm{R}} [k]$. Select two random extensions of this column, namely, $m_1 \in_{\mathrm{R}} \mathbf{M}^i(\bar{c})$ and $m_2 \in_{\mathrm{R}} \mathbf{M}^j(\bar{c})$, and test if the* ith *column of $\Gamma(m_1)$ equals the* jth *column of $\Gamma(m_2)$.*
2. Row test (analogous to the column test). *Select a row-sequence $\bar{r}$ uniformly in $\mathbf{R}$, and $i, j \in_{\mathrm{R}} [k]$. Select two random extensions of this row, namely, $m_1 \in_{\mathrm{R}} \mathbf{M}_i(\bar{r})$ and $m_2 \in_{\mathrm{R}} \mathbf{M}_j(\bar{r})$, and test if the* ith *row of $\Gamma(m_1)$ equals the* jth *row of $\Gamma(m_2)$.*
3. Shift test. *Select a matrix m uniformly in $\mathbf{M}$ and an integer $t \in [k-1]$. Let m' be the matrix obtained from m by shifting each row by t; namely, the* ith *row of m' is $\sigma^t(\bar{r})$, where $\bar{r}$ denotes the* ith *row of m. We test if the $k - t$ first columns of $\Gamma(m)$ match the $k - t$ last columns of $\Gamma(m')$.*

[4] This, in fact, implies Axiom 1.

The test accepts *if all three* (sub)tests *succeed.*

Remark. Actually, it suffices to use a seemingly weaker test in which the row-test and shift-test are combined into the following *generalized row-test*:

> Select a row-sequence $\bar{r}$ uniformly in $\mathbf{R}$, integers $i, j \in_{\mathrm{R}} [k]$ and $t \in_{\mathrm{R}} \{0, 1, \ldots, k-1\}$. Select a random extension of this row and its shift; namely, $m_1 \in_{\mathrm{R}} \mathbf{M}_i(\bar{r})$ and $m_2 \in_{\mathrm{R}} \mathbf{M}_j(\sigma^t(\bar{r}))$, and test if the $(k-t)$-long suffix of the ith row of $\Gamma(m_1)$ equals the $(k-t)$-long prefix of the jth row of $\Gamma(m_2)$.

Our main result asserts that Construction 2.1 is a "good consistency test": If it accepts Γ with high probability, then not only ALMOST ALL ENTRIES *in almost all matrices* are assigned in a consistent manner (which is obvious), but ALL ENTRIES IN ALMOST ALL ROWS *of almost all matrices* are assigned in a consistent manner.

LEMMA 2.1. *Suppose* $\mathbf{M}$ *satisfies Axioms* 1–4. *Then, for every constant* $\delta > 0$, *there exists a constant* $\epsilon > 0$ *so that if a function* $\Gamma : \mathbf{M} \mapsto V^{k \times k}$ *passes the consistency test with probability at least* $1 - \epsilon$, *then there exists a function* $\tau : S \mapsto V$ *so that, with probability at least* $1 - \delta$, *the value assigned by* Γ *to a uniformly chosen matrix matches the values assigned by* τ *to the elements of a uniformly chosen row in this matrix. Namely,*

$$\mathrm{Prob}_{i,m}(\forall j \;:\; \Gamma(m)_{i,j} = \tau(m_{i,j})) \;\; \geq \;\; 1 - \delta,$$

where $m \in_{\mathrm{R}} \mathbf{M}$ *and* $i \in_{\mathrm{R}} [k]$. *The constant* ϵ *does not depend on* k *and* S. *Furthermore, it is polynomially related to* δ.

As a corollary, we get part 1.1 of Lemma 1.2. Part 1.2 follows from Proposition 2.2 (below).

2.3. Proof of Lemma 2.1. As a motivation towards the proof of Lemma 2.1, consider the following mental experiment. Let $m \in \mathbf{M}$ be an arbitrary matrix and e be its (i, j)th entry. First, uniformly select a random matrix, denoted m_1, containing the ith row of m. Next, uniformly select a random matrix, denoted m_2, containing the jth column of m_1. One can show that m_2 is uniformly distributed among the matrices containing the element e. Thus, if Γ passes steps 1 and 2 in the consistency test, then it must assign consistent values to almost all elements in almost all matrices. Yet, this falls short of even proving that there exists an assignment which matches all values assigned to the elements of some row in some matrix. Indeed, consider a function Γ which assigns 0 to all elements in the first ϵk columns of each matrix and 1's to all other elements. Clearly, Γ passes the row-test with probability 1 and the column-test with probability greater than $1 - \epsilon$; yet, there is no $\tau : S \mapsto V$ so that for a random matrix the values assigned by Γ to some row match τ. It is easy to see that the shift-test takes care of this special counterexample. Furthermore, it may be telling to see what is wrong with some naive arguments. A main issue these arguments tend to ignore is that for an "adversarial" choice of Γ and a candidate choice of $\tau : S \mapsto V$, we have no handle on the (column) *location* of the elements in a random matrix on which τ disagrees with Γ. The shift-test plays a central role in circumventing this problem; see subsection 2.3.2 and Claim 2.1.14 (below).

Recommendation. The reader may want to skip the proofs of all claims on the first reading. We believe that all the claims are quite believable and that their proofs (though slightly tedious in some cases) are quite straightforward. In contrast, we believe that the ideas underlying the proof of the lemma are to be found in its high level structure; namely, the definitions and the claims made.

Notation. The following notation will be used extensively throughout the proof. For a k-by-k matrix, m, we denote by $\mathrm{row}_i(m)$ the ith row of m and by $\mathrm{col}^j(m)$ the jth column of m. Restating the conditions of the lemma, we have (from the hypothesis that Γ passes the column test)

$$\mathrm{Prob}_{\bar{c},i,j,m_1,m_2}(\mathrm{col}^i(\Gamma(m_1))=\mathrm{col}^j(\Gamma(m_2))) \geq 1-\epsilon, \tag{2.1}$$

where $\bar{c}, i, j, m_1,$ and m_2 are uniformly selected in the corresponding sets (i.e., $\bar{c}\in\mathbf{C}$, $i,j\in[k]$, $m_1 \in \mathbf{M}^i(\bar{c})$, and $m_2 \in \mathbf{M}^j(\bar{c})$). Similarly, from the hypothesis that Γ passes the row test, we have

$$\mathrm{Prob}_{\bar{r},i,j,m_1,m_2}(\mathrm{row}_i(\Gamma(m_1)) = \mathrm{row}_j(\Gamma(m_2))) \geq 1-\epsilon, \tag{2.2}$$

where $\bar{r} \in_{\mathrm{R}} \mathbf{R}$, $i, j \in_{\mathrm{R}} [k]$, $m_1 \in_{\mathrm{R}} \mathbf{M}_i(\bar{r})$, and $m_2 \in_{\mathrm{R}} \mathbf{M}_j(\bar{r})$. It will be convenient to extend the shift notation to matrices in the obvious manner; namely, $\sigma^t(m)$ is defined as the matrix m' satisfying $\mathrm{row}_i(m') = \sigma^t(\mathrm{row}_i(m))$ for every $i \in [k]$. From the hypothesis that Γ passes the shift-test, we obtain

$$\mathrm{Prob}_{m,t}(\forall j \leq k-t \quad \mathrm{col}^j(\Gamma(m)) = \mathrm{col}^{j+t}(\Gamma(\sigma^t(m)))) \geq 1-\epsilon, \tag{2.3}$$

where $m \in_{\mathrm{R}} \mathbf{M}$ and $t \in_{\mathrm{R}} [k-1]$. Finally, denoting by $\mathrm{entry}_{i,j}(m)$ the (i, j)th entry in the matrix m, we restate the conclusion of the lemma as follows:

$$\mathrm{Prob}_{i,m}(\exists j \text{ so that } \mathrm{entry}_{i,j}(\Gamma(m)) \neq \tau(\mathrm{entry}_{i,j}(m))) \leq \delta, \tag{2.4}$$

where $m \in_{\mathrm{R}} \mathbf{M}$ and $i \in_{\mathrm{R}} [k]$.

2.3.1. Stable rows and columns – part 1. For each $\bar{r} \in \mathbf{R}$ and $\bar{\alpha} \in V^k$, we denote by $p_{\bar{r}}(\bar{\alpha})$ the probability that Γ assigns to the row-sequence $\bar{r}$ the value-sequence $\bar{\alpha}$; namely,

$$p_{\bar{r}}(\bar{\alpha}) \overset{\mathrm{def}}{=} \mathrm{Prob}_{i,m}(\mathrm{row}_i(\Gamma(m)) = \bar{\alpha}),$$

where $i \in_{\mathrm{R}} [k]$ and $m \in_{\mathrm{R}} \mathbf{M}_i(\bar{r})$. Equation (2.2) implies that for almost all row-sequences there is a "typical" sequence of values; see Claim 2.1.3 (below).

DEFINITION 2.1.1 (consensus). *The* consensus *of a row-sequence $\bar{r} \in \mathbf{R}$, denoted* $\mathrm{con}(\bar{r})$, *is defined as the value $\bar{\alpha}$ for which $p_{\bar{r}}(\bar{\alpha})$ is maximum. Namely, $\mathrm{con}(\bar{r}) = \bar{\alpha}$ if $\bar{\alpha}$ is the (lexicographically first) value-sequence for which $p_{\bar{r}}(\bar{\alpha}) = \max_{\bar{\beta}}\{p_{\bar{r}}(\bar{\beta})\}$.*

DEFINITION 2.1.2 (stable sequences). *Let $\epsilon_2 \overset{\mathrm{def}}{=} \sqrt{\epsilon}$. We say that the row-sequence $\bar{r}$ is* stable *if $p_{\bar{r}}(\mathrm{con}(\bar{r})) \geq 1-\epsilon_2$. Otherwise, we say that $\bar{r}$ is* unstable.

Clearly, almost all row-sequences are stable.

CLAIM 2.1.3. *All but at most an ϵ_2 fraction of the row-sequence are stable.*

Proof. For each fixed $\bar{r}$ we have

$$\mathrm{Prob}_{i,j,m_1,m_2}(\mathrm{row}_i(\Gamma(m_1))=\mathrm{row}_j(\Gamma(m_2))) = \sum_{\bar{\alpha}} p_{\bar{r}}(\bar{\alpha})^2,$$

where $i, j \in_{\mathrm{R}} [k]$, $m_1 \in_{\mathrm{R}} \mathbf{M}_i(\bar{r})$, and $m_2 \in_{\mathrm{R}} \mathbf{M}_j(\bar{r})$. Taking the expectation over $\bar{r} \in_{\mathrm{R}} \mathbf{R}$, and using (2.2), we get

$$\begin{aligned} 1-\epsilon &\leq \mathrm{Prob}_{\bar{r},i,j,m_1,m_2}(\mathrm{row}_i(\Gamma(m_1)) = \mathrm{row}_j(\Gamma(m_2))) \\ &= \mathrm{Exp}_{\bar{r}}\left(\sum_{\bar{\alpha}} p_{\bar{r}}(\bar{\alpha})^2\right) \\ &\leq \mathrm{Exp}_{\bar{r}}(p_{\bar{r}}^{\max}), \end{aligned}$$

where $p_{\bar{r}}^{\max} \overset{\text{def}}{=} \max_{\bar{\alpha}}\{p_{\bar{r}}(\bar{\alpha})\}$. Using the Markov inequality, we get

$$\text{Prob}_{\bar{r}}(p_{\bar{r}}^{\max} \le 1 - \sqrt{\epsilon}) < \sqrt{\epsilon}$$

and the claim follows. □

By definition, almost all matrices containing a particular *stable* row-sequence assign this row-sequence the same sequence of values (i.e., its consensus value). We say that such matrices are conforming for this row-sequence.

Definition 2.1.4 (conforming matrix). *Let $i \in [k]$. A matrix $m \in \mathbf{M}$ is called* i-conforming (or conforming for row-position i) *if Γ assigns the* ith *row of m its consensus value; namely, if* $\text{row}_i(\Gamma(m)) = \text{con}(\text{row}_i(m))$. *Otherwise, the matrix is called* i-nonconforming (or nonconforming for row-position i).

Claim 2.1.5. *The probability that for a uniformly chosen $i \in [k]$ and $m \in \mathbf{M}$, the matrix m is i-nonconforming is at most $\epsilon_3 \overset{\text{def}}{=} 2\epsilon_2$. Furthermore, the bound holds also if we require that the* ith *row of m is stable.*

Proof. The stronger bound (on probability) equals the sum of the probabilities of the following two events. The first event is that the ith row of the matrix is unstable; whereas the second event is that the ith row of the matrix is stable and yet the matrix is i-nonconforming. To bound the probability of the first event (by ϵ_2), we fix any $i \in [k]$ and combine Axiom 3 with Claim 2.1.3. To bound the probability of the second event, we fix any stable $\bar{r}$ and use the definition of a stable row. □

Remark. Clearly, an analogous treatment can be applied to column-sequences. In the following, we freely refer to the above notions and to the above claims also when discussing column-sequences.

2.3.2. Stable rows – part 2 (shifts). Now we consider the relation between the consensus of row-sequences and the consensus of their (short) shifts. By a short shift of the row-sequence $\bar{r}$, we mean any row-sequence $\bar{s} = \sigma^d(\bar{r})$ obtained with $d \in \{-(k-1), \dots, +(k-1)\}$. Our aim is to show that the consensus (as well as stability) is usually preserved under short shifts.

Definition 2.1.6 (very-stable row). *Let $\epsilon_4 = \sqrt{\epsilon_2}$. We say that a row-sequence $\bar{r}$ is* very-stable *if it is stable, and for all but an ϵ_4 fraction of $d \in \{-(k-1), \dots, +(k-1)\}$, the row-sequence $\bar{s} \overset{\text{def}}{=} \sigma^d(\bar{r})$ is also stable.*

Claim 2.1.7. *All but at most an ϵ_4 fraction of the row-sequence are very-stable.*

Proof. By a simple counting argument (using the fact that the uniform distribution over $\mathbf{R}$ is preserved under shifts). □

Definition 2.1.8 (superstable row). *Let $\epsilon_5 = \sqrt[3]{\epsilon}$ and $\epsilon_6 = 2(\epsilon_4 + \epsilon_5)$. We say that a row-sequence $\bar{r}$ is* superstable *if it is very-stable, and, for every $j \in [k]$, the following holds: for all but an ϵ_6 fraction of the $t \in [k]$, the row-sequence $\bar{s} \overset{\text{def}}{=} \sigma^{t-j}(\bar{r})$ is stable and* $\text{con}_j(\bar{r}) = \text{con}_t(\bar{s})$, *where* $\text{con}_i(\bar{r})$ *is the* ith *element of* $\text{con}(\bar{r})$.

Note that the tth element of $\sigma^{t-j}(\bar{r})$ is $r_{t-(t-j)} = r_j$. Thus, a row-sequence is superstable if the consensus value of each of its elements is preserved under almost all (short) shifts.

Claim 2.1.9. *All but at most an ϵ_6 fraction of the row-sequence are superstable.*

Proof. We start by proving that almost all row-sequences and almost all of their shifts have approximately matching statistics, where the *statistics vector* of $\bar{r} \in \mathbf{R}$ is defined as the k-long sequence (of functions), $p_{\bar{r}}^1(\cdot), \dots, p_{\bar{r}}^k(\cdot)$, so that $p_{\bar{r}}^j(v)$ is the probability that Γ assigns the value v to the jth element of the row $\bar{r}$. Namely,

$$p_{\bar{r}}^j(v) \overset{\text{def}}{=} \text{Prob}_{i,m}(\text{entry}_{i,j}(\Gamma(m)) = v),$$

where $i \in_{\mathrm{R}} [k]$ and $m \in_{\mathrm{R}} \mathbf{M}_i(\bar{r})$. By the definition of consensus, we know that for every stable row-sequence $\bar{r} \in \mathbf{R}$, we have $p^j_{\bar{r}}(\mathrm{con}_j(\bar{r})) \geq 1 - \epsilon_2$, for every $j \in [k]$. Thus, if both $\bar{r}$ and its shift $\bar{s} = \sigma^t(\bar{r})$ are stable and have approximately matching statistics (i.e., the corresponding $(k-t)$-long statistics subvectors are close), then their consensus must match (i.e., the corresponding $(k-t)$-long subsequences of the consensus are equal).

Subclaim 2.1.9.1. For all but an ϵ_5 fraction of the row-sequences $\bar{r}$, all but an ϵ_5 fraction of the values $d \in [k-1]$ satisfy

$$\sum_v |p^j_{\bar{r}}(v) - p^{j+d}_{\sigma^d(\bar{r})}(v)| < 2\epsilon_5 \quad \text{for every } j \leq k - d.$$

Proof of subclaim. Let *pref*$\mathrm{row}_{i,j}(m)$ denote the j-long prefix of $\mathrm{row}_i(m)$ and *suff*$\mathrm{row}_{i,j}(m)$ its j-long suffix. By the shift-test (see (2.3) and recall $\epsilon = \epsilon_5^3$)

$$\mathrm{Prob}_{m,i,d}(\mathit{pref}\mathrm{row}_{i,k-d}(\Gamma(m)) = \mathit{suff}\mathrm{row}_{i,k-d}(\Gamma(m'))) \geq 1 - \epsilon_5^3,$$

where $i \in_{\mathrm{R}} [k]$, $m \in_{\mathrm{R}} \mathbf{M}$, $d \in_{\mathrm{R}} [k-1]$, and $m' = \sigma^d(m)$. Using Axiom 3 (part 2) and an averaging argument, we get that for all but an ϵ_5 fraction of the $\bar{r} \in \mathbf{R}$, and for all but an ϵ_5 fraction of $d \in [k-1]$,

$$\mathrm{Prob}_{i,m}(\mathit{pref}\mathrm{row}_{i,k-d}(\Gamma(m)) = \mathit{suff}\mathrm{row}_{i,k-d}(\Gamma(m'))) \geq 1 - \epsilon_5, \tag{2.5}$$

where $i \in_{\mathrm{R}} [k]$, $m \in_{\mathrm{R}} \mathbf{M}_i(\bar{r})$, and $m' = \sigma^d(m)$. We fix a pair $\bar{r}$ and d satisfying (2.5), thus fixing also $\bar{s} = \sigma^d(\bar{r})$. A matrix pair (m, m') for which the equality *pref*$\mathrm{row}_{i,k-d}(\Gamma(m)) =$ *suff*$\mathrm{row}_{i,k-d}(\Gamma(m'))$ holds contributes equally to the (appropriate $(k-d)$-long portion of) statistic vectors of the row-sequences $\bar{r}$ and $\bar{s}$. The contribution of a matrix pair, for which the equality does not hold for the difference $\sum_v |p^j_{\bar{r}}(v) - p^{j+d}_{\bar{s}}(v)|$, is at most $\frac{2}{k \cdot |\mathbf{M}_i(\bar{r})|}$ per each relevant j. Thus, the total difference for such $\bar{r}$ and $\bar{s}$ (i.e., satisfying (2.5)) is at most $2\epsilon_5$. The subclaim follows. □

As a corollary we get the following.

Subclaim 2.1.9.2. Let us call a row-sequence, $\bar{r}$, *infective* if for every $j \in [k]$ all but an $2\epsilon_5$ fraction of the $t \in [k]$ satisfy $\sum_v |p^j_{\bar{r}}(v) - p^t_{\bar{s}}(v)| \leq 2\epsilon_5$, where $\bar{s} = \sigma^{t-j}(\bar{r})$. Then, all but a $2\epsilon_5$ fraction of the row-sequences are infective.

Proof of subclaim. We say that $\bar{r}$ is *rightwards-fine* if for all but an ϵ_5 fraction of the $d \in [k]$ and for every $j \leq k - d$, we have $\sum_v |p^j_{\bar{r}}(v) - p^{j+d}_{\sigma^d(\bar{r})}(v)| \leq 2\epsilon_5$. (Indeed, Subclaim 2.1.9.1 asserts that all but an ϵ_5 fraction of the row-sequences are rightwards-fine.) If $\bar{r}$ is rightwards-fine, then for every j there are at most $\epsilon_5 k$ positions $t \in \{j+1, \ldots, k\}$ so that $\sum_v |p^j_{\bar{r}}(v) - p^t_{\sigma^{t-j}(\bar{r})}(v)| > 2\epsilon_5$. Similarly, $\bar{r}$ is *leftwards-fine* if for all but an ϵ_5 fraction of the $d \in [k]$ and for every $j > d$, we have $\sum_v |p^j_{\bar{r}}(v) - p^{j-d}_{\sigma^{-d}(\bar{r})}(v)| \leq 2\epsilon_5$, and whenever $\bar{r}$ is leftwards-fine, then for every j there are at most $\epsilon_5 k$ positions $t \in \{1, \ldots, j-1\}$ so that $\sum_v |p^j_{\bar{r}}(v) - p^t_{\sigma^{t-j}(\bar{r})}(v)| > 2\epsilon_5$. Thus, if a row-sequence $\bar{r}$ is both rightwards-fine and leftwards-fine, then for every $j \in [k]$ all but a $2\epsilon_1$ fraction of the positions $t \in [k]$ satisfy $\sum_v |p^j_{\bar{r}}(v) - p^t_{\sigma^{t-j}(\bar{r})}(v)| \leq 2\epsilon_5$. Now, by Subclaim 2.1.9.1, all but an ϵ_5 fraction of the row-sequences are rightwards-fine. A similar statement holds for leftwards-fine (since the shift-test can be rewritten as selecting $m' \in_{\mathrm{R}} \mathbf{M}$ and $d \in_{\mathrm{R}} [k-1]$ and setting $m = \sigma^{-d}(m')$). Combining all these trivialities, the subclaim follows. □

Clearly, a row-sequence $\bar{r}$ that is both very-stable and infective satisfies, for every $j \in [k]$ and all but at most $\epsilon_4 \cdot (2k-1) + 2\epsilon_5 \cdot k$ of the $t \in [k]$, both

- $\bar{s} \overset{\text{def}}{=} \sigma^{t-j}(\bar{r})$ is stable; it follows that $p^t_{\bar{s}}(\text{con}_t(\bar{s})) \geq 1-\epsilon_2$ and $p^t_{\bar{s}}(u) \leq \epsilon_2$ for all $u \neq \text{con}_t(\bar{s})$.
- $p^t_{\bar{s}}(v) \geq p^j_{\bar{r}}(v) - 2\epsilon_5$, for every v and in particular for $v = \text{con}_j(\bar{r})$.

It follows that $p^t_{\bar{s}}(\text{con}_j(\bar{r})) \geq p^j_{\bar{r}}(\text{con}_j(\bar{r})) - 2\epsilon_5 \geq 1-\epsilon_2-2\epsilon_5$ which (for sufficiently small ϵ) is strictly greater than ϵ_2, and therefore $\text{con}_j(\bar{r}) = \text{con}_t(\bar{s})$ must hold. Thus, such an $\bar{r}$ is superstable. Combining the lower bounds on the fractions of very-stable and infective row-sequences (given by Claim 2.1.7 and Subclaim 2.1.9.2, respectively), the current claim follows. (Actually, we get a better bound; i.e., $\epsilon_4 + 2\epsilon_5$.) □

Summary. Before proceeding let us summarize our state of knowledge. The key definitions regarding row-sequences are of stable, very-stable, and superstable row-sequences (i.e., Definitions 2.1.2, 2.1.6, and 2.1.8, respectively). Recall that a stable row-sequence is assigned the same value in almost all matrices in which it appears. Furthermore, most prefixes (resp., suffices) of a superstable row-sequence are assigned the same values in almost all matrices containing these portions (as part of some row). Regarding matrices, we defined a matrix to be i-conforming if it assigns its ith row the corresponding consensus value (i.e., it conforms with the consensus of that row-sequence); cf. Definitions 2.1.4 and 2.1.1. We have seen that almost all row-sequences are superstable and that almost all matrices are conforming for most of their rows. Actually, we will use the latter fact with respect to columns; that is, almost all matrices are conforming for most columns (cf. Claim 2.1.5 and the remark following it).

2.3.3. Deriving the conclusion of the lemma. We are now ready to derive the conclusion of the lemma. Loosely speaking, we claim that the function τ, defined so that $\tau(e)$ is the value most frequently assigned (by Γ) to e, satisfies (2.4). Actually, we use a slightly different definition for the function τ.

DEFINITIONS 2.1.10 (the function τ). *For a column-sequence $\bar{c}$, we denote by $\text{con}_i(\bar{c})$ the values that $\text{con}(\bar{c})$ assigns to the i*th *element in $\bar{c}$. We denote by $\mathbf{C}_i(e)$ the set of column-sequences having e as the i*th *component. Let $q_e(v)$ denote the probability that the consensus of a uniformly chosen column-sequence, containing e, assigns to e the value v. Namely,*

$$q_e(v) \overset{\text{def}}{=} \text{Prob}_{i,\bar{c}}(\text{con}_i(\bar{c})=v),$$

where $i \in_{\text{R}} [k]$ and $\bar{c} \in_{\text{R}} \mathbf{C}_i(e)$. We consider $\tau : S \mapsto V$ so that $\tau(e) \overset{\text{def}}{=} v$ if $q_e(v) = \max_u\{q_e(u)\}$, with ties broken arbitrarily.

Assume, contrary to our claim, that (2.4) does not hold (for this τ). Namely, for a uniformly chosen $m \in \mathbf{M}$ and $i \in [k]$, the following holds with probability greater that δ

$$\exists j \text{ so that } \text{entry}_{i,j}(\Gamma(m)) \neq \tau(\text{entry}_{i,j}(m)). \tag{2.6}$$

The notion of an annoying row-sequence, defined below, plays a central role in our argument. Using the above (contradiction) hypothesis, we first show that many row-sequences are annoying. Next, we show that lower bounds on the number of annoying row-sequences translate to lower bounds on the probability that a uniformly chosen matrix is nonconforming for a uniformly chosen column position. This yields a contradiction to Claim 2.1.5.

DEFINITIONS 2.1.11 (row-annoying elements). *An element r_j in $\bar{r} = (r_1, \ldots, r_k) \in \mathbf{R}$, is said to be* annoying for the row-sequence $\bar{r}$ *if the* jth *element in* $\text{con}(\bar{r})$ *differs* *from $\tau(r_j)$. A row-sequence $\bar{r}$ is said to be* annoying *if $\bar{r}$ contains an element that is annoying for it.*

Using Claim 2.1.9, we get the following claim.

CLAIM 2.1.12. *Suppose that* (2.4) *does not hold* (for τ). *Then, at least a $\delta_1 \stackrel{\text{def}}{=} \delta - \epsilon_6 - \epsilon_2$ fraction of the row-sequences are both superstable and annoying.*

Proof. Axiom 3 (part 2) is extensively used throughout this proof (with no explicit reference). Combining (2.6) and Claim 2.1.9, with probability at least $\delta - \epsilon_6 - \epsilon_2 = \delta_1$, a uniformly chosen pair $(m, i) \in \mathbf{M} \times [k]$ satisfies the following:

1. there exists a j so that $\tau(\text{entry}_{i,j}(m))$ is different from $\text{entry}_{i,j}(\Gamma(m))$;
2. $\text{row}_i(m)$ is superstable;
3. matrix m is i-conforming; i.e., $\text{entry}_{i,j}(\Gamma(m))$ equals $\text{con}_j(\text{row}_i(m))$, for every $j \in [k]$.

Combining conditions (1) and (3), we get that $e = \text{entry}_{i,j}(m)$ is annoying for the ith row of m. The current claim follows. □

A key observation is that each stable row-sequence which is annoying yields many matrices which are nonconforming for the "annoying column position" (i.e., for the column position containing the element which annoys this row-sequence).

CLAIM 2.1.13. *Suppose that a row-sequence $\bar{r} = (r_1, \ldots, r_k)$ is stable and that r_j is annoying for $\bar{r}$. Then at least a $\frac{1}{2} - \epsilon_2$ fraction of the matrices containing the row-sequence $\bar{r}$ are nonconforming for column-position j.*

We stress that the row-sequence $\bar{r}$ in the above claim is *not* necessarily very-stable (let alone superstable).

Proof. Let us denote by v the value assigned to r_j by the consensus of $\bar{r}$ (i.e., $v \stackrel{\text{def}}{=} \text{con}_j(\bar{r})$). Since r_j annoys $\bar{r}$ it follows that v is different from $\tau(r_j)$. Consider the probability space defined by uniformly selecting $i \in [k]$ and $m \in \mathbf{M}_i(\bar{r})$. Since $\bar{r}$ is stable it follows that in almost all of these matrices the value assigned to r_j by the matrix equals v. Namely,

$$\text{Prob}_{i,m}(\text{entry}_{i,j}(\Gamma(m)) = v)) \quad \geq \quad 1 - \epsilon_2, \tag{2.7}$$

where $i \in_{\text{R}} [k]$ and $m \in_{\text{R}} \mathbf{M}_i(\bar{r})$. By Axiom 4, the jth column of m is uniformly distributed in $\mathbf{C}_i(r_j)$, and thus we may replace $\bar{c} \in_{\text{R}} \mathbf{C}_i(r_j)$ by the jth column of $m \in_{\text{R}} \mathbf{M}_i(\bar{r})$. Now, using the definition of the function τ and the accompanying notations, we get

$$\text{Prob}_{i,m}(\text{con}_i(\text{col}^j(m)) = v) \quad = \quad q_{r_j}(v) \quad \leq \quad \frac{1}{2}\ , \tag{2.8}$$

where, again, $i \in_{\text{R}} [k]$ and $m \in_{\text{R}} \mathbf{M}_i(\bar{r})$. The inequality holds since $v \neq \tau(r_j)$ and by τ's definition $q_{r_j}(v) \leq q_{r_j}(\tau(r_j))$. Combining (2.7) and (2.8), we get

$$\begin{aligned}
&\text{Prob}_{i,m}(\text{entry}_{i,j}(\Gamma(m)) \neq \text{con}_i(\text{col}^j(m))) \\
&\qquad\qquad \geq \text{Prob}_{i,m}(\text{entry}_{i,j}(\Gamma(m)) = v \;\&\; \text{con}_i(\text{col}^j(m)) \neq v) \\
&\qquad\qquad \geq 1 - \epsilon_2 - \frac{1}{2} \;=\; \frac{1}{2} - \epsilon_2
\end{aligned}$$

and the claim follows. □

Another key observation is that superstable row-sequences which are annoying have the property of "infecting" almost all their shifts with their annoying positions, thus spreading the "annoyance" over all column positions.

CLAIM 2.1.14. *Suppose that a row-sequence $\bar{r}$ is both superstable and annoying. In particular, suppose that the jth element of $\bar{r} = (r_1, \ldots, r_k)$ is annoying for $\bar{r}$. Then, for all but at most an ϵ_6 fraction of the $t \in [k]$, the row-sequence $\bar{s} = \sigma^{t-j}(\bar{r})$ is stable and its tth element* (which is indeed r_j) *is annoying for $\bar{s}$.*

Proof. Since $\bar{r}$ is superstable, we know that for all but an ϵ_6 fraction of the t's, $\mathrm{con}_j(\bar{r}) = \mathrm{con}_t(\bar{s})$ and $\bar{s}$ is stable (as well), where $\bar{s} = (s_1, \ldots, s_k) = \sigma^{t-j}(\bar{r})$. Since r_j is annoying for $\bar{r}$, we have $\mathrm{con}_j(\bar{r}) \neq \tau(r_j)$ and $\mathrm{con}_t(\bar{s}) \neq \tau(r_j) = \tau(s_t)$ follows (recall $r_j = s_t$). □

Combining Claims 2.1.12 and 2.1.14, we derive, for almost all positions $t \in [k]$, a lower bound for the number of stable row-sequences that are annoyed by their tth element.

CLAIM 2.1.15. *Suppose that* (2.4) *does not hold* (for τ). *Then, there exists a set $T \subseteq [k]$ so that $|T| \geq (1 - 2\epsilon_6) \cdot k$ and for every $t \in T$ there is a set of at least $\frac{\delta_1}{2k} \cdot |\mathbf{R}|$ stable row-sequences so that the tth position is annoying for each of these sequences.*

Proof. Combining Claims 2.1.12 and 2.1.14, we get that there is a set of super stable row-sequences $A \subseteq \mathbf{R}$ so that

1. A contains at least a δ_1 fraction of $\mathbf{R}$; and
2. for every $\bar{r} \in A$ there exists a $j_{\bar{r}} \in [k]$ so that for all but an ϵ_6 of the $t \in [k]$, the row-sequence $\bar{s} \overset{\mathrm{def}}{=} \sigma^{t-j_{\bar{r}}}(\bar{r})$ is stable and the tth position is annoying for it (i.e., for $\bar{s}$).

By a counting argument it follows that there is a set T so that $|T| \geq (1 - 2\epsilon_6) \cdot k$, and for every $t \in T$ at least half of the $\bar{r}$'s in A satisfy item 2 above for this t (i.e., $\bar{s} \overset{\mathrm{def}}{=} \sigma^{t-j_{\bar{r}}}(\bar{r})$ is stable and the tth position is annoying for $\bar{s}$). Fixing such a $t \in T$, we consider the set, denoted A_t, containing these $\bar{r}$'s; namely, for every $\bar{r} \in A_t$ the row-sequence $\bar{s} \overset{\mathrm{def}}{=} \sigma^{t-j_{\bar{r}}}(\bar{r})$ is stable and the tth position is annoying for it (i.e., for $\bar{s}$). Thus, we have established a mapping from A_t to a set of stable row-sequences which are annoyed by their tth position; specifically, $\bar{r}$ is mapped to $\sigma^{t-j_{\bar{r}}}(\bar{r})$. Each row-sequence in the range of this mapping has at most k preimages (corresponding to the k possible shifts which maintain its tth element). Recalling that A_t contains at least $\frac{|A|}{2} \geq \frac{\delta_1}{2} \cdot |\mathbf{R}|$ sequences, we conclude that the mapping's range must contain at least $\frac{\delta_1}{2k} \cdot |\mathbf{R}|$ sequences, and the claim follows. □

Combining Claims 2.1.15 and 2.1.13, we get a lower bound on the number of matrices which are nonconforming for the jth column, for all $j \in T$ (where T is as in Claim 2.1.15).

CLAIM 2.1.16. *Let T be as guaranteed by Claim* 2.1.15 *and suppose that $j \in T$. Then, at least a $\frac{\delta_1}{6}$ fraction of the matrices are nonconforming for column-position j.*

Proof. By Claim 2.1.15, there are at least $\frac{\delta_1}{2k} \cdot |\mathbf{R}|$ stable row-sequences that are annoyed by their jth position. Out of these row-sequences, we consider a subset, denoted A, containing exactly $\frac{\delta_1}{2k} \cdot |\mathbf{R}|$ row-sequences. By Claim 2.1.13, for each $\bar{r} \in A$, at least a $\frac{1}{2} - \epsilon_2$ fraction of the matrices containing the row-sequence $\bar{r}$ are nonconforming for column-position j. We claim that almost all of these matrices do not contain another row-sequence in A (here we use the fact that A isn't too large); this will allow us to add up the matrices guaranteed by each $\bar{r} \in A$ without worrying about multiple counting.

Subclaim 2.1.16.1. For every $\bar{r} \in \mathbf{R}$

$$\mathrm{Prob}_{i,m}(\exists i' \neq i \text{ s.t. } \mathrm{row}_{i'}(m) \in A) < \frac{\delta_1}{2},$$

where $i \in_{\mathrm{R}} [k]$ and $m \in_{\mathrm{R}} \mathbf{M}_i(\bar{r})$.

Proof of subclaim. By Axiom 3 (part 3), we get that for every $i' \neq i$ the i'th row of $m \in_{\mathrm{R}} \mathbf{M}_i(\bar{r})$ is uniformly distributed in $\mathbf{R}$. Thus, for every $i' \neq i$

$$\mathrm{Prob}_m(\mathrm{row}_{i'}(m) \in A) = \frac{\delta_1}{2k},$$

where $m \in_{\mathrm{R}} \mathbf{M}_i(\bar{r})$. The subclaim follows. □

Using the subclaim, we conclude that for each $\bar{r} \in A$, at least a $\frac{1}{2} - \epsilon_2 - \frac{\delta_1}{2} > \frac{1}{3}$ fraction of the matrices containing the row-sequence $\bar{r}$ are nonconforming for column-position j and do not contain any other row-sequence in A. The desired lower bound now follows. Namely, let B denote the set of matrices which are nonconforming for column-position j, let $B_i(\bar{r}) \stackrel{\mathrm{def}}{=} B \cap \mathbf{M}_i(\bar{r})$ and $B'_i(\bar{r})$ denote the set of matrices in $B_i(\bar{r})$ which do not contain any row in A except for the ith row; then

$$\begin{aligned}|B| &\geq |\cup_{\bar{r}\in A} \cup_{i=1}^{k} B'_i(\bar{r})| \\ &= \sum_{\bar{r}\in A} \sum_{i=1}^{k} |B'_i(\bar{r})| \\ &> \sum_{\bar{r}\in A} \sum_{i=1}^{k} \frac{|\mathbf{M}_i(\bar{r})|}{3} \\ &= |A| \cdot \left(\frac{1}{3} \cdot \frac{k \cdot |\mathbf{M}|}{|\mathbf{R}|}\right) \\ &= \frac{\delta_1}{6} \cdot |\mathbf{M}|\end{aligned}$$

The claim follows. □

The combination of Claims 2.1.15 and 2.1.16 yields that a uniformly chosen matrix is nonconforming for a uniformly chosen column position with probability at least $(1 - 2\epsilon_6) \cdot \frac{\delta_1}{6}$. For a suitable choice of constants (e.g., $\epsilon = (\delta/30)^4$), this yields a contradiction to Claim 2.1.5 (which asserts that this probability is at most ϵ_3).[5] Thus, (2.4) must hold for τ as defined in Definition 2.1.10, and the lemma follows. □

2.4. A construction that satisfies the axioms. Clearly, the set of all k-by-k matrices over S satisfies Axioms 1–4.[6] A more interesting and useful set of matrices is defined as follows.

CONSTRUCTION 2.2 (basic construction). *We associate the set S with a finite field of characteristic at least k. Furthermore, $[k]$ is associated with k elements of the field so that* 1 *is the multiplicative unit and $i \in [k]$ is the sum of i such units. Let* $\mathbf{M}$ *be the set of matrices defined by four field elements as follows. The matrix associated with the quadruple (x, y, x', y') has the (i, j)th entry equal to $(x + jy) + i(x' + jy')$.*

Remark. The column-sequences correspond to the standard pairwise-independent sequences $\{r + is : i \in [k]\}$, where $r, s \in S$. Similarly, the row-sequences are expressed as $\{r + js : j \in [k]\}$, where $r, s \in S$.

PROPOSITION 2.2. *The basic construction satisfies Axioms* 1–4.

[5] Specifically, contradiction follows when $(1 - 2\epsilon_6) \cdot \frac{\delta_1}{6} > \frac{\delta_1}{12} > \epsilon_3 = 2\epsilon_2$. Using $\delta_1 = \delta - \epsilon_6 - \epsilon_2$, we need to have $\epsilon_6 \leq 1/4$ and $\delta > 25\epsilon_2 + \epsilon_6$. Using $\epsilon_2 = \sqrt{\epsilon}$ and $\epsilon_6 = 2(\sqrt[4]{\epsilon} + \sqrt[3]{\epsilon}) < 4\sqrt[4]{\epsilon}$, it suffices to have $\epsilon \leq 2^{-16}$ and $\delta > 29\sqrt[4]{\epsilon}$, which holds for $\epsilon = \min\{2^{-16}, (\delta/30)^4\}$ ($= (\delta/30)^4$ as $\delta \leq 1$).

[6] To see that Axiom 2 holds, one should specify the right shift of $\bar{r} = (r_1, \ldots, r_k)$. A natural choice is to have $\sigma(\bar{r}) = (r_k, r_1, \ldots, r_{k-1})$.

Proof. Axiom 1 as well as the first two items of Axiom 3 are obvious from the above remark. The right-shift of the sequence $\{r+js : j \in [k]\}$ is $\{(r+s)+js : j \in [k]\}$ and Axiom 2 follows. To prove that the third item of Axiom 3 holds, we rewrite the ith row as $\{s_i + j \cdot r_i : j \in [k]\}$, where $s_i = x + ix'$ and $r_i = y + iy'$. Now, for every $i \neq i' \in [k]$, when $x, y, x', y' \in_{\mathrm{R}} S$, the pairs (s_i, r_i) and $(s_{i'}, r_{i'})$ are pairwise-independent and uniformly distributed in $S \times S$, which corresponds to the set of row-sequences. It remains to prove that Axiom 4 holds. We start by proving the following.

FACT 2.2.1. *Consider any $i, j \in [k]$ and two sequences $\bar{r} = (r_1, \ldots, r_k) \in \mathbf{R}$ and $\bar{c} = (c_1, \ldots, c_k) \in \mathbf{C}$ so that $r_j = c_i$. Then, $|\mathbf{M}_i^j(\bar{r}, \bar{c})|$ equals $|S|$.*

Proof of fact. By the construction there exists a unique pair $(a, b) \in S \times S$ so that $a + j'b = r_{j'}$ for every $j' \in [k]$ (existence is obvious and uniqueness follows by considering any two equations; e.g., $a + b = r_1$ and $a + 2b = r_2$). Similarly, there exists a unique pair (α, β) so that $\alpha + i'\beta = c_{i'}$ for every $i' \in [k]$. We get a system of four linear equations in $x, x', y,$ and y' (i.e., $x + ix' = a$, $y + iy' = b$, $x + jy = \alpha$, and $x' + jy' = \beta$). This system has rank 3 and thus $|S|$ solutions, each defining a matrix in $\mathbf{M}_i^j(\bar{r}, \bar{c})$. ◻

Using Fact 2.2.1, Axiom 4 follows since

$$\begin{aligned}
\frac{|\mathbf{M}_i^j(\bar{r}, \bar{c})|}{|\mathbf{M}_i(\bar{r})|} &= \frac{|S|}{|S \times S|} \\
&= \frac{1}{|S|} \\
&= \frac{1}{|\mathbf{C}_i(r_j)|}
\end{aligned}$$

and so does the proposition. ◻

3. A stronger consistency test and the PCP application.

To prove Lemma 1.3, we need a slightly stronger consistency test than the one analyzed in Lemma 2.1. This new test is given access to three related oracles, each supplying assignments to certain classes of sequences over S, and is supposed to establish the consistency of these oracles with one function $\tau : S \mapsto V$. Specifically, one oracle assigns values to k^2-long sequences viewed as 2-dimensional arrays (as before). The other two oracles assign values to k^3-long sequences viewed as 3-dimensional arrays, whose slices (along a specific coordinate) correspond to the 2-dimensional arrays of the first oracle. Using Lemma 2.1 (and the auxiliary oracles) we will present a test which verifies that the first oracle is consistent in an even stronger sense than established in Lemma 2.1. Namely, not only that ALL ENTRIES IN ALMOST ALL ROWS *of almost all* 2*-dimensional arrays* are assigned in a consistent manner, but ALL ENTRIES *in almost all* 2*-dimensional arrays* are assigned in a consistent manner.

3.1. The setting.

Let S, k, $\mathbf{R}$, $\mathbf{C}$, and $\mathbf{M}$ be as in the previous section. We now consider a family, $\mathcal{M}_{\mathtt{c}}$, of k-by-k matrices with entries in $\mathbf{C}$. The family $\mathcal{M}_{\mathtt{c}}$ will satisfy Axioms 1–4 of the previous section. In addition, its induced multiset of row-sequences, denoted $\mathcal{R}$, will correspond to the multiset $\mathbf{M}$; namely, each row of a matrix in $\mathcal{M}_{\mathtt{c}}$ will form a matrix in $\mathbf{M}$ (i.e., the sequence of elements of $\mathbf{C}$ corresponding to a row in a $\mathcal{M}_{\mathtt{c}}$-matrix will correspond to a $\mathbf{M}$-matrix).

AXIOM 5. *For every $\mathtt{m} \in \mathcal{M}_{\mathtt{c}}$ and every $i \in [k]$, there exists $m \in \mathbf{M}$ so that for every $j \in [k]$, the (i,j)*th *entry of* $\mathtt{m}$ *equals the j*th *column of m* (i.e., $\mathrm{entry}_{i,j}(\mathtt{m}) =$

$\mathrm{col}^j(m)$, or, equivalently, $\mathrm{row}_i(\mathtt{m}) \cong m$). *Furthermore, this matrix m is unique.*[7] Analogously, we consider also a family, $\mathcal{M}_{\mathtt{r}}$, of k-by-k matrices, the entries of which are elements in $\mathbf{R}$ so that the rows[8] of each $\mathtt{m} \in \mathcal{M}_{\mathtt{r}}$ correspond to matrices in $\mathbf{M}$.

3.2. The test. As before, Γ is a function assigning (k-by-k) matrices in $\mathbf{M}$ values which are k-by-k matrices over some set of values V (i.e., $\Gamma : \mathbf{M} \mapsto V^{k\times k}$). Let $\Gamma_{\mathtt{c}}$ (resp., $\Gamma_{\mathtt{r}}$) be (the supposedly corresponding) function assigning k-by-k matrices over $\mathbf{C}$ (resp., $\mathbf{R}$) values which are k-by-k matrices over $\overline{V} \overset{\text{def}}{=} V^k$ (i.e., $\Gamma_{\mathtt{c}} : \mathcal{M}_{\mathtt{c}} \mapsto \overline{V}^{k\times k}$).

CONSTRUCTION 3.1 (extended consistency test):

1. Consistency for sequences. *Apply the consistency test of Construction* 2.1 *to* $\Gamma_{\mathtt{c}}$. *Same for* $\Gamma_{\mathtt{r}}$.
2. Correspondence test. *Uniformly select a matrix* $\mathtt{m} \in \mathcal{M}_{\mathtt{c}}$ *and a row* $i \in [k]$, *and compare the* ith *row in* $\Gamma_{\mathtt{c}}(\mathtt{m})$ *to* $\Gamma(m)$, *where* $m \in \mathbf{M}$ *is the matrix formed by the* $\mathbf{C}$*-elements in the* ith *row of* $\mathtt{m}$. *The same goes for* $\Gamma_{\mathtt{r}}$.

The test accepts if both (sub)tests *succeed.*

LEMMA 3.1. *Suppose* $\mathbf{M}, \mathcal{M}_{\mathtt{c}}$, and $\mathcal{M}_{\mathtt{r}}$ *satisfy Axioms* 1–5. *Then, for every constant* $\gamma > 0$, *there exists a constant* ϵ *so that if a function* $\Gamma : \mathbf{M} \mapsto V^{k\times k}$ (together with some functions $\Gamma_{\mathtt{c}} : \mathcal{M}_{\mathtt{c}} \mapsto \overline{V}^{k\times k}$ and $\Gamma_{\mathtt{r}} : \mathcal{M}_{\mathtt{r}} \mapsto \overline{V}^{k\times k}$) *passes the extended consistency test with probability at least* $1-\epsilon$, *then there exists a function* $\tau : S \mapsto V$ *so that, with probability at least* $1-\gamma$, *the value assigned by* Γ *to a uniformly chosen matrix* $m \in \mathbf{M}$ *matches the values assigned by* τ *to each of the elements of* m. *Namely,*

$$\mathrm{Prob}_m\left(\forall i,j \ \ \mathrm{entry}_{i,j}(\Gamma(m)) = \tau(\mathrm{entry}_{i,j}(m))\right) \geq 1-\gamma,$$

where $m \in_{\mathrm{R}} \mathbf{M}$. *The constant* ϵ *does not depend on* k *and* S. *Furthermore, it is polynomially related to* γ.

The proof of the lemma starts by applying Lemma 2.1 to derive assignments to $\mathbf{C}$ (resp., $\mathbf{R}$) which are consistent with $\Gamma_{\mathtt{c}}$ (resp., $\Gamma_{\mathtt{r}}$) on almost all rows of almost all k^3-dimensional arrays (i.e., $\mathcal{M}_{\mathtt{c}}$ and $\mathcal{M}_{\mathtt{r}}$, resp.). It proceeds by applying a degenerate argument of the kind applied in the proof of Lemma 2.1. Again, the reader may want to skip the proofs of all claims in first reading.

3.3. Proof of Lemma 3.1. We start by considering step 1 in the extended consistency test. By Lemma 2.1, there exists a function $\tau_{\mathtt{c}} : \mathbf{C} \mapsto V^k$ (resp., $\tau_{\mathtt{r}} : \mathbf{R} \mapsto V^k$) so that the value assigned by $\Gamma_{\mathtt{c}}$ (resp., $\Gamma_{\mathtt{r}}$), to a uniformly chosen row in a uniformly chosen matrix $\mathcal{M}_{\mathtt{c}}$ (resp., $\mathcal{M}_{\mathtt{r}}$) matches, with high probability, the values assigned by $\tau_{\mathtt{c}}$ (resp., $\tau_{\mathtt{r}}$) to each of the $\mathbf{C}$-elements (resp., $\mathbf{R}$-elements) appearing in this row. Here "with high probability" means with probability at least $1-\delta$, where $\delta > 0$ is a constant, related to ϵ as specified by Lemma 2.1. Namely,

$$\mathrm{Prob}_{i,\mathtt{m}}(\forall j \ \ \mathrm{entry}_{i,j}(\Gamma_{\mathtt{c}}(\mathtt{m})) = \tau_{\mathtt{c}}(\mathrm{entry}_{i,j}(\mathtt{m}))) \geq 1-\delta, \tag{3.1}$$

where $i \in_{\mathrm{R}} [k]$ and $\mathtt{m} \in_{\mathrm{R}} \mathcal{M}_{\mathtt{c}}$.

[7] Uniqueness is an issue only in case $\mathbf{M}$ is a multiset. In such a case, $\mathcal{M}_{\mathtt{c}}$ will be a multiset too, and the furthermore clause establishes a 1-1 correspondence betwen the rows of $\mathcal{M}_{\mathtt{c}}$ and $\mathbf{M}$.

[8] Alternatively, one can consider a family, $\mathcal{M}_{\mathtt{r}}$, of k-by-k matrices, the entries of which are elements in $\mathbf{R}$, so that the columns of each $\mathtt{m} \in \mathcal{M}_{\mathtt{r}}$ correspond to matrices in $\mathbf{M}$. However, this would require modifying the basic consistency test (of Construction 2.1) for these matrices, so that it shifts columns instead of rows.

3.3.1. Perfect matrices and typical sequences. Equation (3.1) relates $\tau_{\mathtt{c}}$ to $\Gamma_{\mathtt{c}}$ (resp., $\tau_{\mathtt{c}}$ to $\Gamma_{\mathtt{c}}$). Our next step is to relate $\tau_{\mathtt{c}}$ (resp., $\tau_{\mathtt{r}}$) to Γ. This is done easily by referring to step 2 in the extended consistency test. Specifically, it follows that the value assigned by Γ, to a uniformly chosen matrix $m \in \mathbf{M}$, matches, with high probability, the values assigned by $\tau_{\mathtt{c}}$ (resp., $\tau_{\mathtt{r}}$) to each of the columns (resp., rows) of m.

Definition 3.1.1 (perfect matrices). *A matrix $m \in \mathbf{M}$ is called* perfect (for columns) *if for every $j \in [k]$, the jth column of $\Gamma(m)$ equals the value assigned by $\tau_{\mathtt{c}}$ to the jth column of m (i.e., $\mathrm{col}^j(\Gamma(m)) = \tau_{\mathtt{c}}(\mathrm{col}^j(m))$). Similarly, $m \in \mathbf{M}$ is called* perfect (for rows) *if $\mathrm{row}_i(\Gamma(m)) = \tau_{\mathtt{r}}(\mathrm{row}_i(m))$, for every $i \in [k]$.*

Claim 3.1.2 (perfect matrices). *Let $\delta_1 \stackrel{\mathrm{def}}{=} \delta + \epsilon$.*
(c) *All but a δ_1 fraction of the matrices in $\mathbf{M}$ are perfect for columns.*
(r) *All but a δ_1 fraction of the matrices in $\mathbf{M}$ are perfect for rows.*

Proof. It will be convenient to view the rows of $\mathtt{m} \in \mathcal{M}_{\mathtt{c}}$ as elements of $\mathbf{M}$ (although, formally, we only have a correspondence between the ith row of $\mathtt{m} \in \mathcal{M}_{\mathtt{c}}$ and a matrix $m \in \mathbf{M}$ so that $\mathrm{entry}_{i,j}(\mathtt{m}) = \mathrm{col}^j(m)$, for all j's). By the correspondence (sub)test, with probability at least $1-\epsilon$, a uniformly chosen row in a uniformly chosen $\mathtt{m} \in \mathcal{M}_{\mathtt{c}}$ is given the same values by $\Gamma_{\mathtt{c}}$ and by Γ (i.e., $\mathrm{row}_i(\Gamma_{\mathtt{c}}(\mathtt{m})) = \Gamma(\mathrm{row}_i(\mathtt{m}))$, for $i \in_{\mathrm{R}} [k]$). In other words, for uniformly chosen $\mathtt{m} \in \mathcal{M}_{\mathtt{c}}$ and $i \in_{\mathrm{R}} [k]$

$$\mathrm{entry}_{i,j}(\Gamma_{\mathtt{c}}(\mathtt{m})) = \mathrm{col}^j(\Gamma(\mathrm{row}_i(\mathtt{m}))) \quad \text{for every } j \in [k].$$

On the other hand, by (3.1), with probability at least $1-\delta$, a uniformly chosen row in a uniformly chosen $\mathtt{m} \in \mathcal{M}_{\mathtt{c}}$ is given the same values by $\Gamma_{\mathtt{c}}$ and by $\tau_{\mathtt{c}}$ (i.e., $\mathrm{entry}_{i,j}(\Gamma_{\mathtt{c}}(\mathtt{m})) = \tau_{\mathtt{c}}(\mathrm{entry}_{i,j}(\mathtt{m}))$, for $i \in_{\mathrm{R}} [k]$ and all $j \in [k]$). Thus, with probability at least $1-(\epsilon+\delta)$, a uniformly chosen row in a uniformly chosen $\mathtt{m} \in \mathcal{M}_{\mathtt{c}}$ is given the same values by Γ and by $\tau_{\mathtt{c}}$ (i.e., $\mathrm{col}^j(\Gamma(\mathrm{row}_i(\mathtt{m}))) = \tau_{\mathtt{c}}(\mathrm{entry}_{i,j}(\mathtt{m}))$, for $i \in_{\mathrm{R}} [k]$ and all $j \in [k]$). Using Axiom 3 (part 2—regarding $\mathcal{M}_{\mathtt{c}}$) and the "furthermore" part of Axiom 5, $\mathrm{row}_i(\mathtt{m})$ is uniformly distributed in $\mathbf{M}$ (for any $i \in [k]$ when $\mathtt{m} \in_{\mathrm{R}} \mathcal{M}_{\mathtt{c}}$). Part (c) of the claim follows (i.e., $\mathrm{col}^j(\Gamma(m)) = \tau_{\mathtt{c}}(\mathrm{col}^j(m))$, with high probability for $m \in_{\mathrm{R}} \mathbf{M}$ and all $j \in [k]$). A similar argument holds for part (r). ☐

A perfect (for columns) matrix "forces" *all* of its columns to satisfy some property Π (specifically, the value assigned by $\tau_{\mathtt{c}}$ to its column-sequences must match the value Γ of the matrix). Recall that we have just shown that almost all matrices are perfect and thus force all their columns to satisfy some property Π. Using a counting argument, one can show that all but at most a $\frac{1}{k}$ fraction of the column-sequences must satisfy Π in *almost all* matrices in which they appear.

Definition 3.1.3 (typical sequences). *Let $\delta_2 \stackrel{\mathrm{def}}{=} 2\sqrt{\delta_1}$. We say that the column-sequence $\bar{c}$ is* typical *if*

$$\mathrm{Prob}_{j,m}(\mathrm{col}^j(\Gamma(m)) = \tau_{\mathtt{c}}(\bar{c})) \geq 1 - \delta_2,$$

where $j \in_{\mathrm{R}} [k]$ and $m \in_{\mathrm{R}} \mathbf{M}^j(\bar{c})$. Otherwise, we say that $\bar{c}$ is nontypical. *Similarly, we say that the row-sequence $\bar{r}$ is* typical *if* $\mathrm{Prob}_{i,m}(\mathrm{row}_i(\Gamma(m)) = \tau_{\mathtt{r}}(\bar{r})) \geq 1 - \delta_2$, *where $i \in_{\mathrm{R}} [k]$ and $m \in_{\mathrm{R}} \mathbf{M}^i(\bar{r})$.*

Claim 3.1.4. *All but at most an $\frac{\delta_2}{2k}$ fraction of the column-sequence* (resp., row-sequences) *are typical.*

We will only use the bound for the fraction of typical row-sequences.

Proof. We mimic part of the counting argument of Claim 2.1.16. Let N be a set of nontypical row-sequences, containing exactly $\frac{\delta_2}{2k} \cdot |\mathbf{R}|$ sequences. Fix any $\bar{r} \in N$

and consider the set of matrices containing $\bar{r}$. By Axiom 3 (part 3—regarding $\mathbf{M}$), at most a $\frac{\delta_2}{2}$ fraction of these matrices contain some other row in N. On the other hand, by definition (of nontypical row-sequence), at least a δ_2 fraction of the matrices containing $\bar{r}$ have Γ disagree with $\tau_{\mathtt{r}}(\bar{r})$ on $\bar{r}$ and thus are nonperfect (for rows). It follows that at least a $\frac{\delta_2}{2}$ fraction of the matrices containing $\bar{r}$ are nonperfect (for rows) and contain no other row in N. Combining the bounds obtained for all $\bar{r} \in N$, we get that at least a $\frac{\delta_2}{2k} \cdot k \cdot \frac{\delta_2}{2} = \delta_1$ fraction of the matrices are not perfect (for rows).[9] This contradicts Claim 3.1.2(r), and so the current claim follows (for row-sequences and similarly for column-sequences). $\square$

3.3.2. Deriving the conclusion of the lemma. We are now ready to derive the conclusion of the Lemma. Loosely speaking, we claim that the function τ, defined so that $\tau(e)$ is the value most frequently assigned by $\tau_{\mathtt{c}}$ to e, satisfies the claim of the lemma.

Definition 3.1.5 (the function τ). *Let $\tau_{\mathtt{c}}(\bar{c})_i$ denote the value assigned by $\tau_{\mathtt{c}}$ to the* ith *element of $\bar{c} \in \mathbf{C}$. Define*

$$q_e(v) \overset{\text{def}}{=} \text{Prob}_{i,\bar{c}}(\tau_{\mathtt{c}}(\bar{c})_i = v),$$

where $i \in_{\text{R}} [k]$ and $\bar{c} \in_{\text{R}} \mathbf{C}_i(e)$ (recall that $\mathbf{C}_i(e)$ denotes the set of column-sequences having e as the ith component). *We consider $\tau : S \mapsto V$ so that $\tau(e) \overset{\text{def}}{=} v$ if $q_e(v) = \max_u\{q_e(u)\}$, with ties broken arbitrarily.*

The proof that τ satisfies the claim of Lemma 3.1 is a simplified version of the proof of Lemma 2.1.[10] We assume, contrary to our claim, that for a uniformly chosen $m \in \mathbf{M}$

$$\text{Prob}_m\left(\exists i, j \text{ so that entry}_{i,j}(\Gamma(m)) \neq \tau(\text{entry}_{i,j}(m))\right) > \gamma. \tag{3.2}$$

As in the proof of Lemma 2.1, we define a notion of an *annoying* row-sequence. Using the above (contradiction) hypothesis, we first show that many row-sequences are annoying. Next, we show that lower bounds on the number of annoying row-sequences translate to lower bounds on the probability that a uniformly chosen matrix is nonperfect (for columns). This yields a contradiction to Claim 3.1.2(c).

Definition 3.1.6 (a new definition of annoying rows). *A row-sequence $\bar{r} = (r_1, \ldots, r_k)$ is said to be* annoying *if there exists a $j \in [k]$ so that the* jth *element in $\tau_{\mathtt{r}}(\bar{r})$ differs from $\tau(r_j)$.*

Using Claim 3.1.2(r), we get the following claim.

Claim 3.1.7. *Suppose that* (3.2) *holds and let $\gamma_1 \overset{\text{def}}{=} \gamma - \delta_1$. Then, at least a $\frac{\gamma_1}{k}$ fraction of the row-sequences are annoying.*

Proof. Combining (3.2) and Claim 3.1.2(r), we get that with probability at least $\gamma - \delta_1 = \gamma_1$, a uniformly chosen matrix $m \in \mathbf{M}$ is perfect for rows and contains some entry, denoted (i, j), for which the Γ value is different from the τ value (i.e., $\text{entry}_{i,j}(\Gamma(m)) \neq \tau(\text{entry}_{i,j}(m))$). Since the $\tau_{\mathtt{r}}$-value of each row of a perfect (for rows)

[9] For each $\bar{r} \in N$, let $M_{\bar{r}}$ denote the number of nonperfect matrices containing $\bar{r}$ but not any other row in N. Then, $M_{\bar{r}} \geq \frac{\delta_2}{2} \cdot \sum_{i=1}^{k} |\mathbf{M}_i(\bar{r})| = \frac{\delta_2}{2} \cdot k \cdot \frac{|\mathbf{M}|}{|\mathbf{R}|}$ and the number of nonperfect matrices is at least $\sum_{\bar{r} \in N} M_{\bar{r}} \geq \frac{\delta_2 |\mathbf{R}|}{2k} \cdot \frac{\delta_2 k |\mathbf{M}|}{2|\mathbf{R}|}$.

[10] The reader may wonder how it is possible that a simpler proof yields a stronger result, as the claim concerning the current τ is stronger. The answer is that the current τ is defined based on a more restricted function over $\mathbf{C}$ and there are also stronger restrictions on Γ. Both restrictions are due to facts that we have inferred using Lemma 2.1 with regard to (w.r.t) $\Gamma_{\mathtt{c}}$ and $\Gamma_{\mathtt{r}}$.

matrix m matches the Γ values, it follows that the ith row of m is annoying. Thus, at least a γ_1 fraction of the matrices contain an annoying row-sequence. Using Axiom 3 (part 2—regarding $\mathbf{M}$), we conclude that the fraction of annoying row-sequences must be as claimed. ◻

A key observation is that each row-sequence that is both typical and annoying yields many matrices which are nonperfect for columns.

Claim 3.1.8. *Suppose that a row-sequence $\bar{r}$ is both typical and annoying. Then, at least a $\frac{1}{2}-\delta_2$ fraction of the matrices, containing the row-sequence $\bar{r}$, are nonperfect for columns.*

Proof. Since $\bar{r}=(r_1,\ldots,r_k)$ is annoying, there exists a $j\in[k]$ so that the jth component of $\tau_{\mathtt{r}}(\bar{r})$ (which is the value assigned to r_j) is different from $\tau(r_j)$. Let us denote by v the value $\tau_{\mathtt{r}}(\bar{r})$ assigns to r_j. Note that $v\neq\tau(r_j)$. Consider the probability space defined by uniformly selecting $i\in[k]$ and $m\in\mathbf{M}_i(\bar{r})$. Since $\bar{r}$ is typical it follows that in almost all of these matrices the value assigned to r_j by the Γ equals v; namely,

$$\mathrm{Prob}_{i,m}(\mathrm{entry}_{i,j}(\Gamma(m))=v) \;\; \geq \;\; 1-\delta_2. \tag{3.3}$$

By Axiom 4 (regarding $\mathbf{M}$), the jth column of m is uniformly distributed in $\mathbf{C}_i(r_j)$. Now, using the definition of the function τ and the accompanying notations, we get

$$\mathrm{Prob}_{i,m}(\tau_{\mathtt{c}}(\mathrm{col}^j(m))_i=v) \;\; = \;\; q_{r_j}(v) \;\; \leq \;\; \frac{1}{2}. \tag{3.4}$$

The inequality holds since $v\neq\tau(r_j)$ and by τ's definition $q_{r_j}(v)\leq q_{r_j}(\tau(r_j))$. Combining (3.3) and (3.4), we get

$$\mathrm{Prob}_{i,m}(\mathrm{entry}_{i,j}(\Gamma(m))\neq\tau_{\mathtt{c}}(\mathrm{col}^j(m))_i) \;\; \geq \;\; \frac{1}{2}-\delta_2,$$

and the claim follows. ◻

Combining Claims 3.1.7, 3.1.4, and 3.1.8, we get a lower bound on the number of matrices which are nonperfect for columns.

Claim 3.1.9. *Suppose that* (3.2) *holds and let $\gamma_2\stackrel{\mathrm{def}}{=}\gamma_1-\frac{\delta_2}{2}$. Then, at least a $\frac{\gamma_2}{3}$ fraction of the matrices are nonperfect for columns.*

Proof. By Claims 3.1.7 and 3.1.4, at least a $\frac{\gamma_1}{k}-\frac{\delta_2}{2k}$ $(=\frac{\gamma_2}{k})$ fraction of the row-sequences are both annoying and typical. Let us consider a set of exactly $\frac{\gamma_2}{k}\cdot|\mathbf{R}|$ such row-sequences, denoted A. Mimicking again the counting argument part of Claim 2.1.16, we bound, for each $\bar{r}\in A$, the fraction of nonperfect (for columns) matrices which contain $\bar{r}$ but no other row-sequence in A. Using an adequate setting of δ_2 and γ_2, this fraction is at least $\frac{1}{3}$. Summing the bounds achieved for all $\bar{r}\in A$, the claim follows. ◻

Using a suitable choice of γ (as a function of ϵ), Claim 3.1.9 contradicts Claim 3.1.2(c), and so (3.2) cannot hold. The lemma follows. ◻

3.4. Application to low-degree testing. Again, the set of all k-by-k-by-k arrays over S satisfies Axioms 1–5. A more useful set of 3-dimensional arrays is defined as follows.

Construction 3.2 (main construction). *Let $\mathbf{M}$ be as in the basic construction (i.e., Construction* 2.2*). We let $\mathcal{M}_{\mathtt{c}}=\mathcal{M}_{\mathtt{r}}$ be the set of matrices defined by applying the basic construction to the element-set $\mathbf{C}=\mathbf{R}$. Specifically, a matrix in $\mathcal{M}_{\mathtt{c}}$ is defined by the quadruple (x,y,x',y'), where each of the four elements is a pair over S,* *so that the* (i,j)th *entry in the matrix equals* $(x+jy)+i(x'+jy')$. *Here* x,y,x', and y' *are viewed as* 2*-dimensional vectors over the finite field* S *and* i,j *are scalars in* S. *The* (i,j)th *entry is a pair over* S *which represents a pairwise independent sequence* (*which equals an element in* $\mathbf{C}=\mathbf{R}$).

PROPOSITION 3.2. *Construction* 3.2 *satisfies Assumptions* 1–5.

Combining all the above with the low-degree test of [GLRSW, RS96] and using the results proved there,[11] we get a low-degree test which is sufficiently efficient to be used in the proof of the PCP-characterization of NP.

CONSTRUCTION 3.3 (low-degree test). *Let* $f : F^n \mapsto F$, *where* F *is a field of prime cardinality, and* d *be an integer so that* $|F| > 4(d+2)^2$. *Let* $\mathbf{M}$, $\mathcal{M}_{\mathtt{c}}$, *and* $\mathcal{M}_{\mathtt{r}}$ *be as in Construction* 3.2, *with* $S = F^n$, $V = F$ *and* $k \stackrel{\text{def}}{=} 4(d+2)^2$. *Let* $\Gamma : \mathbf{M} \mapsto F^{k\times k}$, $\Gamma_{\mathtt{r}} : \mathcal{M}_{\mathtt{r}} \mapsto F^{k^3}$, *and* $\Gamma_{\mathtt{c}} : \mathcal{M}_{\mathtt{c}} \mapsto F^{k^3}$ *be auxiliary tables* (which should contain the corresponding f-values). *The low-degree test consists of the following three steps:*

1. *Apply the extended consistency test* (i.e., Construction 3.1) *to the functions* $\Gamma : \mathbf{M} \mapsto F^{k\times k}$, $\Gamma_{\mathtt{r}} : \mathcal{M}_{\mathtt{r}} \mapsto F^{k^3}$, *and* $\Gamma_{\mathtt{c}} : \mathcal{M}_{\mathtt{c}} \mapsto F^{k^3}$.
2. *Select uniformly a matrix* $m \in \mathbf{M}$ *and test whether the* polynomial interpolation condition (cf. membership test of [GLRSW, p. 37]) *holds for each row; namely, we test that*

$$\sum_{j=1}^{d+2} \alpha_j \cdot \text{entry}_{i,j}(\Gamma(m)) = 0$$

   for all $i \in [k]$, *where* $\alpha_j = (-1)^j \cdot \binom{d+1}{j-1}$.
3. *Select uniformly a matrix in* $\mathbf{M}$ *and test whether* Γ *and* f *agree on a uniformly chosen element in the matrix. Namely, select uniformly* $m \in \mathbf{M}$ *and* $i,j \in [k]$, *and check whether* $\text{entry}_{i,j}(\Gamma(m)) = f(\text{entry}_{i,j}(m))$.

The test accepts if and only if all the above three subtests accept.

PROPOSITION 3.3. *Let* $f : F^n \mapsto F$, *where* F *is a field, and let* $\ell \stackrel{\text{def}}{=} n \cdot \log_2 |F|$. *Then, the low-degree test of Construction* 3.3 *satisfies the following conditions:*

Efficiency. *The test runs in* poly(ℓ)*-time, uses* $O(\ell)$ *random bits, and makes a constant number of queries each of length* $O(\ell)$. (*The queries are answered by strings of length* poly(ℓ).)

Completeness. *If* f *is a degree-*d *polynomial, then there exist* $\Gamma : \mathbf{M} \mapsto F^{k\times k}$, $\Gamma_{\mathtt{r}} : \mathcal{M}_{\mathtt{r}} \mapsto F^{k^3}$, *and* $\Gamma_{\mathtt{c}} : \mathcal{M}_{\mathtt{c}} \mapsto F^{k^3}$ *so that the test always accepts.*

Soundness. *For every* $\delta > 3/(d+2)^2$ *there exists an* $\epsilon > 0$ *so that for every* f *which is at distance at least* δ *from any degree-*d *polynomial and for every* $\Gamma : \mathbf{M} \mapsto F^{k\times k}$, $\Gamma_{\mathtt{r}} : \mathcal{M}_{\mathtt{r}} \mapsto F^{k^3}$, *and* $\Gamma_{\mathtt{c}} : \mathcal{M}_{\mathtt{c}} \mapsto F^{k^3}$, *the test rejects with probability at least* ϵ. *Furthermore, the constant* ϵ *is a polynomial in* δ *which does not depend on* n, d, *and* F.

As a corollary, we get Lemma 1.3.

Proof. The efficiency requirement is immediate from the construction. Also, as usual, the completeness requirement is easy to establish. We thus turn to the soundness requirement. By Proposition 3.2, we may apply Lemma 3.1 to the first subtest and infer that either the first subtest fails with some constant probability (say ϵ_1) or there exists a function $\tau : F^n \mapsto F$ so that, with very high constant probability (say,

[11] Rather than using much stronger results obtained via a more complicated analysis, as in [ALMSS], which rely on the lemma of [AS].

$1 - \delta_1$),

$$\text{entry}_{i,j}(\Gamma(m)) = \tau(\text{entry}_{i,j}(m)) \tag{3.5}$$

holds for all $i \in [k]$ and $j \in [d+2]$. We assume from this point on that this is the case (or else the low-degree test rejects with probability at least ϵ_1). Now, by [GLRSW] (see also [Sud, Thm. 3.3] and [RS96, Thm. 5]), either

$$\text{Prob}_{x,y \in F^n}\left(\sum_{j=1}^{d+2} \alpha_j \cdot \tau(x+jy) \neq 0\right) > \frac{1}{2(d+2)^2} \tag{3.6}$$

or τ is very close (specifically at distance at most $1/(d+2)^2$) to some degree-d polynomial. A key observation is that the main construction (i.e., Construction 3.2) has the property that rows in $m \in_{\text{R}} \mathbf{M}$ are distributed identically to the distribution in (3.6). Thus, for every $i \in [k]$, either

$$\text{Prob}_{m \in \mathbf{M}}\left(\sum_{j=1}^{d+2} \alpha_j \cdot \tau(\text{entry}_{i,j}(m)) \neq 0\right) > \frac{1}{2(d+2)^2} \tag{3.7}$$

or τ is at distance at most $\delta_2 \stackrel{\text{def}}{=} 1/(d+2)^2$ from some degree-d polynomial. Now, we claim that in case (3.7) holds, the second subtest will reject with constant probability. The claim is proven by considering $k = 4(d+2)^2$ pairwise-independent copies of the GLRSW test (i.e., the test in (3.7)), and recalling that the rows in $m \in_{\text{R}} \mathbf{M}$ are distributed in a pairwise-independent manner. Using Chebyshev's inequality and the hypothesis that each copy rejects with probability at least $1/2(d+2)^2$, we conclude that the probability that none of these copies rejects is bounded above by $\frac{2(d+2)^2}{4(d+2)^2} = \frac{1}{2}$. Thus, the second subtest must reject with probability at least $\epsilon_2 \stackrel{\text{def}}{=} \frac{1}{2} - \delta_1$, where δ_1 accounts for the substitution of the τ values by the entries in $\Gamma(\cdot)$. We conclude that τ must be δ_2-close to a degree-d polynomial or else the test rejects with probability at least ϵ_2.

Next, we claim that if f disagrees with τ on a $\delta_3 > \delta_1$ fraction of the inputs then the third subtest rejects with probability at least $\epsilon_3 \stackrel{\text{def}}{=} \delta_3 - \delta_1$ (since the disagreement of f and τ is upper bounded by the sum of the disagreement of f and Γ and the disagreement of Γ and τ).

Thus, if the low-degree test rejects with probability smaller than $\epsilon = \min\{\epsilon_1, \epsilon_2, \epsilon_3\}$, then f disagrees with τ on at most δ_3 fraction of the inputs, where τ is δ_2-close to a degree d-polynomial. (So f is $(\delta_2 + \delta_3)$-close to a degree d-polynomial.) The proposition follows using arithmetic: specifically, we set $\delta_1 = \delta/3$, $\delta_3 = 2\delta/3$, $\epsilon_1 = \text{poly}(\delta_1)$ (where the polynomial is as in Lemma 3.1), and verify that $\delta_3 + \delta_2 \leq \delta$ (since $\delta_2 = (d+2)^{-2} < \delta/3$). Furthermore, $\epsilon = \min\{\epsilon_1, \epsilon_2, \epsilon_3\} = \text{poly}(\delta)$ (since $\epsilon_2 = 0.5 - \delta_1 \geq 0.5 - (1/3) = 1/6$ and $\epsilon_3 = \delta_3 - \delta_1 = \delta/3$). ☐

4. Proof of Lemma 1.1.

There should be an easier and more direct way of proving Lemma 1.1. However, having proved Lemma 2.1, we can apply it[12] to derive a short proof of Lemma 1.1. To this end we view ℓ-multisets over S as k-by-k matrices, where $k = \sqrt{\ell}$. Recall that the resulting set of matrices satisfies Axioms 1–4. Thus,

[12] This is indeed an overkill. For example, we can avoid all complications regarding shifts (in the proof of Lemma 2.1).

by Lemma 2.1 (applied to $\Gamma = F$), in case the test accepts with probability at least $1-\epsilon$, there exists a function $f : S \mapsto V$ such that

$$\mathrm{Prob}_{A\in_{\mathrm{R}} S^k, B\in_{\mathrm{R}} E_{k^2}(A)}(\forall e \in A,\ F(B)_e = f(e)) \geq 1-\delta,$$

where S^k is the set of all k-multisets over S and $E_l(A)$ is the set of all l-multisets extending A (and $F(B)_e$ denotes the value assigned by F to $e \in B$). We can think of this probability space as first selecting $B \in_{\mathrm{R}} S^{k^2}$ and next selecting a k-subset A in B. Thus,

$$\mathrm{Prob}_{B\in_{\mathrm{R}} S^{k^2}, A\in_{\mathrm{R}} C_k(B)}(\exists e \in A \text{ s.t. } F(B)_e \neq f(e)) \leq \delta, \tag{4.1}$$

where $C_k(B)$ denotes the set of all k-multisets contained in B. This implies

$$\mathrm{Prob}_{B\in_{\mathrm{R}} S^{k^2}}(|\{e \in B : F(B)_e \neq f(e)\}| > k) \leq 2\delta,$$

as otherwise (4.1) is violated. (The probability that a random k-subset hits a subset of density $\frac{1}{k}$ is at least $\frac{1}{2}$.) The lemma follows. $\square$

Comment. A previous version of this paper [GS96] has stated a stronger version of Lemma 1.1, where the sequences $F(x_1,\ldots,x_\ell)$ and $(f(x_1),\ldots,f(x_\ell))$ are claimed to be identical (rather than different on at most k locations), for a $1-\delta$ fraction of all possible $(x_1,\ldots,x_\ell) \in S^\ell$. Unfortunately, the proof given there was not correct— a mistake in the concluding lines of the proof of Claim 4.2.9 was found by Sudan [Sud]. Still we conjecture that the stronger version holds as well, and that it can be established by a test which examines two random $(2k-1)$-extensions of a random k-subset.

Acknowledgment. We are grateful to Madhu Sudan for pointing out an error in an earlier version, and for other helpful comments. We also thank the anonymous referees for their useful comments.

VERIFICATION OF IDENTITIES[*]

SRIDHAR RAJAGOPALAN[†] AND LEONARD J. SCHULMAN[‡]

Abstract. We provide an $O(n^2 \log \frac{1}{\delta})$ time randomized algorithm to check whether a given operation $\circ : S \times S \to S$ is associative (where $n = |S|$ and $\delta > 0$ is the error probability required of the algorithm). We prove that (for any constant δ) this performance is optimal up to a constant factor, even if the operation is "cancellative." No sub-n^3 time algorithm was previously known for this task.

More generally we give an $O(n^c)$ time randomized algorithm to check whether a collection of c-ary operations satisfy any given "read-once" identity.

1. Introduction.

Let a set S be given, along with a binary operation $\circ : S \times S \to S$. In this paper, we consider the complexity of checking whether $\circ$ is associative. We provide an algorithm for this problem and then show how our method extends without essential modification to provide a means of checking general "read-once" identities.

Throughout this paper, let $n = |S|$. We provide a randomized, one-sided error algorithm which in time $O(n^2 \log \frac{1}{\delta})$ computes whether the operation $\circ$ is associative. If $\circ$ is associative, then the algorithm does not err in its response, while if $\circ$ is not associative, then the error probability is bounded by δ. It is assumed that the operation $\circ$ is computable in unit time; the same assumption is made throughout the paper, and all runtimes scale linearly in the actual time required for computation of the given operations.

The techniques we develop are more general and can be used to check whether collections of operators satisfy various identities. For instance, given a finite state machine, $\delta : S \times \Sigma \to S$, verify that the machine is "asynchronous," namely $\delta(\delta(s, a), b) = \delta(\delta(s, b), a)\ \forall\ s \in S$ and $a, b \in \Sigma$. This test is sometimes called the diamond test.

In case the identity is not satisfied, our method also provides a witness (e.g., for associativity, a triple a, b, c such that $(a \circ b) \circ c \neq a \circ (b \circ c)$) with only a logarithmic slowdown in the time complexity.

Associativity: Prior work. Prior to our work, except in special cases, no method for verifying associativity was known that was better than the naive $O(n^3)$-time algorithm of examining whether $a \circ (b \circ c) = (a \circ b) \circ c\ \forall\ a, b, c \in S$.

F. W. Light observed in 1949 (see [3]) that, if $R \subseteq S$ is a set of generators of S, i.e., a collection such that every element of S is representable as a product of elements of R, then it suffices to test all triples a, b, c in which b is an element of R. This, however, does not result in a sub-n^3 algorithm for this problem, for two reasons: first, the operation may require a large set of generators, as much as n (and there are such

examples which are associative, so the algorithm would in fact examine all triples)—see Example 1; second, even if the operation does have a small set of generators, we are not aware of any rapid method for obtaining a set of generators of (even close to) minimal size.

Associativity: Cancellative operations. An operation $\circ$ on a finite set S is left (resp., right) cancellative if for every a and b, there is an x (which must be unique) such that $x \circ a = b$ (resp., $a \circ x = b$). A cancellative operation is both left and right cancellative. In other words, every row and column of the table for the operation is a permutation of S.

In the special case that the operation is cancellative, Light's observation is quite useful. Only $O(n^2)$ time is required to test whether $\circ$ is cancellative. Moreover, we will show in section 5 that, given a cancellative multiplication table, one can deterministically compute a set of generators of size $\lfloor \log_2 n \rfloor + 1$ in $O(n^2)$ time. Thus, Light's observation results in an $O(n^2 \log n)$ deterministic algorithm for verifying associativity in the cancellative case. Consequently there is a deterministic $O(n^2 \log n)$ time algorithm to test whether a given set and operation form a group. (Alternatively, a random set of elements may be chosen; a set of $c \log_2 n$ elements will be a set of generators with probability at least $1 - \exp(-c)$. This implies a randomized algorithm analogous to the deterministic one.)

We show in section 5 that any cancellative nonassociative operation has at least $n-2$ nonassociative triples. Therefore, the procedure of checking $O(n^2 \log \frac{1}{\delta})$ random triples will succeed with probability $1 - \delta$, providing essentially the same guarantee as the randomized version of Light's method, while being even simpler. (Both run in time $O(n^2 \log \frac{1}{\delta})$.)

However, just as Light's observation fails to be of use for general operations, because small sets of generators may not exist or may be hard to find, the random sampling approach also fails to be of use for general operations, in this case because for every $n \geq 3$ there exists an operation (noncancellative, of course) with just one nonassociative triple. See Example 2.

Associativity: Lower bound. We show that any randomized algorithm requires time $\Omega(n^2)$ to verify associativity, even in the cancellative case. Thus the runtime of our randomized algorithm as a function of input size is tight up to a constant factor.

Comment on terminology. The pair $(S, \circ)$ is known in the algebra literature as a groupoid [1, 2, 3], a term which is unfortunately also used elsewhere in that literature to mean something entirely different [5, 7]. When $\circ$ is cancellative $(S, \circ)$ is referred to in [1, 2] as a quasi group.

2. Algorithm for checking associativity.

We define the structure $\mathcal{S}/2 = (\mathbb{Z}/2)[S]$ as follows. The elements of $\mathcal{S}/2$ are sums of elements of S, with coefficients in $\mathbb{Z}/2$ (i.e., $\sum_{s \in S} \alpha_s s$ for $\alpha_s \in \mathbb{Z}/2$). $\mathcal{S}/2$ is equipped with the following operations:

(1) Addition: $\sum_s \alpha_s s + \sum_s \beta_s s = \sum_s (\alpha_s + \beta_s) s$.

(2) Scalar multiplication: $\beta \sum_s \alpha_s s = \sum_s (\beta \alpha_s) s$ and $(\sum_s \alpha_s s)\beta = \sum_s (\beta \alpha_s) s$ for $\beta \in \mathbb{Z}/2$.

(3) The operation $\circ$: $(\sum_s \alpha_s s) \circ (\sum_s \beta_s s) = \sum_r \sum_s \alpha_r \beta_s (r \circ s)$.

Thus $\mathcal{S}/2$ is what would be known as the "group algebra" of $(S, \circ)$ over $\mathbb{Z}/2$, were $(S, \circ)$ a group. (In the present circumstance "groupoid algebra" may be an appropriate term.)

Henceforth, we will denote members of $\mathcal{S}/2$ by bold letters, and coefficients by the corresponding Greek lowercase, e.g., $\mathbf{a} = \sum_s \alpha_s s$.

Our method for checking associativity in $(S, \circ)$ is to repeat the following, $O(\log \frac{1}{\delta})$ times:

- *Check the associative identity for three random elements of* $\mathcal{S}/2$.

In other words, select random (uniformly i.i.d.) $\mathbf{a}, \mathbf{b}, \mathbf{c} \in \mathcal{S}/2$, and check that $(\mathbf{a} \circ \mathbf{b}) \circ \mathbf{c} = \mathbf{a} \circ (\mathbf{b} \circ \mathbf{c})$.

THEOREM 2.1. *The algorithm above, running in time $O(n^2 \log \frac{1}{\delta})$, will determine whether $\circ$ is associative, with error probability at most δ if it is not associative and no error if it is associative.*

First note that checking that $(\mathbf{a} \circ \mathbf{b}) \circ \mathbf{c} = \mathbf{a} \circ (\mathbf{b} \circ \mathbf{c})$ can be done in time $O(n^2)$ because $\mathbf{a} \circ \mathbf{b}$ can be computed by brute force in time $O(n^2)$; moreover, the result of this computation is another vector $\mathbf{d} \in \mathcal{S}/2$, so the subsequent computation $\mathbf{d} \circ \mathbf{c}$ can again be computed by brute force in time $O(n^2)$. For the same reason, $\mathbf{a} \circ (\mathbf{b} \circ \mathbf{c})$ can be computed in time $O(n^2)$; and finally, the two sides can be compared in time $O(n)$.

We now show that a single run of the above process succeeds in detecting nonassociativity with probability at least $1/8$; by repeating the process $\log_{8/7} \frac{1}{\delta}$ times, the dependence of the running time on δ follows.

It is easily verified that $\circ$ is associative on S if and only if it is associative on $\mathcal{S}/2$ as well (for a proof see Lemma 3.2).

Let S^k denote the k-wise Cartesian product of S with itself. A *minor* of S^k is a set $A_1 \times A_2 \times \cdots \times A_k \subseteq S^k$ (where each A_i is a subset of S). If H is a commutative group (expressed additively), g is a function $g : S^k \to H$, and T is a subset of S^k, then define $g(T) = \sum_{t \in T} g(t)$.

LEMMA 2.2. *Let H be any commutative group, and let $g : S^k \to H$ be a nonzero function. Then the fraction of minors T of S^k for which $g(T) \neq 0$ is at least 2^{-k}.*

Proof. Fix $\tau = (t_1, \ldots, t_k)$ such that $g(\tau) \neq 0$. Let $T_1 \subseteq S - \{t_1\}, \ldots, T_k \subseteq S - \{t_k\}$. For $1 \leq i \leq k$ define $T_i^0 = T_i$ and $T_i^1 = T_i \cup \{t_i\}$. Observe that $\{\tau\} = \cap_1^k((T_1^1 \times \cdots \times T_k^1) - (T_1^1 \times \cdots \times T_{i-1}^1 \times T_i^0 \times T_{i+1}^1 \times \cdots \times T_k^1))$ and that for $\varepsilon = (\varepsilon_1, \ldots, \varepsilon_k)$ (with $\varepsilon_i \in \{0,1\}\ \forall i$), $T_1^{\varepsilon_1} \times \cdots \times T_k^{\varepsilon_k} = \bigcap_i T_1^1 \times \cdots \times T_{i-1}^1 \times T_i^{\varepsilon_i} \times T_{i+1}^1 \times \cdots \times T_k^1$. Hence inclusion-exclusion gives
